A non-smoker 42 year-old woman with ulcerative colitis diagnosed 3 years previously and treated with corticosteroids and mesalazine, was hospitalised for sudden right hemiplegia. She had no personal medical history of diabetes, hypertension and dyslipidemia and no family history of vascular disease. She had already presented several ischemic strokes, revealing intra-cardiac thrombus, but had refused any oral anticoagulant treatment. At admission, the NIHSS was 19 and blood pressure was 120/80 mmHg. A brain MRI showed a recent ischemic stroke with occlusion of the origin of the right MCA. Cerebral angiography with thrombectomy was performed and complicated by hemorrhagic transformation of the cerebral infarct. Severe bloody diarrhoea was controlled by a high dose of corticosteroids (methylprednisolone 1 mg/kg for 10 d before progressive decrease). Cervical US showed a thrombus in the right internal carotid (Figure 2A). There were biological signs of inflammation with an elevated ESR at 64 mm and CRP at 14.4 mg/L, slight hyperhomocysteinemia (17.9 μmol/L), a low level of LDL-cholesterol at 0.80 g/L, a normal preprandial blood glucose level at 0.90 g/L, and a platelet count of 462 G/L. Ten days later, after partial resorption of cerebral haemorrhage, low molecular weight heparin (LWMH), enoxaparine, was introduced at a dose of 100 UI/kg twice a day. After one week of treatment, cervical US revealed regression of the thrombus with only a tiny plaque on the right internal carotid wall (Figure 2B). LWMH was switched for aspirin as the patient rejected any oral anticoagulant. She was finally transferred to a rehabilitation center with a NIHSS of 6.

DISCUSSION

These observations suggest that 2 factors can contribute to carotid thrombus: abnormalities of the coagulation system and disease of arterial wall[2].

Hypercoagulability is almost always observed during the active phase of IBD and can lead to an arterial or

intracardiac thrombus, as described in the second case. Elevated platelets (with hyperactivation), fibrinogen, factor V, Ⅷ, plasminogen activator inhibitor and decreased antithrombin and tissue plasminogen activator have been described. Vitamin K malabsorption causes not only short partial thromboplastin times but also protein C and S deficiency[3]. There may also be a higher prevalence of antiphospholipid antibodies in IBD patients[4]. Common carotid artery intima-media thickness is significantly higher in IBD patients compared with controls with a significant association with homocysteine levels and age[5]. This is due to modifications of the vessel-wall induced by chronic inflammation: cytokines activate endothelium with conversion to a pro-inflammatory thrombogenic phenotype and increased von Willebrand factor[6]. Accelerated atherosclerosis is found in systemic inflammatory disorders[7], and atherosclerotic plaques were found after resorption of carotid thrombus in both the cases described here, as well as in a similar case described by Lafitte *et al*[8]. In IBD patients, an inflammatory state may also lead to endothelial damage and early atherosclerotic lesions. In the cases we describe, the formation of carotid thrombus may have been due to ulceration of plaques which have activated a pro-thrombotic coagulation state. For both our patients, lysis of the thrombus was obtained after several days of heparin treatment with double impact: fibrinolysis and the still debated anti-inflammatory action[9]. Nevertheless, this approach has only been described in a few cases and should be evaluated with clinical studies, especially as it may provoke mucosal[10] and cerebral bleeding in case of extensive stroke. We also administered corticosteroids to both our patients to decrease the inflammation, hypercoagulation state, to promote mucosal regeneration and then, to potentiate the benefits of heparin.

Internal carotid thrombus is a cause of ischemic stroke in IBD patients, and is a consequence of the combination of early atherosclerotic lesions and hypercoagulation state. Combining heparin and anti-inflammatory therapy may be considered as a synergic treatment but, further work is required to establish efficacy and safety.

Abstract

A postoperative complication after Altemeier operation, so far never reported, is described in a 42 years old mentally disabled patient with external full thickness rectal prolapse who usually had prolonged straining at defecation. After 6 d from perineal rectosigmoidectomy, the patient, was discharged free of complications. Four days later he was readmitted in emergency for strangulated perineal trans-anastomotic ileal hernia that occurred at home during efforts to defecate. The clinical feature required an emergency operation for repositioning the ileal loops into the abdomen, resection of the necrotic ileum, and end colostomy. The outcome of the second operation was free of complication and the patient was discharged on the 6th postoperative day. In conclusion, after Altemeier operation prolonged straining at defecation should be carefully avoided

Strangulated ileal trans-coloanal-anastomotic hernia: A complication of Altemeier's procedure previously never reported. *World J Gastroenterol* 2013; 19(5): 776-777 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/776.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.776

INTRODUCTION

Full thickness rectal prolapse is an uncommon but very disabling anorectal disease affecting any age and in particular mentally disabled patients. Several surgical approaches have been proposed to treat this disorder including abdominal rectopexy and perineal mucosal (Delorme) or full thickness rectal resection (Altemeier). The Altemeier's procedure is usually preferred (1) in elderly, high-risk, frail patients unsuitable for abdominal operation; (2) for emergency incarcerated external prolapse[1] and for gangrenous rectal prolapse[2]; and (3) in mentally disabled patients because of its short, painless postoperative course and low complication rate.

CASE REPORT

A 42-year-old male patient affected by congenital hypothyroidism with a psychomotor retardation, anorexia and bulimia was admitted to our Colorectal Unit because of irreducible full thickness rectal prolapse. From several years the patient used to have prolonged and forced

Figure 1 Strangulated ileal trans-coloanal-anastomotic perineal hernia showing ischaemia of the herniated ileum.

straining at defecation (about 30 min) with exteriorization of the prolapse at every defecation. However, in the last 2 mo the rectal prolapse became irreducible. A perineal rectosigmoidectomy with levatorplasty (Altemeier's operation) was performed under general anesthesia with the patient in jack-knife position. Twelve cm of prolapsed rectum was resected and a hand-sewn interrupted coloanal anastomosis was performed. The patient was discharged on the 6th postoperative day free of complication and oral laxatives and antithrombotic prophylaxis were prescribed. Four days later the patient was re-admitted in emergency since a strangulated ileal trans-coloanal-anastomotic hernia occurred after a prolonged and strain defecation (Figure 1). Laparotomy was urgently performed and no signs of intrabdominal infection or ascites were found. However, the distal part of the ileum (about 2 m) was herniated outside the pelvis through a partial posterior dehiscence of the colo-anal anastomosis with torsion of intestinal loops around the vascular stalk. The large portion of small intestine herniated was reduced with difficulty into the abdomen with the help of a second operator from the perineal side. Once the ileum was replaced into the abdomen, the coloanal anastomosis was fully opened and the anus temporarily closed with continue resorbable suture. The vitality of the herniated ileum (up to 5 cm from the ileo-cecal valve) was poor after one hour and, therefore, it was resected. Then, a hand-sewn ileo-cecal anastomosis and a diverting sigmoid end colostomy were performed. The second postoperative course was uneventful and the patient was discharged on the 6th postoperative day. The patient was re-evaluated at follow-up for 4 mo and he is now waiting for a refashioning of the colo-anal anastomosis.

DISCUSSION

Altemeier's procedure is usually recommended in mentally disabled patients with full thickness rectal prolapse because of its short and painless postoperative course. Postoperative complications are uncommon (less than 10%[3,4] of cases), nevertheless they usually occur in the early postoperative days. The complication we herein described, to our knowledge for the first time, was unexpected since it occurred several days after the patient was discharged in good clinical condition and with normal bowel movements.

We suggest that anamnestic data of the behavior of prolonged straining at defecation in mentally disabled patients should have been considered, and adequate advise given to the relatives to assist patients during defecation in order to prevent strain. Finally, the choice of creating a diverting sigmoidostomy instead of trying to repair the coloanal anastomosis seems more prudent, due to the presence of edema in traumatized anastomotic leakage.

Abstract

Ectopic adrenal cortical neoplasms are extremely rare. Ectopic adrenocortical tissue can be found in locations such as the celiac axis, the broad ligament, the adnexa of the testes, and the spermatic cord; however, they rarely involve the stomach. We report an unusual case of a patient with an ectopic adrenal cortical adenoma in the gastric wall. The patient was a 72-year old female admitted to our hospital with upper abdominal discomfort. Physical examination revealed tenderness below the xiphoid process. Both computed tomography and fibergastroscopy revealed a mass on the lesser curvature side of the gastric antrum; it was initially diagnosed as a gastric stromal tumor. After adequate preparation, the patient underwent surgery. During the procedure, we found a 30 mm × 30 mm mass with medium density in the lesser curvature near the gastric antrum within the serosa. Following immunohistochemistry examination, we corrected the diagnosis to an ectopic adrenal cortical adenoma; the tumor was nonfunctional.

INTRODUCTION

The adrenal gland arises from primordial mesenchyme in the wall of the dorsal coelom adjacent to the dorsal mesentery and urogenital structures. Therefore, most ectopic adrenocortical tissue is found along the path of embryonic migration within the urogenital tract. Ectopic adrenocortical tissue is found in such locations as the celiac axis, the broad ligament, the adnexa of the testes, and the spermatic cord[1]. However, an ectopic adrenal cortical adenoma rarely involves the stomach. We report an unusual case of a patient with an ectopic adrenal cortical adenoma in the gastric wall and review the literature.

CASE REPORT

The patient was a 72-year old female. She was admitted on 17th November, 2011 with upper abdominal discomfort for 4 d, accompanied by postprandial nausea and vomiting. She denied chills, fever, or diarrhea. Her medical and family history were noncontributory.

Physical examination: temperature 37.5 ℃, pulse 90 bpm, respiration 20 bpm, blood pressure 172/96 mmHg. The heart and lungs were normal. The abdomen was flat and soft, with tenderness below the xiphoid process. No enlarged liver, spleen, or mass was palpable. Murphy's sign was negative. Laboratory and radiology findings: Routine blood work showed white blood cell 12.7 × 10^9/L, neutrophils 85.3%. Liver function tests were in normal range. Fasting blood glucose was 8.88 mmol/L. Adrenocorticotropic hormone was in normal range. On B-ultrasonography, the gallbladder was 64 mm × 37 mm. The gallbladder wall was thickened, with a stone incarcerated

Figure 1 Enhanced image of nodule located in the lesser gastric curvature.

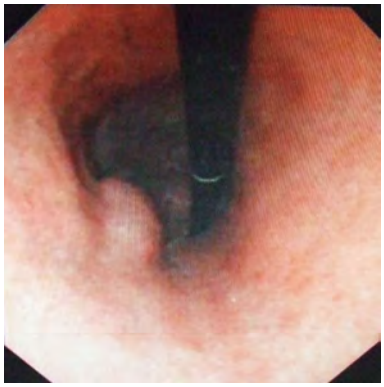

Figure 2 Elevated nodule on the lesser curvature side of the gastric antrum.

in the neck. Computed tomography (CT) scan showed a 15 mm × 25 mm abnormal enhanced nodule located in the submucosa of the lesser curvature of the stomach with a CT value of 150 HU. The size, morphology, and location of the kidneys and adrenal glands were normal bilaterally, and there were multiple cysts in both kidneys. The radiological diagnoses were multiple renal cysts and a gastric stromal tumor (Figure 1). Fibergastroscopy showed no hyperemia in the gastric mucosa. A raised nodule about 30 mm × 25 mm in size was found on the lesser curvature side of the gastric antrum; it was firm with soft mucosa. The endoscopic diagnosis was also a gastric stromal tumor (Figure 2). After adequate preparation, the patient underwent surgery. During the operation, we found a distended gallbladder with a stone inside. There was a 30 mm × 30 mm mass with medium density in the lesser curvature near the gastric antrum and the mass located in the serosa layer. The liver, spleen, pancreas, kidney, and adrenal glands were normal. We resected the gallbladder, ligated the vessels of lesser gastric curvature, and opened the gastric wall 3 cm from the margin of the mass. We found that the gastric mucosa above the mass was integrated, and we performed a simple resection of the mass. On gross examination, the mass was purplish-red in color. It was a 20 mm × 30 mm ellipse with soft margins and a medium texture (Figure 3A). On microscopic exam, the tumor cells were rich in cytoplasm and eosinophilic, and numerous sinusoid capillaries could be seen. The cytoplasm contained melanin, which was confirmed by decolorization. The tumor cells were arranged in cords or gobbets with a low ratio of nucleus to cytoplasm, and rare mitotic figures (Figure 3B, C). Immunohistochemistry: S-100 basement cell negative (Figure 4A), melan-A positive (Figure 4B), P63 basement cell negative, sinusoidal endothelial CD34 positive (Figure 4C). The pathologic diagnosis was of an ectopic adrenal cortical adenoma in the gastric wall.

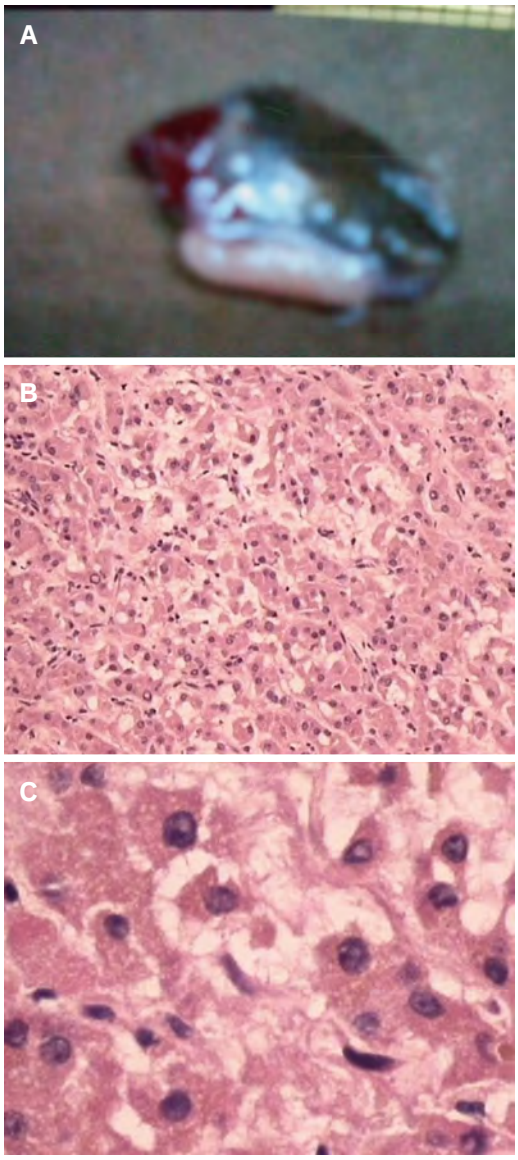

Figure 3 Analysis of tumor cells. A: Gastric wall mass, approximately 20 mm × 30 mm in size; B: Tumor cells under low power magnification; C: Tumor cells under high power magnification.

DISCUSSION

Ectopic adrenal tissue is mostly found in children. According to Anderson *et al*[2], accessory adrenal tissue is found in 50% of post-mortem examinations in neonates

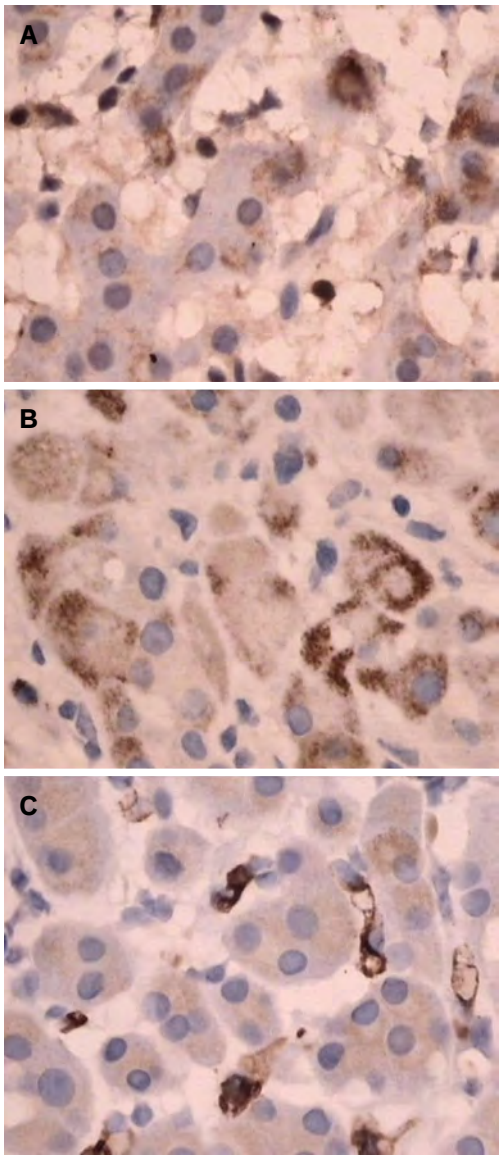

Figure 4 Immunohistochemistry. A: S-100 basement cell negative; B: Melan-A positive; C: CD34 positive.

and children. Usually, maturity leads to atrophy of the ectopic adrenal tissue, so that such tissue is found in only 1% of adults. The adrenal cells have a double embryological origin. The cortex arises from the coelomic mesothelium and the medulla from neural crest ectoderm. At approximately 7 ± 8 wk of pregnancy, the medulla components start moving towards the cortical elements, forming the adrenal gland. During migration of the medulla, fragments of tissue, most frequently the cortex, can be separated, forming accessory adrenal glands. Most ectopic adrenals remain in the vicinity of the adrenal gland, but they are also found to be closely related to the sex organs because of the spatial relationship between the adrenal primordium and the genital ridge in early embryogenesis. Accessory adrenal tissue can also be incorporated into adjacent organs due to incomplete separation of cortical adrenal cells from the coelomic mesothelium. Therefore, most ectopic adrenocortical tissue is found along the path of embryonic migration within the urogenital tract. The most common sites include the fat tissue of the posterior peritoneum near the adrenal glands, the celiac axis, the broad ligament, the adnexa of the testis, and the spermatic cord. There are also rare reported cases of ectopic adrenal cortical adenoma in the lung, spinal region, and brain[3-8].

However, there is no previous report of ectopic adrenal cortical adenoma of the gastric wall in the literature. In the case reported here, the patient presented with abdominal discomfort and the mass was found by CT. It was initially diagnosed as a gastric stromal tumor, which was corrected to ectopic adrenal cortical adenoma by pathology; the tumor was nonfunctional. The patient had no history of operation on adrenal tissue, so we believe the ectopic adrenal cortical adenoma in the gastric wall was due to the malposition or self-differentiation of mesothelial cells during the embryonic period.

Abstract

Lymphangioma, a congenital malformation of the lymphatic system, is usually found in children, and generally occurs in the neck and mediastinum. It is rarely found in the spleen. The clinical features of splenic lymphangioma typically include abdominal pain, nausea, and abdominal distention. Frequently, however, this condition is asymptomatic and is incidentally detected by abdominal ultrasonography or by an abdominal computed tomography (CT) scan. In this paper, we retrospectively describe a case of incidentally detected splenic lymphangioma in a 30-year-old woman with special abdominal contrast material-enhanced CT findings, which was accurately diagnosed by histopathology. The clinical and physical examinations related to the mass were negative. A few cases of splenic lymphangioma have been reported previously; however, the presentation of the mass and the enhancement pattern in the contrast medium-enhanced CT images were quite extraordinary. These findings had misled our abdominal radiologists to consider it as other neoplastic diseases of the spleen.

INTRODUCTION

Splenic lymphangiomas are usually benign tumors that predominantly affect children, whereas only a few cases have been reported in adults[1-3]. Previous case reports revealed no particular findings in the image analysis, which uniformly indicated solitary cysts, or multiple cysts without contrast enhancement or only with slight enhancement of the thin septa[1,3-5], except for one case of a solid mass with diffuse and prolonged enhancement[2]. Here we present a histopathologically proven case in which a solid-cystic mass of the spleen in the computed tomography (CT) images showed no enhancement of the cysts and prominent enhancement of the solid components. To the best of our knowledge, these special contrast-enhanced CT findings are relatively rare.

CASE REPORT

A 30-year year-old woman was admitted to our hospital with a splenic mass detected by abdominal ultrasonography, which was performed for recurrent epigastric pain at another hospital. The epigastric pain was later attributed to gall bladder lithiasis. The patient's past and familial medical histories indicated no abnormalities. There were no positive symptoms related to the splenic mass. Physical examinations detected no mass or splenomegaly in the left upper quadrant of the abdomen. Peripheral blood count, coagulation studies, and liver and kidney function tests were all within normal limits.

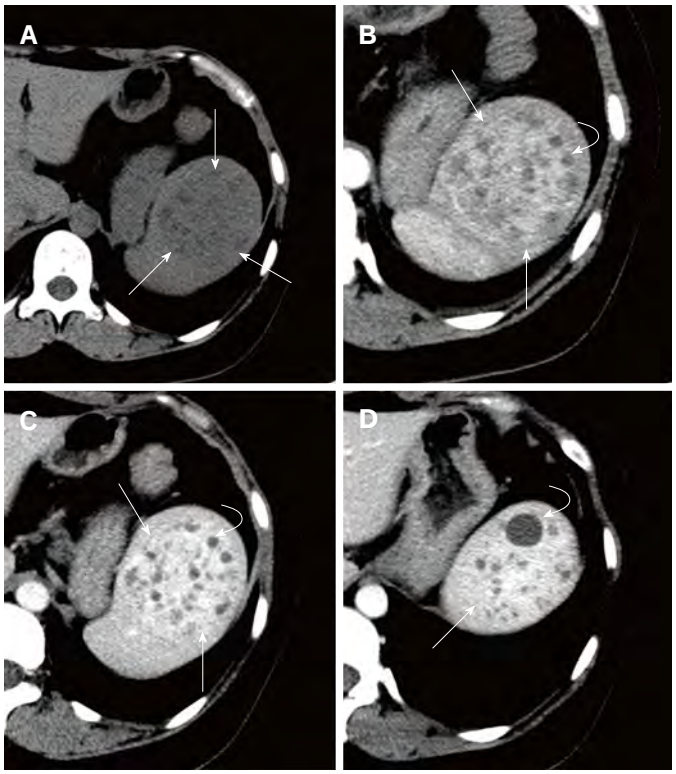

Figure 1 Computed tomography findings of the splenic lymphangioma. A: A heterogeneous solid-cystic mass (straight arrow) with a well-defined margin in the spleen, as shown in the plain image. The solid components show slight hypo-density; B: Arterial phase image shows the mass (straight arrow) with multiple non-enhanced cysts (curved arrow). The solid portions manifest as obvious enhancement; C: Parenchyma phase image shows obviously progressive enhancement of the solid portions; D: Parenchyma phase image of the upper location of the mass showing the same presentation and enhancement pattern.

CT showed a heterogeneous solid-cystic mass with a well-defined margin located in the normal sized spleen in the plain images. Within the mass, there were multiple small cysts of variable size. The cysts showed sharp borders with no enhancement at either the arterial or parenchymal phase, whereas the solid components presented with persistently progressive enhancement (Figure 1). At this point, our radiologists suspected a splenic tumor.

Splenectomy was eventually undertaken for the splenic mass. During the operation, a solid mass was found, which had no clear boundary with the peripheral splenic parenchyma. The final histopathological result was splenic cavernous lymphangioma. The findings revealed multiple lymphatic vesicles of variable size, and the blood sinuses in the red pulp within the mass that were dilated compared with the peripheral red pulp. The vesicles were lined by a single layer of flat endothelial cells, and some vesicles were filled with pink eosinophilic lymphatic fluid (Figure 2).

DISCUSSION

Lymphangiomas are generally considered to be congenital malformations of the lymphatic system, and they occur mostly in the neck, mediastinum and retroperitoneum[4]; they are seldom found in the spleen. Histologically, lymphangiomas are classified into three subtypes according to the congenital dilated lymphatic channels: capillary (super-microcystic), cavernous (microcystic), or cystic (macrocystic)[6]. Our case was ultimately diagnosed as the cavernous type. Cavernous lymphangiomas are composed of numerous irregular cavernous spaces containing amorphous eosinophilic fluid and few lymphocytes, lined by a single layer of flat endothelial cells[7]. Splenic lymphangiomas are mostly asymptomatic; therefore, the final diagnosis should be based on a combination of clinical, radiological, and histopathological findings.

In most cases, splenic lymphangiomas present with thin-walled cystic masses without enhancement or with only slight enhancement of the thin septa in the CT studies. We detailed a histologically confirmed case in which the mass manifested as a solid-cystic lesion. The multiple cysts showed no enhancement, as in previous cases[1,3-5]; however, the solid components showed obvious progressive enhancement. Histopathologically, however, there were no real solid components, and the solid, prominently enhanced portions in the CT images simply represented the dilated blood sinuses in the red pulp within the mass. The presence of reduced blood velocity and collecting blood in the dilated blood sinuses may have resulted in more contrast medium per voxel compared with the peripheral normal sinuses, and may have eventually led to obviously progressive enhancement.

Thus, lymphangioma presenting with this kind of solid-cystic mass in the image studies may be misdiagnosed. The differential diagnoses of splenic lymphangiomas often include other solid and cystic lesions of the spleen, such as hemangioma, chronic infection, lymphoma and metastasis. Hemangiomas may sometimes display solid and cystic portions[8]. Contrast-enhanced CT scans may show delayed enhancement within the solid portion. Punctate calcification can be seen in the central solid portion, and curvilinear calcification may be seen in the cystic areas[8]. Parasitic infection with *Echinococcus granulosus* is the main cause of cystic proliferations of the spleen[9]. The differential factors are the patients' history, calcifica-

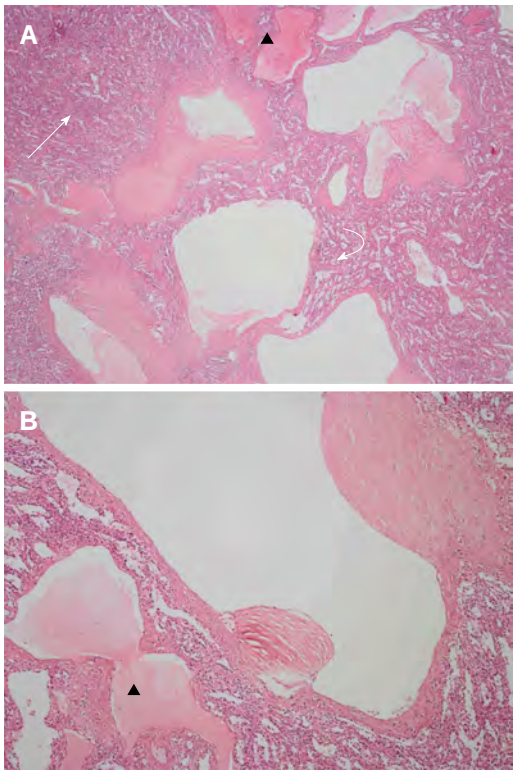

Figure 2 Histopathological findings of the splenic lymphangioma. A: Hematoxylin and eosin (HE) staining of the splenic lymphangioma, × 40, indicates the presence of numerous cystic lesions of variable size, and blood sinuses (curved arrow) in the red pulp within the mass that are dilated as compared with peripheral red pulp (straight arrow); B: HE staining, × 100, indicates that some vesicles are filled with pink eosinophilic lymph sacs (black triangle).

tion in the cystic walls, a cyst with daughter cysts or concomitant cystic lesions in the liver or other organs[10].

In conclusion, dynamic contrast-enhanced CT is a useful method for evaluating splenic lesions. We suggest that lymphangioma should be considered in the differential diagnosis of a splenic mass that manifests as a solid-cystic lesion in the image studies. In our case, the dilated blood sinuses in the red pulp within the mass might have contributed to the indication of solid components with evident enhancement.

ACKNOWLEDGMENTS

We thank Wen-Yan Zhang (Department of Pathology, West China Hospital of Sichuan University) for providing the histopathological resources.

Abstract

Mucositis is a known complication following use of chemotherapy, but fatal mucositis is unusual and management of such cases may be challenging. Pathologically there is denudation of mucosa of gastrointestinal tract. Severe cases can develop ileus and even perforation of bowel wall. We report here a case of multiple myeloma who developed World Health Organization grade 4 gut mucositis following the use of high dose melphalan with the expulsion of "intestine-like" material.

Sharma SK, Handoo A, Choudhary D, Dhamija G, Gupta N. Severe gastrointestinal mucositis following high dose melphalan therapy for multiple myeloma. *World J Gastroenterol* 2013; 19(5): 784-785 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i5/784.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i5.784

TO THE EDITOR

Mucositis is the most common complication of chemotherapeutics agents. Melphalan when used in high doses for treatment for multiple myeloma can lead to severe mucositis[1,2]. Patient can develop gastrointestinal ulcers, vomiting and diarrhea with the use of high dose melphalan as a conditioning regimen for autologous transplant for multiple myeloma[3-5]. Pathologically there is denudation of mucosa of gastrointestinal tract. Severe cases can develop ileus and even perforation of bowel wall. We report here a case of multiple myeloma who developed World Health Organization (WHO) grade 4 gut mucositis following the use of high dose melphalan with the expulsion of "intestine-like" material.

A 62-years-old male was admitted for autologous stem cell transplant for multiple myeloma. He was in complete remission following 4 cycles of bortezomib and dexamethasone. Filgrastim (G-CSF) 10 mg/kg was given for 4 d for peripheral stem cell mobilization followed by melphalan 200 mg/m^2 as conditioning regimen. The CD34+ stem cell dose infused was 6×10^6/kg. Cephasol (supersaturated calcium phosphate rinse) was used six times daily to prevent oral mucositis. On day 3 patient developed vomitings and by day 5 he had WHO grade 4 gut mucositis with ileus. Patient also developed fever and was started on empirical antibiotics including meropenem (1 g three times daily, intravenously), metronidazole (500 mg three times daily, intravenously), and teicoplanin (400 mg once daily, intravenously) as per hospital policy, alongwith Ryle's tube aspiration and parenteral feeding. On day 7 he passed 25 cm × 1 cm pinkish, mucosa coated partly digested material mimicking segment of small intestine (Figure 1). Histopathological section of the segment revealed numerous neutrophils surrounding the partly digested material, without any muscle tissue (Figure 2). Blood culture was negative for bacteria and fungus. Viral serology tests for cytomegalovirus immunoglobulin M (IgM) and herpes simplex virus 1 and 2 IgM were negative. Stool examination did not reveal ova or cysts and was negative for Clostridial difficile toxin. Computed tomography of abdomen showed dilated bowel loops, with caecal wall thickness of 10 mm, there was no evidence of perforation or intussusception. Though he had neutrophil engraftment (absolute neutrophil count

Figure 1 Specimen showing the excreted, blood tinged, elongated material, measuring about 25 cm, resembling part of small intestine.

more than 0.5×10^9/L) on day 13, platelets remained below 10×10^9/L. Patient succumbed on day 20 because of enterocolitis and sepsis.

Oral and gastrointestinal mucositis due to cancer chemotherapy or radiotherapy continues to be an important clinical problem. Alimentary tract mucositis can involve any part of oral and gastrointestinal mucosa, from the mouth to the anus. The incidence of WHO grade 3 or 4 gastrointestinal mucositis can be as high as 20%-60% in patients undergoing hematopoietic stem cell transplantation, depending on the intensity of the conditioning regimen used[3,4]. In the study by Krishna *et al*[2], of the 47 patients who developed lower alimentary tract mucositis there was no mortality. Our patient developed severe gastrointestinal toxicity following high dose of melphalan, with excretion of a large mucosa coated segment mimicking part of the small intestine, and succumbed to the complications related to mucositis.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Gastroesophageal reflux disease (GORD) is highly prevalent in the general population. In the last decade, a potential relationship between *Helicobacter pylori* (*H. pylori*) eradication and GORD onset has been claimed. The main putative mechanism is the gastric acid hypersecretion that develops after bacterial cure in those patients with corpus-predominant gastritis. We performed a critical reappraisal of the intricate pathogenesis and clinical data available in this field. Oesophagitis onset after *H. pylori* eradication in duodenal ulcer patients has been ascribed to a gastric acid hypersecretion, which could develop following body gastritis healing. However, the absence of an acid hypersecretive status in these patients is documented by both pathophysiology and clinical studies. Indeed, duodenal ulcer recurrence is virtually abolished following *H. pylori* eradication. In addition, intra-oesophageal pH recording studies failed to demonstrated increased acid reflux following bacterial eradication. Moreover, oesophageal manometric studies suggest that *H. pylori* eradication would reduce - rather than favor - acid reflux into the oesophagus. Finally, data of clinical studies would suggest that *H. pylori* eradication is not significantly associated with either reflux symptoms or erosive oesophagitis onset, some data suggesting also an advantage in curing the infection when oesophagitis is already present. Therefore, the legend of "crazy acid" remains - as all the others - a fascinating, but imaginary tale.

Zullo A, Hassan C, Repici A, Bruzzese V. *Helicobacter pylori* eradication and reflux disease onset: Did gastric acid get "crazy"? *World J Gastroenterol* 2013; 19(6): 786-789 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/786.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.786

INTRODUCTION

Although *Helicobacter pylori* (*H. pylori*) infection prevalence is declining in developed countries, such infection remains a worldwide spread disease with a definite morbidity and mortality. Indeed, *H. pylori* may cause non-ulcer dyspepsia, peptic ulcer disease, and gastric tumors, including both low-grade mucosa-associated lymphoid tissue lymphoma and adenocarcinoma[1-3]. In addition, an interaction between *H. pylori* with non-steroidal, anti-inflammatory drugs in damaging the gastroduodenal mucosa has been also recognized[4]. Similarly, the role of *H. pylori* in the pathogenesis of different extra-digestive diseases has also been claimed. However, an association has been consistently proven only between *H. pylori* infection and both idiopathic thrombocytopenic purpura and idiopathic iron deficiency anemia[5,6], whilst conflicting data exist for other diseases[7-9].

Gastroesophageal reflux disease (GORD) is a highly prevalent condition in the general population[10]. It is characterized by the reflux of gastric contents into the

oesophagus, leading to mucosal damage and/or typical and atypical symptoms[11]. Several factors may predispose patients to pathologic reflux, including hiatal hernia, lower esophageal sphincter (LES) hypotension, transient lower oesophageal sphincter relaxation, loss of esophageal peristaltic function, abdominal obesity, gastric hypersecretory states, and delayed gastric emptying[12].

In the last decade, a potential relationship between *H. pylori* infection and GORD has been claimed. In detail, it has been suggested that *H. pylori* eradication may cause both reflux symptoms and erosive oesophagitis. We performed a critical reappraisal of the intricate data available in such a topic.

DOES *H. PYLORI* ERADICATION CAUSE GORD?

The beginning

The first study suggesting a possible association between *H. pylori* and GORD was published by Labenz *et al*[13] on 1997. In this study, 25.8% of patients with duodenal ulcer (DU) cured for *H. pylori* infection developed erosive oesophagitis (Savary-Miller classification) at 3-year follow-up as compared to 12.9% of DU patients with ongoing infection ($P < 0.001$). Identified risk factors were male sex, severity of corpus gastritis, and weight gain. These results deserve some considerations. As shown in Figure 1, the incidence of erosive oesophagitis in *H. pylori* eradicated patients constantly increased at follow-up, so that at 3-year follow-up the curve did not still reach the plateau. This would probably suggest that an even higher oesophagitis incidence is expected at longer follow-up in these patients. However, this contrasts with data of a recent 7-year follow-up study which showed that reflux oesophagitis occurred in only 1.9% of DU patients following *H. pylori* eradication[14]. In addition, it should be noted that the curve of oesophagitis incidence in not eradicated DU patients showed a very similar slope as compared to that of eradicated patients (Figure 1). In detail, following a questionable delay of 1 year, reflux oesophagitis started to increase also in *H. pylori* infected patients, and the increase of incidence parallels with that of eradicated patients. A plausible explanation of such phenomenon could be that several not eradicated DU patients were taking anti-acid therapy, at least for the first year follow-up in this study. Indeed, this patient group included either control cases of *H. pylori* eradication trials (75 cases) or *H. pylori* eradication failure patients (141 cases) in whom DU symptoms most likely persisted[13]. Therefore, the observation of a distorted phenomenon could not be ruled out. On the other hand, it was observed that oesophagitis occurred more frequently in those *H. pylori* cured patients with weight gain > 2 kg [odds ratio (OR): 3.2; 95%CI: 1.2-9.4; $P < 0.05$] within 3-year follow-up. Unfortunately, both mean and range of weigh gain was not provided in this study. However, it is plausible that several patients changed their dietary and voluptuary habits following complete DU healing, with consequent body mass index

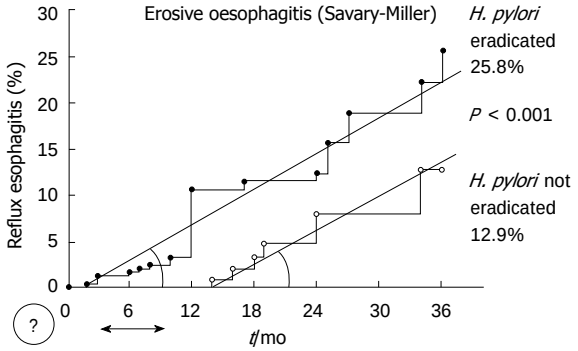

Figure 1 Incidence of erosive oesophagitis in *Helicobacter pylori* eradicated and not eradicated duodenal ulcer patients (Modified from reference 13). The comparable curve slopes would indicate a similar phenomenon. The final difference between patient groups depends on the 1-year delay between curve which remains unexplained. *H. pylori*: *Helicobacter pylori*.

(BMI) increase. The direct relationship between BMI and GORD is widely documented in literature, so that the "guilty" of erosive oesophagitis onset - at least in some patients - probably was the BMI increase rather than the *H. pylori* cure. Unfortunately, the lack of multivariate regression including *H. pylori* eradication as an independent risk factor for GORD does not allow to confirm the significant role observed solely at univariate analysis. Finally, the reason for which the risk of erosive oesophagitis incidence following *H. pylori* eradication was 3.6 (95%CI: 1.1-10.6) higher in males as compared to females remains unclear. This would contrast with the prevalence of GORD in the general population which equally occurs in both sexes[15].

The tale of a "crazy acid"

At least in theory, *H. pylori* eradication could cause GORD by: (1) recovering gastric acid secretion; (2) increasing the amount of reflux in the oesophagus; and (3) reducing the clearance of oesophageal acid exposure.

Regarding the first point, it has been observed that *H. pylori*-associated corpus-predominant gastritis is an independent risk factor (OR: 5.5; 95%CI: 2.8-13.6) for erosive oesophagitis development following *H. pylori* eradication in DU patients[13]. In this study, the body gastritis sum score before *H. pylori* eradication was 4.1 in those who developed oesophagitis as compared to 3.1 of those without oesophagitis onset. Therefore, it has been suggested that the higher degree of recovery leads into a higher acid secretion which, in turn, causes erosive oesophagitis[13]. However, by considering that the sum score (activity plus grade) of gastritis was ranging from 0 (absent) and 8 (severe), it is questionable that acid hypersecretion developed only in those patients in whom corpus gastritis score dropped from 4.1, but not from 3.1, to zero following bacterial cure. At this point, the crucial issue is to understand whether *H. pylori* eradication really causes gastric acid hypersecretion in DU patients. To our knowledge, neither pathophysiology nor clinical studies support such an event. It has been found that infected DU patients have a 3-fold increase of basal acid output (BAO)

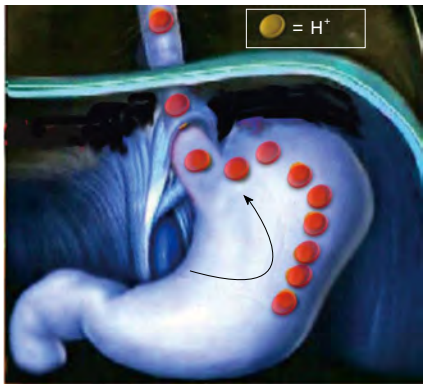

Figure 2 The "tale of a crazy acid". Following *Helicobacter pylori* gastric in duodenal ulcer patients the hypothesized acid hypersecretion would U-turn into the oesophagus instead of in the duodenal bulb.

and a 6-fold increase of stimulated maximal acid output (MAO) as compared to uninfected controls[16]. Of note, both these alterations normalize 1-year following *H. pylori* eradication, suggesting that DU patients cured for the infection completely restore normal acid secretion[16]. The absence of an acid hypersecretive status in these patients is further documented by the clinical observation that DU recurrence is virtually abolished following *H. pylori* eradication[17]. Therefore, it is unclear the reason for which the hypothesized hypersecretion in DU patients after bacterial cure should cause erosive oesophagitis onset, but not DU recurrence. To search for a plausible explication, one could hypothesize the "tale of a crazy acid". According to this theory, following the healing of corpus-predominant gastritis - a typical gastritis pattern of both gastric ulcer and cancer, but infrequent in DU[18] - acid hypersecretion occurs in some DU patients. In these patients the acid should invert its normal route - so failing to cause DU recurrence - and should turn into the oesophagus causing erosions (Figure 2). However, studies on 24-h intraoesophageal pH recording before and after *H. pylori* eradication showed that the percentage time of pH < 4.0 did not significantly change following eradication[19,20]. Other putative mechanisms by which *H. pylori* eradication could favor GORD are alterations of both LES pressure and oesophageal peristalsis. However, two studies found no difference in basal LES pressure between *H. pylori* infected and matched controls[21,22], whilst another study showed an even lower basal LES pressure and higher rate of ineffective oesophageal motility in infected patients[23]. Based on these manometric observations, it could be expected that *H. pylori* eradication would reduce - rather than favor - acid reflux into the oesophagus.

Clinical studies

Several clinical trials assessing the onset of both reflux symptoms and erosive oesophagitis have been performed. A recent meta-analysis evaluated data of 10 trials where data of patients treated for *H. pylori* infection were compared to those receiving placebo[24]. At 8-30 mo follow-up the incidence of reflux symptoms did not significantly differ between the two patient groups (17% *vs* 22.6%), with a trend even favoring bacterial eradication (OR: 0.81; 95%CI: 0.56-1.71). Likewise, erosive oesophagitis equally occurred in both groups (5% *vs* 5.1%; OR: 1.13; 95%CI: 0.72-1.78). Noteworthy, a study on 156 patients with both peptic ulcer and reflux oesophagitis found that the oesophageal lesions improved more frequently in *H. pylori* eradicated patients as compared to those with persistent infection[25]. Overall, these data would suggest that *H. pylori* eradication is not significantly associated with either reflux symptoms or erosive oesophagitis onset, some data suggesting also an advantage in curing the infection when oesophagitis is already present.

CONCLUSION

GORD is highly prevalent in the general population. Several altered mechanisms are involved in its pathogenesis, and different lifestyle and voluptuary habits have been identified as risk factors. In the last decade, *H. pylori* eradication has been charged to cause GORD. The main putative mechanism is that a gastric acid hypersecretion develops following bacterial cure in those patients with corpus-predominant gastritis. However, studies on acid secretion demonstrated that the hypersecretion status of both DU (BAO × 3; MAO × 6) and non-ulcer dyspeptic (MAO × 3) patients observed during *H. pylori* infection normalizes following bacterial eradication[16]. Indeed, DU does not recur following a successful *H. pylori* cure[17]. Therefore, the reported erosive oesophagitis onset after the infection cure in DU patients most likely depends on other factors rather gastric acid hypersecretion (Weight gain? Changes of voluptuary habits?). On the other hand, both oesophageal 24-h pH recording and manometry studies failed to demonstrate a significant role for *H. pylori* in GORD.

Gastric acid secretion may recover with *H. pylori* eradication in those patients with corpus-predominant (or atrophic) gastritis[26]. However, such a gastritis pattern is generally encountered in either gastric ulcer or cancer patients, and it is highly prevalent in Asian countries[18]. However, the reason for which such a hypersecretive status should cause GORD but not DU onset in these patients remains unclear.

The last but not the least, several, placebo-controlled, clinical trials have been recently summarized in a meta-analysis including near 4500 patients[25]. Data found that neither reflux symptoms nor erosive oesophagitis develop following *H. pylori* eradication. Therefore, the legend of "crazy acid" remains - as all the others - a fascinating, but imaginary tale!

Abstract

Eosinophilic oesophagitis (EoE) is a chronic, antigen mediated disease of the disease of the oesophagus that may present in both adults and children. It is characterised by intermittent dysphagia, food bolus obstruction and weight loss. The pathogenesis is incompletely understood but is thought to culminate in poor compliance, or reduced distensibility. The condition is being reported and studied in the literature with increasing incidence, although equally it is highly likely that the diagnosis is being missed altogether with alarming frequency. Diagnosis of the condition requires at least one oesophageal biopsy with an eosinophil count greater than 15 per high power field. Endoscopic features include trachealisation, furrows, white exudate, narrowing and in the most severe cases stricture formation although none are pathognomonic of the condition. Therapy is often not required, but in the acute setting may take the form of dietary therapy or topical steroids. Long term maintenance therapy is usually only required in the most severe cases and the most effective treatment is the subject of ongoing research. There are a number of hurdles to be overcome in the management of patients with EoE. These include; improving our understanding of the aetiology of the condition, investigating the individual causes, assessing the true disease severity and planning the best long term maintenance therapy. Distinguishing EoE from EoE gastro-oesophageal reflux disease is also a hurdle because the two conditions, both being common, can co-exist. In order to overcome these hurdles, a multifaceted approach is required. The management of food bolus obstruction requires a management algorithm that is accepted and endorsed by a number of specialties. National and international disease registers should be established in order to facilitate future research but more importantly to address areas where further education or increased diagnostic capabilities may be required. Assessment of disease severity should become a key goal, and the development of specific biomarkers for EoE should also be a priority. Finally, randomised controlled trials of new agents are required to assess the best treatment in both the acute and long term setting.

INTRODUCTION

Eosinophilic oesophagitis (EoE) is an increasingly common cause of dysphagia or food bolus obstruction. EoE is a chronic antigen mediated disease of the oesophagus. It is characterised symptomatically by oesophageal dysfunction and histologically by eosinophil predominant inflammation. The condition was first described almost 30

years ago in a cohort of patients with > 20 intraepithelial eosinophils (IEE) per high power field seen on oesophageal biopsy, with 11 of the 12 demonstrating normal oesophageal acid exposure on 24 pH monitoring[1]. A further cohort of 10 patients with recurrent dysphagia and high concentrations of IEE at endoscopic biopsy was reported in 1994[2].

Until 2007 only 212 cases had been reported in the literature[3]. Since that time, the reporting of cases of EoE has increased dramatically. More than 750 articles incorporating several thousand patients have been published on the subject since being first described with seventy five per cent being published in the last five years.

EoE is sometimes described as "oesophageal asthma" on account of its association with atopy. Up to 50% of patients also have bronchial asthma or allergic rhinitis, and 20% have atopic dermatitis[4]. Males are affected three times more often than females, and patients typically present either in childhood or during the third or fourth decades of life.

The typical presenting features of this condition include intermittent dysphagia, food bolus obstruction and weight loss. In the paediatric population, patients may also present with nausea, vomiting, weight loss and failure to thrive.

Recent consensus guidelines state that histological evidence of at least 15 intraepithelial eosinophils per high power field (eos/hpf) in at least one oesophageal mucosal biopsy stained with haematoxylin and eosin is required for the diagnosis. However, in the correct clinical setting, patients may be considered to have EoE with < 15 eos/hpf. An example would be an atopic male on a proton pump inhibitor (PPI) at the time of diagnostic endoscopy with typical endoscopic findings. Gastro-oesophageal reflux disease (GORD) should be excluded by demonstrating a lack of response to high dose proton pump inhibitor therapy or normal oesophageal pH monitoring[5,6].

Not only is oesophageal biopsy essential in all patients with food bolus obstruction or dysphagia, regardless of the endoscopic appearance, the number of biopsies taken is also important. A minimum of six biopsies should be taken; two each from the upper, mid and lower oesophagus. Using a benchmark of 15 eos/hpf, it has been shown that the diagnostic sensitivity for EoE is 84%, 97% and 100% when 2, 3 and 6 biopsies are taken respectively[7]. A further study demonstrated 100% sensitivity when 5 biopsies were taken[8].

Estimates of the prevalence of EoE in the general population vary in the literature. In Switzerland, the adult prevalence has been estimated to be 0.02%[9], 0.44% in the United States[10] and 1% in Sweden[11]. In more targeted populations, such as those undergoing oesophageal endoscopy the prevalence is significantly greater and in the region of 6%-15%[12,13].

The current hurdles in the management of patients with EoE include; improving our understanding of the aetiology of the condition, investigating the individual causes, assessing the true disease severity and planning the best long term maintenance therapy. Distinguishing EoE from GORD is also a hurdle because the two conditions, both being common, can co-exist.

AETIOLOGY AND PATHOPHYSIOLOGY

The pathophysiology of this condition is incompletely understood and is the subject of ongoing research and debate. Expert consensus has concluded that the condition arises as a result of an antigen mediated immunologic process resulting in oesophageal inflammation. The specific allergen(s) is yet to be identified but a number of theories have been postulated. Skin prick testing has been shown to have a poor predictive value for the identification of specific food allergens in patients with EoE[14]. Given that the condition is being reported with increasing frequency this raises the possibility of an environmental allergen being involved in the pathogenesis. The "hygiene hypothesis" or declining incidence of *Helicobacter pylori* have both been proposed to play a role given that they have coincided with increased incidence of EoE[15,16].

Acid reflux (GORD) is not usually present in patients with EoE. However, it is standard practice to perform diagnostic biopsies while patients are on PPI to exclude the contribution of reflux injury[5]. When symptoms are atypical, or if there is a mixture of reflux symptoms and dysphagic EoE symptoms then 24 h pH monitoring should be employed to guide therapy. There is a subgroup of symptomatically typical EoE patients, with normal pH profiles who seem to respond to PPI, and these PPI responsive patients will benefit from with maintenance therapy[17].

Oesophageal biopsy specimens from patients with EoE compared to normal controls or patients with GORD show increased levels of the T helper 2 (Th2) cytokines, principally interleukin-5 (IL-5) and IL-13[18-20], with increased levels of the eosinophil chemoattractants eotaxin-1 and eotaxin-3 also reported[20-23]. Other studies have also demonstrated increased levels of other cytokines such as tumour necrosis factor-β1 and fibroblast growth factor-9[24,25]. GORD can be distinguished from EoE by its high level of COX-2 activation, while both show high rates of proliferation (Ki-67)[26].

It is thought that long standing oesophageal inflammation results in remodelling of the oesophageal wall in a similar manner to the airway remodelling seen in patients with bronchial asthma. A potential sequela is a fragile mucosa that is likely to tear easily as demonstrated by reported cases of spontaneous or procedure induced oesophageal rupture.

ASSESSING THE TRUE DISEASE SEVERITY

EoE can present at any age, but is more prevalent in childhood or during the third and fourth decades of life[5]. Adult patients typically present with a long history of intermittent, often severe dysphagia. In the most se-

vere cases the dysphagia may be continuous and associated with odynophagia and chest pain. EoE is also prevalent in the paediatric population, and is often associated with other atopic conditions. The clinical presentation varies with age. Infants and toddlers may present with prolonged feeding time or frank denial of food, whereas older children may present with vomiting and odynophagia. Adolescents, like adults tend to present with dysphagia. Less frequently, the child may present with failure to thrive and weight loss[27,28].

EoE is associated with a number of abnormalities of the oesophagus at endoscopy. These include; oesophageal rings (or trachealisation), furrows, white exudate, narrowing and in the most severe cases stricture formation. The pathogenesis of dysphagia in EoE is believed to be poor compliance, or reduced distensibility. If this affects the esophagus diffusely then a narrow bore oesophagus that fails to distend will result. If there is focal fibrosis, a stricture will be evident. The distinction is important when considering interventions such as dilation[29]. However, normal endoscopic findings do not exclude the diagnosis and neither are the above endoscopic findings pathognomonic of the condition. A number of studies have demonstrated histopathological evidence of EoE in patients with normal appearance of the oesophagus at endoscopy. This highlights the importance of oesophageal biopsy for all patients presenting with food bolus obstruction or dysphagia, even in the presence of a normal looking oesophagus[12,30].

Recent research has also shown that up to half of patients who present acutely with food bolus obstruction have underlying EoE. In a prospective series of 43 patients presenting with food bolus obstruction, of whom 29 had biopsies taken from the proximal and distal oesophagus, 14 (50%) fulfilled the histological criteria for EoE[31]. A further study reported that 17 of 31 (55%) patients presenting with food bolus obstruction fulfilled the histological criteria for EoE[32]. It is for these reasons that the most recent consensus guidelines stress the need for oesophageal biopsy of all patients presenting with dysphagia. In patients presenting with acute food bolus obstruction, oesophageal biopsies should also be taken at the time of disimpaction with arrangements made for appropriate clinical follow up[33]. In countries where the management of acute food bolus obstruction is principally managed by non EoE specialists, efforts should be made to raise awareness of the condition in order to avoid missed diagnoses[34].

A disease specific EoE health related quality of life questionnaire has also been developed[35]. This may be useful in identifying those who may benefit from treatment and in the assessment of response to therapy both in the clinical and research setting. There is a need to identify overall disease severity and to establish if symptoms, endoscopy or pathology can predict therapeutic outcomes.

Attention has also turned towards identifying potential biomarkers of the disease. Serum eosinophil derived neurotoxin has recently been highlighted as a potential diagnostic biomarker for EoE that may also be valid in assessing response to therapy and relapse of symptoms[36].

THERAPY

The acute management of EoE has a fairly well established pattern of treatment algorithms. In the paediatric setting, diet and topical steroids are the mainstay of treatment in the acute phase.In adults non obstructive disease is usually treated with topical steroids as the first line therapy, along with avoidance of known food precipitants. For obstructive EoE dilatation is worthwhile. Long term maintenance therapy is believed to be valuable but there is no evidence in controlled studies with long term follow up. Disease severity is both difficult to score and not predictive of long term natural history. The lack of long term therapy does not necessarily lead to the development of long term complications[37].

Dietary therapy in the acute setting can take on a number of forms. The introduction of an elemental diet has been used effectively to induce remission of symptoms and oesophageal inflammation particularly in the paediatric setting[38], with some recent success reported in adult[39]. In adults, the role of dietary therapy is being assessed but is not well established. The major drawback of this approach is the unpalatable nature of the diet. Some diets are intolerable in the long term, and recurrence of symptoms after cessation of the elemental diet is common. An alternative approach has been attempted, again with some success. This involved the introduction of a six-food elimination diet (wheat, milk, eggs, soya, nuts and rice) over a 6-12 wk period and improved patients' symptoms[40,41]. Further work by the same group highlighted the major drawback of dietary therapy in terms of compliance with the avoidance of particular food groups that are so common in western societies[42]. In the paediatric setting there has been some success with single food introduction following the six food elimination diet, with milk being identified as the most common causative food antigen[43].

Topical steroids in the acute setting are usually very effective with 60%-80% symptom resolution[44]. For long term maintenance topical corticosteroids have demonstrated some efficacy[44,45] although there is a risk of candida infection with long term use. Traditionally, topical steroid therapy is in widespread use for the management of bronchial asthma. In EoE the topical steroid is swallowed as opposed to inhaled. The most frequently employed topical steroid is fluticasone propionate at a dose of 300 to 500 micrograms twice daily, but doses of up to 880 micrograms twice daily have also been reported. The aim is to maximise exposure to the oesophagus and therefore spraying the back of the throat and swallowing the agent coats the oesophagus. This should be undertaken twice daily (morning and night time) to maximise the exposure of topical steroid to the oesophagus over a 24-h period. More recently, oral viscous budesonide has

also been shown to be effective[46,47] and in one case report a superior alternative to swallowed fluticasone[48]. Studies of clinical response to topical steroids do show variation in clinical outcome and also poor correlation of histological response with clinical improvement[49]. It is thought that topical corticosteroid therapy acts by reversing the oesophageal remodelling that occurs in EoE[45]. In a paediatric population fluticasone has been associated with improvements in the endoscopic, histologic and immunological parameters of EoE. However, the improvement was less marked in patients with a history of allergy[50].

In some patients reflux type symptoms and occasionally dysphagia is improved by PPI therapy. It is useful to measure the degree of acid reflux in these patients with 24 h pH monitoring to help gauge the need for combinations of PPI and topical steroid therapy.

Monteleukast, a leukotriene receptor antagonist has been proposed as a long term treatment. In an observational study of twelve patients, monteleukast was associated with a good symptomatic response (dysphagia scores and frequency of bolus obstruction) with an inconsistent reduction in the associated concentration of eosinophils[51]. A similar response has been demonstrated in a small cohort of paediatric patients[52]. The use of monteleukast has been criticised in some quarters on account of the lack of a placebo controlled group in the original paper reporting its use, and a further study has shown that monteleukast is inefficient in maintaining steroid reduced remission in EoE[53].

Oesophageal dilatation has been shown to be a safe and effective therapy in EoE, particularly in the presence of strictures[54]. However, mucosal tears are a worrisome occurrence but may be acceptable if an effective dilatation is achieved. Oesophageal perforation is a recognised complication of this procedure, but rare[55]. As a result, this intervention gained an adverse reputation somewhat prematurely. A recent systematic review has estimated a 0.1% risk of oesophageal perforation as a direct result of oesophageal dilatation[56,57], and this is no different to the risk of perforation when dilating a peptic stricture[58].

EoE may cause a stiffening of the oesophageal wall and produce poor compliance. Subsequent attempts to regurgitate or dislodge a food bolus may then cause a tear (usually partial) in the oesophagus[59-61]. The frequency of perforation seems to be greater from the food bolus itself than with dilatation. Management needs careful assessment because if the perforation is only a dissection, with a contained leak and no free fluid in the chest cavity, then non surgical management may be sufficient. The majority of such perforations heal with such a conservative approach[5].

More recently, attention has turned towards potential monoclonal antibody therapies against specific cytokines. Mepolizumab, a monoclonal antibody against IL-5 has been shown in a small randomised controlled trial to reduce the peak oesophageal eosinophil count, but with no improvement in clinical symptoms[62]. Similarly reslizumab (anti IL-5)[63], infliximab (anti-tumor necrosis factor-α)[64] and omalizumab (anti-IgE)[65] have been shown to reduce peak oesophageal eosinophil counts with no improvement in clinical symptoms. Results from larger randomised trials are awaited.

With thoughts towards the future, potential targets for therapy are being evaluated. One candidate currently in phase Ⅱ clinical trials is the chemoattractant receptor expressed on Th2 cells (CRTH2) antagonist[66]. CRTH2 is a receptor expressed on Th2 cells that is known to bind to prostaglandin in asthmatics. By developing a drug with the ability to block this receptor it is hoped that a key component of the inflammatory response in patients with EoE will be disabled with a subsequent clinical improvement for the patient.

FUTURE CHALLENGES

In order to facilitate future clinical research into this condition then the largest centres should collaborate closely. Both national and international disease registers should be established in order to better understand the epidemiology of this novel condition. National and international registers will enable the identification of the largest centres with the highest incidence and prevalence, but more importantly identify those centres with low or zero prevalence. This will enable targeted education to be focused upon these centres as undoubtedly this represents missed or misinterpreted diagnoses.

With recent research highlighting that up to half of patients presenting with acute food bolus obstruction fulfil the diagnostic criteria for EoE, formal protocols should be implemented to ensure that patients undergo oesophageal biopsy at the time of disimpaction to exclude EoE. In a number of countries where the management of acute food bolus obstruction is managed by specialties with little or no knowledge of the existence of this condition this will require collaborative links to be forged between gastroenterology, ENT and surgical colleagues as appropriate. Ensuring these patients undergo oesophageal biopsy is likely to result in a significant increase in the incidence of EoE and sufficient resources should be in place in order to cope. This will require dissemination of the existence of this condition into primary care.

Abstract

Percutaneous ablation using thermal or chemical methods has been widely used in the treatment of hepatocellular carcinoma (HCC). Nowadays, contrast-enhanced imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and contrast-enhanced ultrasound (CEUS) are widely used to evaluate local treatment response after ablation therapies. CEUS is gaining increasing attention due to its characteristics including real-time scanning, easy performance, lack of radiation, wide availability, and lack of allergy reactions. Several studies have documented that CEUS is comparable to CT or MRI in evaluating local treatment efficacy within 1 mo of treatment. However, little information is available regarding the role of CEUS in the follow-up assessment after first successful ablation treatment. Zheng *et al* found that in comparison with contrast-enhanced computed tomography (CECT), the sensitivity, specificity, positive predictive value, negative predictive value and overall accuracy of CEUS in detecting local tumor progression (LTP) were 67.5%, 97.4%, 81.8%, 94.4% and 92.3%, respectively, and were 77.7%, 92.0%, 92.4%, 76.7% and 84.0%, respectively for the detection of new intrahepatic recurrence. They concluded that the sensitivity of CEUS in detecting LTP and new intrahepatic recurrence after ablation is relatively low in comparison with CECT, and CEUS cannot replace CECT in the follow-up assessment after percutaneous ablation for HCC. These results are meaningful and instructive, and indicated that in the follow-up period, the use of CEUS alone is not sufficient. In this commentary, we discuss the discordance between CT and CEUS, as well as the underlying mechanisms involved. We propose the combined use of CT and CEUS which will reduce false positive and negative results in both modalities. We also discuss future issues, such as an evidence-based ideal imaging follow-up scheme, and a cost-effectiveness analysis of this imaging follow-up scheme.

COMMENTARY ON HOT TOPICS

We read with great interest the recent article by Zheng *et al*[1] evaluating the usefulness of contrast-enhanced ultrasound (CEUS) in the follow-up of patients with he-

patocellular carcinoma (HCC) who had undergone local ablation therapies.

As a minimal invasive and safe treatment method, percutaneous ablation using thermal or chemical methods has been widely used in the treatment of early HCC, recurrent HCC, and even advanced HCC[2-11]. Percutaneous ablation such as radiofrequency ablation (RFA), microwave ablation and ethanol ablation (EA), is regarded as the curative treatment method for early HCC[12,13]. In contrast to surgical resection where the tumor is removed, the tumor is not eradicated from the body but is deactivated by ablation therapy, therefore, it is of paramount importance to evaluate the efficacy of this treatment to determine follow-up treatment and strategy. Currently, the use of contrast-enhanced imaging to detect residual viable tumor or recurrent HCC is widely accepted[14-19]. The underlying mechanism of this imaging method relates to the fact that viable tumor tissue shows arterial hypervascularity (*i.e.*, hyper-enhancement), whereas destroyed tumor shows absence of vascularity (*i.e.*, non-enhancement), thus the distinction between them is achievable. However, this method is not ideal as imaging studies may fail to detect tiny viable tumor tissue, especially when neoangiogenesis is not obvious. Percutaneous biopsy may be another option, however, this technique has significant sample error and it is not ethical and practical to sample all the lesion after ablation. Consequently, contrast-enhanced imaging modalities such as computed tomography (CT), magnetic resonance imaging (MRI), and CEUS are currently widely used to evaluate local treatment response after ablation therapies. Although CT and MRI are accepted as the reference standards, the newly introduced CEUS is also gaining increasing attention due to its characteristics including real-time scanning, easy performance, lack of radiation, wide availability, and lack of allergic reactions[20-38]. Several studies have documented that CEUS is comparable to CT or MRI in evaluating local treatment efficacy within one mo of treatment (Table 1)[18,39-41]. Kim *et al*[42] also reported that they were in favor of CEUS as it had the advantage of being able to detect lesions < 2 cm; therefore, CEUS has been used effectively in diagnostic algorithms for small 1-2 cm newly detected nodules in HCC patients. However, little information is available regarding the role of CEUS in the follow-up assessment after first successful ablation treatment. In the follow-up period, the patient may develop local tumor progression (LTP) or new intrahepatic recurrence, and imaging modalities are used to successfully detect these lesions.

In the study by Zheng *et al*[1], 141 patients with HCCs who underwent percutaneous ablation therapy were assessed by paired follow-up CEUS and contrast-enhanced computed tomography (CECT). Using CECT as the reference standard, the ability of CEUS to detect LTP or new intrahepatic recurrence during follow-up was evaluated. They found that 33 LTP and 131 new intrahepatic recurrent foci were detected on CEUS, whereas 40 and 183 were detected on CECT, respectively (both $P < 0.05$). Compared with CECT, the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and overall accuracy of CEUS in detecting LTP were 67.5%, 97.4%, 81.8%, 94.4% and 92.3%, respectively, and were 77.7%, 92.0%, 92.4%, 76.7% and 84.0%, respectively for the detection of new intrahepatic recurrence. They concluded that the sensitivity of CEUS in detecting LTP and new intrahepatic recurrence after ablation was relatively low compared with CECT, and that CEUS can not replace CECT in the follow-up assessment after percutaneous ablation for HCC. Their results are interesting and meaningful, and we agree with the authors regarding the role of CEUS in the follow-up of HCC patients after ablation therapy.

The discordance in imaging features between CT and CEUS is well recognized, and is largely due to the difference in pharmacokinetics between CT contrast medium and ultrasound contrast agent[35,43]. The CT contrast medium diffuses into the interstitial space, while the ultrasound contrast agent is a pure blood pool tracer. The CEUS characteristic of real-time scanning is helpful in detecting subtle lesions with transient arterial hyper-enhancement which is hard to visualize on CT. Some lesions may show arterial iso-enhancement on CT and hyper-enhancement on CEUS due to the limited time window in CT scanning[44-49]. On the other hand, CEUS also has its shortcomings as shown by Zheng *et al*[1] who found that image quality was affected by lesions located near the liver dome, and obscuration due to gas from the lung or intestine. The development of new foci may be located in different lobes of the liver, and the arterial hyper-enhancement on CEUS only lasts for several seconds, thus it is difficult to detect all hypervascular lesions in one scanning procedure. Most importantly, in comparison with CT/MRI, there is universal bias in readers' minds with regards to ultrasound images. The quality of the procedure and subsequent results are largely operator-dependent, thus less uniformity is encountered in clinical practice (Table 2).

The data in the above-mentioned article are detailed and reasonable results have been obtained. However, there is still controversy over the role of CEUS *vs* CECT in the diagnosis of HCC after ablation, which is largely dependent on individual opinion and familiarity with the techniques. Frieser *et al*[39] concluded that CEUS is equal to CECT in evaluating treatment response. Gallotti *et al*[46] found that CEUS was excellent in evaluating treatment response after RFA, whereas it was inadequate for evaluating treatment response after EA. It should be noted that despite the vast number of published studies on the subject, a unanimous consensus has not been achieved.

There are a number of unsolved issues regarding the use of CEUS and CECT including the following: (1) The authors should recommend the combined use of CT and CEUS in clinical practice when CEUS is available, which will reduce the number of false positive and negative findings in both modalities[50]. In a study of liver lesion characterization, although no follow-up assessment after

Table 1 Diagnostic values of contrast-enhanced imaging in evaluating treatment response after ablation for liver cancer

Table 2 Comparison between contrast-enhanced ultrasound and contrast-enhanced computed tomography in the follow-up scheme after liver cancer ablation

	CEUS	CECT
Pharmacokinetics of the contrast	Early vascular phase; followed by diffusion into the interstitial space	Pure blood pool tracer; without diffusion into the interstitial space
Strong points	Real-time scanning, easy to perform, no radiation, wide availability, and no allergic reactions	High image quality; operator-independent; panoramic imaging; easy to interpret
Weak points	Image quality is apt to be affected by lesions located near the liver dome, and obscuration by gas from the lung or intestine; Inability to imaging multiple lesions in one procedure; operator-dependent	Inferior temporal resolution; allergic reaction to the contrast-medium; unsuitable for patients with kidney function impairment; radiation; inferior availability

CEUS: Contrast-enhanced ultrasound; CECT: Contrast-enhanced computed tomography.

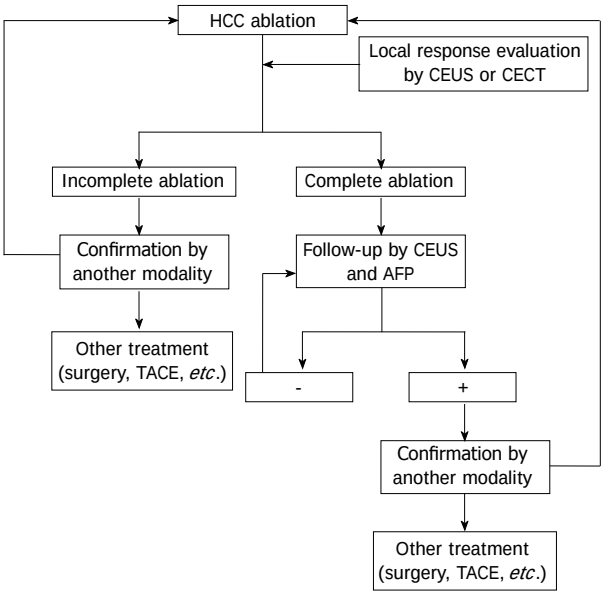

Figure 1 The proposed algorithm combining the strengths of the radiologic techniques of contrast-enhanced ultrasound and contrast-enhanced computed tomography. HCC: Hepatocellular carcinoma; CEUS: Contrast-enhanced ultrasound; CECT: Contrast-enhanced computed tomography; AFP: α fetoprotein; TACE: Transarterial chemoembolization; -: Negative finding; +: Positive finding.

ablation was carried out, the authors found that combined assessment using CEUS/CT provided higher sensitivity (97%, both readers) than separate assessment using CEUS (88% reader 1; 87% reader 2) and CT (74% reader 1; 71% reader 2; $P < 0.05$), while no change in specificity was observed using the combined analysis. The combined assessment of hepatocellular nodule vascularity using CT and CEUS improved diagnostic sensitivity of malignancy in patients with liver cirrhosis[50]. However, the study by Zheng *et al*[1] was retrospective, thus it is difficult to assess the value of the combined diagnostic procedures in clinical practice, which has prompted a future prospective study to evaluate this issue. Fusion imaging may be another solution which combines the virtues of both modalities[51]; (2) The ideal imaging follow-up scheme is not yet available. Future evidence-based studies are necessary to establish this scheme. Every practicing clinician must make a decision on the most accurate, cost-effective radiologic test to be used in the follow-up of liver lesions after local treatment. A reasonable algorithm is proposed and is shown in Figure 1, however, further study is mandatory to evaluate its efficacy; (3) A cost-effectiveness analysis should be performed to select the best imaging follow-up scheme; and (4) Long-term follow-up studies are needed to help guide our approach and therapy.

Abstract

Non-alcoholic fatty liver disease (NAFLD) is recognized as the most common type of chronic liver disease in Western countries. Insulin resistance is a key factor in the pathogenesis of NAFLD, the latter being considered as the hepatic component of insulin resistance or obesity. Adiponectin is the most abundant adipose-specific adipokine. There is evidence that adiponectin decreases hepatic and systematic insulin resistance, and attenuates liver inflammation and fibrosis. Adiponectin generally predicts steatosis grade and the severity of NAFLD; however, to what extent this is a direct effect or related to the presence of more severe insulin resistance or obesity remains to be addressed. Although there is no proven pharmacotherapy for the treatment of NAFLD, recent therapeutic strategies have focused on the indirect upregulation of adiponectin through the administration of various therapeutic agents and/or lifestyle modifications. In this adiponectin-focused review, the pathogenetic role and the potential therapeutic benefits of adiponectin in NAFLD are analyzed systematically.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is the most common type of chronic liver injury in many countries[1,2]. NAFLD includes a spectrum of syndromes, ranging from simple steatosis, non-alcoholic steatohepatitis (NASH) to fibrosis, cirrhosis and hepatocellular carcinoma[3]. The overall prevalence of NAFLD is 15%-40% in Western countries and 9%-40% in the Asian population[4]. NAFLD has dramatically increased over the past 15 years, mainly as a consequence of its close association with two major worldwide epidemics, obesity and type 2 diabetes mellitus (T2DM)[5]. Mortality in patients with NAFLD is significantly higher than in the age and gender-matched general population[6]. Disease progression to NASH and cirrhosis appears to be very slow, and only a few patients develop life-threatening advanced liver disease.

In many cases of NAFLD, the risks of developing metabolic and cardiovascular morbidities are much higher than the risks of developing hepatic diseases[7,8]. In fact, NAFLD is considered as the hepatic manifestation of the metabolic syndrome, which refers to a cluster of cardiovascular risk factors associated with insulin resistance, including central obesity, hypertension, dyslipidemia and T2DM[9]. The association between NAFLD and metabolic syndrome has been established in many cross-sectional and prospective studies[8]. NAFLD significantly increases the risk of diabetes and is a better predictor of the development of metabolic disorders than obesity

itself[10]. Some studies have reported an association of NAFLD with multiple classical and non-classical risk factors for cardiovascular diseases[7]. NAFLD predicts future cardiovascular events independently of other prognostic factors, including the component of metabolic syndrome. In summary, NAFLD is associated with a future high incidence of cardiovascular and metabolic complications and should be considered beyond a liver disease confined to classical boundaries. Understanding the disease and its management is a vital issue in current clinical practice.

PATHOGENESIS OF NAFLD

Although the pathogenesis of NAFLD remains largely unknown, insulin resistance, oxidative stress and inflammation play important roles in the development and progression of NAFLD[11,12]. Fatty liver itself is a status of insulin resistance. Hepatic fat accumulation can lead to hepatic insulin resistance, which may occur before the alterations in peripheral insulin actions and may induce peripheral insulin resistance[13,14]. Insulin regulates the uptake, oxidation and storage of fuel within insulin-sensitive tissues including the liver, skeletal muscle and fat. Peripheral insulin resistance impairs glucose uptake from blood into skeletal muscle and adipose tissue; serum non-esterified fatty acid (NEFA) levels may also be elevated because of the failure of insulin to suppress lipolysis[15,16]. In the liver, insulin resistance is associated with increased cellular contents of fatty acids and their metabolites (fatty acyl-CoAs, diacylglycerides and ceramides)[17-19]. Hyperinsulinemia caused by insulin resistance, in the presence of increased circulating levels of NEFA, enhances the hepatic uptake of fatty acid and promotes lipogenesis[1,20]. In addition, defects in mitochondrial β-oxidation, enhanced fatty acid synthesis and impaired secretion of triacylglyceride-rich very low density lipoproteins also contribute to hepatic steatosis[21-23]. A growing body of evidence from animal models suggests a "two-hit" hypothesis as being responsible for the development of NAFLD[24-26]. According to this theory, the first hit is the occurrence of fatty liver (steatosis), followed by a second event leading to the development of NASH. The potential secondary hits include endotoxin exposure, alcohol consumption and virus infections, which expand hepatic lipid stores, cause hepatocellular injury, and promote oxidative stress and inflammation in the liver. Lipotoxicity, and the release of cytokines and other pro-inflammatory mediators, play important roles during this process. Moreover, inflammation in the development of NASH can further impede insulin signaling[27]. Histologically, NASH is manifested by hepatocyte nuclear ballooning, hepatocyte apoptosis, Mallory's hyaline and inflammation foci[28]. NAFLD patients have a high circulating free fatty acids (FFAs) level that correlates with the severity of liver disease. Overloaded FFAs may exhibit lipotoxicity by inducing the expression of proinflammatory cytokines, such as tumor necrosis factor alpha (TNF-α)[29].

VISCERAL OBESITY, ADIPOKINES AND NAFLD

Obesity, especially visceral obesity, is frequently associated with NAFLD and their coexistence in the same individual increases the likelihood of having more advanced forms of liver disease[30,31]. NAFLD occurs in 60%-95% of people with obesity[32]. Visceral fat is a key mediator of NASH and is strongly associated with alanine aminotransferase (ALT) levels in the nondiabetic obese population[31,33,34]. The importance of visceral fat in the pathogenesis of NAFLD has also been shown in many animal models, including *fa/fa* obese rats. In these animals, surgical resection of intra abdominal fat depots reverses hepatic insulin resistance and steatosis[35].

Recent evidence suggests that visceral adipose tissue is a metabolic and inflammatory organ that signals and modulates the action and metabolism of the brain, liver, muscle and cardiovascular system[36,37]. The imbalanced production of pro- and anti-inflammatory adipokines secreted from fat contributes to the pathogenesis of NAFLD[38]. Modulation of endocrine/immune/inflammatory interactions of adipose tissue may provide novel therapeutic (pharmacological) targets for the treatment of NAFLD. For example, in patients with severe lipodystrophy, injection with leptin reverses nonalcoholic fatty liver diseases[39,40]. However, in cases of NAFLD associated with obesity, serum levels of leptin are increased, and the liver becomes refractory to the "anti-steatotic" effects of leptin[41-43]. Leptin infusion is therefore unlikely to be of therapeutic value for patients with NAFLD. TNF-α, a pro-inflammatory adipokine that interferes with insulin signaling and favors steatosis, may play a casual role in the pathogenesis of NASH[38]. Circulating levels of TNF-α and hepatic expression of its type 1 receptor are increased in NASH, but could not discriminate steatohepatitis from steatosis[44-46]. Neutralization of TNF-α activity improves fatty liver disease in animals[47]. Conversely, nutritional steatohepatitis can still be produced experimentally in both TNF-α and TNF-α type 1 receptor knockout mice, suggesting that this adipokine might not be an essential mediator of NAFLD[48,49]. In contrast to leptin and TNF-α, adiponectin is more closely implicated in the pathogenesis of NAFLD/NASH. Unlike other adipokines, serum levels of adiponectin are decreased in obesity and its associated medical complications[50]. A negative association between serum levels of adiponectin and liver enzyme levels has been shown in healthy subjects[51]. Numerous epidemiological investigations in diverse ethnic groups have identified lower adiponectin level as an independent risk factor for NAFLDs and liver dysfunctions[37]. Compared with healthy controls, adiponectin levels are lower by more than 50% in NASH patients[52]. Adiponectin expression is decreased by 20%-40% during the development of NAFLD, from simple steatosis to NASH[52,53]. Moreover, NASH patients with lower levels of adiponectin show higher grades of inflammation, suggesting that adiponectin deficiency is an important risk factor

for the development of fatty liver, steatohepatitis and other forms of liver injuries[52-55]. In patients with T2DM, plasma adiponectin concentrations are inversely related to hepatic fat content[56]. There is a direct relationship between hypoadiponectinemia and NASH, independent of insulin resistance[52]. Animal-based studies have demonstrated that adiponectin possesses potent protective activities against various forms of liver injury, including those induced by carbon tetrachloride, lipopolysaccharide (LPS)/*D*-galactosamine, pharmacological compounds, bile duct ligations and methionine-deficient diet[57-61]. In animal models of both alcoholic and nonalcoholic steatohepatitis, exogenous adiponectin reduces hepatomegaly, depletes lipid accumulation, quenches hepatic inflammation and decreases hepatic expression and plasma concentrations of TNF-α[62]. Adiponectin knockout mice exhibit an enhanced pattern of hepatic fibrosis induced by carbon tetrachloride[58]. The lack of adiponectin expression could accelerate hepatic tumor formation in a NASH model in mice[63]. Among the known adipokines, adiponectin stands out for its insulin-sensitizing and anti-inflammatory roles, and may be used as a promising drug candidate for the treatment of liver diseases.

HEPATOPROTECTIVE FUNCTIONS OF ADIPONECTIN: STRUCTURAL BASIS AND SIGNALLING MECHANISMS

Four independent groups originally identified adiponectin, also termed Acrp30, AdipoQ, apM1 or GBP28, in both mice and humans[64-67]. This adipokine has attracted much attention because of its multiple beneficial effects on a cluster of obesity-related metabolic and cardiovascular dysfunctions. Hypoadiponectinemia is a key etiological factor contributing to almost all the major pathological conditions associated with obesity[68]. The physiological functions and clinical relevance of adiponectin in obesity-related medical complications have been extensively reviewed elsewhere[50,69-72]. In the following sections, we will discuss recent advances on the structural regulations of adiponectin as well as the molecular evidence supporting the role of adiponectin as a major protective agent against obesity-related NAFLD.

Polymorphism of the multimeric structures of adiponectin

A unique feature of the structure of adiponectin is its ability to assemble into several characteristic oligomeric isoforms, including trimers [low molecular weight (LMW)], hexamers [middle molecular weight (MMW)] and the oligomeric complexes comprising 18 protomers or above [high molecular weight (HMW)][73]. Adiponectin presents predominantly in the circulation as these three oligomeric complexes[74-79]. Trimeric adiponectin is the basic building block of adiponectin. The subunits in the trimer are associated *via* hydrophobic interactions. Two LMW adiponectin molecules linked by disulfide bonds form hexameric adiponectin. The structural properties of the HMW adiponectin remain poorly characterized because of the heterogeneous nature of this isoform. Analysis of adiponectin oligomers by non-denaturing and non-heating gel electrophoresis shows that the human HMW adiponectin composes of a mixture of 18-30 mers, or even larger molecular weight species[73,78,80,81]. Dynamic light scattering and transmission electron microscopy shows that the bovine HMW adiponectin forms a bouquet-like architecture resembling that of complement C1q[82]. Six globular objects can be seen atop a thin stalk, which presumably correspond to the six LMW adiponectins. The stalks bunch together in a manner that is consistent with the requirement for NH2-terminal disulfide bonding. The side views of HMW adiponectin suggest a conical structure of the oligomer with the COOH-terminal portion forming the base. Interestingly, these globular domains are arranged in a tight ring. This circular arrangement might enable polyvalent interactions of the globular domains with a single receptor. Recently, the HMW oligomeric structures formed by multiples of adiponectin trimers have been determined by single-particle analysis of electron micrographs[83]. Pleiomorphic ensembles of collagen-like stretches of the trimers lead to a highly dynamic structure of HMW adiponectin, which can be classified into two major classes: the fan-shaped (Class Ⅰ) and bouquet-shaped (Class Ⅱ). In both of these conformations, the globular domains assume a variety of arrangements, covering an area of up to 4.9 × 105 Å^2 and up to 320 Å apart. The conformational flexibility of the HMW oligomer can allow it to access and cluster disparate target ligands or receptors, which may be necessary to activate cellular signaling leading to the remarkable functional diversity of adiponectin.

HMW adiponectin as a major bioactive form in liver

Obese individuals have different distribution of adiponectin oligomers compared with lean controls. Relatively lower content of HMW adiponectin is closely associated with obesity-related metabolic complications[81]. The increases in the ratio of HMW *vs* total adiponectin, but not total adiponectin level *per se*, correlate well with improved insulin sensitivity during treatment with the insulin-sensitizing drug thiazolidinediones, in both diabetic mice and patients with T2DM. On the other hand, weight reduction by either calorie restriction or gastric bypass surgery results in a selective elevation of the HMW adiponectin, but not the trimeric and hexameric complexes[84-86]. An independent inverse association exists between ALT and HMW adiponectin[87]. Taken together, these epidemiological and genetic data suggest that the beneficial effects of adiponectin in humans might be mediated primarily by its HMW isoform, and the deficiency of this oligomer is an important etiological factor that links obesity with its medical complications.

Evidence from both *in vitro* and animal-based studies also supports the role of the HMW oligomer as the major active form in mediating the multiple actions of adiponectin in liver tissue. Recombinant adiponectin pro-

duced from mammalian cells, which can form the HMW oligomers, potently decreases hyperglycemia in diabetic mice through inhibition of hepatic glucose production[88]. However, bacterially generated full-length adiponectin, which lacks the capacity to form the HMW adiponectin, is almost inactive. Intravenous injection of the HMW adiponectin, but not the hexameric adiponectin, leads to a dose-dependent decrease in serum glucose levels[81]. The formation of the HMW oligomers is obligatory to mediate the insulin sensitizing effects of adiponectin on suppression of hepatic gluconeogenesis in primary rat hepatocytes[80]. Acute injection of recombinant adiponectin enriched with the HMW oligomers results in a marked activation of AMP-activated kinase (AMPK) in the liver, while chronic infusion with this protein leads to prolonged alleviation of hyperglycemia and insulin resistance in *db/db* diabetic mice[89]. This animal-based evidence is consistent with the clinical observations showing that the ratio of HMW/total adiponectin correlates closely with hepatic insulin sensitivity[81]. The role of the HMW oligomer as a predominant active form of adiponectin mediating its hepatic actions is also supported by two recent independent reports demonstrating that the insulin-sensitizing effects of the peroxisome proliferator-activated receptor gamma (PPAR-γ) agonists thiazolidinediones were diminished in *ob/ob* obese mice with the targeted mutation of the adiponectin gene[90,91]. Notably, treatment with thiazolidinediones causes a selective elevation of the HMW oligomeric adiponectin[79,81]. In addition to the hepatic insulin-sensitizing activity, the HMW adiponectin has also been suggested to be the most potent isoform for alleviation of fatty liver disease in high fat diet-induced obese mice[92], and inhibition of apolipoprotein B and E release from human hepatocytes[93]. HMW adiponectin dose-dependently suppressed growth factor-induced hepatic stellate cell proliferation[94]. Taken together, these data suggest that the HMW form predominantly mediates the beneficial effects of adiponectin in hepatic tissue.

Receptors and postreceptor signaling pathways mediating the hepato-protective functions of adiponectin

Two adiponectin receptors (adipoR1 and adipoR2) have been identified and found to be expressed in various tissues[95]. AdipoR1 is abundantly expressed in skeletal muscles, whereas adipoR2 is present predominantly in the liver, suggesting a role of adipoR2 in hepatic adiponectin signaling[68,96]. Recently, several laboratories have investigated the physiological roles of adipoR1 and adipoR2 in *adipoR1/2* knockout mice. Both *adipoR1* and *adipoR2* knockout mice exhibit mild insulin resistance[97]. In *adipoR1/R2* double knockout mice, the binding and actions of adiponectin are abolished, resulting in increased tissue triglyceride content, inflammation and oxidative stress[97]. *AdipoR2* knockout mice reported by Liu *et al*[98] displayed reduced diet-induced insulin resistance, but promoted T2DM. These data support the physiological roles of adipoR1 and adipoR2 as the predominant receptors for adiponectin in the regulation of glucose and lipid metabolism. Despite this information, the detailed roles and expression of adipoRs in NAFLD are not conclusive[38,99-102].

Adiponectin stimulates AMPK in almost all its major target tissues, including skeletal muscle, liver, heart, endothelium, adipocytes and brain[75,89,103-106]. Notably, most biological effects of adiponectin in these target tissues are abrogated by expression of a dominant negative version of AMPK, supporting its obligatory role in mediating adiponectin's multiple actions. The precise mechanisms whereby adiponectin activates AMPK through its receptors remain to be determined. APPL1, an adaptor protein containing a pleckstrin homology domain, a phosphotyrosine binding domain and a leucine zipper motif, appears to be a key signaling molecule that couples adiponectin receptors and its downstream AMPK activation[103,107]. Adiponectin enhances the binding of APPL1 to both adipoR1 and adipoR2, and these interactions are essential for subsequent phosphorylation and activation of AMPK. Studies also indicate the important role of APPL1 in the metabolic syndrome[108,109]. AMPK activation in turn phosphorylates acetyl Coenzyme A carboxylase (ACC) and attenuates ACC activity. Inhibition of ACC reduces lipid synthesis and enhances fatty acid oxidation by blocking the production of malonyl-CoA, an allosteric inhibitor of carnitine palmitoyl transferase 1, the rate-limiting enzyme in fatty acid oxidation. In addition, activation of AMPK downregulates the expression of sterol regulatory element-binding protein 1c (SREBP1c), a transcription factor that regulates cholesterol and lipid synthesis. Reduction of SREBP1c results in downregulation of genes involved in lipogenesis, including ACC, fatty acid synthase, and glycerol-3-phosphate acyltransferase[104,110,111].

PPARα is a transcription factor controlling the transcription of a panel of genes encoding fatty acid oxidation enzymes, such as FATP, acyl-CoA oxidase and long chain acyl-CoA synthetase. Adiponectin stimulates PPARα activity possibly through PPARγ coactivator-1α[112]. These adiponectin-mediated signaling pathways lead to enhanced fat oxidation, reduced lipid synthesis and prevention of hepatic steatosis (Figure 1).

Cellular mechanisms contributing to the anti-inflammatory activities of adiponectin in NAFLD

Inflammatory cytokines are key mediators of hepatic inflammation, cell death, and fibrosis, as well as regeneration after massive or focal liver injury[38,113]. Adiponectin levels are negatively associated with mediators of inflammation, including interleukin-6 (IL-6) and C-reactive protein; but positively related to anti-inflammatory cytokine IL-10[114,115]. It suppresses TNF-α functions by inhibiting its expression and antagonizing its activities[61,62,116,117]. In the liver, cytokines such as IL-6 and TNF-α, are mainly produced from Kupffer cells and hepatic stellate cells (HSC), and partly from inflamed hepatocytes[52,118,119]. Adiponectin ameliorates NASH and liver fibrosis by suppressing the activation of Kupffer

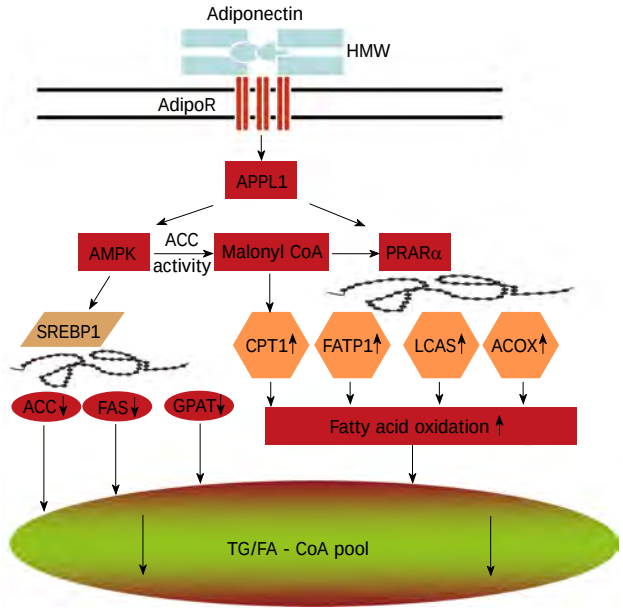

Figure 1 Summary of multiple signaling pathways that mediate the anti-steatotic effects of adiponectin. HMW: High molecular weight; AdipoR: Adiponectin receptor; APPL1: Adaptor protein, phosphotyrosine interaction, PH domain and leucine zipper containing 1; AMPK: AMP-activated kinase; ACC: Acetyl Coenzyme A carboxylase; CPT1: Carnitine palmitoyl transferase 1; SREBP1: Sterol regulatory element-binding protein 1; FAS: Fatty acid synthase; GPAT: Glycerol-3-phosphate acyltransferase; ACOX: Acyl-CoA oxidase; LCAS: Long chain acyl-CoA synthetase; FATP: Fatty acid transport protein; PPARα: Peroxisome proliferator-activated receptor α; TG: Triacylglyceride; FA: Fatty acid.

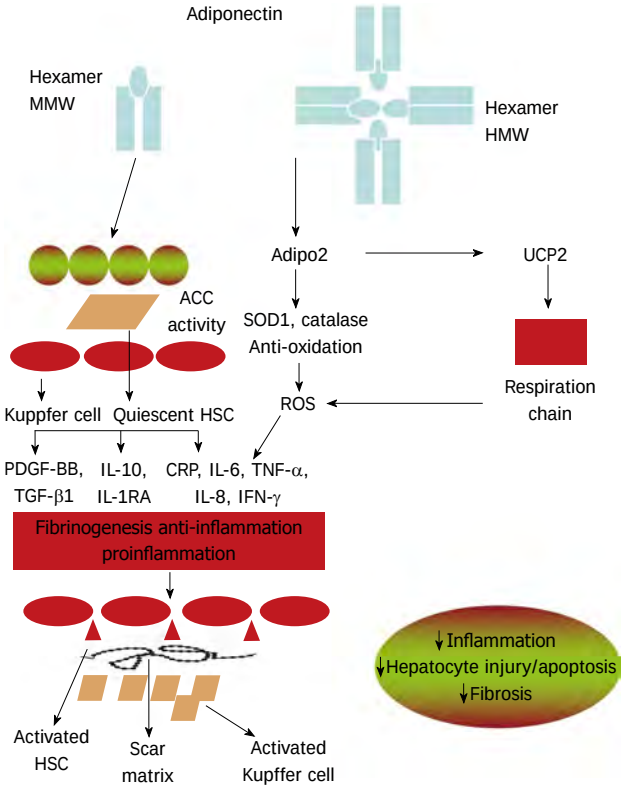

Figure 2 Summary of multiple pathways underlying the protective effects of adiponectin against liver injury. MMW: Middle molecular weight; HMW: High molecular weight; AdipoR: Adiponectin receptor; UCP: Uncoupling protein; SOD1: Superoxide dismutase 1; ROS: Reactive oxygen species; PDGF-BB: Platelet-derived growth factor BB; TGF-β1: Transforming growth factor-β1; CRP: C-reactive protein; IL: Interleukin; IL-1RA: Interleukin-1-receptor antagonist; TNF-α: Tumor necrosis factor-α; HSC: Hepatic stellate cells; IFN-γ: Interferon-γ.

cells and HSC (Figure 2). In porcine blood-derived macrophages, adiponectin suppresses both TNF-α and IL-6 production stimulated by LPS and induces IL10 expression. The attenuation of proinflammatory cytokine production by adiponectin is mediated in part by attenuating the translocation of nuclear factor kappa B (NF-κB) to the nucleus[120]. Adiponectin can also induce the expression of the anti-inflammation cytokine interleukin-1-receptor antagonist[121,122]. The anti-inflammatory effects of adiponectin in macrophages may involve the toll-like receptor-4 (TLR-4) signaling pathway. However, the mechanisms by which adiponectin suppresses TLR-4 mediated responses are not well understood[123].

The transformation of HSC into myofibroblasts is the key step that initiates the fibrotic process during liver injury[124,125]. The activated hepatic stellate cells increase the accumulation of extracellular matrix. Both adiponectin receptors, adipoR1 and adipoR2, are expressed in HSC. Adiponectin treatment maintains HSC quiescence, inhibits platelet-derived growth factor-stimulated proliferation and migration of human HSCs, and reduces the secretion and of monocyte chemoattractant protein-1 through AMPK-dependent mechanisms[94,125,126]. Additionally, adiponectin also regulates hepatic expression of TGFβ1, a pro-fibrotic factor involved in HSC activation[58,127] that plays an important role in neofibrogenesis of NAFLD[128].

Inhibition of adipoR2 expression by short hairpin RNAi-expressing adenovirus can induce TGFβ1 expression, and overexpression of adipoR2 diminishes TGFβ1 mRNA level.

Regulatory role of adiponectin on mitochondria activities

Mitochondrial dysfunction represents a central mechanism linking obesity with associated metabolic complications[129]. In patients with NASH, the hepatic mitochondria exhibit ultrastructural lesions and decreased activity of the respiratory chain complexes[130,131]. In this condition, the decreased activity of the respiratory chain results in accumulation of reactive oxygen species (ROS) that oxidize fat deposits to form lipid peroxidation products, which in turn, cause steatohepatitis, necrosis, inflammation and fibrosis. The increased mitochondrial ROS formation in steatohepatitis could directly damage mitochondria DNA and respiratory chain polypeptides, induce NF-κB activation and the hepatic synthesis of TNFα[132]. Oxidative phosphorylation reactions mediated by mitochondria respiratory chain (MRC) complexes are directly involved in regulating intracellular ROS activities and preventing accumulation of lipids and lipid peroxidation products in the liver.

Mice without adiponectin show an increased lipid

accumulation even under normal chow feeding[117]. This pre-existing hepatic steatotic condition might be the direct consequence of dysregulated mitochondria functions[117]. Adiponectin treatment restores the MRC activities, decreases the levels of mitochondrial lipid peroxidation products through regulating hepatic mitochondrial functions, which might represent a common mechanism underlying the multiple beneficial activities of this hormone in various obesity-related pathologies. Moreover, we have provided evidence supporting an essential role of uncoupling protein 2 (UCP2), a mitochondria inner membrane transporter, in mediating the beneficial effects of adiponectin on MRC activities. The protein and mRNA levels of UCP2 are decreased in the liver tissues of adiponectin knockout mice and can be significantly upregulated by adiponectin treatment. Overexpression of adipoR2 upregulates mRNA levels of UCP2, catalase, and superoxide dismutase 1 in the liver[97]. Furthermore, the effects of adiponectin on MRC activities are dramatically attenuated in *Ucp2*-deficient mice, suggesting that the increased UCP2 expression might be obligatory for adiponectin to elicit its activities on mitochondria functions (Figure 2). UCP2 possesses anti-oxidant activities through inhibition of ROS production from mitochondria[133]. It can also inhibit the production of pro-inflammatory cytokines in both macrophage and Kupffer cells[134]. A growing body of evidence suggests that UCP2 may play a beneficial role in various stages of fatty liver diseases[134,135]. These results suggest the existence of a reciprocal relationship between uncoupling proteins and adiponectin. However, the detailed signaling mechanisms underlying adiponectin-induced UCP2 expression are not clear and warrant further investigation.

ELEVATION OF ADIPONECTIN PRODUCTION AS A THERAPEUTIC STRATEGY FOR TREATMENT OF NAFLD

To date, there have been very few effective drug treatments for NAFLD and NASH. Early diagnosis and management of the underlying condition remains the mainstay of treatment. The present "gold standard" for treatment of NAFLD is weight reduction or a reduction of central obesity[4]. These "life-style adjustment" or anti-obesity measures (including bariatric surgery) impressively reduce liver cell injury, inflammation and hepatic fibrosis, as well as steatosis[136,137]. The potential for correcting steatosis by dietary or pharmacological approaches should provide a sound therapeutic approach for the treatment of steatosis and steatohepatitis. Strategies to block oxidative stress are of great interest, with some evidence that ALT normalization or histological improvement occurs with vitamin E (alone or with vitamin C or pioglitazone) and betaine[138].

Adiponectin and its agonists might represent emerging therapeutic agents for the treatment and/or prevention of liver dysfunctions[139-141]. Adiponectin replacement therapy is not yet available as a treatment option. Pharmacological intervention aimed at elevating adiponectin production might hold promise for the treatment and/or prevention of NAFLD.

CONCLUDING REMARKS

Based on our data, polymorphic UCP1 (AG + GG) obese patients with low adiponectin levels appear to be high-risk subjects for worsening of liver steatosis, an NAFLD, possibly requiring a second-step evaluation by liver biopsy[142].

The role of adiponectin in systemic inflammation and critical illness is not well defined. Early data suggest that plasma levels of adiponectin are decreased in critical illness[143]. Whether this is a result of the disease process itself or whether patients with lower levels of this hormone are more susceptible to developing a critical illness is not known. This observation of lower adiponectin levels then raises the possibility of therapeutic options to increase circulating adiponectin levels[143]. The various options for modulation of serum adiponectin (recombinant adiponectin, thiazolidinediones) are discussed.

Nevertheless, adiponectin-based therapeutics for NAFLD represent a promising area for further investigation.

CONCLUSION

Adiponectin is an abundant adipocyte-derived hormone with well established anti-inflammatory and insulin sensitizing properties. The significance of adiponectin in protecting obesity-related NAFLD has been increasingly recognized. Despite the advances made in recent years, the detailed molecular and cellular mechanisms underlying its hepato-protective functions remain largely uncharacterized.

Abstract

Pancreatic cancer is one of the most aggressive human cancers, with more than 200 000 deaths worldwide every year. Despite recent efforts, conventional treatment approaches, such as surgery and classic chemotherapy, have only slightly improved patient outcomes. More effective and well-tolerated therapies are required to reverse the current poor prognosis of this type of neoplasm. Among new agents, histone deacetylase inhibitors (HDACIs) are now being tested. HDACIs have multiple biological effects related to acetylation of histones and many non-histone proteins that are involved in regulation of gene expression, apoptosis, cell cycle progression and angiogenesis. HDACIs induce cell cycle arrest and can activate the extrinsic and intrinsic pathways of apoptosis in different cancer cell lines. In the present review, the main mechanisms by which HDACIs act in pancreatic cancer cells *in vitro*, as well as their antiproliferative effects in animal models are presented. HDACIs constitute a promising treatment for pancreatic cancer with encouraging anti-tumor effects, at well-tolerated doses.

INTRODUCTION

Pancreatic cancer is one of the most lethal human cancers and continues to be a major unsolved health problem at the beginning of the 21st century. Worldwide, over 200 000 people die annually of pancreatic cancer, with the highest incidence and mortality rates found in developed countries. Pancreatic cancer is the 4th and 6th leading cause of cancer death in United States and Europe, respectively. Pancreatic cancer incidence and mortality rates are almost equal because of the high fatality rate. A lack of illness indicators and screening tests mean that pancreatic cancer is usually diagnosed at the late stages of the natural history of the disease[1,2].

In Western communities, the 1- and 5-year survival rates for pancreatic cancer are less than 25% and 5%, respectively, and the mortality rates are essentially identical. Although survival rates are highest (16.6%) when the tumor is localized at diagnosis, less than 10% of tumors are detected at that time. On the other hand, the survival rates have been only slightly improved over the past decade because of a lack of significant medical advances in early detection and the poor outcome of treatment approaches. Pancreatic cancer is rare in the first three decades of life. The majority of pancreatic cancers occur

in the exocrine pancreas and the vast majority (> 90%) have ductal differentiation. Men consistently have higher incidence and mortality rates than women, worldwide[3].

Treatment of advanced pancreatic cancer

Traditionally, 5-fluorouracil (5-FU)-based chemotherapy and/or radiotherapy have been used in the treatment of locally advanced pancreatic cancer; however, the value of radiotherapy remains unclear[4]. Today, *gemcitabine*-based therapy is the acceptable treatment approach for both unresectable locally advanced and metastatic pancreatic cancer. Several phase Ⅲ trials were undertaken with gemcitabine in combination with a range of chemotherapy agents. However, combining gemcitabine with 5-FU[5], as well as *irinotecan*, *oxaliplatin*, *pemetrexed*, *exatecan* and *cisplatin*[6-10], all failed to show superiority over gemcitabine monotherapy. In a recent phase Ⅲ trial, the combination of *capecitabine* with gemcitabine significantly improved the objective response rate and progression-free survival, but did not show superiority in overall survival in patients with advanced pancreatic cancer[11]. Additionally, in a randomized phase Ⅱ trial of *folfirinox* (5-FU/leucovorin, irinotecan, and oxaliplatin) versus gemcitabine, the median overall survival was 11.1 mo in the folfirinox group compared with 6.8 mo in the gemcitabine group, indicating that folfirinox is an option for the treatment of patients with metastatic pancreatic cancer[12].

Targeted therapies have also been investigated for advanced pancreatic cancer. Erlotinib is a small-molecule tyrosine kinase inhibitor of the human epidermal growth factor receptor (EGFR). A multicenter, randomized, double-blind, placebo-controlled phase Ⅲ clinical trial of erlotinib in combination with gemcitabine, in patients with locally advanced or metastatic pancreatic adenocarcinoma met its primary endpoint, with the combination regimen being the first gemcitabine combination to demonstrate a statistically significant survival advantage over gemcitabine monotherapy and the regimen was consequently approved for metastatic disease[13].

Many molecular-targeted agents that interact with crucial pathways for cell survival in pancreatic cancer are currently being explored. These include agents that target *poly ADP*-ribose polymerase, histone deacetylase (*HDAC*), *Src/Abl kinases,* and mammalian targets of rapamycin[14].

Histone acetyltransferases and deacetylases

The principal structure of eukaryotic chromatin is the nucleosome. Each nucleosome consists of approximately 146 bp of DNA wrapped around a core of eight basic proteins called histones, two each of H2A, H2B, H3 and H4. Nucleosomal structure not only facilitates packing DNA into a relatively small nucleus, but also exerts important regulatory functions. The N- and C- terminal tails of the nucleosomal core undergo post-translational modifications, participating in chromatin assembly regulation and/or DNA accessibility. Nucleosomes containing highly charged hypoacetylated histones bind tightly to the phosphate backbone of DNA, inhibiting transcription, preventing transcription factors, regulatory complexes and RNA polymerase to access the DNA. Acetylation neutralizes the charge of the histones generating a more open DNA conformation. Transcription factors may then access the DNA, promoting the expression of the corresponding genes. Therefore, histone acetylation is generally associated with transcriptional activation. Histone acetylation is carried out by a group of proteins called histone acetyl transferases (HATs), and the acetyl groups can be removed by HDACs. These molecules play a pivotal role in cellular functions, such as chromosome remodelling, gene transcription and cell proliferation[15,16].

Eighteen different human HDAC isoforms have been described and are classified into four classes. Class Ⅰ HDACs (HDACs 1, 2, 3 and 8) are associated with RPD3 deacetylase, and are primarily located in the nucleus. Class Ⅱ HDACs are divided into two subclasses, class Ⅱa (HDACs 4, 5, 7 and 9) and class Ⅱb (HDACs 6 and 10) and are homologous to the yeast Hda1 deacetylase. Class Ⅲ HDACs consists of seven HDACs (SIRT1 to SIRT7) that share homologies with the yeast silent information regulator 2 (Sir2) family. The class Ⅳ family of HDACs has only one member, HDAC11. Classes Ⅰ, Ⅱ and Ⅳ require Zn^{2+} for activity, while class Ⅲ has a unique catalytic mechanism that requires the co-factor NAD^{+}. To achieve the acetylation of histones, an acetyl group of acetyl coenzyme A is linked to the ε-amino group of lysine by HATs, which can be removed by HDACs. When HDACs remove the acetyl group from a histone lysine, a positive charge on the lysine residue condensing the structure of nucleosomes is restored. The active site of HDACs consists of a cylindrical pocket in which the lysine residue fits when deacetylation takes place. Zn^{2+} is located near the bottom of the cylindrical pocket[17].

In addition to deacetylating histones, HDACs have also been reported to interact with non-histone proteins. Such protein targets of HDACs include transcription factors and regulators, signal transduction mediators, DNA repair enzymes, nuclear import regulators, chaperone proteins, structural proteins, inflammation mediators and viral proteins. These HDAC substrates are involved in numerous important cell pathways, including control of gene expression, regulation of cell proliferation, differentiation, migration and death. Altered expression of HDACs has been reported in several types of human neoplasms[18,19].

HDAC inhibitors

HDAC inhibitors (HDACIs) have three common structural characteristics: a Zn binding moiety, an opposite capping group, and a straight chain alkyl, vinyl or aryl linker connecting the two. The majority of HDACIs are designed to interfere with the catalytic domain of HDACs, blocking substrate recognition and inducing gene expression. Aberrant expression of different HDAC isoforms has been associated with different malignancies; thus, HDACIs represent a potent and specific strategy for cancer treatment. Most of the described HDACIs only

affect the Zn-dependent classes I and Ⅱ HDACs. The HDACIs described so far vary in structure and origin, being divided into different classes based on their chemical properties. The *hydroxamic acids* include trichostatin A (TSA), SAHA (vorinostat), LBH589 (panobinostat) and PXD101 (belinostat). The *short-chain fatty acids* comprise another class, including sodium butyrate (NaBu), 4-phenylbutyrate and valproic acid. A third class includes the *cyclic tetrapeptides*, such as FK228/depsipeptide (romidepsin). A fourth class of HDACIs is the *benzamides*, including MS-275 (entinostat), CI-994 and MGCD0103[20,21].

The mechanisms of action of HDACIs are complex and not completely understood. HDACIs have multiple biological effects related to acetylation of histones and many non-histone proteins, such as those involved in regulation of gene expression, apoptosis, cell cycle progression, DNA repair, cell migration and angiogenesis. HDACIs induce cell cycle growth arrest in both normal and transformed cells, and can activate the extrinsic and intrinsic pathways of apoptosis. Both *in vitro* and *in vivo* data and ongoing clinical trials have indicated that HDACIs could be used against different solid tumors and hematological malignancies; thus, comprising one of the most promising classes of new anticancer agents[22,23]. In the present review, the latest knowledge on the effect of HDACIs on pancreatic cancer is discussed.

EXPERIMENTAL *IN VITRO* STUDIES

The data available so far regarding the different classes of HDACIs used in pancreatic cancer cell lines are presented in the following section. Additionally, the targets modulated by different HDACI compounds are listed in Table 1.

Hydroxamic acids

Suberoylanilide hydroxamic acid (SAHA, *N*-hydroxy-*N*'-phenyl-octanediamide, vorinostat) is a synthetic hydroxamic acid that is structurally related to the natural product, trichostatin A {TSA, 7-[4-(dimethylamino)phenyl]-*N*-hydroxyl-4,6-dimethyl-7-oxo-(2*E*,4*E*,6*R*)-2,4-heptadienamide}, which is produced by selected strains of *Streptomyces platensis*, *Streptomyces hygroscopicus* Y-50 or *Streptomyces sioyaensis*. Hydroxamic acids have a high affinity to biometals, including Fe^{3+}, Ni^{2+} and Zn^{2+}. The synthesis of SAHA and its potency to induce differentiation of murine erythroleukemia (MEL) cells was first reported in 1996. SAHA and TSA contain a hydroxamic acid-based metal-binding domain that coordinates the catalytic Zn^{2+} in the HDAC active site, a 5 (TSA) or 6 (SAHA)-membered carbon-based linker that mimics the Cα functional group of lysine, and a hydrophobic motif that interacts with the periphery of the HDAC binding pocket[24].

TSA: TSA strongly inhibited the cellular growth of nine pancreatic adenocarcinoma cell lines (MiaPaCa-2, PANC1, PSN1, PT45P1, CFPAC1, HPAF-Ⅱ, T3M4, PaCa44 and PC), although a marked difference in sensitivity to the drug was noted. TSA-induced cell cycle arrest was associated with a block in the G2 phase and apoptotic death. TSA treatment in T3M4 and PaCa44 cell lines resulted in p21WAF1/CIP1 induction, an increase in caspase-3 activity and the downregulation of p27 and cyclin A2 mRNA expression[25].

Global gene expression profiles were also examined in several pancreatic cancer cell lines (CFPAC1, HPAF, MiaPaCa-2, Panc1, PC, PSN1, PT-45P1 and PaCa44) post-TSA treatment. Three point four percents of genes involved in a wide variety of cellular processes, such as cell proliferation, signaling, regulation of transcription, and apoptosis, were altered after TSA treatment. The cyclin-dependent kinase (cdk) inhibitors p21, p19 and p57 were all upregulated, while cyclin A and cdk10 were downregulated. Additionally, BIM, a proapoptotic BCL-2 family member, was significantly induced, while the expression of the antiapoptotic genes *BCL-XL* and *BCL-W* was repressed by TSA treatment[26].

Different pancreatic cancer cell lines co-express high-level TNF-related apoptosis-inducing ligand receptor (TRAIL-R), Fas and TNF-R1 but are strongly resistant to apoptosis triggered by the death receptors. The drug combinations geldanamycin/PS-341, TSA/PS-341 and TSA/geldanamycin with low-dose TRAIL were tested and all were found to be effective in initiating apoptosis in four pancreatic cancer cell lines (AsPC-1, BxPC-3, MiaPaCa-2 and Panc-1) compared with single drug-based treatments. This killing effect was enhanced when Bcl-XL was depleted. When Bcl-XL-depleted cells and control counterparts were exposed to TSA/PS-341, TRAIL induced cell death in Bcl-XL knockdown cells. However, under the same experimental conditions fewer control cells were killed, indicating that Bcl-XL depletion significantly increased TSA/PS-341 killing effects on pancreatic cancer cells in the presence of TRAIL[27].

TSA and SAHA induced apoptosis in pancreatic cancer cell lines IMIM-PC-1, IMIM-PC-2 and RWP-1, independently of their intrinsic resistance to conventional antineoplastic agents. Caspase-3 activity was slightly increased in IMIM-PC-1 and RWP-1 cells, but significantly increased in IMIM-PC-2 cells after TSA treatment. On the other hand, caspase-8 and -9 activities were not altered. In addition, PARP-1 was only partially cleaved after TSA treatment. An inhibitor of the human serine protease Omi/HtrA2, called ucf-101, was able to block the cell death induced by TSA in the three cell lines through a caspase-independent mechanism. In the same experimental setting, Bax protein levels were dramatically increased, but those of Bcl-2 and p21 were not significantly modified[28].

TSA and SK-7041, a novel hybrid synthetic HDACI, both induced apoptosis and G2-M cell cycle arrest in the pancreatic cancer cell lines Panc-1 and ASPC-1. They caused increased H4 histone acetylation, and also suppressed the expression of the antiapoptotic proteins Mcl-1 and Bcl-XL, but did not affect either Bcl-2 or the proapoptotic Bax and Bak proteins. TSA and SK-7041 also enhanced the expression of p21 and of cyclin D2

Table 1 Histone deacetylase inhibitors and targets modulated in different pancreatic cancer cell lines

HDACI compound		Targets modulated		Ref.
		Upregulated	Downregulated	
Hydroxamic acids	TSA	p21, p19, p57, Bim, Bax, caspase-3, -7, cyclin D2, TGF-β, OC18, MGMT, TFAR19, maspin, CDKN1C, MUC2, MUC5B, miR-107	p27, cyclin A2 , -B1, cdk6, cdk10, Bcl-XL, Mcl-1, PARP-1, NF-κB, K-Ras, MEK1/2, phosph. MEK, ERK1/2, NPM, TCTP	[25-30,37-52]
	SAHA	p21, p27, p57, Bax, RARa, E-cadherin, C/EBPa, caspase-3, -7, HHIP, RELN, DAB1	Bcl-2, cyclin D1, -B1, c-myc, Ptc-1, survivin, EGFR, NF-κB, RelA/p65	[53-60,62,63,66]
Cyclic peptides	FK228	p21, p16, caspase-3, DR5, GATA4	Survivin	[68-70]
Short chain fatty acids	VPA	NEP/CD10, RELN, DAB1		[62,73]
	4-PB	p21, p16, miR-127, caspase-8, Bid, JNK	Bcl-6, PARP	[78-80]
	NaBu	ALP, K23, NEP/CD10, caspase-3, -7, -9, GnT-Ⅳa, 5-hydroxytryptamine, CEA, DU-PAN-2, CA19-9, IRT, Lcu7, synaptophysin, p21, p27, Bax	Bcl-XL, TGF-α, PKC, b4 and b7 integrin, EGFR, ezrin, cyclin D1, mut-p53, Bcl-2, survivin	[73,82-99]
Benzamides	MS-275	p21, p27, gelsolin, caspase-3	pRb, Bcl-2, cyclin D1	[101,102]

HDACI: Histone deacetylase inhibitor; TSA: Trichostatin A; SAHA: Suberoylanilide hydroxamic acid; VPA: Valproic acid; NF-κB: Nuclear factor kappa B; TGF: Transforming growth factor; EGFR: Epidermal growth factor receptor; CEA: Carcinoembryonic antigen.

and reduced that of cyclin B1[29].

TSA and the selective 26S proteasome inhibitor PS-341, synergistically induced apoptosis in eight pancreatic adenocarcinoma cell lines (AsPC-1, BxPC-3, CFPAC-1, Capan-2, Mia PaCa-2, Panc-1, SU86, and SW1990). Combining TSA with PS-341 induced apoptosis by increasing caspase-3 and -7 activities and enhanced PARP cleavage. Their combination also effectively blocked nuclear factor kappa B (NF-κB) signaling pathway and downregulated the NF-κB dependent anti-apoptotic factor Bcl-XL. Moreover, they inactivated the Ras-MAP kinase pathway by depleting several key components of MAP kinase cascades, including K-Ras, MEK1/2, phosphorylated MEK and ERK1/2[30].

TSA strongly inhibited proliferation of pancreatic endocrine carcinoma cell lines (CM, metastatic insulinoma; BON, metastatic carcinoid; and QGP-1, somatostatinoma) by causing cell cycle G2/M arrest and apoptosis. TSA-induced apoptosis of CM cells was shown to be a retarded event with respect to that observed in BON and QGP-1 cells. Such effect was ascribed to modifications in the expression of proteins related to cell proliferation, gene expression, signal transduction, cytoskeleton organization, chromatin organization, as also RNA splicing and protein folding[31]. Another study examined the effect of TSA or 5-Aza-C, a DNA methyltransferase inhibitor, treatment on the proliferation of the pancreatic endocrine cancer cell lines QGP-1, CM and BON. TSA treatment resulted in cell cycle arrest at G1 (QGP-1) or G2 (BON and CM) phase, whereas 5-Aza-C blocked the cell cycle in G2 phase only in BON cells. The combined treatment did not significantly increase the cytostatic effect obtained with TSA alone, suggesting that the synergistic cell growth inhibition by the two drugs may be not caused by cell cycle arrest[32].

TSA and gemcitabine synergistically inhibited the proliferation of several human pancreatic adenocarcinoma cell lines (T3M4, PANC1, PC, CFPAC1, YAPC, DANG and Panc-89). In the cell lines tested, TSA enhanced apoptosis, but not the cell cycle arrest induced by gemcitabine[33,34]. TSA significantly inhibited the viability of BxPC-3 cells in a time- and dose-dependent manner by inhibition of cell proliferation and induction of apoptosis. Cell cycle analysis showed an increase of cells in the G0/G1 phase post-TSA treatment, indicating cell cycle arrest. Additionally, TSA induced the apoptosis of BxPC-3 cells and led to alterations in the expression levels of miRNAs. Although some variation at the gene transcription level was observed among Panc-1, BxPC-3, SOJ-6 and MiaPaCa-2 cell lines, the amount of HDAC proteins produced seemed to be comparable[35]. The effects of known inhibitors of class Ⅲ HDACs, such as Nicotinamide and Sirtinol, on the growth of pancreatic cancer cells, in addition to those of TSA, were also examined. Treatment of pancreatic cells with different drugs concentrations resulted in a dose-dependent inhibition of cell growth, with TSA being the most effective compound. Sirtinol induced G1 arrest in SOJ-6; however, TSA induced G1 arrest in BxPC-3 cells. Treatment of cells with HDACIs resulted in elevated cell numbers in the sub-G1 peak region, suggesting induction of cell DNA degradation by Sirtinol and TSA. Sirtinol and TSA treatment also involved the mitochondrial pathway of apoptosis induction[36].

Transforming growth factor beta (TGF-β) plays a significant role in the growth inhibition of most normal epithelial, and some cancer, cells. TGF-β mediates its biological affects through cell surface receptors known as type Ⅰ (RⅠ) and Ⅱ (RⅡ) receptors. TGF-β resistance caused by loss of receptors expression has been linked to tumor formation and progression. The TGF-β RⅡ promoter contains two consensus Sp1 sites. The Sp gene family consists of four members, whose protein products are referred to as Sp1-Sp4. Sp1, Sp2 and Sp4 are activators of gene transcription, whereas Sp3 can be an activator or a repressor. In this aspect, TSA treatment of MiaPaCa-2 cell line induced accumulation of acetylated histones in chromatin associated with the TGF-β RⅡ gene. MiaPaCa-2 pancreatic cancer cells acquired resistance to growth inhibition by TGF-β associated with

reduced transcription of TGF-β RⅡ. Accumulation of TGF-β RⅡ with highly acetylated histones H3 and H4 was noted in TSA-treated compared to untreated MiaPaCa-2 cells[37]. Furthermore, TSA activated TGF-β RⅡ promoter activity in a panel of five pancreatic cancer cell lines (BxPC-3, PANC-1, CFPAC-1, MiaPaCa-2 and UK Pan-1), by mechanisms involving induction of Sp1 acetylation and changes in a multiprotein complex containing p300, PCAF, Sp1 and NF-Y[38,39].

Treating the pancreatic carcinoma cell line MIA PaCa-2 with TSA, increased the O(6)-Methylguanine-DNA methyltransferase (MGMT) mRNA and protein levels by 2-3-fold, caused by increased histone acetylation in the endogenous MGMT promoter region, which was also associated with CBP/p300. MGMT is a suicide enzyme that repairs pre-mutagenic, pre-carcinogenic and pre-toxic DNA damage O(6)-methylguanine. MGMT also likely protects against therapy-related tumor formation caused by highly mutagenic drugs. The MGMT expression level provides important information on cancer susceptibility and the success of therapy[40]. TSA treatment also resulted in a marked (5-fold) induction of 2.3% of genes in AsPC1, 1.9% in Hs766T, 1.1% in MiaPaCa2, and 2.5% in Panc1. A large panel of novel targets for silencing by histone deacetylation were identified, including several known tumor suppressor or cell cycle-regulatory genes, such as *ING1*, *p57KIP2*, *CHES1*, *CHFR* and *GADD45B*. One of the novel findings of this study was that TSA alone induced the expression of four of the 11 genes whose CpG islands were identified as aberrantly methylated in pancreatic cancer[41]. Among the proteins with altered expression post-TSA treatment in Paca44 and T3M4 pancreatic cancer cell lines, of particular interest are the two downregulated proteins nucleophosmin and translationally controlled tumor protein, which are involved in oncogenesis and tumor reversion, respectively. Additionally, several other proteins were found to be upregulated, including programmed cell death protein 5 (TFAR19), which is involved in the regulation of cell apoptosis, and stathmin (OC18), which promotes microtubule depolymerization during interphase and late mitosis. TSA could inhibit cell proliferation of the pancreatic adenocarcinoma cell line Paca44 by cell growth arrest at the G2 phase and apoptosis[42,43].

Maspin is a unique member of the serpin family of protease inhibitors with tumor suppressive activity in different cancer types. Interestingly, the maspin gene is located on chromosome 18q21.3 and its promoter region contains the binding sites of several transcription factors that positively regulate its expression, including Ets, AP1, HER and p53. When PANC-1 cells were exposed to 5-Aza-C, maspin mRNA expression was restored in a dose dependent manner. TSA also led to re-expression of maspin[44]. Five pancreatic cancer cell lines (AsPC1, CFPAC1, Hs766T, MiaPaCa-2, and Panc1) were screened for genes that displayed expression patterns associated with hypomethylation. This analysis identified 1485 transcripts that were likely to be variably expressed in pancreatic cancer cell lines. Among the 1485 transcripts identified, 392 were found to be elevated by 3-fold or greater in any of the pancreatic cancer cell lines after combined treatment with 5-Aza-C and TSA. This list included several genes that have been reported to be overexpressed in pancreatic cancer, such as those encoding cysteine-rich protein 1 (CRIP1), decay accelerating factor for complement (CD55), maspin/SERPINB5, S100 calcium-binding protein P (S100P), and tissue-type plasminogen activator (PLAT). Treatment of MiaPaCa-2 cells with 5-Aza-C restored the expression of maspin mRNA, whereas treatment with TSA alone did not, but combined treatment with 5-Aza-C and TSA strongly induced the maspin expression in a synergistic manner[45,46]. CDKN1C is a potent inhibitor of several G1 cyclin complexes, and is a negative regulator of cell proliferation. Treatment of the pancreatic cancer cell lines AsPC1 and BxPC3, where the CDKN1C gene was silenced, with 5-Aza-C or TSA, or their combination, resulted in restoration of CDKN1C expression, more potently with TSA and the combined treatment[47].

MUC2, *MUC5AC*, *MUC5B* and *MUC6* mucin genes encode large secreted O-glycoproteins that participate in mucus formation and play an important role as a physiological barrier against various attacks on the underlying epithelia. Among the four 11p15 mucin genes, *MUC2* and *MUC5B* were highly susceptible to DNA methylation and histone modifications, whereas *MUC5AC* was rarely influenced by epigenetic regulation and *MUC6* was not. In this context, pancreatic cell lines CAPAN-1 and PANC-1 were treated with 5-Aza-C or TSA. In PANC-1 cells TSA treatment induced MUC2 expression, while in CAPAN-1 cells 5-Aza-C treatment induced an increase of *MUC5AC* mRNA and *MUC5B* expression. Histone deacetylation was also involved in *MUC5B* repression, as TSA treatment induced its expression[48]. Treatment of the human pancreatic cancer cell lines PANC1 (MUC2-negative) and BxPC3 (MUC2-positive) with both 5-Aza-C and TSA, resulted in a definite increase of the expression level of *MUC2* mRNA[49]. In pancreatic cancer, *MUC4* overexpression is associated with a bad prognosis and has become an important molecular target. In this aspect, the pancreatic cancer cell lines PANC-1, CAPAN-1 and CAPAN-2 were tested. In *MUC4*-nonexpressing pancreatic PANC-1 cells, treatment with 5-Aza-C and TSA induced *MUC4* expression at the mRNA level, and at protein level in a small number of cells. In *MUC4*-high expressing pancreatic CAPAN-1, 5-Aza-C treatment did not affect MUC4 mRNA, whereas TSA treatment induced a strong inhibition of *MUC4* mRNA levels, correlated to a strong decrease of the apomucin level in the cells[50].

Two pancreatic cancer cell lines, MiaPACA-2 and PANC-1, were treated with 5-Aza-C or TSA, and their combination. Fourteen miRNAs were upregulated by ⩾ 2-fold in each of the cell lines following exposure to both agents. Enforced expression of miR-107 in MiaPACA-2 and PANC-1 cells downregulated *in vitro* growth that was associated with repression of the putative miR-107 target,

cdk6, thereby providing a functional basis for the epigenetic inactivation of this miRNA in pancreatic cancer[51].

Evaluating the *in vitro* growth inhibition of several pancreatic cancer cell lines established from primary tumors, as well as that of others established from metastatic tumors, to gemcitabine and 5-FU, newer generation cytotoxic agents (oxaliplatin, irinotecan), targeted therapy (gefitinib) and TSA, demonstrated that the combination of TSA and irinotecan increased growth inhibition on the highest percentage of cell lines (80%). TSA proved to be the best partner for all drugs, with the exception of 5-FU. Notably, PSN1, the most sensitive cell line to single-drug treatments, became the most resistant cell line to all combined treatments. In addition, all pairwise combinations were less effective in PaCa3, which contains a functional p53 gene, supporting the hypothesis that the p53 gene status may by not relevant for cell sensitization by TSA[52].

SAHA: Both SAHA and its novel compounds 17a and 9, inhibited PANC-1 and PT-45 cells' proliferation in a dose dependent manner, with the novel compounds having a more potent antiproliferative activity. Although p21 gene expression of PANC-1 cells was significantly increased after treatment with SAHA and 17a, none of the HDACIs tested affected the expression of the p27 gene[53].

In another study, SAHA inhibited the growth of BxPC-3 and COLO-357 cell lines, by 42% and 50%, respectively, but not that of PANC-1 cells. SAHA induced a G1 cell cycle arrest and upregulation of p21 in BxPC-3 and COLO-357. On the other hand, PANC-1 cells remained unaffected. According to this study, p21 upregulation was necessary for SAHA-induced cell cycle arrest in COLO-357, but not in BxPC-3 cells. PANC-1 cells, which were resistant to gemcitabine alone, exhibited a marked increase in sensitivity when treated with both gemcitabine and SAHA[54].

Additive and time-dependent reduction of cell proliferation and induction of apoptosis by SAHA and the novel DNA methyltransferase inhibitor Zebularine was reported in pancreatic cancer cell lines YAP C, DAN G and Panc-89. In fact, the apoptosis induction was associated with downregulation of Bcl-2 and upregulation of Bax[55]. SAHA inhibited the cell growth in six pancreatic cancer cell lines in a dose-dependent manner. G2/M cell cycle arrest was also induced by SAHA in most cell lines. Remarkably, SAHA and 5-Aza-C treated cells, presented higher levels of acetylated-H3 than those noted in cells treated with SAHA alone. Treatment with SAHA markedly enhanced histone H3 acetylation in the promoter region of the p21 gene. In PANC-1 cells, p21 protein expression increased to the same levels after exposure to either 5-Aza-C, SAHA or both, while p27, Bax and Bcl-2 levels remained unaltered. Levels of p57, E-cadherin and RARa increased in the presence of SAHA, either alone or with 5-Aza-C. Additionally, SAHA decreased expression of cyclin D1, B1 and c-myc independently of the β-catenin pathway and increased C/EBPa[56].

Treatment of PANC1, MiaPaca2 and ASPC-1 cells with concentrations of SAHA and sorafenib that are sustainable in patient serum resulted in a greater than additive increase in tumor cell killing, as assessed by short-term death assays, and a synergistic increase in killing assessed by colony formation assays. Suppression of caspase 8 function, as well as expression of dominant negative caspase 9 or Bcl-XL also blunted sorafenib-SAHA lethality. Sorafenib-SAHA, but not treatment with the individual drugs, activated CD95 and caused formation of a death-inducing signal complex containing caspase 8, FADD, ATG5 and Grp78/BiP. Additionally, a clinically relevant and sustainable concentration of sodium valproate, another HDACI, enhanced sorafenib lethality in a synergistic fashion in pancreatic tumor cells derived from either humans or rodents. Finally, it was speculated that small-molecule antagonists of Bcl-2 family proteins (HA14-1, GX15-070) enhanced sorafenib-HDACI lethality *via* autophagy and partial activation of the intrinsic apoptosis pathway, independently of death receptor functionality[57-59].

A combination of SAHA and the Smoothened antagonist, SANT-1, was evaluated for their ability to suppress growth of the gemcitabine-resistant pancreatic adenocarcinoma cell lines Panc-1 and BxPC-3. The combination of SAHA and SANT-1 supra-additively suppressed cellular proliferation and colony formation *via* induction of apoptotic cell death, cell cycle arrest in G0/G1 phase and ductal epithelial differentiation. Cell death was associated with nuclear localization of survivin, increased Bax expression and activation of caspases-3 and -7. Consistent with the cell cycle arrest and cytodifferentiation, the CdkIs p21 and p27 were upregulated and cyclin D1 was downregulated. The potentiated anti-proliferative effect by the combination of SAHA and SANT-1 was attributed to cooperative suppression of the Hedgehog pathway activity, as shown by the upregulation of hedgehog interacting protein by SAHA, and enhanced repression of Ptc-1 mRNA expression[60].

SAHA induced apoptosis in IMIM-PC-1, IMIM-PC-2 and RWP-1 cell lines with a serine protease-dependent and caspase-independent mechanism. SAHA induced a decrease in the number of cells in S phase in all three cell lines, while an increase in the sub-G1 peak was noted, suggesting that the three cell lines underwent apoptosis[28].

SAHA and the proteasome inhibitor bortezomib (PS-341) were tested in a panel of pancreatic cancer cell lines. Both SAHA and TSA blocked bortezomib-induced aggresome formation in pancreatic cells, which is a cytoprotective mechanism, and dramatically sensitized aggresome-positive cells to bortezomib-induced apoptosis[61].

RELN, a key regulator of neuronal migration, is frequently silenced in pancreatic cancers. RELN is a secreted extracellular protein that plays an essential role in brain development and function. Underexpression of RELN and its components (ApoER2, VLDLR and DAB1) is related to cell motility, invasiveness, and colony-forming ability in cancer. Treatment of pancreatic adenocarcinoma cell lines Panc1 and AsPC1 with SAHA and valproic acid, restored

the expression of RELN and DAB1 in a dose-dependent manner, and also inhibited cell migration[62]. SAHA inhibited proliferation of MiaPaCa-2 and AsPC-1 PDAC cells in a dose-dependent manner and further enhanced the radiation-induced apoptosis (additive but not synergistic). Radiosensitization of these cells was ascribed to inhibition of DNA repair and suppression of radiation-induced EGFR and NF-κB prosurvival signaling pathways[63]. In another study, using 3-D agarose colonies of MiaPaCA cells, synergy occurred when SAHA was combined with carboplatin at short exposure times, providing evidence that SAHA may allow a reduction in the standard dose of carboplatin, with improvement in the overall therapeutic index[64]. Thirty genes were identified as constitutively silenced in PANC-1 cells, and were upregulated post-SAHA and/or 5-Aza-C treatment. Interestingly, among them, 10 genes were known cancer antigens, suggesting that many of these antigens may be silenced by acetylation and/or methylation in PANC-1 cells[65]. The Rel/NF-κB family consists of various members of transcription factors, such as RelA/p65, which are responsible for the regulation of cytokines, their receptors and cell adhesion molecules. Overexpression or dysregulation of certain regulatory proteins of the NF-κB pathway, have been associated with poor prognosis in different cancer types. Treatment of the pancreatic cancer cell line PANC-1 with SAHA resulted in a time dependent reduction of RelA/p65 activity of up to 50%, while valproic acid (VPA) treatment decreased RelA/p65 activity by approximately 25%, affecting also its subcellular localization. Neither SAHA nor VPA affected the protein levels of IκBα, but inhibited its phosphorylation. According to this study, strong antineoplastic effects of SAHA could be partly based on an alteration of the NF-κB signaling pathway[66].

Cyclic peptides

FK228 (FR901228, depsipeptide, romidepsin): Depsipeptide (1S,4S,7Z,10S,16E,21R)-7-ethylidene -4,21-bis (1-methyletheyl)-2-oxa-12,13-dithia-5,8,20,23-tetraazabicyclo [8.7.6] tricos-16-ene-3,6,9,19,22-pentone, is a bicyclic peptide isolated from *Chromobacterium Violaceum* and has demonstrated potent *in vitro* cytotoxic activity against human tumor cell lines and *in vivo* efficacy against human tumor xenografts. Upon entering cells, FK228 is reduced to an active compound, capable of preferentially interacting with the zinc in the active site of the HDAC class I enzymes; however, it is still generally classified as a broad-spectrum inhibitor as it also inhibits class Ⅱ enzymes. It was approved by the United States Food and Drug Administration for the treatment of cutaneous T-cell lymphoma[67].

FK228 markedly inhibited the proliferation of five pancreatic cancer cell lines, with the greatest effect on MIAPaCa-2 cells. FK228 treatment induced cell cycle arrest at the G1 or G2/M phase and subsequent apoptosis. The induced hyperacetylation of histone H3 was accompanied by p21 overexpression and caspase-3 activation, leading to cleavage of p21, and by dramatic downregulation of survivin[68]. Treatment with FK228, bortezomib or both, sensitized two out of three pancreatic cancer cell lines tested, to NK cells. Tumors sensitized to NK cell cytotoxicity showed a significant increase in surface expression of DR5, which induces the TRAIL pathway of apoptosis. Expressions of MHC class I , MIC-A/B, DR4 and Fas did not alter in different cell lines[69]. Interestingly, in another study, depsipeptide could induce demethylation of both the p16 and GATA4 promoters in PANC1 cells, among other cancer cell lines, assayed with bisulfite sequencing (region D of the p16 promoter and region B of the GATA4 promoter). Additionally, depsipeptide could induce a significant inhibition of cell proliferation in PANC1 cells. In this study, a novel mechanism of HDACI-mediated DNA demethylation *via* suppression of histone methyltransferases was suggested[70].

Short chain fatty acids

VPA: VPA is now an established antiepileptic drug through its effect on the function of the neurotransmitter GABA. The finding that VPA was an effective inhibitor of HDACs came from the observations that VPA was able to relieve transcriptional repression of a peroxisomal proliferation and activation of a glucocorticoid receptor (GR)-peroxisome-proliferation-associated receptor (PPAR)ε hybrid receptor and a RAR-dependent reporter gene expression system, suggesting that it acts on a common factor in gene regulation, such as corepressor-associated HDACs, rather than on individual transcription factors or receptors. Consistent with this finding, it was shown that VPA causes hyperacetylation of the N-terminal tails of histones H3 and H4 *in vitro* and *in vivo* and was found to inhibit HDAC enzymatic activity at a concentration of 0.5 mmol/L[71]. VPA has shown potent antitumor effects in a variety of *in vitro* and *in vivo* systems, by modulating multiple pathways, including cell cycle arrest, apoptosis, angiogenesis, metastasis, differentiation and senescence. Most of preclinical and clinical data on the anticancer effects of VPA has been generated for malignant hematological diseases[72].

Neutral endopeptidase (NEP/CD10) is a cell surface Zn metalloprotease that inactivates multiple physiologically active peptides. Loss of, or decrease in, NEP/CD10 expression has been reported in many types of malignancy. VPA treatment resulted in increase of NEP/CD10 protein expression accompanied with a significantly reduced growth in PATU-8988T and HUP-T4 cells. The VPA effect on the proliferation in HUP-T4, as well as in HUP-T3, cells was much lower than in the high NEP/CD10-expressing PATU-8988T cells[73]. VPA treatment of DanG cells resulted in a significant reduction of cell proliferation, an effect that was depended on the drug exposure time. VPA evoked a significant blockade of both DanG tumor cell adhesion to HUVECs, particularly when the compound was applied for 5 days. Additionally, VPA treatment modified the integrin surface profile on pancreatic cancer DanG cells[74]. MiaPaCa2 and Panc1 cell lines were also treated with the topoisomerase Ⅱ inhibitor etoposide and VPA. VPA-mediated depletion of HDAC2

was observed in MiaPaCa2 and Panc1 cells. The apoptotic fraction of VPA/etoposide co-treated MiaPaCa2 and Panc1 cells was significantly increased compared to etoposide-treated pancreatic cancer cells. Sensitization by VPA to etoposide (DNA-damage induced apoptosis) was noted in both cell lines. This effect was not observed when VPA was used in combination with other drugs, such as gemcitabine, 5-FU or oxaliplatin. Such data suggested that HDAC2 inhibition might result in specific sensitization towards DNA damage-induced apoptosis[75]. Treatment of Panc1 cells with VPA and SAHA, at different concentrations, induced the mRNA expression of RELN and DAB1 in a dose-dependent manner. VPA was also shown to prevent the epigenetic downregulation of RELN, leading to the inhibition of migration of Panc-1 cells[62].

4-phenylbutyrate: 4-phenylbutyrate (4-PB) is a short-chain fatty acid that reversibly inhibits class I and Ⅱ HDACs. It is considered as an HDAC inhibitor of the first generation, as the HDAC inhibitory effect is not specific. Working concentrations are rather high, in the millimolar range, and the effects are pleiotropic. 4-PB exerts multiple effects in the cell, including the modulation of protein isoprenylation, which regulates the ras proto-oncoprotein, and activation of the nuclear steroid PPAR[76]. 4-PB exerts a potent antitumor effect *in vitro* and causes growth inhibition and differentiation in various human cancer cell lines[77].

A set of normal fibroblast and cancer cell lines, among them the pancreatic cancer CFPAC-1, were treated with 5-Aza-C and 4-PB. Upregulation of the cell cycle inhibitors p16 and p21 was induced post-5-Aza-C and 4-PB treatment. Interestingly, both normal and cancer cells presented very similar induction levels after combination treatment[78]. Expression profiling of different cancer cell lines revealed upregulation of several miRNAs by simultaneous treatment with 5-Aza-C and 4-PB. One of these, miR-127, is embedded in a CpG island and is highly induced from its own promoter after treatment. miR-127 is usually expressed as part of an miRNA cluster in normal but not in cancer cells, suggesting that it is subject to epigenetic silencing. Additionally, the proto-oncogene *BCL6,* a potential target of miR-127, was translationally downregulated after treatment of several lines with the combination of drugs[79]. 4-PB inhibited HDAC activity by 60%-70% in the cancer cell lines T3M-4 and BxPc3. Treatment with 4-PB inhibited growth and induced apoptosis of Panc1, T3M-4, COLO 357 and BxPc3 pancreatic adenocarcinoma cell lines in a dose- and time-dependent manner. Concentration-dependent cell cycle arrest was noted in T3M-4 and COLO 357 cells, which was not verified in Panc 1 and BxPc3 cells. In addition, 4-PB increased gap junction communication between T3M-4 cells, allowing exchange of apoptotic signals between neighboring cells. Furthermore, 4-PB inhibited cellular export mechanisms. 4-PB increased gemcitabine-mediated apoptosis of two resistant cell lines T3M-4 and BxPc3. Activation of caspase-8 was enhanced, as well as that of Bid and PARP-cleavage. No differences in the expression levels of caspase -2 and -3 and IAPs were noted. Finally, no influence of MEK or p38 on gemcitabine-mediated cell death in these cells was found. In contrast, inhibition of JNK completely abolished the sensitizing effect of 4-PB[80].

Sodium butyrate (NaBu): Sodium butyrate has multiple effects on cultured mammalian cells, including inhibition of proliferation, induction of differentiation and induction or repression of gene expression. NaBu inhibits most HDACs, except class Ⅲ HDAC and class Ⅱ HDAC6 and -10. Promoters of butyrate-responsive genes have butyrate response elements, and the action of butyrate is often mediated through Sp1/Sp3 binding sites[81].

NaBu induced a dramatic decrease in cell proliferation and an increase in ALP activity in PANC-1 cells. NaBu also induced a number of morphologic alterations in these cells, including increase in the cytoplasmic secretory elements and enhancement of differentiation[82]. Both NaBu and the natural butyrate prodrug tributyrin, inhibited growth and induced apoptosis in MiaPaca-2 and Capan-l cells and stimulated differentiation in Capan-l cells, as indicated by alterations of ALP levels[83]. NaBu also induced differentiation and apoptosis in the human pancreatic cancer cell line AsPC-1, as well as increased K23 mRNA levels[84]. NaBu treatment resulted in a significant reduced cell growth of PATU-8988T cells and an increase of NEP/CD10 protein levels[73]. Additionally, NaBu treatment induced cell growth inhibition and apoptosis in four lines (ASPC-1, PANC-1, PT45 and PACA44) with different susceptibility. Bcl-xL expression was strongly downregulated by NaBu in a time-dependent manner, whereas Bax expression was not affected. NaBu enhanced the intrinsic pathway of apoptosis, including mitochondrial membrane depolarization, cytochrome c translocation to the cytosol, caspase-3 and -9 activation, although it had no effect on caspase-8. NaBu also enhanced the extrinsic pathway of apoptosis, sensitizing pancreatic cancer cell lines to Fas-mediated signals[85]. Moreover, NaBu inhibited the ability of several pancreatic cell lines to form colonies in soft agar. Cellular ALP levels were markedly increased post-treatment[86,87]. Treatment of pancreatic cancer cell line CAPAN-1 with 1 mmol/L NaBu reduced the rate of cellular growth and inhibited colony forming ability in soft agar, but did not suppress cell growth. These effects were completely reversible on removal of NaBu and were therefore not causing a terminal differentiation step or a loss of cell viability. Significant changes in proteins and glycoproteins of CAPAN-1 occurred with NaBu treatment[88]. Treatment with NaBu strongly inhibited growth of pancreatic carcinoid BON cell line. It was found that NaBu increased levels of 5-hydroxytryptamine in the cells, as a differential effect[89]. TGF-α but not TGF-β mRNA levels were decreased after NaBu treatment in CAPAN-1 cells, while the membrane-bound protein kinase C activity was also reduced[90].

Oligosaccharide antigens are commonly used as tumor markers. Such antigens control tumor cell adhesion,

motility and invasiveness, being synthesized by a series of glycosyltransferases. In MiaPaCa-2, PSN-1 and PK59 cell lines, the expression of GnT-IVa (N-acetylglucosaminyltransferase-IVa) was increased after NaBu treatment[91]. Carcinoembryonic antigen (CEA) expression of human pancreatic adenocarcinoma cells and differentiation features were studied and compared in the well differentiated and CEA-producing CAPAN-1 and the poorly differentiated PANC-1 cell line post-NaBu treatment. NaBu reduced colony formation in both cell lines by approximately 50%. Significant ultrastructural alterations were noted only in the PANC-1 cells, including increased intercellular desmosomes, tonofilaments and lipid droplets. NaBu increased CEA expression in CAPAN-1 cells, but had no effect on CEA expression in PANC-1 cells. Thus, CEA expression and state of differentiation were independently affected[92]. NaBu inhibited the growth of pancreatic cancer cell lines PC-1 and PC-1.0 (hamster) and HPAF, CD11, CD18 and PANC-1 (human), and induced cell enlargement, an increase in secretory material, microfilaments and pseudopodia. NaBu increased the expression of blood group A, DU-PAN-2 and CA 19-9 tumor associated antigens[93]. Treatment with NaBu, slightly increased immunoreactive trypsin 1 (IRT) levels in both human pancreatic adenocarcinoma cell lines CF-PAC-1 (established from a patient with cystic fibrosis) and CAPAN-1, while growth inhibition was significant. Consequently, IRT levels or differentiation state did not correlate with cellular growth[94].

NaBu treatment inhibited the cell growth of four pancreatic cancer lines (PT45, PaTu-Ⅱ, Panc-1 and A818-1) more potently than all-trans retinoic acid (ATRA). Additionally, neuroendocrine markers synaptophysin and Lcu7 in Panc-1 cells were highly expressed[95]. The expression of b4 and b7 integrin chains correlates with tumor invasiveness. In this aspect, it was documented that NaBu inhibited b4 integrin expression in AsPC-1 cells, inhibiting pancreatic tumor invasion. NaBu also reduced the expression of the b7 integrin chain, which was expressed only in the more aggressive pancreatic cancer cell lines[96]. The cellular morphological characteristics of the PANC-1 cell line treated with NaBu appeared more differentiated, in a dose-dependent manner. The EGFR expression of NaBu-treated PANC-1 cells was decreased in a dose-dependent manner. Ezrin is a cytosolic molecule that cross-links the plasma membrane to actin filaments and has functions related to cell motility, signal transduction, cell-cell and cell-matrix recognition, invasion and metastasis. Both membranous ezrin expression of PANC-1 cells and mRNA expression of ezrin were decreased[97].

A novel bioconjugate (HA-But) obtained by the esterification of butyric acid (BA) with hyaluronic acid (HA), the main constituent of the ECM, which selectively recognizes transmembrane receptor CD44, was developed. All HA-But treated cell lines, including the pancreatic cancer cell line MiaPaCa, were responsive to the antiproliferative effect of HA-But in a dose-dependent manner with cell growth inhibition higher than that observed in the presence of BA alone. Like BA, HA-But induced hyperacetylation of histone H4, a dose-dependent overexpression of some G1/S transition-related proteins, including the CdkIs p27 and p21, and the block of cell growth in the G0/G1 phase of the cell cycle[98]. In another study, HA-But induced a dose-dependent inhibitory effect with an almost complete suppression of MIA PaCa-2 cell growth at the highest concentration used. A decrease in the number of cells in S phase and a concomitant increase of those in G0/G1 or G2/M phase were noted. HA-But decreased cyclin D1 and mut-p53 and increased p27 and p21 protein levels. Additionally, HA-But slightly increased the level of Bax and caspase-7, slightly decreased Bcl-2, but strongly decreased survivin protein levels, providing to be active on both Bcl-2 and survivin-mediated apoptosis pathways[99].

Benzamides

MS-275: This synthetic benzamide derivative 3-pyridylmethyl-N-{4-[(2-aminophenyl)carbamoyl]benzyl}carbamate inhibits HDACs, and has anti-tumor activity in many preclinical models. The first clinical trial with this agent in 2005 included patients with advanced solid tumors or lymphoma. At high concentrations of MS-275, there is a marked induction of reactive oxygen species, mitochondrial damage, caspase activation and apoptosis. Treatment of sensitive tumor cell lines with MS-275 induces gelsolin, a maturation marker, and produces a change in the cell cycle distribution with a decrease in S phase and an accumulation of cells G_1. The *in vivo* therapeutic efficacy of MS-275 has been demonstrated in a variety of human tumor xenograft models[100].

The addition of MS-27-275 to cell cultures resulted in the accumulation of hyperacetylated H4 molecules. MS-27-275 transcriptionally induced p21 and gelsolin (tumor suppressor) through acetylation of histones affecting cell cycle progression. In addition, pRb molecules were reduced. The response of Capan-1 cell line, presenting a p53 mutation, to MS-27-275 treatment was moderate, although expression of gelsolin was induced. The gelsolin induction by MS-27-275 seemed to have no correlation with the sensitivity of the cells to the treatment. Additionally, p21 induction was considered crucial for the action of MS-27-275[101].

TSA, NaBu and MS-275 inhibited the growth of the NET cell lines CM and BON in a dose-dependent manner. In both cell lines, HDAC inhibition resulted in a dose-dependent increase of caspase-3 enzyme activity without affecting cell membrane integrity or exerting immediate necrotic effects. Treatment with HDACIs resulted in cell cycle arrest of the NET cells at G1, thereby decreasing those in the S phase. MS-275 treatment of CM and BON cells resulted in a dose-dependent decrease of Bcl-2, whereas Bax remained unaffected in both cell lines. Cyclin D1 was also downregulated in CM and BON cells by MS-275 treatment, while p21 and p27 were markedly increased[102].

MGCD0103: MGCD0103 is an isotype-specific aminophenylbenzamide that inhibits HDAC classes I and Ⅳ,

Table 2 Studies of histone deacetylase inhibitors and different pancreatic cancer cell lines in xenograft models

HDAC inhibitor	Pancreatic cancer cell line	Time schedule	Dosage schedule	Results	Ref.
TSA (+ gemcitabine)	T3M4	q28 d	0.25 mg/kg *ip*, biweekly	50% tumor weight reduction 3-fold H4 increase	[33]
SAHA (+ bortezomib)	L3.6pl	q21 d	50 mg/kg *ip*, daily	About 70% tumor weight reduction aggresome disruption	[61]
SAHA (+ Zebularine)	Panc-89, YAP C	(1) q7 d or q14 d (2) q7 d	(1) 50 mg/kg *ip*, daily (2) 50 mg/kg *ip*, daily	Tumor growth inhibition Upregulation of CK7, CK20 Downregulation of CK8, Vimentin, chromogranin-A	[55]
FK228	CAPAN-1	q14 d-q21 d	1.5 mg/kg *ip*, biweekly	50% tumor growth inhibition	[108]
MS-275	CAPAN-1	q28 d	(1) 12.3 mg/kg per os (2) 24.5 mg/kg per os (3) 49 mg/kg per os, 5 × weekly	Moderate growth inhibitory effect	[101]
	CAPAN-1, MiaPaca, Panc-1, Panc-15	Not defined	per os once daily (dosage not defined)	Mixed response: moderate growth inhibitory effect/ resistant to inhibition	[109]
NVP-LBH589 (+ gemcitabine)	HPAF-2, L3.6pl	q28 d	25 mg/kg *ip*, 5 × weekly	63% tumor weight reduction (HPAF-2) About 80% tumor weight reduction (L3.6pl) MIB-1 slight reduction TUNEL slight induction (HPAF-2)	[113]

HDAC: Histone deacetylase; TSA: Trichostatin A; HPAF: Suberoylanilide hydroxamic acid; TUNEL: Transferase dUTP nick end labeling.

with almost no class Ⅱ effect. MGCD0103 is well-tolerated and exhibits favorable pharmacokinetic and pharmacodynamic profiles, demonstrating target inhibition and clinical responses. It induces cell death and autophagy, synergizes with proteasomal inhibitors and affects non-histone targets, such as microtubules[103].

A comparative study in order to estimate the pharmacological properties of second generation HDACIs with the hydroxamate and benzamide head group, namely SAHA, LAQ824/LBH589, CI-994, MS-275 and MGCD0103 was carried out. SAHA and LAQ824/LBH589 seemed to behave as quite unselective HDACIs, while the benzamides CI-994, MS275 and MGCD0103 were more selective HDAC1 and HDAC3 inhibitors. All the compounds induced histone H3 hyperacetylation, as well as cell differentiation and apoptosis and inhibited proliferation. A broad cytotoxicity was seen across different tumor cell lines, among them the pancreatic lines AsPC-1, BxPc3 and Panc-1, with LAQ824/LBH589 being the most potent agents[104,105]. The inhibitory activities of MGCD0103, MS-275 and SAHA were also compared using a panel of cancer cell lines, among them Panc-1. Although the measured IC50 values varied between cell lines, MGCD0103 was always more potent than the comparator molecules in all cases examined, being at least 7-fold more potent than SAHA in PANC-1 pancreatic cancer cells[106].

IN VIVO EXPERIMENTAL STUDIES

The data available so far regarding the different classes of HDACIs used in *in vivo* animal studies of pancreatic cancer are presented in the following section and are listed in Table 2.

Hydroxamic acids

TSA: *In vivo* studies on xenografts of pancreatic cancer line T3M4 in nude mice, showed that the combination of TSA (0.25 mg/kg) and gemcitabine (2.5 mg/kg), given biweekly for 4 wk, led to a reduction in the mean tumor weight by about 50% compared to control or single drug treatments. Additionally, TSA treatment resulted in only a 3-fold increase of H4 acetylation levels *in vivo* compared to the 18-fold increase noted *in vitro*. None of the treatments produced any toxicity, as indicated by lack of change in body weight, and none of the animals developed ulcerating tumors[33]. Finally, TSA exerted an inhibitory effect on the DMBA-induced carcinogenesis model and the growth of pancreatic ductal adenocarcinoma in rats, by upregulating *KiSS-1*, a metastasis suppressor gene located on 1q32, which is considered to exert an important role in inhibiting the invasion and metastasis of pancreatic cancer[107].

SAHA: Effects of bortezomib and SAHA in orthotopic human pancreatic tumors (cell line L3.6pl) were investigated. Tumors were treated biweekly with 1 mg/kg bortezomib, daily with 50 mg/kg SAHA, or a combination of the two agents for 21 d. *In vivo* data showed aggresome disruption by the combination and reduction of pancreatic tumor weight, with minimal toxicity noted, what there was being related to bortezomib[61]. Another experiment in mice presented tumor suppression when treated with SAHA and the DNA methyltransferase inhibitor Zebularine. The first experimental setting included a single intraperitoneal (*ip*) bolus injection with SAHA (50 mg/kg), Zebularine (1 g/kg) or the combination of both agents, and the animals were sacrificed after 7 or 14 d. For daily treatment, animals received the same doses of drugs over a time-course of 1 wk. Gemcitabine as a control therapy was administered *ip* every fourth day. The hypermethylated cell line Panc-89 was more susceptible to SAHA than YAP C. No adverse effects were noted and all animals

survived. Furthermore, the expression of CK7, which is a marker associated with pancreatic cancer cell differentiation, was higher in Zebularine and combined Zebularine/SAHA-treated xenografts, as well as that of the glandular differentiation marker CK20. The expression of CK8, Vimentin and chromogranin-A was lower or constant in Zebularine and Zebularine/SAHA-treated animals[55].

Cyclic peptides

FK228 (FR901228, depsipeptide): More than 90% of human pancreatic cancers are associated with oncogenic mutations of RAS, in particular K-RAS at codon 12. The Tyr-kinase inhibitors, PP1 and AG, block the RAS mutation-induced activation of PAK1, which is the Rac/CDC42-dependent Ser/Thr kinase. PAK1 is essential for RAS-transformation. Based on these data, the therapeutic potential of either FK228, the combination of these two Tyr-kinase inhibitors or GL-2003, a water-soluble derivative of AG 879, on human pancreatic cancer (Capan-1) xenograft in mice, was examined. Capan-1 cells were injected sub-cutaneously (*sc*) into several groups of nude mice. Each group was treated *ip* with either FK228 (1.5 mg/kg), GL-2003 (20 mg/kg), a combination of PP1 and AG 879 (20 mg/kg of each drug), a combination of PP1 and GL-2003 (20 mg/kg of each drug), or vehicle alone (0.1 mL of 1% DMSO in PBS) as the control, twice a week for 2-3 wk. No adverse effects were detected. The most effective combination was that of GL-2003/PP1 that suppressed cell growth by around 80%, while FK228 alone showed only 50% inhibition. The synergy between GL-2003 and PP1 in blocking the RAS-induced PAK1 activation was not observed *in vitro*[108].

Benzamides

MS-275: MS-275 administered orally, once daily, 5 d per week for 4 wk, strongly inhibited the growth in 7 out of 8 tumor cell lines implanted into nude mice, although most of these did not respond to 5-FU. Tumors were passaged several times before starting *in vivo* antitumor testing, a tumor lump (2-3 mm in diameter) was transplanted *sc* into the flank of a nude mouse, and the therapeutic efficacy of MS-27-275 was examined. MS-27-275 at 49 mg/kg showed a moderate effect against the only pancreatic Capan-1 tumor. The drug at 24.5 mg/kg and 12.3 mg/kg also showed significant effects against these tumors. As the dose of 49 mg/kg was the maximum tolerated one in this administration schedule, and apparent signs of toxicity, such as weight loss and poor appearance, were reported. The maximum dose of the drug was lowered to 24.5 mg/kg, at which no gross weight loss was observed[101]. Additionally, the pancreatic carcinoma cell lines Capan1, MiaPaCa, Panc1 and Panc15 were grown as xenografts in nude mice and afterwards, treated per os once daily with MS-275. For most cell lines used, antitumor activity and dose-dependent response of MS-275 *in vivo* were observed. While various tumor cell lines from other malignancies showed an almost complete response, in pancreatic cell lines a mixed response was achieved, with half of the models tested to present either a moderate growth inhibitory effect or resistance to treatment[109].

CI-994: CI-994 or N-acetyldinaline[4-(acetylamino)-N-(2-amino-phenyl) benzamide] is a novel oral compound with a wide spectrum of antitumor activity in preclinical models. The mechanism of action may involve inhibition of histone deacetylation and cell cycle arrest. CI-994 is currently undergoing clinical trials. Although several changes in cellular metabolism induced by the drug have been characterized, the primary molecular mechanism of its antitumor activity remains unknown[110].

CI-994 was previously identified as having cytotoxic and cytostatic activity against several murine and human xenograft tumor models. CI-994 had activity against 8/8 solid tumors tested among them pancreatic adenocarcinoma 02 and 03[111]. Notably, CI-994 was active against a Pan-02 pancreatic tumor of C57BL/6 mouse origin[112].

Other HDACIs

Pancreatic tumors were induced in nude mice by *sc* injection of HPAF-2 and L3.6pl cells. Animal groups received either NVP-LBH589 (25 mg/kg, 5 × weekly) or gemcitabine (5 mg/kg, 1 × weekly) or a combination of both (NVP-LBH589 at 25 mg/kg, 5 × weekly plus gemcitabine at 5 mg/kg, 1 × weekly) *ip*, whereas the control group received placebo only, for 28 consecutive days. Three days after commencement of NVP-LBH589 or combination treatment, HPAF-2 cell tumors showed a significantly reduced volume compared with the control. Combination therapy was significantly more efficient than gemcitabine treatment alone and significantly more efficient than NVP-LBH589 therapy alone, in both cell lines. Regarding side effects, weight loss was 6% and 25% for the combination treatment in HPAF-2 and L3.6pl cell tumor bearing mice, respectively. Treatment with NVP-LBH589 and the combination slightly reduced proliferation (Ki-67 index) and slightly induced apoptosis markers in HPAF-2 cell bearing mice, whereas proliferation was not decreased and apoptosis only slightly increased in L3.6pl cell bearing mice[113].

CONCLUSION

In this review, the recent advances in the understanding and clinical development of HDACIs were discussed. The exact mechanism and the molecular basis for the antitumor effects of these new drugs are complex and not completely understood. HDACIs regulate the acetylation of histones and many non-histone proteins that are involved in gene expression, cell proliferation, migration and death. HDACIs have been shown to induce differentiation and cell cycle arrest, activate the extrinsic or intrinsic pathways of apoptosis and to inhibit invasion, migration and angiogenesis in different cancer cell lines. Normal cells are relatively more resistant to HDACIs-induced cell death. Although not completely elucidated, the main mechanisms by which HDACIs act in pancre-

atic cancer are common. The cdk inhibitor p21 is one of the most commonly induced genes in various pancreatic cancer cell lines by all HDACIs tested. Transcriptional induction of p21 is associated with G1 cell cycle arrest and growth inhibition. Cell cycle arrest and growth inhibition is also correlated with transcriptional activation of other cell cycle regulatory genes such as p16, p27, cyclin E and gelsolin, while inhibition of cyclins A, B1, D1 and D2 were also noted in many cancer cell lines. The pro-apoptotic proteins Bax, Bad and Bim were upregulated, among others, whereas anti-apoptotic proteins, such as Bcl-2, Bcl-XL and survivin, were downregulated. HDACIs reduced the expression of angiogenetic factors, such as VEGF receptors -1 and -2, and affected the expression of a panel of metastasis promoting genes (Table 1).

Additionally, these drugs exhibited antiproliferative effects in cancer animal models. Various pancreatic carcinoma cell lines were grown as xenografts in nude mice and treated with HDACIs (Table 2). For most lines used, anti-tumor activity and dose-dependent response were observed, with reduction of cell proliferation (Ki-67 index) and induction of apoptosis (transferase dUTP nick end labeling test). The reduction of pancreatic tumor weight was achieved with minimal toxicity.

These results support the efficiency that HDACIs presented *in vitro;* however, more studies and well-controlled experiments are required to obtain stronger *in vivo* data. Furthermore, phase Ⅱ/Ⅲ trials including patients with pancreatic cancer are needed to determine the clinical efficacy of these new drugs.

Abstract

Insulinomas, the most common cause of hypoglycemia related to endogenous hyperinsulinism, occur in 1-4 people per million of the general population. Common autonomic symptoms of insulinoma include diaphoresis, tremor, and palpitations, whereas neuroglycopenic symptoms include confusion, behavioural changes, personality changes, visual disturbances, seizure, and coma. Diagnosis of suspected cases is based on standard endocrine tests, especially the prolonged fasting test. Non-invasive imaging procedures, such as computed tomography and magnetic resonance imaging, are used when a diagnosis of insulinoma has been made to localize the source of pathological insulin secretion. Invasive modalities, such as endoscopic ultrasonography and arterial stimulation venous sampling, are highly accurate in the preoperative localization of insulinomas and have frequently been shown to be superior to non-invasive localization techniques. The range of techniques available for the localization of insulinomas means that blind resection can be avoided. Intraoperative manual palpation of the pancreas by an experienced surgeon and intraoperative ultrasonography are both sensitive methods with which to finalize the location of insulinomas. A high proportion of patients with insulinomas can be cured with surgery. In patients with malignant insulinomas, an aggressive medical approach, including extended pancreatic resection, liver resection, liver transplantation, chemoembolization, or radiofrequency ablation, is recommended to improve both survival and quality of life. In patients with unresectable or uncontrollable insulinomas, such as malignant insulinoma of the pancreas, several techniques should be considered, including administration of ocreotide and/or continuous glucose monitoring, to prevent hypoglycemic episodes and to improve quality of life.

INTRODUCTION

Insulinomas are the most common functioning endocrine neoplasm of the pancreas[1-4]. They are insulin-secreting tumors of pancreatic origin that cause hypoglycemia[5-7]. Insulinomas occur in 1-4 people per million in the general population and represent 1%-2% of all pancreatic neoplasms[8-10]. Insulinomas can occur at any age and have an equal gender distribution. As many as 90% of insulinomas have been reported to be benign, 90% are solitary, > 90% occur at intrapancreatic sites, and 90% are < 2 cm in

diameter[10-13]. Insulinomas are evenly distributed over the entire pancreas. Most insulinomas are located in the pancreas or are attached directly to the pancreas. Extrapancreatic insulinomas causing hypoglycemia are extremely rare (incidence < 2%); extrapancreatic insulinomas are most commonly found in the duodenal wall[8]. The etiology and pathogenesis of insulinomas are not known.

Following biological and biochemical confirmation of an insulinoma, preoperative localization is sought using computed tomography (CT)[14-16], magnetic resonance imaging (MRI)[16-19], endoscopic ultrasonography (EUS)[20-22], intra-arterial calcium stimulation test with hepatic venous sampling[23], and/or angiography and arterial stimulation venous sampling (ASVS)[24-28]. Surgical resection is the primary treatment modality for insulinomas, and so accurate localization of the tumor before or during surgery is important. Intraoperative manual palpation of the pancreas by an experienced surgeon and intraoperative ultrasonography are both sensitive methods with which to localize insulinomas, supporting the argument by some surgeons that preoperative localization of the tumors is not necessary[29-33]. The present review describes some of the latest findings regarding the clinical diagnosis and medical management of insulinomas in the adult population that are not associated with either multiple endocrine neoplasms or von Hippel-Lindau disease.

CLINICAL SIGNS

Insulinomas are the most common cause of hypoglycemia related to endogenous hyperinsulinism. The episodic nature of the hypoglycemic attack is due to the intermittent secretion of insulin by the tumor[8]. Common autonomic symptoms of an insulinoma include diaphroresis, tremor, and palpitations, whereas neuroglycopenenic symptoms include confusion, behavioral changes, personality changes, visual disturbances, seizures and coma[34,35].

Diagnosis of insulinomas can be challenging. Although it was originally considered that symptoms only became evident in the fasting state or following exercise, it is now known that patients with an insulinoma can also present with postprandial symptoms[36,37]. The classical diagnosis of insulinoma depends on satisfying the criteria of Whipple's triad, which remains the cornerstone of the screening process: (1) hypoglycemia (plasma glucose < 50 mg/dL); (2) neuroglycopenic symptoms; and (3) prompt relief of symptoms following the administration of glucose (Table 1)[38]. In adults with symptoms of neuroglycopenia or documented low blood glucose levels, the gold standard for biochemical diagnosis remains measurement of plasma glucose, insulin, C-peptide, and proinsulin during a 72-h fast (Table 1). This prolonged fasting test can detect up to 99% of insulinomas[39]. Endogenous hypoglycemia due to insulinomas was previously based on findings of abnormal serum levels of insulin, C-peptide, and, more recently, proinsulin at the time of fasting hypoglycemia. To date, there is some general agreement regarding the diagnostic thresholds that must be reached for insulin, C-peptide, and proinsulin levels to be considered abnormal. Several years ago, ratios calculated from insulin and blood glucose levels were used, with the insulin/C-peptide ratio in patients diagnosed with insulinoma reported to be < 1.0[40,41]. It is of note that a normal insulin level does not exclude the disease, because the absolute insulin level is not elevated in all patients with insulinoma. In addition, because the proportion of proinsulin secreted by insulinoma cells is generally higher than that secreted by normal β-cells, high proinsulin levels have been suggested as being diagnostic of insulinoma, regardless of concomitant blood glucose levels[42]. The availability of proinsulin assays has led to the use of serum proinsulin thresholds as a diagnostic tool: it has been recommended that a cut-off level of 20 pmol/L proinsulin at the time of hypoglycemia < 45 mg/dL is indicative of the presence of an insulinoma (Table 1)[42-44].

Table 1 Diagnosis of insulinoma

Classical diagnosis
Hypoglycemia (plasma glucose < 50 mg/dL)
Neuroglycopenic symptoms
Prompt relief of symptoms following the administration of glucose
Present consensus
At the time of hypoglycemia during a 72-h fasting test:
5 mIU/L (36 pmol/L) insulin threshold
0.6 ng/mL (0.2 nmol/L) C-peptide threshold
Insulin/C-peptide ratio < 1.0
20 pmol/L proinsulin cut-off level
Absence of sulfonylurea (metabolites) in the plasma or urine

Delays in the diagnosis of insulinoma are common because the symptoms usually precede detection of a tumor and there may be misattribution of the symptoms to psychiatric, cardiac, or neurological disorders[45]. Once a diagnosis of insulinoma is considered, it is important that patients are managed in a timely and safe manner. As a general rule, patients with insulinoma can be cured by surgical resection of the tumor. The need for preoperative localization of insulinomas and the methods used remain contentious. In the past, confirmation of the presence of the Whipple triad (symptoms known or likely to be caused by hypoglycemia; a low plasma glucose measured at the time of the symptoms; relief of symptoms when the glucose is raised to normal) usually meant that a patient was led directly to surgery[46,47]. However, at present, most agree that knowledge of the site of the tumor before surgery is helpful in that it allows one to determine not only whether enucleation (the surgical removal of a mass) of the neoplasm or pancreatic resection is likely to be required, but also whether the tumor is amenable to removal *via* a laparoscopic approach. Preoperative localization should also mean that the operation itself can be performed more quickly, thereby reducing associated morbidity and mortality[27]. It is important to remember that most tumors are intrapancreatic, 90% are solitary, 90% are < 2 cm in diameter, and the tumors are distributed equally within the head, body and tail of the pancreas.

Figure 1 Computed tomography of insulinoma of the pancreas. Typically, insulinomas (arrow) are hypervascular and, as a result, demonstrate a greater degree of enhancement than normal pancreatic parenchyma during the arterial and capillary phases of contrast bolus.

NON-INVASIVE IMAGING

A number of non-invasive techniques are available for the localization of a suspected insulinoma, including transabdominal ultrasonography, CT and/or MRI. The sensitivity of transabdominal ultrasonography in the localization of insulinomas is poor (ranging from 9% to 64%)[48]. However, insulinomas demonstrate characteristic features when imaged with both CT and MRI and the sensitivity of these techniques has been reported to be 33%-64% and 40%-90%, respectively[10,49]. The sensitivity and specificity of MRI is generally superior to that of CT, as is the detection of extrapancreatic extensions[16].

CT is a safe and simple procedure to perform that is operator independent. CT visualizes the exact location of an insulinoma, its relationship to vital structures, and the presence of metastases[49]. Typically, insulinomas are hypervascular and, as a result, demonstrate a greater degree of enhancement than normal pancreatic parenchyma during the arterial and capillary phases of contrast bolus (Figure 1)[16]. An atypical CT appearance of insulinomas is occasionally encountered and can include hypovascular and hypodense lesions post-contrast, hyperdense lesions precontrast, cystic masses, and calcified masses[16]. Calcification, when it occurs, tends to be discrete and nodular, and is more common in malignant than benign tumors[50,51]. Technical advances have improved the quality of CT, with a recent study reporting that using a multidetector CT enabled visualization of 94.4% of insulinomas[52]. CT is currently accepted as the first-line investigation for the visualization of insulinomas.

Currently, there is strong evidence emerging for the use of MRI in the imaging of insulinomas, and investigators have shown a high sensitivity for MRI in the detection of insulinomas[16,49]. Like CT, MRI is safe, non-invasive, rapid, and facilitates the detection of metastases. Insulinomas generally demonstrate low signal intensity on T_1-weighted images and high signal intensity on T_2-weighted images (Figure 2)[50]. However, limitations in the use of MRI in the detection of insulinomas include the standard contraindications for MRI. The modern MRI system allows rapid triphasic, breath-held T_1 rapid gadolium-enhanced sequences, and/or diffusion-weighted imaging[19,49]. These sequences significantly reduce motion artifacts and enable accurate assessment of the pancreas in both the arterial and venous phase[49]. MRI has all the advantages of CT and recent evidence suggests that it may be the more sensitive tool. In current practice, MRI is a second-line investigation for the localization of insulinomas, but it could potentially take over from CT in the future as it becomes more widely available and expertise improves.

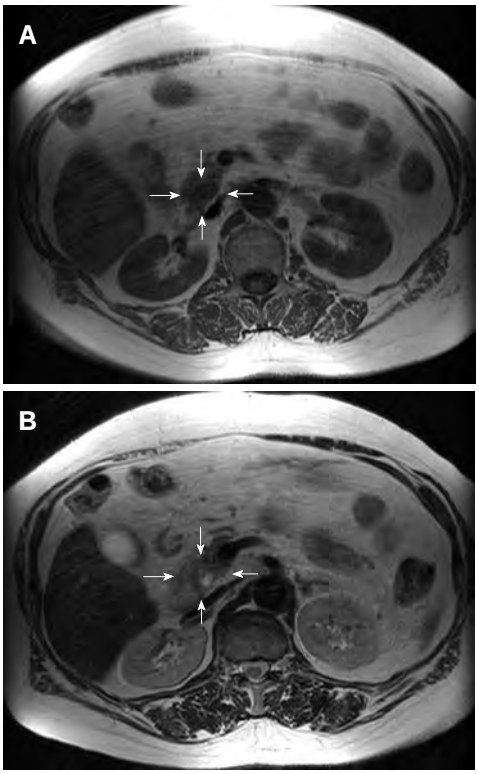

Figure 2 Magnetic resonance imaging of insulinoma of the pancreas. Insulinomas (arrows) generally demonstrate low signal intensity on T1-weighted images (A) and high signal intensity on T2-weighted images (B).

INVASIVE DIAGNOSTIC MODALITIES

The diagnostic procedure in cases of suspected insulinoma is based on standard endocrine examinations, especially the prolonged fasting test. Non-invasive imaging procedures are used to localize the source of pathological insulin secretion after a diagnosis of insulinoma has been established[20]. Invasive modalities, such as EUS and ASVS, have been shown to be highly accurate in the preoperative localization of insulinomas, and have frequently been shown to be superior to non-invasive localization techniques.

EUS is currently the test of choice in most Western centers, with reported detection rates of 86.6%-92.3%[10,46]. The appearance of insulinomas on EUS is quite characteristic, with most tumors homogeneously hypoechoic, rounded in shape, and with distinct margins (Figure 3).

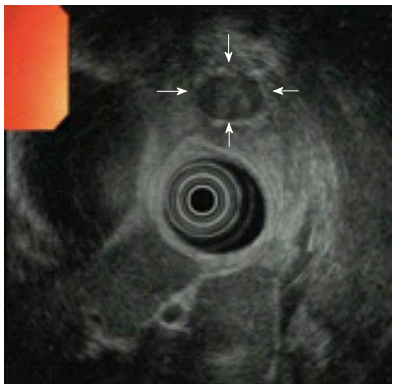

Figure 3 Endoscopic ultrasound features of insulinoma of the pancreas. The appearance of insulinomas (arrows) on endoscopic ultrasonography is quite characteristic, with most tumors homogeneously hypoechoic, rounded in shape, and with distinct margins.

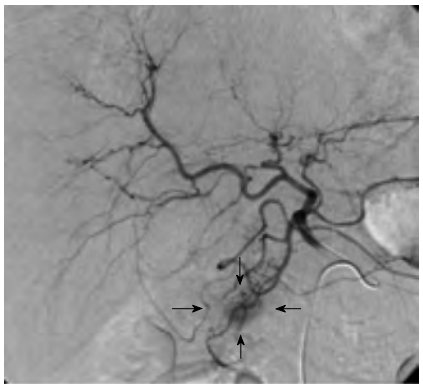

Figure 4 Angiography and arterial stimulation venous sampling. Using arterial stimulation venous sampling, insulinomas (arrows) are seen as well-defined, round or oval vascular blushes that are of increased vascularity compared with the surrounding normal pancreatic parenchyma.

Although EUS is a highly reliable procedure for the preoperative localization of insulinomas, there are several problems associated with the detection of these tumors using EUS. First, EUS may yield both false-positive and false-negative results, with the quality of the EUS findings largely dependent on the examiner's experience[22]. Second, some insulinomas are missed by preoperative EUS because they are completely isoechoic. A low body mass index, female gender, and young age may be risk factors for negative imaging[20]. Third, the sensitivity of EUS for insulinomas depends on the location and size of the tumor; sensitivity is greatest for tumors in the head of the pancreas and lowest for those in the tail of the pancreas or those that are extrapancreatic[10]. Once the site of the tumor has been determined, fine-needle aspiration (FNA) of the pancreas allows for a preoperative diagnosis of insulinoma. Advances in EUS have made EUS-guided FNA particularly useful in the diagnosis of insulinomas, because most functioning tumors are small. EUS-guided FNA is becoming increasingly popular, and it seems likely that it will eventually become the standard for the diagnosis and staging of pancreatic tumors[9].

There can be little doubt that angiography combined with ASVS should not precede non-invasive investigations, such as CT and MRI, but it remains a highly sensitive technique for the precise localization of insulinomas and will usually provide more information than EUS[27]. Morphological imaging modalities do not reflect hormonal function; however, the addition of ASVS helps regionalize a tumor by verifying hormonal function[24]. The use of ASVS allows for a more accurate surgical approach and can minimize the likelihood of re-operation[24]. For atypical insulinomas, preoperative localization of insulinomas by ASVS is particularly important. The accuracy of ASVS in localizing insulinomas has been reported to range from 94% to 100%[23,28]. Using ASVS, insulinomas are seen as well-defined, round or oval vascular blushes that are of increased vascularity compared with the surrounding normal pancreatic parenchyma (Figure 4). Insulinomas are visualized during the early arterial phase and persist for a variable length of time into the venous phase of the run. The localization of an insulinoma by ASVS relies on the fact that a hyperosmolar concentration of calcium in the vessels supplying the tumor will cause degranulation of cells within the neoplasm, releasing insulin into the portal venous system, which results in a detectable rise in insulin in venous samples obtained from the hepatic vein[27]. The splenic, gastroduodenal, superior mesenteric, and proper hepatic arteries are the vessels most commonly studied during ASVS; an increase in insulin concentrations in the hepatic vein will localize the insulinoma to the body/tail of the pancreas, an anterosuperior site of the pancreatic head, and postero-inferior site of the pancreatic head, respectively. An increase in insulin concentrations after injection of calcium into the proper hepatic artery suggests that hepatic metastases may be present. Changes in serum insulin levels plotted as a function of time after calcium injection indicate that insulin concentrations are markedly elevated only in the feeding arteries of the insulinoma (Figure 5).

The range of imaging modalities now available means that blind resection for insulinoma can be avoided because of accurate preoperative and intraoperative localization of the tumor[53]. Manual palpation of the pancreas by an experienced surgeon and ultrasonography are both sensitive methods for the intraoperative detection of the site of insulinomas[29-31]. The sensitivity of these two methods is clinically acceptable and has been reported as 75%-95% and 80%-100%, respectively[29,32,54].

MEDICAL MANAGEMENT OF BENIGN INSULINOMAS

Most patients with benign insulinomas can be cured with surgery, although other techniques for the management of insulinomas, including injection of octreotide, EUS-guided alcohol ablation, radiofrequency ablation (RFA), or embolization of an insulinoma of the pancreas, have been described[55-61].

After identification of an insulinoma, surgery is indicated for all localized tumors. The choice of procedure will depend on the features of the tumor mass, such as

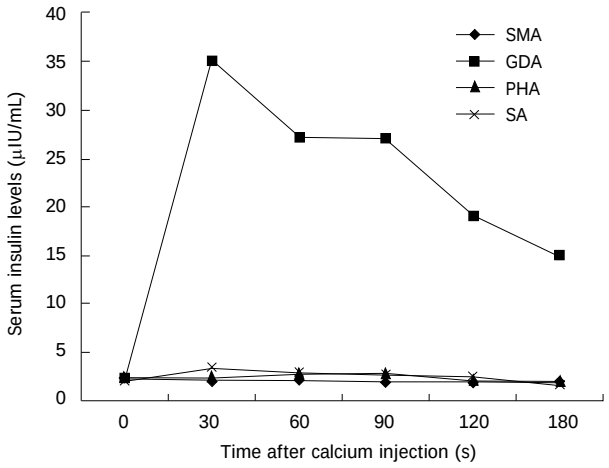

Figure 5 Changes in serum insulin levels. Changes in serum insulin levels plotted as a function of time after calcium injection indicate that insulin concentrations are markedly elevated only in the feeding arteries of the insulinoma. SMA: Superior mesenteric artery; GDA: Gastroduodenal artery; PHA: Proper hepatic artery; SA: Splenic artery.

type, size, and localization. Atypical resection, including enucleation, partial pancreatectomy, or middle pancreatectomy, has the advantage of preserving the pancreatic parenchyma as much as possible, thereby reducing the risk of late exocrine/endocrine insufficiency[62]. To date, laparoscopic resection has often been performed for insulinomas that are benign, small, and/or located in the body or tail of the pancreas[63]. Radical resection should be considered for patients in whom the lesion is not single, not well-capsulated, > 4 cm in diameter, and involves or is near the main pancreatic duct. Lymphadenectomy is not usually performed. Although the cure rate after resection for insulinoma is very high, it is necessary to be aware of the potential for postoperative complications after pancreatic surgery, especially postoperative pancreatic fistula[64-66].

However, there is a considerable risk of morbidity and mortality associated with the surgical management of insulinomas, which precludes surgery in high-risk patients. Alcohol ablation and RFA have been established as minimally invasive procedures in the treatment of primary liver tumors and hepatic metastases. Recently, successful EUS-guided alcohol ablation and CT-guided RFA of pancreatic insulinomas have been reported in humans[56,57]. These two patients were in poor general condition and were experiencing recurrent symptomatic episodes of hypoglycemia. Because it was considered that surgical management for benign insulinoma of the pancreas was impossible in both cases, ablation of the solitary mass was performed. Both patients were discharged without any complications and reported no further hypoglycemic episodes. Embolization of an insulinoma of the pancreas is another non-surgical alternative[55,67,68]. Because angiographically the insulinoma is demonstrated in the arterial phase as a hypervasculated mass, embolization could be performed using flow to direct particles exclusively into the tumor. Although it remains contentious as to whether these procedures are a viable treatment for patients with an insulinoma, they may be offered as an alternative for certain patients, such as those who refuse surgery, those who are of advanced age, those with a poor general condition, those who have already undergone multiple abdominal surgeries, or those with an increased risk of postoperative complications due to other reasons.

Insulinomas are rare endocrine tumors, most of which can be cured by surgery. Medical treatment to normalize blood glucose is useful during the preoperative period, as well as for patients who cannot be cured by surgery, such as those with diffuse β-cell disease, multiple insulinomas, unresectable malignant insulinoma, those in whom surgery is contraindicated, or patients who refuse surgery[59]. Octreotide is a somatostatin analog that inhibits insulin secretion and the peripheral action of many gastrointestinal hormones, primarily *via* activation of somatostatin sst_2 receptors. Octreotide has been used for the treatment of insulinoma, with successful control of blood glucose levels[60,61]. In addition, ocreotide may have an antiproliferative effect, as well as a moderate antitumoral action, on pancreatic endocrine tumors[69]. Therapy may be initiated with short-acting ocreotide two to four times daily, or 20-30 mg long-acting ocreotide every 4 wk[70]. Initiation of therapy with short-acting ocreotide can be used to assess systemic tolerability, particularly any gastrointestinal side-effects[71]. Thus, pharmacotherapy with somatostatin to control hypoglycemia represents a feasible option for the non-surgical management of insulinomas.

MEDICAL MANAGEMENT OF MALIGNANT INSULINOMAS

To be considered malignant, insulinomas must show evidence of local invasion into the surrounding soft tissue or there must be verification of lymph node or liver metastasis[72]. The reported incidence of malignant insulinomas ranges between 7% and 10%[72-74], and the 10-year survival has been reported to be 29%[2]. The major sites of metastasis or recurrence are the liver and regional lymph nodes. Aggressive surgical resection is recommended because these tumors are much less virulent than their malignant ductal exocrine counterparts, in which there are severe hormonal symptoms that cannot be controlled by medical treatment. RFA can be used to reduce the tumor mass in the liver, thereby reducing hormonal symptoms[58,75]. Selective embolization alone or in combination with intra-arterial chemotherapy is an established procedure to reduce both hormonal symptoms and liver metastases. Although experience is limited, liver transplantation for multiple liver metastases of malignant insulinomas may be considered in patients with no extrahepatic metastases[76,77]. Aggressive sequential multimodal therapy (chemoembolization, RFA, liver resection, liver transplantation) can prolong the survival of patients with sporadic malignant insulinoma, even in the presence of liver metastases.

Malignant insulinomas remain extremely rare tumors. In many patients with malignant insulinomas, the tumors are unresectable and medical treatment therapy is limited

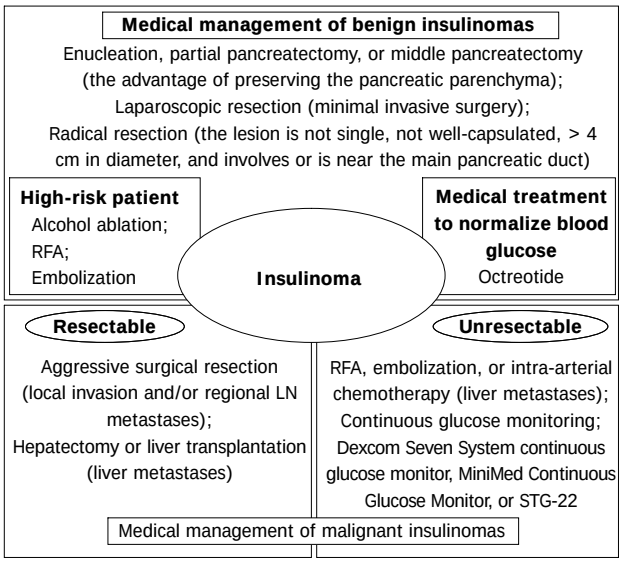

Figure 6 In patients who have unresectable or uncontrollable malignant insulinomas of the pancreas, several strategies need to be considered to both control hypoglycemic episodes and improve quality of life, including administration of ocreotide and continuous glucose monitoring. RFA: Radiofrequency ablation; LN: Lymph node.

in its ability to prevent hypoglycemic episodes[78,79]. Continuous glucose monitoring in patients with insulinomas can detect hypoglycemia, monitor responses to medical therapy, and confirm a cure postoperatively. In the literature, continuous glucose monitoring has been reported using a Dexcom Seven System continuous glucose monitor (Dexcom, San Diego, CA, United States) or the MiniMed Continuous Glucose Monitor (CGM Medtronic MiniMed, Northridge, CA, United States)[78,79]. These studies reported that continuous glucose monitoring is a useful addition to the armamentarium for the prevention of hypoglycemia. These techniques are considered an effective adjunct to therapy to reduce hypoglycemic episodes by alerting patients to low glucose concentrations before they develop neuroglycopenic symptoms; however, patients should respond promptly to oral glucose intake after hypoglycemia has been detected by these machines. In patients with a poorer general condition, malignant insulinomas that are unresectable, and uncontrolled hypoglycemia, it is proposed that blood glucose concentrations are monitored using the STG-22 (Nikkiso Co., Tokyo, Japan). The STG-22 is a reliable and accurate device for the measurement of blood glucose concentrations compared with the ABL 800FLEX machine (Radiometer Medical ApS, Brønshøj, Denmark) that is recommended by the National Committee for Clinical Laboratory Standards[80,81]. The STG-22 closed-loop glycemic control system is composed of a glucose sensor for the detection and/or monitoring of glucose and pumps for infusing an appropriate amount of insulin or glucose. The insulin and glucose pumps are computer regulated based on a target blood glucose value that is defined prior to initiation of the system[82,83]. It is has been proven clinically that the STG-22 device is safe and beneficial for maintaining glycemic control without hypoglycemic episodes in surgical patients[84-86] (Figure 6).

CONCLUSION

Insulinomas are the most common neuroendocrine tumors of the pancreas and cause hypoglycemia related to endogenous hyperinsulinism. More than 90% of insulinomas are benign and usually small, well-encapsulated, solitary tumors. Surgical resection is the treatment of choice for insulinomas and offers the only chance for cure. Most insulinomas can be identified intraoperatively by an experienced surgeon. However, what should be done in an operating theater when an insulinoma cannot be identified? Based on information presented in this review, we recommended the use of various non-invasive and invasive imaging modalities when the tumor cannot be detected using conventional diagnostic procedures. Blind surgical resection of the pancreas should not be undertaken in any patient who suffers from hypoglycemic episodes due to an insulinoma. Identifying the location of the insulinoma enables the surgeon to proceed with surgery uninterrupted, minimizing time in the operating theater, reducing the likelihood for re-operation, limiting perioperative complications, and ensuring, in most cases, a successful outcome[38].

In patients with malignant insulinomas, aggressive surgical resection, including extended pancreatic resection, liver resection, and/or liver transplantation, should be attempted when possible to improve patient survival[58,75-77]. Furthermore, aggressive secondary treatments may be indicated, such as chemoembolization or RFA for liver metastases from malignant insulinomas of the pancreas to control hypoglycemia. In patients who have unresectable or uncontrollable malignant insulinomas of the pancreas, several strategies need to be considered to both control hypoglycemic episodes and improve quality of life, including administration of ocreotide and continuous glucose monitoring. Insulinomas of the pancreas remain rare and may occur simply by chance. To refine the diagnosis and management of these tumors, epidemiologic and pathologic data should continue to be collected.

Abstract

Some studies showed that in celiac patients the immunological response to vaccination is similar to that one found in general population except for vaccine against hepatitis B virus (HBV). The non-responsiveness to HBV vaccine has also been described in healthy people, nevertheless the number of non-responders has been demonstrated to be higher in celiac disease (CD) patients than in healthy controls. Several hypothesis explaining this higher rate of unresponsiveness to HBV vaccine in CD patients have been described, such as the genetic hypothesis, according with CD patients carrying the disease-specific haplotype HLA-B8, DR3, and DQ2, show a lower response to HBV vaccine both in clinical expressed CD patients and in healthy people carrying the same haplotype. On the other hand, it has been demonstrated that the gluten intake during the vaccination seems to influence the response to the same vaccine. Moreover, it has been demonstrated a possible genetic predisposition to hepatitis B vaccine non-responsiveness likely due to the presence of specific human leukocyte antigen haplotypes and specific single nucleotide polymorphism in genes of cytokine/cytokine receptors and toll like receptors, but the pathogenic mechanism responsible for this low responsiveness still remains unclear. The aim of this review is to focus on the possible pathogenic causes of unresponsiveness to HBV vaccine in CD patients and to propose an alternative vaccination schedule in order to improve the responsiveness to HBV vaccine in this at-risk patients.

Hepatitis B vaccine in celiac disease: Yesterday, today and tomorrow. *World J Gastroenterol* 2013; 19(6): 838-845 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/838.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.838

INTRODUCTION

It is estimated that more than one third of the world's population has been infected with the hepatitis B virus (HBV), causing acute and chronic liver diseases, ranging from fulminant hepatitis to cirrhosis and eventually hepatocellular carcinoma, with an incidence of 620 000 death per year[1-3].

On this regard, in order to prevent this serious health problem, since 1982 a safe and effective hepatitis B vaccine has been available. The first vaccines were plasma-derived, which contained purified hepatitis B surface antigen (HBsAg) obtained from the plasma of people with chronic HBV infection. In the following years, recombinant DNA hepatitis B vaccine has been developed, containing purified HBsAg obtained by culturing genetically engineered yeast or mammalian cells carrying the *HBsAg* gene. Currently recombinant DNA hepatitis B vaccines are predominant-

ly being used, while plasma-derived hepatitis B vaccines are still being used in several low-income countries[4].

At the beginning, the hepatitis B vaccine was considered for use in high risk individuals for acquiring HBV infection. Actually, it has become more widely used and recommendations for hepatitis B vaccination have been extended to all infants in an attempt to achieve protection against HBV infection[5]. Despite these recommendations, 8 countries in Northern Europe (Denmark, Finland, Iceland, Ireland, Netherlands, Norway, Sweden, and the United Kingdom) have yet to implement such a policy, currently adopting an "at-risk" strategy. In 2007, Zuckerman *et al*[6] recommend a reassessment in these country of their hepatitis B prevention strategies considering the difficulty in identifying all at-risk individuals and the lack of effectiveness of the vaccination on at-risk subjects in reducing the overall incidence of hepatitis B.

Italy was one of the first countries to implement an universal strategy of hepatitis B vaccination[7]. Since 1984 HBV vaccination has been recommended and offered free of charge by the National Health Service to high-risk groups-*e.g.*, family members of HBsAg carriers, healthcare workers and in 1991, vaccination became mandatory for all new born and for twelve year-old adolescents[8].

Consequent to this global strategy, a decrease in prevalence of chronic HBV infection among vaccinated children and adolescents has been documented, including people living in high risk area such as China, Hong Kong, Taiwan, the Gambia, Senegal, Alaska and Italy[9].

Usually, a single course of three doses of hepatitis B vaccine administered in a variety of schedules, such as at birth, 1 and 6 mo schedule, the 6, 10 and 14 wk doses and the 2, 4 and 6 mo schedule induces protective levels of antibody to HBsAg in nearly 95% of healthy infants and children[10].

The antibody response to hepatitis B vaccine has been found occurring in more than 90% of the healthy vaccinated subjects[11-13]. However some studies showed that serum anti-HBs levels decreases with the time following vaccination[14,15]. Several factors, such as age, body mass index and smoking at the time of vaccination, have been found to be associated with a lower rate of antibody response to hepatitis B vaccine[16,17], and the decline of HBs antibody titer seemed mainly to be proportional to the antibody titer originally obtained[18].

Long-term follow-up studies of newborn vaccination showed that antibodies become negative in 15%-50% among the vaccine responders within 5 to 10 years[19-21].

The clinical significance of the disappearance of specific antibodies in immunocompetent patients responders to previous vaccination remains object of discussion.

Successfully vaccinated people who have lost antibodies after primary vaccination, usually show a rapid anamnestic response when boosted. This means that the immunological memory for HBsAg can outlast antibody detection, providing long-term protection against the disease. Hence, there is consensus that there is no need to administer booster doses of vaccine to ensure long-term protection in immunocompetent patients[22-25].

On the other hands some authors suggest specific strategies for the vaccination of certain groups of people at high risk such as haemodialysis, celiac and thalassemia patients[26-31].

Vaccinated subjects with an anti-HBs titer less than 10 mIU/mL after completion of primary vaccine series are called "no responders".

Several factors have been associated with a non response to the HBV vaccine. These include inappropriate vaccine storage conditions, vaccination in buttocks, obesity, smoking, drug abuse, infections[32]. There are also chronic conditions, such as chronic alcoholism, chronic kidney disease, human immunodeficiency virus infection, immune-suppression, type I Diabetes Mellitus and Celiac disease that are characterized by a lower response to HBV vaccination[33-45]. Recently, it has been demonstrated a possible genetic predisposition to hepatitis B vaccine non-responsiveness likely due to the presence of specific human leukocyte antigen (HLA) haplotypes and specific single nucleotide polymorphism (SNP) in genes of cytokine/cytokine receptors and toll like receptors (TLR)[42,46], but the pathogenic mechanism responsible for this low responsiveness still remains unclear.

CELIAC DISEASE AND HBV VACCINE: THE HISTORY

Celiac disease (CD) is an autoimmune disorder characterized by a permanent intolerance to ingested gluten, which results in immunologically mediated inflammatory damage to intestinal mucosa[47]. Genetic, environmental and immunological factors seem to be responsible for the disease.

CD is usually characterized by various gastrointestinal (GI) symptoms (*e.g.*, diarrhea, malabsorption, weight loss) associated with consumption of grains containing gluten (wheat, barley, rye). Although some CD patients may have primarily GI symptoms, CD may be detected due to associated extra intestinal disorders, even without GI symptoms, or due to screening for CD based on a positive family history. CD has a strong association with HLA-DQ2 and HLA-DQ8[48]. HLA-DQ2 is present in 90% to 95% of patients with CD[49].

The link between HBV infection and celiac disease seems to be controversial. Relatively little data exist on the relationship between HBV and CD, although one third of the world's population (around 2 billion people) have been infected with HBV. It has been reported that the response rate to HBV vaccination in CD-infected individuals is lower (30%-50%) than in the general population (4%-10%)[42,43] (Table 1). Recently, it has been hypothesized that non intestinal inflammatory diseases may trigger immunologic gluten intolerance in suscepti-

ble individuals, and HBV as far as hepatitis C virus (HCV) were thought to be suitable candidates. However this assumption is still matter of debate. Relatively few data exist on the relationship between HBV and CD. It could be speculated that HBV as well as HCV infections may trigger immunologic gluten intolerance in genetically susceptible people and that chronic HBV segregates a higher percentage of CD patients[50,51]. However this assumption is still a matter of debate.

Possible activation of CD due to the treatment of hepatitis infection is another controversial point. There have been some reports indicating that autoimmune disorders such as insulin-dependent diabetes mellitus and celiac disease can develop during treatment with interferon (IFN)-α for viral hepatitis because of its immune modulatory properties[52,53]. CD activation during interferon α or interferon α plus ribavirin therapy has recently been observed in HCV-positive patients[54], confirming that IFN-α therapy could trigger CD in susceptible subjects during treatment. In the study of Leonardi *et al*[30], although evidence suggested that IFN-α can activate CD4T cells in the lamina propria and cause intestinal tissue damage[55], no patient treated in childhood showed any serological marker of CD at the time of the present study. Due to the small sample size authors could not claim that there was no association between CD and HBV, although a sample size more representative of the prevalence of CD in Italy should help to better examine the relationship between CD and HBV.

Some studies showed that in celiac patients the immunological response to vaccination is similar to that one found in general population except for vaccine against HBV[42,56]. On this regard, it is well known that unresponsiveness to hepatitis B vaccine in healthy people has been attributed to failure of class II major histocompatibility complex molecules in the interaction with processed protein antigen, in the stimulation of T-helper cells, or in both[57,58].

Analysis of previous studies suggested a very high incidence of a particular extended HLA haplotype in no responders to hepatitis B vaccine. In fact, homozygotes for HLA-B8, DR3, and DQ2 were found to have a significantly higher incidence of hepatitis B vaccine non-response[58]. In 1989, Alper *et al*[59] prospectively vaccinated 5 homozygotes and 9 heterozygotes for extended MHC aplotype (HLA-B8, SC01, DR3). Four of the 5 homozygotes produced low levels of HBsAb two months after their third HBV vaccination, whereas all 9 heterozygotes had significantly higher titers of HBsAb. In 1995, Livenson *et al*[60] studied 153 patients with end-stage renal disease immunized with a recombinant HBV vaccine. Homozygotes for HLA-A1, HLA-B8, HLA-DR3 and HLA-DQ2 were found almost exclusively in the non-responder group and a significant higher number of heterozygotes for these alleles was found in the non-responder group compared to the responders[59]. In the same year, Martinetti *et al*[61] performed an HLA study in 9 absolute non-responder (serum titer of anti-HBsAg < 2 mIU/mL) and 8 low-responder (serum antibody level between 2 and 9.9 mIU/mL) infants who underwent, in neonatal period, HBV vaccination. The investigation pointed out that many of these subjects carry HLA haplotypes classically involved in autoimmune diseases: HLA DR7, DQ2, DR4, DQ8 and DR3. Further Godkin *et al*[58] investigated the binding affinities of envelope and core peptides of HBV to particular HLA glycoproteins, and their data supported the direct involvement of HLA-DR3 in HBV vaccine no responsiveness.

Table 1 People who have anti-HBs titre after completion of primary vaccine series less than 10 mIU/mL

	Celiac patients (no responders, %)	Control subjects (no responders, %)
Leonardi *et al*[30]	30/60 (50)	7/60 (11.7)
Ahishali *et al*[42]	8/25 (32)	0/20 (0)
Zingone *et al*[43]	31/51 (60.7)	13/48 (27.08)
Ertekin *et al*[44]	20/52 (38.5)	2/20 (10)
Noh *et al*[56]	13/19 (68.4)	-

Since the HLA-DQ2 haplotype is over-represented in celiac population, it has been postulated that this genetic profile may play a crucial role in predisposing celiac patients to a lower grade of immunization to hepatitis B vaccine[62].

On the other hand some studies argue that in celiac individuals gluten intake at the time of vaccination may influence the vaccine-induced immune response[41,44].

Nevertheless all these hypotheses are still argument of debate and no responsiveness of celiac patients to the HBV vaccine remains a significant public health problem, since the worldwide spread of the disease although there is no convincing evidence that patients with viral hepatitis B carry an increased risk of celiac disease[63].

In 2003, Noh *et al*[62] studied 19 celiac patients and found that 13 did not respond to vaccination. HLA typing was performed on 15 of these subjects (13 no responders and two responders). All tested subjects were apparently either homozygous or heterozygous for DQ2. The authors postulated that the non responsiveness to the hepatitis vaccine in celiac patients is due to the suppression of the Th2 response and to the B cell differentiation due to the high protection performed by the IFN-gamma.

In 2009, Leonardi *et al*[30] retrospectively analysed the response to HBV vaccine in 60 celiac patients and they found that 30 of 60 CD patients (50%) and 7 of 60 control subjects (11.6%) were non-responders to HBV vaccination ($P < 0.0001$).

It is well known that in celiac disease the intestinal damage is caused by interaction between specific deaminated glutamine residues of gliadin and HLA-DQ2 or DQ8 molecules[63].

Both HBsAg protein fragments and gliadin peptides bind to HLA-DQ2 molecules, and their competition

may result in a defective antibody response against the recombinant HBsAg vaccine in active CD[49].

In 2008, Nemes *et al*[41] studied 128 children and adolescent with celiac disease and 113 age-matched control subjects. For all celiac patients diet compliance and CD activity were monitored by measurement of antibodies against transglutaminase and endomysium. The authors demonstrated that the rate of primary non-response to the standard regimen of recombinant HBV vaccination was surprisingly high (74.1%) in undiagnosed and untreated celiac adolescents.

In 2010, Ertem *et al*[64] evaluated anti-HBs titer in celiac patients and healthy children. They found that anti-HBs negativity was significantly higher in celiac patients than in healthy controls. They also demonstrated that response to HBV vaccine in children with CD who were compliant with the gluten free diet (GFD) was not different from that found in the healthy population.

In 2010, even Zingone *et al*[44] hypothesized the possible role of dietary gluten in induction of a suboptimal immune response in celiac patients. They studied 51 celiac patients who were on a GFD and were negative for anti-transglutaminase-IgA antibody at the time of testing. Eleven years after primary vaccination the proportion of vaccinated subjects with anti-HBs antibody $\geqslant$ 10 mIU/mL was significantly lower in celiac than in controls (68.6% *vs* 91.7%; $P < 0.01$). Only three (5.9%) celiac patients were on GFD at the time of primary vaccination. Fourteen out of 16 (87.5%) celiac patients and all controls with anti-HBs < 10 mIU/mL received a booster dose of vaccine. Two weeks after the booster dose, 4 (28.6%) celiac patients and 3 (75%) controls showed an anamnestic response. Three out of 10 celiac patients who did not respond to the booster dose agreed to complete a new vaccine cycle. One month after vaccination completion, all showed anti HBs between 10 and 100 mIU/mL. Thus, the authors concluded that the gluten intake at the time of vaccination could decrease the efficacy of the same vaccination.

To confirm the role of gluten in the unresponsiveness to HBV vaccine in celiac patients, Ertekin *et al*[45] observed 52 children with CD and 20 age healthy children who received HBV vaccination according to the standard immunization schedule. They found that anti-HBs positivity was significantly higher in celiac patients who were compliant to GFD than in those who were noncompliant.

Even in the study leaded by Leonardi *et al*[30], the authors found a significantly higher number of responders in patients younger than 18 mo at diagnosis and a significantly lower number of responders in adolescent patients older than 14 years at diagnosis. This data confirms that in celiac patients a complete cycle of revaccination during a well controlled GFD might be more effective than the primary vaccination performed on a gluten-containing diet.

FUTURE DIRECTION

We have underlined how celiac disease is characterized by a low responsiveness to vaccinations such as HBV vaccine, and both for the widespread of celiac disease, that is high in prevalence of morbidity, and for the wild range of not response to HBV vaccine. The problem of unresponsiveness could represent a matter of world health, because the group of non-responders patients could be considered as a large reservoir of HBV-susceptible people that will persist as healthy carriers, leading to a diffusion of the diseases even in healthy subjects.

This problem drew the literature research towards possible reassessments of immunization strategies to protect this population and to achieve the goal of universal protection.

It would be important, therefore, to assess the possible vaccination strategy in order to reduce this "healthy-reservoir" of infection. On this regard, new vaccination strategies for celiac patients were proposed in literature: the first one the use of booster doses of HBV vaccine by intramuscular route (IM), the second one is the performance of booster doses of HBV vaccine by intradermal route (ID).

In their scientific paper, Zingone *et al*[44] gave an IM dose of HBV vaccine to celiac patients with anti HBs titre < 10 mIU/mL and found that, one month after vaccination completion, all showed anti-HBs titer between 10 and 100 mIU/mL. They concluded that celiac patients may require higher doses of vaccine and/or more injection to achieve full protection. Supporting this hypothesis, in 2008, Ashaili *et al*[43] studied 25 celiac patients and control subjects who were negative for anti-HBs. HBV vaccine was administered to all celiac patients and control subjects in three doses, at month 0, 1, 6 by intramuscular injection into the deltoid muscle. Four weeks after the last dose, anti-HBs was measured quantitatively. Seventeen celiac patients (68%) and all control subjects (100%) were found to respond to HBV vaccination[44].

On the other hands, supporting the hypothesis of a possible role of gluten in the unresponsiveness to HBV vaccine in celiac patients and in severe liver disease[40], Nemes *et al*[41] recommended a revaccination by IM route for celiac patients after treatment with gluten-free diet. They administered a dose of IM vaccine to anti-HBs-negative patients with CD during a controlled gluten-free diet and found that 97.3% of them seroconverted after revaccination. They concluded that the no responder status to primary HBV vaccination is not permanent in CD and may improve after gluten exclusion.

The second strategy addresses on the use of ID booster of HBV vaccine in non-responders patients. The rational of this is that in contrast to IM, which relies on a T-cell mediated response, vaccines introduced directly into the skin activate a dendritic-cell-mediated immune response through a lower doses of antigen[65].

According to these results, in 2010, Leonardi *et al*[66]

revaccinated celiac patients who were non-responders to HBV vaccination with a 2 mg dose of recombinant hepatitis B vaccine administered intradermally. After the first ID dose we found that 40% of patients achieved anti-HBs titer ⩾ 1000 mIU/mL, 20% between 100 and 1000 mIU/mL, and 15% between 10 and 99 mIU/mL.

In order to compare the efficacy and the safety of the two HBV vaccination strategy (IM *vs* ID) in a non-responder population, in 2011, Leonardi *et al*[67] re-vaccinated non-responder celiac patients with ID or IM vaccine. The Authors found a higher percentage of "responders" after the first booster dose (ID = 76.7% *vs* IM = 78.6%) and a deeper increase after the third dose (ID = 90% *vs* IM = 96.4%) of vaccine in both groups. These data seem to suggest that both ID and IM route are effective options to administer a booster dose of HBV vaccine in celiac patients. However the ID route seems to be a better vaccination strategy, as demonstrated by the higher percentage of patients with an anti-HBs title > 1000 IU/L found in ID than in IM group.

In literature there are no other studies comparing the efficacy of HBV vaccination administered by IM or ID route in celiac patients. The two different methods are extensively compared in other pathologic conditions in which we observed a low responsiveness to HBV vaccination. For example in a meta-analysis about the HBV vaccination response in patients with chronic kidney disease, the authors found that pooling of study results demonstrated a decreased risk of failure to respond to HBV vaccine among patients who were vaccinated by intradermal *vs* intramuscular route[27].

There is another topic that should be considered. Actually it is still not clear if non-responder patients are characterized by an immunological anergy since birth, or they lose their immune competence during the time. With this regard, there is general consensus in literature that successfully vaccinated people who have lost antibodies years after primary vaccination usually show a rapid anamnestic response when boosted[68]. This means that the immunological memory for HBsAg can outlast antibody detection, providing long-term protection against the disease and the development of the carrier state. Hence, there should be no need to administer booster doses of vaccine to ensure long-term protection in subjects initially responding to vaccination[22-25]. Thus, it is still not clear if celiac non-responders show an immunity anergy since birth and do not respond since the first dose of vaccination or they loose their antibody protection with the flow of time, as physiologically happens in normal people, even if in a shorter period of time, remaining, thus, protected by an intra-cellular immunity.

For this reason it would be important an early identification of potential "pure" non-responsive patients through the identification of specific markers of unresponsiveness. Recent acquisitions show a possible role of toll-like receptors, cytokines and cytokine receptors polymorphisms associated with no response to hepatitis B vaccine in healthy population. As a matter of fact, Chen *et al*[46] hypothesized that the variations in these structures may act individually or cooperatively in the influence of the duration and intensity of immune response elicited by the hepatitis B vaccine, finding that 4 specific SNPs in the *IL-4*, *IL-4RA*, *IL-13* and *TLR2* genes were closely associated with the serum anti HBsAg response to HBV vaccine. These cytokines and TLR2 seemed to be associated with a status of hepatitis B vaccine-induced protective humoral immune response. If an early identification of responsiveness to HBV vaccine could be speculated in general population by the analysis of specific SNPs, it could be postulated the use of the same analysis in celiac patients, in whom the rate of non-responsiveness is higher, representing a specific marker of the "pure" non-responders. Nevertheless, further studies should clarify the role of these polymorphisms and their possible use as markers of un-responsiveness to HBV vaccine.

In conclusion, we suggest that all patients with CD should be revaccinated to achieve the goal of universal protection. In consideration of the possible relationship between anti-HBs titers and compliance with GFD, they should be revaccinated after the decrease of specific celiac antibodies, that usually occurs after about 1 year of a strict GFD. We also suggest the use of the intradermal route for the revaccination of these patients. The increase of anti-HBs antibodies is in fact satisfactory after ID injection in all patients, a lower dose of the vaccine can be used for immunization and the cellular immune responsiveness to HBsAg can be easily assessed by the development of a skin reaction at the injection site[31]. Thanks to the appearance of this reaction there is no need to test the serum anti-HBs concentration after the booster dose to value the vaccine efficacy, and this could represent a less expensive strategy for the Health Organization to perform HBV booster doses[69]. A recent retrospective cost-benefit analysis of ID hepatitis B vaccination reported a cost reduction exceeding 50% compared with a standard IM vaccine regimen[63]. Moreover the ID route would allow a lower performance of venous withdraws in all patients, reducing the costs linked to serial follow-up withdraws. In literature it is also demonstrated that strong immunological memory persists more than 10 years after immunisation of infants and adolescents with a primary course of vaccination[70]. Furthermore, we suggest to administer a booster dose of vaccine every 10 years to all celiac patients, independently their status of "pure" unresponsiveness, and as they are genetically predisposed to loose their anticorpal memory, these boosters would favour a better immunologic strategy in order to protect celiac non-responders from a possible HBV infection.

Abstract

AIM: To investigate the effects of chronic obstruction on enteric reflexes evoked by electrical stimulation (EFS) or intraluminal distension of the rat hypertrophic ileum.

METHODS: Motor responses to EFS and to intraluminal distension were studied in the absence and in the presence of various inhibitors of enteric mediators. Ileum segments from operated (chronic ileal obstruction), sham-operated (control) and normal rats were horizontally mounted, connected to a pressure transducer and intraluminally perfused. The effects of selective serotonin receptor (5-HTR) blockers were investigated on distension-induced responses. The cellular localization of 5-HT3Rs was also examined in control and hypertrophic tissues through confocal microscopy.

RESULTS: In non-obstructed segments, EFS elicited tetrodotoxin (TTX)-sensitive responses with high amplitude contraction followed by weak relaxation. In hypertrophic tissues, EFS lowered the baseline pressure and evoked TTX-sensitive contractions significantly larger than normal ($P < 0.01$) or control ($P < 0.05$), and devoid of any relaxation phase ($P < 0.01$ *vs* normal). Incubation with atropine and guanethidine [non-adrenergic non-cholinergic (NANC) conditions] did not modify intestinal tone in normal and control preparations, but reversed the accommodation produced by EFS in hypertrophic tissues, and depressed the amplitude of contractions in all types of tissues. L-NAME and α-chymotrypsin blocked residual NANC motility in all tissues and augmented intraluminal pressure in hypertrophic segments ($P < 0.05$ *vs* NANC conditions). Intraluminal distension of the intestinal wall evoked non-propulsive cycles of contractions and relaxations in non-obstructed tissues. In all hypertrophic segments, strong propulsive strokes, markedly wider ($P < 0.001$), and larger than normal ($P < 0.001$) or control ($P < 0.05$) were elicited. Both motor patterns were blocked under NANC conditions and with simultaneous incubation with L-NAME and α-chymotrypsin. In all types of tissues, incubation with ketanserin or GR125487 did not modify distension-induced motility. In contrast, blockade of 5-HT3Rs by ondansetron concentration-dependently inhibited motor responses in normal and control tissues, but only slightly impaired enteric reflexes in the hypertrophic preparations. Finally, confocal microscopy did not reveal a different cellular distribution of 5-HT3Rs in control and hypertrophic ileum.

CONCLUSION: Accommodation and distension-induced peristalsis of rat hypertrophic ileum are controlled by cholinergic and peptidergic transmission and are negligibly affected by 5-HT3Rs, which modulate distension-induced motility in non-obstructed tissues.

Accommodation and peristalsis are functional responses to obstruction in rat hypertrophic ileum. *World J Gastroenterol* 2013; 19(6): 846-854 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/846.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.846

INTRODUCTION

Small bowel obstruction is a common clinical problem resulting from a variety of causes: intraluminal (food bolus, gallstones), intramural (neoplasms, strictures) or extramural (adhesions, hernias) factors. It can be partial or complete and, if not properly diagnosed and treated, it may rapidly lead to death[1]. Experimentally, striking morphological and neurochemical changes, affecting all the layers of the gut wall, have been reported to occur orally to the site of a mechanical long-standing partial obstruction. Massive thickening of the muscle coats, neuronal hypertrophy, neoangiogenesis and neoformation of collagen[2], a loss of interstitial cells of Cajal[3,4] and an altered expression of enteric neuropeptides[3,5] are the most prominent alterations detected in the obstructed intestine. Functionally, along with pronounced changes in biomechanical and motility patterns, detected both *in vitro*[6,7] and *in vivo*[8], preservation of the peristaltic reflex in the isolated guinea pig ileum has also been described[9]. Indeed, peristaltic reflex, responsible for the mixing and aboral propulsion of luminal contents *in vivo*, is the result of a highly sophisticated and localized integration between neural and myogenic components; *in vitro*, it can be initiated by local mechanical stimulation of the mucosa or by muscle stretch, as elegantly shown by Trendelenburg's pioneering work[10]. Hypertrophic growth, induced by mechanical obstruction of the rat ileum, affects the functional responses of both smooth muscle layers and of intrinsic innervation[7,11]. Therefore, the present work focused on the consequences of a partial long-standing stenosis on enteric reflexes evoked by electrical field stimulation (EFS) or by intraluminal distension of rat isolated terminal ileum. To this end, the changes in intraluminal pressure elicited by neurogenic stimulation of rat obstructed intestine were investigated in the absence and in the presence of different inhibitors of enteric neurotransmitters which control gut motility, and compared with those triggered in preparations obtained from normal or sham-operated (control) rats. Secondly, given the pivotal role played by endogenous serotonin (5-HT) in the initiation and propagation of enteric reflexes, such as the peristaltic reflex[12,13], special attention was directed at evaluation of its role in specific distension-induced motor patterns exhibited by non-hypertrophic and hypertrophic tissues by investigating the effects of different selective 5-HT receptor (5-HTR) antagonists. The cellular localization of 5-HT_3R was also investigated through confocal microscopy.

MATERIALS AND METHODS

Surgical procedure

Adult female Wistar rats (180-200 g), bred from a local colony, were housed in single cages with a 12 h/12 h light/dark cycle and received food and water *ad libitum*. The rats were randomly assigned to normal group (age-matched animals that did not undergo any type of surgery), a control group (age-matched sham-operated animals subjected to the same intestinal manipulation except for ileal obstruction) and an operated group (25 animals per group). Under general anesthesia (sodium pentobarbital 33 mg/kg *ip*), the rats were operated on according to Gabella's method[14], as previously described[7]. Briefly, a polyethylene ring of diameter 1-2 mm larger than that of the intestine, was applied around the ileum, proximal to the ileo-cecal junction, keeping it initially free for turning around. Postoperatively, the animals were monitored daily with regard to weight, general well-being and distension of the abdomen. Fourteen days after ileal obstruction, when previous experiments had shown that intestinal hypertrophy is fully and homogeneously developed over 10 cm aboral to the stenosis[7], the rats were killed, and functional or immunohistochemical studies were performed on ileal tissue. The experimental protocol complied with the requirements of animal care and was approved by Ministero della Salute, Italy (DL 116/92).

Functional studies

Rats were killed by CO_2 asphyxiation. Full-thickness 4-cm long segments of terminal ileum, immediately proximal to the site of occlusion excised from operated rats, and loops of the same part of the gut excised from normal or control rats, were cleared of their contents by flushing with Krebs-Henseleit solution (composition: NaCl 118.9 mmol/L, KCl 4.6 mmol/L, $CaCl_2$ 2.5 mmol/L, KH_2PO_4 1.2 mmol/L, $NaHCO_3$ 25 mmol/L, $MgSO_4$ 1.2 mmol/L, glucose 11 mmol/L). From each animal, only one preparation was obtained either immediately proximal to the point of obstruction, where hypertrophy was maximal and uniform, or from the corresponding portion of terminal ileum of normal and control rats. According to the method described by Costall *et al*[15], the segments were cannulated at the oral and anal ends, and were mounted in a Mayflower horizontal 20-mL tissue bath (Hugo Sachs Elektronik-Harvard Apparatus GmbH D-79232 March Hugstetten, Germany) filled with Krebs-Henseleit solution gassed with a mixture of 5%CO_2/95%O_2 at 37 ℃, and stretched at their initial length of 4 cm. The inlet cannula was connected *via* tubing to a reservoir filled with nutritive solution, maintained at 37 ℃ and continuously oxygenated, and to a pressure transducer (TSD104A Biopac Systems, 2Biological Instruments, Besozzo, VA, Italy) connected to a MacLab digital data acquisition system to record changes in the intraluminal pressure. The outflow tube at the aboral end had two outlets: one at the level of the bath (A) while the other (B) could be raised above the level of the tissue. A continuous flow of fresh

oxygenated solution was delivered intraluminally at a flow rate of 0.5 mL/min and extraluminally at a speed of 2 mL/min by means of the same peristaltic pump (Gilson Minipuls-3, Gilson Italia SRL, MI, Italy) to remove perfusate and extraluminal solution from the bath. The extraluminal flow was temporarily suspended during the period of incubation of drugs.

Electrical field stimulation: After a period of equilibration of 30 min, during which the fluid level in the outflow tube was equal to that in the bath (drain A open), the intraluminal pressure was augmented by closing drain A and by raising drain B 5 cm above the level of the tissue in the bath (5 cm hydrostatic resistance or low distension, corresponding to a pressure of 3.68 mmHg); 30 V square pulses of 1 ms duration were then delivered to the tissues at 3 Hz frequency through platinum wire electrodes positioned at the two opposite sides of ileum and connected to a generator that provided trains lasting 20 s at 120 s intervals. EFS-evoked changes in intraluminal pressure were registered in the absence (basal conditions) and in the presence of the muscarinic receptor antagonist atropine 1 μmol/L and sympatholytic agent guanethidine 4 μmol/L [non-adrenergic non-cholinergic (NANC) conditions]. The effects produced by the application of nitric oxide synthase (NOS) inhibitor N^G-nitro-*L*-arginine methyl ester (L-NAME) (300 μmol/L) and by the protease α-chymotrypsin (10 IU/mL) on NANC responses evoked by EFS were investigated. Drugs were added to the extraluminal solution.

Distension-induced motility: In a second series of experiments, after a period of equilibration of 30 min, drain A was closed and drain B was elevated 8 cm above the level of the tissue in the bath (8 cm hydrostatic resistance or high distension, corresponding to a pressure of 5.88 mmHg). After another 30 min, once regular motility had been evoked by the increase in the intraluminal pressure, the effects of simultaneous application of atropine 1 μmol/L and guanethidine 4 μmol/L or of single concentrations of the 5-HT_{2A}R antagonist ketanserin (1 μmol/L), the 5-HT_3R antagonist ondansetron (1-10 μmol/L) and the 5-HT_4R antagonist GR125487 (1 μmol/L) were studied over the next 30 min. Each preparation was challenged with a single application of each drug in order to minimize time-dependent variability. About 25% of non-obstructed tissues, which failed to develop a regular motility following distension, were discarded from further investigation in the experiment.

Immunohistochemistry

Tissue preparation and processing. Full-thickness 2-cm long segments of terminal ileum, excised as described above from hypertrophic and control animals, were cleared of their contents by flushing with phosphate buffered saline (PBS) 100 mmol/L at pH 7.4, opened along the mesenteric border, cleaned and pinned flat onto slabs of Sylgard 184 (Dow Corning), with the serosal side exposed. After 2 h fixation with 4% formaldehyde in 100 mmol/L PBS, whole-mount preparations containing the longitudinal muscle layer and the adherent myenteric ganglia were peeled off from the mucosa and the circular muscle under a dissection microscope using fine forceps, and were processed by the immunofluorescence method for double labeling using a free floating technique. After washing in 100 mmol/L PBS, whole mounts were incubated with a mixture of rabbit-anti-rat immunoglobulin G (IgG) primary antibody directed against 5-HT_3R 1:500 (No. 95247, a generous gift from CURE/UCLA Digestive Disease Research Center, Los Angeles, CA, United States) and mouse-anti-rat clathrin IgG 1:100 (Becton Dickinson Italia SpA) for 48 h at 4 ℃. This was followed by a 2-h incubation period at room temperature with a mixture of Alexafluor 488 donkey-anti-rabbit IgG 1:100 (Invitrogen Ltd, United Kingdom) and DyLight 549-conjugated AffiniPure donkey-anti-mouse IgG 1:200 (Jackson ImmunoResearch). Tissues were finally washed with 100 mmol/L PBS, mounted on slides and cover-slipped with ProLong Gold Antifade Reagent (Invitrogen Ltd, United Kingdom). Specificity controls were obtained by omitting primary or secondary antibodies from the incubation solution. Primary and secondary antibodies were diluted in Triton X-100 (0.5% in 100 mmol/L PBS, Sigma). Normal donkey serum (Jackson ImmunoResearch) was added to a final concentration of 10% to reduce the unspecific background staining.

Confocal microscopy specimens were analyzed with a confocal system LSM 510 Meta scan head integrated with the Axiovert 200 mol/L inverted microscope (Carl Zeiss, Jena, Germany). Specimens were observed through a 63 × 1.4 NA oil objective. Alexafluor and DyLight were excited with 488 nm argon and 543 nm He-Ne laser lines, respectively. Image acquisition was carried out in a multitrack mode, with the relevant beamsplitters; barrier filters were 505-530 band pass and 585 long pass for the above signals, respectively. A series of x-y sections was acquired with a z-step of 0.5 μm, to cover the whole height of the samples.

Presentation of results

Data were expressed as mean ± SE of 5 distinct experiments. The following parameters were measured: changes in intestinal tone (baseline intraluminal pressure), index of accommodation capacity; amplitude (area under the pressure-time curve or area under curve for each wave of contraction/relaxation), height and frequency of electrically- or distension-induced contractions/relaxations over a 15 min period immediately prior to and after 15 min incubation with each drug tested. When peristalsis, identifiable by propagating and propulsive waves of contraction (visually confirmed as rings of contraction within 1 cm from the oral end of the loop moving towards the distal end), was induced by distension, a preparatory and an emptying phase could be detected. During the preparatory phase, the intraluminal pressure increased slowly until the threshold pressure was reached and the emptying phase, marked by an abrupt increase in the intraluminal

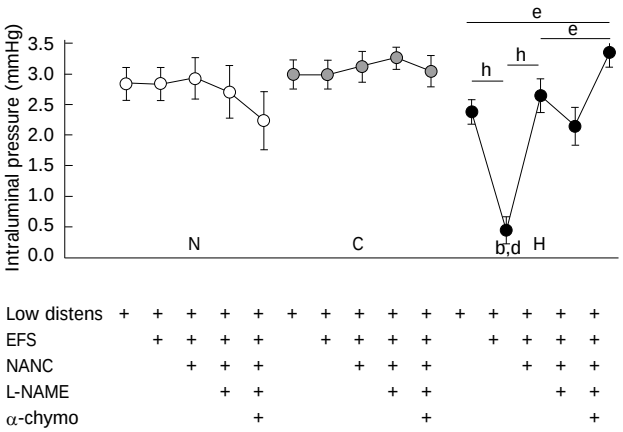

Figure 1 Basal intestinal tone. Changes in basal intestinal tone of normal (N), control (C) and hypertrophic (H) ileal segments, expressed as values of intraluminal pressure (mmHg), exposed to different subsequent conditions: hydrostatic pressure of 5 cm H_2O (Low distens), electrical field stimulation (EFS), NANC conditions (NANC), incubation with N^G-nitro-*L*-arginine methyl ester (L-NAME) 300 μmol/L (L-NAME), incubation with α-chymotrypsin 10 IU/mL (α-chymo). Each value is the mean ± SE of 5 distinct experiments per group. $^bP < 0.001$ *vs* corresponding normal values; $^dP < 0.001$ *vs* corresponding control values; $^eP < 0.05$; $^hP < 0.001$; analysis of variance test followed by Bonferroni's post-test.

pressure, was triggered (peristaltic stroke). The average compliance of the intestinal wall during the preparatory phase (volume infused in the preparatory phase/change in pressure in the preparatory phase) and the average power generated by the intestine during the peristaltic stroke (average pressure in emptying phase × volume expelled/duration of emptying phase) were measured according to Waterman *et al*[16] for 5-8 complete waves of contraction immediately prior to and after 15 min incubation with the drug. In order to calculate the average power, the volume of fluid expelled from the aboral end of the intestine by each peristaltic wave was measured with a measuring cylinder.

Statistical analysis

Data acquisition and analysis were carried out using MacLab digital data acquisition system and applying PowerLab Chart v4.1.1 software (PowerLab/4SP ADI Instruments, Ugo Basile, Comerio, VA, Italy). Statistical analysis was performed by two-way analysis of variance test followed by Bonferroni's post-test unless otherwise indicated. A P value < 0.05 was considered significant, a P value < 0.01 highly significant and a P value < 0.001 extremely significant.

Drugs

The following drugs were used: tetrodotoxin citrate (TTX), atropine sulfate, guanethidine sulfate, L-NAME, α-chymotrypsin, ketanserin tartrate, ondansetron hydrochloride dihydrate, purchased from Sigma Aldrich (St Louis, MO, United States), and GR125487 sulfamate, bought from Tocris Bioscience (Bristol, United Kingdom). All other reagents were of the highest grade commercially available. The stock solutions were prepared by dissolving all drugs in distilled water. The working solutions were prepared fresh on the day of the experiment by diluting the stock solutions with distilled water or nutritive solution. The volume of the drugs added to the organ bath was 1% of the final volume of the bath solution.

RESULTS

Motor responses to electrical field stimulation

During the equilibration period, normal, control and hypertrophic tissues exhibited no or only sporadic spontaneous motility. The raising of the outflow block to 5 cm above the level of the tissue in the bath increased the intraluminal pressure by about 2.5-3.0 mmHg in all the tissues tested (Figure 1), but it did not evoke any wave of contraction or relaxation. In normal and sham-operated segments, EFS did not further modify the intestinal tone but elicited biphasic TTX-sensitive responses comprising a transient high amplitude contraction followed by a weak relaxation (Figure 2A, B and D). In hypertrophic tissues, EFS lowered the intraluminal pressure almost to the same level as in the equilibration phase ($P < 0.001$ *vs* low distension), in contrast to that observed in normal and control tissues ($P < 0.001$) (Figure 1). EFS also evoked TTX-sensitive phasic contractions of significantly larger amplitude in hypertrophic tissue (95.5 ± 17.1 mmHg.s) compared with that in normal tissue (40.3 ± 8.9 mmHg.s, $P < 0.01$) or control tissue (56.0 ± 8.7 mmHg.s, $P < 0.05$), and which were devoid of any relaxation phase ($P < 0.01$ *vs* normal, Figure 2C and D). Incubation with atropine 1 mmol/L and guanethidine 4 mmol/L (NANC conditions) did not modify the intestinal tone in normal and sham-operated preparations but reversed the accommodation produced by EFS in hypertrophic tissues, with intraluminal pressure slowly increasing to the same level reached after raising the outflow block (Figures 1 and 2A-C). Furthermore, the amplitude of contractions in all types of tissues was markedly depressed (Figure 2D). Subsequent exposure to the NOS inhibitor L-NAME 300 mmol/L moderately, although not significantly, increased the contractile responses compared with NANC conditions, while simultaneous incubation with the protease α-chymotrypsin 10 IU/mL blocked the residual NANC motor activity in all the tissues (Figure 2D) and significantly augmented intraluminal pressure in hypertrophic segments ($P < 0.05$ *vs* low distension and *vs* NANC conditions) (Figure 1).

Distension-induced motility

Distension of the intestinal wall, produced by elevating the outflow block to 8 cm above the level of the tissue in the bath, evoked distinct motor patterns in normal and control preparations compared with hypertrophic tissue. In normal and control tissues, intraluminal pressure increased steeply by about 6.5-7.0 mmHg, and non-propulsive, local cycles of contractions and relaxations were exhibited by 75% of the preparations (Figure 3A and B). In contrast, in all hypertrophic segments, intestinal tone first gradually and slowly increased up to a threshold pressure. At this point, rhythmic, anally propagating, strong propulsive strokes, markedly wider than normal and control tissues ($P < 0.001$) (Figure 3D) and markedly

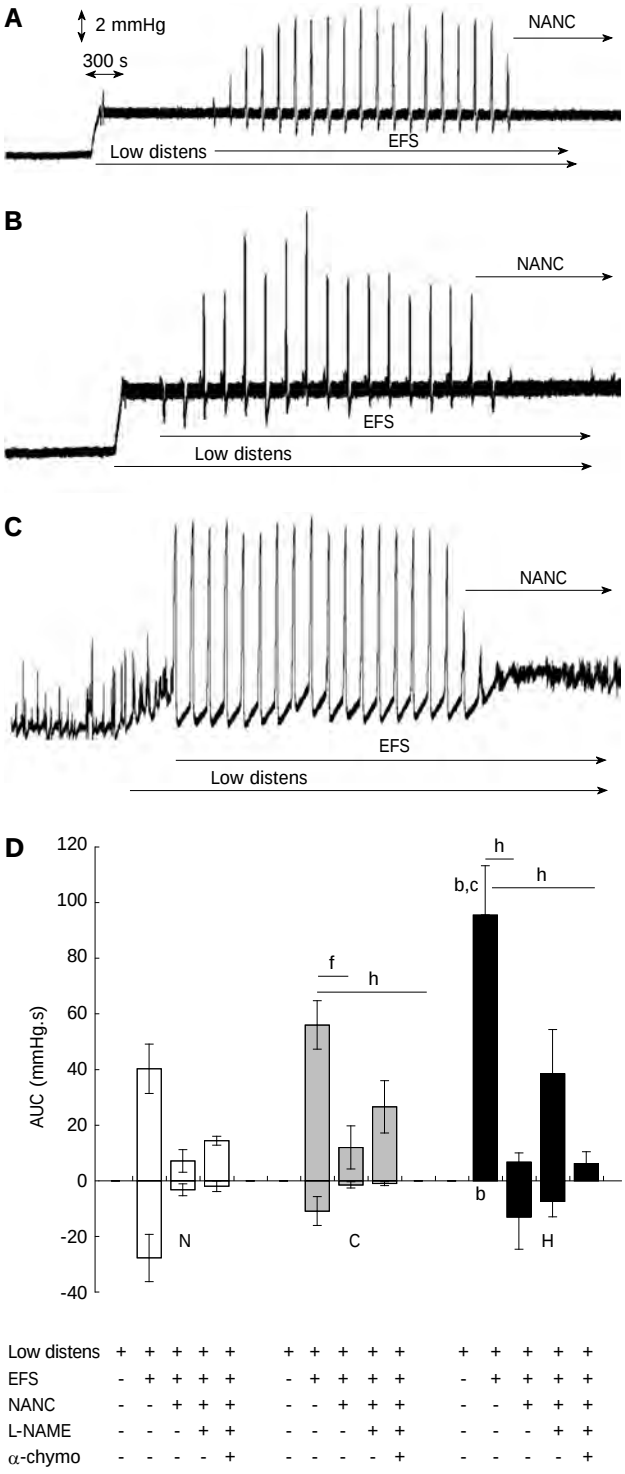

Figure 2 Motor responses to electrical field stimulation. Original tracings representing changes of intraluminal pressure of ileal segments in basal conditions and following subsequent application of a hydrostatic pressure of 5 cm H_2O (Low distens), EFS (30 V, 1 ms, 3 Hz, trains lasting 20 s every 120 s) and NANC conditions (NANC). A: Normal tissues; B: Control tissues; C: Hypertrophic tissues; D: Area under the pressure-time curve of motor responses in normal (N), control (C) and hypertrophic (H) ileal segments following subsequent application of a hydrostatic pressure of 5 cm H_2O (Low distens), EFS (30 V, 1 ms, 3 Hz, trains lasting 20 s every 120 s), NANC conditions (NANC), incubation with L-NAME 300 μmol/L (L-NAME) and incubation with α-chymotrypsin 10 IU/mL (α-chymo). Each value is the mean ± SE of 5 distinct experiments per group. $^{b}P < 0.01$ *vs* corresponding normal values; $^{c}P < 0.05$ *vs* corresponding control values; $^{f}P < 0.01$; $^{h}P < 0.001$; analysis of variance test followed by Bonferroni's post-test.

higher than normal ($P < 0.001$) or control tissue ($P < 0.05$) (Figure 3E) were elicited; simultaneously, basal intraluminal pressure progressively decreased to equilibration values (Figure 3C). Both motor patterns were blocked under NANC conditions and with simultaneous incubation with L-NAME 300 μmol/L and α-chymotrypsin 10 IU/mL (data not shown). In all types of tissues, incubation with the 5-HT_{2A}R antagonist ketanserin 1 μmol/L did not modify any parameter of the distension-induced motility (Figure 3D-F). In contrast, blockade of 5-HT_3R by ondansetron concentration-dependently reduced the amplitude, height and frequency of contractions and relaxations in normal and control tissues; in hypertrophic preparations, only the highest concentration of ondansetron tested (10 μmol/L) had an effect, with a decreased height of the peristaltic strokes without modification of their area or frequency (Figure 3D-F). Regarding antagonism of 5HT_4R by GR125487 1 μmol/L, no significant changes were produced in the distension-induced motility of any tissue (Figure 3D-F).

When the propulsive ability of hypertrophic tissues was taken into consideration, none of the 5-HTR antagonists tested modified the average compliance of the intestinal wall during the preparatory phase (Figure 4), or the efficacy of the propulsion of luminal fluid during the emptying phase, expressed by the average power (data not shown).

Immunohistochemistry

In both sham-operated and hypertrophic specimens, 5-HT_3R immunoreactivity was detected in many neurons and fibers of the ileal myenteric plexus, appearing concentrated primarily near the neuronal plasma membrane; only slight staining was observed also in the cytoplasm (Figure 5A and D). Double-labeling with immunoreactivity for 5-HT_3R and clathrin, a marker for early endosomes, whose distribution seemed mainly cytosolic (Figure 5B and E), did not show any clear significant co-localization, suggesting that in control and hypertrophic tissues the internalization of this ligand-gated ionotropic receptor appeared as an occasional event under basal conditions (Figure 5C and F).

DISCUSSION

The results of the present study indicate that hypertrophy of the intestinal wall induced by a partial chronic obstruction located at the terminal portion of rat ileum is associated with striking changes in the shape and nature of motor patterns elicited by EFS and by intraluminal distension. In particular, an increased accommodation capacity and little involvement of serotonergic neurotransmission in the control of enteric reflexes in hypertrophic tissues compared with normal and control reflexes can be hypothesized. First, when the motor responses evoked by electrical stimulation of intrinsic innervation are taken into consideration, it is worth noting that the typical biphasic profile, comprising a transient contraction fol-

lowed by a weak relaxation in normal and control tissues, was converted into a high-amplitude monophasic contraction in hypertrophic tissue. This modification, similar to that already detected in electrically stimulated hypertrophic ileum when longitudinally mounted[7], can be accounted for by two different factors: a greater force of contraction due to increased muscle mass developed by hypertrophic growth; an increased accommodation capacity as shown by the quick drop in basal intraluminal pressure at the onset of EFS. The subsequent pharmacological investiga-

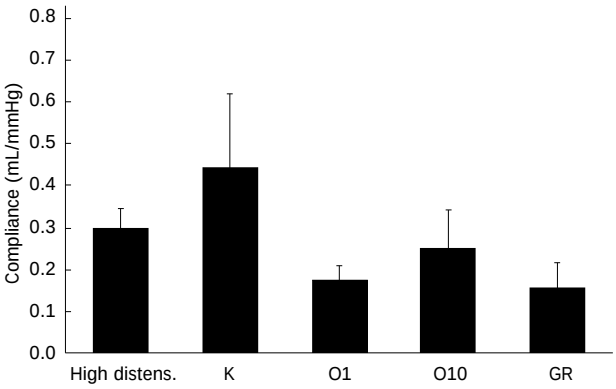

Figure 4 Average compliance of hypertrophic ileum. Changes of the average compliance of hypertrophic intestinal wall following application of a hydrostatic pressure of 8 cm H_2O (high distens.) and incubation with ketanserin 1 μmol/L (K), ondansetron 1 (O1) or 10 (O10) μmol/L or GR125487 1 μmol/L (GR). Each value is the mean ± SE of 5 distinct experiments per group.

tion confirmed the pivotal role played by acetylcholine not only as an excitatory neurotransmitter in normal, control and especially hypertrophic tissues[7], but also as one of the primary transmitters of descending interneurons, corroborating the findings collected in guinea pig small intestine[17]. Indeed, incubation with atropine and guanethidine markedly reduced the contractile phase in all preparations and nearly abolished it in hypertrophic tissues. Furthermore, in obstructed segments, atropine and guanethidine impaired the accommodation reflex elicited by electrical stimulation, by increasing the intraluminal pressure to pre-stimulation values.

Along with acetylcholine, other mediators were involved in the regulation of intestinal motility both in physiological conditions and after chronic obstruction: only simultaneous incubation with the NOS inhibitor L-NAME and the protease α-chymotrypsin completely blocked neurogenic motor responses in all the preparations and further impaired the accommodation capacity in the obstructed tissue. It is worth noting that an increased sensitivity to relaxing mediators, including nitric oxide and vasoactive intestinal peptide (VIP), was exhibited by hypertrophic smooth muscle layers compared with non-obstructed ones[11], possibly concurring with the higher accommodation capacity shown by hypertrophic ileum in these conditions.

In the second part of the research, the increase in hydrostatic pressure on the intestinal wall and the resulting distension triggered atropine- and α-chymotrypsin-sensitive typical motor patterns in normal, control and hypertrophic tissues. In particular, in chronically obstructed segments, distension evoked wide, rhythmic and propulsive peristaltic waves propagating aborally, with shape similar to those elicited by electrical stimulation in the same type of tissues and totally different from the stationary, non-propulsive clusters of cycles arising in normal and control preparations in these experimental conditions. The precise mechanisms underlying this particular motor pattern are not known and the possible contribution given by each morphological and neurochemical alteration, already thoroughly described in the hypertrophic intestine[2-5], requires further investigation. The augmented total collagen content, possibly acting as a force transducer among the components of the contractile system[18], or the higher density of inhibitory neurons expressing VIP or pituitary adenylate cyclase-activating polypeptide[3], may be only two of the reasons for this motor behavior.

The collected results seem however to be consistent with the enhanced responsiveness to contractile agents and relaxing mediators which is seen in isolated hypertrophic smooth muscle layers[11], both aspects likely playing a critical role in the powerful peristaltic reflex. According to the original idea attributed to Bulbring *et al*[13], intraluminal distension initiates the peristaltic reflex through stimulation of intrinsic sensory primary afferent neurons by 5-HT released into the wall of the gut from enterochromaffin cells. Starting from this premise it seemed interesting to investigate the role played by endogenous 5-HT in the modulation of enteric motor reflexes through the application of selective $5HT_{2A}R$, $5\text{-}HT_3R$ or $5\text{-}HT_4R$ antagonists both in non-obstructed and in hypertrophic distended ileum. The findings provided by the present work suggest that in normal and control tissues, distension-induced motility is independent of the activation of smooth muscle $5\text{-}HT_{2A}R$, mediating rat ileum contraction[19], and only slightly affected by blockade of $5HT_4R$. These receptors are chiefly located on terminals of submucosal intrinsic primary afferent neurons, where, by promoting the release of acetylcholine and calcitonin gene-related peptide, they are reported to play a critical role in facilitating the peristaltic reflex along with the putative $5\text{-}HT_{1P}R$[20], towards which no selective antagonist is currently available. Also $5\text{-}HT_3R$ are involved in peristalsis: they are mainly localized on extrinsic sensory nerves and on myenteric neurons, where they initiate giant migrating contractions[20], and may participate in the triggering and propagation of the peristaltic reflex[21,22]. The application of $5\text{-}HT_3R$ antagonist concentration-dependently inhibited distension-induced motor responses in normal and control tissues, while, only slightly at the highest tested concentration did it impair the motor reflexes activated by wall distension in hypertrophic segments, which were refractory to the other 5-HTR antagonists. With regard to this behavior, it is tempting to speculate, and worth further investigation, that the mucosa, hypertrophied following chronic obstruction[23], could contain massive levels of 5-HT, stored in enterochromaffin cells. The mediator, once released by distension of the gut wall, may strongly stimulate $5\text{-}HT_3R$, possibly leading to two effects: the initiation of the peristaltic reflex and the internalization of the ligand-gated ion channel. Indeed, a long-term increase in 5-HT content in the intestinal mucosa has been demonstrated by Freeman *et al*[24] to result in a pronounced $5\text{-}HT_3R$ internalization in myenteric neurons of rat ileum. The results obtained through confocal microscopy in the present study do not seem to support the hypothesis of a different cellular localization of $5\text{-}HT_3$ receptors in control and hypertrophic tissues: on the contrary, in the adopted experimental conditions, internalization of this receptor subtype appears equally unlikely in both kinds of preparations. This

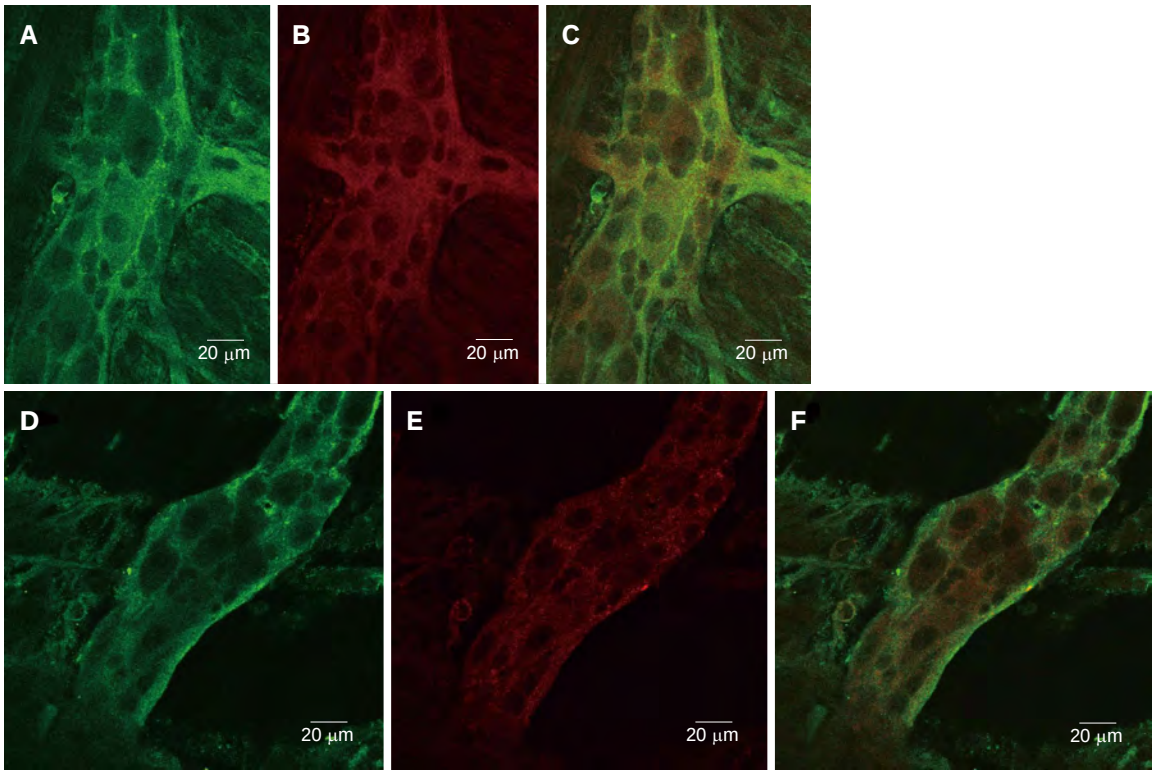

Figure 5 Cellular localization of 5-HT3 receptors in control and hypertrophic ileum. finding, together with the inability of ondansetron even at high concentrations to affect the peristaltic response, casts doubts over the actual involvement of 5-HT$_3$R in the motor reflexes stimulated by mechanical distension in hypertrophic ileum. Given the complexity of factors possibly altering 5-HT availability and metabolism and, therefore, also affecting the pharmacological response to 5-HT$_3$R antagonists, future studies will help to elucidate the role exerted by 5-HT in this experimental model and in intestinal secreto-motor disorders in general, where refractoriness to blockade of 5HT$_3$R has sometimes emerged[25].

In conclusion, on the basis of the findings of this study, it is rational to hypothesize that the ability of hypertrophic intestine to elicit a powerful peristaltic reflex *in vitro* is an expression of the functional plasticity of neural and muscular intestinal tissue, a property aimed at preserving its physiological role in more demanding conditions, and allowing it to maintain chyme propulsion even in the presence of a point of abnormal resistance. This distinctive motor pattern appears to be primarily controlled by cholinergic and peptidergic mediators and only slightly affected by serotonergic transmission, which is critically involved, *via* 5-HT$_3$R, in the modulation of non-propulsive motility triggered by mechanical distension in non-obstructed tissues.

ACKNOWLEDGMENTS

The authors wish to thank Professor Catia Sternini (CURE/UCLA Digestive Disease Research Center, Los Angeles, CA, United States) for kindly providing rabbit-anti-rat IgG primary antibody directed against the 5-HT3R (No. 95247); Dr. Giuseppe Domenichini for his skilful technical assistance and the University of Parma (FIL 2009) for financial support.

COMMENTS

Background

Intestinal obstruction is a frequently encountered clinical problem, resulting from congenital malformations (as in Hirschsprung's disease) or by an acquired obstruction, such as a surgical-induced stenosis or a neoplasm, possibly leading to death if not properly diagnosed and treated. Morphological, biomechanical and neurochemical changes have been thoroughly described orally to the site of an experimental chronic obstruction; however, functional investigations, which would help to gain a deeper insight into the regulatory mechanisms of motility in this pathological condition, are still limited.

Research frontiers

Disruption of digestive motor activity, changes in slow wave activity but also preservation of the peristaltic reflex have been functionally described in different experimental models of intestinal stenosis. In rat ileum, hypertrophic growth, induced by mechanical obstruction, has been demonstrated to affect the responses of both smooth muscle layers and of intrinsic innervation, but no information is available on its effects on a highly sophisticated and integrated process between neural and myogenic components such as intestinal peristalsis.

Innovations and breakthroughs

To the best of knowledge, this is the first report showing that, following obstruction, rat isolated terminal ileum develops a propulsive activity triggered simply by intraluminal distension. Furthermore, the peristaltic activity exhibited by rat hypertrophic ileum appears only slightly affected by serotoninergic transmission, a property quite unexpected on the basis of the pivotal role played, in

general, by endogenous serotonin in the initiation and propagation of enteric reflexes and, in particular, in the non-propulsive motility triggered by mechanical distension in non-obstructed tissues.

Applications

The results of this research improve the understanding of the changes in motility patterns and enteric reflexes triggered by intestinal obstruction, through a pharmacological investigation. Moreover, the observed refractoriness to 5-HT_3 antagonists makes this system an interesting model to study conditions of variable sensitivity to blockade of 5-HT_3 receptors, such as that described for diarrhea-predominant irritable bowel syndrome in female patients treated with alosetron.

Terminology

Peristalsis: A coordinated motor behavior, which allows the intestine to propel its contents in an anal direction; Accommodation: Indicates the ability of the intestine to adapt itself to the distension pressure, and, conversely, is a reflection of the resistance of the intestinal wall to the infused fluid; 5-HT_3 receptor: Ligand-gated ion channel receptor activated by serotonin or 5-HT, localized on extrinsic sensory nerves and on myenteric neurons, where they initiate giant migrating contractions and may participate in the triggering and propagation of the peristaltic reflex.

Peer review

This is a nice study, the findings are interesting and potentially important for clinical medicine. The authors showed that accommodation capacity and distension-induced peristalsis of rat hypertrophic ileum are primarily controlled by cholinergic and peptidergic transmission and negligibly by 5-HT_3 receptors.

Abstract

AIM: To assess the usefulness of contrast-enhanced ultrasound (CEUS) during follow-up after percutaneous ablation therapy for hepatocellular carcinoma (HCC).

METHODS: A total of 141 patients with HCCs who received percutaneous ablation therapy were assessed by paired follow-up CEUS and contrast-enhanced computed tomography (CECT). The follow-up scheme was designed prospectively and the intervals between CEUS and CECT examinations were less than 14 d. Both images of follow-up CEUS and CECT were reviewed by radiologists. The ablated lesions were evaluated and classified as local tumor progression (LTP) and LTP-free. LTP was defined as regrowth of tumor inside or adjacent to the successfully treated nodule. The detected new intrahepatic recurrences were also evaluated and defined as presence of intrahepatic new foci. On CEUS and CECT, LTP and new intrahepatic recurrence both were displayed as typical enhancement pattern of HCC (*i.e.*, hyper-enhancing during the arterial phase and washout in the late phase). With CECT as the reference standard, the ability of CEUS in detecting LTP or new intrahepatic recurrence during follow-up was evaluated.

RESULTS: During a follow-up period of 1-31 mo (median, 4 mo), 169 paired CEUS and CECT examinations were carried out for the 141 patients. For a total of 221 ablated lesions, 266 comparisons between CEUS and CECT findings were performed. Thirty-three LTPs were detected on CEUS whereas 40 LTPs were detected on CECT, there was significant difference ($P < 0.001$). In comparison with CECT, the numbers of false positive and false negative LTPs detected on CEUS were 6 and 13, respectively; the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and overall accuracy of CEUS in detecting LTPs were 67.5%, 97.4%, 81.8%, 94.4% and 92.3%, respectively. Meanwhile, 131 new intrahepatic recurrent foci were detected on CEUS whereas 183 were detected on CECT, there was also significant difference ($P < 0.05$). In comparison with CECT, the numbers of false positive and false negative intrahepatic recurrences detected on CEUS were 13 and 65, respectively; the sensitivity, specificity, PPV, NPV and overall accuracy of CEUS in detecting new intrahepatic recurrent foci were 77.7%, 92.0%, 92.4%, 76.7% and 84.0%, respectively.

CONCLUSION: The sensitivity of CEUS in detecting LTP and new intrahepatic recurrence after percutaneous ablation therapy is relatively low in comparison

with CECT.

Role of contrast-enhanced ultrasound in follow-up assessment after ablation for hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(6): 855-865 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/855.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.855

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth most common cancer worldwide, the incidence of which is continuously increasing in both western and eastern countries[1]. Percutaneous ablation therapy, such as radiofrequency ablation (RFA) and microwave ablation (MWA), as a minimally invasive and effective treatment modality, has been accepted in the management of hepatic malignance and regarded as one of the best treatment options for patients with early stage HCC who are not suitable for resection or transplantation[2-5]. Several randomized clinical trials have also confirmed that for small HCC, treatment efficacy of thermal ablation is comparable to that of surgical resection[2,6,7].

The evaluation of treatment efficacy after percutaneous ablation therapy for HCC is essential for the determination of subsequent treatment and follow-up strategy[8], which is usually performed by means of imaging modalities such as contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI)[2,9,10]. Both of them have been regarded as reliable and accurate imaging tools for post-treatment efficacy evaluation and follow-up[2]. However, contrast-enhanced CT (CECT) and contrast-enhanced MRI (CEMRI) are relatively expensive. In addition, CECT is unsuitable for patients with renal function impairment and allergic reaction to contrast agent. Finally, the radiation exposure in CT examination is always a concern for both clinicians and patients.

The technique of contrast-enhanced ultrasound (CEUS) has the potential to be a substitute for CECT or CEMRI. By using ultrasound contrast agents (UCAs) and contrast specific imaging techniques, CEUS is able to depict the micro- and macro-circulation in the liver and the treated lesion, thus allowing assessment of the treatment efficacy for HCC after percutaneous ablation therapy in a similar fashion with CECT or CEMRI[2,8,11-14]. Besides, UCAs are very safe and the incidence of severe hypersensitivity or allergic reaction is lower than that of current X-ray contrast agents and comparable to MR contrast agents[13,15]. CEUS has been confirmed to be comparable to CECT for characterization of HCC[16-19]. A prospective multicenter study also proved that CEUS is equal to CECT or CEMRI for the assessment of the local treatment response after ablation therapy[11,12]. After local treatment response assessment, the patient is always enrolled into a long-term follow-up scheme for surveillance of local tumor progression (LTP) or new intrahepatic foci[11,12]. In theory, CEUS may be inferior to CECT or CEMRI since the development of new foci may be multiple and may be located in different lobes of the liver, and the arterial enhancement on CEUS only lasts several seconds, thus it is hard to detect all the hypervascular lesions. In addition, the new foci in the blind areas such as liver dome may be invisible on CEUS. To our knowledge, there has been no study evaluating the role of CEUS in the follow-up assessment after percutaneous ablation therapy for HCC[2,12,19,20]. To confirm the hypothesis that CEUS might not be competent to CECT in follow-up assessment after local ablation for HCC, the study was carried out to assess the usefulness of CEUS in detecting LTP and new intrahepatic recurrence in the follow-up after ablation therapy for HCC, with CECT as the reference standard.

MATERIALS AND METHODS

Patients

Between May 2007 and March 2011, 466 consecutive patients with HCCs were referred to the institution for ultrasound (US)-guided percutaneous ablation therapy. These patients met the following enrollment criteria: (1) single HCC not greater than 6 cm in diameter; (2) multiple HCCs up to 5 in number with each tumor measuring 3 cm or smaller; (3) absence of portal venous thrombosis or extrahepatic metastases; (4) liver cirrhosis classified as Child-Pugh class A or B; and (5) prothrombin time ratio greater than 50% and platelet count greater than 60 000/mm^3 (60 × 10^9 /L). Among them, 141 patients (132 men, 9 women; mean age, 53.4 ± 12.1 years; age range, 27-81 years) were enrolled to this follow-up study after ablation. The inclusion criteria were as follows: (1) the patients had no allergic reaction to iodinated contrast agent; (2) CECT confirmed complete ablation of the tumors within 1 mo after ablation therapy; and (3) paired CEUS and CECT were performed during the follow-up and the time interval between CEUS and CECT was less than 14 d. All the data of the 141 patients, including baseline data, clinical data, and imaging data, were collected prospectively and stored in a dedicated database for further analysis. The study was approved by the Institutional Review Board, and written informed consent was obtained from all patients.

Among the 141 patients, 60 patients had recurrent HCCs after partial hepatectomy for primary HCCs and the remaining 81 patients with primary HCCs were treated by US-guided percutaneous ablation therapy as the first therapy. The diagnoses of HCC were confirmed by histopathological examination with specimens obtained from US-guided percutaneous biopsy (n = 35) or clinical data (n = 106). The clinical diagnostic criteria for HCC mainly followed the AASLD and EFSUMBS

practice guideline: the presence of typical CECT and CEUS features (*i.e.*, hyper-enhancement in arterial phase and washout in portal-venous or late phase)[2,15]. Among the clinically confirmed 106 patients, 46 were diagnosed by characteristic imaging findings on CECT and serum α-fetoprotein ≥ 200 ng/mL; 60 patients were diagnosed by history of partial hepatectomy for HCC and typical appearance of HCC recurrence on CECT. The US-guided percutaneous ablation therapies for them included radiofrequency ablation (RFA) (n = 83), percutaneous ethanol ablation (EA) (n = 29), RFA in combination with EA (n = 26), and microwave ablation (MWA) (n = 3).

Ablation techniques

Percutaneous ablation therapy for HCC was performed with local anesthesia and conscious sedation. RFA was carried out with a cooled-tip RFA ablation system (Cool-tip, Radionics, MA, United States), which is a 480 kHz alternative current generator that can produce a maximum power of 200W through a 17 Gmonopolar, cooled-tip needle electrode. The radiofrequency electrode temperature was maintained at less than 18 ℃ by the application of a circulating chilled saline solution to the cannula sheath. A single 3 cm exposed tip RFA electrode was applied[21,22]. MWA was carried out with a microwave delivery system (FORSEA; Qinghai Microwave Electronic Institute, Nanjing, China), which consisted of an MTC-3 microwave generator (FORSEA) with a frequency of 2450 MHz, a power output of 10-150 W, a flexible low-loss cable, and a 14-gauge cooled-shaft antenna. The RFA electrode or MWA antenna was firstly placed at the bottom of the tumor and withdrawn 1.5-2 cm each time to ablate the more superficial portion for large tumors. Multiple insertions were applied to treat tumors larger than 1.5 cm for RFA and 3.0 cm for MWA[21,22]. EA was performed using a Quadra-Fuse™ multi-pronged needle (Rex Medical, Radnor, PA, United States). In general, no greater than 30 mL of 95% ethanol was injected until the hyperechoic cloud covered the whole tumor. For patients with tumor adjacent to critical structures such as hilum or great vessels, RFA was performed in combination with EA. In general, EA was carried out in advance of RFA and RFA was performed 5 min after EA, the aim of which was to increase the coagulation volume whereas limit the damage to adjacent critical structures[23-25]. To prevent possible bleeding or tumor seeding, the needle track was cauterized when the RFA electrode or the MWA antenna was withdrawn. The aim of the procedure was to completely ablate the tumor along with an ablative margin of 0.5-1.0 cm[26,27].

Contrast-enhanced US examination

All the US examinations were performed by one of three skillful radiologists who had more than 7 years experience in CEUS and were unaware of clinical and other imaging information of the patients. Two US machines were used in this study. One was an Acuson Sequoia 512 machine (Siemens Medical Solutions, Mountain View, CA, United States) and the other was an Aplio XV machine (Toshiba Medical Systems, Tokyo, Japan). A 4V1 vector transducer with a frequency range of 1.0-4.0 MHz was applied for Sequoia 512 and a 375 BT convex transducer with a frequency range of 1.9-6.0 MHz was applied for Aplio XV. The installed contrast-specific imaging modes were contrast pulse sequencing (CPS) for Sequoia 512 and contrast harmonic imaging (CHI) for Aplio XV. Both modes work under low acoustic power, and the corresponding mechanical index (MI) ranges were 0.15-0.21 for CPS in Sequoia 512 and 0.05-0.08 for CHI in Aplio XV.

Baseline US (BUS) investigation in B-mode was firstly applied to scan the whole liver, including Doppler technique. Once the treated lesion was found, the lesion size, echogenicity, and location were recorded, and the images that showed best the above-mentioned features were stored digitally in the US machine. Then the transducer was moved to scan other liver to detect if there were suspected new recurrence foci and the above-mentioned features were also recorded if new foci were present. Afterward, the imaging mode was shifted to CEUS mode and the imaging settings were optimized to ensure sufficient tissue cancellation with the maintenance of adequate depth penetration, with the diaphragm remaining barely visible.

The US contrast agent used was SonoVue (Bracco, Milan, Italy), a sulfur hexafluoride-filled microbubble contrast agent. A total of 2.4 mL contrast agent was given intravenously as a 2.4 mL bolus within 2-3 s through the antecubital vein, followed by 5 mL saline flush. Upon start of the SonoVue injection, the stop clock was started and digital cine was recorded simultaneously. During early period of CEUS procedure, the transducer was firstly kept in a stable position to observe the enhancement pattern of the treated lesion and then switched to scan other liver parenchyma. The first 2 min was continuously observed and subsequent intermittent scanning was performed until the disappearance of contrast agent in liver parenchyma. According to the previous studies, the CEUS process was divided into arterial (*i.e.*, 8-30 s from the beginning of contrast agent administration), portal (31-120 s), and late (121-360 s) phases[11,15]. A second or third injection of SonoVue was performed when suspicious new foci were documented on BUS or hypoenhancing new foci were detected in the late phase on CEUS. No patient received more than 3 injections.

Contrast-enhanced CT examination

For the CT examination, the Aquilion 64-slice helical CT machine (Tokyo, Japan) was used. The intervals between CEUS and CECT examinations were less than 14 d and no additional treatment was carried out during this period. The imaging protocol for CT examinations was as follows: 0.5 mm × 64 mm collimation, 120 kV, 150-200 mAs for 64-slice helical CT examination. The standard triphasic scan procedure was used. An unenhanced helical sequence scan through the liver was performed first; thereafter nonionic iodinated contrast material (Ultravist,

Schering, Berlin, Germany) (1.5 mL/kg) was administered via antecubital vein with power injection at a rate of 4 mL/s for 64-slice helical CT. The arterial phase sequence was obtained 25-32 s after contrast material administration, followed by a portal venous phase sequence 70 s after contrast agent administration.

Image interpretation

Two of the three skillful radiologists, who had more than 7-year experience in liver CEUS, evaluated the CEUS images and two experienced radiologists, who had more than 15-year experience in liver CECT, evaluated the treatment response using the CT images. The reviewers were not involved in the US or CT scanning, and were unaware of clinical and other imaging information of the patients. The findings of the treated lesions and new intrahepatic recurrence were observed and the treatment response was evaluated. Complete ablation was defined as nonenhancement in the ablated area; otherwise, ablation was considered incomplete. During the follow-up period, local tumor progression (LTP) was defined as regrowth of tumor inside or adjacent to the successfully treated nodule, which appeared as a hyper-enhancing area during the arterial phase and wash-out during portal-late phases inside the treated lesion on CEUS or CECT[3]. Non-enhancement in the treated area was defined as LTP-free. New intrahepatic recurrence was defined as presence of intrahepatic new foci with typical enhancement pattern of HCC on CEUS or CECT (*i.e.*, hyper-enhancing during the arterial phase and wash-out in the late phase). Development of portal venous tumor thrombosis was also defined as new intrahepatic recurrence. Non-recurrence was defined as no additional HCC lesions found.

Follow-up assessment

In the study design, the local effectiveness of ablation was assessed by CEUS or CECT within one month after ablation. Only the patients with complete ablation were enrolled into the prospectively designed follow-up scheme, and those with incomplete ablation were referred to further treatment, *e.g.*, additional ablation, transcatheter arterial chemoembolization (TACE), Sorafenib, *etc.*, according to the liver function status and tumor staging.

In the follow-up scheme, all patients were evaluated simultaneously with CECT and CEUS every 3 mo for the first 6 mo. If no positive findings were present and the ablation area shrank or disappeared, follow-up at an interval of 6-12 mo was made. At the same time, all patients were also monitored monthly with abdominal color Doppler US, serum AFP, chest radiography and liver function tests for the first 6 mo, and thereafter every 3 to 6 mo. When there were suspicious findings on US (*i.e.*, enlargement of the treated area, changes in US pattern, presence of intralesional Doppler signal, and appearance of new lesion) or elevated AFP, then paired CEUS and CECT were performed to confirm the diagnosis. Once the LTP or new intrahepatic recurrences were detected, the follow-up was over and the patients were referred to further treatment.

Statistical analysis

Continuous data were expressed as mean ± SD. The χ^2 test was used to compare the differences in detecting LTP and new intrahepatic recurrence between CECT and CEUS. Two-tailed $P < 0.05$ was considered statistically significant. With CECT as the reference standard, the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and overall accuracy of CEUS in detecting LTP were computed on the basis of the assessment results of the ablation lesions on each follow-up examination, and those of CEUS in detecting new intrahepatic recurrence were computed on the basis of the patients' screening results on each follow-up examination. Statistical analysis were performed using the SPSS 13.0 software package (SPSS Inc., Chicago, IL, United States).

RESULTS

After percutaneous ablation therapy, the 141 patients with 221 HCCs (the maximum diameter ranged from 0.6 cm to 5.7 cm; mean ± SD, 2.4 ± 1.0 cm) were followed up for 1-31 mo (median, 4 mo; mean ± SD, 6.7 ± 6.4 mo) after complete ablation was confirmed by CECT 1 mo after ablation. The interval between every paired CEUS and CECT examination ranged from 0 to 14 d (median, 1 d; mean ± SD, 3.1 ± 4.3 d).

During the follow-up period, the 141 patients received 169 (once, $n = 118$; twice, $n = 18$; three times, $n = 5$) paired CEUS and CECT examinations. For the 221 ablated lesions (the diameter ranged from 1.2 cm to 7.4 cm; mean ± SD, 4.1 ± 1.1 cm), 266 comparisons between CEUS and CECT findings (185 ablated lesions were examined once; 27 ablated lesions were examined twice; 9 ablated lesions were examined three times) were performed.

During the follow-up, 40 LTPs (the diameter ranged from 0.4 cm to 5.5 cm; mean ± SD, 2.0 ± 1.1 cm) and 183 new intrahepatic recurrences (the diameter ranged from 0.3 cm to 3.8 cm; mean ± SD, 1.5 ± 0.8 cm) were detected on CECT, whereas only 33 and 131 were detected on CEUS. The locations of the LTPs and the new intrahepatic recurrences are summarized in Table 1.

In the 266 comparisons between paired CECT and CEUS for all ablation lesions, CEUS determined that 233 lesions were LTP-free and all showed non-enhancement in the arterial, portal, and late phases (Figure 1A and B). The remaining 33 lesions were determined to be LTP on CEUS and all showed hyper-enhancement in the arterial phase and wash-out ($n = 28$) (Figure 2A and B) or iso-enhancement ($n = 5$) in the portal-late phases. However, on CECT, 226 lesions were determined to be LTP-free and all showed non-enhancement in the arterial, portal, and late phases (Figure 1C and D); and the remaining 40 lesions were determined to be LTP and all showed hyper-enhancement in the arterial phase and wash-out in the portal-late phase (Figure 2C and D).

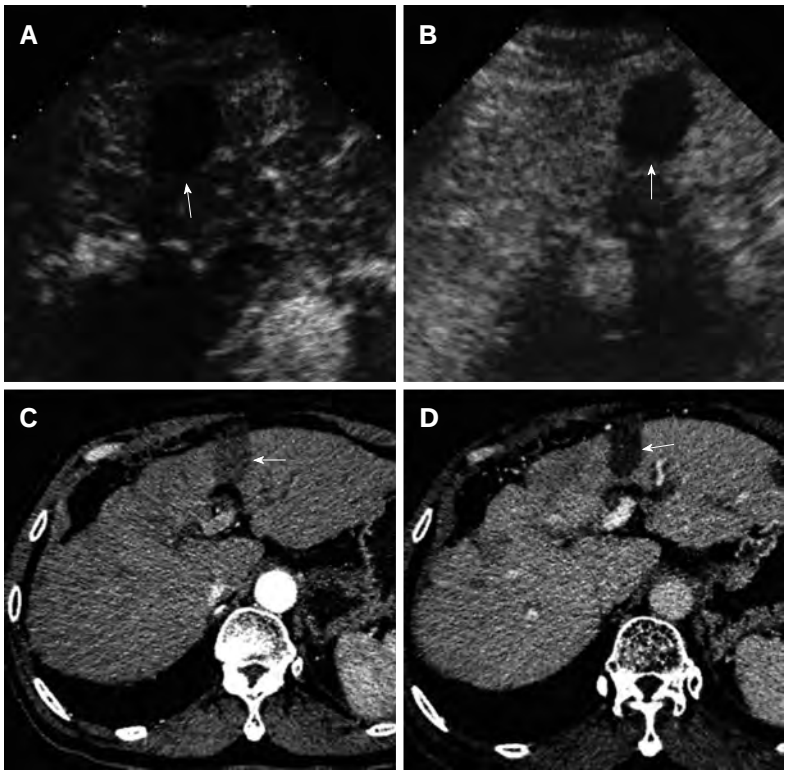

Figure 1 A 57-year-old male patient with hepatocellular carcinoma. Two months after radiofrequency ablation for hepatocellular carcinoma in segment 3 of the liver. On both contrast-enhanced computed tomography (A, B) and contrast-enhanced ultrasound (C, D), the treated lesion (arrow) showed complete necrosis without any enhancement in all vascular phases.

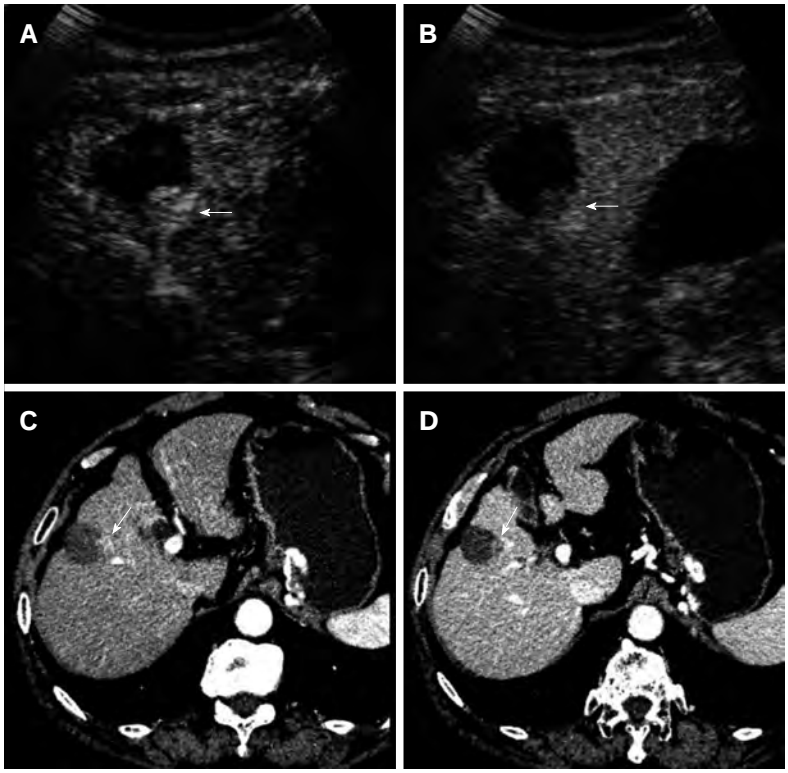

Figure 2 A 70-year-old male patient with hepatocellular carcinoma. Local tumor progression (arrow) was detected 6 mos after radiofrequency ablation in combination with ethanol ablation for hepatocellular carcinoma in segment 5 of the liver. Local tumor progression showed hyper-enhancement in the arterial phase and iso-enhancement in the portal-late phase on contrast-enhanced ultrasound (A, B), whereas hyper-enhancement in the arterial phase and wash-out in the portal-venous phase on contrast-enhanced computed tomography (C, D).

By comparing the number of the ablated lesions, there was significant difference between CECT and CEUS in detecting LTP ($P < 0.001$, Table 2). Differences between CECT and CEUS were also found in the subgroups (< 3 cm *vs* ≥ 3 cm in diameter; single *vs* multiple ablated lesions), (both $P < 0.001$) (Table 2). With CECT as the reference standard, the sensitivity, specificity, PPV, NPV and overall accuracy of CEUS in detecting LTP after percutaneous ablation were 67.5% (27/40), 97.3% (220/226), 81.8% (27/33), 94.4% (220/233), 92.9% (247/266), respectively.

A total of 183 new intrahepatic recurrences were detected on CECT and all showed hyper-enhancement in the arterial phase and wash-out in the portal-venous

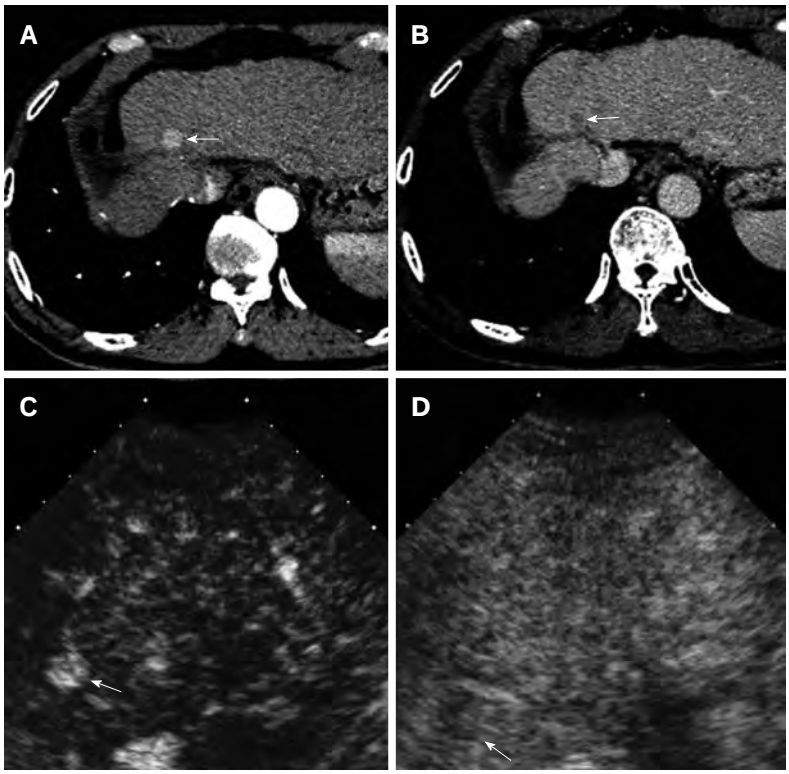

Figure 3 The same patient as shown in Figure 1. A, B: Two months after radiofrequency ablation for hepatocellular carcinoma. A new intrahepatic recurrence (arrow) was detected in segment 4 of the liver, which showed hyper-enhancement in the arterial phase and wash-out in the portal-venous phase on contrast-enhanced computed tomography; C, D: Similar findings were found in the arterial phase and the portal-late phases with contrast-enhanced ultrasound.

Table 1 Location of local tumor progression and new intrahepatic recurrence on contrast-enhanced computed tomography and contrast-enhanced ultrasound

Location	Local tumor progression		New intrahepatic recurrence	
	CEUS	CECT	CEUS	CECT
S1	0	0	1	2
S2	1	2	14	22
S3	2	2	7	13
S4	8	10	27	38

S6	7	5	14	23
S7	3	4	17	18
S8	7	10	25	36
PV	0	0	9	11
HV	0	0	0	2
Total	33	40	131	183

Data show the number of the detected lesions. S: Liver segment; PV: Portal vein; HV: Hepatic vein; CEUS: Contrast-enhanced ultrasound; CECT: Contrast-enhanced computed tomography.

phases (Figure 3A and B). Conversely, only 131 recurrent lesions were detected on CEUS (Figure 3C and D). Among them, 107 lesions were in the arterial phase with hyper-enhancement (n = 104) or iso-enhancement (n = 3) and the remaining 24 lesions were missed during the arterial phase. And 124 lesions showed wash-out in the portal-late phases on CEUS and the remaining 7 lesions showed iso-enhancement.

There was significant difference between the follow-up CECT and CEUS in detecting new intrahepatic recurrence when comparing the number of the detected lesions (P = 0.02, Table 3) or the number of the patients with detected lesions (P < 0.01, Table 3). With CECT as the reference standard, the sensitivity, specificity, PPV, NPV and overall accuracy of CEUS in detecting recurrence were 77.7% (73/94), 92.0% (69/75), 92.4% (73/79), 76.7% (69/90), 84.0% (142/169), respectively. The numbers of new intrahepatic recurrence in each patient detected by each follow-up CEUS and CECT are shown in Table 4.

The numbers of false positive and false negative LTPs detected on CEUS were 6 and 13, respectively. Compared with CECT, among the 6 false positive LTPs, 5 misinterpreted hepatic blood vessels (Figure 4) and 1 new intrahepatic recurrence were misdiagnosed as LTPs. The main reasons for false negative LTPs (Figure 5) on CEUS were as follows: near liver dome and obscuration by lung gas (n = 5); deep location (n = 1; depth > 10 cm); obscuration by gastrointestinal tract gas (n = 2); obscuration by enhanced portal vein (n = 1); small lesion (n = 3, all < 0.7 cm in diameter); misdiagnosis as new intrahepatic recurrence (n = 1).

Compared with CECT, the numbers of false positive and false negative intrahepatic recurrences detected on CEUS were 13 and 65, respectively. The causes of false positive recurrences were as follows: 3 regenerative nodules, 9 misinterpreted hepatic blood vessels and 1 LTP were misdiagnosed as new intrahepatic recurrence. Among the 65 false negative recurrences, 4 regenerative nodules and 1 LTP were misdiagnosed as recurrence, and the remaining 60 new intrahepatic recurrences were missed on CEUS. Compared with CECT, the reasons for the missed new intrahepatic recurrences were as follows: multiple lesions (n = 7, > 2 in number), obscuration by gastrointestinal tract gas (n = 10); deep location (n = 4, > 10 cm in depth), near liver dome and obscuration by lung gas (n = 19), small lesion (n = 5, < 1 cm in diameter) and

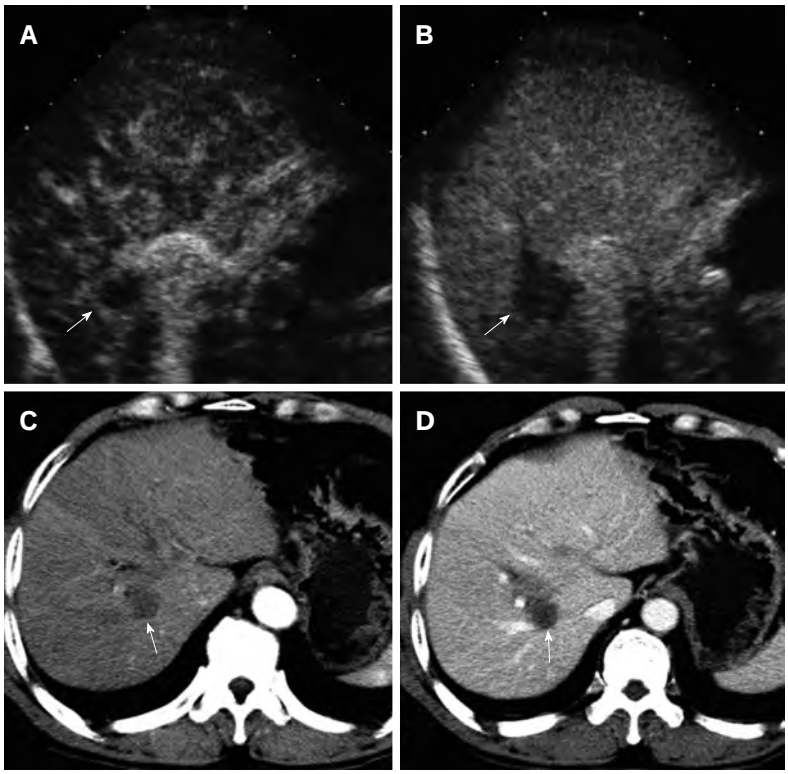

Figure 4 A 62-year-old male patient with hepatocellular carcinoma. Two months after percutaneous ethanol ablation for hepatocellular carcinoma in segment 8 of the liver. A, B: The false positive local tumor progression (arrow) was detected. It showed rim-like hyperenhancement in the arterial phase, wash-out in the portal-late phase on contrast-enhanced ultrasound; C, D: On contrast-enhanced computed tomography, the treated area (arrow) showed complete necrosis without any enhancement in all the vascular phases, but several enhanced hepatic vessels around the treated area.

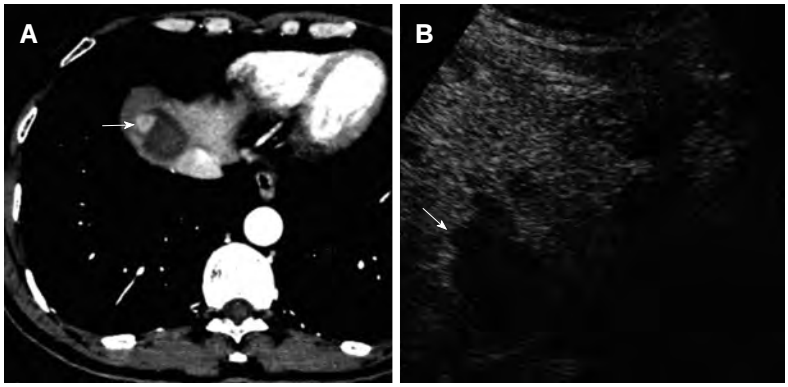

Figure 5 A 54-year-old male patient with hepatocellular carcinoma. Three months after radiofrequency ablation in combination with ethanol ablation for hepatocellular carcinoma in segment 8 of the liver. A: Contrast-enhanced computed tomography showed local tumor progression (arrow) at the periphery of the treated area; B: On contrast-enhanced ultrasound, local tumor progression (arrow) could not be detected, and the treated area was not clearly observed due to unfavorable location near the liver dome.

unknown causes (n = 15).

DISCUSSION

The treatment efficacy assessment after percutaneous ablation therapy for HCC mainly involves short-term local treatment response evaluation and long-term follow-up assessment. The short-term local treatment response evaluation is difficult as microscopic residual viable HCC is hardly detected by current imaging techniques. There-

Data show the numbers of detected new intrahepatic recurrence and lesion on CEUS and CECT. The χ^2 test with Yates's correction indicated significant difference in detecting intrahepatic recurrence ($\chi^2 = 5.40$, $P = 0.02$) and lesion ($\chi^2 = 8.33$, $P < 0.01$) between CEUS and CECT. CEUS: Contrast-enhanced ultrasound; CECT: Contrast-enhanced computed tomography.

fore, follow-up scheme after ablation therapies is important. Early detection of LTP or new recurrence during follow-up after percutaneous ablation for HCC is critical and will facilitate retreatment at an early stage[3]. The short-term local treatment response evaluation is usually carried out within 1 mo after ablation therapy[2,8,28]. Contrast-enhanced imaging studies are the most widely accepted modalities to assess the local treatment response[10,12,28]. In contrast to the follow-up assessment, local treatment response focused on the specified known lesion, whereas not the whole liver. Many studies have shown that in local treatment response evaluation, CEUS is comparable with CECT or CEMRI[11,13,20].

However, up till now, no studies have been performed to evaluate the efficacy of CEUS in the follow-up assessment. This issue is very important since some centers may only use CEUS for follow-up because of the convenience of CEUS and the unwareness of the limitations of CEUS. In this study, the efficacy of CEUS in follow-up was firstly evaluated, in comparison with the widely accepted modality of CECT. The long-term follow-up assessment (up to 31 mo; mean ± SD, 6.7 ± 6.4 mo) provided a sufficient surveillance for HCC progression after ablation and the short interval (3.1 ± 4.3 d) between the paired CEUS and CECT examination was able to guarantee that the lesions were observed under the same status of vascularity for comparison between CEUS and CECT.

Many studies have confirmed the accuracy of CEUS in local treatment response evaluation, with the CECT or CEMRI as the reference standard. Among these studies, a prospective multicenter study showed that the sensitivity and the accuracy were as high as 97.0% and 94.2%, respectively[11,20]. The accuracy (92.9%) of follow-up CEUS in detecting LTP in this study was comparable to that in local treatment response evaluation, so were the specificity (97.3%), PPV (81.8%) and NPV (94.4%). However, the relatively low sensitivity (67.5%) showed that CEUS was not comparable to CECT ($P < 0.001$). The low sensitivity was partly due to short arterial phase duration of CEUS and the intrinsic shortcomings of US technique such as inability to detect the lesions in the dome or small lesions, and obscuration by gas from gastrointestinal tract or lung.

It is unknown whether CEUS is competent for the detection of new intrahepatic recurrence after HCC ablation as compared with CECT. According to the published literatures, although CEUS is comparable with CECT/MRI in the detection of liver metastasis, CEUS is incompetent to CECT for HCC surveillance, owing to the insufficient access to the lesion near the liver dome, short duration in arterial phase and the variable appearances in late phase[15,29-31]. Correas *et al*[32] found that CEUS had a sensitivity of 78% and an accuracy of 70% for detection of liver metastases by scanning entire liver parenchyma, similar to the 77.7% and 84% for detection of new intrahepatic recurrences in our study. In this study, CECT was significantly superior to CEUS for the detection of new intrahepatic recurrent foci and CEUS was unable to detect 65 (35.5%) of 183 lesions. The possible reasons might be as follows: small lesion, unfavorable location (i.e., deep location, near liver dome, near gastrointestinal tract or large hepatic blood vessel), atypical enhancement pattern, and background of fatty or cirrhotic liver[19,28,33,34].

During the routine CEUS procedure, the hepatic arterial phase starts from 10-20 s after injection of UCAs, and lasts approximately 10-15 s. Furthermore, the arterial phase presents the optimal contrast enhancement for detecting LTPs and recurrence[15]. However, the short duration of the arterial phase makes it hard to scan the whole liver and screen all suspected lesions, while CECT can scan the entire liver in a few seconds[35]. In this study, a total of 24 (18.3%, 24/131) new intrahepatic recurrences were missed in the arterial phase.

In the portal-late phases, though CEUS can guarantee sufficient duration for whole liver scan, some LTPs and new intrahepatic recurrences usually show iso-enhancement [5 (15.2%, 5/33) and 7 (5.3%, 7/131) in this study, respectively], making them indistinguishable from the surrounding liver parenchyma[28,33,36].

Besides the above-mentioned limitations of CEUS, there were some factors related to the false negative results on CEUS, *e.g.*, near liver dome and obscuration by lung gas (5 LTPs and 19 recurrences) and obscuration by gastrointestinal tract gas (2 LTPs and 10 recurrences), which usually were displayed on CECT whereas not on CEUS. On the other hand, deep location (depth > 10 cm; 1 LTP and 4 recurrences) and small size (< 1.0 cm in diameter; 1 LTP and 5 recurrences) were not easy to be detected on CEUS due to acoustic attenuation and inconspicuous enhancement. Additionally, in this study 15 recurrences were missed on CEUS and it was unable to figure out definite reason in comparison with CECT.

It was notable that the misinterpreted abnormal hepatic blood vessels due to the presence of hepatic blood vessel enhancement in the vicinity of suspicious lesion (Figure 4) was the main reason of the false positive results

N represents the number of the detected recurrence in each patient. Data are the numbers of follow-up examinations and data in parenthesis are the numbers of new intrahepatic recurrences (detected on CEUS/CECT). CEUS: Contrast-enhanced ultrasound; CECT: Contrast-enhanced computed tomography.

on CEUS, which mainly involved arteriovenous shunting or marginally enhanced artifact of large vessel and may be caused by the ablation or severe liver cirrhosis. The misinterpreted hepatic blood vessels usually showed hyperenhancement in the arterial phase and iso-enhancement in the portal-late phase on CEUS[13,34]. In this study, a total of 14 misinterpreted hepatic blood vessels were misdiagnosed as false positive LTPs (83.3%, 5/6) or new intrahepatic recurrence (69.2%, 9/13) by CEUS.

There are some limitations in this study: firstly, although the study was designed prospectively, not all the HCC patients who underwent ablation therapy received follow-up assessment by this paired CEUS and CECT examinations due to the low compliance of the patients, which may lead to bias of patient selection. Secondly, CECT was used as the reference standard in this study and not all the detected LTPs and new intrahepatic recurrences were confirmed by pathology. However, it was hard to obtain pathological results for all the lesions found in the follow-up due to the ethical concern and under current situation CECT is still acceptable to be used as the standard. Thirdly, we did not evaluate the role of CEUS using different ablation techniques. There might be some differences of the incidence of LTP or new intrahepatic recurrence between different ablation techniques such as RFA and EA, *etc*., because they have different efficacies in treating HCC. However, the role of the study was not to evaluate the treatment efficacy of different ablation therapies, but to evaluate the ability of CEUS in treatment response assessment. In theory, the viable tumor tissue will show arterial hypervascularity on CEUS, whether it is residual tumor tissue or the recurrent tumor, and whether it is after RFA or after EA. In addition, the number of patients undergoing EA was small. Finally, further prospective study with a large number of cases is necessary to confirm the results of the present study and to evaluate the real value of CEUS in the follow-up.

In conclusion, the sensitivity of CEUS in detecting LTP and new intrahepatic recurrence after percutaneous ablation therapy is relatively low in comparison with CECT. CEUS cannot replace CECT in the follow-up assessment after percutaneous ablation for HCC.

COMMENTS

Background

For the patients with hepatocellular carcinoma (HCC) after percutaneous ablation therapy, the regular follow-up after ablation can detect local tumor progression (LTP) and new recurrence as early as possible, so as to facilitate further treatment in time, and therefore can benefit the survival. Thus the follow-up assessment, similar to surveillance and diagnosis, plays a key role in the management of HCC. However, at present, only contrast-enhanced computed tomography (CECT) and contrast-enhanced magnetic resonance imaging (CEMRI), are recommended as accurate and reliable imaging tools and applied to the follow-up assessment. Unfortunately, some factors, such as high cost, radiation and side effect of agents, limit its application.

Research frontiers

Contrast-enhanced ultrasound (CEUS) is a new imaging technique developed in recent decade. A lot of previous studies have demonstrated that CEUS is comparable to CECT and CEMRI in the area of characterization and treatment response assessment of HCC. Regarding the role of CEUS in follow-up assessment for HCC after ablation, most studies just focus on targeted lesion assessment and seldom investigate its capability of detecting LTP and new intrahepatic recurrence by scanning whole liver. Whether CEUS can be competent to this follow-up assessment is still controversial.

Innovations and breakthroughs

In most of the previous studies, CEUS has a good performance for treatment response assessment after HCC ablation, while just for the specific lesions. In this study, the authors aimed to investigate the ability of CEUS by scanning whole liver for detecting the LTPs and new intrahepatic recurrences, most of which are unknown in number, size and location, *etc*. It is concluded that CEUS is inferior to CECT in the follow-up assessment of HCC after ablation, which is mainly due to the innate defect of CEUS, such as limited acoustic penetration, display scope and relatively short duration of artery phase. Additionally, the incompetence of CEUS in the follow-up assessment might result from some traits of LTPs and new intrahepatic recurrences after HCC ablation, such as its small size, deep location, and atypical enhancement patterns.

Applications

The study results suggest that in follow-up assessment after HCC ablation CEUS can not take place of CECT and CEMRI for whole liver scanning, but can act as an adjuvant imaging tool for assessing the specific lesions.

Terminology

Treatment response assessment is performed in a month after HCC ablation by using CECT or CEMRI to assess the efficacy of ablation. Follow-up assessment: after complete ablation of HCC is confirmed by treatment response assessment, the patients will be follow-up regularly for monitoring the progression and recurrence.

Peer review

In this prospective study, the authors investigated extensively the role of CEUS in the follow-up of HCC patients undergoing radiofrequency ablations with CECT as the reference standard. The conclusion drawn by the authors is that the ability of CEUS in detecting LTP and new intrahepatic recurrence after percutaneous abla-

tion therapy is inferior to CECT. This is the first study to evaluate the role of CEUS in the follow-up assessment after percutaneous ablation therapy for HCC and the results are relevant and objective. The conclusions are very important, which indicate that people should not overestimate the role of CEUS in the follow-up even though it is meaningful in local treatment evaluation.

Abstract

AIM: To investigate the role of suppressor of cytokine signaling 3 (SOCS3) silencing in epithelial-mesenchymal transition (EMT) involved in a human hepatocellular carcinoma MHCC97H cell line.

METHODS: MHCC97H cells were transiently transfected with SOCS3 small-interfering RNA (siRNA). Morphological changes of the transfected cells were observed under microscope. Expressions of E-cadherin, Vimentin and α-smooth muscle actin (α-SMA) were identified with immunofluorescence. Furthermore, protein expressions and mRNA levels of characteristic markers of EMT (E-cadherin, Vimentin, α-SMA and Snail) were detected by Western blotting, quantitative real-time polymerase chain reaction. Transforming growth factor-β1 (TGF-β1) levels in the supernatant were measured with enzyme-linked immunosorbent assay.

RESULTS: The transfected cells with SOCS3 siRNA showed a morphological alteration from a typical cobblestone morphology to mesenchymal spindle-shaped and fusiform features. SOCS3 siRNA lessened immunofluorescent expression of E-cadherin, but elicited immunofluorescent expressions of Vimentin and α-SMA in MHCC97H cells. More importantly, compared with the negative control, depletion of SOCS3 resulted in the decrease of the epithelial marker E-cadherin ($P < 0.05$), and the increase of the mesenchymal markers Vimentin and α-SMA and the transcription factor Snail in MHCC97H cells ($P < 0.05$). Moreover, compared with the negative control, SOCS3 siRNA evidently enhanced TGF-β1 secretion in MHCC97H cells (200.20 ± 29.02 pg/mL *vs* 490.20 ± 92.43 pg/mL, $P < 0.05$).

CONCLUSION: SOCS3 silencing is able to promote EMT in MHCC97H cells *via* changing the phenotypic characteristics and modulating the characteristic markers.

Interference of suppressor of cytokine signaling 3 promotes epithelial-mesenchymal transition in MHCC97H cells. *World J Gastroenterol* 2013; 19(6): 866-873 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/866.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.866

INTRODUCTION

Hepatocellular carcinoma (HCC), the primary malignancy of the liver, ranks the sixth in incidence and the third in cancer-related deaths worldwide[1]. Poor prognosis of HCC is associated with a high potential of vascular invasion, metastasis, and recurrence even after curative surgical resection[2]. The main cause of death in HCC patients is intrahepatic metastasis, but the underlying mechanism is still not fully understood. Epithelial-mesenchymal transition (EMT) is the morphological and molecular change that occurs when epithelial cells lose their characteristics, gain mesenchymal properties and become motile, which is a key event in tumor invasion and metastasis[3-5]. The most common character of EMT is that the cells turn to spindle-like morphology from compact and well-arranged epithelial structure[6]. The epithelial marker E-cadherin plays a central role in cell-cell adhesion junctions in maintenance of cell polarity[7-9]. Loss of E-cadherin expression is commonly related to tumor invasiveness, metastasis and poor prognosis, including HCC[8]. Furthermore, the expression of mesenchymal markers such as vimentin and α-smooth muscle actin (α-SMA), along with the expression of transcription factors such as Snail is an essential molecular marker of EMT[10]. Snail is able to repress E-cadherin and overexpression of Snail has been reported to be correlated with HCC metastasis through the induction of EMT[11,12]. Moreover, the levels of transforming growth factor-β1 (TGF-β1) are very high in many cancer cells, which are related to EMT and a high incidence of metastasis[4]. In particular, TGF-β1 induced-EMT has been found to be associated with HCC invasion and metastasis[13]. EMT is being increasingly recognized as a crucial step that promotes tumor invasiveness and metastasis, thus understanding the influential factor of EMT could allow the development of novel therapies targeting at HCC invasion and metastasis.

Suppressor of cytokine signaling (SOCS) family proteins have been implicated in the negative regulation of various cytokines[14,15]. Recently, emerging evidence suggests that SOCS may be tumor suppressors. It has been postulated that SOCS can decelerate or inhibit the progression of cirrhosis and HCC[16,17]. Intriguingly, SOCS3 silencing is a significant predictor or poor survival indicating that SOCS3 might play a special role in limiting late-stage HCC progression[18]. Although SOCS3 may be involved in the suppression of tumor growth and metastasis of HCC[19,20], its role in hepatoma carcinoma cells has not been completely established. Thus, it will be of interest to learn more about whether SOCS3 depletion is able to promote EMT of HCC. The objectives of the present study were to primarily investigate the role of SOCS3 silencing in EMT involved in MHCC97H cells.

MATERIALS AND METHODS

Reagents

Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were purchased from Gibco BRL (Carlsbad, CA, United States). Polyclonal anti-human E-cadherin, Vimentin, Snail, SOCS3, anti-α-SMA and anti-β-SMA antibodies were products of Santa Cruz Biotechnology (Santa Cruz, CA, United States). Human TGF-β1 enzyme-linked immunosorbent assay (ELISA) kit was obtained from Invitrogen (Carlsbad, CA, United States). siRNA specific for SOCS3 (siGENOME SMARTpool, M-004299-08-0005) and negative control siRNA (siGENOME Non-Targeting siRNA Pool, D-001206-13-05), siGLO Green (6-FAM) Transfection Indicator (D-001630-01-05), DharmaFECT 4 transfection reagent (T-2002-04), and siGLO Green (6-FAM) Transfection Indicator (D-001630-01-05) were purchased from Dharmacon (Lafayette, CO, United States)

Cell culture

Human MHCC97H cell, a typical HCC cell line with a high metastatic potential[21], was obtained from Liver Cancer Institute of Fudan University (Shanghai, China). MHCC97H cells were cultured with DMEM supplemented with 10% FBS in a humidified incubator at 5% CO_2 and 37 ℃.

Small-interfering RNA transfection

MHCC97H cells (1×10^5) were seeded into 6-well plates and were grown until 60%-80% confluent. The cells were transiently transfected with 25 nmol/L of SOCS3 small-interfering RNA (siRNA) or negative control siRNA (NC siRNA) using Dharma FECT 4 transfection reagents according to the manufacturer's instructions. After 24 h, fluorescent images of transfected cells were observed under fluorescence microscope (Nikon, Japan). After 48 h, protein expression and mRNA levels of SOCS3 were detected by Western blotting, quantitative real-time polymerase chain reaction (PCR) and reverse transcription (RT)-PCR. Transfection rates of 60%-70% of the cells were accepted for all the experiments.

Examination of morphological changes

After application of NC siRNA or SOCS3 siRNA for 48 h, morphological changes of the transfected cells were observed under an inverted phase-contrast microscope (Nikon, Japan). The photographs were taken at 100× and 200× magnifications by a digital camera.

Immunofluorescence

MHCC97H cells were plated on cover slips and grown to confluence, and were transiently transfected with 25 nmol/L of SOCS3 siRNA or NC siRNA for 48 h. After the treatment, the cells were fixed with 4% formaldehyde-PBS for 15 min. The cell membranes were fenestrated with 0.3% Triton-100-PBS, and nonspecific binding sites were blocked with 10% goat serum. The cells were incubated with anti-human antibody including E-cadherin (1:100) or Vimentin (1:200) or α-SMA (1:100) and then incubated with the secondary antibody conjugated to fluorescein isothiocyanate. The immunolabeled cells were observed under fluorescence microscope (Nikon, Japan).

Table 1 Primers used for real-time polymerase chain reaction analysis

Gene	Primer sequence	Accession number	Expected size (bp)
E-cadherin	5′-CCCGGGACAACGTTTATTAC-3′ 5′-GCTGGCTCAAGTCAAAGTCC-3′	NM_004360.3	190
Vimentin	5′-AAAGTGTGGCTGCCAAGAAC-3′ 5′-AGCCTCAGAGAGGTCAGCAA-3′	NM_003380.2	200
α-SMA	5′-GCGCAAATACTCGGTGTGGA-3′ 5′-CCCCCCCATTGAGAAGATTC-3′	NM_001141945.1	170
Snail	5′-TGGTTGCTTCAAGGACACAT-3′ 5′-GTTGCAGTGAGGGCAAGAA-3′	NM_003068.3	141
SOCS3	5′-CAGGAATGTAGCAGCGATGGAA-3′ 5′-CCTGTCCAGCCCAATACCTGA-3′	NM_003955.3	125
β-actin	5′-ATCGTGCGTGACATTAAGGAGAAG-3′ 5′-AGGAAGGAAGGCTGGAAGAGTG -3′	NM_001101	179

α-SMA: α-smooth muscle actin; SOCS3: Suppressor of cytokine signaling 3.

ELISA

After application of NC siRNA or SOCS3 siRNA for 48 h, concentration of TGF-β1 in the supernatant of the cells was measured by ELISA kits according to the manufacturer's instructions.

Western blotting analysis

As described previously[22], protein samples (25 μg) were separated on sodium dodecyl sulfate polyacrylamide gel electrophoresis gels and transferred onto a polyvinylidene difluoride membrane (Bio-Rad Laboratories, Hercules, CA, United States). The membranes were blocked with 5% nonfat dry milk in Tris-buffered saline containing 0.1% Tween 20, and incubated with specific antibodies against E-cadherin (1:200), Vimentin (1:200), Snail (1:100), SOCS3 (1:200), α-SMA (1:400) and β-actin (1:400). The expression of β-actin was used as a loading control. Reagents (Pierce Corp., Rockford, IL, United States) for the enhanced chemiluminescence were applied to the blots, and the light signals were detected by X-ray film. Optical densities of the bands were scanned and quantified with the Syngene Gene Tools (Syngene Corp., Cambridge, United Kingdom). Three independent experiments were carried out to study protein expression.

Quantitative real-time PCR and RT-PCR

mRNA levels were determined by our previous method[22]. Total RNA was isolated using a TRIzol Kit (Invitrogen Corp., Carlsbad, CA, United States). cDNA was synthesized from 1 μg samples of total RNA using Revert Aid™ First Strand cDNA Synthesis Kit (Fermentas, St. Leon-Rot, Germany) following the manufacturer's instructions. Real-time PCR was performed with the SYBR Premix Ex Taq™ Ⅱ Perfect Real Time kit (Takara, Japan) on an ABI QPCR System (Applied Biosystems, CA, United States) following the manufacturer's instructions. The samples were run in triplicate. Primers for human E-cadherin, Vimentin, Snail, SOCS3, α-actin and β-actin were designed with Beacon designer v 4.0 (Premier Biosoft, United States) (Table 1). Traditional PCR was performed according to the manufacturer's instructions. The RT-PCR products were analyzed by electrophoresis through 2% agarose gels containing ethidium bromide. A melting point dissociation curve generated by the instrument was used to confirm that only a single product was present. Quantization of relative gene expression was calculated by the comparative Ct method ($2^{-\Delta\Delta CT}$) as described by the manufacturer. Data were normalized to human β-actin mRNA levels. Three independent experiments were carried out to study mRNA levels.

Statistical analysis

All data were expressed as the mean ± SD from three different experiments. Statistical analysis were carried out with Student's *t* test for independent samples. In all cases, a value of $P < 0.05$ was considered statistically significant.

RESULTS

Fluorescent detection of transfected cells

After MHCC97H cells were transiently transfected with SOCS3 siRNA (25 nmol/L) and siGLO Green Transfection Indicator (50 nmol/L) for 24 h, fluorescent expression was observed under fluorescence microscope. Compared with the control, the transfected cells with SOCS3 siRNA showed a green fluorescence (Figure 1). The results illustrated that SOCS3 siRNA had been successfully transfected into MHCC97H cells.

Effect of SOCS3 siRNA on morphological changes of MHCC97H cells

To investigate the role of SOCS3 in morphological changes of MHCC97H cells, the cells were transiently transfected with NC siRNA or SOCS3 siRNA for 48 h. As shown in Figure 2, knockdown of SOCS3 resulted in a significant change in cell morphology, as demonstrated by phase-contrast microscopy, with transition from a typical cobblestone morphology to mesenchymal spindle-shaped and fusiform features. The acquisition of a fibroblastic morphology suggested that MHCC97H cells could undergo the mesenchymal change after treated with SOCS3 siRNA.

Effect of SOCS3 siRNA on immunofluorescent expressions of E-cadherin, Vimentin and α-SMA in MHCC97H cells

To examine the effect of SOCS3 on immunofluorescent expressions of E-cadherin, Vimentin and α-SMA in MHCC97H cells, the cells were transiently transfected with NC siRNA or SOCS3 siRNA for 48 h, and expressions of E-cadherin, Vimentin and α-SMA were identified with immunocytofluorescence. The results showed that SOCS3 siRNA might lessen immunofluorescent expression of E-cadherin, but elicit immunofluorescent expressions of Vimentin and α-SMA in MHCC97H cells (Figure 3).

Effect of SOCS3 siRNA on characteristic markers of EMT in MHCC97H cells

To further explore the impact of SOCS3 on characteristic markers of EMT in MHCC97H cells, the cells were

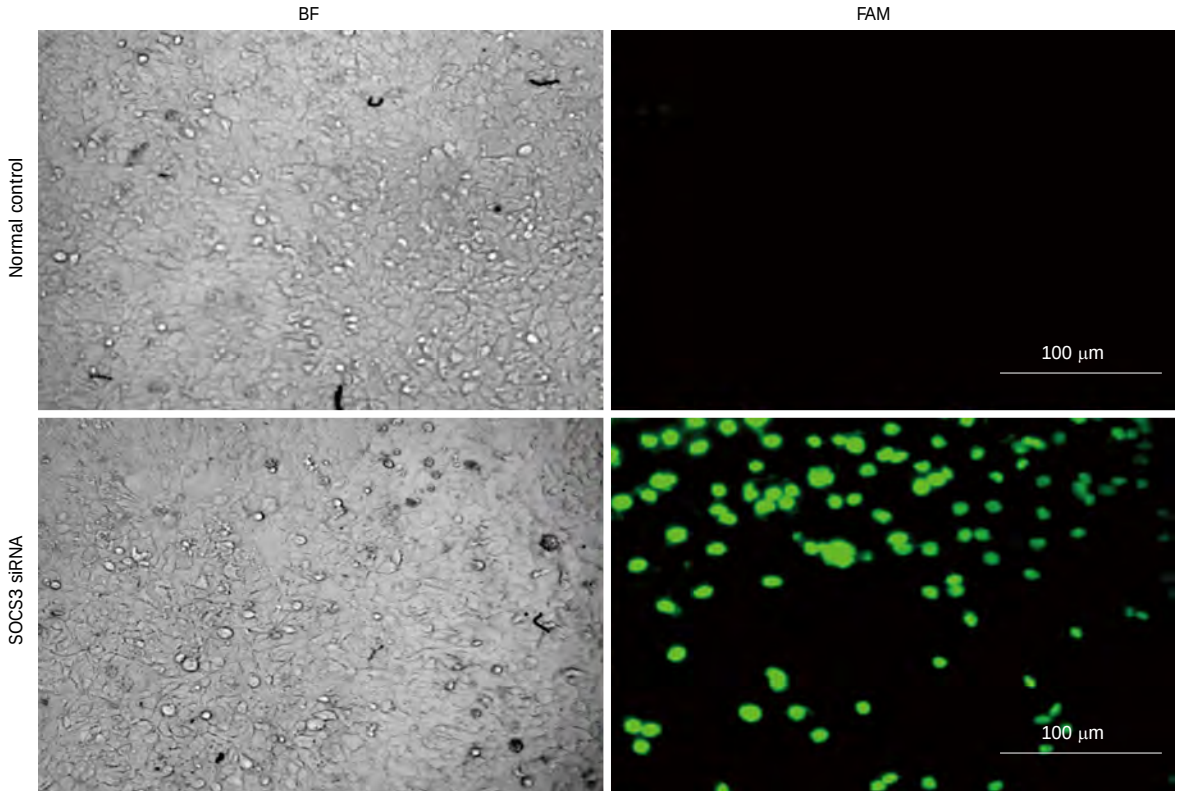

Figure 1 Fluorescent detection of transfected cells. MHCC97H cells were transiently transfected with suppressor of cytokine signaling 3 (SOCS3) small-interfering RNA (siRNA) for 24 h, green fluorescence was observed under fluorescence microscope. BF: Bright field; FAM: Fluorescence from fluorescein-labeled scramble-siRNA.

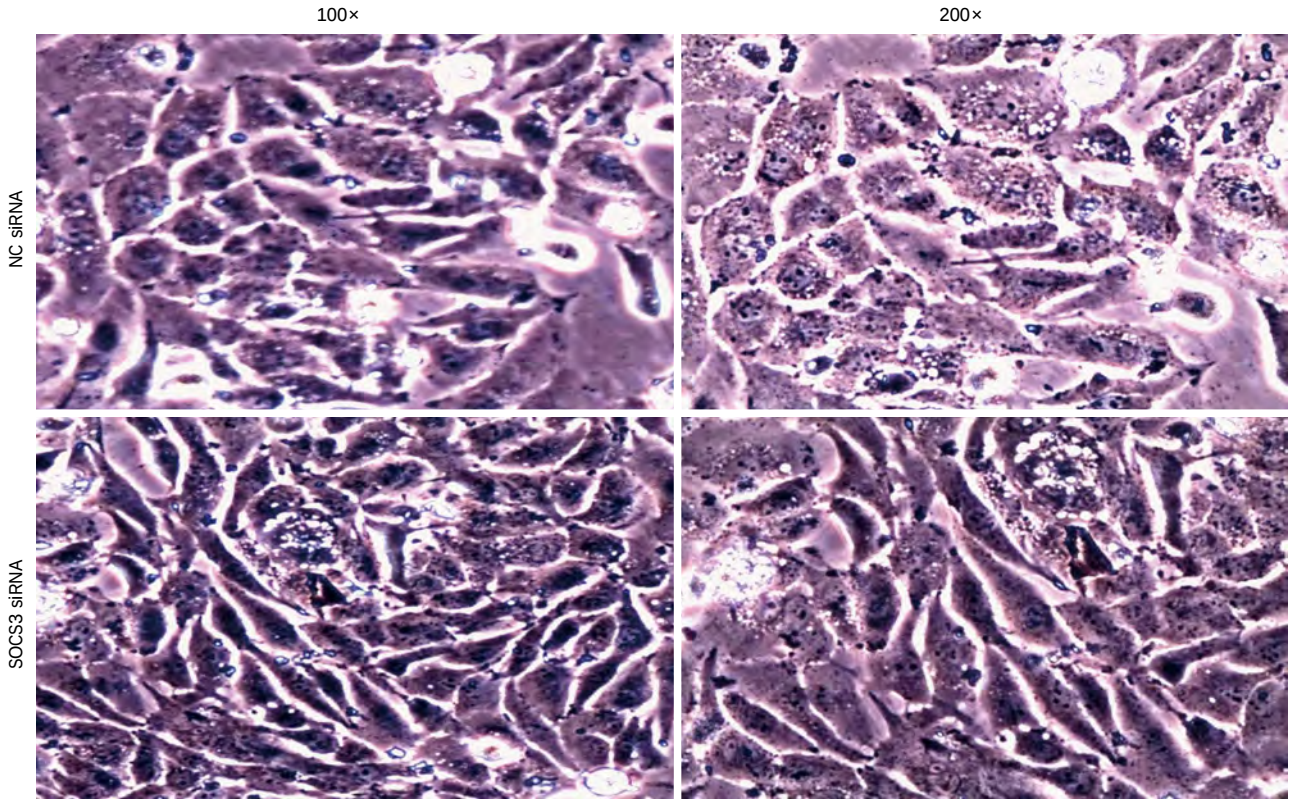

Figure 2 Effect of suppressor of cytokine signaling 3 small-interfering RNA on morphological changes of MHCC97H cells. After application of negative control (NC) small-interfering RNA (siRNA) or suppressor of cytokine signaling 3 (SOCS3) siRNA for 48 h, morphological changes of cells were recorded with an inverted phase-contrast microscope.

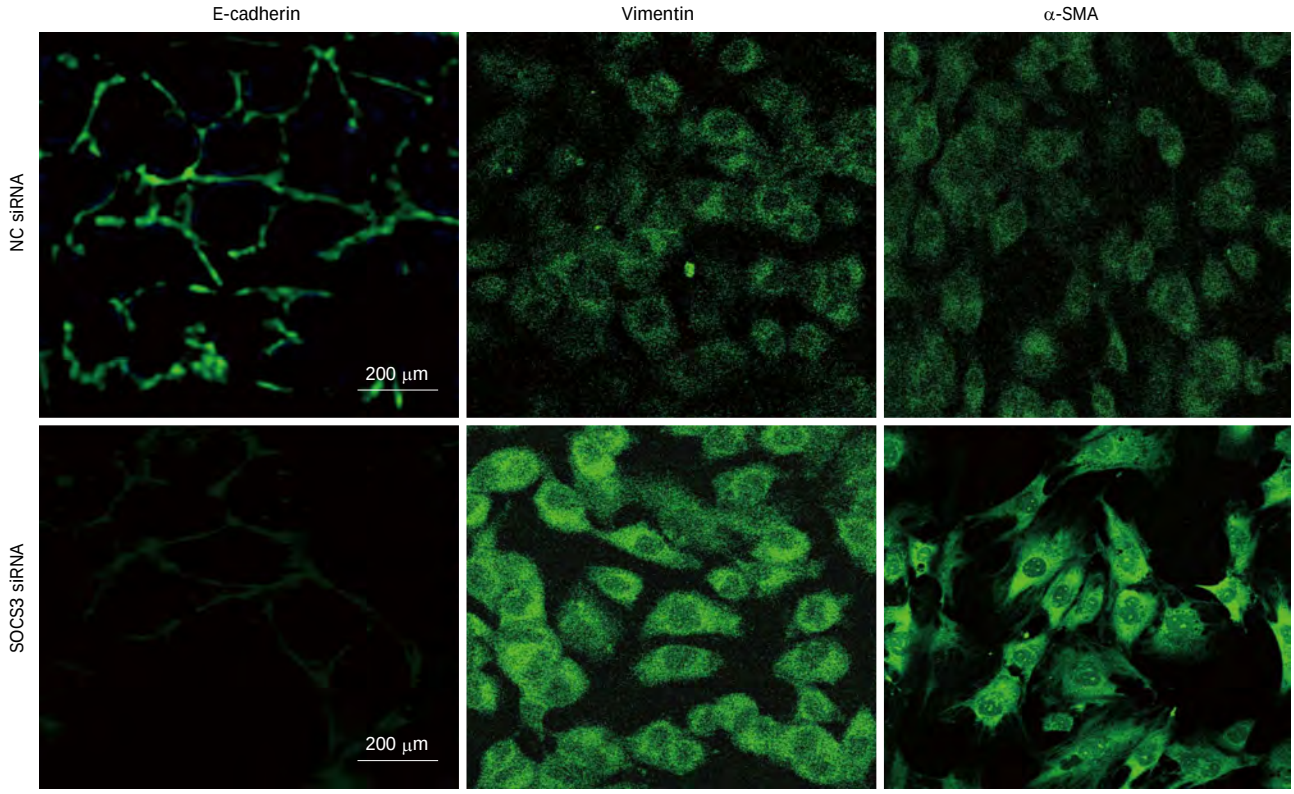

Figure 3 Effect of suppressor of cytokine signaling 3 small-interfering RNA on immunofluorescent expressions of E-cadherin, Vimentin and α-smooth muscle actin in MHCC97H cells. The cells were transiently transfected with negative control (NC) small-interfering RNA (siRNA) or suppressor of cytokine signaling 3 (SOCS3) siRNA for 48 h, expressions of E-cadherin, Vimentin and α-smooth muscle actin (SMA) were identified with immunofluorescence.

transiently transfected with NC siRNA or SOCS3 siRNA for 48 h, and protein expression and mRNA levels of SOCS3 were detected. Knock down efficiency of SOCS3 was 69.2% or 63.5% as determined by Western blot or quantitative real-time PCR ($P < 0.05$) (Figure 4A and B). These results showed that SOCS3 siRNA could efficiently reduce protein expression and mRNA levels of SOCS3. Meanwhile, depletion of SOCS3 resulted in the decrease of the epithelial marker E-cadherin, and the increase of the mesenchymal markers Vimentin, α-SMA and Snail in MHCC97H cells ($P < 0.05$) (Figure 4C and D).

Effect of SOCS3 siRNA on TGF-β1 levels in MHCC97H cells

The above characteristic markers of EMT (E-cadherin, Vimentin, α-SMA and Snail) modulate the process of EMT, and TGF-β1 is believed to play a major role in this process. We then observed TGF-β1 levels in MHCC97H cells after SOCS3 silencing. As described in Figure 5, compared with the negative control, depletion of SOCS3 remarkably aggravated TGF-β1 secretion in MHCC97H cells (200.20 ± 29.02 pg/mL *vs* 490.20 ± 92.43 pg/mL, $P < 0.05$), suggesting that SOCS3 is able to decrease TGF-β1 generation of MHCC97H cells.

DISCUSSION

The present study demonstrated that the transfected cells with SOCS3 siRNA showed a morphological alteration from a typical cobblestone morphology to mesenchymal spindle-shaped and fusiform features, suggesting that MHCC97H cells might adopt the mesenchymal cell phenotype. More importantly, we found that lack of SOCS3 resulted in the decrease of the epithelial marker E-cadherin, and the increase of the mesenchymal markers Vimentin and α-SMA and the expression of transcription factor Snail in MHCC97H cells. In addition, SOCS3 siRNA evidently enhanced TGF-β1 secretion in MHCC97H cells. These results reveal that interference of SOCS3 is able to facilitate EMT involved in MHCC97H cells.

SOCS3 functions as a negative regulator of the Jak/Stat signal transduction pathway and has been described as a tumor suppressor in human cancers[23,24]. It has also been reported that SOCS3 silencing plays a role in human HCC and SOCS3 has a tumor suppressor role in mouse models of HCC[25]. So far, the relationship between SOCS3 and EMT in HCC is still elusive. As a result, our present study has focused on the effect of SOCS3 silencing on EMT in MHCC97H cells. We found for the first time that SOCS silencing was associated with EMT process in MHCC97H cells because of changes of the phenotypic characteristics.

EMT is a key and dynamic process that facilitates invasion of tumor cells. In addition to changes of the phenotypic characteristics, tumor cells are reported to gain the molecular characteristics of EMT including down-regulation of epithelial marker (E-cadherin) and up-regulation of mesenchymal markers (Vimentin and α-SMA)[26].

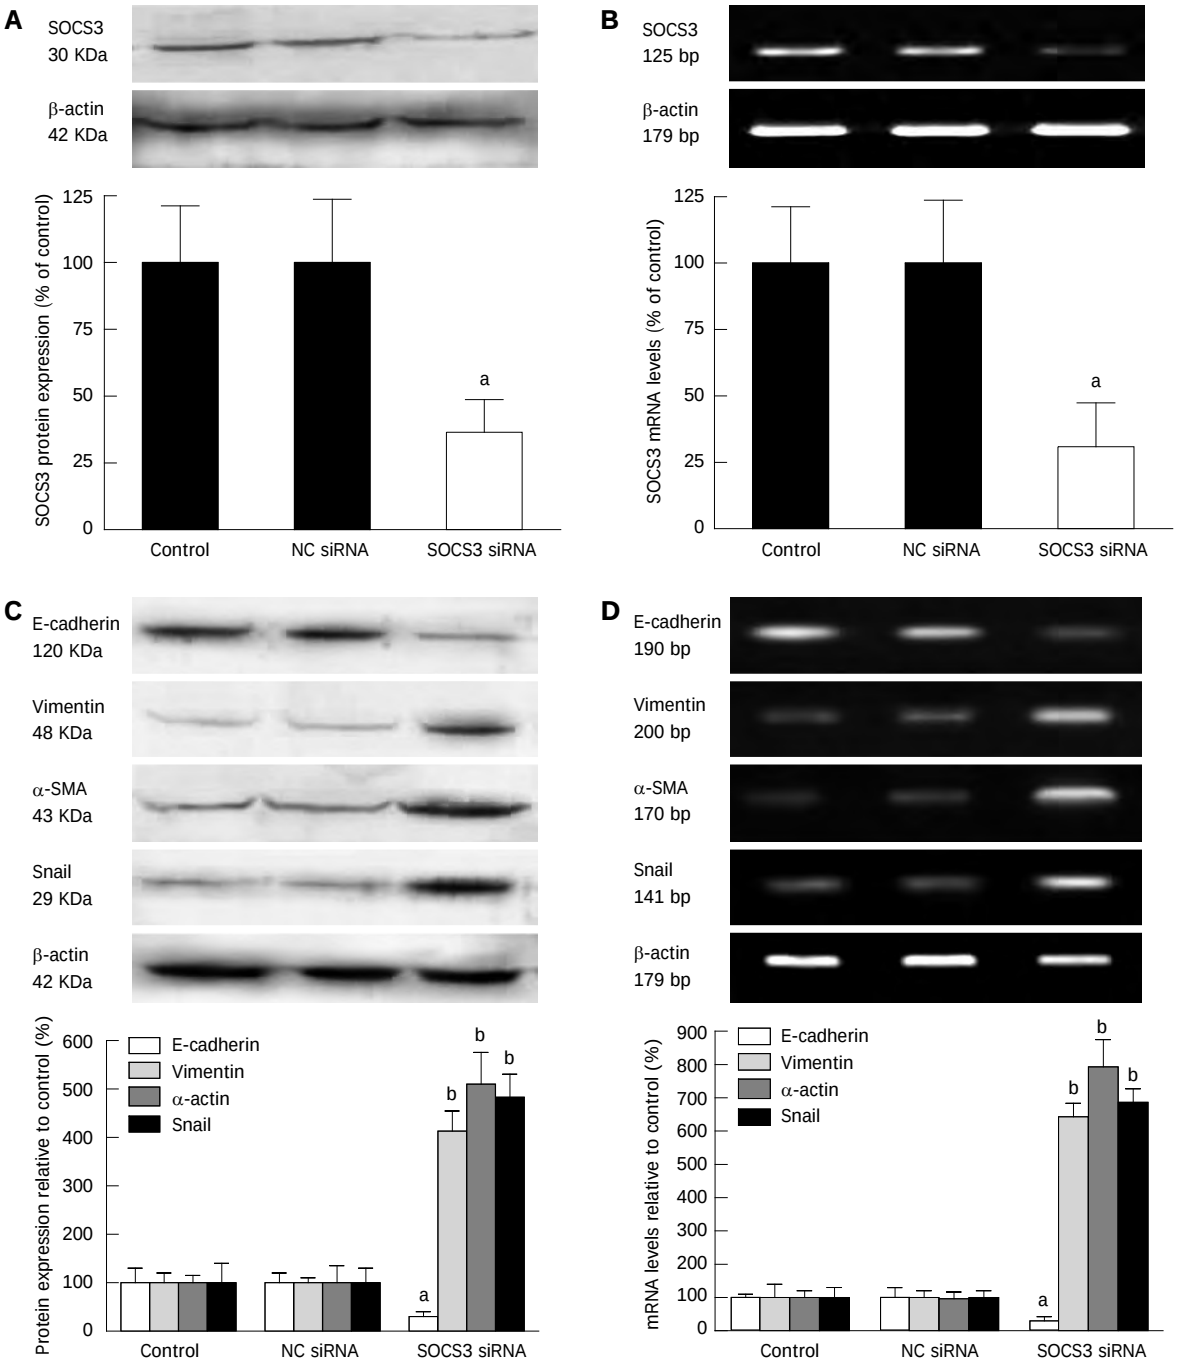

Figure 4 Effect of suppressor of cytokine signaling 3 small-interfering RNA on expression of epithelial-mesenchymal transition-associated molecules in MHCC97H cells. The cells were transiently transfected with negative control (NC) small-interfering RNA (siRNA) or suppressor of cytokine signaling 3 (SOCS3) siRNA for 48 h. A: Protein expression and mRNA levels of SOCS3 in MHCC97H cells were detected by Western blotting; B: Reverse transcription-polymerase chain reaction (RT-PCR) and quantitative real-time PCR; C: Protein expression and mRNA levels of epithelial-mesenchymal transition-associated molecules in MHCC97H cells were analyzed by Western blotting; D: RT-PCR and quantitative real-time PCR after normalization to β-actin mRNA. Data are presented as the mean ± SD from three independent experiments. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* NC siRNA.

Loss of E-cadherin and gain of Vimentin or α-SMA are the most important consequence of EMT that facilitate invasion and metastasis of tumor cells[27-29]. In the present study, transfection of MHCC97H cells with SOCS3 siRNA resulted in down-regulation of epithelial marker E-cadherin and up-regulation of mesenchymal markers Vimentin and α-SMA, further confirming the promotion of EMT by SOCS3 silencing in MHCC97H cells.

Snail has been shown to be a strong repressor of transcription of the E-cadherin gene and evokes tumorigenic and invasive properties in epithelial cells upon overexpression[30]. It has been reported that the high expression of Snail leads to EMT and enhances motility and invasiveness of tumor cells[31]. Inverse correlation of Snail and E-cadherin was detected in HCC-derived cell lines[32]. In the present study, examination of Snail expression in

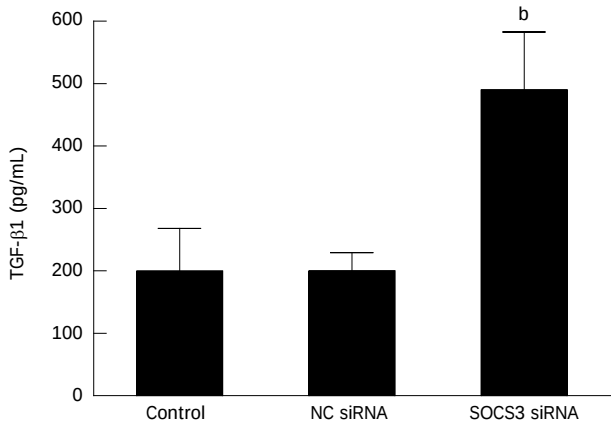

Figure 5 Effect of suppressor of cytokine signaling 3 small-interfering RNA on transforming growth factor-β1 levels in MHCC97H cells. After application of negative control (NC) small-interfering RNA (siRNA) or suppressor of cytokine signaling 3 (SOCS3) siRNA for 48 h, concentration of transforming growth factor-β1 in the supernatant of the cells was measured by enzyme-linked immunosorbent assay. Data are presented as the mean ± SD from three independent experiments. $^{b}P < 0.01$ *vs* NC siRNA. TGF: Transforming growth factor.

MHCC97H cells with SOCS3 siRNA transfection indicated a significant increase in protein expression and mRNA levels of Snail, possibly leading to loss of E-cadherin resulting in the induction of EMT. These results are consistent with the mechanism of induction of EMT[11,12].

TGF-β1 is known to be the most potent inducer of EMT, and it initiates morphological transition of the cells from an epithelial to a fibroblastic appearance, accompanied by loss of epithelial cell marker such as E-cadherin and a gain of mesenchymal cell marker such as Vimentin[33,34]. During the late stages of HCC tumorgenesis, TGF-β1 stimulates cellular invasion through the EMT program[35]. A previous study also demonstrates that TGF-β1 expression is enhanced by SOCS3 gene deletion in HCC[25]. In this work, we further detected TGF-β1 levels in MHCC97H cells transfected with SOCS3 siRNA. The results displayed that depletion of SOCS3 remarkably aggravated TGF-β1 secretion in MHCC97H cells, further illustrating the induction of EMT by SOCS3 silencing.

In conclusion, the present study provides direct evidence that SOCS3 silencing is able to promote EMT in MHCC97H cells *via* changing the phenotypic characteristics and modulating the characteristic markers, suggesting that SOCS3 could play a potential role in EMT in MHCC97H cells. We also identified a novel relationship between SOCS3 silencing and EMT in MHCC97H cells, however, further *in vitro* and *in vivo* studies are necessary to find out the exact molecular mechanism associated with the effect of SOCS3 in EMT of HCC.

COMMENTS

Background

The main cause of death of patients with hepatocellular carcinoma (HCC) is intrahepatic metastasis, but the underlying mechanism is still not fully understood. Epithelial-mesenchymal transition (EMT) is being increasingly recognized as a crucial step that promotes HCC invasiveness and metastasis. However, the role of suppressor of cytokine signaling (SOCS) in EMT involved in HCC is not well documented.

Research frontiers

This study demonstrated that depletion of SOCS3 resulted in the decrease of the epithelial marker E-cadherin, and the increase of the mesenchymal markers Vimentin and α-smooth muscle actin and the expression of transcription factor Snail in MHCC97H cells. In addition, SOCS3 small-interfering RNA evidently enhanced transforming growth factor-β1 secretion in MHCC97H cells. These results reveal that interference of SOCS3 is able to facilitate EMT involved in MHCC97H cells.

Innovations and breakthroughs

The present study provides direct evidence that SOCS3 silencing has the ability to promote EMT in MHCC97H cells *via* changing the phenotypic characteristics and modulating the characteristic markers, suggesting that SOCS3 could play a potential role in EMT in MHCC97H cells.

Applications

The authors found a novel relationship between SOCS3 silencing and EMT in HCC, thus understanding the influential factor of EMT could allow the development of novel therapies targeting at HCC invasion and metastasis.

Terminology

EMT is the morphological and molecular changes that occur when epithelial cells lose their characteristics, gain mesenchymal properties and become motile, which is a key event in tumor invasion and metastasis; The SOCS proteins are a family of negative regulatory proteins related to wide cytokine and growth correlation factor, especially by the signal molecule in the pathway of Janus kinase/signal transducer and transcription activator.

Peer review

This study presented results suggesting that SOCS3 silencing has the ability to promote EMT in MHCC97H cells. It will help to define the role of SOCS3 as a tumor suppressor in HCC. The manuscript is well presented and of interest and it can contribute to increase the knowledge of SOCS3 silencing on EMT involved in MHCC97H cell line.

Abstract

AIM: To report the largest patient cohort study investigating the diagnostic yield of intraductal ultrasound (IDUS) in indeterminate strictures of the common bile duct.

METHODS: A patient cohort with bile duct strictures of unknown etiology was examined by IDUS. Sensitivity, specificity and accuracy rates of IDUS were calculated relating to the definite diagnoses proved by histopathology or long-term follow-up in those patients who did not undergo surgery. Analysis of the endosonographic report allowed drawing conclusions with respect to the T and N staging in 147 patients. IDUS staging was compared to the postoperative histopathological staging data allowing calculation of sensitivity, specificity and accuracy rates for T and N stages. The endoscopic retrograde cholangio-pancreatography and IDUS procedures were performed under fluoroscopic guidance using a side-viewing duodenoscope (Olympus TJF 160, Olympus, Ltd., Tokyo, Japan). All procedures were performed under conscious sedation (propofol combined with pethidine) according to the German guidelines. For IDUS, a 6 F or 8 F ultrasound miniprobe was employed with a radial scanner of 15-20 MHz at the tip of the probe (Aloka Co., Tokyo, Japan).

RESULTS: A total of 397 patients (210 males, 187 females, mean age 61.43 ± 13 years) with indeterminate bile duct strictures were included. Two hundred and sixty-four patients were referred to the department of surgery for operative exploration, thus surgical histopathological correlation was available for those patients. Out of 264 patients, 174 had malignant disease proven by surgery, in 90 patients benign disease was found. In these patients decision for surgical exploration was made due to suspicion for malignant disease in multimodal diagnostics (computed tomography scan, endoscopic ultrasound or magnetic resonance imaging). Twenty benign bile duct strictures were misclassified by IDUS as malignant while 14 patients with malignant strictures were initially misdiagnosed by IDUS as benign resulting in sensitivity, specificity and accuracy rates

of 93.2%, 89.5% and 91.4%, respectively. In the subgroup analysis of malignancy prediction, IDUS showed best performance in cholangiocellular carcinoma as underlying disease (sensitivity rate, 97.6%) followed by pancreatic carcinoma (93.8%), gallbladder cancer (88.9%) and ampullary cancer (80.8%). A total of 133 patients were not surgically explored. 32 patients had palliative therapy due to extended tumor disease in IDUS and other imaging modalities. Ninety-five patients had benign diagnosis by IDUS, forceps biopsy and radiographic imaging and were followed by a surveillance protocol with a follow-up of at least 12 mo; the mean follow-up was 39.7 mo. Tumor localization within the common bile duct did not have a significant influence on prediction of malignancy by IDUS. The accuracy rate for discriminating early T stage tumors (T1) was 84% while for T2 and T3 malignancies the accuracy rates were 73% and 71%, respectively. Relating to N0 and N1 staging, IDUS procedure achieved accuracy rates of 69% for N0 and N1, respectively. Limitations: Pretest likelihood of 52% may not rule out bias and overinterpretation due to the clinical scenario or other prior performed imaging tests.

CONCLUSION: IDUS shows good results for accurate diagnostics of bile duct strictures of uncertain etiology thus allowing for adequate further clinical management.

Intraductal ultrasound substantiates diagnostics of bile duct strictures of uncertain etiology. *World J Gastroenterol* 2013; 19(6): 874-881 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/874.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.874

INTRODUCTION

There is still ongoing debate about adequate diagnostics in bile duct strictures of unknown etiology. The application of endoscopic retrograde cholangio-pancreatography (ERCP) is considered to be an essential tool in bile duct strictures in which additional need for intervention is given[1]. The main advantage of ERCP over other imaging modalities is the ability to achieve biliary decompression and to take transpapillary specimens for histological or cytological analysis in the very same session. A large trial on biliary brush cytology, however, described poor results thus indicating the need for further studies in the analysis of appropriate tissue sampling[2]. The use of intraductal ultrasound (IDUS) performed during ERCP enables the investigator to obtain additional information concerning the bile duct wall and the periductal tissue[3]. Specifically, IDUS gives clinically important data by visualizing the wall layers in biliary strictures and estimating the extent of potentially cancerous infiltration, also enabling the investigator to perform targeted biopsies. Thus, IDUS might be instrumental in choosing the appropriate therapeutic approach and may improve our potential to differentiate benign and malignant strictures. In this matter, however, previous studies, although partly of a prospective design, have only investigated limited numbers of patients[4-6]. On the other hand, cholangioscopy is at present time a promising diagnostic technique in diagnosing bile duct strictures of unknown origin. However, so far only limited data evaluating the diagnostic impact of cholangioscopy is available. In a prospective study with 35 patients included, the sensitivity of SpyGlass-directed biopsy of intraductal lesions was 71%[7,8].

In the present large cohort of patients, we aimed to evaluate the diagnostic yield of IDUS in patients scheduled for ERCP due to indeterminate strictures or filling defects of the common bile duct.

MATERIALS AND METHODS

Data collection

At the tertiary referral center of Münster University Hospital, we retrospectively analyzed the data of our patient cohort undergoing ERCP in combination with IDUS for diagnostics of indeterminate strictures of the bile duct during 2002-2009. All patients with bile duct stenosis who had undergone ERCP and IDUS during the study period could be identified by looking for codes K83.1 and procedures 3.055 and 1440.6 according to the International Classification of Diseases. A total of 397 patients were found in our analysis who were referred to the Department of Medicine B at Münster University Hospital. Clinical records of patients were collected and carefully analyzed. Baseline characteristics, diagnostic techniques employed and histopathology were retrieved as shown in Table 1.

Exclusions

Patients not having been histopathologically controlled by surgery, forceps biopsy or with an endoscopic follow-up < 1 year in suspected benign biliary stenosis were excluded from this study.

Procedures

All 397 patients enrolled in the present study underwent ERCP with the additional application of intraductal ultrasound. In our cohort, there was no case in which a positive tissue diagnosis was already known at the time of IDUS investigation. The individual procedure was performed after written informed consent had been obtained from the patients or related persons for the endoscopic procedures. All endoscopic maneuvers were executed by highly experienced investigators according to the generally accepted guidelines with an ERCP case volume above 200/year[9]. The ERCP and IDUS procedures were performed under fluoroscopic guidance using a side-viewing duodenoscope (Olympus TJF 160, Olympus, Ltd., Tokyo, Japan). All procedures were performed

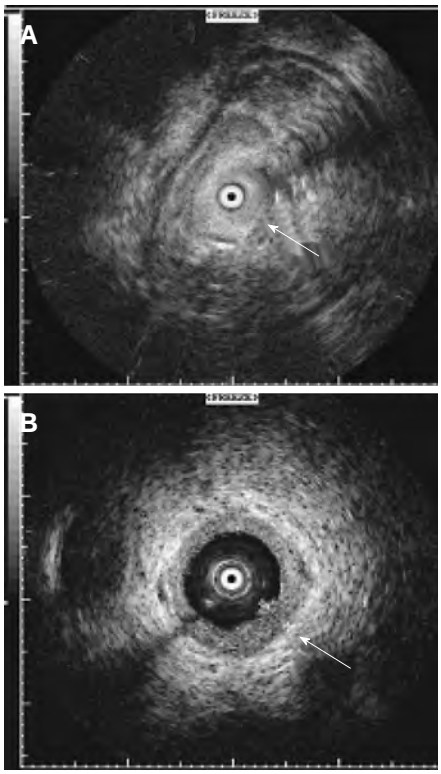

Figure 1 An exemplary benign and malignant bile duct stenosis. A: Benign bile duct stricture showing a homogeneous hyperechoic lesion with smooth margins (arrow); B: Malignant stricture showing bile duct wall thickening and irregular margins (arrow).

under conscious sedation (propofol combined with pethidine) according to the German guidelines[10]. For IDUS, a 6 F or 8 F ultrasound miniprobe was employed with a radial scanner of 15-20 MHz at the tip of the probe (Aloka Co., Tokyo, Japan). Thus a radial real-time image of 360° view was possible for optimum investigation of the area surrounding the probe. The visible depth was about 20 mm with a resolution of up to 0.1 mm (Figure 1). Three hundred and twelve IDUS procedures included additional forceps biopsies. Endoscopic transpapillary biopsies (n = 4-8 specimens) were taken out of the biliary strictures by straight or angled endoscopic forceps (MTW Endoscopy, Wesel, Germany). If insertion of the forceps into the stricture was not feasible, biopsies were retrieved from the distal margins of the bile duct stenosis[11]. Patients with eligibility for surgery were transferred to the Department of General Surgery, Münster University Hospital.

IDUS T and N staging

Two hundred and sixty-four patients were surgically explored (66% of patients). In 174 cases malignancy was proven, of those 14 patients were initially misdiagnosed by IDUS as benign, thus in these cases uT stages were not available. Thirteen of the 174 patients had surgical exploration but due to extended disease with inoperability T and N stage assessment was not done. Thus, retrospective analysis of the endosonographic report allowed drawing conclusions with respect to the T and N staging in 147 patients. IDUS staging was based on the latest TNM classification system[12]. IDUS classification of N stages was as follows: N0-no regional lymph node metastasis; N1-regional lymph node metastasis. Lymph nodes were considered positive, if at least one of the following criteria could be assessed: lymph node larger than 10 mm, delineated borders, hypoechoic structure resembling the primary tumor, roundish shape.

IDUS staging was compared to the postoperative histopathological staging data allowing calculation of sensitivity, specificity and accuracy rates for T and N stages. Due to the limited penetration depth of IDUS, M staging was not performed.

Follow-up

All patients with suspected benign strictures had routine follow-up the day following intervention as well as every three months the first year, every 6 mo the second year and annually up to the third year after intervention at our department. The follow-up procedure was performed according to a surveillance protocol and included laboratory testing and abdominal ultrasound. In cases of biliary plastic stent insertion, the follow-up procedures included ERCP and where appropriate biliary plastic stent changing.

Statistical analysis

Data were analyzed using SPSS 17.0 (Chicago, IL, United States). Results were expressed as medians and ranges. For each of the diagnostic measures, sensitivity, specificity and accuracy rates were calculated for each individual T and N stage. In all cases, gold standard was the histopathologic staging of specimens. Comparison of accuracy rates between groups (localization of stricture) was performed by using the Mann-Whitney U test and the χ^2 test as appropriate. Differences were considered statistically significant if $P < 0.05$. For statistical analysis, sensitivity, specificity, pre-test likelihood and accuracy rates were calculated as follows: sensitivity = true positives/(true positives + false negatives); specificity = true negatives/(true negatives + false positives); pre-test likelihood = truly malignant cases/total cases; accuracy = (true positives + true negatives)/total cases.

RESULTS

Patient characteristics

The study cohort included 397 patients (210 men and 187 women; median age 61.4 ± 13 years). Two hundred and sixty-four patients were referred to the department of surgery for operative exploration, thus surgical histopathological correlation was available for those patients. Out of 264 patients, 174 had malignant disease proven by surgery, in 90 patients benign disease was found. In these patients decision for surgical exploration was made due to suspicion for malignant disease in multimodal diagnostics [computed tomography (CT) scan, endoscopic ultrasound (EUS) or magnetic resonance imaging (MRI)]. A total of 133 patients were not surgically explored.

CBD: Common bile duct; PSC: Primary sclerosing cholangitis; M: Man; F: Female; IDUS: Intraductal ultrasound.

Thirty-two patients had palliative therapy due to extended tumor disease in IDUS and other imaging modalities. In 6 patients calculus extraction was performed due to choledocholithiasis. Ninety-five patients had benign diagnosis by IDUS, forceps biopsy and radiographic imaging and were followed by a surveillance protocol with a follow-up of at least 12 mo; the mean follow-up was 39.7 mo (Table 1). A flow chart showing the enrollment of the study patients with distribution based on IDUS diagnosis is presented in Figure 2.

IDUS

IDUS was performed in all patients enrolled. Pre-test likelihood for malignant stenosis in our patient cohort of 52% (95%CI: 47%-57%) was calculated. Twenty benign bile duct strictures were initially misclassified by IDUS as malignant while 14 malignant bile duct strictures were initially interpreted by IDUS as benign resulting in sensitivity, specificity and accuracy rates of 93.2%, 89.5% and 91.4%, respectively (Tables 2 and 3). In the subgroup analysis of malignancy prediction, IDUS showed best performance in cholangiocellular carcinoma as underlying disease (sensitivity rate, 97.6%) followed by pancreatic carcinoma (93.8%), gallbladder cancer (88.9%) and ampullary cancer (80.8%) (Tables 2 and 3).

Accuracy rates of IDUS for malignant stenoses in the proximal, middle or distal third of the common bile duct did not differ statistically in terms of localization (Table 4).

Accuracy of IDUS in T and N staging

Overall T and N staging results with the intraductal ultrasound miniprobe are given in Tables 5 and 6. The accuracy rate for discriminating early T stage tumors (T1) was 84% while for T2 and T3 malignancies the accuracy rates were 73% and 71%, respectively (Table 5). Relating to N0 and N1 staging, IDUS achieved accuracy rates of 69% each (Table 6).

DISCUSSION

Endoscopic ultrasound has proved to be an accurate imaging device in the diagnostics and staging of malig-

IDUS: Intraductal ultrasound.

nant bile duct strictures[13]. However, in previous studies, although partly of a prospective design, only limited numbers of patients were investigated[4-6]. Therefore, in the present to our knowledge largest patient cohort, we aimed to substantiate the diagnostic yield of IDUS.

IDUS has also proved superior to other imaging modalities such as CT and MRI[14-16]. Its limitation, however, is the minor ultrasonic penetration depth. Consequently, intraductal ultrasonography tends to understage tumors of the pancreaticobiliary tract. Therefore, IDUS does not seem useful in extensive lymph node staging[17].

It is consistently accepted that in the bilio-pancreatic tract depiction of tumors by means of ultrasound and CT is difficult, but these tumors can appropriately be represented through endoscopic ultrasound[18] or IDUS[19,20]. Although IDUS is superior to EUS regarding diagnostics of tumor extension in the pancreatic and biliary duct, the use of IDUS has not been taken up widely yet.

A promising diagnostic tool in the differentiation of bile duct strictures is single- operator peroral cholangioscopy (SOC) as it provides direct visualization of the bile duct and facilitates diagnostic procedures and therapeutic intervention. The diagnostic utility of SOC for indeterminate biliary lesions has been the topic of a few recently published studies[21,22].

However, only limited data with smaller patient cohorts exist. Promising results with an accuracy of SOC for diagnosing malignant lesions has been reported to range between 64% and 89%. SOC-guided biopsies have been shown to be adequate in 72% to 82%[21-23]. Therefore, its therapeutic and diagnostic yield in patients with bile duct strictures remains uncertain. A prospective randomized trial comparing various endoscopic imaging and radiographic imaging modalities with each other would be desirable, especially in a multi-center study design.

In our patient cohort of 397 patients with bile duct strictures of initially unknown etiology, using IDUS we observed sensitivity, specificity and accuracy rates of 93%, 89% and 91%, respectively, for discriminating malignant from benign lesions. In previous studies with a limited number of patients, IDUS accuracy rates between 84% and 95% are described as presented in Table 7. IDUS also showed excellent results in regard to localization of biliary stenoses with an accuracy rate of 93% (proximal part of bile duct), 93% (middle) and 89% (distal), respectively (*P* values not significant) (Table 4). In our study, endoscopic transpapillary biopsies (ETP) were additionally obtained in 312 cases. Out of 226 bile duct strictures initially diagnosed to be benign by ETP, 101 cases eventually turned out as malignancies. There were no false-positive results in forceps biopsy histopathology leading to sensitivity, specificity and accuracy rates of 46%, 100% and 67.6%, respectively[11]. Thus the authors conclude that ETPs are of limited value for detecting additional malignant bile

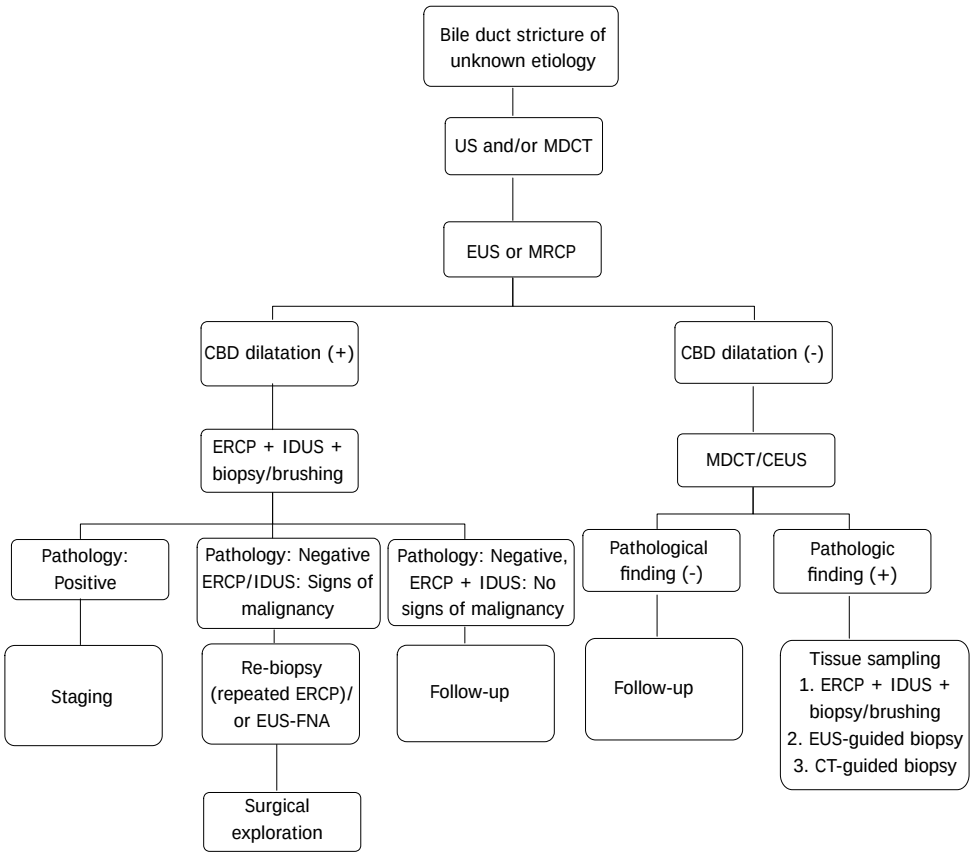

Figure 3 Suggested algorithm for the evaluation of bile duct strictures of uncertain etiology. IDUS: Intraductal ultrasound.

duct strictures.

In matters of tumor entity, IDUS demonstrated best results in cholangiocellular carcinoma (CCC) with accuracy and sensitivity rates of 92% and 98%, respectively. As far as T staging is concerned, upon IDUS the normal bile duct wall appears as either two or three layers. However, in some patients differentiation of the fibromuscular layer from the perimuscular connective tissue can be difficult thus limiting the ability to distinguish CCC stages 1 and 2, although this distinction is usually not clinically relevant with respect to treatment options[24]. According to a study conducted earlier by our group[25], the various layers of the extrahepatic bile duct wall as described by the Union for International Cancer Control 7th tumor-node-metastasis (TNM) classification[12] are not consistently demonstrable histomorphologically, immunohistochemically or by endosonographic imaging. Domagk *et al*[25] suggested that difficulties in distinguishing tumor invasion encroaching beyond the bile duct (T2) and into the pancreas (T3) pose problems for the present TNM-classification. A better metric may be to combine T2- and T3-staged tumors into one single class.

T staging of other tumor entities such as pancreatic, ampullary or gallbladder cancer may be limited in mini-probe intraductal ultrasound due to its maximum penetration depth of 20 mm. The T stage, *e.g.*, of pancreatic tumors among other factors relies on tumor size. Further, the assessment of vascular tumor infiltration is restricted due to the technical limitation of penetration depth and absence of potential duplex sonography. In a study by Tamada *et al*[26,27], vascular infiltration of CCC was assessed: Depiction of the right hepatic artery was possible in 100% of the cases while in less than 20% of the cases depiction of the common hepatic artery or the left hepatic artery succeeded. On that account, the assessment of tumor infiltration into the above mentioned vessels was inaccurate.

In summary, IDUS tends to understage tumors of the pancreaticobiliary tract. Specific analysis of our patient cohort revealed overall T staging accuracy rates as follows: T1 84%, T2 73% and T3/T4 71% as displayed in Table 5. N staging accuracy was calculated as 69% (Table 6).

In recent years, other imaging techniques like magnetic resonance cholangio-pancreatography (MRCP) and multi-detector computed tomography have also been evaluated for their diagnostic sensitivity and specificity in biliary duct tumors. In a first prospective comparison of the diagnostic accuracy of ERCP, MRCP, CT and EUS in biliary duct strictures by Rösch *et al*[28], 50 patients were

analyzed. In their patient cohort, relating to diagnosis of malignancy sensitivity and specificity rates of 85%/75% for ERCP/PTC, 85%/71% for MRCP, 77%/63% for CT, and 79%/62% for EUS were observed. Those authors concluded that although MRCP provides the same imaging information as direct cholangiography, it has only limited specificity for the diagnosis of malignant strictures[28]. A prospective study by our group confirmed superiority of ERCP supplemented by IDUS in differentiating benign from malignant strictures as compared with MRI[29]. Classification of T stages by endolumenal ultrasound was also the topic of an investigation conducted by Menzel *et al*[15] demonstrating similar accuracy rates (77.7%) for T staging as shown in the present study.

Admittedly, as limitations of the present study the retrospective design and certain bias have to be mentioned. In our cohort, there was no case in which a positive tissue diagnosis was already known at the time of IDUS investigation but our pre-test likelihood of 52% may not rule out bias and over-interpretation due to the clinical scenario or other prior performed imaging tests. Our patient cohort is certainly a highly selected one making the probability of malignant bile duct stricture more obvious. On the one hand, the prevalence of malignancy in our patient cohort was 52% as expressed by the pre-test likelihood. On the other hand, the accuracy of IDUS for detecting malignant bile duct strictures exceeds 91%. Therefore, our analysis of a very large patient cohort shows good results of IDUS with regard to accurate diagnostics of bile duct strictures of uncertain etiology and, thus, allows for adequate further clinical management. In particular, IDUS is suitable for early T stage prediction.

Summing up, we suggest the following algorithm for the evaluation of bile duct strictures of uncertain etiology as displayed in Figure 3.

ACKNOWLEDGMENTS

Thanks to Professor Gary L Powell for helpful and valuable suggestions regarding the manuscript and true friendship for over 25 years.

COMMENTS

Background

Adequate diagnostics in bile duct strictures of unknown etiology is still a challenging task. Many different imaging techniques compete with each other. Intraductal ultrasound (IDUS) might be instrumental in choosing the appropriate therapeutic approach and may improve our potential to differentiate benign and malignant strictures.

Research frontiers

The authors undertook the largest European retrospective study to evaluate the diagnostic yield of IDUS in patients scheduled for endoscopic retrograde cholangio-pancreatography due to indeterminate strictures of the common bile duct.

Innovations and breakthroughs

IDUS shows good results for accurate diagnostics of bile duct strictures of uncertain etiology thus allowing for adequate further clinical management. In particular, IDUS is suitable for early T stage prediction.

Applications

By analyzing the accuracy of IDUS in the diagnostics of bile duct strictures of uncertain etiology, the authors contribute to a better diagnostic strategy of this difficult issue. This may lead to an improved patient care with an optimal diagnostic approach to patients with bile duct strictures of uncertain etiology.

Terminology

IDUS enables the investigation of the common bile duct wall and the periductal tissue with high resolution.

Peer review

Authors evaluated the role of IDUS in the differential diagnosis of indeterminate biliary strictures. This retrospective study involved such a large number of patients with surgical standards. It is a well-written paper, in which the authors have studied an important issue in hepatobiliary medicine.

Abstract

AIM: To determine the splanchnic blood flow and oxygen uptake in healthy-subjects and patients and to relate the findings to body-composition.

METHODS: The total splanchnic blood flow (SBF) and oxygen uptake (SO_2U) were measured in 20 healthy volunteers (10 women) and 29 patients with suspected chronic intestinal ischemia (15 women), age 40-85 years, prior to and after a standard meal. The method is based on the Fick principle using the continuous infusion of an indicator (99mTechnetium-labelled mebrofenin) and catheterization of an artery and the hepatic vein. An angiography of the intestinal arteries was performed during the same investigation. A whole-body dual-energy x-ray absorptiometry scan was performed in healthy volunteers to determine body composition.

RESULTS: Angiography revealed no atherosclerotic lesions in the intestinal arteries. The mean baseline SBF was 1087 mL/min (731-1390), and this value increased significantly to 1787 mL/min after the meal in healthy volunteers ($P < 0.001$). The baseline SBF in patients was 1080 mL/min, which increased to 1718 mL/min postprandially ($P < 0.001$). The baseline SBF was independent of age, sex, lean body mass and percentage of body fat. The mean meal-induced increase in SBF was equal to 282 mL/min + 5.4 mL/min × bodyweight, ($P = 0.025$). The SO_2U in healthy volunteers and patients was 50.7 mL/min and 48.0 mL/min, respectively, and these values increased to 77.5 mL/min and 75 mL/min postprandially, respectively. Both baseline and postprandial SO_2U were directly related to lean body mass. Age and sex exerted no impact on SO_2U.

CONCLUSION: A direct correlation between body weight and the postprandial increase in SBF was observed. The effect of body weight should be considered in the diagnosis of chronic intestinal ischemia.

INTRODUCTION

Hepatic and total splanchnic blood flow (SBF) can be

quantified using the Fick principle with the continuous infusion of an indicator, the catheterization of the liver vein and subsequent blood sampling. This method has been thoroughly described in the literature[1,2], and it has been validated[3]. SBF is used for the investigation of splanchnic oxygen uptake (SO_2U) or liver metabolism[4] and the examination of the liver clearance of endogen substances and pharmaceuticals[5]. This method is used in Scandinavian countries as a diagnostic tool for chronic intestinal ischemia (CII)[6,7]. SBF is measured at baseline and after a meal to quantify the meal-induced SBF response.

The diagnosis of CII is based on the inability to enhance SBF after a standard meal, and an increase less than 250 mL/min is abnormal[6-8]. Reference values for SBF are based on few and often young individuals without consideration of their body composition or the morphology of their intestinal arteries[6,8,9]. The lack of this information is deplorable because atherosclerotic lesions in the intestinal arteries are commonly observed in a population of otherwise healthy middle-aged individuals[10,11]. Furthermore, patients suffering from CII are frequently severely underweight[7,12], and the large variation in the anthropometrics of individuals may influence SBF values. Therefore, investigations are required to explore the association between SBF, SO_2U, age, and body composition.

The present study determined the SBF and SO_2U prior to and after a standard meal in a group of middle-aged healthy volunteers with angiography-proven normal intestinal arteries. This study also related SBF and SO_2U values to anthropometric measures of the body in healthy volunteers and in a cohort of patients with suspected chronic intestinal ischemia due to weight loss and abdominal pain but with angiography-proven normal intestinal arteries.

MATERIALS AND METHODS

Ethical approval

The protocol was performed under a license from the Ethical Committee, Central Denmark Region, and the Danish Data Protection Agency. Individually signed informed consent forms were obtained according to the Helsinki II declaration. No complications or side effects were encountered in the study. Twenty healthy volunteers aged 40-70 year (10 women) participated in the present study. None of the volunteers exhibited any signs of cardiovascular disease, abdominal complaints or weight loss one year prior to the investigation. Apart from appendectomy $n = 2$, no former abdominal surgery was performed in any of the volunteers. A total of 180 patients with suspected CII were routinely referred for SBF measurements due to weight loss and abdominal pain from June 2002 to October 2011. Patients with a digital subtraction angiography that revealed three normal intestinal arteries were included in the present study for comparison only. Therefore, 32 patients participated in the study; 31 (97%) patients suffered from postprandial abdominal pain, and 25/32 had experienced unintentional weight loss (mean 10.4 kg). Three patients were excluded: two patients due to ischemic colitis as verified on biopsy and one patient due to pulmonary cancer that had metastasized to the ventricle and colon. Table 1 presents the anthropometric data of the healthy volunteers and patients.

Table 1 Demographic data from 20 healthy volunteers and 29 patients suspected of chronic intestinal ischemia but normal intestinal arteries

	Healthy volunteers		Patients suspected of CII, normal angiography		
	Female $n = 10$	Male $n = 10$	Female $n = 15$	Male $n = 14$	*P* value
Age (yr)	53.8 (40-64)	54.5 (43-69)	63 (44-85)	60.4 (45-76)	0.01
Weight (kg)	72 (55.0-92.0)	83 (65.0-94.8)	57.9 (34.0-114)	74.9 (52.0-98.0)	0.02
Height (cm)	165 (160-170)	177 (170-188)	165 (153-172)	176 (170-186)	0.88
BMI (kg/m^2)	26.5 (21.2-34.5)	26.6 (21.7-30.6)	21.4 (12.5-41.9)	24 (15.0-31.6)	0.02
Body fat (%)	34.4 (28.0-48.2)	21.9 (13.1-29.4)	NA	NA	
LBM (kg)	47.4 (39.6-54.6)	65.5 (55.8-70.6)	NA	NA	
BSA (m^2)	1.81 (1.56-2.07)	2.01 (1.77-2.16)	1.61 (1.25-2.29)	1.89 (1.64-2.19)	0.02

All results are given as mean and range. The *P* value is the difference between healthy volunteers and patients. CII: Chronic intestinal ischemia; LBM: Lean body mass; BSA: Body surface area; BMI: Body mass index; NA: Not available.

All of the healthy volunteers and patients underwent the following protocol.

Catheterization

Subjects underwent catheterization of the femoral artery and vein in the morning following an overnight fast using the Seldinger technique under local analgesia. A 5F sheath was used for the artery, and a 7F sheath was used for the vein. The venous catheter (Schwan-Ganz, Edwards, CA, United States) was placed in a central hepatic vein using fluoroscopy, and the arterial catheter (pigtail catheter, Cordis, NJ, United States) was positioned in the abdominal aorta.

SBF and SO_2U

The SBF equals the hepatic blood flow in normal subjects, and it was measured using a standardized protocol of the indirect Fick principle with 99mTechnetium labeled Bridatec (Mebrofenin®, GE Healthcare, Suluggia, Italy) [99mTc-Mebrofenin (MBF)] as the indicator. This method was originally introduced by Bradley[1], and it was used with corrections for unsteady state and small urinary excretion of 99mTc-MBF, as recommend by Henriksen *et al*[2].

Briefly, a bolus injection of 99mTc-MBF was administered followed by a constant infusion at 2.02 mL/min (range: 1.96-2.17 mL/min), which equaled an infusion rate of 0.323 MBq/min. Less than 80 MBq was used in total. An equilibration period of 20 min was interposed

before blood samples were collected to obtain steady state measurements. Splanchnic plasma flow (SPF) was calculated as SPF = E/(Ca-Cv), where E is the hepatobiliary excretion rate of 99mTc-MBF, which equals the corrected infusion rate[2]. Ca and Cv are the concentrations of 99mTc-MBF in the abdominal aorta and the hepatic vein, respectively. The level of 99mTc-MBF in plasma samples was determined using a Cobra Ⅱ Auto-Gamma counter (Packard Bioscience Company, Frankfurt, Germany). At least 10 000 counts were obtained and corrected for decay, background and dead time.

SBF was calculated as SPF/(1-hematocrit fraction). The splanchnic oxygen uptake (SO_2U) was calculated as hemoglobin × (arterial oxygen saturation-hepatic venous oxygen saturation) × SBF × 1.34 mL O_2/g of hemoglobin. The blood samples were analyzed using an ABL 700 series (Radiometer Medical A/S, Brønshøj, Denmark), which was operated according to the manufacturer's instructions.

Blood samples were taken from a central hepatic vein and the abdominal aorta simultaneously every ten minutes during the first hour. A mean baseline value was calculated. The participants ingested a 4000 kJ/400 mL standard liquid meal that consisted of 33% protein, 33% carbohydrates and 33% fat after one hour. Blood samples were collected every ten minutes for an additional hour, and blood glucose levels were measured at each sampling time as a control of gastric emptying and intestinal absorption. The extraction fraction (EF) of 99mTc-MBF was calculated as (Ca-Cv)/Ca.

The wedged and free hepatic vein pressures were measured using a capacitance transducer at the end of the session to exclude the presence of portal hypertension and resulting porto-systemic shunting. The mean gradient wedged-to-free hepatic vein pressure was 2.5 mmHg (range 1-5 mmHg).

Angiography

An angiography was performed during the same session *via* a 4F pigtail catheter in the abdominal aorta as a control for the morphology of the intestinal arterial blood supply. The angiography included an antero-posterior and lateral horizontal abdominal projection to visualize the individual origin of the mesenteric artery branches. Iomeprol (Iomeron® 200 mg iodine/mL, Bracco, Milan, Italy; 15 mL for each image) was used as a contrast agent, and a total of 45 mL was administered on average.

Each artery was classified as normal (0%-9% lumen reduction) or exhibiting slight stenosis (10%-49% lumen reduction), moderate stenosis (50%-69% lumen reduction), significant stenosis (70%-99% lumen reduction) or occlusion. The investigator who evaluated the angiographies was blinded to the results of the SBF, and both positive and negative controls were included.

Dual-energy x-ray absorptiometry-scanning

Only healthy volunteers were subjected to a dual-energy x-ray absorptiometry (DEXA) scan. Body composition, which was evaluated as the percentage of body fat and fat-free mass, was measured using whole-body scanning in a Delfi Discovery A S/N 70879 and software version 12.6 (Hologic, MA, United Stastes) for quantification. Each participant was immobilized in supine position during evaluation with the arms and legs away from the body. The equipment was calibrated daily according to the manufacturer's instructions.

Statistical analysis

Statistical analysis was performed using STATA®11 (StataCorp LP, Station, Texas, United States). All results are presented as mean values, SD and ranges. Paired and unpaired Student's *t* tests were used for intergroup comparisons. Relationships between variables were analyzed using linear or multiple linear regression analysis and repeated measurements when appropriate. A P value < 0.05 was considered statistically significant.

RESULTS

The average values and ranges of SBF and SO_2U during fasting and after the meal are presented in Table 2. Significant differences ($P < 0.01$) between these values were observed at baseline and after the standard meal. The mean body weight among patients (65.4 kg) was significantly ($P = 0.016$) smaller than the group of healthy volunteers (77.5 kg). Eleven of the 29 patients were underweight [defined as body mass index (BMI) < 20]. None of the healthy volunteers were underweight. However, no differences in the mean baseline SBF were observed between patients (1080 mL/min) and healthy volunteers (1087 mL/min) ($P = 0.95$) or the mean postprandial SBFs, which were 1718 mL/min in patients and 1787 mL/min in healthy volunteers. Figure 1 presents the mean SBF and standard deviation as a function of time in healthy volunteers and the patient group.

Healthy volunteers

Visceral arteriography revealed no significant stenotic vessels or occlusions in the group of healthy volunteers. A slight stenosis (10%-49% lumen reduction) of the celiac artery was present in five cases. The presence of these minor stenoses did not impact the SBF at baseline (1001 mL/min, $P = 0.31$) or alter the postprandial increase (648 mL/min, $P = 0.49$). Baseline SBF and SO_2U values did not change over time (1045 mL/min to 1068 mL/min, $P = 0.89$ and 48 mL O_2/min to 50 mL O_2/min, $P = 0.66$, respectively). Variations in SBF were significantly larger between individuals than within individuals ($P = 0.002$), and the mean baseline SBF was 1087 mL/min (range 731-1390 mL/min), which increased to 1787 mL/min (range 1387-2343 mL/min) postprandially ($P < 0.001$). The corresponding SO_2U increased from 50.7 mL O_2/min (range 32.1-84.5 mL O_2/min) to 77.5 mL O_2/min (range 49.1-118.9 mL O_2/min) ($P < 0.01$).

The baseline values and the increase in SBF after meals were independent of age, sex, body weight, body surface area, and lean body mass in the group of healthy volunteers. However, SO_2U differed significantly between gen-

Table 2 Results of glucose, splanchnic blood flow and oxygen consumption from 20 healthy volunteers and 29 patients suspected of chronic intestinal ischemia but normal intestinal arteries

	Healthy volunteers		Patients suspected of CII, normal angiography		
	Female n = 10	Male n = 10	Female n = 15	Male n = 14	*P* value
Fasting plasma glucose (mmol/L)	5.7 (5.1-6.9)	5.8 (5.2-6.9)	5.7 (4.5-11.6)	5.6 (4.7-7.5)	0.59
Postprandial plasma glucose (mmol/L)	6.8[b] (5.9-7.8)	7.2[b] (6.3-8.8)	7.0[b] (5.4-12.1)	7.2[b] (5.9-9.9)	0.27
Mean fasting SBF (mL/min)	1044 (731-1319)	1129 (800-1390)	1040 (619-2781)	1123 (429-2740)	0.95
Mean postprandial SBF (mL/min)	1731[b] (1386-1987)	1844[b] (1485-2343)	1581[b] (906-2340)	1863[b] (1332-3163)	0.54
Postprandial rise in SBF (mL/min)	686 (515-915)	714 (314-1145)	542 (-441-1014)	707 (293-1325)	0.47
Mean fasting oxygen consumption (mL/min)	43.4 (32.1-53.8)	58.1 (40.5-84.5)	44.5 (34.6-76.1)	51.8 (15.2-78.2)	0.48
Mean postprandial oxygen consumption (mL/min)	65.5[b] (49.1-84.0)	89.6[b] (60.1-118.9)	68.3[b] (46.2-104.7)	82.2[b] (45.0-118.2)	0.63

All results are given as mean and range. The *P* value is the comparison difference between healthy volunteers and patients. [b]$P < 0.001$ *vs* fasting values. CII: Chronic intestinal ischemia; SBF: Splanchnic blood flow.

ders ($P = 0.001$). This difference disappeared when gender was corrected for lean body mass ($P = 0.99$). Therefore, the gender-related differences in baseline SO_2U and the postprandial increase were solely attributed to the gender-related difference in lean body mass ($P = 0.001$). Lean body mass did not influence SBF. Therefore, the SO_2U increase was accommodated by a larger oxygen extraction from the blood, which lowered hepatic venous blood saturation (data not shown).

The percentage of body fat influenced baseline SO_2U, but it did not influence the postprandial increase ($P = 0.003$). The baseline SO_2U decreased by 4.4 mL/min for a five percent increase in body fat percentage.

Figure 2 illustrates the EF as a function of time in each healthy volunteer. The arrow indicates the time of the standard meal. The mean EF of 99mTc-MBF decreased significantly ($P < 0.01$) from 0.46 to 0.39 during the baseline period. A steep drop in EF from 0.39 to 0.24 ($P < 0.01$) and an increase in SBF were observed 20 min after the meal. The EF did not change thereafter.

Patients

Figure 3A presents the mean baseline SBF for individual patients and healthy volunteers as a function of weight. Two of the patients exhibited high baseline SBF values (2740 and 2781 mL/min). Figure 3B presents the postprandial increase in SBF in individuals as a function of weight. One of the outliers with hyperperfusion at baseline experienced a decreased SBF after the meal; this individual had the negative increase in Figure 3B.

The increase in baseline and postprandial SBF did not depend on weight ($P = 0.47$ and $P = 0.12$, respectively). However, weight did exert a significant ($P = 0.025$) impact on the postprandial increase but not the baseline SBF in all individuals ($n = 49$) independent of health status. Therefore, an average person weighing 60 kg would demonstrate a 605 mL/min (95%CI: 510-701 mL/min) postprandial increase in SBF. Each additional kg in bodyweight would augment the postprandial increase by 5.4 mL/min. No significant difference between genders or any relationship to age was observed. Baseline and postprandial SO_2U values were 48.0 mL O_2/min and 75.0 mL O_2/min, respectively, and these values in patients did not differ significantly from the healthy volunteers ($P = 0.48$ and $P = 0.68$). Patients also exhibited a significant difference between genders in postprandial SO_2U ($P = 0.03$).

DISCUSSION

Despite the redundancy in the visceral circulation, with its numerous interconnections between the three abdominal arteries, the celiac trunk, and the superior and inferior mesenteric arteries, symptoms of CII ultimately arise when the genuine and collateral arteries can no longer accommodate the postprandial oxygen demand. Therefore, investigations of the morphology of the intestinal arteries cannot stand alone; functional tests that evaluate the physiological consequences are required[12]. An understanding of splanchnic hemodynamics and SO_2U in healthy volunteers is crucial. None of the healthy volunteers with stable weight exhibited a BMI < 20. Therefore, a group of patients who underwent SBF measurements due to a suspicion of CII with weights of 34 to 114 kg and angiography-proven normal intestinal arteries served as a control group. The mean baseline SBF of 1087 mL/min and the increase to 1787 mL/min after the ingestion of a standard meal that was observed in this study are consistent with Madsen *et al*[8], who performed a study in a comparable population of healthy volunteers but without knowledge of arterial morphology.

Previous investigations of SBF have been performed in volunteers who were 20 to 30 years of age. This age group is not representative of the population of interest for CII. These studies reported a total splanchnic

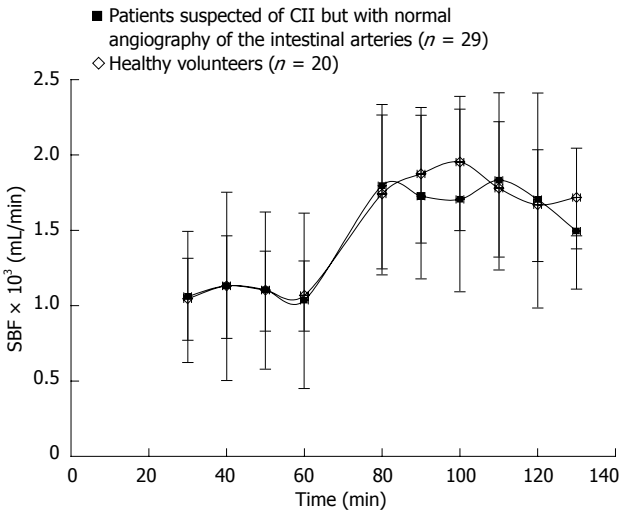

Figure 1 Splanchnic blood flow ± SD at each sampling time. The standard meal of 4000 kJ was served after 60 min. CII: Chronic intestinal ischemia; SBF: Splanchnic blood flow.

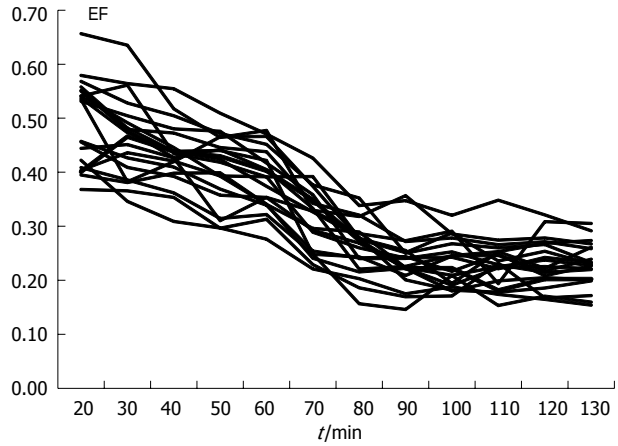

Figure 2 Extraction fraction as a function of time for each of the healthy individuals. The standard meal is served after 60 min as marked by the line, which causes a sharper decrease in extraction fraction (EF) during the first 20 min after the meal.

plasma flow of 900 mL/min during fasting[4,9,13], which corresponds to an SBF of 1500 mL/min given a normal hematocrit. These flow values are 35% higher than the results in the present study. Although we did not observe an age-related effect in participants aged 40 to 85 years, age may be a factor in comparisons of young adults to middle-aged and elderly individuals.

The frequent presence of atherosclerotic changes in asymptomatic 60- to 70-year-old adults renders the knowledge of arterial morphology in a study population essential. However, this knowledge has been neglected in previous studies. The present study demonstrated no atherosclerosis in any mesenteric arteries in healthy volunteers, and only patients with normal intestinal arteries were included.

Healthy volunteers demonstrated no correlation between SBF and body composition, which was described as body weight, body surface area and lean body mass. This result contrasts a previous study[8] in which both baseline SBF and SO_2U were directly related to the body surface area. One reason for this discrepancy may be that the ranges of body surface area or lean body mass in the healthy volunteers in the present study were too small to detect a correlation. This limitation was encountered because of the use of a group of patients with a weight range from 34 to 114 kg. The inclusion of weight in the analysis further augmented the postprandial increase by 5.4 mL/min for each kg bodyweight. Even patients who weighed 34 kg, which represented the lightest patient at our clinic, should have experienced a mean postprandial SBF increase of 465 mL/min (95%CI: 275-656) using this calculation. The exclusion of two patients with hyperperfusion at baseline slightly changed these values (the mean postprandial SBF increased 4.9 mL/min for each kg of bodyweight). These results support previous studies[6,8], which have reported that all individuals should demonstrate a postprandial response larger than 250 mL/min independent of body weight. However, the present study recommends the consideration of body weight when postprandial SBF is used to diagnose CII.

Interestingly, weight did not influence baseline SBF. A minor tendency toward an increase in baseline SBF of 2.2 mL/min (95%CI: -1.6 to 6.1, $P = 0.25$) for each kg increase in body weight was observed. However, a significant correlation between weight and baseline SBF must be rejected.

A significant difference in SO_2U between genders was observed in both groups. These differences between genders were uniquely correlated to the differences in lean body mass in the healthy volunteers who underwent a DEXA scan. This difference may also apply to the patient group, but this group did not undergo DEXA scans. Therefore, the correlation of gender differences in SO_2U to differences in body mass remains unknown in this group. The whole-body DEXA scan can reveal the body composition in each region of the body. A large total lean body mass is closely associated with a large truncal lean body mass, which may explain the increased demand for oxygen in the splanchnic territory that was observed in the present study.

The observed decrease in the EF of 99mTc-MBF in healthy volunteers was most pronounced in the 20 min following the meal. This decrease is an inherent consequence of the Fick principle in which the EF decreases with an increase in flow according to the following formula: SPF = E/(Ca-Cv). However, the decrease in EF throughout the baseline period, which was characterized by a constant SBF, remains unexplained. The decrease in EF during continuous infusion has been observed previously in pigs[3] and patients with fatty liver and cirrhosis[2]. This observation may be due to the limited capacity of hepatocytes to process 99mTc-MBF from the blood to the bile.

International guidelines[14,15] on CII suggest the exclusive use of investigations that describe the morphology of the intestinal arteries for the diagnosis of CII. The diagnostic criteria include a combination of relevant symptoms, such as postprandial abdominal pain and

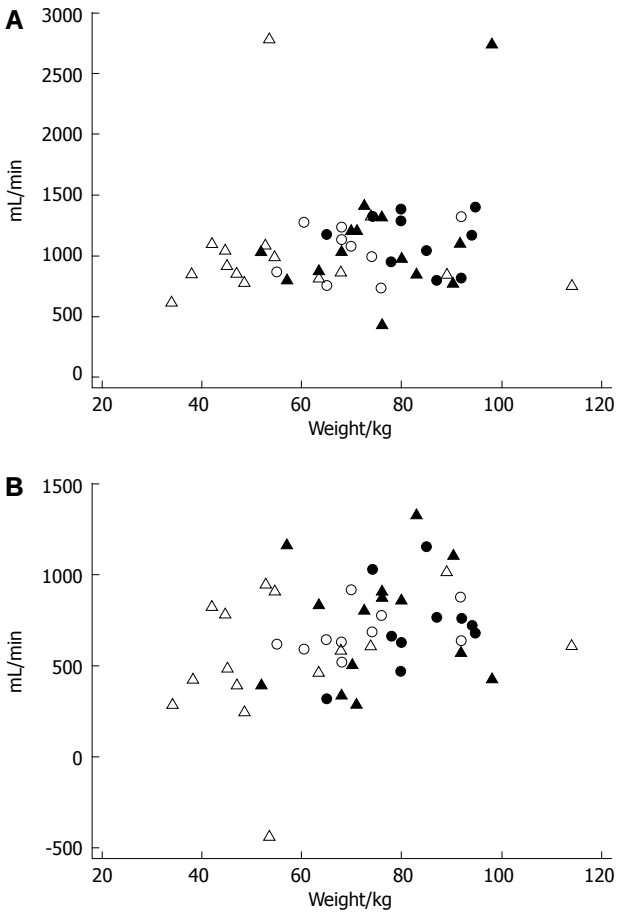

Figure 3 Postprandial increase in splanchnic blood flow for each individual as a function of bodyweight. A: Baseline splanchnic blood flow (SBF): the linear correlation between bodyweight and baseline SBF is given by the equation. SBF = 858 mL/min + 3.2 mL/min × bodyweight, the correlation is however not significant (P = 0.35); B: Postprandial increase in SBF: the linear correlation between bodyweight and the postprandial increase in SBF can be described by the equation: SBF (increase) = 282 mL/min + bodyweight × 5.4 mL/min (P = 0.025). △: Female patients with normal angiography; ▲: Male patients with normal angiography; ○: Healthy female volunteers; ●: Healthy male volunteers.

weight loss, and at least two significant stenoses/occlusions in the intestinal arteries. This approach ignores the well-documented knowledge of the frequent presence of inconsequential arterial stenosis[11,16,17]. Furthermore, patients with single-vessel disease or non-occlusive mesenteric ischemia are neglected.

The major drawbacks of physiological investigations, such as SBF measurements or tonometry, are that these techniques are often time consuming[18,19] and invasive. Therefore, the use of non-invasive investigations, such as duplex ultrasound (DUS) and MRI, are widely used. The wide availability and non-invasive nature of DUS make it an attractive screening tool. The overall accuracy, sensitivity and specificity for the identification of stenotic or occluded vessels for both the CA and the SMA are above 90% compared to DSA[20]. The meal-induced differences in blood flow velocity responses and the resistivity index in the celiac and superior mesenteric arteries can be assessed using DUS[21] as a surrogate marker for blood flow in healthy young volunteers. However, the calculation of blood flow volume is dependent on an accurate cross-sectional area of the vessel, which is difficult to obtain using DUS, especially in the intestinal arteries, and this area is almost impossible to obtain in patients with disseminated atherosclerosis. Therefore, DUS exhibits a disadvantage because only the morphology of the vessels is examined. Another major disadvantage of DUS is the requirement of an experienced examiner because obesity and overlying bowel gas may compromise the results and the lack of the visualization of the inferior mesenteric artery.

MRI has demonstrated promising results for the quantification of blood flow in the portal and superior mesenteric veins[22,23], and MR angiography has a short acquisition time (17 s)[24]. Another promising study reported the possible quantification of small bowel perfusion for the differentiation of normal individuals from patients with CII[25]. However, the capability of a functional assessment of CII using MRI has not been applied in a clinical setting despite the promise of previous reports. This fact assigns the measurement of SBF as one of a few clinical applicable investigations for the functional evaluation of CII.

In conclusion, the present study recommends the consideration of body weight in the diagnosis of CII using the postprandial increase in SBF.

COMMENTS

Background

Chronic intestinal ischemia is characterized by postprandial abdominal pain and weight loss. Atherosclerosis of the intestinal arteries is the most common cause of chronic intestinal ischemia. However, the rich collateral blood supply in the intestines may further develop in the presence of arterial stenosis to provide an adequate blood flow despite the significant stenosis of the intestinal arteries. Therefore, the application of physiological testing is required. The measurement of the splanchnic blood flow prior to and after a meal allows for an assessment of the physiological consequences of arterial stenosis in the intestines.

Research frontiers

Reference values for the total splanchnic blood flow and splanchnic oxygen uptake are lacking. The effect of body size and body composition should be considered because the majority of patients are underweight.

Innovations and breakthroughs

Previous investigations of the splanchnic blood flow have not considered the morphology of the intestinal arteries or the possible effect of body composition. An intestinal angiography and a whole-body dual-energy X-ray absorptiometry scan were performed in each of the healthy volunteers in the present study. A group of patients was included as a second group to achieve a weight range that represented individuals with very low bodyweight. All patients exhibited a completely normal angiography of the intestinal arteries. The splanchnic blood flow during fasting was independent of age, sex, body weight and body composition, but the meal-induced increase was directly related to body weight.

Applications

The study suggests that the meal-induced increase in splanchnic blood flow is directly related to body weight. This relationship should be considered in the diagnosis of chronic intestinal ischemia based on splanchnic blood flow measurements.

Terminology

Chronic intestinal ischemia is a clinical entity that is characterized by abdominal pain after eating. The pain causes the patient to eat smaller meals at longer intervals, which often leads to weight loss. The total splanchnic blood flow equals the blood flow through the liver, which can be calculated using the Fick principle.

Peer review

The paper makes sense to search for and refine new diagnostic tools, espe-

cially with regard to the functional aspects of the chronic mesenteric ischemia. The study design is valid and the data is sufficient.

Abstract

AIM: To investigate the effect of mesalazine granules on small intestinal injury induced by naproxen using capsule endoscopy (CE).

METHODS: This was a single center, non-randomized, open-label, uncontrolled pilot study, using the PillCam SB CE system with RAPID 5 software. The Lewis Index Score (LIS) for small bowel injury was investigated to evaluate the severity of mucosal injury. Arthropathy patients with at least one month history of daily naproxen use of 1000 mg and proton pump inhibitor co-therapy were screened. Patients with a minimum LIS of 135 were eligible to enter the 4-wk treatment phase of the study. During this treatment period, 3 × 1000 mg/d mesalazine granules were added to ongoing therapies of 1000 mg/d naproxen and 20 mg/d omeprazole. At the end of the 4-wk combined treatment period, a second small bowel CE was performed to re-evaluate the enteropathy according to the LIS results. The primary objective of this study was to assess the mucosal changes after 4 wk of mesalazine treatment.

RESULTS: A total of 18 patients (16 females), ranging in age from 46 to 78 years (mean age 60.3 years) were screened, all had been taking 1000 mg/d naproxen for at least one month. Eight patients were excluded from the mesalazine therapeutic phase of the study for the following reasons: the screening CE showed normal small bowel mucosa or only insignificant damages (LIS < 135) in five patients, the screening esophagogastroduodenoscopy revealed gastric ulcer in one patient, capsule technical failure and incomplete CE due to poor small bowel cleanliness in two patients. Ten patients (9 female, mean age 56.2 years) whose initial LIS reached mild and moderate-to-severe enteropathy grades (between 135 and 790 and ⩾ 790) entered the 4-wk therapeutic phase and a repeat CE was performed. When comparing the change in LIS from baseline to end of treatment in all patients, a marked decrease was seen (mean LIS: 1236.4 ± 821.9 *vs* 925.2 ± 543.4, $P = 0.271$). Moreover, a significant difference between pre- and post-treatment mean total LIS was detected in 7 patients who had moderate-to-severe enteropathy gradings at the inclusion CE (mean LIS: 1615 ± 672 *vs* 1064 ± 424, $P = 0.033$).

CONCLUSION: According to the small bowel CE evaluation mesalazine granules significantly attenuated mucosal injuries in patients with moderate-to-severe enteropathies induced by naproxen.

Rácz I, Szalai M, Kovács V, Regőczi H, Kiss Gy, Horváth Z. Mucosal healing effect of mesalazine granules in naproxen-induced small bowel enteropathy. *World J Gastroenterol* 2013; 19(6): 889-896 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/889.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.889

INTRODUCTION

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most commonly prescribed medications worldwide[1,2]. The side effects of NSAIDs on the upper gastrointestinal tract are well-known, however, toxicity to the small bowel mucosa is an increasingly recognized problem and is emerging as a more prevalent site of injury than the stomach[3-7].

Advances in small bowel imaging have led to direct observation at enteroscopy and during the last decade by video capsule endoscopy (CE) allowing a full investigation of the entire small intestine[8-15].

Capsule endoscopy is capable of demonstrating NSAIDs-induced pathology in the small bowel. CE studies comparing NSAIDs users and healthy volunteers found a higher rate of lesions in the former group (55%-76% *vs* 7%-11%)[16-19]. The most common NSAID-induced lesions in the small bowel are mucosal breaks, reddened folds, petechial or red spots, and blood in the lumen without a visualized source of bleeding. The conclusion from these initial studies was that CE is the optimal diagnostic tool to obtain direct evidence of macroscopic injury of the small intestine, resulting from short-term (2-4 wk) administration of conventional NSAIDs.

Studies in long-term NSAID users suggest that 60%-70% have an asymptomatic enteropathy characterized by increased intestinal permeability and mild mucosal inflammation[18,20]. Occult intestinal bleeding resulting from long-term NSAID usage is an increasing clinical challenge, especially in elderly patients[21,22].

Management options for NSAID enteropathy are limited. Co-administration of proton pump inhibitors failed to prevent NSAID-induced small intestinal damage[7,8]. Cessation of NSAIDs is not tolerable for most arthropathy patients. Cyclooxygenase (COX)-2 inhibitors have fewer toxic effects in the small bowel[23-25]. However, due to increased cardiovascular event risk many physicians prefer to prescribe conventional NSAIDs[17]. Although a recently published short-term study showed promising results indicating that prostaglandin (PG) reduced the incidence of small-intestinal lesions induced by diclofenac sodium[19], there are no convincing long-term clinical data on the usefulness of PG co-therapy with NSAIDs. Sulfasalazine significantly reduced NSAID-provoked intestinal permeability in an experimental study[26].

Mesalazine has not yet been studied in the treatment of NSAID-induced enteropathy. However, according to the release patterns of the oral preparations of mesalazine some therapeutic efficacy was noted in Crohn's disease, *e.g.*, with Salofalk® tablets from the duodenum to the ileum[27-29]. Pharmacokinetic data indicate a release pattern of 5-aminosalicylate from Salofalk® granules preparation starting in the same intestinal region as that for Salofalk® tablets[30].

Thus, it would be valuable in a clinical setting to determine the therapeutic effect of mesalazine granules on NSAID-induced small intestine injury. Therefore, we investigated the effect of mesalazine granules on small intestinal injury induced by NSAIDs in an open label, uncontrolled pilot study. We assessed naproxen-induced mucosal changes using CE before and after 4 wk of treatment with 3 g mesalazine granules.

MATERIALS AND METHODS

This was a single center, non-randomized, open label, uncontrolled pilot study. Entry criteria included men and women, 18-75 years of age, with at least one month history of daily naproxen use of 1000 mg for osteoarthrosis, rheumatoid arthritis, or nonspecific arthritis. To avoid gastroduodenal mucosal injury, the patients were treated with a standard dose of proton pump inhibitor. A complete small bowel CE examination within 7 d of inclusion was performed to diagnose small bowel NSAID-induced enteropathy. Patients with a Lewis CE scoring index of at least 135 were eligible to enter the 4-wk treatment phase of the study. During this treatment period 3 × 1000 mg/d mesalazine granules (Salofalk® Granu-Stix®) medication was added to ongoing 1000 mg/d naproxen and 20 mg/d omeprazole therapy. At the end of the 4-wk combined therapy period, a second small bowel CE examination was performed to re-evaluate the CE enteropathy scoring index.

Patients with evidence of small bowel strictures as previously proven by barium small bowel follow through, enteroclysis or patency test capsule, or with swallowing disorders, gastroduodenal ulcer in the patient history or proven by upper endoscopy were excluded. Further exclusion criteria were a history of IBD and colon diverticulosis, mesalazine treatment within 12 wk and corticosteroid treatment within 30 d prior to baseline endoscopy. Known previous or concurrent malignancy was also an exclusion criterion.

This study was approved by the central ethics committee of the National Health Scientific Board, and all patients provided written informed consent before their enrollment in this study.

Capsule endoscopy

We used the PillCam SB capsule endoscopy system with RAPID 5 software (Given Imaging Ltd, Yokneam, Israel). The patients had a liquid diet on the day before the CE examination. For preparation of the small bowel, 2 L of polyethylene glycol (PEG) solution on the day before and 1 L of PEG on the morning of the CE examination were administered. The CE procedure and methodology for review of images were conducted as previously described[5,7]. Briefly, the patients were equipped with a sensor array and recorder-battery belt pack, and then swallowed a capsule, which continuously transmitted video images at 2 frames per second for 8 h, at which point, the apparatus was disconnected and the images were processed. All video images were independently analyzed by 2 reviewers per video for pathology detection. All images were saved for final comprehensive analysis.

Evaluation of small bowel injury

We investigated the Lewis Index Score (LIS) for small

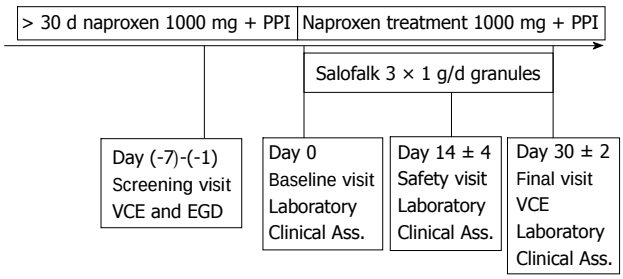

Figure 1 Study design. PPI: Proton pump inhibitor; VCE: Video capsule endoscopy; EGD: Esophagogastroduodenoscopy; ASS.: Assessment.

bowel enteropathy alterations to strengthen the validity of the results[31,32]. The LIS is incorporated as an integral part of Given's RAPID 5 version. The scoring index is based on three capsule endoscopy variables: villous appearance, ulceration, and stenosis. The changes in villous appearance and ulceration were assessed by tertiles, dividing the small bowel transit time into three equal time allotments. Villous appearance was defined as edema where villous width was equal or greater than villous height. Ulcerations were defined as mucosal breaks with white or yellow bases surrounded by red or pink collars. Ulcer size was based on the entire lesion including its surrounding collar and was measured according to the percentage of the capsule image occupied by the ulcerated lesion. The evaluation of stenosis was carried out for one entire study. The total score was the sum of the highest tertile score plus the stenosis score. The results were classified into the three categories by the final numerical score: normal or clinically insignificant change (< 135), mild change (between 135 and 790), and moderate-to-severe change (≥ 790).

The rate of successful arrival of the capsule in the cecum was assessed on the capsule endoscopic images. Gastric transit time was defined as the time taken from the first gastric image to the first duodenal image. Small bowel transit time was defined as the time from the first duodenal image to the first cecal image.

Small bowel cleanliness was graded using a 4-point scale (excellent[1] or good[2], fair[3] or poor[4]) for each tertile. Each small bowel tertile was scored separately, with the final cleansing score being the average of the sum of the three tertile cleansing scores[31].

Study protocol

At the screening visit, patients taking 1000 mg/d naproxen and 20 mg/d omeprazole first underwent esophagogastroduodenoscopy (EGD) to exclude active peptic ulcer. Those without active ulcer underwent the baseline CE examination. Eligible patients with LSI higher than 135 were administered 1000 mg mesalazine granules three times daily and 500 mg naproxen two times daily, and 20 mg omeprazole once daily immediately after meals for a period of 4 wk. Post-treatment CE was performed within 24 h after completion of the drug regimen (Figure 1). Patients who developed symptoms that warranted withdrawal from the study or with incomplete CE were excluded from the study and analysis.

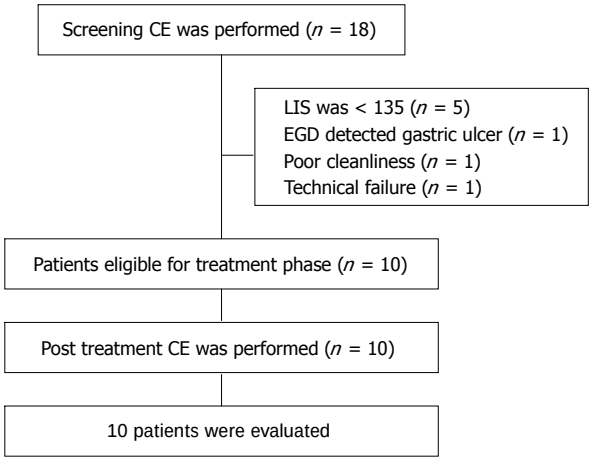

Figure 2 Flow chart of the study patients. LIS: Lewis Index Score; EGD: Esophagogastroduodenoscopy; CE: Capsule endoscopy.

Statistical analysis

The Lewis Index Score results, gastric transit time, small bowel transit time, cleanliness scores, hemoglobin results, results of baseline CE and the 4 wk control were compared and tested using the Wilcoxon signed rank test. In addition, paired *t* tests were also performed. Data were expressed as mean ± SD. *P* values < 0.05 were considered statistically significant. The effect of treatment on the presence of ulcers with a diameter of at least 3 mm was tested using the binomial sign test. McNemar tests were also performed but due to the small sample size, the binomial test was more relevant.

RESULTS

A total of 18 patients (16 females), ranging in age from 46 to 78 years (mean age 60.3 years) were screened, all had been taking 1000 mg/d naproxen for at least one month. Eight patients were excluded from the mesalazine therapeutic phase of the study for the following reasons: the screening CE showed normal small bowel mucosa or only insignificant damage (LIS < 135) in five patients, the screening EGD revealed gastric ulcer in one patient, and capsule technical failure and incomplete CE due to poor small bowel cleanliness in two patients (Figure 2). Ten patients whose initial LIS reached the mild and moderate-to-severe enteropathy grades (between 135 and 790, and ≥ 790, respectively) entered the therapeutic study phase and a second CE was carried out 4 wk later (Table 1). The CE enteropathy scores for small bowel are presented in Table 2.

At the screening CE, seven out of the ten enteropathy patients showed moderate-to-severe abnormalities according to the LIS grades (≥ 790).

In six of these seven moderate-to-severe small bowel enteropathy cases, the characteristic alterations were already seen in the first tertile, and in only three patients in the third tertile.

Table 1 Baseline characteristics of the intent-to-treat patient population (n = 10)

NSAID: Non-steroidal anti-inflammatory drugs; LIS: Lewis Index Score.

The average small bowel cleanliness grades were 1.3 ± 0.67 at the screening CE, and 1.4 ± 0.69 at the control CE examinations, respectively. The mean hemoglobin levels at screening and at the end of therapy were 131.1 ± 5.8 g/L and 127.1 ± 7.8 g/L, respectively (Table 3).

The most frequently observed NSAID-induced morphological alterations were villous edema which was present in all 10 patients at inclusion, and 19 ulcers were detected at baseline CE examinations (Figure 3). No stenosis was seen in any of the patients, either at inclusion or at the control CE examinations.

No dyspepsia or other significant abdominal symptoms were reported by the patients at any of the study visits. When comparing the LIS results assessed at inclusion and at the control CE after treatment with mesalazine granules, a marked decrease was seen (mean LIS: 1236.4 ± 821.9 *vs* 925.2 ± 543.4), however, the difference was not significant (P = 0.271).

Table 3 Capsule endoscopy results of the patients with naproxen and naproxen + mesalazine granules therapy (n = 10)

	Inclusion	After mesalazine gran therapy	P value
Total Lewis Index Score	1236.4 ± 821.9	925.2 ± 543.4	0.271
1st tertile	952.8 ± 584.9	894.4 ± 534.3	0.569
2nd tertile	699.3 ± 877.9	545.9 ± 580.9	0.649
3rd tertile	415.3 ± 561.5	319.3 ± 403.3	0.247
Ulcers with a diameter of > 3 mm, n			
1st tertile	8	7	1.000
2nd tertile	8	6	0.625
3rd tertile	3	4	1.000
Gastric transit time (min)	43.8 ± 32	49.8 ± 35.6	0.470
Small bowel transit time (min)	261.9 ± 108	250.9 ± 93.9	0.470
Cleanliness score	1.3 ± 0.67	1.4 ± 0.69	0.345
Hemoglobin	131.1 ± 5.8	127.1 ± 7.8	0.103

In contrast, a significant difference in pre- and post-treatment LIS was detected in the seven patients who had moderate-to-severe enteropathy gradings at the inclusion CE visit (mean LIS: 1615 ± 672 *vs* 1064 ± 424, P = 0.033). Further analysis showed that two patients (subject number 9 and 10) in the group with moderate-to-severe NSAID-induced enteropathy at inclusion, the total LIS score was unchanged or worsened after mesalazine treatment. However, even in these two patients a decrease in LIS scores was detected either in the first or second small bowel tertile which was also seen in the other 5 cases (Figure 4).

DISCUSSION

In the present pilot study we found that mesalazine granules reduced the severity of small intestine lesions induced by the administration of naproxen, a non-selective NSAID. Patients, who received naproxen therapy with mesalazine granules showed markedly lower enteropathy scores compared with the period when naproxen was taken alone. Importantly, the co-administration of mesalazine granules significantly attenuated the mucosal damage caused by naproxen in patients with moderate-to-severe enteropathy.

NSAIDs are known to increase intestinal permeability; the severity of the mucosal injury is dose-dependently related to the potency of NSAIDs to inhibit COX-1. The increase in intestinal permeability is the most important factor which provokes NSAID-induced inflammation and injury in the small intestine[2,3].

Previous studies evaluating NSAID-associated mucosal injury have shown various ways to interpret and compare CE data. Goldstein *et al*[17], who compared the effects of naproxen versus celecoxib on the small bowel, simply counted the number of mucosal breaks per tertile to measure adverse drug effects. Graham *et al*[18] assessed small bowel mucosal injury in chronic NSAIDs users. In their study, CE lesions were scored as normal, red spots, small erosions, large erosions or ulcers. Maiden *et al*[16]

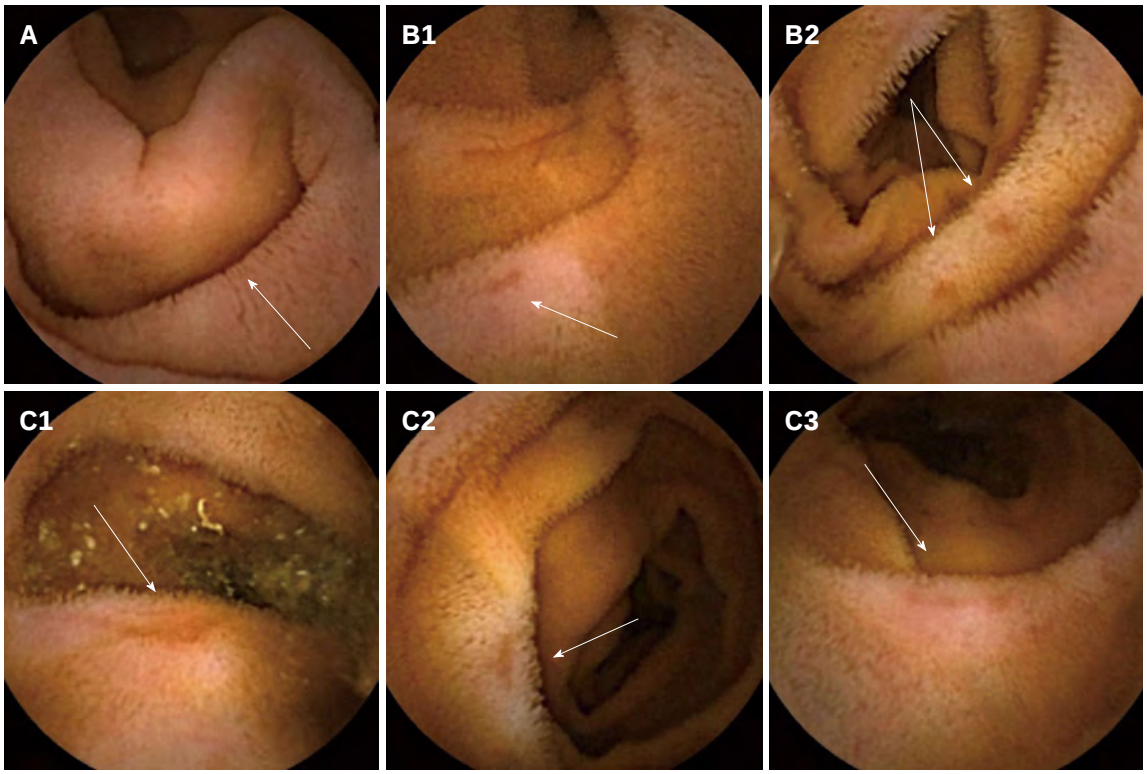

Figure 3 Examples of capsule endoscopy images in non-steroidal anti-inflammatory drug-induced enteropathy patients. A: Villous edema (arrow); B: Erosions (arrows); C: Non-steroidal anti-inflammatory drug- induced ulcers (arrows).

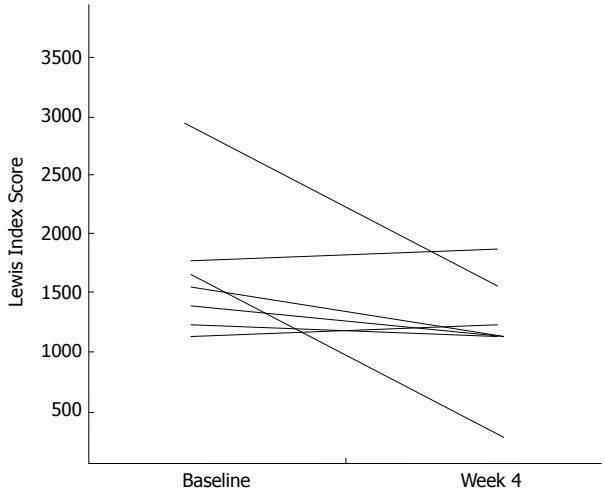

Figure 4 Lewis Index Score results before and after mesalazine granules treatment in patients with moderate-to-severe naproxen-induced enteropathy (n = 7).

graded diclofenac-induced lesions as category 1 (reddened folds), category 2 (denuded area), category 3 (petechia/red spot), category 4 (mucosal break), or category 5 (presence of blood without a visualized lesion).

A new score index has been developed by Gralnek *et al*[32] to assess mucosal changes in the small bowel detected by CE. The LIS offers objective scoring of small bowel injuries and has the potential to measure and document mucosal healing in response to therapy[33-36]. Therefore, in our study we used the LIS to assess the mucosal effect of naproxen as well as the effects of mesalazine granules therapy.

In the present pilot study we found mild and moderate-to-severe changes in the LIS in 66% of patients (10/15) who received NSAID and proton pump inhibitor therapy. These results are in a good correlation with the data from other CE studies in which NSAID-induced intestinal injury was directly evaluated. Maiden *et al*[16] found intestinal lesions using CE in 68% of healthy volunteers; Goldstein *et al*[17] reported that 55% of subjects on naproxen developed small-bowel injuries, while Fujimori *et al*[19] found small bowel mucosal breaks in 53% of subjects taking diclofenac. In these three studies, CE examinations were performed in healthy volunteers after two wk of NSAID medication. Graham *et al*[18] performed small bowel CE in chronic NSAID users with at least 3 mo history of daily NSAIDs for rheumatologic diseases. Small bowel injury was seen in 71% of these patients. Similar to this study we also recruited patients taking NSAIDs chronically which better reflects the real life situation in the small bowel compared to short-term NSAID exposure.

We analyzed the LIS results for NSAID-induced mucosal changes according to the small bowel tertiles. This analysis revealed that mucosal injuries tended to decrease in severity in the distal part of the small bowel. This result is inconsistent with a previous report in which chronic low dose aspirin-associated ulcers were observed mainly in the distal part of the small bowel[36]. However, there are no other available data regarding the topical dis-

tribution of NSAID-induced small bowel changes.

Management of NSAID-induced enteropathy is an unsolved problem. Moreover, the clinical significance of small bowel lesions is also a challenge. Proton-pump-inhibitors have been proved to be ineffective for the prevention of NSAID-induced injury[16-19]. Celecoxib, a selective COX-2 inhibitor effectively decreased the number of mucosal breaks and the percentage of subjects with at least one mucosal break[17]. Nevertheless, due to the risk of cardiovascular events, the use of COX-2 inhibitors is limited. In a recent pilot study co-administration of misoprostol was effective in preventing small bowel injury induced by NSAID medication in healthy volunteers[19]. Although the results of this short-term trial are promising, the clinical outcome of misoprostol therapy in typical chronic NSAIDs users is still an open question.

The role of sulfasalazine has been evaluated in 40 patients with rheumatoid arthritis on NSAIDs[26]. After 3-9 mo treatment, sulfasalazine (1.5-3.5 g/d) significantly reduced intestinal permeability, as measured by ^{111}In-labelled leucocytes.

Mesalazine has not yet been studied for the prevention or treatment of NSAID-induced enteropathy. Based on the hypothesis that mesalazine granules may have some therapeutic effect against NSAID-induced small bowel injury we designed a short-term therapeutic trial instead of a preventive trial. The primary objective of our pilot study was to assess the mucosal changes according to the LIS results detected by CE after 4 wk of treatment with mesalazine granules in patients receiving naproxen therapy. To avoid to inclusion of patients with clinically insignificant small bowel injuries, only patients with a LIS > 135 were recruited into the mesalazine granules therapeutic phase. When comparing the pre- and post-therapeutic LIS results in all 10 patients, a marked but not significant improvement in NSAID-induced enteropathy was observed. However, in the analysis of the 7 patients with moderate-to-severe initial enteropathy a significant improvement in the LIS was seen after treatment with mesalazine granules. These results demonstrate that patients whose initial enteropathy was more advanced benefited most from mesalazine treatment. Importantly, the improvement in LIS results was detected mainly in the first and second small bowel tertiles indicating that the mesalazine granules were effective even in the upper part of the small intestine. Although this is in contrast to the normal release profile of mesalazine, this may be due to the concomitant therapy with omeprazole.

According to the patient diaries and despite continuous NSAID treatment, our patients did not have dyspeptic symptoms or any other adverse effects. Significant anemia was not detected, either at inclusion or at the controls during the treatment phase. Ulcer-like clinical symptoms and dyspepsia are driven most probably by the gastroduodenal effect of NSAIDs which can be abolished or prevented by omeprazole co-therapy.

This is the first study to demonstrate using CE that mesalazine granules can reduce NSAID-induced macroscopic damage throughout the small intestine. This was also the first study to use the LIS system to evaluate the therapeutic effect of mesalazine granules on NSAID-induced small bowel injury. However, the trial has some inherent limitations. First, our study included only a small number of patients. Second, there was no parallel control group included to test the mucosal effect of the NSAID without mesalazine treatment. Third, this study was an open-label trial, which has a potential bias against neutrality.

Consequently, further studies are necessary to confirm the beneficial effect of mesalazine granules detected in the present pilot study.

We thank Dr. Ralph Müller for help during our clinical research and also for the advices during the manuscript preparation.

COMMENTS

Background

The side effects of non-steroidal anti-inflammatory drugs (NSAIDs) on the upper gastrointestinal tract are well-known, however, toxicity to the small bowel mucosa is an increasingly recognized problem and is emerging as a more prevalent site of injury than the stomach. Capsule endoscopy (CE) is capable of demonstrating NSAID-induced pathology in the small bowel. CE is the optimal diagnostic tool to obtain direct evidence of macroscopic injury of the small intestine, resulting from short-term (2-4 wk) administration of conventional NSAIDs. Studies in long-term NSAID users suggest that 60%-70% have an asymptomatic enteropathy characterized by increased intestinal permeability and mild mucosal inflammation. Management options for NSAID-induced enteropathy are limited. Mesalazine has not yet been studied in the treatment of NSAID-induced enteropathy. In this article the authors investigated the effect of mesalazine granules on small intestinal injury induced by naproxen in an open label, uncontrolled pilot study. The authors assessed naproxen-induced mucosal changes using CE before and after 4 wk of treatment with 3 g mesalazine granules.

Research frontiers

Entry criteria included men and women, 18-75 years of age, with at least one month history of daily naproxen use of 1000 mg for osteoarthrosis, rheumatoid arthritis, or nonspecific arthritis. To avoid gastroduodenal mucosal injury, the patients were treated with a standard dose of proton pump inhibitor. A complete small bowel CE examination within 7 d of inclusion was performed to diagnose small bowel NSAID-induced enteropathy. Patients with a Lewis capsule endoscopy scoring index of at least 135 were eligible to enter the 4-wk treatment phase of the study. During this treatment period, 3 × 1000 mg/d mesalazine granules (Salofalk® Granu-Stix®) medication was added to ongoing 1000 mg/d naproxen and 20 mg/d omeprazole therapy. At the end of the 4-wk combined therapy period, a second small bowel CE examination was performed to re-evaluate the capsule endoscopy enteropathy scoring index.

Innovations and breakthroughs

The authors found that mesalazine granules reduced the severity of small intestine lesions induced by the administration of naproxen, a non-selective NSAID. Patients, who received naproxen therapy with mesalazine granules showed markedly lower enteropathy scores compared with the period when naproxen was administered alone. Importantly, the co-administration of mesalazine granules significantly attenuated the mucosal damage caused by naproxen in patients with moderate-to-severe enteropathy.

Applications

This study offers a better understanding of the NSAID-induced enteropathy changes evaluated by the Lewis Index Score (LIS). The results demonstrated that patients whose initial naproxen-induced enteropathy was the most advanced benefited most from treatment with mesalazine granules.

Terminology

The LIS was used to investigate small bowel enteropathy alterations to

strengthen the validity of the results. The LIS is incorporated as an integral part of Given's RAPID 5 version. The scoring index is based on three capsule endoscopy variables: villous appearance, ulceration, and stenosis. The changes in villous appearance and ulceration were assessed by tertiles, dividing the small bowel transit time into three equal time allotments. The results were classified into the three categories by the final numerical score: normal or clinically insignificant change (< 135), mild change (between 135 and 790), and moderate-to-severe change (⩾ 790).

Peer review

Management of NSAID enteropathy is an unsolved problem. The authors present a pilot study in a group of patients with NSAID macroscopic lesions found in small intestine. The authors evaluate the effect of treatment by mesalazine in this group of patients using CE and an objective score (LIS). The result has limited statistical power due to the scarce number of patients included in the study. Nevertheless, the figures are promising and, as said by the authors, open an investigational field on NSAID side effects prevention/treatment, needing further investigation.

Abstract

AIM: To investigate sonographically the effect of *Gonogronema latifolium* (*G. latifolium*) on gastric emptying of semi-solid meals in healthy dogs.

METHODS: In a randomized, placebo-controlled experiment, twenty-five clinically healthy dogs were randomly allotted into five groups of five dogs in each group. The placebo group served as the control, and the low, moderate and high dose groups ingested the methanolic leaf extract of *G. latifolium* in capsules at 100 mg/kg, 250 mg/kg and 500 mg/kg, respectively, while the prokinetic group ingested 0.5 mg/kg capsules of metoclopramide. After a 12-h fast, each group ingested its treatment capsules 30 min before the administration of a test meal. Measurements of gastric emptying and blood glucose levels were obtained 30 min before and immediately after the ingestion of the test meal and thereafter every 15 min for 4 h. This was followed by further measurements every 30 min for another 2 h.

RESULTS: The gastric emptying times of the placebo, low dose, moderate dose, high dose and prokinetic dose groups were 127.0 ± 8.2 min, 135.5 ± 3.7 min, 155.5 ± 3.9 min, 198.0 ± 5.3 min and 59.0 ± 2.5 min, respectively. Gastric emptying times of the moderate and high dose groups were significantly slower than in the placebo control group (155.5 ± 3.9 min, 198.0 ± 5.3 min *vs* 127.0 ± 8.2 min, $P = 0.000$). No significant difference in gastric emptying between the low dose and placebo control groups was noted (135.5 ± 3.7 min *vs* 127.0 ± 8.2 min, $P = 0.072$). Gastric emptying of the prokinetic group was significantly faster than that of the control group (59.0 ± 2.5 min *vs* 127.0 ± 8.2 min, $P = 0.000$). The hypoglycaemic effect of *G. latifolium* and gastric emptying were inversely related ($r = -0.95$, $P = 0.000$).

CONCLUSION: *G. latifolium* delays gastric emptying and lowers postprandial blood glucose in healthy dogs. It reduces the postprandial blood glucose by delaying gastric emptying.

INTRODUCTION

Gastric emptying (GE) is the rate with which substances

leave the stomach after ingestion[1]. The process involves the storage of food, mixing with gastric secretions, grinding the solid food into particles of 1-2 mm in diameter, and subsequent delivery of the chyme into the small intestine at a rate designed to optimize digestion and absorption[2]. GE is one of the factors that affect the rate and completeness of intestinal nutrient absorption[3] and is a major determinant of postprandial glycaemic excursions not only in healthy subjects but in type 1 and type 2 diabetic patients[2].

The GE process can be influenced by a variety of physiological, pathological, pharmacological and dietary factors[4]. The effect on GE of *Gongronema latifolium* (*G. latifolium*) (Asclepiadaceae), which is used as a dietary and pharmacological agent for the control of postprandial blood glucose excursions[5,6], has, as far as we know, not been investigated previously. None of the relatively scanty information available on the mechanism(s) of action of *G. latifolium* relates to its effect on GE. We hypothesized that ingestion of a hypoglycaemic agent like *G. latifolium* might accelerate gastric emptying in healthy individuals just as insulin does[7].

In this study we investigated with the use of ultrasonography the effect of the methanolic leaf extract of *G. latifolium* on GE in health, as well as the relationship between its hypoglycaemic effect and GE, using the dog as an animal model. The study further investigated whether the effect of *G. latifolium* on GE in healthy individuals is dose dependent. This study is important as new therapies that aim to change blood glucose by modulating GE are being actively explored and evaluated.

MATERIALS AND METHODS

Plant preparation

Fresh *Gongronema latifolium* leaves were supplied, identified and authenticated by Mr. Ozioko AO, a taxonomist with the Bioresources Development and Conservation Programme Center, Nsukka, South Eastern Nigeria, an International Centre for Enthomedicine and Drug Development (INTERCEDD). A voucher specimen (INTERCEDD/170) was deposited for reference at the centre. The fresh *G. latifolium* leaves were air-dried, pulverized and the extract was prepared according to the previously described method by Ugochukwu and Babady[5]. The 2.2 kg dried powder of *G. latifolium* was extracted with 80% Romil-SA Methanol (MRS Scientific Ltd Essex United Kingdom) and dried in a hot air oven (Gallenkamp, England) at 40 ℃. The filtrates were concentrated at 40 ℃ using a vacuum rotary evaporator and freeze-dried to yield about 146.6 g of green coarse powder. The powder was further pulverized and encapsulated in doses of 100 mg, 250 mg and 500 mg for use in the study.

Animals

Clinically healthy mongrel dogs with no clinical and laboratory evidence of gastrointestinal disease, diabetes, gastroparesis, cardiovascular, pulmonary, renal, and hepatic diseases as ascertained by a veterinary doctor were used in this study. Pregnant female dogs confirmed by palpation and ultrasound were excluded. The dogs were dewormed with 5 mg/kg Levamizole® (Levamisole hydrochloride, Eagle chemical Co. Ltd, N. Korea) one week prior to the GE study. Food was withheld from the dogs for 12 h while water was withheld for 2 h before the study. The age, weight and fasting blood glucose concentration of the dogs did not differ between the control and the treatment groups ($P = 0.7$; $P = 0.2$; $P = 0.7$) (Table 1).

Table 1 Demographic and baseline clinical characteristics of the healthy groups (mean ± SD)

Characteristics	Placebo control	Low dose	Moderate dose	High dose	Prokinetic dose
Age (mo)	6.6 ± 0.7	6.5 ± 1.1	5.9 ± 0.8	6.4 ± 1.1	6.1 ± 0.3
Weight (kg)	6.2 ± 0.7	5.3 ± 0.3	5.6 ± 0.4	5.8 ± 0.7	5.7 ± 0.5
FBG (mmol/L)	4.0 ± 0.6	3.9 ± 0.1	4.0 ± 0.5	3.9 ± 0.2	4.2 ± 0.1

FBG: Fasting blood glucose.

Test meal

The test meal used consisted of 100 g proprietary canned Nestle Cerelac (Maize and Milk infant cereal, Nestle Nigeria plc) food and 150 mL of water. The calories and nutritional components in the 100 g food and 150 mL water are: Calories 1730 KJ (414 kcal); Protein 15 g; Fat 9 g; Carbohydrates 68.2 g; Dietary fibre 2 g; Minerals (ash) 3.3 g; Moisture 2.5 g.

Study design

The study was approved by the University of Nigeria Ethical Committee UNTH Enugu. The guidelines of the National Institutes of Health (NIH) *Principles of Laboratory Animal Care* (NIH Publication No. 86-23, revised 1985) were followed. This clinic-based experimental study was carried out in the University of Nigeria Veterinary Teaching Hospital, Nsukka. A randomized, placebo-controlled experimental design was adopted in this study and the dog was used as an animal model because of its established performance in the assessment of gastrointestinal motility[3] and in many physiological and pharmacological studies[8]. The dogs were randomly allotted into five groups of five dogs in each group. The placebo group served as the control; the low, moderate and high dose groups ingested the *G. latifolium* leaf extract capsules at 100 mg/kg, 250 mg/kg, 500 mg/kg, respectively, while the prokinetic dose group ingested 0.5 mg/kg capsules of metoclopramide (Mederax® 10 mg, Jiangsu Peng YAO Pharmaceutical Inc China). The prokinetic dose group served as prokinetic control. The prokinetic effect of metoclopramide is comparable to the insulin effect on gastrointestinal motility[7].

After a 12-h fast, each group ingested its treatment capsules 30 min before the administration of the test meal. Measurements of GE and blood glucose levels were obtained 30 min before and immediately after the ingestion of the test meal and then every 15 min for 4 h for each dog. Further measurements were made every 30 min for another 2 h. The three doses of *G. latifolium* were

Group	GE (min)	AUC of *i*PPBG (mmol/L × min)
Placebo control	127.0 ± 8.2	1028.6 ± 204.2
Low dose	135.5 ± 3.7	938.1 ± 40.0
Moderate dose	155.5 ± 3.9[b]	559.1 ± 101.8[b]
High dose	198.0 ± 5.3[b]	223.5 ± 52.2[b]
Prokinetic dose	59.0 ± 2.5[b]	1426 ± 108.2[b]

[b]$P < 0.0001$ *vs* control group. *i*PPBG: Incremental postprandial blood glucose concentrations; GE: Gastric emptying; AUC: Area under the curve.

introduced to assess its dose-dependent effect. The minimum dose of 100 mg/kg was based on the dose used in mice and rats[5,9]. All the treatment capsules ingested by the dogs were visually identical. The dogs ingested the test meal under natural free-feeding circumstances.

Measurement of gastric emptying

Gastric emptying was measured using an ultrasound technique as described by Chalmers *et al*[10] and McLellan *et al*[11]. The examinations were performed using a veterinary ultrasound machine with a 6-8 MHz microconvex transducer (Medison SA-600 v; 2006; Medison Co., Ltd., South Korea). Each dog was gently restrained while erect and the transducer was placed in a longitudinal orientation on the ventral midline, caudal to the xiphoid. The ultrasound beam was maintained in the sagittal plane and directed cranially until the liver was located and the stomach identified immediately caudal to it. The stomach was observed using real-time imaging, allowing the image to be frozen between peristaltic contractions when it was at a constant, maximal distension. Electronic callipers were used to measure the craniocaudal and ventrodorsal diameters of the antrum between the serosal margins. The antral area was calculated by using the software incorporated in the ultrasound machine to predict the area inside the elliptical shape defined by the craniocaudal and ventrodorsal diameters of the stomach. Three measurements of antral area were taken at each time, and their mean was used for further calculations. Baseline values were subtracted from the measurements made at each subsequent time point and the values expressed as a percentage of maximal antral area. The percentages of the maximal antral areas measured during each test were plotted against time. The gastric half-emptying time with ultrasonography (T50) that correlated significantly with $t_{1/2}$ of carbon 13-labelled octanoic acid breath test in dogs[11] was used to describe the rate of GE. The T50 was defined as the time at which the antral area decreased to 50 percent of its maximal area. T50 was calculated by linear interpolation between two points in the curve.

Measurement of blood glucose

Five millilitres of blood was drawn from each dog's ear at specific time intervals indicated in the study design. Blood glucose was determined by using a portable Accu-chek® Advantage glucometer (Roche Diagnostics GmbH Mannheim Germany). The incremental blood glucose concentrations were computed and plotted against time, and the blood glucose area under the curve (AUC) was calculated from the blood glucose curve.

Statistical analysis

All the data were expressed as mean ± SD. Dunnett's test was used for parametric multiple comparisons between the control and the treatment groups. Analysis of variance linear trend test was used to assess the dose trend. Pearson correlation was used to assess the linear association between the values of two variables. The values were considered to be significant when the P value was less than 0.05. Graphpad prism version 5.03 for windows (Graphpad Software San Diego California United States) and SPSS 15.0 for Windows Evaluation Version (United States) were used for statistical analysis.

RESULTS

Effect of G. latifolium leaf extract on GE

The GE times of the moderate and high dose groups were significantly ($P = 0.000$) slower than in the placebo control, while the GE of the prokinetic group was significantly ($P = 0.000$) faster than in the placebo control group (Table 2). No significant ($P = 0.072$) difference in GE was observed between the low dose and control groups. The effect of *G. latifolium* on GE was also significantly ($P = 0.000$) dose dependent (Figure 1A).

Effect of G. latifolium leaf extract on postprandial blood glucose concentration

The AUC values of incremental postprandial blood glucose concentrations (*i*PPBG) of the moderate and high dose groups were significantly ($P = 0.000$) smaller than in the placebo control, while the AUC of *i*PPBG of the prokinetic group was significantly ($P = 0.000$) larger than that of the placebo control (Table 2). No significant ($P = 0.442$) difference in AUC of *i*PPBG was observed between the low dose and control groups. The effect of *G. latifolium* on AUC of *i*PPBG of healthy dogs was significantly ($P = 0.000$) dose-dependent (Figure 1B).

The hypoglycaemic effect of G. latifolium and GE

The hypoglycaemic effect of *G. latifolium* and GE were inversely related ($r^2 = 0.95$) (Figure 2).

DISCUSSION

The gastric emptying process can be influenced by a variety of physiological, pathological, pharmacological and dietary factors[4] but the effect on GE of *G. latifolium*, which is used as a dietary and pharmacological agent for the control of postprandial blood glucose excursions[5,6], has, as far as we know, not been investigated in animals/humans previously. In this study, we demonstrate that the ingestion of the methanolic extract of *G. latifolium* delayed the gastric emptying of a semi-solid meal dose-dependently.

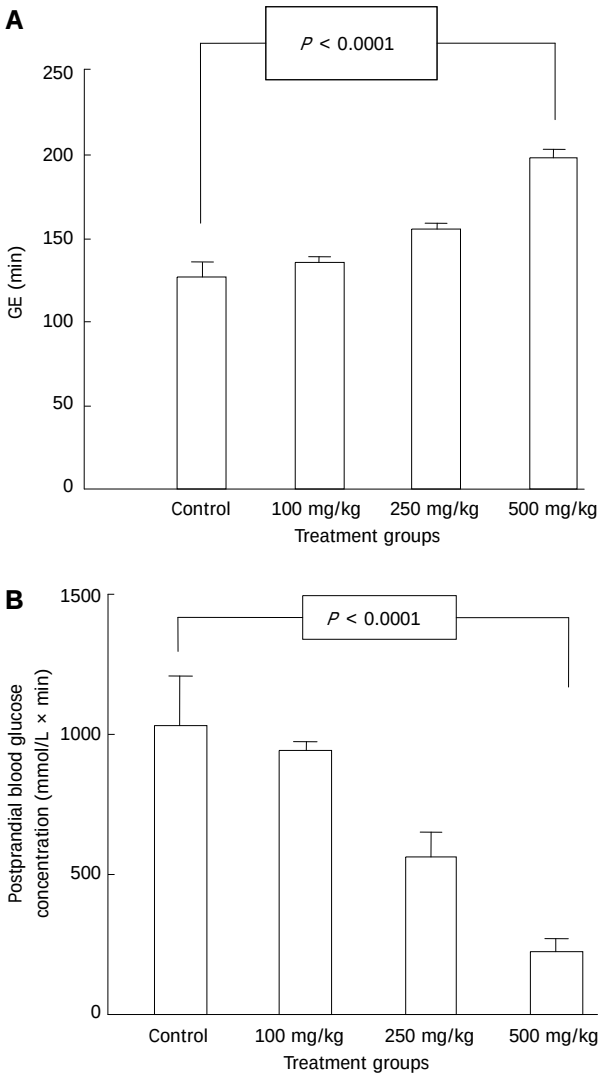

Figure 1 Dose-dependent effect of *Gongronema latifolium* on gastric emptying and postprandial incremental blood glucose concentrations. A: Dose-dependent effect of *Gongronema latifolium* (*G. latifolium*) on gastric emptying; B: Dose-dependent effect of *G. latifolium* on postprandial incremental blood glucose concentrations. GE: Gastric emptying.

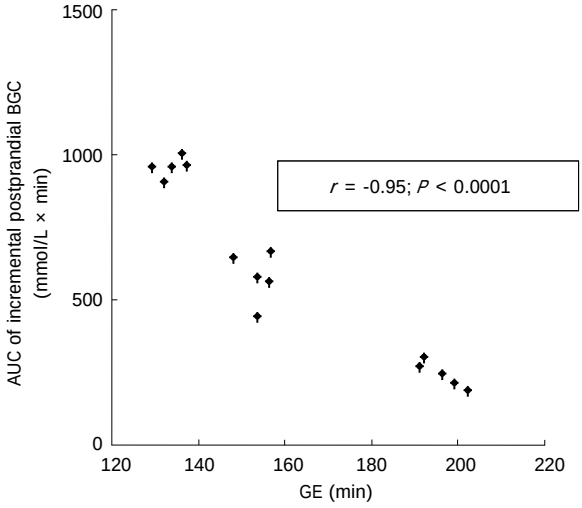

Figure 2 Relationship between the hypoglycaemic and gastric emptying effects of *Gongronema latifolium*. GE: Gastric emptying; AUC: Area under the curve; BGC: Blood glucose concentration.

The effect is similar to that of *Trigonella foenum-graecum*[12] and that of *Gymnema sylvestre*[13,14] which belong to the same Asclepiadaceae plant family as *G. latifolium*[15,16], but opposite to that of metoclopramide as noted in this study.

The presence of saponins in *G. latifolium*[17] and *G. sylvestre*[13,14] may be responsible for the similarity in their GE effects. Saponins significantly and dose-dependently delay gastric emptying[12-14,18]. GE is linearly associated with changes in the antral area[11,19,20]; therefore, our data suggest that *G. latifolium* causes less rapid reductions in antral areas and an increase in antral areas. This agrees with works which associated substances that slow GE with a relative increase in the content of the distal stomach[21,22] and inhibition of antral motility[23]. The more rapid reductions in antral areas and a decrease in antral areas observed with metoclopramide in this study are because it improves GE by increasing amplitude and frequency of antral contractions[4]. Therefore, the observed difference between the GE effect of metoclopramide and that of *G. latifolium* in this study may be due to their different mechanisms of action.

The mechanisms underlying the delayed effects of *G. latifolium* on GE were not evaluated in this study, but we speculate that the effect may be mediated by vagal mechanisms[21,24-26] and/or the release of gastrointestinal hormones[27]. *G. latifolium* may have elicited a gastrointestinal motor and/or sensory function that caused antral distension and subsequently suppressed antral contractions to result in a slower rate of antral delivery of the ingested semi-solid meals. The demonstration of the potential of *G. latifolium* to slow the rate of antral delivery of the ingested semi-solid meals from the stomach into the small intestine by this study is very important as new therapies that aim to change blood glucose by modulating GE are being actively explored and evaluated. The effect has hitherto not been demonstrated in animals or humans.

This study also demonstrates that there is an inverse relationship between the GE effect of *G. latifolium* and blood glucose concentration. It agrees with the fact that the pharmacologic acceleration of GE results in higher postprandial glucose concentrations, while delaying GE results in lower postprandial glucose concentrations after a physiologic meal[28]. Although the demonstration of a correlation does not establish causation, this finding suggests that *G. latifolium* when ingested with a meal may, through the mechanism of delayed GE, slow digestion and prolong the postprandial absorption of food, with a resultant improvement or reduction in postprandial blood glucose concentrations after a semi-solid meal. The rates of meal-derived glucose appearance in the systemic circulation are determined mainly by GE[29,30]. A previous work indicates that saponins with hypoglycaemic activity also inhibited GE while other saponins that have no hypoglycaemic activity did not affect GE[31]. Thus, saponins in *G. latifolium* may be responsible for the correlation between GE and its hypoglycaemic effects in healthy dogs. Some authors have proposed that saponin compounds act as hypogly-

caemic agents by delaying the transfer of glucose from the stomach to the small intestine, the main site of glucose absorption, and by inhibiting the glucose transport at the site of intestinal brush border membranes[32,33].

In this study, 100 mg/kg of *G. latifolium* did not significantly slow GE, probably due to low dose-response effect. The 100 mg/kg dose of *G. latifolium* might be below the threshold required to cause a significant delay on GE. Our findings that *G. latifolium* in a dose-dependent manner affects both the rate and extent of carbohydrate absorption by slowing the transfer of food from the stomach into the small intestine and thereby reducing or delaying exposure of nutrient to small bowel mucosa are clinically relevant with regard to improving postprandial blood glucose and triglycerides and consequently lowering the risk of chronic disease. Distension of the stomach is one factor that promotes the feeling of satiety[34]. Therefore, *G. latifolium* may, through the mechanism of delayed GE, play an important role in the regulation of appetite and energy intake. Finally, since interventions directed at modulating upper gastrointestinal motor and absorptive functions have a major effect on postprandial blood glucose excursion and are likely soon to enter the mainstream of therapy for diabetes[2,35], *G. latifolium* may be relevant in the current treatment and management of diabetes. Alternatively hyperglycaemia can cause a decrease in GE rate[36,37]. This factor is unlikely to have influenced the result of this study much since there was no statistically significant difference between the preprandial blood glucose concentrations in the subgroups when compared with the placebo control.

The neural, humoral and cellular mechanisms by which *G. latifolium* affects GE were not investigated, therefore further studies are required to elucidate them. Although the dog is an animal model for the study of human GE in many physiological and pharmacological studies[8] and an established model for the assessment of gastrointestinal motility[3], the pattern of findings may not be exactly the same in humans as demonstrated in this study.

Gongronema latifolium delays GE and lowers postprandial blood glucose in healthy dogs. It reduces the postprandial blood glucose by delaying GE. The effect has also been noted to be dose-dependent. Therefore it can play an important role in the current dietary and pharmacological approaches in the prevention, treatment and management of metabolic diseases like diabetes.

ACKNOWLEDGMENTS

We would like to thank Dr. Anya KO of the University of Nigeria Veterinary Teaching Hospital, Nsukka for the assistance in taking care of the dogs.

COMMENTS

Background

Gastric emptying is a major determinant of postprandial glycaemic excursions not only in healthy subjects but in diabetic patients. Interventions directed at modulating gastric emptying have a major effect on postprandial blood glucose excursion. *Gongronema latifolium* (*G. latifolium*) (Asclepiadaceae) is currently used as a dietary and pharmacological agent for the control of postprandial blood glucose excursions, but its effect on gastric emptying has, as far as we know, not been reported.

Research frontiers

Previous studies have demonstrated the hypoglycaemic effect of *G. latifolium*, but none of the relatively scanty information available on its mechanism(s) of action relates to its effect on gastric emptying. In this study, the authors demonstrated that the gastric emptying delaying effect of *G. latifolium* could be one of the pathways for reducing the postprandial blood glucose level.

Innovations and breakthroughs

New therapies that aim to change blood glucose by modulating gastric emptying are being actively explored and evaluated. This is believed to be the first study to explore the effect of *G. latifolium* on gastric emptying in health as well as the relationship between its hypoglycaemic effect and gastric emptying.

Applications

The findings that *G. latifolium* in a dose-dependent manner slows the rate of antral delivery of the ingested semi-solid meals from the stomach into the small intestine may be clinically relevant in the management approach of postprandial blood glucose and triglycerides and consequently in diabetics.

Terminology

Gastric emptying is the rate with which substances leave the stomach after ingestion. The process involves the storage of food, mixing with gastric secretions, grinding the solid food into particles of 1-2 mm in diameter, and subsequent delivery of the chyme into the small intestine at a rate designed to optimize digestion and absorption. *G. latifolium* (Asclepiadaceae) is an edible tropical rainforest plant that is widely used in folk medicine.

Peer review

The authors present data on the effects of various doses of the methanolic leaf extract of *G. latiifolium* on gastric emptying and postprandial plasma glucose levels in a dog animal model. Gastric emptying was measured by ultrasonography. The data demonstrate dose related effects on inhibiting gastric emptying and plasma glucose.

Abstract

AIM: To assess the outcomes of ampulla dilation with different sized balloons to remove common bile duct (CBD) stones.

METHODS: Patients (n = 208) were divided into five groups based on the largest CBD stone size of < 5, 6-8, 8-12, 12-14, and > 14 mm. Patients underwent limited endoscopic sphincterotomy (EST) alone or limited EST followed by endoscopic papillary balloon dilation with 8, 10, 12 and 14 mm balloons, such that the size of each balloon did not exceed the size of the CBD. Short- and long-term outcomes, such as post-endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis, perforation, bleeding, and pneumobilia were compared among the five groups.

RESULTS: The overall rate of successful stone removal in all groups was 100%, and all patients were cured. Eight (3.85%) patients had post-ERCP pancreatitis, none had perforations, and 6 (2.9%) had bleeding requiring transfusion. There were no significant differences in early complication rates among the five groups. We observed significant correlations between increased balloon size and the short- and long-term rates of post-ERCP pneumobilia. Post-ERCP pancreatitis and bleeding correlated significantly with age, with post-ERCP pancreatitis occurring more frequently in patients aged < 60 years, and bleeding occurring more frequently in patients aged > 70 years. We observed a significant correlation between patient age and the diameter of the largest CBD stone, with stones > 12 mm occurring more frequently in patients > 60 years old.

CONCLUSION: Choosing a balloon size based on the largest stone diameter is safe and effective for removing CBD stones. Balloon size should not exceed 15 mm.

INTRODUCTION

Endoscopic sphincterotomy (EST) and endoscopic papillary balloon dilation (EPBD) with balloons < 12 mm in diameter are the methods of choice for the removal of stones from the common bile duct (CBD)[1-4]. Both methods, however, have distinct advantages and disadvantages. EST is associated with serious short-term complications, such as hemorrhage, perforation, and pancreatitis,

and long-term complications such as permanent loss of sphincter of Oddi (SO) function and recurrent bile duct infection[5-7]. Although complications of bleeding and perforation seldom occur during EPBD[8-10] and SO function can be preserved[11,12], it is difficult to remove large CBD stones using EPBD because the biliary opening is not as enlarged as it is with EST, and EPBD is associated with a higher rate of post-endoscopic retrograde cholangiopancreatographic (ERCP) pancreatitis.

More recently, EPBD with large sized balloons (12-20 mm) has been used to remove large CBD stones following limited EST[13-16]. It is unclear, however, whether the increase in balloon size is associated with increased rates of short-term complications, such as perforation and hemorrhage, or with preservation of SO function. Combining the advantages of EST and EPBD, by selecting the correct sized balloon and EST incision length to achieve a high rate of stone extraction, while minimizing complications of both procedures, would be of great benefit to the patients. We therefore prospectively investigated the short- and long-term outcomes of different sized balloons, chosen according to each patient's maximum CBD stone size, to dilate the papilla following limited EST.

MATERIALS AND METHODS

Patients

Patients with possible CBD stones, as diagnosed by biliary symptoms and abnormality of biliary enzymes, or whose presence was suspected through imaging modalities, such as ultrasound (US), computed tomography (CT) and/or magnetic resonance imaging (MRI) were screened. Patients were excluded if they had (1) severe acute pancreatitis (APACHE Ⅱ $\geqslant$ 8, or Balthazar CT score $\geqslant$ 4); (2) severe cholangitis with disturbance of consciousness and shock; (3) coagulopathies; (4) malignant diseases; (5) a history of previous EPBD or EST; (6) age > 85 years; (7) a CBD filled with stones; and (8) had undergone a Billroth Ⅱ gastrectomy. Patients who met these criteria and lived in Shanghai, enabling follow-up, were fully informed about the methods and possible complications of the procedure, and were asked to provide written informed consent before ERCP. The study was approved by the Ethics Committee of Shanghai Gongli Hospital, and was supported by the Shanghai Municipal Health Bureau.

Patients were enrolled if selective deep cannulation to the CBD was successful, CBD stones were diagnosed by ERC, and an incision was made to the mid-portion of the papilla with a pull-type sphincterotomy. The diameter of the largest stone was determined by comparing it with the size of the endoscope tip. Patients were divided into five groups based on the largest CBD stone size, of (1) < 5 mm, (2) 6-8 mm, (3) 8-12 mm, (4) 12-14 mm, and (5) > 14 mm. These groups underwent limited EST alone without EPBD, and EPBD with balloons of 8, 10, 12 and 14 mm in diameter, respectively, such that the size of each balloon did not exceed the size of the CBD.

Methods

Pharyngeal anesthesia and premedication before the procedure, including the intravenous administration of diazepam, meperidine hydrochloride, and scopolamine, were performed in the same manner as for general endoscopy. ERCP was performed with a side-viewing endoscope (JF240; JF260V; Olympus, Tokyo, Japan).

Limited EST was performed according to the standard methods using a pull-type sphincterotomy. The incision was made up to the mid-portion of the papilla.

Endoscopic papillary balloon dilation

A balloon dilation catheter of 8, 10, 12 or 14 mm in diameter (Wilson-Cook Medical Inc., NC, United States), was inserted and inflated slowly with diluted contrast fluid until the waistline was obliterated under fluoroscopic monitoring and maintained for one min at 6 atm or 8 atm as required. After the balloon was deflated, the stones were extracted using a retrieval basket (Wilson-Cook Medical Inc., NC, United States) and/or a retrieval balloon (Extracter XL; Boston Scientific Corporation, MA, United States).

When the stone diameter was > 16 mm, as shown by diagnostic ERCP, a mechanical lithotripter (ML; BML-4Q; Olympus Corporation, Tokyo, Japan) was used to break the stones into fragments.

Follow-up

All patients were seen at the outpatient clinic six months to one year after discharge and every year thereafter. At each visit, blood and liver function tests, abdominal US and CT were performed. Other relevant examinations were performed when deemed necessary. If stone recurrence was suspected from symptoms, laboratory data, and/or images, ERCP was performed, and the recurrent stone was removed.

Outcome measures

Short-term outcomes included the rates of post-ERCP pancreatitis, bleeding requiring transfusion, perforation, pneumobilia and mortality. Long-term (2-5 years) outcomes included the rates of reflux cholangitis, pneumobilia, and recurrence of CBD stones.

Statistical analysis

Statistical analyses were performed using statistical software (SPSS 12.0 for Windows; SPSS Inc., Chicago, IL, United States). Quantitative data were presented as the mean ± SD. The χ^2 test or Fisher's exact test was used to compare sex distribution, and rates of mechanical lithotripter (ML) use, gallbladder *in situ*, concomitant gallbladder stones, and early and later complications in the 5 groups. ANOVA was used to compare age, number of stones, diameter of largest stone, and relationships between age and post-ERCP pancreatitis and bleeding in the 5 groups. A P value < 0.05 was considered statistically significant.

RESULTS

Patient characteristics and early complications

We enrolled 208 consecutive patients (95 males and 113 females), all of whom were diagnosed with CBD stones by ERC and underwent successful selective deep cannulation to the CBD at our institution between January 1, 2006, and January 1, 2008. Mean patient age was 62.4 ± 15.0 years. Stones were successfully removed from all the patients in all 5 groups. The demographic data and baseline characteristics of the 5 groups are shown in Table 1.

We observed a significant correlation between patient age and the diameter of the largest stone, with stones > 12 mm occurring more frequently in patients > 60 years old. The ML was used more often in patients with larger CBD stones, especially for stones > 16 mm in diameter. Although the overall success rate of stone removal was 100% in all groups, two patients in the 14 mm balloon group and one in the 12 mm group each required 2 sessions for stone removal due to patient intolerance of a long operation time to remove large stones.

Early complications

All patients were cured, none died, and none had a perforation. We found that 8 (3.85%) patients had post-ERCP pancreatitis, including 1 in the 10 mm balloon dilation group who had severe pancreatitis. All patients were cured by conservative treatments. Six (2.9%) patients experienced upper gastrointestinal bleeding requiring transfusions, including 2 patients with bleeding in the stomach and 4 with bleeding in the duodenal papilla. Two patients were cured by angiographic embolization and 1 by laparotomy to ligate the bleeding vessel after 2 attempts of endoscopic clamping and 1 of angiographic embolization all failed. The other 3 patients were cured conservatively. There were no significant differences in early complication rates among the five groups.

Pneumobilia occurred in 55 (26.4%) patients at a mean of 4.9 ± 0.7 d (range, 3-7 d) after ERCP. We observed a significant correlation between increased balloon size and the incidence of pneumobilia, suggesting that dilation with a large balloon may cause more damage to SO function. Details of early complications are described in Table 2.

Interestingly, post-ERCP pancreatitis and bleeding correlated significantly with age, with post-ERCP pancreatitis occurring more frequently in patients aged < 60 years, and bleeding occurring more frequently in patients aged > 70 years. The 8 patients with post-ERCP pancreatitis were significantly younger than the 200 who did not develop post-ERCP pancreatitis (51.1 ± 8.3 years *vs* 63.5 ± 15.1 years, P = 0.026). Conversely, the 6 patients with bleeding were significantly older than the 202 who did not develop bleeding (75.7 ± 7.1 years *vs* 61.4 ± 15.0 years, P = 0.024).

Later complications

Of the 208 patients, 192 (92.3%) were followed up for at least 2 years, with a mean follow-up time of 3.2 ± 1.1 years (range, 2-5 years). There were no significant differences in the rates of later complications, including reflux cholangitis and recurrence of CBD stones, among the 5 patient groups.

The incidence of pneumobilia one year after ERCP was significantly lower than shortly after ERCP, suggesting that SO function had recovered, at least partially, in these patients. We observed a significant correlation between the size of the dilation balloon and the 1-year incidence of pneumobilia, suggesting that larger balloons may cause more damage to SO function. The details of later complications in each group are shown in Table 2.

DISCUSSION

As no standard endoscopic procedure has been developed to date to maximize the effects and minimize the complications of EST and EPBD[17,18], we prospectively assessed a method combining EPBD with limited EST. CBD stone sizes vary, from 3-5 mm in diameter to 15-30 mm in diameter, or even larger, suggesting that an endoscopic treatment method should be based on stone size. We therefore utilized limited EST alone for CBD stones < 5 mm in diameter, and limited EST followed by EPBD with balloons of 8, 10, 12 and 14 mm for CBD stones 6-8, 8-12, 12-14 and > 14 mm, respectively. We found that tailoring balloon size to stone size was safe and effective,

Table 2 Early and later complications in the 5 patient groups

	Balloon size					
	EST alone (n = 42)	8 mm (n = 35)	10 mm (n = 87)	12 mm (n = 29)	14 mm (n = 15)	P value
Early complications						
Post-ERCP pancreatitis	1	2	3	1	1	0.918
Perforation	0	0	0	0	0	
Bleeding	1	1	3	1	0	0.961
Incidence of pneumobilia	7	5	25	11	7	0.039
Later complications						
Long term outcome						
Incidence of pneumobilia	2	1	10	5	4	0.029
Reflux cholangitis	0	0	2	2	1	0.235
Recurrence of CBD stones	0	0	2	1	0	0.624

ERCP: Endoscopic retrograde cholangiopancreatography; EST: Endoscopic sphincterotomy; CBD: Common bile duct.

with low rates of short- and long-term complications.

Limited EST was sufficient to remove CBD stones < 5 mm in diameter, as the biliary opening was large enough to remove these stones. EBPD was not required as balloons larger than CBD stones can cause more damage to SO function. We found that limited EST did not cause any perforations, an often fatal complication and even more serious than pancreatitis and bleeding, and preserved SO function.

We also found that limited EST followed by EPBD with balloons < 12 mm in size could partially preserve SO function. Although limited EST plus EPBD with balloons 12-14 mm in size did not cause any perforations, it was associated with higher rates of pneumobilia, both shortly after ERCP and ⩾ 2 years later, compared with limited EST alone or followed by EPBD with smaller balloons, suggesting that large balloons result in greater damage to SO function.

Limited EST followed by EPBD has several benefits, including a lower incidence of post-ERCP pancreatitis. After EST, the openings of the pancreatic duct and common bile duct separate, decreasing the pressure on the pancreatic duct caused by EPBD and papillary edema[19]. Using limited EST in all our patients with CBD stones, we found that the overall incidence of post-ERCP pancreatitis was 3.85%, lower than previously reported[5-7,10]. Limited EST combined with EPBD can also make cannulation easier and reduce the procedure and fluoroscopy times[20] by shortening the cannulation length, and is safer than full EST or EPBD alone, because full EST may lead to perforation, while EPBD alone may lead to post-ERCP pancreatitis. Furthermore, limited EST is easier to perform than full EST. We have successfully utilized this method to remove large CBD stones since 1999[21], and have found that it is a good choice for different sized CBD stones.

Large balloon dilation of the papilla may make the removal of CBD stones easier, reducing the need for an ML, and shortening cannulation and stone removal times, thus decreasing the incidence of post-ERCP pancreatitis. However, we did not use a balloon > 15 mm. A recent study in animals showed that EPBD with balloons < 15 mm was safe, with no perforations, whereas balloons > 15 mm was associated with a significantly higher rate of perforation[22]. In contrast, the use of 8 mm balloons in animals showed that EPBD was not associated with fibrosis or altered papillary architecture[23] and many clinical reports have shown that EPBD with large balloons > 15 mm was effective and safe[13-16]. However, the risk of perforation is higher with large balloons, prolonging hospitalization and increasing costs. We also found that increased dilation size was significantly associated with an increased incidence of pneumobilia, indicating that dilation with large balloons may cause more damage to SO function. Although we found no significant differences in later complications, such as reflux cholangitis and recurrence of CBD stones among the 5 patient groups, follow-up time may not have been sufficiently long. SO function is important in preventing biliary diseases, such as acute cholecystitis, cholangitis and recurrence of CBD stones[24], suggesting that preserving SO physiological function may be advantageous, especially in younger patients. Our findings also indicate that 14 mm balloons were large enough to remove CBD stones > 15 mm, assisted by an ML. Taken together, our findings indicate that limited EST, followed by EPBD with balloons < 15 mm is safe.

We found that the rate of post-ERCP pancreatitis and bleeding correlated with patient age, with patients < 60 years more frequently having post-ERCP pancreatitis and patients > 70 years more prone to bleeding. The progressive decline in pancreatic exocrine function with age may protect older patients from pancreatic injury[25,26]. In contrast, the Oddi muscle may be stronger in younger than in older patients, resulting in more difficult dilation in the former and a higher rate of pancreatitis. Although bleeding has seldom been reported after EBPD, we found that 6 (2.9%) of our patients had upper gastrointestinal bleeding requiring transfusions. All 6 were > 65 years old, with a mean age of 76 years. Older patients may be more prone to bleeding due to the relative inelasticity of their blood vessels. We also observed a correlation between CBD stone size and patient age, with stones > 12 mm occurring more frequently in patients > 60 years old.

The main limitation of this study was that we evaluated SO function by pneumobilia incidence, and not by endoscopic manometry. Manometry requires cannulation to the CBD, making it painful for patients and unacceptable during follow-up. Other limitations include the performance of this study at a single center, the relatively small number of patients, and the relatively short follow-up period.

In conclusion, limited EST, alone or followed by EPBD with balloons 8-14 mm, is safe and effective for the removal of different sized CBD stones. Choosing balloon size based on CBD stone size can maximize outcomes and minimize the complications of both EST and EPBD. Balloons > 15 mm in size are not necessary.

COMMENTS

Background

Common bile duct (CBD) stones are very common, and patients are traditionally treated by open CBD exploration. With the advent of invasive endoscopic techniques, more patients are being treated endoscopically. However, endoscopists are often faced with difficult treatment decisions: endoscopic sphincterotomy (EST) or endoscopic papillary balloon dilation (EPBD)? Both methods have distinct advantages and disadvantages. The authors of this study prospectively investigated the short-and long-term outcomes of different sized balloons to dilate the papilla following limited EST.

Research frontiers

Both EST and EPBD are used for patients with CBD stones. Limited EST combined with EPBD has become popular for the removal of CBD stones in recent years, as it is thought to maximize outcomes and minimize the complications of both EST and EPBD.

Innovations and breakthroughs

This study investigated the short- and long-term outcomes of different sized balloons, chosen according to each patient's maximum CBD stone size, to dilate the papilla following limited EST. The authors found that choosing a balloon size no more than 15 mm based on the diameter of each patient's largest CBD stone is a good choice for removing CBD stones.

Applications

EPBD using a balloon size no more than 15 mm based on the diameter of patient's largest CBD stone following limited EST was proven to be a safe and effective treatment for CBD stones, and should be recommended for patients with CBD stones.

Terminology

ERCP: endoscopic retrograde cholangiopancreatography, a technique that combines the use of endoscopy and fluoroscopy to diagnose and treat certain problems of the biliary or pancreatic ductal systems; EST: endoscopic sphincterotomy, a minimally invasive surgery that was developed on the basis of ERCP to treat biliary or pancreatic ductal disease, the incision is made up to the full-portion of the papilla; Limited EST: like EST, the incision is made up to the mid-portion of the papilla; EPBD: endoscopic papillary balloon dilation, the papilla is dilated with a balloon to facilitate the removal of CBD stones.

Peer review

This is a good study in which authors evaluate the short- and long-term outcomes of different sized balloons to dilate the papilla following limited EST. The results are interesting and suggest that choosing balloon size no more than 15 mm based on the diameter of each patient's largest CBD stone is a good choice for removing CBD stones.

Abstract

AIM: To give a comprehensive report of E-cadherin gene (*CDH1*) variations in a population at a high risk for gastric cancer (GC).

METHODS: The samples consisted of 178 men and 58 women with a mean age of 62.3 ± 9.4 years and an age range of 30-84 years. A total of 240 cancer-free controls were recruited (mean age of 61.8 ± 10.1 years, age range of 26-82 years). Samples were screened for *CDH1* germline mutations by high-resolution melting analysis or directly sequencing. Luciferase reporter assay, RNA splicing assay and bioinformatic analysis were used to evaluate the effect of mutations.

RESULTS: Four novel *CDH1* sequence alterations were identified in GC patients including a G>T transition 49 bp before the start codon; a three-nucleotide deletion, c.44_46del TGC; one missense mutation, c.604G>A (V202I); and one variation in the intron, c.1320+7A>G. In addition, polymorphism frequencies were observed for *CDH1*-164delT, -161C>A, -73A>C, c.48+6C>T, c.48+62_48+63delinsCGTGCCCCAGCCC, c.894C>T (A298A), c.1224G>A (A408A), c.1888C>G (L630V), c.2076T>C (A692A), and c.2253C>T (N751N) which is similar to the data reported in http://www.ncbi.nlm.nih.gov/projects/SNP/. RNA splicing analysis suggested that the c.1320+7A>G and c.1224G>A variations did not affect exon splicing ability. Luciferase reporter assay demonstrated that the c.-49T variation might be helpful for *E-cadherin* transcription, though the increase in transcription activity is limited (only 33%). SIFT score and PolyPhen analysis both demonstrated that the L630V missense mutation probably damages protein function, while the V202I variant does not.

CONCLUSION: This study reveals novel mutations in sporadic GC patients which had been poorly investigated for susceptibility genes.

Novel *CDH1* germline mutations identified in Chinese gastric cancer patients. *World J Gastroenterol* 2013; 19(6): 909-916 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/909.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.909

INTRODUCTION

Gastric cancer (GC) is one of the most common malignancies worldwide and the leading cancer in East Asian countries[1]. There are two histopathological types of gastric cancer, differentiated and undifferentiated[2], or intestinal and diffuse, respectively[3]. Genetic factors are important for the etiology of GC. The E-cadherin gene (*CDH1*), a calcium-dependent transmembrane glycoprotein, is critical for epithelial architecture, intercellular adhesion, and cell invasion[4]. E-cadherin consists of a large extracellular domain composed of five repeat domains and smaller transmembrane and cytoplasmic domains[5]. Mutations in the *CDH1* gene and perturbation of E-cadherin expression are the most frequent genetic alterations in hereditary diffuse gastric cancer (HDGC)[6,7]. The *CDH1* germline mutation spectrum is heterogeneous and includes point mutations, small deletions, and insertions distributed along the entire coding sequence[8-10]. In *CDH1* germline variation carriers, the lifetime penetrance is estimated to be approximately 70%[11]. The identification of *CDH1* mutations offers the opportunity for the development of cancer risk-reduction strategies for unaffected at-risk individuals. About 90% of gastric carcinoma presents a sporadic setting and only 10% shows a familial cluster; among this group, about 15% are considered as hereditary syndromes, such as the HDGC. For sporadic GC, germline *CDH1* mutations are seldom reported.

In this study, we carried out a comprehensive screen of *CDH1* germline mutations in 236 Chinese GC patients (175 sporadic cases and 61 cases with hereditary predisposition) (Table 1) and identified four novel germline *CDH1* mutations in sporadic GC patients. In addition, the *CDH1* polymorphism frequencies in Chinese GC patients and controls were determined. Furthermore, functional assays were carried out to evaluate the impact of the novel mutations identified.

MATERIALS AND METHODS

Subjects

Gastric cancer patients from the East District of China having disease onset between January 1 and December 31, 2008, in whom tumors had been confirmed using histology, were investigated. The samples consisted of 178 men and 58 women with a mean age of 62.3 ± 9.4 years and an age range of 30-84 years. A total of 240 cancer-free controls were recruited (mean age of 61.8 ± 10.1 years, age range of 26-82 years) (Table 1). Details regarding the following information are summarized in Table 1: gastric cancer family history, age of onset and histological and tumor-node-metastasis (TNM) staging classifications. Informed consent, according to the Ethics Committee of the Medical School of Nanjing University, was obtained from all subjects who underwent genetic testing.

Table 1 Frequency distributions of variables in gastric cancer cases and controls *n* (%)

Variables	Cases	Controls	*P* value
Number	236	240	
Age (yr)			0.997

Genotyping analysis

Genomic DNA was extracted from peripheral blood leukocytes using the QIAamp DNA Blood Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. Mutation screening of *CDH1* exons 2-16 and neighboring intronic sequences was performed using

polymerase chain reaction (PCR) and high-resolution melting analysis using a LightScanner system (Idaho technology, Salt Lake City, UT, United States). The samples that presented abnormal profiles were sequenced on an ABI 3130-Avant automated sequencer (Applied Biosystems, Foster City, CA, United States). The region around the transcription start site (TSS) of the *CDH1* gene (From promoter region to intron 1 of *CDH1* gene) was genotyped using PCR and directly sequenced on the ABI 3130-Avant automated sequencer. Primer sequences and PCR conditions are available upon request.

Promoter luciferase activity assay

A dual-luciferase reporter assay system (http://www.promega.com) was used to examine the effects of novel sequence variation in the promoter region on the transcriptional activity of *CDH1*. Briefly, DNA fragments around the TSS (-345 to 271 bp) were amplified by PCR using genomic DNA containing either the particular variant sequence or *CDH1* wild type as a template. The amplified fragments were designed to contain the region possessing basal promoter activity. The following primer sequences were used: 5'-ATGCCTCGAGCCATCTCCAAAACGAACAAAC-3' (forward) and 5'-ATGCAAGCTTGAAGGGAAGCGGTGACGAC-3' (reverse), which include the restriction sites (underlined) for Xho I and Hind Ⅲ, respectively. The PCR products were digested with Xho I and Hind Ⅲ and subsequently cloned into the pGL3-basic vector carrying the firefly luciferase gene (Promega). The nucleotide sequence of the fragment inserted into each plasmid was confirmed by DNA sequencing. Plasmids were then transiently transfected into Hela cells using the Lipofect transfection reagent (Tiangen Biotech, Beijing, Co., Ltd., China). All plasmids were co-transfected with the renilla luciferase gene containing the pRL-CMV plasmid (Promega) as an internal standard. Cell extracts were prepared, and luciferase activity was measured by a luminometer instrument (Promega) using the dual-luciferase reporter assay system (Promega). The transcriptional activity in each cell extract was determined from the level of firefly luciferase after normalization to renilla luciferase activity. Four independent experiments were performed using DNA from plasmid preparations.

RNA splicing analysis on clinical samples

Because it has been recognized that DNA sequence variants localized in exon-intron boundaries could be pathogenic by affecting exon definition and the splicing of pre-mRNA[12,13], we used RNA splicing assay to evaluate the variant located at the 5' terminal of intron 9. Total RNA from frozen tumor tissue and paired normal tissue was extracted using RNAiso Plus (TaKaRa Biotechnology [(Dalian) Co., Ltd.]. Reverse transcription (RT)-PCR was performed in 2 steps. First strand cDNA synthesis was performed using PrimerScript RT reagent Kit (TaKaRa) with random DNA hexamers and oligo-dT primer according to the manufacturer's protocol. cDNA was amplified in the region of exons 7-10. Primer sequences were 5'-GGACCGAGAGAGTTTCCCTACG-3' (sense) and 5'-GTTATTTTCTGTTCCATAAATG-3' (antisense). PCR conditions were as follows: 35 cycles at 94 ℃ for 30 s, 58 ℃ for 30 s and 72 ℃ for 30 s, followed by a final extension at 72 ℃ for 5 min. Agarose gel electrophoresis was carried out using 2% gels run at 100 V for 40 min. The purified amplification products were sequenced on the ABI 3130-Avant automated sequencer.

Bioinformatics analysis of CDH1 variants

The impact of amino acid allelic variants on protein structure/function can be predicted via analysis of multiple sequence alignments and protein 3D-structures. The sorting intolerant from tolerant (SIFT) algorithm and *Poly*morphism *Phen*otyping (PolyPhen) were adopted.

SIFT is a program that predicts the effect of amino acid substitutions on protein function based on sequence conservation during evolution and the nature of the amino acids substituted in a gene of interest[14]. The SIFT score was calculated online (http://sift.jcvi.org/). If the value is less than 0.05, the amino acid substitution is predicted as intolerant, while those with a value greater than or equal to 0.05 are classified as tolerated.

PolyPhen is an automatic tool for prediction of the possible impact of an amino acid substitution on the structure and function of a human protein based on straightforward physical and comparative considerations[15] (http://genetics.bwh.harvard.edu/pph/). Each of the two amino acid residues [the original residue and the single-nucleotide polymorphism (SNP)] was entered and the difference between the position-specific independent counts (PSIC) scores of the two residues was computed. The higher a PSIC score difference is, the higher the functional impact a particular amino acid substitution is likely to have. A PSIC score difference of 1.5 and above is considered to be damaging.

Statistical analysis

χ^2 tests or Fisher's exact tests were used to compare the distribution of variables between cases and controls. Luciferase activities were compared using Student's unpaired *t* test. All statistical tests were two-sided, with a *P* value of 0.05 considered to be significant, using SPSS software (version 16).

RESULTS

Characteristics of the study population

The study was comprised of 236 gastric cancer cases and 240 cancer-free controls. There were no significant differences in the distributions of age or gender between the cases and controls ($P = 0.997$ and 0.915, respectively) (Table 1). The majority of studied cases were sporadic; approximately 20% had a family history of cancer. The tumor type was assessed in 162 cases, and more than 80% of the cases had poorly differentiated or moderately differentiated adenocarcinoma; more than 70% of the cases were in TNM Stage Ⅲ (Table 1).

Table 2 Novel *CDH1* mutations and polymorphism identified in Chinese gastric cancer patients *n* (%)

Gene location	Sequence variant	Consequence	Genotype

CDH1 genetic screening revealed four novel germline sequence variants

Four novel *CDH1* germline variations were identified in gastric cancer patients. One of the variants was located in the *CDH1* 5'UTR (c.-49 G>T) and is seemed to be a polymorphism since it is found in both the cases and controls. The other three were only detected in the GC cases and not seen in the controls. One was a missense mutation in the coding region [c.604G>A (V202I)], one was a three-nucleotide deletion in exon 1 (c.44_46del TGC) and the other was an intronic variation (c.1320+7A>G) (Figure 1 and Table 2). In addition, ten *CDH1* polymorphisms (and their frequencies) were observed. The polymorphisms frequencies are similar to the data available at the SNP website (http://www.ncbi.nlm.nih.gov/projects/SNP/) (Table 3).

Clinical-pathologic characteristics of the GC cases with novel CDH1 mutations

The cases carrying novel *CDH1* mutations were all sporadic GC patients, with poorly differentiated or moderately differentiated adenocarcinoma (Table 4). The case with *CDH1* c.604G>A (V202I) mutation harbors the *MLH1* c.2101C>A (Q701K) mutation as well[16].

Functional characterization of the novel CDH1 variants

c.-49T variation contribute a slightly higher promoter activity of the *CDH1* gene than the wild type: The c.-49T alteration was near the TSS of the *CDH1* gene (49 bp before the start codon, and +76 bp relative to the TSS). To examine the potential effect of the c.-49T variation on E-cadherin gene transcription, a 616-bp promoter of the E-cadherin gene (-345 to 271) carrying either the G or T allele was inserted upstream of the luciferase gene in the pGL3 promoterless enhancer plasmid vector. The activity of the E-cadherin G/T promoter-luciferase reporter gene constructs was assessed using transient transfection assays in Hela cells. As shown in Figure 2, slightly higher luciferase activities were observed for the pGL-T construct compared with the pGL-G (wild type)

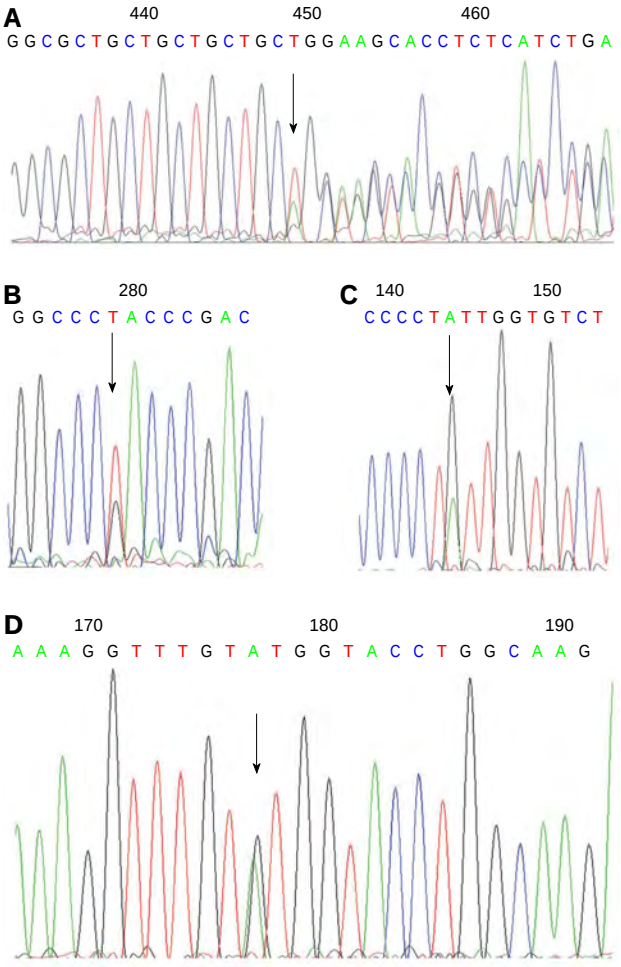

Figure 1 Novel variations detected in this study. A: c.44_46del TGC; B: c.-49G>T; C: c.604G>A (V202I); D: c.1320+7A>G.

construct. The average activity of the promoter having the c.-49T variation was 133.7% (P = 0.002) relative to the *CDH1* wild type promoter.

c.44_46del TGC variant causes the loss of one leucine in the signal peptide region of the E-cadherin protein: Codon sequence analysis demonstrated that the three-nucleotide deletion c.44_46del TGC causes the loss of a single amino acid [the 15th codon (Leucine)] in exon 1 of CDH1, which is in the signal peptide region of the E-cadherin protein.

Intron variation (c.1320+7A>G) and the silent mutation [c.1224G>A (A408A)] do not induce CDH1 splicing defects: To evaluate functional consequence of those novel mutations detected on pre-mRNA splicing, we analyzed cDNA produced *in vivo* from tissues retrieved from the patients harboring the novel mutations. The PCR fragment generated using primers flanking the silent mutation [c.1224G>A (A408A)] and the one intron variation (c.1320+7A>G) indicated normal-sized mRNA. This result demonstrated that a splicing defect was not likely to occur as a consequence of these mutations (Figure 3).

Table 5 *CDH1* missense mutations analyzed by sorting intolerant from tolerant and PolyPhen

Sequence variant	Structural alteration	SIFT scores	PSIC score difference	Prediction
c.604G>A	V202I	0.20	0.381	Benign
c.1888C>G	L630V	0.02	1.748	Probably damaging

SIFT: Sorting intolerant from tolerant; PSIC: Position-specific independent counts.

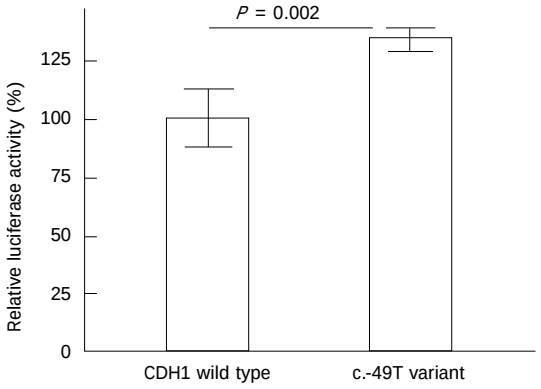

Figure 2 Luciferase reporter assay for the *CDH1* c.-49 G>T variant. The average relative luciferase activity (with standard deviation) is shown. The activity of *CDH1* wild type was defined as 100%.

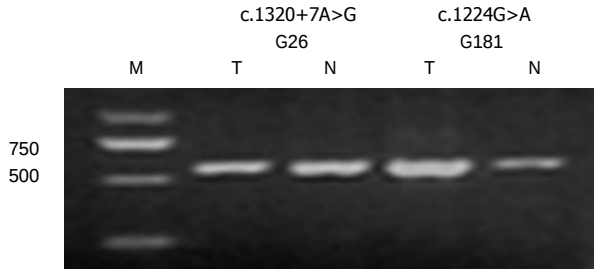

Figure 3 Results of reverse transcription polymerase chain reaction for *CDH1* in patient G26 (c.1320+7A>G, intron 9) and patient G181 [c.1224G>A(A408A), exon 9] using primers in exons 7 and 10. Both patients had an expected band of 567 bp. M: Molecular size markers; T: Tumor tissue; N: Paired normal tissue.

c.1888C>G (L630V) missense mutation might impair E-cadherin protein function while the V202I mutation does not: Two *CDH1* missense mutations were detected. Both the SIFT score and the PolyPhen analysis demonstrated that the L630V variant was sorted as being intolerant, suggesting that this amino acid substitution is predicted to damage protein function. The other variant, V202I, of CDH1 was sorted as tolerant (Table 5).

DISCUSSION

The discovery of genetic variants responsible for the pathogenesis of gastric cancer is important in understanding this disease. Although screening of *CDH1* germline mutations in hereditary GC has been fairly well established, the report of *CDH1* germline mutations in

sporadic GC is limited. Bacani *et al*[17] identified a germline deletion (nt41delT) in a 30-year-old sporadic GC patient and suggested that 2%-3% of cases of early-onset gastric cancer in North America may be owing to high-risk genetic mutations. Garziera *et al*[18] reported a germline missense mutation in *CDH1* exon 6, c. 820 G>A (G274S) in one sporadic Italian gastric cancer patient. Here, we report a population-based study of GC to determine the role of germline mutations in a population at a high risk for GC. The majority of studied cases were sporadic. We have studied all of the coding and promoter core regions of the most important gene implicated in GC and have identified four novel *CDH1* sequence variants distributed along the entire coding sequence and the non-coding regions in the *CDH1* gene. This is consistent with previously published reports[19], suggesting that *CDH1* mutations have arisen without mutational hotspots.

The c.-49 G>T transition was detected in 4/236 (1.7%) of GC patients and 3/240 (1.3%) of cancer-free controls; however, these differences did not achieve significance (P = 0.723, Table 2). One patient with this variant had low familial recurrence for gastric cancer, but IHC showed normal CDH1 protein expression. Previous studies have demonstrated that a fragment spanning -399 to +31 bp relative to the TSS of the *CDH1* gene possesses basal promoter activity[20]. As this variant is around the TSS of the *CDH1* gene, a luciferase reporter assay was carried out. This *in vitro* assay showed that the c.-49T promoter had 33% higher activity than the promoter containing the c.-49G (Figure 2). So this polymorphism might be helpful for E-cadherin transcription, though the increase in transcription activity is limited (only 33%).

The c.44_46del TGC variant was detected in two sporadic GC patients of 51 years and 66 years and was not detected in the 240 controls. One patient's pathological data was available, which showed a poorly differentiated adenocarcinoma (Table 4). To the best of our knowledge, this variant has never been reported in the open access mutation database and literatures. As the parents of the probands are not available for mutation analyzing, we are not certain whether it's a *de novo* mutation. This variant seems to be a rare variant with an allele frequency in GC patients of 0.85% and can even be considered as a kind of mutation hotspot, as it has been detected in two patients with no relationship. Recently rare variants have been reported in several diseases, include cancer. The identified rare variants often have functional effects on protein-protein interactions. Further, rare variants might confer a stronger increase in disease risk than common variants and may make a substantial contribution to the multifactorial inheritance of common chronic diseases[21-24]. Codon sequence analysis demonstrated that the c.44_46del TGC variant causes the loss of a single amino acid [the 15th codon (Leucine)] in exon 1 of CDH1 which is in the signal peptide region of the E-cadherin protein. This amino acid loss might have effect on E-cadherin protein, and further functional analysis should be carried out to investigate associations of the variant with phenotype.

Growing evidence has shown that rare single base substitutions localized in exon-intron boundaries can disrupt one of the cis-transcriptional elements known as exonic splicing enhancers and affect normal pre-mRNA splicing[12,13]. Therefore, it appears reasonable to verify the effect of variants at the mRNA level. The sequence alteration c.1320+7A>G, located in an exon-intron boundary, was detected in a 56-year-old GC patient and not in the 240 controls (Table 2). RNA splicing assay demonstrated that this variation did not affect exon splicing ability (Figure 3) and might be rare polymorphism.

The CDH1 molecule consists of five tandemly repeated extracellular domains (EC1-EC5, containing exons 4-13), each about 110 amino acids in length. This large extracellular domain is responsible for Ca^{2+} binding and is important for cell-cell adhesion. The NH2-terminal EC1 domain is required for lateral E-cadherin dimerization contributing to the intercellular junction[25-27]. A novel missense mutation, V202I, is located in the middle of EC1. While EC1 shows remarkably high conservation between various species[28], SIFT and PolyPhen analyses both showed that V202I might be a tolerant variation (Table 5). The GC patient with this variation carried the *MLH1* c.2101C>A (Q701K) mutation as well. IHC analysis in the index patient demonstrated a loss of MLH1 protein and normal expression of MSH2 and E-cadherin[16]; therefore, we suggest that the *MLH1* c.2101 C>A (Q701K) mutation, and not the *CDH1* c.604G>A (V202I) variation, might be the cause of GC in this patient.

In addition, frequencies of *CDH1* polymorphisms in Chinese GC patients and controls were reported which were similar to those reported at http://www.ncbi.nlm.nih.gov/projects/SNP/ (Table 3). It needs to say something about the rare polymorphism, c.1888C>G (L630V). The SIFT score of the CDH1 variants and the PolyPhen analysis both showed that the L630V variant probably damages protein function (Table 5). However, data from case-control analysis did not support an effect of this L630V variant (Table 3). Accordingly, the pathogenic role of this polymorphism remains elusive and *in vitro* approaches should be performed to elucidate its function.

In conclusion, this study reveals novel mutations in sporadic GC patients in China, a high-incidence country for GC. Though the pathogenic role of the variants remains still uncertain, our findings display the necessity to scan germline *CDH1* variants in sporadic gastric cancer population.

COMMENTS

Background

Although E-cadherin gene (*CDH1*) germline mutations are well implicated in hereditary diffuse gastric cancer, the report of *CDH1* germline mutations in sporadic gastric cancer (GC) is limited.

Research frontiers

Here, the authors report a population-based study of GC to determine the role

of *CDH1* germline mutations in a population at a high risk for GC. The majority of studied cases were sporadic.

Innovations and breakthroughs

The authors have studied all of the coding and promoter core regions of *CDH1* and identified four novel *CDH1* sequence variants, including one transition near the transcription start site, one three-nucleotide deletion in code region, one missense mutation, and one variation in exon-intron boundary. Three of the four variants were detected only in sporadic GC patients and not in the 240 cancer-free controls. Though the functional significance of the variants remains still uncertain, this study reveals novel mutations in sporadic GC patients which had been poorly investigated for susceptibility genes

Applications

The findings display the necessity to scan germline *CDH1* variants in sporadic gastric cancer population.

Terminology

High-resolution melting analysis, is a high-throughput single-nucleotide polymorphism genotyping technology based on the analysis of the melting profile of polymerase chain reaction products.

Peer review

In this study, the authors identified 4 novel *CDH1* germline mutations in different patients harbouring GC with a sporadic setting. The identification of mutations represents an important discovery, to assess the cancer risk for the novel generations.

Abstract

AIM: To investigate the effects of early enteral nutrition (EEN) on the immune function and clinical outcome of patients with severe acute pancreatitis (SAP).

METHODS: Patients were randomly allocated to receive EEN or delayed enteral nutrition (DEN). Enteral nutrition was started within 48 h after admission in EEN group, whereas from the 8th day in DEN group. All the immunologic parameters and C-reactive protein (CRP) levels were collected on days 1, 3, 7 and 14 after admission. The clinical outcome variables were also recorded.

RESULTS: Sixty SAP patients were enrolled to this study. The CD4+ T-lymphocyte percentage, CD4+/CD8+ ratio, and the CRP levels in EEN group became significantly lower than in DEN group from the 7th day after admission. In contrast, the immunoglobulin G (IgG) levels and human leukocyte antigen-DR expression in EEN group became significantly higher than in DEN group from the 7th day after admission. No difference of CD8+ T-lymphocyte percentage, IgM and IgA levels was found between the two groups. The incidences of multiple organ dysfunction syndrome, systemic inflammatory response syndrome, and pancreatic infection as well as the duration of intensive care unit stay were significantly lower in EEN group than in DEN group. However, there was no difference of hospital mortality between the two groups.

CONCLUSION: EEN moderates the excessive immune response during the early stage of SAP without leading to subsequent immunosuppression. EEN can improve the clinical outcome, but not decrease the hospital mortality of SAP patients.

Sun JK, Mu XW, Li WQ, Tong ZH, Li J, Zheng SY. Effects of early enteral nutrition on immune function of severe acute pancreatitis patients. *World J Gastroenterol* 2013; 19(6): 917-922 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/917.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.917

INTRODUCTION

Severe acute pancreatitis (SAP) is a systemic disease characterized by a high mortality because of multiple organ dysfunction syndrome (MODS) and infectious complications[1,2]. During recent years, numerous studies concluded that immune dysregulation might play an important role in the development of MODS and infectious complications in SAP patients[3-5]. In the early stage of SAP, immune imbalance mainly appears as excessive immune

response, which is associated with systemic inflammatory response syndrome (SIRS) and MODS[3-6]. Therefore, some clinicians advocate using immunomodulatory therapy in the acute phase of SAP[4,7,8]. However, no consensus on the efficacy of immunotherapy has been reached due to the conflicting results of relevant experiments.

As an essential therapeutic modality for SAP, early enteral nutrition (EEN) could increase antioxidant activity, modulate inflammatory response, and decrease the incidence of SIRS and subsequent MODS[9]. Hence, we infer that EEN might exert some underlying influence on the immune function of SAP patients. However, there have been few trials investigating the effects of EEN on the immune function of the patients during the initial stage of SAP. Zou *et al*[10] reported that enteral immunonutrition enhanced the immune function in pigs with SAP. Belabed *et al*[11] found that the immune enhancing diets was efficient in preserving lymphocyte function in head-injured rats. Nevertheless, the impact of standard enteral nutrition on the immunologic function of SAP patients remains unclear.

Therefore, this study aimed to investigate the influence of EEN on the immune function and clinical outcome of early-stage SAP patients.

MATERIALS AND METHODS

Study design

This is a single-center, prospective, and randomized controlled clinical trial. Patients were randomly allocated to receive either EEN or delayed enteral nutrition (DEN) on admission. The study protocol was approved by the Ethics Committee of the hospital, and informed consent was obtained from each patient or his/her first-degree relatives. This study was also registered at Clinical Trials.gov (Identifier: NCT01507766).

Patients

All adult SAP patients (aged 18-70 years) admitted within 3 d of symptom onset to the Surgical Intensive Care Unit (SICU), the Department of General Surgery, Jinling Hospital from September 2010 to September 2011 were enrolled into this study. SAP was defined as presence of one or more local complications (*e.g.*, pseudocyst, necrosis or abscess) or/and organ failure and acute physiology and chronic health evaluation Ⅱ (APACHE Ⅱ) score > 8 according to the widely used Atlanta criteria formulated in 1992[12]. Patients with chronic organs dysfunction or immunodeficiency or malnutrition, patients who had received artificial nutrition (either enteral nutrition or parenteral nutrition) before admission, and patients with ileus or pancreatitis in pregnancy were all excluded. All the SAP patients received specialized medical therapy for SAP[2,13] such as intensive monitoring, oxygen administration, fluid resuscitation, stopping oral feeding, exocrine pancreatic suppression, and antibiotic prophylaxis.

Patients in EEN group received enteral nutrition within 48 h after admission, whereas patients in the DEN group received enteral nutrition beginning from the 8th day after admission.

Nutrition protocols

A nasojejunal tube (size 10F, Flocare, Nutricia Ltd, Wuxi, China) was placed beyond the Treitz' ligament endoscopically or radiologically, and the position of tip was confirmed by fluoroscopy. The tube was placed within 24 h after admission in EEN group, and enteral nutrition was started from the next 24 h. Patients in DEN group received feeding on the 8th day after admission, and a nasojejunal tube was placed on the 7th day. Peptide-based formula (Peptisorb, Nutricia Ltd) was used in the first 24-48 h of feeding, and if patients were tolerant, whole protein formula (Nutrison Fibre, Nutricia Ltd) would be established subsequently. The goal intake of enteral nutrition was calculated as 20-25 kcal/kg per day and protein need was calculated as 1.5 g/kg per day[14,15]. The feeding rate was initiated at 15-20 mL/h and increased gradually by 15-20 mL every 6-8 h, using a pump. If the patients were intolerant due to abdominal distension and so on, we would slow down the feeding rate, dilute the feedings concentration, and use prokinetic agents to improve the intestinal motility.

Total parenteral nutrition was given during the first week of admission in DEN group. The caloric intake of parenteral nutrition was determined as 20-25 kcal/kg per day and the calorie: nitrogen ratio was calculated as 120-150:1[16,17]. Fifty to seventy percentages of total energy need were supplied by glucose, and the use of lipids was on the basis of serum triglyceride levels[16]. Furthermore, sufficient vitamins, electrolytes, trace elements, and insulin were also added into the intravenous solution.

Data collection

The baseline characteristics of patients including age, sex, body mass index, and etiology were recorded on admission. The APACHE Ⅱ score, sequential organ failure assessment score, and C-reactive protein (CRP) levels were also collected. The CRP levels and the immunologic parameters including CD4+, CD8+ T-lymphocyte percentage, CD4+/CD8+ ratio, human leukocyte antigen-DR (HLA-DR), immunoglobulin A (IgA), IgG and IgM in peripheral blood were collected on days 1, 3, 7 and 14 after admission[4,6,18]. T-lymphocyte subset percentage and HLA-DR expression were detected by flow cytometry (BD FACS Aria, United States). IgA, IgG and IgM were measured by enzyme-linked immunosorbent assay. The incidences of SIRS and MODS during the first 2 wk after admission, the incidence of surgical operation, the development of pancreatic infection, the duration of ICU stay, and the hospital mortality were also recorded.

Statistical analysis

All the data were presented as median (interquartile range), if not stated otherwise. Categorical variables were expressed as absolute numbers or in percentages, and were analyzed using χ^2 test. Continuous variables were com-

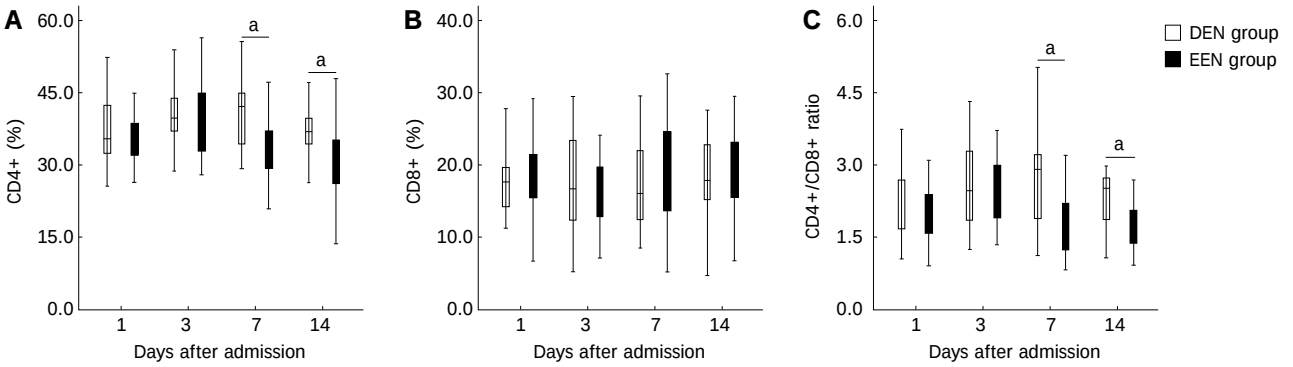

Figure 1 Comparisons of T-lymphocyte subsets percentage between early enteral nutrition and delayed enteral nutrition groups. Results are expressed as median (interquartile range). A: Comparison of CD4+ T-lymphocyte percentage between early enteral nutrition (EEN) and delayed enteral nutrition (DEN) groups; B: Comparison of CD8+ T-lymphocyte percentage between EEN and DEN groups; C: Comparison of CD4+/CD8+ ratio between EEN and DEN groups. $^{a}P < 0.05$, EEN groups *vs* DEN groups.

Table 1 Demographic data and clinical parameters on admission

	DEN group (n = 30)	EEN group (n = 30)	P value
Age (yr)	43 (34.5-51)	45 (35-52)	0.594
Sex (male:female)	18:12	20:10	0.287
Etiology n (%)			
Biliary origin	17 (57)	19 (63)	0.278
Hyperlipidemia	8 (27)	6 (20)	0.373
Alcohol abuse	3 (10)	4 (13)	1.000
Idiopathic	2 (7)	1 (3)	1.000
BMI	24.6 (23.5-26.8)	25.8 (23.9-28.8)	0.158
APACHE Ⅱ score	9.5 (8.5-11)	10 (8-11.5)	0.994
SOFA score	4.5 (3.5-5.5)	4 (3-5)	0.880
CRP (mg/L)	203.5 (188-253)	195 (161-247.5)	0.214

DEN: Delayed enteral nutrition; EEN; Early enteral nutrition; BMI: Body mass index; APACHE Ⅱ: Acute physiology and chronic health evaluation Ⅱ; SOFA: Sequential organ failure assessment; CRP: C-reactive protein.

pared by the Mann-Whitney *U* test or Wilcoxon signed-rank test as appropriate. Statistical Package for the Social Sciences (SPSS, version 17.0, Chicago, IL, United States) software was used for statistical analysis. $P < 0.05$ was considered statistically significant.

RESULTS

A total of 60 eligible patients with SAP (30 in each group) were enrolled into this clinical trial during the study period. The principal etiological factors of SAP were biliary origin (60%, 36/60) and hyperlipidemia (23%, 14/60). The demographic data and clinical parameters of the patients on admission are presented in Table 1. Three patients (5%, 3/60) died of MODS and septic shock during hospital stay.

Comparison of immune parameters and CRP levels between two groups

Figure 1 shows the differences of T-lymphocyte subsets percentage between DEN and EEN groups. As shown in Figure 1A, patients in EEN group had significantly lower CD4+ T-lymphocyte percentage from the 7th day ($P < 0.05$) after admission. Similar results were detected in the CD4+/CD8+ ratio (Figure 1C). However, there was no difference of CD8+ T-lymphocyte percentage between the two groups during the two weeks after admission (Figure 1B).

Figure 2 presents the disparities of immunoglobulin subtypes between the two groups. As shown in Figure 2A, patients in EEN group had significantly higher IgG levels from the 7th day ($P < 0.05$) after admission. Nevertheless, no difference of IgM and IgA between the two groups was found during the two weeks after admission (Figure 2B and C).

As shown in Figure 3A, patients in EEN group had significantly higher HLA-DR expression from the 7th day ($P < 0.05$) after admission. In contrast, the CRP levels of patients in EEN group were significantly lower than in patients of the DEN group from the 7th day ($P < 0.05$) after admission (Figure 3B).

Table 2 Clinical outcome variables n (%)

	DEN group (n = 30)	EEN group (n = 30)	P value
Hospital mortality	1 (3)	2 (7)	1.000
ICU stay (d)	12 (8-21)	9 (5-14)	0.033
Pancreatic infection	10 (33)	3 (10)	0.028
MODS	13 (43)	5 (17)	0.024
SIRS	22 (73)	12 (40)	0.009
Surgical operation	4 (13)	2 (7)	0.671

DEN: Delayed enteral nutrition; EEN: Early enteral nutrition; ICU: Intensive care unit; MODS: Multiple organ dysfunction syndrome; SIRS: Systemic inflammatory response syndrome.

Comparison of outcome variables between two groups

As presented in Table 2, patients in EEN group had significantly lower incidences of MODS, SIRS and pancreatic infection as well as shorter ICU stay during hospital stay. However, no difference of hospital mortality and operation incidence was found between the two groups.

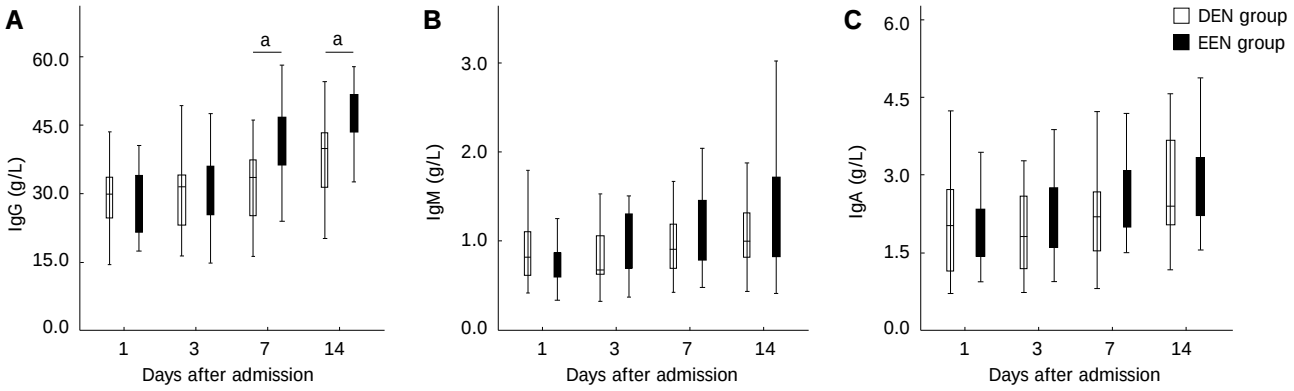

Figure 2 Comparisons of immunoglobulin subtypes between early enteral nutrition and delayed enteral nutrition groups. Results are expressed as median (interquartile range). A: Comparison of immunoglobulin G (IgG) levels between early enteral nutrition (EEN) and delayed enteral nutrition (DEN) groups; B: Comparison of IgM levels between EEN and DEN groups; C: Comparison of IgA levels between EEN and DEN groups. [a]*P* < 0.05, EEN groups *vs* DEN groups.

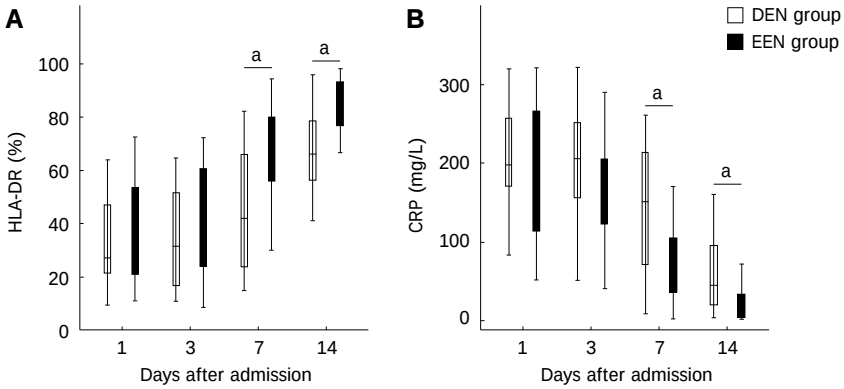

Figure 3 Comparisons of human leukocyte antigen-DR expression and C-reactive protein levels between early enteral nutrition and delayed enteral nutrition groups. Results are expressed as median (interquartile range). A: Comparison of human leukocyte antigen-DR (HLA-DR) expression between early enteral nutrition (EEN) and delayed enteral nutrition (DEN) groups; B: Comparison of C-reactive protein (CRP) levels between EEN and DEN groups. [a]*P* < 0.05, EEN groups *vs* DEN groups.

DISCUSSION

This clinical study investigated the effects of EEN on the immune function as well as on the clinical outcome of SAP patients. We found that EEN could moderate the excessive immune response during the early stage of SAP without leading to subsequent immunosuppression. Moreover, EEN administration could improve the clinical outcome, but not decrease the hospital mortality of SAP patients.

Immune dysregulation is one of the main causes responsible for a high mortality of SAP. Recent studies have shown that excessive immune response might play an important role in the development of SIRS and MODS in the early stage of SAP[3-6,19]. The imbalance of Th1/Th2 cells (differentiated from the Th0 cells which were derived from CD4+ T-lymphocytes) is the principal mechanism of excessive immune response[4,19]. Th1 cells mainly produce some anti-inflammatory factors, such as interleukin 10 (IL-10) and IL-4, whereas Th2 cells mainly release the pro-inflammatory factors, such as IL-6, and tumor necrosis factor-α (TNF-α)[3,4,19]. Pietruczuk *et al*[19] found that Th1 cells were suppressed more strongly than Th2 cells in the acute phase of SAP, thus the pro-inflammatory factors produced by Th2 cells were over-activated and then triggered the strong inflammatory reaction. For this reason, some researchers considered using immunosuppressive therapy for the patients with early-stage SAP. Up till now, a number of immunosuppressive agents (*e.g.*, dexamethasone, IL-10, and anti-tumor necrosis factor monoclonal antibodies) have been studied in SAP animal experiments[4,8]. Unfortunately, the findings were inconsistent or even conflicting, and very few of these studies involved SAP patients. Moreover, inappropriate immunosuppression might be associated with subsequent infectious complications during the late stage of SAP[3,4,6]. Therefore, the effects of immunomodulatory therapy in SAP were still unclear, and further clinical trails are extremely needed.

Gut is the primary immune organ providing an initial barrier against extraneous antigens and microbes[20,21]. The previous studies reported that gut immune response was highly associated with enteral nutrition, and deficiency of enteral stimulation might induce immune suppression[20,21]. In addition, enteral nutrition (especially EEN) had been confirmed to modulate inflammatory response, maintain gut integrity, and release immunomodulating agents[9,22]. Based on the above findings, we postulated that EEN might have some underlying impacts on the immune function of SAP patients, however, few clinical trials about it have been conducted. Therefore, the principal purpose of this clinical study was to investigate the influence of EEN on the immune function of early-stage SAP patients.

CD4+, CD8+ T-lymphocyte percentage and CD4+/CD8+ ratio were closely related to the cellular immune

function of SAP[23,24]. Uehara *et al*[5] observed that both CD4+ percentage and CD4+/CD8+ ratio were significantly reduced in patients with acute pancreatitis, whereas Liu *et al*[6] reported that the CD4+ percentage was increased significantly on the 7th day in SAP patients after admission. In the present study, we found that EEN could reduce CD4+ T-lymphocyte percentage as well as CD4+/CD8+ ratio from the 7th day after admission. And patients in EEN group also had significantly lower CRP levels from the same day. Furthermore, the initial incidences of SIRS and MODS in EEN group were significantly lower than in DEN group. These results indicated that EEN might be able to suppress the excessive immune response during the early phase of SAP. It has been demonstrated that EEN can prevent the release of pro-inflammatory mediators (*e.g.*, IL-6 and TNF-α) and promote the release of anti-inflammatory factors (*e.g.*, IL-10)[8,9]. In other words, EEN might suppress the overactivation of Th2 cells and promote the production of Th1 cells, and then moderate the imbalance of Th1/Th2 cells. This may be the underlying mechanisms of our conclusion.

In addition, since excessive or prolonged immunosuppressive therapy might induce the development of infectious complications, whether EEN could lead to subsequent immunosuppression still need to be further investigated. Immunoglobulin concentrations and HLA-DR expression levels were also closely related to the immune function of SAP patients. Zou *et al*[10] reported that the serum IgG levels of SAP pigs were significantly decreased on day 2 after induction of SAP, and then were increased significantly on day 8. Yu *et al*[25] found that continuous HLA-DR suppression was highly associated with infectious complications and poor outcome in SAP patients, and the HLA-DR suppression was inversely correlated with CRP levels. In our study as shown in Figures 2A and 3A, patients in EEN group had significantly higher IgG levels and HLA-DR expression from the 7th day after admission. And the IgM and IgA levels of patients in EEN group were also not lower than that of patients in DEN group. Furthermore, the incidence of pancreatic infection in EEN group was significantly lower than in DEN group, and this result is also consistent with the findings of previous studies[9,22]. These phenomena suggested that EEN did not lead to immunosuppression during the late stage of SAP.

There are several limitations in this study. Due to the small sample size and the single-center design, our results might be uncertain for a definite conclusion, and the accuracy should be tested by further large-sized studies. Moreover, since this study did not base on a pathophysiological model, the precise mechanisms of EEN in SAP patients should be verified by more basic experiments.

In conclusion, EEN could moderate the excessive immune response during the early stage of SAP without leading to subsequent immunosuppression. Moreover, EEN could improve the clinical outcome, but not decrease the hospital mortality of SAP patients. However, the precise mechanisms of EEN for SAP are still not clear, and further studies are required to verify our conclusions.

COMMENTS

Background

The immune dysregulation might play an important role in the development of multiple organ dysfunction syndrome (MODS) and infectious complications in severe acute pancreatitis (SAP) patients. In the early stage of SAP, immune imbalance mainly appears as excessive immune response, therefore, some clinicians advocate using immunomodulatory therapy for SAP. However, no consensus on the efficacy of immunotherapy has been reached due to the conflicting results of relevant experiments.

Research frontiers

Early enteral nutrition (EEN) could increase antioxidant activity, modulate inflammatory response, and decrease the incidence of systemic inflammatory response syndrome (SIRS) and subsequent MODS. Hence, the authors infer that EEN might have some underlying influence on the immune function of SAP patients. However, there have been few trials investigating the effects of EEN on the immune function of the patients with SAP at the initial stage.

Innovations and breakthroughs

The study found that EEN could moderate the excessive immune response during the early stage of SAP without leading to subsequent immunosuppression; and EEN could improve the clinical outcome, but not decrease the hospital mortality of SAP patients.

Applications

The results of this study indicate that enteral feedings should be provided as early as possible to correct the immune dysregulation of SAP patients.

Terminology

MODS, is a progressive condition usually characterized by combined dysfunction of multiple organs or systems due to various etiological factors in critically ill patients; SIRS, is diagnosed when two or more of the following criteria are met: body temperature < 36 ℃ or > 38 ℃; heart rate > 90 beats/min; tachypnea > 20 breaths/min, or an arterial partial pressure of carbon dioxide < 32 mmHg; white blood cell count less than 4 × 10^9/L or greater than 12 × 10^9/L, or the presence of > 10% immature neutrophils (band forms).

Peer review

Overall, presented paper is of a very good quality. Study design is appropriate and clear, helps to answer a clinical relevant question. Data analysis is sufficient. Manuscript is well structured, language is of sufficient quality.

Abstract

AIM: To estimate hepatitis B virus (HBV) infection testing rate in cancer patients before chemotherapy with a focus on HBV reactivation.

METHODS: A retrospective study was conducted from January 1, 2009 to June 30, 2010. Inclusion required that patients be naïve to cancer chemotherapy but have indications for it. Patients who did not receive chemotherapy for any reason were excluded. Important clinical information, such as the levels of HBV DNA and serological markers were collected. HBV reactivation was defined as an increase in serum HBV DNA to > 1 log higher than that of the pre-exacerbation baseline, or serum HBV DNA conversion from negative to positive. HBV DNA levels > 1000 copies/mL were defined as HBV DNA positive. The χ^2 or Fisher's exact test was used for analysis of categorized data. Multiple logistic regression analysis was used to estimate the odd ratio and 95%CI of the HBV screening rate.

RESULTS: Of 6646 patients, 5616 (84.5%) received chemotherapy. Only 17.1% of the cancer patients received pre-chemotherapy HBV testing (43.2% for hematological malignancies and 14.9% for solid tumors). Patients who had received rituximab therapy, had elevated aminotransferase levels, or had hematological malignancies were more likely to receive HBV testing. The prevalence of hepatitis B surface antigen (HBsAg) positivity was 13.4%. HBV reactivation (appearance of HBV DNA or an increase in HBV DNA levels by 1 $\log_{10}$) was observed in 33.1% (53/160) of the patients after chemotherapy. Among patients without prophylactic antiviral therapy, the reactivation rate was 43.9% (43/98) in the solid tumor group. Two reactivation cases occurred in patients who were HBsAg negative, but positive for hepatitis B core antibody. HBV reactivation was more likely to occur in patients with lymphoma, high levels of HBV DNA, or hepatitis B e antigen, and in men.

CONCLUSION: Less than 20% of patients received HBV testing before chemotherapy. HBV reactivation would have occurred in about 50% of infected patients with solid tumors without antiviral prophylaxis.

Testing for hepatitis B infection in prospective chemotherapy patients: A retrospective study. *World J Gastroenterol* 2013; 19(6): 923-930 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/923.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.923

INTRODUCTION

Hepatitis B virus (HBV) infection is a global health problem. According to estimates of the World Health Organization, nearly 2 billion people worldwide have been infected with HBV, and > 350 million have chronic infection[1]. Hepatitis B is endemic in China, and the weighted prevalence of hepatitis B surface antigen (HBsAg) for the Chinese population is 7.2%[2]. Cancer patients receiving intensive chemotherapy may be at risk for HBV reactivation[3-8]. A previous study has reported that the reactivation rate of HBV infection after chemotherapy was as high as 73%[8]. It has been observed in a meta-analysis that the average reactivation rate of HBV infection was nearly 34% (162/475 patients), and the mortality rate was about 7% (27/394 patients)[9]. HBV reactivation might lead to a delay in chemotherapy, therefore, antiviral therapy should be administered immediately[3]. However, this might affect the efficacy of chemotherapy.

Corticosteroids, monoclonal antibodies (such as rituximab and alemtuzumab), and nearly all types of chemotherapeutic agents have been involved in HBV reactivation[5]. A diagnosis of lymphoma is another risk factor for HBV reactivation[4]. A multivariate analysis has revealed that patients with lymphoma or breast cancer are more likely to develop HBV reactivation after chemotherapy[10].

Recently, more attention has been paid to HBV testing before chemotherapy. Many clinical practice guidelines, such as the associated guidelines of the European Association for the Study of Liver Disease (EASL) and the American Association for the Study of Liver Diseases, advise HBV testing before starting chemotherapy[11,12]. The United States Centers for Disease Control and Prevention (CDC) also recommend testing for chronic HBV infection in cancer patients receiving chemotherapy[13]. It has been reported in recent years that the HBV infection testing rates before chemotherapy in Canada and the United States were 14%[14] and 16.7%[15], respectively. However, to the best of our knowledge, few studies have focused on this issue in a high endemic region of HBV infection such as China.

The aim of this study was to assess the rate of HBV serological testing prior to initiation of chemotherapy and the rate of HBV reactivation after chemotherapy in cancer patients in China.

MATERIALS AND METHODS

Patients

From January 1, 2009 to June 30, 2010, all cancer patients who were seen in the Cancer Center of West China Hospital were analyzed. Inclusion in this study required that patients be naïve to cancer chemotherapy but have indications for it. Patients who did not receive chemotherapy for any reason were excluded. This study was approved by the Institutional Review Board of West China Hospital and carried out according to the provisions of the Helsinki Declaration.

Methods and definitions

A retrospective study of the chart information on cancer patients was undertaken. HBV reactivation was defined as an increase in serum HBV DNA to > 1 log higher than that of the pre-exacerbation baseline, or serum HBV DNA conversion from negative to positive[16]. In our center, HBV DNA levels > 1000 copies/mL were defined as HBV DNA positive. Important clinical information, such as the levels of HBV DNA and serological markers [including HBsAg, hepatitis B surface antibody (anti-HBs), hepatitis B e antigen (HBeAg), HBeAg antibody and hepatitis B core antibody (anti-HBc)], were collected and measured by a microparticle enzyme-linked immunosorbent assay (Santa Cruz Biotechnology, CA, United States). All hepatitis B serological marker results were reported as positive or negative. EASL guidelines recommend that all patients requiring chemotherapy be tested for HBsAg and anti-HBc prior to initiation of treatment[11], therefore, the presence of either HBsAg-positive or isolated anti-HBc-positive results was defined as positivity for an HBV serological marker (HBV-sm). HBV DNA levels were tested using a real-time polymerase chain reaction detection system (Applied Biosystems, Foster City, CA, United States). Individuals with chronically elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST) should be routinely tested for HBV[12], and ALT and AST levels were analyzed using an automatic biochemistry analyzer (Olympus AU5400, Olympus Corporation, Tokyo, Japan). Values for ALT or AST above the upper limit of normal (58 IU/L in our hospital) were defined as elevated.

Statistical analysis

Frequencies and percentages were used for statistical descriptions. The χ^2 or Fisher's exact test was used for analysis of categorized data. A nonparametric Mann-Whitney/Wilcoxon test or *t* test was used for analysis of quantitative data. Multiple logistic regression analysis was used to estimate the odd ratio (OR) and 95%CI of the HBV screening rate. All statistical analyses were carried out using SPSS version 18.0 statistical software, and statistical significance was defined as $P < 0.05$.

RESULTS

Patient characteristics

From the beginning of January 2009 to the end of June 2010, a total of 6646 cancer patients were reviewed. Among these patients, 5616 (84.5%) received chemotherapy (Figure 1). Combined with other chemotherapeutic agents, rituximab was given to 49 patients (17.4%) and/or steroids were given to 203 (72.2%) patients with hematological malignancies. Patient characteristics are shown in Table 1.

Testing for HBV infection

As shown in Figure 1, 49.3% (2770/5616) patients were screened for HBV before initiation of chemotherapy.

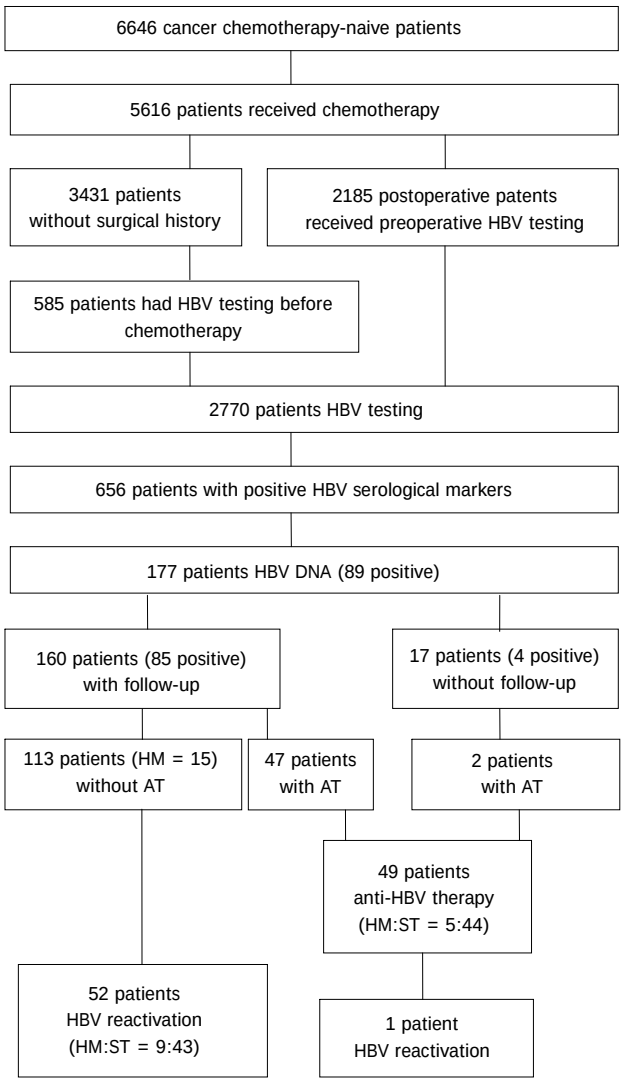

Figure 1 Study flow diagram. HM: Hematological malignancy; ST: Solid tumor; AT: Anti-HBV therapy; HBV: Hepatitis B virus.

The testing rate for patients with hematologic malignancies and solid tumors was 47.7% (134/281) and 49.4% (2636/5335), respectively. However, the reason for HBV serological testing in 2185 patients was not in preparation for chemotherapy, but as a routine check before surgery. Only 17.1% (585/3431) of the cancer patients received pre-chemotherapy HBV testing. The exact pre-chemotherapy testing rate for hematological malignancies and solid tumors was 43.2% (112/259) and 14.9% (473/3172), respectively. As shown in Table 2, in univariate analysis, the characteristics of age > 50 years, male sex, history of HBV infection, rituximab use, elevated aminotransferases, and hematological malignancies were associated with HBV testing. In multiple logistic regression analysis, patients with rituximab therapy (OR: 1.96, 95%CI: 1.04-3.67, $P < 0.05$), elevated aminotransferase levels (OR: 10.88, 95%CI: 8.01-14.78, $P < 0.001$), and hematological malignancies (OR: 4.17, 95%CI: 3.10-5.61, $P < 0.001$) were more likely to have received pre-chemotherapy HBV serological testing.

HBV serological markers

The prevalence of HBsAg positivity was 13.4%. The prevalence of HBV-sm positivity was 23.7%. The prevalence of HBsAg positivity ($P < 0.001$) and HBsAg and/or anti-HBc positivity ($P < 0.001$) in the male patients were significantly higher than in the female patients. In patients < 20 years old, the rate of HBV-sm positivity was significantly lower than in patients in the older age group ($P < 0.001$) (Table 3).

HBV DNA and antiviral therapy

Among the 656 patients who were positive for HBV serological markers, 177 (27.0%) received HBV DNA testing and 160 (24.4%) underwent re-examination. The HBV DNA testing rate was significantly higher in the hematological cancer group ($P < 0.001$). Antiviral therapy (lamivudine) was given to 55.1% (49/89) of the patients who were positive for HBV DNA. All five HBV-DNA-positive patients with hematological malignancies received antiviral therapy, but only 52.4% (44/84) of the HBV-DNA-positive patients with solid tumors were given antiviral therapy (Figure 1 and Table 3).

HBV reactivation

Two cases of reactivation occurred in HBsAg-negative but anti-HBc-positive patients. One patient had diffuse large B-cell lymphoma while the other had breast cancer. As shown in Figure 1, HBV reactivation was observed in 33.1% (53/160) of patients after chemotherapy. Within the virus-untreated cohort ($n = 113$), the reactivation rate was 46.0% (52/113 patients). Among the 47 patients who received antiviral therapy, only one case of reactivation (2.1%) occurred. However, HBV reactivation was observed in 60.0% (9/15 patients) in the hematological malignancy group and 43.9% (43/98) in the solid tumor group who had not received any antiviral therapy. The median onset time of HBV reactivation was 11 wk (range: 3-25 wk) after initiation of chemotherapy. HBV reactivation developed earlier ($P < 0.001$) in patients with lymphoma (9 wk, range: 4-14 wk) than in those with other cancers (15 wk, range: 9-21 wk). HBV reactivation also developed earlier ($P < 0.001$) in patients receiving CHOP (cyclophosphamide, doxorubicin, vincristine and prednisolone)-like regimens (8 wk, range: 3-15 wk) compared to non-CHOP protocols. Baseline HBV status (positive or negative) was not significantly associated with the time interval between initiation of chemotherapy and onset of HBV reactivation. In multivariate analysis (Table 4), HBV reactivation was more likely to occur in patients with lymphoma, high levels of HBV DNA, HBeAg positivity, and male patients. It was also found that antiviral prophylaxis for patients who were positive for HBV DNA significantly reduced the incidence of chemotherapy-induced HBV reactivation (OR: 0.009,

95%CI: 0.001-0.073, $P < 0.001$).

Chemotherapy drugs and HBV reactivation

Of the 160 patients who were re-tested for HBV, 13 had received corticosteroids (all patients had lymphoma) and 61.5% (8/13) developed HBV reactivation. In univariate analysis, HBV reactivation was more likely to occur in patients who had received corticosteroids ($P = 0.023$) and botanical chemotherapeutic drugs ($P = 0.048$). However, the components of the chemotherapy regimens (including corticosteroids) seemed not to be associated with HBV reactivation in multivariate analysis.

Hepatitis C virus co-infection

Of 5616 patients, 2679 (47.7%) were tested for hepatitis C virus (HCV). In this group, 305 and 12 patients were HBsAg positive and HCV RNA positive, respectively. Only four out of 305 patients (1.3%) were both HBsAg and HCV-RNA positive, and none of these patients developed HBV reactivation.

DISCUSSION

In recent years, many organizations have advocated that all chemotherapy candidates should receive HBV serological testing before starting treatment[11-13]. In the present study, it was observed that 49.3% of patients had received HBV serological testing prior to chemotherapy, which was much higher than reports from Canada (14%)[14] and the United States (16.7%)[15]. However, most of the patients were not for HBV infection because of impending chemotherapy, but as part of a preoperative routine (Figure 1). Therefore, only 17.1% of the cancer patients received pre-chemotherapy HBV testing, which is close to the testing rates in other published studies[14,15].

Patients with elevated aminotransferase levels prior to chemotherapy were more likely to be screened for HBV infection (OR: 10.88, $P < 0.001$). This is reasonable because elevated aminotransferase levels usually indicate liver inflammation, which may lead physicians to screen for HBV as a possible etiology. Guidelines have recommended that individuals with chronically elevated ALT or AST should be routinely screened for HBV infection[12]. However, not all patients with elevated aminotransferases receive HBV testing. It has been reported that only 30%-70% of oncologists screen for HBV infection before chemotherapy in patients with abnormal liver-associated enzymes[17,18]. The testing rate of only 62.4% in the current study is consistent with the data from other studies. The lack of HBV testing might be because some patients without a history of HBV infection had only slightly elevated aminotransferase levels that were insufficiently high to be a contraindication for chemotherapy.

In the current study, a relationship was found between the type of tumor and the rate of HBV serological testing. Patients with hematological malignancies (OR: 4.17, $P < 0.001$) were more likely to receive HBV testing before chemotherapy. The same phenomenon was also observed in an American study[19], which might be partly because lymphoma is a known risk factor for HBV reactivation[4,10]. Rituximab is a standard treatment for diffuse large B-cell lymphoma. Rituximab treatment was found to be an important indicator associated with HBV testing prior to chemotherapy (OR: 1.96, $P = 0.038$) in the present study. Testing for HBV infection before anticancer therapy is likely because of the known risk of HBV reactivation after rituximab administration[20].

In the current study, the HBV reactivation rate was found to be 33.1%, which was very close to the average reactivation rate (34%) observed in a prior meta-analysis[9].

The median onset time of HBV reactivation after initiation of chemotherapy was 11 wk (range: 3-25 wk), which was similar to that reported previously (16 wk, range: 4-36 wk)[21]. HBV reactivation was observed to occur earlier in patients with lymphoma and those receiving CHOP-like regimens in the current study. Previous studies have identified many risk factors related to HBV reactivation during anticancer therapy, such as male sex, younger age, absence of anti-HBs, HBeAg seropositivity, diagnosis of lymphoma or breast cancer, high pre-chemotherapy HBV DNA levels, and the use of steroids or rituximab[4,10,20,22]. In addition, it has also been reported that HBV DNA contains a glucocorticoid responsive element that stimulates HBV replication[23,24]. Multivariate analysis in the present study identified high baseline levels of HBV DNA, male patients, HBeAg positivity, and lymphoma to be predictive of HBV reactivation (Table 4). Further study is needed to determine the relationship between HBV reactivation and steroids (including their dose).

HBV reactivation rates were significantly higher in the non-lamivudine group compared with the lamivudine group (46.0% *vs* 2.1%). Moreover, multivariate analysis identified that antiviral prophylaxis significantly reduced the incidence of chemotherapy-induced HBV reactivation, which has also been reported previously[25-28]. Therefore, for patients with high baseline levels of HBV DNA, prophylactic lamivudine might be considered before chemotherapy. This is already recommended by EASL and CDC[11,13]. However, high baseline HBV viral loads are associated with the development of resistance to lamivudine (an antiviral agent with a low genetic barrier)[29]. After prophylactic administration of lamivudine, the rate of HBV reactivation was 5%-13.3% in previous studies[25,27,28]. It was observed in some small studies that none of the HBsAg-positive patients receiving chemotherapy or immunosuppressive therapy developed HBV reactivation after prophylactic entecavir[30,31]. Therefore, prophylactic administration of other antiviral agents with high genetic barriers to resistance, such as entecavir or tenofovir, might be considered suitable substitutes for lamivudine for HBV prophylaxis prior to chemotherapy.

In the current study, it was observed that 372 patients (13.4%) were HBsAg seropositive (Table 3). According to an epidemiological serological survey of hepatitis B[2], the

weighted prevalence of HBsAg for the Chinese population aged 1-59 years was 7.2%. Therefore, the prevalence of HBsAg in the current study seems to be higher. This might be because most of the patients in our study were > 20 years old (Table 3), and therefore, born before the introduction of the universal vaccination program[32]. Another reason might be that our patients with a history of HBV or elevated aminotransferases were more likely to be tested for HBV infection (Table 2).

Previous studies have reported that 0.72%-3.3% of patients who were negative for HBsAg developed *de novo* HBV-related hepatitis after chemotherapy[33-35]. Therefore, it is not sufficient to test for the presence of HBsAg alone as a marker of HBV infection. This is consistent with the EASL recommendations that cancer patients should be tested for both HBsAg and anti-HBc before chemotherapy[11]. In the current study, 284 patients (10.5%) were HBsAg negative but anti-HBc positive (Table 3), and two of these had HBV reactivation; one with diffuse large-B lymphoma and the other with breast cancer.

As mentioned before, high baseline HBV DNA levels are an independent risk factor for HBV reactivation[10,22]. EASL has recommended that cancer patients who are HBsAg or anti-HBc positive should have their HBV DNA levels measured[11]. In the current study, of the 656 patients who were HBsAg positive and/or anti-HBc positive, only 177 patients (27.0%) had been tested for HBV DNA (Table 3). Oncology physicians should pay more attention to this problem.

A high prevalence of occult HBV infection has been observed in HCV-infected patients[36,37]. The HCV co-infection rate among HBsAg carriers ranged from 3% to 18%[38,39], depending on the geographic location and selection of patients. In the current study, 4 patients (1.3%) were positive for both HBsAg and HCV RNA, and none developed HBV reactivation. This might have been because HCV replication is suspected to suppress HBV replication strongly[40].

The limitations of this study include the fact that it was a single-institution, retrospective study. Some important information was not recorded, such as the reasons why physicians made decisions regarding testing for HBV infection. This limitation may be resolved by a prospective study in the future.

In conclusion, only 17.1% of cancer patients received complete HBV testing prior to chemotherapy. Patients who were to receive rituximab therapy, had elevated aminotransferase levels, or had hematological malignancies were more likely to receive HBV testing. Only 27% of the patients who were positive for HBsAg and/or anti-HBc received testing for HBV DNA. HBV reactivation was observed in 33.1% of the patients, and was more likely to occur in patients with lymphoma, high levels of HBV DNA, HBeAg positivity, and male patients. Prophylactic antiviral therapy for patients with positive HBV DNA can significantly reduce the incidence of chemotherapy-induced HBV reactivation.

COMMENTS

Background

Cancer patients receiving intensive chemotherapy may be at risk for hepatitis B virus (HBV) reactivation. Recently, more attention has been paid to HBV testing before chemotherapy. Many clinical practice guidelines advise HBV testing before starting chemotherapy. However, few studies have focused on this issue in regions of high HBV endemicity, such as China.

Research frontiers

Authors demonstrated that only 17.1% of cancer patients received pre-chemotherapy HBV testing (43.2% for hematological malignancies and 14.9% for solid tumors). Patients who had received rituximab therapy, had elevated aminotransferase levels, or had hematological malignancies were more likely to receive HBV testing. HBV reactivation was more likely to occur in patients with lymphoma, high levels of HBV DNA, hepatitis B e antigen positivity, and male patients.

Innovations and breakthroughs

In recent years, more organizations have advocated that all chemotherapy candidates should receive HBV serological testing before starting treatment. This is believed to be the first study to report the exact pre-chemotherapy HBV testing rate in China; a region of high endemicity for HBV infection. The rate of HBV reactivation after chemotherapy and the median onset time are also reported.

Applications

Many clinical practice guidelines advise HBV testing before starting chemotherapy. However, the results in this study showed that only 17.1% of cancer patients received pre-chemotherapy HBV testing.

Terminology

HBV reactivation was defined as an increase in serum HBV DNA to > 1 log higher than that of the pre-exacerbation baseline, or serum HBV DNA conversion from negative to positive.

Peer review

In this retrospective analysis, the authors assessed the rate of HBV serological testing prior to the initiation of chemotherapy and the rate of HBV reactivation after chemotherapy in Chinese patients with cancer. The authors concluded that < 20% of patients received HBV testing before chemotherapy, and HBV reactivation would have occurred after chemotherapy in nearly half of these infected patients who did not receive pre-emptive antiviral therapy.

Abstract

AIM: To investigate quadruple therapy with rabeprazole, amoxicillin, levofloxacin and furazolidone for the eradication of *Helicobacter pylori* (*H. pylori*) infection.

METHODS: A total of 147 patients were divided into the experimental treatment group (n = 78) and the standard triple treatment group (n = 69). The experimental treatment group received rabeprazole 20 mg, amoxicillin 1.0 g, levofloxacin 0.2 g and furazolidone 0.1 g, twice daily. The standard triple treatment group received omeprazole 20 mg, amoxicillin 1.0 g and clarithromycin 0.5 g, twice daily.

RESULTS: One month after treatment, the ^{13}C urea breath test was carried out to detect *H. pylori*. The eradication rate using per-protocol analysis was 94.3% in the experimental treatment group and 73% in the standard triple treatment group (P < 0.05), and using intention to test analysis, these figures were 86% and 67% in the two groups, respectively. Side effects were observed in 34 patients, and included mild dizziness, nausea, diarrhea and increased bowel movement. Eleven of the 34 patients needed no treatment for their side effects.

CONCLUSION: Rabeprazole, amoxicillin, levofloxacin and furazolidone quadruple therapy is a safe method for the eradication of *H. pylori* with high efficacy and good tolerability.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is closely related to a number of gastrointestinal diseases. It is the main pathogenic factor in chronic gastritis and peptic ulcer disease, and is also the initiating factor in gastric cancer and gastric mucosa-associated lymphoid tissue lymphoma[1]. The ability to reliably eradicate this pathogen is important in the management of these diseases[2-5].

The eradication of *H. pylori* has been a research focus for the effective treatment of the above diseases. Currently, the worldwide standard triple therapy consists of a proton pump inhibitor (PPI) or bismuth, amoxicillin and metronidazole or clarithromycin. However, with the extensive use of antibiotics and the irregularity of treatment, there is increasingly high *H. pylori* resistance, especially resistance to metronidazole and clarithromycin. The effectiveness of "legacy triple therapy", which was recommended by the Maastricht Ⅲ Consensus Report, has demonstrated disappointingly low treatment success (*i.e.*, below 80%) worldwide[6]. The difficulty of *H. pylori* eradication is increasing. The consensus of the Third National Lushan Conference held at Lushan Mountain in Jiangxi in August 2007 states that there is high *H. pylori* resistance to metronidazole and clarithromycin, but low resistance to furazolidone, tetracycline and quinolones,

therefore, the effects of these antibiotics are relatively high, and may be used as the initial treatment choice. In our study, quadruple therapy with rabeprazole, amoxicillin, levofloxacin and furazolidone achieved good results.

MATERIALS AND METHODS

General information

All 147 patients underwent the treatment with either rabeprazole 20 mg, amoxicillin 1.0 g, levofloxacin 0.2 g and furazolidone 0.1 g, twice daily or omeprazole 20 mg, amoxicillin 1.0 g and clarithromycin 0.5 g, twice daily at the First Affiliated Hospital of Henan University of Science and Technology from January 2009 to December 2011 and were included in this study as sample cases. However, 78 patients who chose treatment with rabeprazole 20 mg, amoxicillin 1.0 g, levofloxacin 0.2 g and furazolidone 0.1 g, twice daily were included in the experimental treatment group, and 69 patients who chose treatment with omeprazole 20 mg, amoxicillin 1.0 g and clarithromycin 0.5 g, twice daily were included in the standard triple treatment group. All patients, who did not receive treatment before enrolling in this study, were diagnosed with chronic erosive gastritis or peptic ulcer disease by endoscopy. In addition, all patients had a positive rapid urease test and antrum mucosal tissue was obtained to detect the presence of *H. pylori*.

The patients by their own volition, were divided into the experimental treatment group (n = 78) and the standard triple treatment group (n = 69). The experimental treatment group consisted of 41 males and 37 females, aged 20 to 65 years, with an average age of 44.5 years; 34 patients had chronic erosive gastritis, 28 had a gastric ulcer and 16 had a duodenal ulcer. The standard triple treatment group consisted of 38 males and 31 females, aged 22 to 67 years, with an average age of 43.5 years; 31 patients had chronic erosive gastritis, 17 had a gastric ulcer and 21 had a duodenal ulcer. There were no statistically significant differences between the two groups regarding age and gender (Table 1).

Exclusion criteria

Patients with a history of gastrointestinal surgery, gastroesophageal reflux disease, non-steroidal anti-inflammatory drug-related stomach problems or ulcers, those taking PPIs or H_2 blockers, bismuth, antibiotics or other drugs which might affect gastric physiology two weeks before enrolling in the study and those who were allergic to the medicine tested were excluded.

Methods

The experimental treatment group received rabeprazole (Jiangsu Stockhausen Pharmaceuticals, Nanjing, China) 20 mg, amoxicillin (Shiyao Pharmaceutical Group, Shijiazhuang, China) 1.0 g, levofloxacin (Jiangsu Yabang Epson Pharmaceutical, Nanjng, China) 0.2 g and furazolidone (Wuhan Huawei Medicine, Wuhan, China) 0.1 g; the standard triple treatment group received omeprazole (Beijing Taiyang Pharmaceutical, Beijing, China) 20 mg, amoxicillin (Shiyao Pharmaceutical Group, Shijiazhuang, China) 1.0 g and clarithromycin (Guangzhou Baiyunshan Pharmaceutical Group, Guangzhou, China) 0.5 g. The drugs were given half an hour before meals in the morning and evening for 7 d.

Table 1 Baseline characteristics of the patients

Group	No. of patients	Age (yr)	Male[1]	Female[1]	Chronic erosive gastritis[2]	Gastric ulcer[2]	Duodenal ulcer[2]
Experimental treatment	78	44.5	41	37	34	28	16
Standard treatment	69	43.5	38	31	31	17	21

[1]χ^2 = 0.093, P > 0.05; [2]χ^2 = 2.96, P > 0.05.

Observed indicators

Patients were followed up four weeks after treatment, and the ^{13}C urea breath test (^{13}C-UBT) was carried out to detect the presence of *H. pylori*.

Ethics

This was a clinical study carried out in humans, and the protocol for this work was approved by the Institutional Ethics Committee of the First Affiliated Hospital of Henan University of Science and Technology. Before the study began, the patients signed an informed consent form which included name, age, gender, chief complaint, drug history and past medical history.

Statistical analysis

The *H. pylori* eradication rate was assessed based on intention-to-treat (ITT) and per-protocol (PP) analysis. The 95%CI were also calculated for both the ITT and PP analyses and the eradication rate. The patients who were lost to follow-up or could not complete the treatment course due to severe adverse reactions, were considered treatment failures and were excluded in the PP analysis. The χ^2 test and Fisher's exact test were used to compare the differences between the two groups in terms of baseline data, eradication rate and adverse reactions. $P < 0.05$ was considered significant.

RESULTS

Treatment results

In the experimental treatment group, 7 of the 78 patients were lost to follow up (9%), and of the 71 remaining patients, 67 were negative by the ^{13}C-UBT. In the standard triple treatment group, 6 of the 69 patients were lost to follow up (8.6%), and of the remaining 63 patients, 46 were negative by the ^{13}C-UBT.

The eradication rate following the PP analysis in the experimental treatment group was 94.3% (67/71), and was 73% (46/63) in the standard triple treatment group. The eradication rate following the ITT analysis was 86%

Table 2 ***Helicobacter pylori*** **eradication rate in the two groups**

Group	Eradication	No eradication	Follow-up lost	Eradication rate[1] (PP) (95%CI)	Eradication rate[2] (ITT) (95%CI)
Experimental treatment group	67	4	7	94% (88%-99%)	86% (78%-94%)
Standard triple treatment	46	17	6	74% (64%-84%)	67% (57%-77%)

[1]χ^2 = 12.10, P < 0.05; [2]χ^2 = 7.615, P < 0.05. PP: Per-protocol; ITT: Intention-to-treat.

Table 3 ***Helicobacter pylori*** **eradication rates in relation to disease *n* (%)**

Group	Chronic erosive gastritis	Gastric ulcer	Duodenal ulcer
Experimental treatment	29 (34)	24 (28)	14 (16)
Standard treatment	21 (31)	11 (17)	14 (21)

χ^2 = 2.29, P > 0.05

and 67% in the two groups, respectively. The eradication rates in the two groups were statistically significant (P < 0.05) (Table 2). The eradication rate in patients with different diseases in the two groups was not significantly different (Table 3).

Side effects

Major adverse reactions were abdominal pain, dry mouth, dizziness, nausea, vomiting and bloating symptoms, however, these reactions were mild and well tolerated. All patients were able to complete the treatment regimen (Table 4).

DISCUSSION

Warren and Marshall reported the isolation of Campylobacter unidentified (unidentified curved bacilli) from the stomach in 1983, which was officially named *H. pylori* in 1989. *H. pylori* is considered to be the etiologic cause of gastritis, peptic ulcer disease and is associated with the development of gastric cancer[7-9]. It is a spiral or curved gram-negative microaerophilic flagellated bacillus. The prevalence of *H. pylori* infection varies worldwide, and depends on socioeconomic status and sanitation conditions[10]. The diagnosis of *H. pylori* can be performed using invasive and noninvasive methods. Invasive methods include the urease test, which has a sensitivity ranging from 79.7% to 97.5% and a specificity from 97.2% to 100%[11-14], it is performed in the endoscopy unit and is a suitable rapid indirect test to confirm the presence of *H. pylori* in biopsy samples. The urea breath test is considered the gold standard for the diagnosis of *H. pylori* infection, and has a sensitivity and a specificity ranging from 90% to 100%[15-18]. Therefore, we suggest using the ^{13}C-UBT, or esophagogastroduodenoscopy for the assessment of *H. pylori* status.

With increased research on bacteria and drug treatment trials for *H. pylori* infection, it is now clear that antibiotics, antacids, metal preparations and other drugs are effective. Antibiotics used in the treatment of *H. pylori* infection include amoxicillin, tetracycline, clarithromycin, quinolones, furazolidone, metronidazoles and other drugs which have either bactericidal or bacteriostatic effects. Antacids include PPIs and histamine2-receptor antagonists. PPI-clarithromycin-amoxicillin or metronidazole treatment for 7 to 14 d is the first treatment choice for *H. pylori* infection[19]. However, several large clinical trials and meta-analyses have shown that the eradication rate with standard triple therapy has generally declined to unacceptable levels (*i.e.*, 80% or less) recently[20,21].

With increasing clinical use of antibiotics, *H. pylori* resistance appears to have significantly increased. Abuse and irrational drug use as well as repeated anti-*H. pylori* treatment failure are important causes of drug resistance[22].

According to the *H. pylori* Study Group of Digestive Diseases Division of the Chinese Medical Association, which investigated multiple regions of the country in 2007, the resistance rates of *H. pylori* to metronidazole, clarithromycin and amoxicillin were 75.6%, 27.6% and 2.7%, respectively[23]. *H. pylori* resistance to antibiotics is the most important factor in treatment failure. Therefore, the choice of antibiotics is the key to successful eradication of *H. pylori*, in the absence of drug susceptibility testing, and it is safe to use the less frequently used antibiotics which are less likely to induce antibiotic resistance.

The mechanism of action of PPIs involve: (1) direct inhibition of the growth of *H. pylori*; (2) inhibition of urease activity; and (3) increased intragastric pH and enhanced antibiotic activity[24]. Hepatic oxidation is mediated by the cytochrome P450 2C19 (CYP2C19) gene which is polymorphic and produces fast metabolizers and low metabolizers. This is another important factor in the failure of *H. pylori* eradication therapy, and one study suggested that this is the second leading cause of bacterial resistance[25]. The elimination of omeprazole, lansoprazole and pantoprazole involves hepatic oxidation mediated by cytochrome CYP2C19 and CYP3A4, while that of rabeprazole involves its reduction *via* a non-enzymatic pathway to rabeprazole-thioether and partial metabolism by CYP2C19 and CYP3A4[21]. Thus, rabeprazole is less susceptible to the influence of genetic polymorphisms of either CYP2C19 or CYP3A4, and was found to depend only on its pharmacokinetic and pharmacodynamic characteristics. The pKa of rabeprazole is 5.0 and those of other PPIs, such as omeprazole and lansoprazole, are around 4.0, rabeprazole accumulates in an acidic space up to a concentration ten-fold greater than do other PPIs. In addition, rabeprazole is known to transform into the acid-activated form much faster than other PPIs, which further contributes to the inhibition of proton pumps immediately after the arrival of rabeprazole at the target site[26].

Levofloxacin is a third-generation fluoroquinolone, its antibacterial mechanism involves inhibition of bacterial type Ⅱ topoisomerase. Topoisomerase controls DNA to-

Table 4 Side effect profile of patients

Group	No adverse reactions	Abdominal pain	Nausea	Vomiting	Dry throat	Bloating	Dizziness	Total

Standard triple	55	7	6	5	3	2	1	24
Total episodes	113	15	16	11	7	7	8	64

$\chi^2 = 2.13$, $P > 0.05$.

pology in DNA replication and repair, it is a key enzyme in transcription. Levofloxacin, blocks DNA replication by inhibiting bacterial DNA gyrase A subunit and inhibits topoisomerase Ⅳ activity, thus has a bactericidal effect[27]. In addition, levofloxacin has no cross-resistance to *B*-lactam and macrolide antibiotics.

The clinical use of furazolidone is not very extensive, and it is not a commonly used drug in the standard regimen. However, it has a significant effect on *H. pylori* and does not tend to produce drug resistance. The reported furazolidone sensitivity rate is generally 100%[28], and it is inexpensive, therefore, we chose this medication for our *H. pylori* infected patients, and the results showed that inclusion of this drug in the quadruple regimen for *H. pylori* infection resulted in a high eradication rate, thus, this agent has good efficacy. The most common side effects of furazolidone are nausea, vomiting and other gastrointestinal reactions. In this study, gastrointestinal reactions were seen in patients taking furazolidone, however, multiple neuritis was not noted, and the drug was well tolerated.

In summary, these experimental results demonstrated that rabeprazole - amoxicillin - levofloxacin - furazolidone quadruple combination therapy is a safe, highly effective and well tolerated regimen for eradication of *H. pylori*.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) eradication rates with standard triple therapy are declining worldwide. The optimal management of *H. pylori* is evolving and new treatment combinations for antibiotic resistant *H. pylori* strains are required.

Research frontiers

Standard triple therapy represents the accepted standard therapy for *H. pylori* as the organism is known to be susceptible to clarithromycin, and local antimicrobial resistance rates are below 20%, while newer treatment regimens (sequential, quadruple, concomitant and hybrid therapies) and various combinations of new and old antibiotics aimed at eradicating the organism more effectively are increasing in popularity.

Innovations and breakthroughs

In this study, the authors provide further evidence of the efficacy and tolerability of quadruple eradication therapy for *H. pylori* infection.

Applications

Empirical therapy can be employed to treat *H. pylori* infection if antimicrobial sensitivity data are unavailable.

Terminology

A 7-d quadruple therapy consisting of rabeprazole (20 mg *bid*) amoxicillin (1.0 g, *bid*) levofloxacin (0.2 g, *bid*) and furazolidone (0.1 g, *bid*), has high efficacy in the treatment of *H. pylori* infection with an eradication rate of 86% by intention-to-treat analysis and 94% by per-protocol analysis.

Peer review

This is a nice study, particularly for populations who have a relative high prevalence of CYP2C19 polymorphism. The article represents an important contribution to the treatment of *H. pylori*.

Abstract

AIM: To systematically assess the association between diabetes and incidence of gastric cancer.

METHODS: We searched MedLine (PubMed), EMBASE, and the Cochrane Library without any limitations with respect to publication date or language, we also searched the references of qualifying articles. Case-control studies and cohort studies comparing the risk of gastric cancer between diabetic patients and control subjects were included. We excluded studies reporting only standardized incidence ratios without control groups and those that investigated only mortality but not incidence. Seventeen studies met our criteria, and the qualities of these studies were assessed using the Newcastle-Ottawa Quality Assessment Scale. We performed a meta-analysis of pre-existing diabetes and gastric cancer incidence using the DerSimonian-Laird method for random-effects. For subgroup analyses, we separated the studies by study type, region, sex and method to determine confounding factors and reliability. We also conducted subgroup analyses to examine the effects of smoking, *Helicobacter pylori* (*H. pylori*) infection, and cancer site. Publication bias was evaluated using Begg's test.

RESULTS: A random-effects model meta-analysis showed an increased gastric cancer risk in diabetic patients [relative risk (RR) = 1.19; 95%CI: 1.08-1.31]. Subgroup analyses indicated that this result persisted in cohort studies (RR = 1.20; 95%CI: 1.08-1.34), in studies on populations of both Western (RR = 1.18; 95%CI: 1.03-1.36) and Eastern countries (RR = 1.19; 95%CI: 1.02-1.38), in a female subgroup (RR=1.24; 95%CI: 1.01-1.52), and in highly qualified studies (RR = 1.17; 95%CI: 1.05-1.31). Moreover, these results persisted when the analysis was confined to studies adjusted for well-known gastric cancer risk factors such as smoking (RR = 1.17; 95%CI: 1.01-1.34) and *H. pylori* infection (RR = 2.35; 95%CI: 1.24-4.46).

CONCLUSION: Pre-existing diabetes mellitus may increase the risk of gastric cancer by approximately 19%. This effect seems to be unrelated to geographical region.

INTRODUCTION

Diabetes mellitus is currently an epidemic. Approximately 171 million individuals worldwide had diabetes mellitus in 2000, and it is estimated that 366 million people will have diabetes by 2030, which corresponds to nearly 4.5% of the global population[1]. The estimated prevalence of diabetes among adults in the United States currently ranges from 5.9% to 12.4% (median 8.3%)[2], and some cancers, such as colorectal, endometrial, breast, liver, and pancreatic cancer, are reportedly more prevalent in diabetes patients[3-7]. Diabetes mellitus has also been associated with an increased risk of long-term and all-cause mortality in cancer patients[8].

Although the incidence and associated mortality of gastric cancer is decreasing, it remains the fourth most common cancer and the second leading cause of cancer-related mortality worldwide[9]. Despite the success in gastric cancer control, the persistence of the public health burden of gastric cancer indicates the need to expand efforts to identify and address the individual and social determinants of the disease. The public health significance of a potential causal link between diabetes mellitus and gastric cancer highlights the need for a systematic assessment of the association between these 2 diseases.

Therefore, several systematic reviews have recently been performed to examine the above mentioned associations. One review suggested that diabetic individuals have an increased risk of gastric cancer[10]. However, this review had some limitations as it included studies without control groups[11-14] and excluded appropriate studies[15,16]. Two other reviews showing inconclusive results[17,18] did not include any recent studies[19,20], and did not differentiate between "incidence" and "mortality" in terms of describing the risk[17]. Such methodological weaknesses of the previous meta-analysis made it difficult to understand the association between preexisting diabetes mellitus and the risk of gastric cancer.

In the present study, we aimed to clarify the association between diabetes and gastric cancer through an extensive search of the literature, which we reviewed using strict criteria.

MATERIALS AND METHODS

Methods

The procedures performed in this meta-analysis are in accordance with recent guidelines for the reporting of meta-analysis (PRISMA guidelines).

Data sources and searches

We conducted a systematic search of electronic databases and the bibliographies of all eligible studies to identify all relevant studies. We initiated the search on February 7, 2012 without any limitations with respect to publication date or language. The electronic databases searched included MedLine (PubMed), EMBASE, and the Cochrane Library. The search strategy included terms for diabetes (glucose, diabetes, or hyperglycemia), gastric cancer (stomach cancer, gastric cancer, stomach malignant neoplasm, or gastric malignant neoplasm), and risk (incidence, prevalence, or risk). We also searched the references of included articles.

Study selection

Case-control studies, cohort studies, and randomized controlled trials comparing the risk of gastric cancer between diabetic patients and control subjects were eligible for inclusion. We included studies evaluating self-reported diabetes, registered diabetes, and high HbA1c and blood glucose levels. To be included in our meta-analysis, articles had to contain both of the following: (1) a risk estimate (hazard ratio, relative risk, or odds ratio relating preexisting diabetes to subsequent occurrences of gastric cancer); and (2) an estimate of precision (standard error or 95%CI). We also included articles that failed to report precision directly, but from which we could reconstruct a precision estimate using the data described[21,22]. We excluded studies reporting only standardized incidence ratios without control groups. We also excluded studies that investigated only mortality without incidence and studies in which the classification of the subjects' diabetes status (diabetic or non-diabetic) was not possible due to insufficient ranges in blood glucose levels. Studies were excluded if either the abstract[23] or the full text[24] was unavailable after author contact was made.

Data extraction and quality assessment

The titles, abstracts, and full articles were reviewed independently by two authors (Yoon JM and Son KY). Yoon JM performed a full abstraction of the data, and Son KY verified the accuracy. Disagreements were resolved by discussion, consensus, and arbitration by a third author (Park SM). Abstracted data included type of study, study population characteristics, criteria for diabetes mellitus or hyperglycemia, duration of follow-up, incidence of cancer, adjustment variables, and study quality. Quality was assessed using the Newcastle-Ottawa Quality Assessment Scale (NOS) for case-control or cohort studies.

Statistical analysis

To avoid overlapping patient populations, we compared data sources and geographic locations. If a patient population was found to overlap, we included the article with the most comprehensive population or the most adjusted risk estimate associated with preexisting diabetes. If an article reported estimates separately by sex[15,19,25-29] or by different cohorts[16], we regarded the study as 2 independent studies. If an article did not report the risk ratio and confidence interval, we estimated the risk using Fisher's exact test without adjustment[20-22], and the estimates were rounded off to the nearest hundredth. In case-control studies, odds ratios were regarded as relative risks because of the low prevalence of gastric cancer[9,30,31].

For the meta-analysis, we calculated pooled estimates for all the studies. For the subgroup analyses, we separated studies by study type, region, sex, and method to determine the confounding factors and reliability. We also

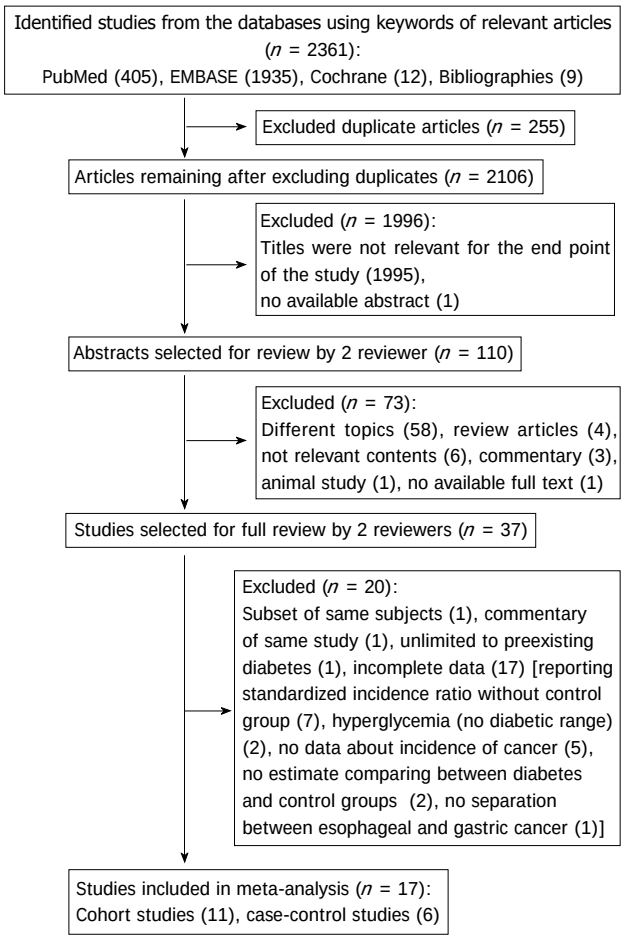

Figure 1 Flow diagram of studies identified and selected.

conducted subgroup analyses to examine the effects of smoking, *Helicobacter pylori* (*H. pylori*) infection, and cancer site, which are major factors influencing the risk of gastric cancer[32-34]. We calculated all the pooled estimates using the DerSimonian-Laird method for random effects. We also reported I^2 values for heterogeneity assessment. Publication bias was evaluated using Begg's test. All analyses were conducted using Stata software(version12.1, StataCorp, United States).

RESULTS

The systematic literature search identified 2361 relevant references (Figure 1). After screening the titles, we excluded 255 duplicated and 1996 non-relevant studies. By reviewing the abstracts, we further excluded 73 articles. The full texts of the 37 remaining articles were retrieved for formal review. After independent review, 20 studies were excluded; 2 studies[35,36] used the same populations as another trial[37], and 1 did not limit the exposure group to individuals with preexisting diabetes[38].

Seventeen studies reported only limited data (uncertain diabetes diagnosis[39,40], usage of a standardized incidence ratio[11,13,14,41-44], lack of an acceptable control group[45,46], reporting of only mortality data[47-51], and uncertain gastric cancer diagnosis[52]). Table 1 provides the details of the 17 studies that met our predefined inclusion and exclusion criteria. In total, 11 cohort[15,16,19,22,26-28,37,53-55] and 6 case-control[20,21,25,29,56,57] studies were used. We were unable to find any suitable randomized control trials.

Description of studies

The 17 articles included in our analysis were heterogeneous in many respects. Geographically, 6 studies were conducted in East Asia, 1 in West Asia, 5 in North America, and 5 in Europe. According to the cohort studies, the prevalence of diabetes varied from 3.0% to 13.2%. Four studies used measurement criteria to define diabetes mellitus, and 2 studies differentiated between gastric cardia and non-cardia cancer. The reporting of age and follow-up time varied widely. In 13 studies, a time interval of more than 1 year between the diagnoses of diabetes and cancer was required in order to minimize reverse causality, although 2 studies showed only the estimates without time intervals[16,54]. Quality varied from 4 to 9 stars according to the NOS, but 3 studies were downgraded because we used recalculated estimates without adjusting for pooled analysis[20-22]. After downgrading, the mean NOS score was 7.3. We therefore conducted subgroup analysis according to methodological quality (with "high-quality" defined as a score of $\geqslant 8$).

Fifteen studies included both sexes and 10 reported data separated by sex. In one of the latter, fewer than 5 female patients were diagnosed with both diabetes mellitus and subsequent gastric cancer[15]; the estimate was therefore not reported. In total, we found 28 independent groups separated by sex and cohort, and we yielded 27 eligible estimates. Only 2 studies described the specific risk ratios of cardia and non-cardia gastric cancers[20,22].

Overall

As shown in Figure 2, diabetes mellitus was associated with a significantly increased risk of gastric cancer in all included studies using random effects model analysis [relative risk (RR) = 1.19; 95%CI: 1.08-1.31; I^2 = 70.7%; 95%CI: 56.8%-80.2%].

Subgroup meta-analysis

We examined methodological differences when determining the quality of the studies. According to Figure 2, subgroup meta-analysis by study design revealed significant associations in cohort studies (RR = 1.20; 95%CI: 1.08-1.34), while the results of case-control studies were not statistically significant. Positive associations were observed in more reliable subgroup studies using the registration record or laboratory measurements as diabetes criteria and studies that were highly graded by NOS. A subgroup meta-analysis of studies designed to minimize reverse causality, including the shortest cancer-free interval, indicated that diabetes seemed to increase subsequent gastric cancer (Table 2).

Regional and gender-based differences are presented in Table 2. East Asian (RR = 1.19; 95%CI: 1.02-1.38) and Western studies (RR = 1.18; 95%CI: 1.03-1.36) showed

[1]Interval between diabetes mellitus (DM) and gastric cancer to be selected as population; [2]Calculated from table without adjustment by Fisher's exact test; [3]No estimate was reported due to less than 5 cases in DM patients; [4]Energy, fat, salt, vitamin, dietary fibers; [5]The first numbers are Newcastle-Ottawa Quality Assessment Scale (NOS) of original studies. The second numbers in brackets are downgraded NOS because we calculated new estimates without adjustment. Subgroup analysis were done according to the second numbers. CS: Cohort study; CC: Case control study; NCC: Nested case-control study; BMI: Body mass index; FBS: Fasting blood glucose; FHx: Family history; TC: Total cholesterol; CVD: Cardiovascular disease; IHD: Ischemic heart disease; ORLS: Oxford Record Linkage Study; *H. pylori*: *Helicobacter pylori*; COPD: Chronic obstructive pulmonary disease.

similar increased risks. In the sexual subgroup, only women exhibited statistical significance (RR = 1.24; 95%CI: 1.01-1.52).

Pooled estimates adjusted for well-known gastric cancer risk factors (cigarette smoking and *H. pylori* infection) were also significant. The pooled estimate adjusted for ciga-

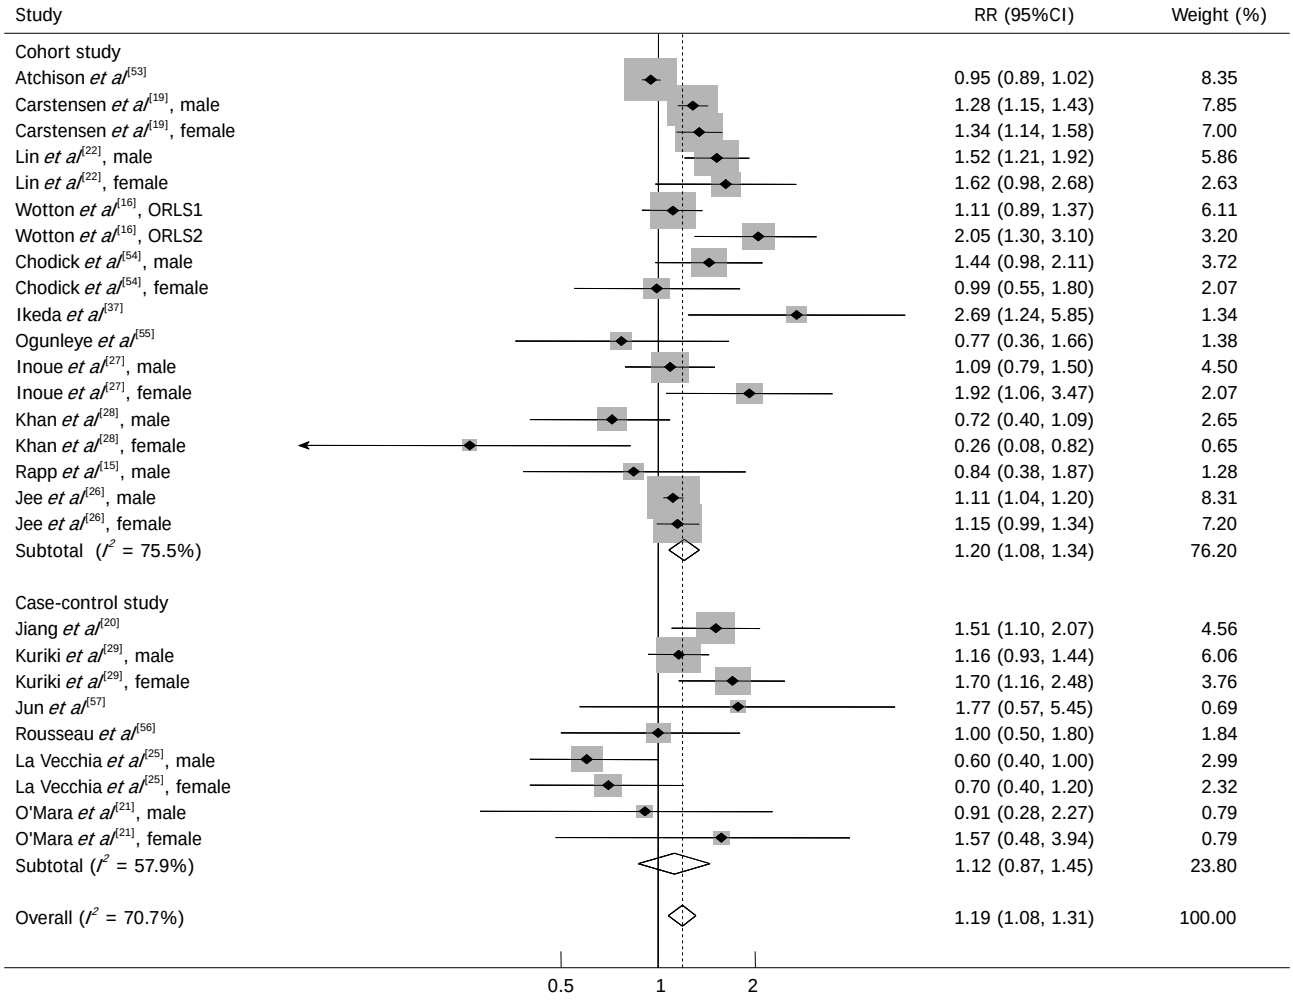

Figure 2 Meta-analysis and pooled relative risk of gastric cancer comparing non-cancer population with and without preexisting diabetes mellitus by random effect model. ORLS: Oxford Record Linkage Study.

rette smoking status was similar to the overall results (RR = 1.17; 95%CI: 1.01-1.34). The pooled estimate adjusted for *H. pylori* infection was greater than the overall estimate (RR = 2.35; 95%CI: 1.24-4.46). Nevertheless, subgroup analyses on either cardia or noncardia cancer did not produce significant results.

Publication bias

Begg's test indicated no publication bias in our analysis (Figure 3).

DISCUSSION

Summary of results

We found a significant association between preexisting diabetes and gastric cancer incidence. In diabetic patients, we found that the risk of subsequent gastric cancer incidence was increased by approximately 19%, and this effect was significant in women. The subgroups of cohort, Western and Eastern studies, showed similar results. These results persisted in studies using self-reported criteria and those adjusted for known risk factors such as cigarette smoking and *H. pylori* infection.

Explanations

We observed some discrepancy between our analysis and previous meta-analysis. Three previous meta-analysis have explored the association between diabetes and gastric cancer incidence. One of these, a meta-analysis of cohort studies[18], produced a misleading result due to the exclusion of appropriate cohort studies[16,19,54] and the inclusion of a study using a glucose level that was not clearly defined and an unrepresentative range of diabetes mellitus[40]. The study also presented an incomprehensible method for summarizing 2 estimates of cardia and noncardia cancer from the same control group. A different study[17] used the term "risk" without a distinction between incidence and mortality. This methodological weakness made the result heterogeneous and biologically implausible. Another meta-analysis[10] also excluded several recent studies[15,16,19,20] and included studies reporting a standardized incidence ratio without quality assessment.

To supplement the previous insufficient meta-analyses, we restricted inclusion in our analysis to studies reporting a risk ratio compared to a control group, and we assessed the quality of these studies using various criteria. As a result, we found that diabetes and the risk of gastric

Table 2 Preexisting diabetes and risk of gastric cancer by subgroup meta-analysis using random effect model

RR: Relative risk; UC: Unable to calculate due to low degree of freedom; NOS: Newcastle-Ottawa Quality Assessment Scale; *H. pylori*: *Helicobacter pylori*.

cancer were positively associated with each other. This positive association may be reliable based on consistent results from well-designed studies including cohort studies, studies of high quality based on assessment with the NOS, studies examining the time interval between onset of diabetes and subsequent gastric cancer, and studies using objective diabetic criteria (diabetes registry or laboratory measurements) that were adjusted based on important factors (smoking or *H. pylori* infection). Although a time interval of 1 year between diabetes and gastric cancer may be insufficient evidence of a causal relationship, we were able to minimize the reverse causality.

Regarding biological plausibility, the results of this study are consistent with previous studies in which preexisting diabetes was associated with an increased risk of a variety of cancers. The oncogenic properties of diabetes have been well documented. The increased insulin concentration in early diabetes can stimulate cell proliferation through activation of the insulin receptor or insulin-like growth factor-I receptor (IGF-IR) and the inhibition of IGF binding proteins, which may result in increased free and bioavailable IGF-I[58]. Additionally, a high level of serum IGF-I has been demonstrated to increase the risk for development of several carcinomas including gastrointestinal carcinomas[59]. Exogenous IGFs stimulate the proliferation of gastric cancer cells, while the blocking of

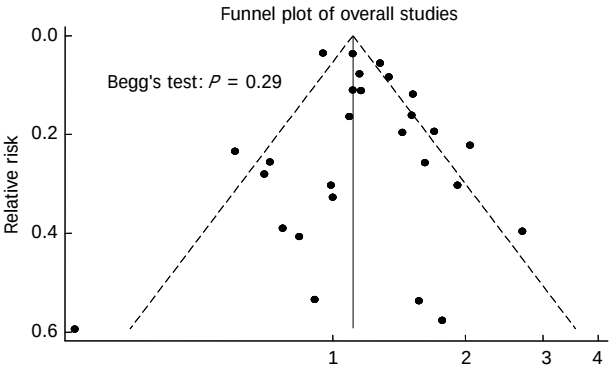

Figure 3 Funnel plots for publication bias.

IGF-IR inhibits tumor development[60,61].

Vascular endothelial growth factor (VEGF), the levels of which are increased in the blood of diabetic patients[62], is another cytokine that is related to the oncogenic properties of diabetes. VEGF is correlated with tumor vascularity and the frequency of hepatic metastasis, and it induces the proliferation and dilation of lymphatics culminating in node metastasis[63-65]. Moreover, the IGF/IGF-IR axis has also been shown to interact with the VEGF/VEGFR system in various tumors including gastrointestinal malignancies[66,67].

DNA damage in diabetic patients is another potential mechanism of oncogenesis. The increased production of reactive oxygen species could result in greater oxidative damage to DNA[68]. Furthermore, in an experimental study, high blood glucose levels were shown to directly induce DNA damage[69].

While we found that the association between diabetes and gastric cancer persisted irrespective of *H. pylori* infection, it nevertheless seems probable that diabetes and *H. pylori* infection, which is a known risk factor for gastric cancer, work synergistically to increase the risk of gastric cancer. Indeed, a previous cohort study in Japan demonstrated that a high HbA1c level and a concomitant *H. pylori* infection increased the gastric cancer risk synergistically[37]. It is possible that reactive oxygen-dependent DNA damage enhances the modifying effect of *H. pylori* on epithelial cell proliferation.

To confirm this synergistic effect, we also performed subgroup analyses by cancer site. Although noncardia gastric cancers were known to be strongly associated with *H. pylori* infection[70,71], we failed to show a similar relationship between diabetes mellitus and specific sites of gastric cancer. As further studies dealing with site-specific data are performed, a reassessment will be required.

Potential confounders

A positive association between diabetes and gastric cancer incidence was observed among women but not among men. These results must be interpreted carefully as there were only a few studies differentiating men and women. Sex hormones could represent one possible reason for this difference. In breast cancer, it is well established that

estrogen and IGF-1 interactively affect cell proliferation[72]. Gastrointestinal tissues, whether normal or cancerous, contain estrogen receptor β, and estrogen can bind to them[73,74]. Through an undefined mechanism, estrogen levels in diabetic women could influence or stimulate the proliferation of gastric cancer cells.

This gender-based difference could also be due to disparate methods of diabetes intervention. Metformin[46,75], aspirin[76,77], and statins[78] are known to protect against a number of cancers, while insulin is reported to increase the risk of several cancers[75]. Although gender differences in this matter were not explored in many previous studies, clues were obtained from the following studies: One study suggested that gender differences in adherence to diabetes management were minimal[79]. However, an Italian study reported that diabetic women were more likely to use insulin than men[80]. According to an American study, men use statins more frequently in type 2 diabetes mellitus[81]. These factors, however small, might contribute to the above-mentioned gender differences.

Limitations

Our study has several limitations. First, the studies we examined were highly heterogeneous. In particular, diabetes mellitus was defined by various methods and cut-off values. Diabetic prevalence and subject age also differed. Second, dietary food factors such as salt, nitrite[82-84], and fresh vegetable[85] intake could not be considered in the analysis despite being potential confounders. Finally, the selected studies contained no details regarding diabetes interventions that were sufficient to adjust for the effects of diabetes treatments.

In conclusion, despite the limitations, our meta-analysis suggests that preexisting diabetes mellitus may increase the risk of gastric cancer. Further prospective studies assessing confounders such as diabetes interventions are needed to specifically test the effects of diabetes mellitus on gastric cancer risk.

COMMENTS

Background

The burden of diabetes mellitus is increasing globally. Gastric cancer is the fourth most common cancer and the second leading cause of cancer-related mortality worldwide. Although the association between diabetes mellitus and a variety of cancers is well established, the association between diabetes mellitus and gastric cancer is currently unclear.

Research frontiers

Over the past 3 decades, many studies have been performed to understand the associations between preexisting diabetes mellitus and subsequent gastric cancer incidence. Moreover, several systematic reviews were recently performed to investigate these associations. However, these reviews were methodologically insufficient and thus could not achieve a comprehensive conclusion.

Innovations and breakthroughs

Based on this meta-analysis, preexisting diabetes mellitus may increase the risk of gastric cancer by approximately 19%. Similar associations were indicated in subgroup analyses of East Asian, Western, cohort, and high-quality studies. These findings were not presented clearly in previous systematic reviews.

Applications

Diabetes mellitus appears to be either directly or indirectly associated with the risk of gastric cancer. An exploration of the mechanism for this association may help them to reduce the gastric cancer risk.

Terminology

Insulin-like growth factors (IGFs) are proteins similar to insulin. IGF is a part of the cellular communication system. Recently, IGFs were proposed to play a role in aging. Vascular endothelial growth factor (VEGF) is a protein related to angiogenesis. In diabetes mellitus, the level of VEGF in the blood is high.

Peer review

This is a well-performed meta-analysis of currently available studies on the potential role of diabetes mellitus in the development of gastric cancer. The authors found that pre-existing diabetes mellitus may increase the risk of gastric cancer by approximately 19%. This finding was found to be unrelated to geographical region. This is a good meta-analysis and the authors have included many relevant issues missed by other research groups.

Abstract

Hyperbilirubinemia has been presumed to prevent the process of atherogenesis and cancerogenesis mainly by decreasing oxidative stress. Dubin-Johnson syndrome is a rare, autosomal recessive, inherited disorder characterized by biphasic, predominantly conjugated hyperbilirubinemia with no progression to end-stage liver disease. The molecular basis in Dubin-Johnson syndrome is absence or deficiency of human canalicular multispecific organic anion transporter MRP2/cMOAT caused by homozygous or compound heterozygous mutation(s) in *ABCC2* located on chromosome 10q24. Clinical onset of the syndrome is most often seen in the late teens or early adulthood. In this report, we describe a case of previously unrecognized Dubin-Johnson syndrome caused by two novel pathogenic mutations (c.2360_2366delCCCTGTC and c.3258+1G>A), coinciding with cholestatic liver disease in an 82-year-old male patient. The patient, suffering from advanced atherosclerosis with serious involvement of coronary arteries, developed colorectal cancer with nodal metastases. The subsequent findings do not support the protective role of Dubin-Johnson type hyperbilirubinemia.

INTRODUCTION

Recent data have indicated the potent antioxidant properties of mild or moderately elevated serum bilirubin levels with substantial positive clinical consequences and especially their protective effect on atherogenesis and cancerogenesis[1]. A direct link between low serum bilirubin levels and peripheral vascular disease and the protective

effect of mild or moderate unconjugated hyperbilirubinemia on atherosclerosis were confirmed in numerous clinical trials[2-5]. Antiproliferative, cytostatic and pro-apoptotic effects of bilirubin are well-known and have been demonstrated in both *in vitro* and *in vivo* studies[6-10]. However, conflicting data on the possible protective effect of elevated bilirubin levels against sporadic colorectal carcinoma have been reported in the literature[11-13].

Dubin-Johnson syndrome (DJS, OMIM 237500) is a rare, autosomal recessive disorder characterized by non-hemolytic hyperbilirubinemia with no progression to end-stage liver disease[14]. Both the conjugated and unconjugated form of bilirubin can be elevated in DJS subjects, with the former ranging from 17% to 88% of the total bilirubin with a mean value of 60%[14,15]. In addition to the fluctuating jaundice caused by biphasic hyperbilirubinemia due to absence or deficiency of human canalicular multispecific organic anion transporter MRP2/cMOAT[16-18], DJS subjects may suffer from non-specific symptoms such as weakness and abdominal discomfort. Urinary coproporphyrin output is normal; however, 80% of the coproporphyrin fraction is represented by coproporhyrin I (normally 25%)[19]. The biliary excretion of anionic dyes including bromosulfophthalein, indocyanine green and cholescintigraphy radiotracers is delayed. Liver histology in DJS shows an accumulation of distinctive melanin-like lysosomal pigment in an otherwise normal liver, which gives the organ a characteristic dark pink or even black colour[14,20].

In this report, we describe the case of unintentionally detected DJS complicating liver injury in an 82-year-old patient who was being followed for previously diagnosed colorectal cancer and ischemic heart disease.

CASE REPORT

An 82-year-old Caucasian male patient, a normotensive non-smoker with a history of right-sided hemicolectomy due to colorectal adenocarcinoma with nodal metastases five years ago and ischemic heart disease, was referred to the hospital due to clinical jaundice with elevated serum bilirubin (total bilirubin 220 μmol/L, direct bilirubin 171 μmol/L), gamma-glutamyltransferase (γGT) activity (4.7 μkat/L) and fluctuating alkaline phosphatase (ALP) activity (1.3-3.6 μkat/L) to exclude bile duct obstruction or metastatic liver disease. The patient complained of slight upper abdominal discomfort without pruritus or nausea. Complete blood count and serum electrolyte levels were normal, as was his serum lipid profile (serum cholesterol 3.5 mmol/L, high-density lipoprotein cholesterol 0.9 mmol/L, low-density lipoprotein cholesterol 2.5 mmol/L, triglycerides 1.3 mmol/L). Abdominal ultrasonography, endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography did not detect any obstacle or dilation of the biliary tree, and only slightly imperfect filling of the ductus choledochus was observed. Serological examinations for viral hepatitis (hepatitis A virus, hepatitis B virus and hepatitis C virus) and autoantibodies were completely negative. During the patient's hospitalization, the activity of γGT and ALP gradually decreased but, due to persistent marked hyperbilirubinemia, a percutaneous liver biopsy was performed.

The liver tissue obtained at biopsy was standardly processed. Sections cut at 4-6 μm were stained with hematoxylin and eosin, periodic acid Schiff, Schmorl's and van Gieson's method. Analysis of the liver biopsy specimen revealed preserved architecture of liver parenchyma with perivenular and perisinusoidal fibrosis, subtle steatosis and only discrete intracellular cholestasis in centrilobular hepatocytes. The most striking feature, however, was an intense parenchymal pigmentation, with centrilobular and midzonal accentuation, consisting of coarse brown black pigment (Figure 1, Panel A-C). Special stainings (Gömöri, silver ammonium complex-Masson's and Perls Prussian blue method) for pigment characterization were added. The pigment was negative in the Perls reaction and displayed rudimentary autofluorescence with gradually increasing intensity, especially in Shandon mounting medium and simultaneously reduced Masson's solution. A retrospective analysis of the patient's medical records back to 1994 revealed long-term, persistent, mixed, predominantly conjugated hyperbilirubinemia (total bilirubin fluctuating within the range 23.0-215.6 μmol/L, conjugated bilirubin 17.7-170 μmol/L). The conjugated-to-total bilirubin ratio was within the range of 40% (total bilirubin 202 μmol/L and conjugated bilirubin 80.6 μmol/L in 2009) to 89% (total bilirubin 41.8 μmol/L and conjugated bilirubin 37.2 μmol/L in 1994). Taking into account the normal activity of aminotransferases, γGT and ALP, DJS was suspected.

For immunohistochemical analysis, 4 to 6 μm-thick sections were incubated with the anti-MRP2 mouse monoclonal antibody (clone M2Ⅲ-6, Kamiya, Seattle, WA). The EnVision Peroxidase Kit (Dako, Glostrup, Denmark) was used for visualization and counterstaining with Harris's hematoxylin was performed. As a positive control, sections of an adult liver without cholestasis were stained, and liver sections incubated without primary antibody were used as negative controls. Immunohistochemical analysis for MRP2 protein was completely negative (Figure 1D).

Ultrastructural analysis was performed on the liver sample fixed with 4% buffered paraformaldehyde, osmicated, dehydrated in ascending ethanol solutions and embedded into Epon-Araldite mixture. Ultrathin sections were double-stained with uranyl acetate and lead nitrate and then examined under a JEM 1200 EX electron microscope. Intralysosomal localization of the pigment was demonstrated.

A mutation analysis of the *ABCC2* gene was indicated to confirm the diagnosis of DJS at the molecular level. Written informed consent was obtained from the patient before the genetic investigation. *ABCC2* was analyzed by direct sequencing of genomic DNA extracted from peripheral leucocytes. All 32 exons, with the adjacent parts of the intronic sequences, were amplified by polymerase chain reaction (PCR) using the intronic oligonucleotide primers listed in Table 1. Amplified fragments were gel-purified, extracted from the gel with QIA quick spin col-

umns (Qiagene, Hilden, Germany), and sequenced on an ABI 3130 Genetic Analyzer (Applied Biosystems, Foster

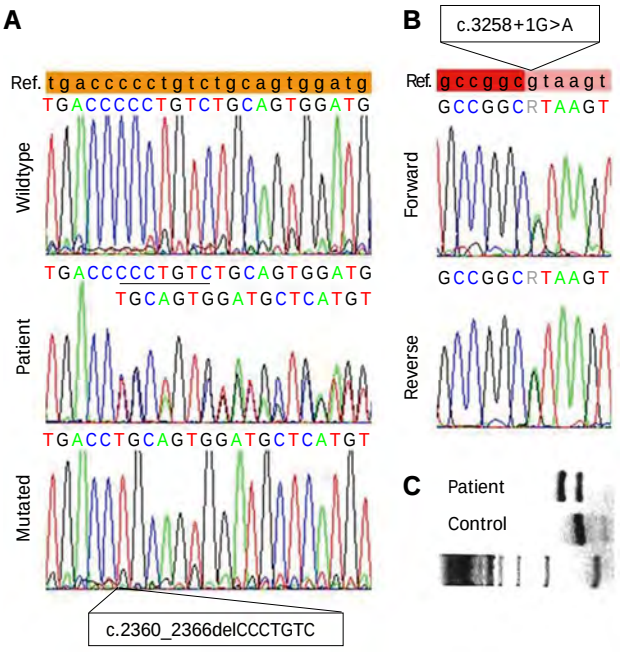

Figure 2 Mutation analysis results. A: Presence of a heterozygous deletion c.2360_2366delCCCTGTC in exon 18 of *ABCC2* (panel A, middle lane) was confirmed by sequence analysis of individual alleles separated by cloning (wildtype allele - panel A, upper lane; mutated allele - panel A, lower lane); B: In addition, a heterozygous splice site mutation c.3258+1G>A was detected in intron 23; C: Presence of the latter mutation was confirmed by polymerase chain reaction-Bsh1236I restriction fragment length polymorphism analysis.

City, CA). The obtained sequence was compared with the reference sequences GenBank NM_000392 (mRNA) and NT_030059 (genomic DNA). An exon with suspected deletion was cloned into a pCR4.1-TOPO plasmid vector (Invitrogen, Carlsbad, CA), and the wild-type and mutated alleles were sequenced separately. Presence of the second mutation was confirmed by PCR-restriction fragment length polymorphism analysis (PCR-Bsh1236I RFLP).

Analysis of the *ABCC2*/*MRP2* gene disclosed two novel mutations: a heterozygous deletion c.2360_2366delCCCTGTC in protein coding exon 18 (Figure 2A), and a heterozygous mutation c.3258+1G>A in intron 23 (Figure 2B and C). The former mutation in exon 18 was predicted to cause a reading frame shift and premature termination of DNA translation at position 803 with protein alteration p.Pro787LeufsX7. The latter mutation affecting the donor splice site of intron 23 was predicted to cause abnormal splicing of mRNA. Therefore, both mutations were considered as pathogenic. Histochemistry and mutation analysis accordingly established the diagnosis of DJS.

The patient suddenly died several months after being released from the hospital. The patient's autopsy revealed no liver metastases and confirmed the diagnosis of advanced atherosclerosis with serious involvement of coronary arteries with signs of chronic myocardial ischemia.

DISCUSSION

The diagnosis of DJS is indicated by the presence of fluctuating predominantly conjugated hyperbilirubinemia, an increased ratio of urinary coproporphyrin I to coproporphyrin Ⅲ, and a unique cholescintigram showing delayed visualization of the liver and biliary tract. Neither a percutaneous liver biopsy with evidence of melanin-like pigment and the absence of MRP2 protein nor mutation analysis are necessary for the diagnosis. Nonetheless, both methods may be helpful in complicated cases to establish the correct diagnosis and rule out more serious liver pathology.

In our patient, neither an examination of urinary coproporphyrin levels nor cholescintigraphy was performed. The diagnosis was based on biochemical evidence of fluctuating biphasic hyperbilirubinemia and characteristic findings in the liver biopsy, and further supported by disclosure of two pathogenic mutations by subsequent mutational analysis. Considering the clinical picture and the results of laboratory tests, the two mutations are supposed to be in transposition. Unfortunately, no living relatives of the patient were found to confirm our presumption.

As the clinical onset of DJS is most often seen during the teenage years or in early adulthood, the first recognition of the disease in old age is highly unusual. To the best of our knowledge, our patient is the oldest reported newly diagnosed DJS patient confirmed by mutation analysis.

The clinical presentation and laboratory findings of our case indicated the coincidence of DJS with mild cholestatic liver damage, the etiology of which remained obscure. The simultaneous occurrence of the syndrome with another hepatobiliary disease is well-known and the coincidence with another disease or pathologic stimulus can modify the clinical picture and results of laboratory tests, including histomorphology[21-24].

A significant fact in our case is the presence of colorectal adenocarcinoma with nodal metastases in a patient with chronic mixed hyperbilirubinemia. Numerous clinical trials have demonstrated the protective effects of hyperbilirubinemia against the development of sporadic colorectal cancer and an association of low bilirubin levels with an increased risk of colon cancer morbidity and mortality[10-12].

In addition, there are reports describing the protective effect of bilirubin on the development of atherosclerosis emphasizing the antioxidative and anti-inflammatory properties of bilirubin[2-5]. Interestingly, our patient, a lifelong normotensive non-smoker with normal lipidogram, suffered from ischemic heart disease and advanced atherosclerosis affecting both large arteries and peripheral circulation, especially coronary arteries.

In conclusion, our case demonstrates that DJS should be included in the differential diagnosis of liver diseases even in atypical age categories. The fact that our patient with DJS developed colorectal adenocarcinoma and clinically significant atherosclerosis indicates that Dubin-Johnson hyperbilirubinemia may not be sufficient to protect from atherogenesis and cancer development, even in the absence of established risk factors.

Abstract

A 76-year-old woman with hepatitis C cirrhosis presented with tarry stools and hematemesis. An endoscopy demonstrated bleeding duodenal varices in the second portion of the duodenum. Contrast-enhanced computed tomography revealed markedly tortuous varices around the wall in the duodenum. Several afferent veins appeared to have developed, and the right ovarian vein draining into the inferior vena cava was detected as an efferent vein. Balloon-occluded retrograde transvenous obliteration (BRTO) of the varices using cyanoacrylate was successfully performed in combination with the temporary occlusion of the portal vein. Although no previous publications have used cyanoacrylate as an embolic agent for BRTO to control bleeding duodenal varices, this strategy can be considered as an alternative procedure to conventional BRTO using ethanolamine oleate when numerous afferent vessels that cannot be embolized are present.

Successful balloon-occluded retrograde transvenous obliteration for bleeding duodenal varices using cyanoacrylate. *World J Gastroenterol* 2013; 19(6): 951-954 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/951.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.951

INTRODUCTION

Bleeding duodenal varices is a rare complication in patients with portal hypertension, occurring in only 0.4% of these patients, and is often life-threatening because of the difficulty in diagnosis and treatment[1]. Treatment options include a surgical procedure, endoscopic treatment[2], and endovascular treatment, including transjugular intrahepatic portosystemic shunts (TIPS)[3,4] and balloon-occluded retrograde transvenous obliteration (BRTO)[5-10]. Although several studies have reported successful results using BRTO alone[5-8], some difficult cases with large varices or numerous collaterals requiring a combined approach have been reported[7,9], and no previous publications have used cyanoacrylate as an embolic agent for BRTO to control bleeding duodenal varices. We herein report a case with bleeding duodenal varices that were successfully embolized using cyanoacrylate and BRTO in combination with temporary occlusion of the portal vein.

CASE REPORT

A 76-year-old woman with liver cirrhosis secondary to hepatitis C presented with tarry stools and hematemesis. An urgent endoscopy demonstrated bleeding varices in the second portion of the duodenum (Figure 1A). She had no esophageal or gastric varices. Although banding

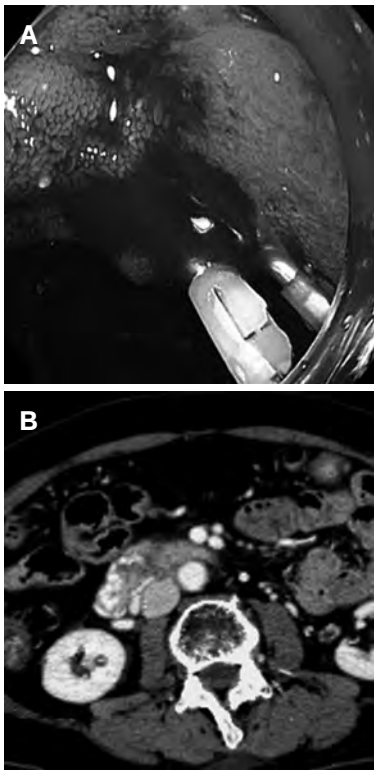

Figure 1 Endoscopy and computed tomography of the duodenum. A: Endoscopy demonstrates bleeding varices in the second portion of the duodenum; B: Contrast-enhanced computed tomography reveals markedly tortuous varices around the wall in the second and third portion of the duodenum.

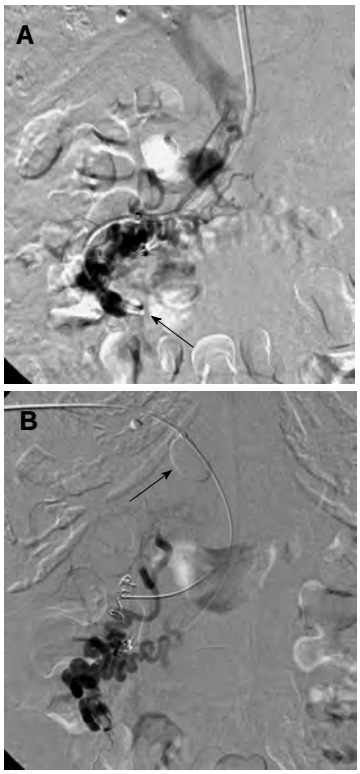

Figure 2 Balloon-occluded retrograde venography. A: Balloon-occluded retrograde venography (BRTV) shows the dilated efferent vein and the duodenal varices, but the contrast material quickly disappears through several afferent veins. Note that the balloon was inflated in the right ovarian vein (arrow); B: BRTV with occlusion of the main portal trunk (arrow) after embolization of one of the afferent veins reveals the complete opacification of the duodenal varices.

and clipping for the varices was attempted, the bleeding continued and frequent blood transfusions were required. Laboratory findings were as follows: red blood cell, 232 $\times 10^4/\mu L$; hemoglobin, 6.8 g/dL; hematocrit, 20.4%; platelets, 96 000/mL; total bilirubin, 1.36 mg/dL; serum albumin, 3.3 g/dL; and prothrombin time, 15.7 s (reference, 11.3 s). Neither ascites nor encephalopathy was observed. Child-Pugh's classification was graded as B. Contrast-enhanced computed tomography (CT) revealed markedly tortuous varices around the wall in the second and third portion of the duodenum (Figure 1B). Several afferent veins of the varices appeared to have developed, and the right ovarian vein draining into the inferior vena cava was detected as an efferent vein. We planned BRTO to embolize the duodenal varices after obtaining informed consent from the patient.

An 8-French guiding sheath introducer was inserted into the inferior vena cava *via* the right internal jugular vein. A 5.2-French, 9-mm cobra-shaped balloon catheter was inserted into the efferent vein through the right ovarian vein, and the balloon was inflated to occlude the efferent vein. Balloon-occluded retrograde venography (BRTV) showed that the dilated efferent vein and the duodenal varices were filled with contrast material, but the contrast material quickly disappeared through several afferent veins (Figure 2A). Because BRTO alone may have failed to achieve adequate sclerosant accumulation because of the leakage into the portal vein, antegrade transhepatic embolization of the afferent veins was attempted.

A 5-French sheath introducer was inserted through the left lateral portal branch, and one of the afferent veins was embolized using two microcoils (MicroNester coil; Cook, Inc, Bloomington, Indiana, United States). However, several remaining afferent veins could not be embolized, and the contrast material also disappeared through the afferent veins. We then placed a balloon catheter into the main portal trunk to control the hepatopetal flow of the afferent veins. BRTV with occlusion of the main portal trunk revealed the disappearance of the hepatopetal portal flow and complete opacification of the duodenal varices (Figure 2B). A microcatheter was coaxially advanced to the duodenal varices through the retrograde route, and a total of 4 mL of 20% cyanoacrylate with ethiodized oil was injected into the duodenal varices (Figure 3).

The following day, a contrast-enhanced CT examination confirmed the complete accumulation of the ethiodized oil replacement in the duodenal varices (Figure 4) and the patency of either portal vein or systemic circulation. Liver function was preserved after the procedure. Four days after the procedure, an endoscopy showed that hemostasis of the bleeding duodenal varices had been achieved. No evidence of bleeding of the duodenal varices was found on follow-up CT and endoscopy examinations performed four months after the procedure.

Figure 3 Radiograph after embolization of the duodenal varices demonstrates complete and adequate accumulation of the ethiodized oil in the varices.

Figure 4 Contrast-enhanced computed tomography after embolization of the duodenal varices shows the complete accumulation of ethiodized oil in the varices.

DISCUSSION

BRTO is an established endovascular treatment for gastric varices[11] but has only been described for the treatment of bleeding duodenal varices in a few reports with limited numbers of clinical patients[5-10]. The advantages of BRTO over TIPS for duodenal varices are that it can completely embolize targeted varices and that it does not reduce portal flow, avoiding further exacerbation of hepatic function and encephalopathy without a significant mortality rate[4,8]. However unlike gastric varices, successful treatment with BRTO alone for duodenal varices is not always feasible and often require combined therapies with an endoscopic or anterograde transhepatic approach, as significant communications or complex hemodynamics between the efferent and afferent veins often complicate treatment and necessitate combined therapy[7,9].

In the present case, some of the afferent veins may have enabled collateral hepatopetal flow during balloon occlusion of the afferent vein, and pressure among the duodenal varices varied, resulting in insufficient filling with the contrast material. At first, coil embolization was attempted *via* a transhepatic portal venous approach, as reported by previous investigators[5,7-9], but not all the afferent veins could be embolized because of the difficulty in catheterizing the tortuous vessels. Second, we performed temporary balloon occlusion of the portal vein. This method was effective because a change in the hemodynamics of the duodenal varices occurred. Temporary occlusion of the main portal trunk may increase the pressure of hepatopetal flow, and the direction of flow in the afferent veins changes from hepatopetal to hepatofugal. This mechanism is similar to that of temporary balloon occlusion of the splenic artery during BRTO for gastric varices to control the portal pressure gradient[12].

In our case, we used cyanoacrylate, not ethanolamine oleate, as a sclerosant. Every investigator has used ethanolamine oleate as the most suitable sclerosant during BRTO for duodenal varices[5-10]. However, ethanolamine oleate was not suitable in our case, because it requires several hours to achieve full effort and may increase the risk of portal venous thrombosis under temporary portal venous balloon occlusion. On the other hand, cyanoacrylate rapidly solidifies with fast polymerization upon exposure to an ionic solution[13], and we believe that this was the best way of minimizing the duration of portal venous occlusion. The potential shortcomings of cyanoacrylate are adhesion to the balloon catheter system or inadvertent embolization upon balloon removal. This should be kept in mind as a note of caution whenever attempting to use cyanoacrylate. To prevent this complication, it would be advantageous to ensure that a microcatheter is advanced to the targeted duodenal varices and only duodenal varices are embolized, with minimal volume of cyanoacrylate.

Endoscopic injection sclerotherapy using cyanoacrylate has been performed as an effective measure[2], but it has the drawback of perforation, tissue injury, and unclear visualization because of massive hemorrhage. Moreover, endoscopic injection of cyanoacrylate also carries a risk of embolism of either portal vein or systemic circulation[14]. Endovascular injection of cyanoacrylate can prevent untargeted embolization such as portal vein or pulmonary artery, confirming the hemodynamics of the duodenal varices using contrast material.

Bleeding duodenal varices is a rare condition that is difficult to diagnose and is potentially life-threatening. BRTO using cyanoacrylate was successfully performed for control of bleeding duodenal varices in the present case. This is an alternative procedure to conventional BRTO using ethanolamine oleate when insufficient filling of the varices with sclerosant occurs and several afferent vessels cannot be adequately embolized.

Abstract

Iatrogenic gastric perforation is one of the most serious complications during therapeutic endoscopy, despite significant advances in endoscopic techniques and devices. This case study evaluated the clinical efficacy and safety of the rescue endoscopic band ligation (EBL) technique in iatrogenic gastric wall perforation following the failure of primary endoclip closure. Five patients were enrolled in this study. These patients underwent emergency endoscopy following the onset of acute gastric wall perforation during endoscopic procedures. The outcome measurements were primary technical success and immediate or delayed procedure-related complications. Successful endoscopic closure using band ligation was reported in all patients, with no complication occurring. We conclude that EBL may be a feasible and safe alternate technique for the management of acute gastric perforation, especially in cases where closure is difficult with endoclips.

INTRODUCTION

The management of gut perforation, including successful primary endoscopic repair, has been increasingly reported in endoscopic trials. Primary endoscopic therapy is now often recommended as an alternative to surgical intervention in select cases[1-3]. However, the commonly used endoclip technique for endoscopic closure has some limitations, depending on the perforation size and anatomic site. Endoscopic clip closure may be difficult for a large perforation, one with a tangential angle, and/or on a necrotic or ulcerated surface. Even when clipping is successful, dehiscence might occur due to strong wall tension. Newly developed devices have been introduced and show promise, but many of these devices are expensive, require additional equipment, and are not readily available in many countries[2,3].

Endoscopic band ligation (EBL) is commonly performed in the management of varix or Dieulafoy's bleed-

ing[4-6]. EBL is a safe and feasible method that can reduce procedure time and be useful in the primary repair of colonic or duodenal perforations[7-9]. Our group previously reported the use of EBL to successfully close two colonic perforations in which endoclip closure initially failed due to the presence of a large perforation and a severe tangential angle in endoscopic procedures assisted with a transparent cap[9].

In this case study, we evaluated the clinical efficacy and safety of the rescue EBL technique in iatrogenic gastric wall perforations in which primary endoclip closure failed.

CASE REPORT

Patients with acute gastric wall perforations were enrolled in this study between September 2011 and August 2012. Written informed consent was obtained from all patients and the study was approved by the institutional ethics committee.

All patients underwent emergency endoscopy following the onset of acute gastric wall perforation during endoscopic procedures. Primary endoscopic closure using an endoclip (Endoclip HX-600-090L; Olympus Optical Co., Ltd., Tokyo, Japan) was attempted initially, immediately upon recognition of the perforation. Patients in whom primary endoclip closure failed or was technically difficult subsequently underwent rescue EBL to achieve closure. After endoscopic confirmation of the perforation site, the endoscope was withdrawn and reinserted after attachment of a pneumoactive, single-band ligator (MD-48709; Akita Sumitomo Bakelite Co, Ltd, Tokyo, Japan). The hood of the ligation device was then placed over the target lesion site. Following successful ligation of the approximate targeted edge of the perforation, additional bands or clips were used to completely close the site (Figure 1). After endoscopic closure, patients' recovery was managed with vital sign monitoring, no oral intake, and intravenous fluid therapy with broad-spectrum intravenous antibiotics and acid suppression. Early oral intake was allowed when clinical symptoms such as abdominal pain or fever resolved, appetite and bowel function returned, and laboratory test values were normalized. Surgical intervention was planned if the patient's clinical condition deteriorated.

The outcome measurements were primary technical success and immediate or delayed procedure-related complications. All endoscopic procedures, including EBL, were performed by experienced faculty endoscopists in tertiary referral centers.

Table 1 presents the clinical characteristics of five patients who underwent rescue closure by EBL. Gut perforation rates following therapeutic endoscopic procedures were ranging from 0.9% to 1.8% in two participated units. Three patients underwent endoscopic mucosal resection with ligation (EMR-L) due to gastric adenoma (n = 2) or neuroendocrine tumor (n = 1); one patient received endoscopic submucosal dissection due to adenocarcinoma; and one patient underwent endoscopic biopsy due to a chronic gastric ulcer. The mean perforation size was 8.6 (range 5-11) mm. The primary causes of endoclip failure were difficulty in approximating the location of adjacent gastric mucosa due to wall tension and a tangential angle. In the case of ulcer base perforation occurred by biopsy (iatrogenic perforation following biopsy; Figure 2), the fibrotic ulcer base made endoscopic clipping difficult.

Table 1 Baseline patient characteristics

No.	Age (yr)/sex	Diagnosis	Cause	Perforation location	Size (mm)	Causes of clip failure
1	65/M	Neuroendocrine tumor	EMR-L	Fundus	9	Tangential angle and wall tension
2	52/M	Gastric adenoma	EMR-L	Angle	11	Severe belching
3	68/M	Gastric adenoma	EMR-L	Upper body, great curvature	8	Tangential angle
4	91/F	Gastric ulcer	Biopsy	Angle	5	Fibrotic tissue and tension
5	73/M	Adenocarcinoma	ESD	Antrum, great curvature	10	Friable mucosa

EMR-L: Endoscopic mucosal resection with ligation; ESD: Endoscopic submucosal dissection; M: Male; F: Female.

Table 2 Procedure outcomes of rescue endoscopic band ligation

No.	Procedure time for endoclips (s)	Procedure time for EBL (s)	No. of bands	No. of clips before/after EBL	Success	Days until diet resumption/discharge
1	198	66	1	3/3	Yes	3/7
2	102	42	2	2/1	Yes	4/5
3	138	78	1	0/4	Yes	2/4
4	894	334	2	6/0	Yes	7/14
5	353	39	1	1/2	Yes	4/7

EBL: Endoscopic band ligation.

The rescue EBL technique was performed successfully in all patients (Table 2). The mean procedure time for complete band ligation was 111.8 (range 39-334) s. Two band ligations were performed in the cases of large and ulcer base perforations. Additional endoclips were applied in four cases to achieve complete closure. No procedure-related complication or delayed dehiscence occurred following successful EBL with or without clipping. Patients resumed their normally scheduled diet an average of 4 (range 2-7) d after the procedure, and were discharged an average of 7.4 (range 4-14) d after the procedure.

DISCUSSION

Iatrogenic gut perforations occurring during endoscopic procedures are generally managed surgically. Although surgical operation remains the gold standard treatment for intestinal perforation, the clinician's familiarity with endoclips and their immediate availability and proper use

may replace surgery for a selected group of patients with a high surgical risk. The mainstays of treatment of early perforations without systemic upset are nasogastric suction, antibiotics, bowel rest, and parenteral nutrition. This type of conservative management may be undertaken in patients with asymptomatic perforations or localized

peritonitis that is expected to improve clinically without complication[1,10-14]. In presented cases, perforation was recognized immediately during procedure, and treated by endoscopic band and clipping successfully. So that, did not use nasogastic suction. However, in patients whose condition deteriorates despite conservative management or alternative endoscopic management, surgical treatment should be considered immediately.

Recent studies have reported high technical success rates for primary closure of an acute iatrogenic perforation with endoclips, newly developed devices, or a band[1,10-12]. Endoscopic repair using endoclips can be limited in large perforations or in those with tangential angles. A wide perforation is difficult to close because of slippage of the perforation edge from the clip while the clip is maneuvered across the defect to grasp the opposite edge of the perforation. Everted perforation edges also make it impossible to grasp the tissue with endoclips. Newly developed devices have recently been introduced and successfully used to close perforations[15]. These devices include through-the-scope (TTS) clips, such as the QuickClip 2 (Olympus Inc., Center Valley, PA, United States), the Resolution clip (Boston Scientific Inc., Natick, MA, United States), and the Tri-Clip and Instinct clip (Cook Medical, Winston-Salem, NC, United States); the over-the-scope clip (OTSC) system (Ovesco Endoscopy AG, Tubingen, Germany); and endoscopic suturing devices such as T-tags (Ethicon Endo-Surgery, Cincinnati, OH, United States) and the flexible Endo Stitch (Covidien, Mansfield, MA, United States). Closure of luminal perforation > 20 mm in size may be difficult. For larger gastric defects, TTS clips can be placed around the circumference of the perforation and lassoed together with a detachable plastic snare (Endo-loop; Olympus)[16]. Among the newly developed devices, OTSC was approved for the closure of perforation < 20 mm in size, and ex vivo studies shown that colon defects 10 to 30 mm in size can be closed with a single OTSC[2]. However, although some techniques have been developed to correct deficits in clip placement, they are not commonly practiced. Some of these devices may prove suitable for the closure of defects throughout the intestinal tract, but their use is limited by the endoscopist's experience, device availability, and cost[2]. Currently, no particular technique has demonstrated proven efficacy or greater reliability than other closure modalities.

EBL was first used in 1988 to treat bleeding from esophageal varices[15]. The simplicity of the technique and low complication rates compared with sclerotherapy have contributed to its growing popularity[4]. Technically, EBL is a simple procedure, even if the targeted site must be approached tangentially or is located in the posterior wall of the proximal body. EBL has been widely used in the management of non-variceal hemorrhage from Dieulafoy's ulcer, gastric angiodysplasia, and polypectomy-induced bleeding[4-6]. In addition, several reports have described the use of EBL in rectal and duodenal perforations during EMR[7-9]. Our group previously reported the use of EBL to successfully close two colonic perforations when endoscopic closure with endoclips initially failed[9]. Primary endoscopic repair can be difficult in some cases because the clips may not hold the tissue of large perforations together successfully, the tissue may slip in perforations with everted edges, or a fibrotic ulcer base may hinder successful manipulation. In contrast, acute perforations with no hardening can be readily closed with suction and band ligation.

Theoretically, EBL can readily approximate both edges of the perforation. Thus, complete suture to the remaining wall by additional bands or endoclips may be simple, even with a large perforation. EBL can also reduce procedure time in comparison with clipping. Immediate closure could prevent the need for surgery or the development of serious peritonitis caused by gastric content leakage. Additionally, in the case of ulcer base perforation, clipping of the fibrotic membrane is difficult due to strong wall tension, which may result in tearing or dehiscence after closure. EBL with suction could reduce such damage throughout the lesion. No dehiscence occurred after EBL in our cases. Finally, the use of additional clips to suture the perforation after EBL might not be necessary. Follow-up endoscopy has detected clip deterioration, with only the band holding the perforated mucosa tightly. Prudent banding may thus be important for successful closure, and one or more band ligations may be sufficient. However, due to the limited number of cases included in our study, we could not confirm that additional clipping is unnecessary, and we generally recommend additional clipping to maintain tight closure of the primary band.

Several factors can be identified as limitations in our study. Our case study was not comparative and included a limited number of patients, preventing us from drawing concrete conclusions. Also, this result cannot be generalized due to an experimental trial. Additionally, we did not evaluate closure dehiscence or ischemic necrosis following band ligation. Although ischemic necrosis induced by band ligation is limited to the mucosa or submucosa, further prospective studies should be conducted to examine whether the perforation risk may be lower with conventional sclerosant injection therapy, heater probe therapy, or electrocoagulation[4,17]. Secondary risks may also develop due to suction of the adjacent mesentery. None of these complications was observed in our study. In summary, EBL can be used as a rescue method to repair full-thickness perforations and may facilitate complete repair by enabling the approximation of the perforation when initial band ligation is not sufficient to achieve complete closure. EBL may be a feasible and safe alternate technique for the management of acute gastric perforation, especially in cases where closure with endoclips is difficult due to tangential angles, severe belching, or narrow space availability. To evaluate the suitability of EBL for wide clinical use, comparative controlled studies should be conducted.

Abstract

Left supraclavicular lymph node metastasis is a rare presentation of hepatocellular carcinoma (HCC). This phenomenon is easily neglected in the clinic. A 56-year-old man presented with HCC. On examination, a 1cm long left supraclavicular lymph node was palpated. Auxiliary examination indicated a lesion located in the right lobe of the liver. Fine needle aspiration cytology (FNAC) of the enlarged lymph node was performed; however, only necrosis was found. Hepatectomy was performed and HCC was confirmed by Hematoxylin-Eosin staining. However, 14 d after surgery, significantly enlarged left supraclavicular lymph nodes, a new intrahepatic lesion, and pulmonary and mediastinal metastasis appeared. An excisional biopsy of the left supraclavicular lymph node was performed, and its findings confirmed metastatic HCC. The patient's HCC rapidly progressed and he died one month later. It is possible for HCC to metastasize to the left supraclavicular lymph node. Surgeons should always consider an overall physical examination. When left supraclavicular lymphadenopathy of unknown origin is encountered, FNAC should be performed initially. If the results are negative, an excisional biopsy and subsequent Positron emission tomography - computed tomography scanning should be performed. These are very important for making the correct diagnosis and for selecting reasonable therapies.

Misdiagnosis of left supraclavicular lymph node metastasis of hepatocellular carcinoma: A case report. *World J Gastroenterol* 2013; 19(6): 960-963 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i6/960.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i6.960

INTRODUCTION

Hepatocellular carcinoma (HCC) is a common malignancy of the digestive tract. The main route of spread is hematogenous, that is, by invasion of the portal venous system or hepatic venous system[1]. Lymphatic metastases are uncommon. For patients with HCC larger than 5 cm, tumor-related factors predict outcomes and survival[2]. Left supraclavicular lymphadenopathy may be the sign of a metastatic tumor, mostly from lung cancer, gastric cancer, nasopharyngeal cancer and breast cancer[3]. However, HCC rarely metastasizes to the left supraclavicular lymph node and few relevant reports are available in the literature. Here, we present a case of HCC that manifested as left supraclavicular lymphadenopathy and analyze the reasons for the initial misdiagnosis.

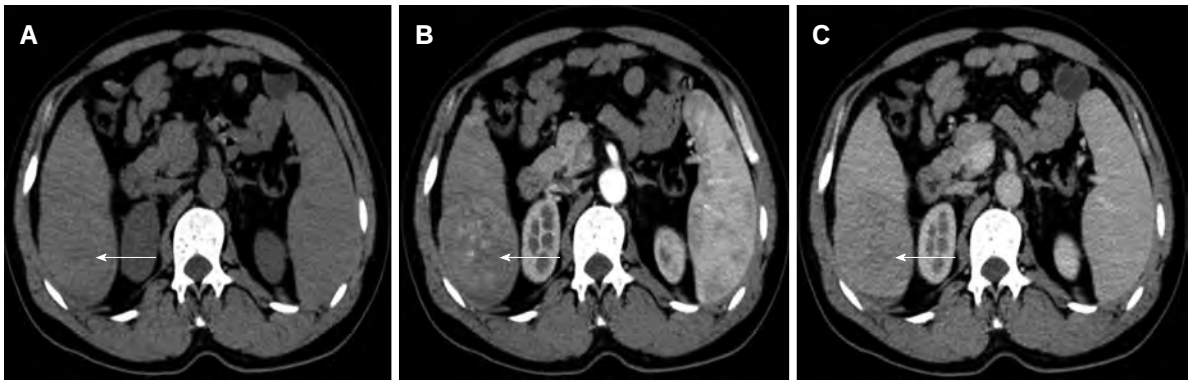

Figure 1 Abdominal computed tomographic images before surgery. A: Non-contrast-enhanced computed tomography scan showing the lesion (arrow) located in the right lobe of the liver; B: The lesion (arrow) showed enhancement during the hepatic arterial phase; C: The lesion (arrow) showed no enhancement during the portal phase.

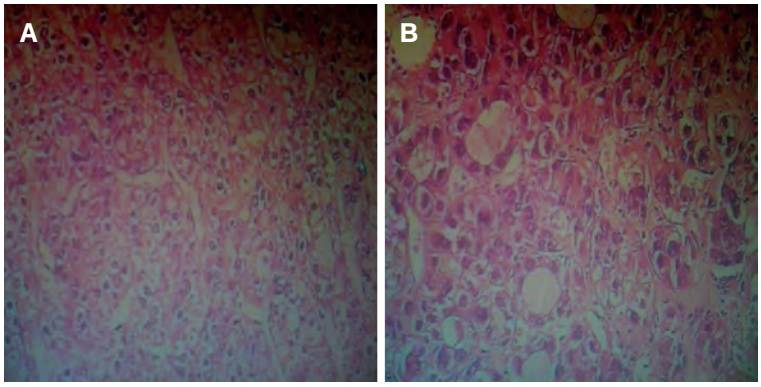

Figure 2 Histopathology of the primary tumor and enlarged left supraclavicular lymph node. A: Cancer cells having oval and single nuclei, with less mitosis and less heteromorphosis in the primary lesion; hematoxylin and eosin (HE) stain, ×400; B: The same changes in cell morphology in left supraclavicular lymph node; HE stain, ×400.

CASE REPORT

A 56-year-old man suffering from HCC was referred to our hospital. His chief complaint was abdominal pain. He had hypertension that was successfully treated with oral medication. On examination, a 1 cm long left supraclavicular lymph node was palpated and it was slightly tender. Examination of the chest did not reveal any signs of bronchospasm. Varicose veins on the thoracic and abdominal wall were not observed. Neurological examination did not demonstrate any deficit. Laboratory examination revealed a platelet count of 89×10^9/L. His alpha-fetoprotein (AFP) level was 695.4 ng/mL (normal < 10.9 ng/mL). Serum hepatitis B surface antigen was positive. HBV DNA quantification was within normal limits. Renal and liver function tests, coagulation function, electronic laryngoscopy and gastroscopy were also normal. Abdominal computed tomography indicated an 8 cm lesion located in the right lobe of the liver (VI segment) (Figure 1A), which was showed significant enhancement during the hepatic arterial phase (Figure 1B), but no enhancement during the portal phase (Figure 1C). The vascular system was normal, and no enlarged lymph nodes were found. No new lesions were found by contrast-enhanced ultrasound. A chest X-ray revealed no lung metastasis. Fine needle aspiration cytology (FNAC) of the enlarged left supraclavicular lymph node showed only necrosis. A hepatectomy was performed without hepatic hilar occlusion. Doppler ultrasound was used to define the tumor margin during the operation. The dissection line was 1 cm outside the tumor margin. Diagnosis was confirmed as HCC with moderate differentiation by Hematoxylin-Eosin staining (Figure 2A), and the resection margin was negative. Initially, the patient showed a good recovery. However, 14 d after surgery, enlarged left supraclavicular lymph nodes were observed to be firm and fixed. To exclude the possibility of malignant lymphoma, an excisional biopsy of the left supraclavicular lymph node was performed, and its findings confirmed metastatic HCC (Figure 2B). Thoracic computed tomography showed significantly enlarged left supraclavicular lymph nodes (Figure 3A), part of which were fused into masses (Figure 3B). Their diameters ranged from 2 cm to 6 cm. Enlarged lymph nodes appeared in mediastinum (Figure 3C) and round nodules were distributed in both lungs (Figure 3D and E). A new lesion was detected in the liver *via* Doppler ultrasound (Figure 3F). Laboratory examination revealed an AFP level > 1050 ng/mL. The patient rapidly declined and died one month later.

DISCUSSION

Distant metastasis of HCC occurs in three main ways: Hematogenous dissemination, lymphatic metastasis and implantation metastasis. Hematogenous dissemination is common, whereas lymphatic metastasis is uncommon. Lymphatic metastasis has been documented in 25.5% of patients at different stages of HCC. Hilar lymph nodes

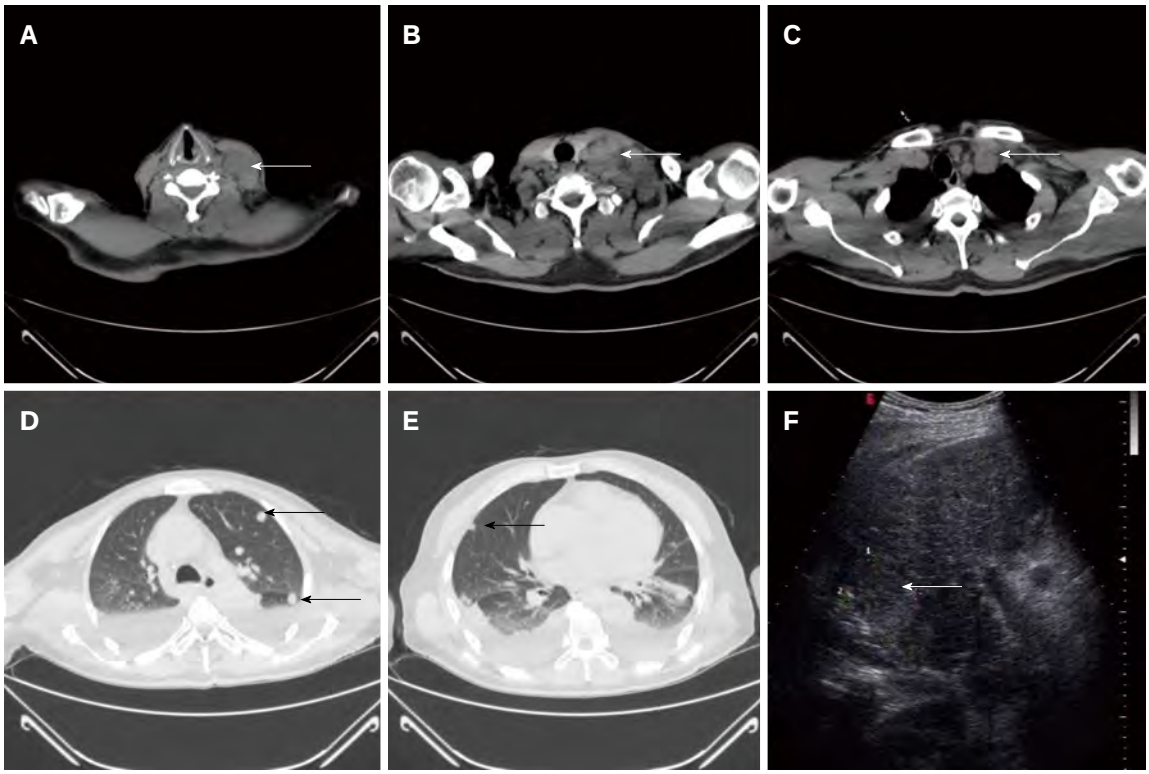

Figure 3 Thoracic computed tomographic and Doppler images after surgery. A: Non-contrast-enhanced computed tomography scan showing enlarged left supraclavicular lymph nodes (arrow), which were easily observed; B: Part of enlarged left supraclavicular lymph nodes (arrow) fused into the mass; C: Enlarged lymph nodes in the mediastinum (arrow) was observed; D and E: Round nodules (arrows) distributed in both lungs; F: A new intrahepatic lesion (arrow) was detected in the non-operating region *via* Doppler ultrasound.

and para-aortic nodes are the major metastatic sites[4]. Nowadays, a hepatectomy has become one of the most popular treatments for HCC, and understanding lymph node metastasis in HCC is indispensable at surgery for improving the patient's prognosis. A previous study revealed that the incidence of lymph node metastasis in operable HCC patients was low, but patients with lymph node metastasis had a poorer prognosis[5].

HCC metastasis to left supraclavicular lymph nodes, although uncommon, does occur, probably *via* the hepatic node and then through the thoracic duct[6]. Early discovery of distant metastasis is important for tumor staging, prognosis judgment and therapy determination in those patients with HCC. However, left supraclavicular lymphadenopathy is not the initial presentation in most conditions; therefore, overall physical examination, especially of the supraclavicular fossa, should not be overlooked. When the left supraclavicular lymph node is involved in the tumor, patients already have advanced disease. In this situation, it is more appropriate for patients to adopt non-operative treatment, including hepatic arterial chemoembolization, molecular targeted therapy, chemotherapy and radiotherapy, instead of surgery. For palpable left supraclavicular lymph nodes, FNAC is not only useful for diagnosing various lesions, but also can help in deciding on appropriate management[7]. However, the diagnosis may sometimes be difficult, with the potential for clinically important diagnostic errors. Therefore, FNAC can also show false negative results for positive lesions[8]. It is presumed that multiple factors can result in misdiagnosis[9], including inadequate specimens, poor smears, inaccurate puncture location, and lack of ancillary studies (cell blocks, immunocytochemistry and electron microscopy)[10].

For a patient with left supraclavicular lymphadenopathy who is highly suspected to have a metastatic tumor, FNAC can be used as a first line diagnostic modality in the evaluation of enlarged lymph nodes. If negative findings are obtained, an excisional biopsy is necessary, which is the gold standard for diagnosis, and Positron emission tomography - computed tomography (PET-CT) scanning should be performed, which allows identification of the primary site and metastatic lesions, including bone and soft tissue metastases, in a single examination.

In our case, an enlarged left supraclavicular lymph node was noticed preoperatively. The negative findings of FNAC and no further examination resulted in incorrect tumor staging. The disease progressed rapidly after surgery. Metastatic HCC was not confirmed until an excisional biopsy was performed.

In summary, we have presented an uncommon case of advanced HCC with left supraclavicular lymph node metastasis. When similar cases are encountered, FNAC should be performed initially. When the results of FNAC, are negative, further tests, such as an excisional biopsy and PET-CT scanning will help to achieve a definitive diagnosis. Such diagnoses will help to prioritize the patient's management protocol.

Abstract

Emergency ABO-incompatible (ABO-I) liver transplantations (LTx) have been performed increasingly to treat severe liver failure. Herein, we report a case of severe hepatic necrosis after ABO-I LTx. A 53-year-old man with blood group O was diagnosed as having severe hepatitis B and acute-on-chronic liver failure, and underwent an emergency liver transplantation implanting a blood-group-B liver from a cardiac-death donor. A routine anti-rejection, anti-infection and anti-virus therapy was given after operation. On post-operative day (POD) 16, the recipient had fever and erythra. Laboratory and radiographic examinations suggested a severe hepatic necrosis of unknown causes. The patient was managed with a 10-d methylprednisolone pulse therapy. He was discharged on POD 35 with stable condition, and no recurrent disease was found during the follow-up.

INTRODUCTION

Acute-on-chronic liver failure (ACLF) has a poor prognosis and a high mortality. It may result in multiple syndromes, including jaundice, coagulopathy, ascites, and even multiple organ dysfunction syndrome induced by precipitating factors (*e.g.*, hepatotropic virus reactivation, infection/sepsis, and hepatotoxic drugs), and secondary compensated liver diseases (*e.g.*, chronic hepatitis and stable liver cirrhosis). ACLF is characterized by acute deterioration of hepatic function, which develops aggressively[1,2]. Given the long-term survival without liver transplantation (LTx) or self-recovery in ACLF subjects is very low, emergency LTx has been introduced as a first-line therapy to significantly improve the short- and long-term survival of the patients[3], in spite of the recently emerging debate on the benefit of artificial liver support to improve the short-term prognosis[4-7].

ABO blood group is considered as a barrier to LTx. Immune rejection, especially antibody-mediated rejection (AMR), is the main cause of graft loss in ABO-incompatible (ABO-I) LTx. Due to the presence of A/B antigen on the surface of vascular endothelium, bile duct epithelium and liver sinusoidal endothelial cells, an ABO-I graft might be attacked by the existing hemagglutinin, causing damage to the blood vessel and bile duct of the graft, characterized by liver parenchymal necrosis and biliary strictures. Other causes of graft loss include vascular or biliary complications, and recurrence of viral hepatitis.

Therapeutic advancement has improved the outcomes of ABO-I LTx and made a long-term survival possible[8-10]. In this report, we present a case of severe hepatic necrosis of unknown reasons after ABO-I LTx. However,

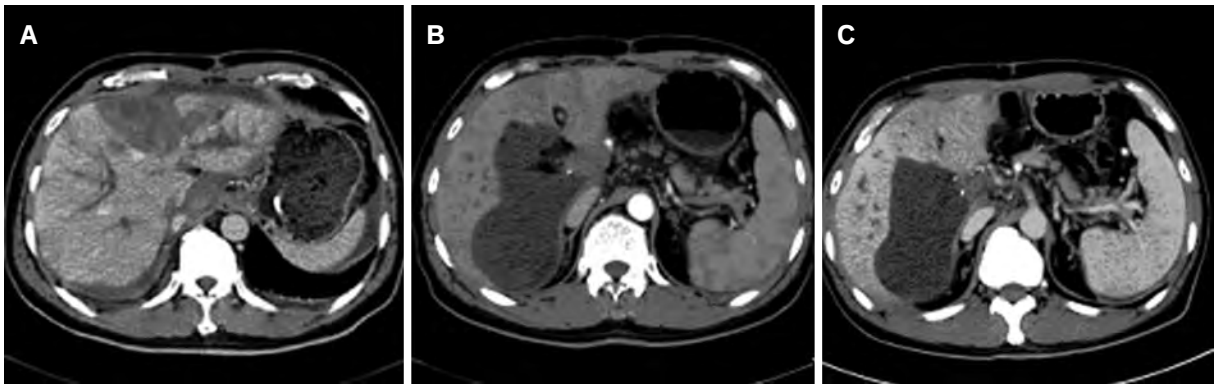

Figure 1 Computed tomography scan and computed tomography angiography images. A: Intrahepatic bile duct expansion and left lobe liver necrosis on post-operative day (POD) 19; B: A low-density cyst (6.1 cm × 13 cm) and a filling defect (2.1 cm × 1.9 cm) at portal area on POD 48; C: Computed tomography (CT) scan and CT angiography on POD 118 showed a smaller low-density cyst (5 cm × 10 cm) and a same-sized filling defect (2.1 cm × 1.9 cm) at portal area on POD 118 compared with earlier findings.

the patient was cured and discharged.

CASE REPORT

A 53-year-old male patient was transferred from the internal medical ward to the liver transplant unit after he was diagnosed as having severe hepatitis B and ACLF, and he then underwent an emergency ABO-I LTx. The liver graft was obtained from a cardiac-death donor with blood group B, which mismatched the recipient's blood group O. Cold ischemia time of the graft was 5 h. The modified piggy orthotopic liver transplantation was performed with a 60-min anhepatic phase and without splenectomy. Massive ascites (about 4000 mL), omentum and gallbladder edema, enlarged tough spleen and severe atrophic and cirrhotic liver were visualized after a right upper incision, confirming the diagnosis of ACLF. The operation was successful. Basiliximab 20 mg and methylprednisolone 1000 mg were administered for immune-induction and hepatitis B immunoglobulin (HB-Ig) 1000 U for prevention of hepatitis B virus (HBV) recurrence before anhepatic phase. A quadruple therapy was given to prevent rejection: (1) Rituximab 100 mg on post-operative day (POD) 1 and Basiliximab 20 mg on POD 4 for induction of immune tolerance; (2) Tacrolimus (Tac) at a dose adjusted according to a blood level of 10-15 ng/mL; (3) Methylprednisolone (MP) at a dose gradually reduced from 1000 mg *qd* to a maintenance of 10 mg *bid*; and (4) Mycophenolatemofetil, 0.5 g, *bid*. Other treatments included administration of antibiotics, antiviral therapy with lamivudine, proton pump inhibitor and liver-protective medication. Primary monitoring examinations included blood routine, liver function, coagulation function, HBV serum virology, serum drug level of Tac, B-ultrasound (B-US) and computed tomography (CT) scan. Pathological examination, lymphocyte subsets analysis and ImmuKnow Assay (T cell function test) results showed no rejection. On POD 16, the patient had fever and erythra. B-US displayed a sub-hepatic, pelvic and thoracic fluid sonolucent area, while CT scan showed abnormal left liver lobe infusion and slight intrahepatic bile duct dilatation (Figure 1). Both alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were elevated (ALT 54.3 U/L and AST 26.5 U/L *vs* ALT 1204.2 U/L and AST 1555.3 U/L at POD 12 and 16, respectively). All these results indicated a severe hepatic necrosis. After a 10-d MP pulse therapy, the patient's symptoms were relieved and aminotransferase was reduced. The patient was discharged on POD 35, and was followed up once a month. The patient is doing well without any recurrent disease.

DISCUSSION

The initial clinical impression of severe hepatic necrosis on POD 16 was rejection. AMR is triggered by alloantibody binding and compliment activation. In the case of ABO-I solid organ transplantation, A, B or AB blood group antigens expressed on graft could be detected by specific natural antibodies. Incompatible blood group antigens activated B cells directly with the help of T cells and resulted in transcription of cytokines and antibodies[11]. AMR can be caused by performed antibodies, anamnestic B-cell responses, early *de novo* and late *de novo* B-cell responses. The strength of isohemagglutinins and natural antibodies in ABO-I recipients can be detected and quantified by multiple methods. Antibody titer is reported to correlate with the survival of recipients. ABO-I living donor liver transplantation with high preoperative and postoperative immunoglobulin (Ig) G and IgM levels sustained bile duct complication and hepatic necrosis, respectively[12], while the safe value of isohemagglutinin titer is $\leqslant$ 1:16 for kidney transplantation[13,14] and $\leqslant$ 1:4 for pediatric heart transplantation[15,16]. In this case, on POD 16, the recipient run a fever, and had poor liver function, and CT scan showed intrahepatic bile duct dilatation and liver necrosis in the left lobe (Figure 1A). But lymphocyte subset analysis indicated a slight increase of T cells and a drop of B cells (CD3+ 77.9%, CD3+CD4+ 49.7%, CD3+CD8+ 23.9%, CD3-CD16+56 14.4% and CD19+ 1%), which was contradictory to AMR with an enhanced B cell function. Meanwhile, ImmuKnow Assay (T cell function tests) before LTx and on POD 34 and

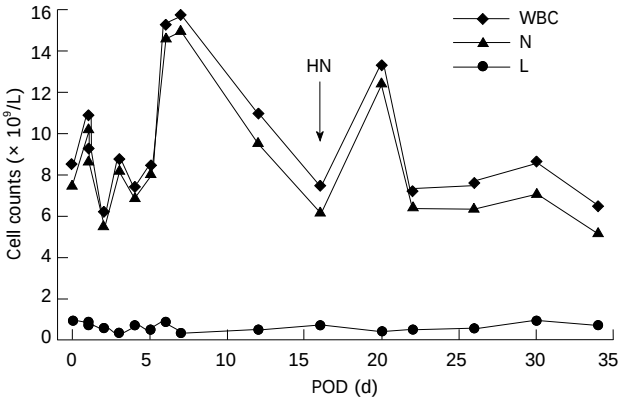

Figure 2 Blood routine test results after ABO-incompatibleliver transplantation. Due to treatment with tacrolimus and methylprednisolone, the number of lymphocyte stayed stable before and after the occurrence of severe hepatic necrosis, while the total number of white blood cell counts was mainly affected by neutrophil changes, which might be induced by non-specific reasons, *e.g.*, phagocytose and absorption of necrotic tissues. LTx: Liver transplantation; POD: Post-operative day; HN: Hepatic necrosis; WBC: White blood cell; L: Lymphocyte; N: Neutrophil.

90 were 156.7 ng/mL, 101.7 ng/mL and 70.3 ng/mL, respectively, suggesting a depression of T cell function after LTx resulting from immunosuppressive therapy[17,18]. The total number of white blood cell was mainly affected by neutrophils (Figure 2). Levels of IgG, IgA, IgM, C3 and C4 were normal or almost normal before LTx and on POD 118 (18.1 g/L, 3.45 g/L, 0.94 g/L, 0.20 g/L and 0.0159 g/L *vs* 7.1 g/L, 1.38 g/L, 0.51 g/L, 1.07 g/L and 0.305 g/L, respectively). Therefore, rejection was not considered as the cause of hepatic necrosis initially.

Another factor leading to severe hepatic necrosis after LTx was recurrent diseases. To prevent recurrent hepatitis B, HB-Ig and/or lamivudine was administered. A 10-year follow-up study in 24 individuals with chronic hepatitis B demonstrated the effectiveness of HB-Ig and/or lamivudine[19]. Nineteen patients were alive after the follow-up duration with well-functioning graft. None of them developed recurrent hepatitis B. Among them, 12 patients received HB-Ig and lamivudine, 3 received lamivudine only, 1 received adefovir, and 3 received no antivirals. HbsAg and HbcAb were both positive in the serum virology test in this patient before LTx. Antiviral treatments included HB-Ig 1000 U injection during LTx and lamivudine *p.o.* after operation. Post-LTx HBV examination results were all negative. Pathological examination of the explanted liver showed classic necrotic changes, without hepatocellular carcinoma. Taken together, there was no recurrent hepatitis or carcinoma till the last follow-up in this case, although CT scan showed dilation of bile duct and inflammation of left liver lobe (Figure 1A), which could result from recurrent viral hepatitis[20].

Blood supply disorders and biliary complications could also lead to hepatic necrosis after LTx. CT scan and CT angiography (CTA) also suggested normal hemodynamics on POD 3, but a low-density cystic echo (6.1 cm × 13 cm) and a filling defect (2.1 cm × 1.9 cm) at the portal area (Figure 1B). However, as shown in Figure 3A, total bilirubin and creatinine levels turned normal on

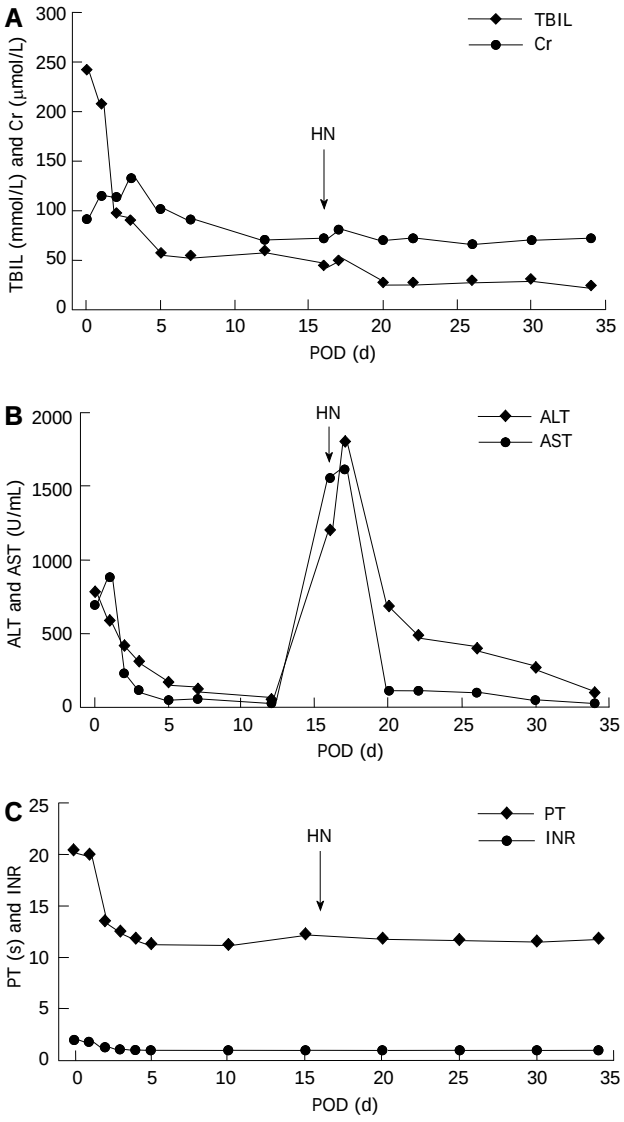

Figure 3 Total bilirubin and creatine, liver function, prothrombin time and international normalized ratio changes after liver transplantation. A: Total bilirubin (TBIL) and creatine (Cr) levels elevated after graft implantation and then decreased in 2 wk. Severe hepatic necrosis resulted in a slight rise, which was reversed by methylprednisolone(MP) pulse therapy; B:Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) dropped significantly within 5 d after liver transplantation (LTx), and then remained in a low level till post-operative day (POD) 16. Severe hepatic necrosis led to a sharp increase of both ALT and AST which were under control after 4-d intravenous drip of 500 mg MP. Dosage of MP was reduced gradually to 40 mg on POD 25; C: Prothrombin time (PT) and international normalized ratio (INR) changes after LTx. Coagulation function became normal within 5 d. HN: Hepatic necrosis.

POD 7 according to Li *et al*[21], and remained stable during hepatic necrosis after LTx. Besides, ALT and AST levels started to fall on POD 20, *i.e.*, 4 d after an MP pulse therapy for severe hepatic necrosis, indicating that liver function had been improved (Figure 3B). As demonstrated in Figure 3C, PT and INR became normal on POD 5[21], and B-US on POD 16 showed no sign of intrahepatic thrombosis and stricture. To prevent postoperative bleeding, hemocoagulase was injected which would not result in prothrombin increase and thrombosis. So we excluded vascular or biliary complications. Low molecular weight

heparin calcium injection was also given till POD 30 for 14 d. However, CT scan and CTA on POD 118 showed a smaller low-density cyst (5 cm × 10 cm) and a same-sized filling defect (2.1 cm × 1.9 cm) at portal area compared with the earlier findings (Figure 1C), which indicated no deterioration of blood supply.

In conclusion, coagulatory, immunologic and hepatic functions after LTx were complicated, and we have not encountered such case before at our center. This patient had severe hepatic necrosis on POD 16, which might be attributed to the rejection with atypical manifestation due to immune suppressive therapy. However, the patient recovered in liver function after treatment with MP, and discharged on POD 34. Till the last follow-up 10 mo after LTx, there were no symptoms or signs indicating bad prognosis. Although the mechanism for hepatic necrosis and recovery of similar cases needs further studies, our experience has provided evidence that emergency ABO-I LTx is an effective treatment option for ACLF, and secondary liver necrosis of unknown causes might be treated by MP.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Treatment of inflammatory bowel disease (IBD) is traditionally based on several drugs, including salicylates, corticosteroids, and antibiotics; in addition, the therapeutic armamentarium has considerably evolved with the advent of newer, effective therapeutic measures (such as the biological agents) that are able to improve in a considerable manner both the clinical and endoscopic variables. Thus, mucosal healing, at least considered from an endoscopic point of view, is today regarded as the ultimate endpoint for treatment of these conditions. However, it is also increasingly clear that endoscopic healing is not necessarily paralleled by histological healing; There are few doubts that the latter should be considered as a true, objective healing and the ultimate goal to reach when treating patients with IBD. Unfortunately, and surprisingly, only a few, incomplete, and somewhat conflicting data exist on this topic, especially because there is still the need to standardize both histological assessment and the severity grading of these disorders; Issues that have not been yet been resolved for clinical practice and therapeutic trials. Hopefully, with the help of an increased awareness on the clinical researchers' side, and the availability of dedicated pathologists on the other side, this matter will be effectively faced and resolved in the near future.

Key words: Crohn's disease; Healing; Histology; Inflammatory bowel diseases; Ulcerative colitis

Villanacci V, Antonelli E, Geboes K, Casella G, Bassotti G. Histological healing in inflammatory bowel disease: A still unfulfilled promise. *World J Gastroenterol* 2013; 19(7): 968-978 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/968.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.968

INTRODUCTION

The medical treatment of inflammatory bowel disease (IBD), including Crohn's disease (CD) and ulcerative colitis (UC), is based on several different approaches relying on aminosalicylates, antibiotics, corticosteroids, and immunomodulatory agents, in addition to the newest biological agents[1]. At present, there is also a strong impulse toward treatment paradigms directed to achieve specific targets, such as a decrease in hospital admissions, the need for surgery, and mucosal healing[2]. The latter point seems to be particularly important, because reaching this goal would also produce a domino effect, resulting in less complications, hospitalization, and surgical procedures related to IBD[3].

However, mucosal healing could be considered as an ambiguous term, because it may be related to both the endoscopic and histological aspects, and at present

a standardized definition for IBD patients does not exist[4]. Actually, by considering mucosal healing in IBD, histological remission is not recommended as primary endpoint for therapeutic trials[5], whereas the suggested endpoint is to obtain a genuine endoscopic healing (defined as absence of friability, blood, erosions, and ulcers in all visualized segments)[5].

Strictly speaking, the optimal treatment goal should be the complete resolution of the inflammatory process, and this is reached only when confirmed by the corresponding histological assessment. In fact, the presence of endoscopic healing does not necessarily imply that this also happens at a microscopic level[6], as also shown (for instance) in celiac disease, in which a gluten-free diet restores the normal endoscopic aspect, but rarely does the microscopic assessment show completely normal features[7].

Moreover, there are objective reasons that probably hamper the use of histological healing as an end point for therapeutic trials. For instance, it has been recently stated that, concerning histopathological assessment of IBD, "…bewildering variations can be observed in the terminology employed to report either individual lesions or diagnostic categories"[8]. In addition, significant differences may exist between UC and CD concerning this aspect. In fact, in UC (in which lesions are usually limited to the mucosa) mucosal/histological healing may represent the ultimate therapeutic goal, whereas in CD (a transmural process) mucosal/histological healing should be achieved as a minimum therapeutic target[9]. Thus, even considering the potentiality of the new therapeutic approaches, the importance of achieving also histological healing might add further value to future trials[10].

A generally accepted definition of histological mucosal healing does however not exist. Histological healing could be defined as "a normal mucosa" or as a disappearance of inflammation, and hence, "a mucosa with limited architectural abnormalities but normally differentiated epithelial cells and no signs of active inflammation (presence of neutrophils) or an increased density of lymphocytes and plasma cells". Usually, histological assessment, when performed during drug trials, has focused mainly on improvement and regression of inflammatory features. The assessment is usually based on the analysis of microscopic sections stained routinely with haematoxylin and eosin. This is a cheap and simple technique which is widely available.

ONLINE SEARCH

We made a comprehensive online search of Medline and the Science Citation Index using the keywords "inflammatory bowel disease", "ulcerative colitis", "Crohn' s disease", "mesalazine", "immunosuppressant", "biologics", "infliximab", "azathioprine", "corticosteroids", "prednisolone", "beclomethasone", "endoscopy", "histologic", "mucosal", and "healing" in various combinations with the Boolean operators "and", "or", and "not". We included only articles that related to human studies, and we performed manual cross referencing, selecting articles published in English between January 1965 and April 2012. A search of non-English language articles and journals older than 1965 was also performed in our library. We excluded letters, and we reviewed abstracts only when the full papers were unavailable.

HISTOPATHOLOGICAL CONSIDERATIONS

An important point is that most literature on this topic originates from only rectal sampling[6]. Thus, it is important that the pathologist receives an adequate number of biopsies correctly oriented from several sites, including the rectum and the terminal ileum. The biopsies should always be accompanied by a report including the age of the patient, clinical information, duration of disease, and type of treatment[11].

The pathological assessment of IBD basically relies on two types of lesions, combined with each other in various ways, represented by architectural abnormalities (that include crypt branching/shortening, decreased crypt density, and irregular mucosal surface) and inflammatory features (transmucosal increase of lamina propria mononuclear cells and the presence of epithelioid granulomas)[6,12].

Moreover, it should be always kept in mind that the histological features of IBD are variable in time, due to both the natural evolution of the disease and the different therapeutic measures. For instance, crypt distortion in UC is usually absent in early stages[13], and the development of architectural abnormalities may take up to 2 mo to appear[14]. Also, decreased crypt density is usually not observed in the first week of the disease, and it is present in about 75% of UC patients with longstanding disease in remission[15]. Again, irregular mucosal surface (present in about 40% of IBD patients) is generally observed in subjects presenting with symptoms for > 2 wk, and it is more common in UC than in CD[6,16,17]. Thus, the absence of mucosal architectural abnormalities in the early phases may present difficulties in the differential diagnosis with acute colitis and during follow-up[18].

Concerning inflammatory features, an increase in cellularity of the lamina propria (especially when localized in its basal third) allows us to distinguish longstanding IBD patients from normal subjects in almost 90% of cases[19]. Another useful clue is an increase of plasma cells, a population increased in IBD rectal samples compared to controls[20]; indeed, blind evaluation of IBD and control specimens has revealed that > 50% of patients displayed basal plasmacytosis[17]. However, it must always kept in mind that inflammatory features also are not constant over time; for instance, a prospective study has demonstrated that focal basal plasmacytosis was found in 40% of IBD patients with symptoms for < 2 wk, but disappeared after 1 year follow-up in half of those without relapse[13]. Granulomas, a distinctive feature of CD, are not constantly present, and are more frequent in

Table 1 Score for histological assessment of ulcerative colitis

No significant inflammation	Mucosa free from active inflammation; no erosions or crypt abscesses; surface and glandular epithelial cells intact; general architecture of the mucosa often disturbed; edema and fibrosis of the lamina propria with occasional foci of lymphocytes
Mild to moderate inflammation	Epithelium usually intact; Glandular tubules irregularly arranged and often showing increased proliferative activity; Edema, vascular congestion, and interstitial hemorrhage presented in the lamina propria; Lymphocytes, plasma cells, and eosinophils increased in number, neutrophils often present, but less numerous than in the more severely affected specimens; Variation in intensity of inflammatory change in individual specimens giving a range of appearances from relatively quiescent to active inflammation
Severe inflammation	Mucosal surface often irregular due to edema, interstitial, hemorrhage, or inflammatory exudate in the lamina, propria; Small epithelial breaches common, sometimes with frank erosions and purulent exudate; Neutrophils and eosinophils passing through the damaged epithelium; Areas of flattened and cuboidal cells especially found near erosions; Mucosa showing heavy interstitial infiltration by lymphocytes, plasma cells, eosinophils and neutrophils; Glandular abnormalities (neutrophilic invasion of the tubules, epithelial focal degeneration and shedding of necrotic/viable cells into the glandular lumina; crypt abscesses (neutrophils, eosinophils, and epithelial debris); Sometimes, breaking down of the wall of the tubule with inflammatory exudate passing from the tubule into the lamina propria

Adapted from Truelove *et al*[23], 1956.

children and in the early phases of the disease[6,21].

It must also be stressed that in CD, being a transmural disease, mucosal healing may not be sufficient even though the mucosa may return to almost normal after treatment. Deeply situated lesions may persist, and endoscopy with biopsy can however not assess the deeper layers of the digestive tract[22].

An important point to be addressed is that, to date, there is no standardized histological scoring system for the assessment of disease activity in IBD, although many scores have been proposed. A scoring system was firstly introduced many years ago for UC[23], and in subsequent years many other histological scores have been proposed, all based on routine haematoxylin-eosin (HE) staining. As a result of the more homogeneous distribution of the lesions, most of these scores have been described in UC, many during the 1980s[24-28], a few in the 1990s[29-32], and only two more recently[33,34], although some proposal for CD also exist[35-37]. However, even recent consensus conferences on CD and UC have not included a formal histological score for the pathological evaluation of these patients[38-41].

This is partly due to the possible impact of sampling error, to the limits of routine HE staining, and to the existence of some poorly known variables. Histologically, disease activity is usually based upon the combination of the presence of neutrophils and epithelial damage, because neutrophils can be recognized reliably and it is known that they release molecules that are capable of damaging the tissue. Other cells, however, might also have deleterious effects. The activity status of cells such as macrophages and lymphocytes can however not be assessed on HE-stained sections. The influence of eosinophils is still unclear. Elevated levels of eosinophils have been observed in colonic biopsy samples from UC patients, and increased numbers of these cells and eosinophil-derived granular proteins (major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil derived neurotoxin) have been shown to correlate with morphological changes in the gastrointestinal tract, disease severity, and gastrointestinal dysfunction[42,43].

Finally, the natural evolution of the disease and its histological features are not well known. Inflammatory features may however decrease over time and the distribution pattern may change[44].

HISTOLOGICAL HEALING IN UC

Corticosteroids

These agents were introduced early in the therapeutic armamentarium of IBD, and are still commonly used in the acute phases; moreover, their ability to induce at least macroscopic mucosal healing at endoscopy is well recognized[45]. Concerning histological healing, only a few studies are available in literature, and none recent.

The first study to tackle this topic in 40 patients with active UC investigated the effect of 1 wk treatment with rectally administered hydrocortisone hemisuccinate sodium[46]. Histological variables were analyzed by a previously described scoring system[23] (Table 1), and showed significant improvement compared to baseline and to placebo in patients treated with steroids, in whom there was a 50% decrease in severe grading and 64% in moderate grading. Moreover, 55% shifted toward mild grading after treatment. However, no normalization of histological variables was reported in this study. Interestingly, the authors of the histological scoring system stated that "…this system of grading depends to a large extent on subjective judgments"[23].

In a study of 215 patients with UC, cell counts revealed that acute inflammation as indicated by neutrophils was decreased most notably following treatment with prednisone (and/or 6-mercaptopurine). Chronic inflammation as indicated by the presence of plasma cells was also reduced after prednisone and equally after 6-mercaptopurine and salicylazosulfapyridine. The authors further demonstrated an increase of epithelial goblet cells and lamina propria macrophages during healing[47]. Although these results are particularly interesting, the method used is time consuming and probably difficult to apply routinely.

Another 2-wk study compared the effects of aqueous hydrocortisone enema and a suspension of hydrocortisone in an inert foam base in 30 UC patients with proctosigmoiditis[48]. Histological assessment was carried

Table 2 Modified scoring system for histological assessment of ulcerative colitis

Inflammation grade	Score	Intensity	Histological criteria
Active inflammation	0	Normal	Neutrophils not present in crypt or surface epithelium and no exudate, erosion or ulceration
	1	Low grade	Neutrophils present transmigrating through the crypt epithelium or within crypt lumina in < 20% of crypts; no erosions or ulcers
	2	Moderate	Neutrophilic infiltration in > 20% of crypts or presence of erosions
	3	High grade	Presence of ulcers
Chronic inflammation	0	No increase	Normal number of chronic inflammatory cells present primarily in the superficial lamina propria
	1	Moderate	Moderate number of mononuclear cells Aggregated between crypts at the base of the lamina propria
	2	Severe	Marked increase in chronic inflammation shown by sheets of chronic cells
Crypt distortion	0	None	Crypts had normal outlines with only artifactual irregularities
	1	Mild	Scattered or rare crypts showing irregular (bent, forked) outline
	2	Moderate	Approximately 25%-50% of crypts with an irregular outline
	3	Severe	> 50% of crypts with an irregular outline

Adapted from Hanauer *et al*[50], 1998.

out by means of an active inflammation score (0-3 for each of the following three characteristics: polymorph infiltration, mucus depletion, and superficial epithelial degeneration, allocating a score of 0-9 to each biopsy). In the enema group there was a significant ($P < 0.05$) improvement in active inflammation score (from 4.4 to 2.5) compared to baseline, but this was not observed in the foam group (inflammation score 5.2 *vs* 4.9). However, this apparent superiority for enema treatment was not confirmed when the two treatments were directly compared.

Lee *et al*[49] subsequently compared the effect of mesalazine foam enema (2 g) and prednisolone foam enema (20 mg) in 295 patients with relapsing distal UC. After 4 wk treatment, histological remission (score 0), using the above scoring system[48] was obtained in 27% of patients in the mesalazine group and 21% of patients in the prednisolone group.

In another study, 233 patients with active distal UC/proctitis were randomized to either a placebo enema or budesonide enema at a dose of 0.5 mg/100 mL, 2.0 mg/100 mL, or 8.0 mg/100 mL[50]. Biopsy specimens were histologically graded for active inflammation, chronic inflammation, and crypt distortion, and graded according to a modification of the Truelove and Richards scoring system[23] (Table 2). After treatment, total histopathological score (defined as the sum of the three above components) significantly improved in the 2.0 and 8.0 mg groups, compared to placebo, whereas no differences were found for the 0.5 mg dose. However, remission rate in this study did not include histological remission.

A study conducted on 17 patients with severe UC compared the effect on unfractionated heparin and corticosteroids, and demonstrated an improvement of histopathological grading (that, however, was not formally described), not significantly different between the two treatments (63% in the heparin group and 50% in those treated with steroids) at the end of the study[51].

Rizzello *et al*[52] have evaluated the effect of oral 5-aminosalicylic acid (5-ASA) (3.2 g/d) compared to oral beclometasone dipropionate (5 mg/d) and to placebo in 118 patients with extensive or left-sided mild to moderate UC. After 4 wk of treatment, the histological score[23] was significantly improved compared to baseline, but no differences between treatment groups were observed and no specific histological description was given.

In a more recent study, two budesonide formulations (foam and enema) were compared in 449 patients with distal UC/proctitis[53]. Histological assessment was conducted according to the score proposed by Riley *et al*[29], which takes into account six features [acute inflammatory cell infiltrate (neutrophils in the lamina propria), crypt abscesses, mucin depletion, surface epithelial integrity, chronic inflammatory cell infiltrate (round cells in the lamina propria), and crypt architectural irregularities], each graded on a 4-point scale (0 = none; 1 = mild; 2 = moderate; 3 = severe). At the end of treatment, a similar histological improvement was obtained in both groups (51% foam, 57% enema). Again, no specific histological description was given.

Overall, by considering the above studies, although steroid treatment seems to improve histological abnormalities in UC patients, true remission rates are probably quite low, and no more than 30%.

Salicylates

Overall, not many studies are available in the literature that have assessed the effect of these drugs on histological healing in UC, and it should be stressed that these studies included different subtypes of patients and used different pharmacological formulations and modes of administration. The study by Sommers *et al*[47] mentioned earlier did show some beneficial effects on inflammatory cell cell counts in the lamina propria.

The first study to assess this topic was that of Rao *et al*[54], who compared the effects of olsalazine (2 g/d) and sulfasalazine (3 g/d) in 37 patients with mild to moderate active distal UC. The degree of inflammation in rectal biopsies was graded as absent (without inflammation), mild (chronic glandular damage with definite increase in inflammatory cells), moderate (mild inflam-

mation plus small foci of ulceration), or severe (moderate inflammation in the presence of crypt abscesses and widespread ulceration). In both groups, a similar histological improvement (44% for olsalazine and 46% for sulfasalazine) was seen after 1 mo, even though this was not as impressive as the improvement of endoscopic appearance or clinical response. However, no histological details were given in this study, apart from generic statements (improved, unchanged, worsened), nor it was stated whether histological remission was achieved.

In a 12-wk multicenter double-blind parallel group study, the effects of balsalazide (6.75 g/d) or sulfasalazine (3 g/d) were compared in 57 UC patients, stratified for disease severity; topical and/or oral steroids were administered if clinically needed[55]. Histological assessment (only graded as 0, normal; 1, mild UC; 2, moderate UC; 3, severe UC) showed a similar improvement in both groups at the end of treatment. No histological details were given.

The same authors carried out another study with the same drug regimens (but without concomitant use of steroids) in 50 patients with mild to moderate UC[56]. Pathological assessment was used to identify patients in whom clinical remission was also associated with histological remission. Rectal biopsies, obtained at baseline and after 8 wk) were graded on a 4-point scale (0, normal; 1, minimal inflammation but not active disease; 2, moderate inflammation; 3, severe inflammation); all patients included in the study had at least mild inflammation at baseline, with 58% displaying severe inflammation. After treatment, histological grades improvement was observed in both groups, but only 34% of patients were free from inflammation. No other histological details were given.

In another study, 264 patients with distal active UC were treated with 5-ASA foam or liquid enema[57]. Histological assessment (no details were given), performed after 4 wk, showed similar improvement in both groups (46% generically defined remission in the foam group and 50% in the enema group).

An 8-wk double-blind multicenter trial compared three doses of 5-ASA (1.5, 3 and 4.5 g/d) in 321 patients with active UC[58]. Colonic biopsies were obtained at baseline and at the end of the study, and were assessed according to a previously described scoring system[29], considering histological improvement as reduction of at least one point of the histological activity index. At the end of study period, histological improvement was documented in 42% patients in the 1.5 g group, 65% of the 3 g group, and 63% of the 4.5 g group. Once again, no details on histological assessment were given.

Other authors compared the effects of slow-release (MMx) mesalazine with topical 5-ASA in 79 patients with active left-side UC[59]. The tissue inflammatory response was evaluated according a previously described score[26], and graded as follows: grade 1, normal mucosa; grade 2, enhanced glands with intraepithelial granulocytes. In the stroma, enhancement beyond normal of lymphocytes, plasma cells, or eosinophils (slight inflammation); grade 3, goblet cells depletion, loss of tubular parallelism, reduced mucin production in some glands, intraepithelial granulocytes, marked increase of inflammatory cells in the stroma (intermediate inflammation); grade 4, marked gland and mucosal atrophy, evident crypt abscesses and pus on the surface, massive increase of acute inflammatory cells and follicle formation in deeper cell layers (severe inflammation); and grade 5, ulceration with pus, gland and mucosal atrophy, crypt abscesses, extensive stromal inflammation, and deep follicles (fulminant inflammation). Histological remission (defined generically according to the above score) was obtained in only 15% patients of the MMx group and in 8.0% of those receiving enemas. No other histological details were given.

A more recent study compared two different scheduling dosages (3 g *oid* or 1 g *tid*) of mesalazine granules in 380 UC patients[60]. Biopsy samples were obtained at the start and the end of the trial, and were scored according to previously published criteria[29], with the total histological index based on the more severely affected colonic segment. Histological remission (grade 0), observed in 35% patients in the oid group and in 41% of the tid group, did not show significant differences between the two regimens.

Overall, the available evidence for salicylates in histological healing of UC patients suggests that an improvement may be obtained in 30%-60% of patients (obviously depending on the formulation and the dose scheduling), but the actual healing rate is lower (10%-30%).

Immunomodulators

There are still only a few data on histological healing with immunomodulatory agents. A study conducted in 32 patients with refractory active UC[61] showed that after 6 mo azathioprine treatment, 78% of patients in remission were free of histological inflammation graded according to previously described criteria[23]. However, after a median of 4 years follow-up, histological relapse was found in almost 90% of these patients. No histological details were given.

Another study compared the effects of intravenous cyclosporine A to those of methylprednisolone in 30 patients with severe UC[62]. Histological assessment, carried out according to a previously described scoring system[33] (Table 3), was done at baseline, and after 7 and 30 d therapy; after 1 wk no effects were seen, and only after 1 mo therapy was there a significant decrease in inflammatory cells, and severity of epithelial damage was similarly observed in both groups, although only small changes in the architectural mucosal disturbances were seen. Overall, it seems however that these agents have a beneficial effect on mucosal histology.

Biological agents

Concerning biological therapy, although anti-tumor necrosis factor (TNF)-α therapy can lead to endoscopically assessed mucosal healing in patients with UC[63,64],

Table 3 Histological scoring system for ulcerative colitis and Crohn's disease

Ulcerative colitis	
Grade 0	Structural (architectural change)
0	No abnormality
0.1	Mild abnormality
0.2	Mild or moderate diffuse or multifocal abnormalities
0.3	Severe diffuse or multifocal abnormalities
Grade 1	Chronic inflammatory infiltrate
1	No increase
1.1	Mild but unequivocal increase
1.2	Moderate increase
1.3	Marked increase
Grade 2	Lamina propria neutrophils and eosinophils
2A. Eosinophils	
2A.0	No increase
2A.1	Mild but unequivocal increase
2A.2	Moderate increase
2A.3	Marked increase
2B. Neutrophils	
2B.0	None
2B.1	Mild but unequivocal increase
2B.2	Moderate increase
2B.3	Marked increase
Grade 3	Neutrophils in epithelium
3	None
3.1	< 5% crypt involved
3.2	< 50% crypt involved
3.3	> 50% crypt involved
Grade 4	Crypt destruction
4	None
4.1	Probable-local excess of neutrophils in part of crypt
4.2	Probable-marked attenuation
4.3	Unequivocal crypt destruction
Grade 5	Erosion or ulceration
5	No erosion, ulceration, or granulation tissue
5.1	Recovering epithelium plus adjacent inflammation
5.2	Probable erosion-focally stripped
5.3	Unequivocal erosion
5.4	Ulcer or granulation tissue
Crohn's disease	
Epithelial damage	
0	Normal
1	Focal pathology
2	Extensive pathology
Architectural changes	
0	Normal
1	Moderately disturbed (< 50%)
2	Severely disturbed (> 50%)
Infiltration of mononuclear cells in the lamina propria	
0	Normal
1	Moderate increase
2	Severe increase
Infiltration of polymorphonuclear cells in the lamina propria	
0	Normal
1	Moderate increase
2	Severe increase
Polymorphonuclear cells in the epithelium	
1	In surface epithelium
2	Cryptitis
3	Crypt abscess
Presence of erosions and/or ulcers	
0	No
1	Yes
Presence of granuloma	
0	No
1	Yes
No. of biopsy specimens affected	
0	None (0 of 6)
1	< 33% (1 or 2 of 6)
2	33%-66% (3 or 4 of 6)
3	> 66% (5 or 6 of 6)

Each topic scored independently. Moderate increase, up to twice the number of cells that can normally be expected; severe increase, more than twice the normal number of cells.

histological data are still scarce. A 10-wk study conducted on nine moderate to severe UC patients[65], using a score that included polymorphonuclear infiltration of the epithelium and lamina propria, crypt abscesses, loss of glandular parallelism, crypt shortening and/or ramification, mucus epithelial depletion, involvement of muscularis mucosae and/or submucosa. Each histological variable was scored from 0 (normal) to 1 (mild), 2 (moderate) and 3 (severe). In addition, the total number of neutrophils, lymphocytes, and plasma cells in the lamina propria was counted in five high-power fields. At week 10, histological score significantly decreased only in responders (67% of patients), but normal architecture was observed only in 33% of these patients. The histological improvement was mainly due to a decrease in neutrophils associated with restoration of normal crypt architecture and mucus content in epithelial cells. No significant reduction of mononuclear cell infiltration was observed in responders and non-responders.

Another study took into account the ultrastructural features of the colon in seven patients with UC refractory to standard treatment, before and after 2 wk treatment with infliximab[66]. Before treatment, severe alterations of the epithelium were present, such as microvilli depletion, shattering of epithelial junctions, cytoplasmic vacuolization, dilatation of the endoplasmic reticulum, pycnotic nuclei, altered structure of mitochondria and Golgi complexes, in addition to rarefaction of the goblet cells with abnormal mucus formation and secretion. The chorion showed structural alteration of component cells, obstructed capillaries, erythrocyte extravasation, and many plasmocytes and neutrophils. After infliximab, there was improvement in morphology and function of the epithelial organelles, rich mucus secretion, and recovery of the chorionic components.

Miscellaneous

D'Ovidio *et al*[67] have evaluated the effects of granulocyte-monocyte apheresis in 12 patients with mild to moderate UC refractory to therapy/steroid dependent. After 6 wk, complete histological remission, defined as grade 1 according to the score of Florén *et al*[26], was obtained in six (50%) patients, and histological improvement in five (42%) patients. Once again, no further details on histology were given. In general, it seems that various drugs can lead to microscopic healing and a normal mucosa in a minority of patients (with a maximum of approximately 30%).

HISTOLOGICAL HEALING IN CD

Corticosteroids

These agents are frequently employed for treatment of disease flares; however, clinical and endoscopic data demonstrate that mucosal healing in CD is unlikely (less than one third of treated patients) after steroid treatment[68]. Moreover, there have been few studies evaluating histological healing in CD after steroid treatment.

In a study comparing 1 year treatment with budeso-

nide or azathioprine in 77 CD patients, histological assessment was carried out with a previously developed score[37] (Table 3). At the end of the study, the histological score fell significantly versus baseline only in the azathioprine group and was significantly lower than in the budesonide group at the end of the study[69]. This improvement was observed for all acute parameters (epithelial damage, acute lamina propria inflammatory cell infiltration, erosions and/or ulcers) irrespective of disease location, whereas glandular architecture and the presence (but not the degree) of chronic inflammation were not influenced by azathioprine treatment.

A 2-wk regimen of 20 mg oral prednisone showed, in individual biopsies of 30 CD patients undergoing surveillance colonoscopy, a decrease in the overall histological activity (assessed by a previously reported scoring system[33]) compared to placebo, whereas no significant differences were found with respect to the overall severity of inflammation[70]. No other details on histological assessment were given.

Immunomodulators

These agent represent to date the cornerstone of treatment in CD, thus researchers' interest has given rise to a few studies aimed at evaluating their effects on histological healing as well.

Azathioprine: A first study assessed the effect of 6 mo of therapy in 19 patients with severe postoperative recurrent CD[71]. Histological evaluation was done in seven patients (four with complete mucosal healing and three with near-complete healing at endoscopy). Only in patients with complete healing did comparison of the biopsy specimens taken before and after azathioprine show persistent mucosal architectural changes with complete disappearance of the inflammatory infiltrate. The same authors then reported pre/post-therapy data on 20 CD patients with colitis-ileocolitis taking azathioprine for at least 9 mo[72], using a histological disease severity score[37]. A decrease in histological score paralleled endoscopic healing, even though it was not as complete as shown by endoscopy. In patients with endoscopic complete healing, the colon showed a global decrease in histological score from 10 to 3 and inflammatory score from 5 to 2; in the ileum, global histological score decreased from 7 to 2 and inflammatory score decreased from 2 to 0. No significant changes were documented in patients without endoscopic healing while taking azathioprine. The study of Mantzaris *et al*[69], comparing azathioprine with budesonide, has been discussed above.

Methotrexate: Methotrexate has been even less frequently investigated in this setting. A pilot study evaluated the effects of adding this agent to standard treatment (steroids, mesalazine) in 14 CD patients with refractory disease[73]; four patients (28.5%) were reported to have normal histology at 12 wk. Another study compared the effects of methotrexate with those of azathioprine and infliximab in 40 patients with CD[74]. After 3 mo treatment, the scoring of microscopic activity[37] was similar in the three groups. No further histological data or data on histological healing were given.

Biological agents

A few studies have been carried out on biological agents. D'Haens *et al*[75] investigated histological healing in 30 CD patients treated with infliximab in a placebo-controlled trial. After 4 wk intravenous administration of 5, 10 or 20 mg/kg infliximab or placebo as a single infusion, inflammatory infiltrate disappeared only in infliximab-treated patients but architectural changes persisted in most of them. Another study from the same group evaluated the effects of a single infusion of infliximab in 15 patients with steroid-refractory CD[76]. Histological activity scores, assessed 4 wk after infusion showed, compared to placebo, a significant decrease mainly due to the reduction of inflammatory activity. Immunohistochemical assessment also revealed a decrease in inflammatory features due to global reduction of $CD4^+$ and $CD8^+$ T lymphocytes and $CD68^+$ mononuclear cells.

A follow-up study conducted in CD patients evaluated histological improvement by a previously described scoring system[37] after 54 wk of treatment with infliximab, and showed that histological mucosal healing was associated with a consistent decrease in the expression of inflammatory markers[77]. The use of etanercept (another anti-TNF-α agent) in 10 patients with refractory active CD did not result in any significant histological improvement after 2 wk of therapy[78].

Miscellaneous

Yamamoto *et al*[79] evaluated 28 patients with active CD, treated with an elemental diet for 4 wk. Histology was evaluated by a previously described scoring system[80], taking into consideration enterocyte appearance, extent of crypt inflammation, and the intensity of mononuclear and neutrophilic lamina propria inflammation. Each feature was given a score of 0-3, depending on the severity of the abnormality. The scores were added, and a total score was calculated. Grade 0 (no inflammation) was assigned a total score of 0 or 1, grade 1 (mild) was scored 2-4, grade 2 (moderate) was scored 5-8, and grade 3 (severe) was scored 9-12. Histological healing was defined as grade 0, and histological improvement (including healing) was defined as a decrease of at least 1 grade. At the end of treatment, histological healing and improvement rates were 19% and 54% in the terminal ileum and 20% and 55% in the large bowel, respectively.

A retrospective study carried out in 39 patients with refractory severe colonic CD evaluated the effect of anti-*Mycobacterium avium* ss *paratuberculosis* therapy[81]. Histological acute and chronic ileitis or colitis were recorded as the most severe inflammation found in available biopsies, and were generically reported by a pathologist as ranging from inactive chronic inflammation to mild, moderate, and severe active inflammation. After an aver-

age 3 years of therapy, 15/39 (38.5%) patients showed a marked reduction of acute and chronic inflammatory infiltrates; however, only in six (15.4%) patients was normalization of histological variables observed. No other histological variables or details were given.

HISTOLOGICAL HEALING IN IBD: WHERE ARE WE, AND WHERE ARE WE GOING?

Although mucosal healing has been associated with positive outcomes in IBD, most of the supporting data are retrospective and largely based on endoscopic assessment; in addition, it is not clear whether complete mucosal healing produces better outcomes than partial healing[82]. It has been stated that, in clinical practice, evaluation of mucosal healing (again, by an endoscopic point of view) should be considered in patients with persistent symptoms despite adequate therapy and when treatment discontinuation is being considered[83].

However, it must be stressed that histological assessment of mucosal healing, the only way to establish in an objective manner that the mucosa has reverted to a normal state, is at present not recommended as a primary end point for therapeutic trials because of the lack of a standardized approach[5]. Thus, it is unknown whether patients who achieve and maintain deep remission may stop treatment without having further/future problems[84].

As reported above, true histological healing may be grossly obtained in only about 30% of treated patients; this may justify the high (20%-40%) loss of response to even newer therapeutic approaches[85]. A recent study has shown that adding histological and mucosal gene panel assessment may predict the lack of response to infliximab (directed against TNF-α) treatment in patients with UC or Crohn's colitis, whereas no such predictive gene set could be identified for ileal disease[86,87].

Therefore, adding histological healing as an endpoint, at least in clinical trials, would substantially improve the evaluation of the actual effectiveness of a given treatment. Histological assessment is cheap and widely available. The features of disease activity are known. They include the presence of neutrophils in the lamina propria and the epithelium, epithelial cell damage (loss of cells, mucin depletion, cryptitis, crypt abscesses, erosion), and an increase in lymphocytes and plasma cells. Some of these features such as the presence of neutrophils can reliably be evaluated with good interobserver agreement. In addition, histology could help the management of the patient. Some histological variables are indeed associated with relapse. They include persistence of neutrophils, basal plasmacytosis and persistence of eosinophils in the lamina propria[29,88,89]. Furthermore, microscopic activity may be related to the development of dysplasia[90].

We realize that adding data on histological healing to investigations and trials on IBD patients might be a relatively difficult goal to achieve, and that such an approach would increase the investigators' burden. Furthermore, there are several unresolved issues. It has been shown that UC may become a discontinuous inflammatory process during its natural course or following medical treatment. This means that several biopsies would be needed for an adequate microscopic evaluation; the optimal number of samples has however not yet been determined. Although routine HE staining is a good tool for identification of neutrophils, epithelial damage and even eosinophils as markers of active disease, it is less appropriate for the evaluation of lymphocytes. The presence of lymphocytes can be determined adequately but the activation status is beyond the scope of routine histology and requires immunohistochemical staining. Yet, the application of this technique and the markers needed are not yet well determined.

CONCLUSION

In conclusion, it appears to us that histological healing should be considered as an end point in the treatment of IBD patients, especially for UC. Therefore, additional studies looking for optimal sampling, standardizing scores and features should be performed.

Abstract

To clarify the trend in colorectal cancer mortality in Asian countries. We analyzed the colorectal cancer mortality in four Asian countries using the World Health Organization mortality database and the Korea National Statistics Office database. The annual age-standardized rates and truncated rated for the three age groups (30-49, 50-69 and ⩾ 70 years) for Hong Kong of China (1969-2009), Japan (1955-2009), South Korea (1985-2006), and Singapore (1966-2009) were estimated. A joinpoint regression model was used to detect significant trends in mortality rates. Colorectal cancer mortality in men started to decrease in 1992 in Japan followed by Singapore and Hong Kong of China in 1995. The mortality rates in women stared to decrease in 1980 in Singapore, followed by Hong Kong of China and Japan in 1996. In all countries and both genders, except for women in Singapore, the decrease in mortality began in the younger age groups. The colorectal cancer mortality in the four studied Asian countries has started to decrease, and the decrease occurred first in the younger age groups.

INTRODUCTION

Colorectal cancer is responsible for 8% of all cancer deaths worldwide, with an estimated 608 000 deaths annually, and it is ranked as the fourth most common cause of death from cancer[1]. It has been estimated that the numbers of deaths due to colorectal cancer will reach approximately 376 700 by 2020 in Asia[1].

A decline in colorectal cancer mortality has been observed in most western and northern European countries[2] and the United States[3]. Among Asian countries, the mortality started to decrease in the early 1990s in Japan[4,5]. The trends in colorectal mortality differ by geographic region, sex, and age group[6]. In this review, we analyzed the trends in colorectal cancer mortality in 4 Asian countries stratified by sex and age groups.

DATA ANALYSIS

Colorectal cancer mortality data were extracted from the World Health Organization (WHO) mortality data-

base[7]. The 3 countries or regions with data available for the longest period were Japan (since 1955), Singapore (since 1966) and Hong Kong of China (since 1969) were included in the analysis. In addition, Korean data were available from the WHO mortality database for 1985 to 2006 and from the Korea National Statistics Office for 2007 to 2010 and were included in the study[8]. The annual age-standardized rates (ASR) and the truncated rates for the 3 age groups (30-49, 50-69 and ⩾ 70 years) were estimated using the world standard population.

The trends in colorectal cancer mortality were tested using joinpoint regression models, using Joinpoint software version 3.5.3. The software was developed by the Surveillance Research Program of the United States National Cancer Institute and is based on the Poisson assumption[9]. A maximum of 3 joinpoints was allowed, and the default settings were used.

Table 1 shows the age-adjusted mortality rates for colorectal cancer in the 4 countries. Singapore showed the highest female mortality rates of the 4 countries from 1966 to 2009. Singapore also showed the highest male mortality during the same period, except for 2005, when males in Hong Kong of China showed a slightly higher rate. Korean men and women showed the lowest rates among the 4 countries.

Table 2 shows the results for the joinpoint regression analyses. Colorectal cancer mortality in men started to decrease in 1992 in Japan, followed by Singapore and Hong Kong of China in 1995. The mortality rates in women stared to decrease in 1980 in Singapore, followed by Hong Kong of China and Japan in 1996. In South Korea, the mortality rates plateaued in 2002 in men and started to decrease in 2004 in women.

In men, the decline in mortality started for younger age groups first. In Japan, mortality started to decrease in 1977 for the 30-49 years age group, in 1995 for the 50-69 years age group, and in 1998 for the 70 and older age group (Table 2). A similar trend was observed for Hong Kong of China, Singapore and South Korea. Similarly, a significant decrease in APC was first observed for younger age groups in Hong Kong of China, Japan and South Korea in women. For example, in Hong Kong of China, female mortality began to decrease in 1992 for the 30-49 years age group, in 1994 for the 50-69 years age group, and in 2002 for the 70 years and older age group. Whereas, for women in Singapore, the decrease began in 1980 in the 50-69 years age group, which was 4 years earlier than among the 30-49 years age group (Table 2). Figure 1 shows the trends in colorectal cancer mortality rates for the 3 age groups in Hong Kong of China, Japan, South Korea, and Singapore between 1955 and 2010.

DISCUSSION

Colorectal cancer mortality in the European Union has declined since the early 1980s. These decreases were observed in most western and northern European countries, whereas a persistent excess in mortality was observed in Hungary and the Czech Republic[6]. In the United States, colorectal cancer mortality rates in white men began to decline in 1978[10]. The APC for white men was -0.6% between 1973 and 1978 and -2.0% in 1986[10]. The decline in the mortality of white women was more rapid, with an APC of -2.1% between 1973 and 1997[10].

In Asia, a reduction in colorectal cancer mortality has been observed for economically advanced regions, such as Japan, Hong Kong of China, Singapore, and more recently, in South Korea. Notably, the decline started in younger age groups. A more favorable mortality trend and a consequent widening of the survival gap between the elderly and middle age groups were observed in Europe[2,6,11].

In contrast, the incidence rates for colorectal cancer in these countries have increased, except for men and women in Japan and women in Hong Kong of China[4,12-14]. Singapore experienced a sharp increase in the colorectal cancer incidence between 1968 and 2002, particularly among older men[12]. In Hong Kong of China, the ASR peaked in 1994 and has since declined in women, whereas the ASR progressively increased in men[14]. The increase was notable among men above 60 years old and women above 70 years old[14]. Similarly, the APCs for the incidence rate of colorectal cancer was prominent among older Korean men and women between 1999 and 2009[13]. Japan is the only Asian country in which the incidence rates for colorectal cancer have decreased in both men and women[4]. The Osaka Cancer Registry data showed that the overall colorectal cancer incidence in women has decreased since 1995. In men, the rate has been stabilized since 1996[9].

Changes in risk factors, particularly those related to lifestyle, have been suspected as main contributors to the colorectal cancer increase. Among modifiable lifestyle factors, alcohol consumption, obesity, cigarette smoking, and dietary habits (*e.g.*, red meat and processed meat consumption) have been associated with colorectal cancer risk[15,16]. In a study for population-attributable fractions of cancer in Japan, 31%-33% of the colorectal cancer incidence or mortality was explained by known preventable risk factors, such as alcohol consumption, cigarette smoking, obesity, and physical inactivity[17] when men and women combined. Among them, alcohol consumption was attributed for the greatest portion, followed by cigarette smoking and obesity. In a Chinese study, the population-attributable fraction of known preventable risk factors for cancer death was 14.6% for colon cancer and 2.2% for rectal cancer[18]. Alcohol consumption was accountable for 32.9% of male colorectal cancer and 2.1% of female colorectal cancer in Japan[17]. In China, alcohol consumption was accountable for 2.1% and 0.2% of colorectal cancer cases in men and women, respectively[19]. The prevalence and amount of alcohol consumption in these countries and South Korea have not decreased during the last few decades[17,18,20]. However, the prevalence of obesity, particularly in men, and a sedentary lifestyle has increased in Hong Kong of China, South Korea, and Japan[14,17,21]. Fortunately, the prevalence of cigarette smoking has declined in South Korea, Japan, and China[17,18,20]. These changes may explain the transition in the colorectal cancer epidemiology in these Asian countries.

Table 1 Colorectal cancer mortality rates in Hong Kong of China, Japan, South Korea and Singapore, 1955-2010 (age-standardized mortality rates per 100 000)

Country or area	Period	Men				Women

[1]$P < 0.05$ *vs* the younger age groups. APC: Annual percent change.

A rapid increase in the incidence among older age groups may reflect the accumulated exposure to risk factors[22]. In contrast, a major contributor to the mortality reduction for colorectal cancer in the younger generation is the adaptation of screening programs. In Japan, a colorectal cancer screening program using a fecal occult blood test (FOBT) has been in place since 1992 under the Health Services Law for the Aged[23]. Colorectal cancer screening programs were introduced as a part of the National Cancer Screening Program for Medical Aid

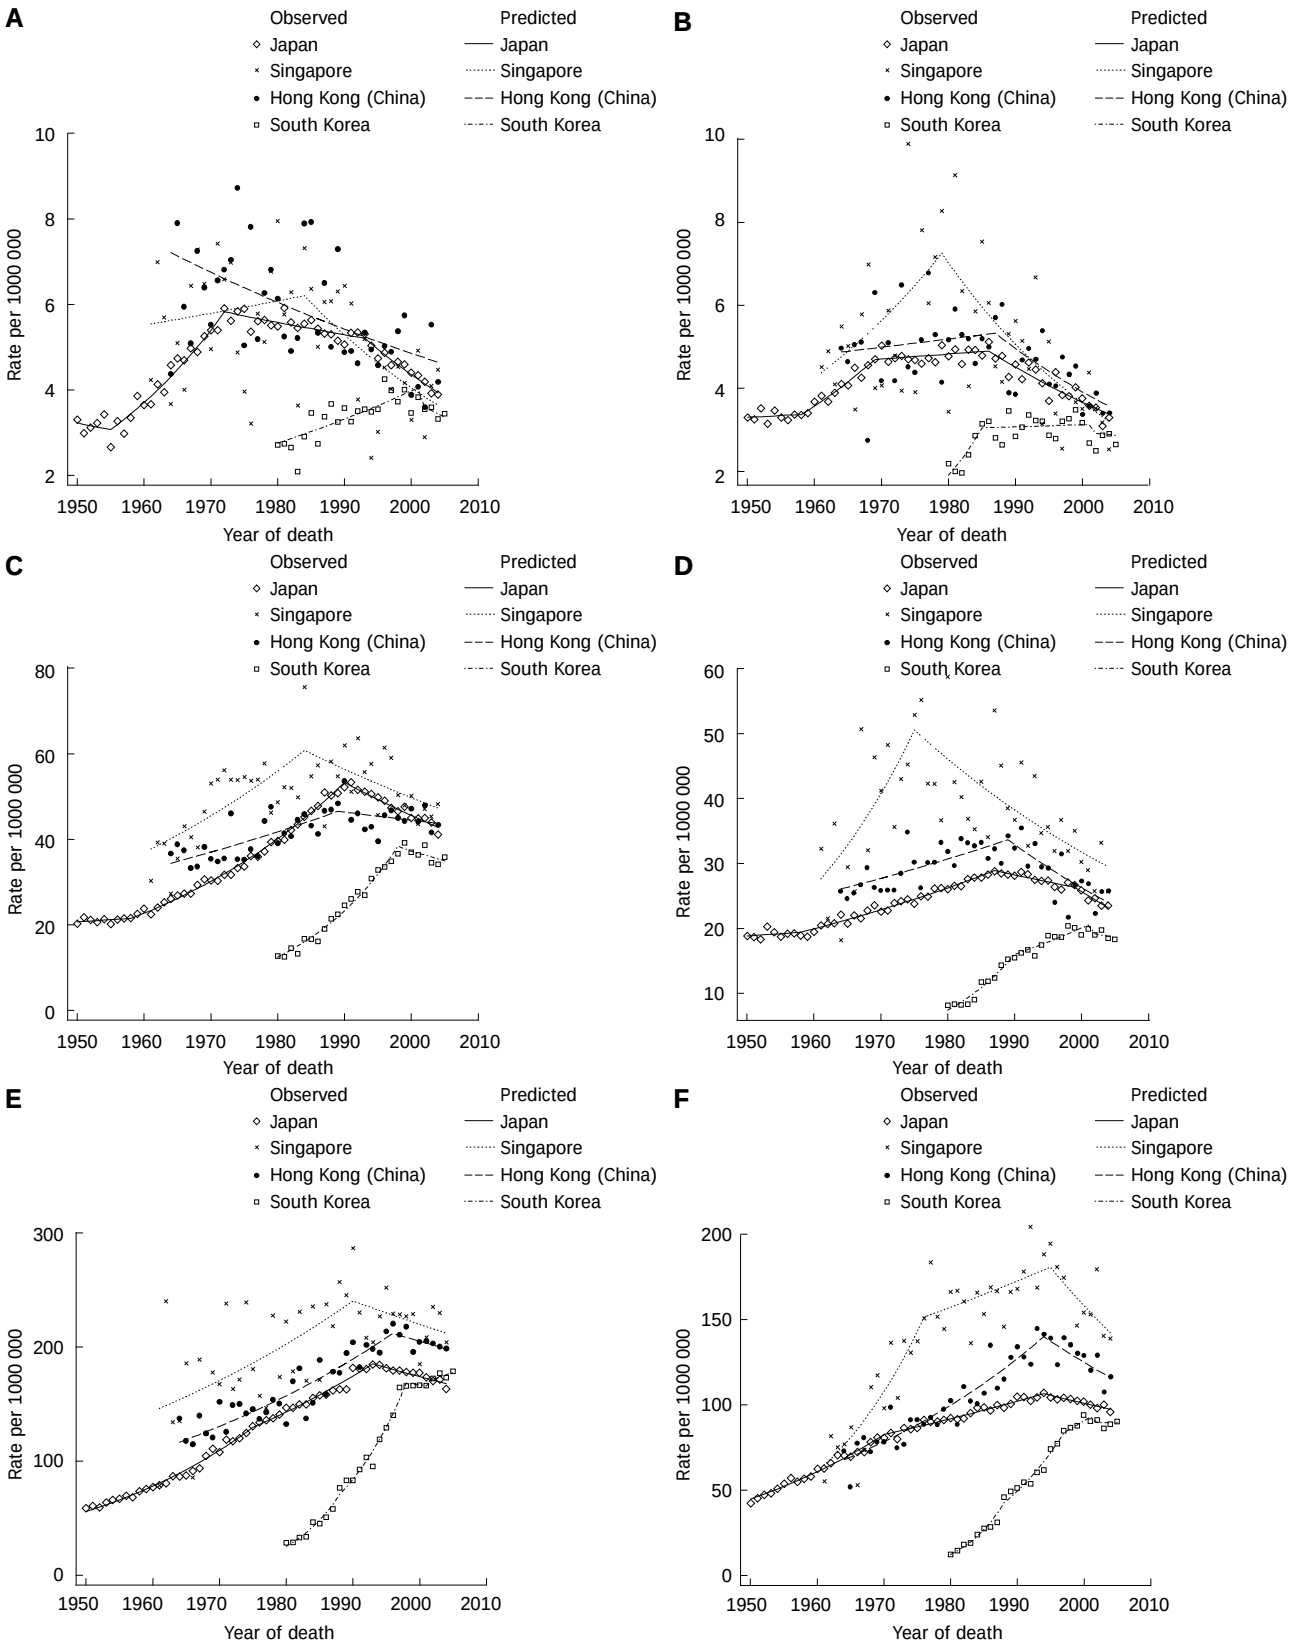

Figure 1 Trends in age-standardized colorectal cancer mortality rates per 100 000 in Hong Kong of China, Japan, South Korea and Singapore, 1955-2010. A: Men 30-49 yr; B: Men 50-69 yr; C: Men ≥ 70 yr; D: Women 30-49 yr; E: Women 50-69 yr; F: Women ≥ 70 yr.

recipients and National Health Insurance beneficiaries in the lower income bracket in 2004 in South Korea[24]. The FOBT is provided free of charge as a primary modality for men and women aged 50 years or older. FOBT-positive individuals were provided follow up by either colonoscopy or a double-contrast barium enema[24]. According to the Korean National Cancer Screening Survey, which covers both organized and opportunistic cancer screen-

ing programs, the lifetime screening rates for colorectal cancer were 25.3% in 2004 and 54.2% in 2010[25]. Although colorectal cancer screening for the average-risk population is recommended to start at 50 years of age, a national screening program is not available in Singapore[26]. However, compliance with opportunistic screening in Singapore was reasonably high[26].

CONCLUSION

In Hong Kong of China, Japan, South Korea and Singapore in which economic development and the westernized lifestyle were adopted early, colorectal cancer mortality has started to decrease. The decline or stabilization of mortality occurred the earliest in younger age groups and in women. The most important contributor to the decline in mortality is the introduction of colorectal cancer screening programs, although the role of the transition of lifestyle risk factors needs to be addressed.

Abstract

Cancer is one of the leading causes of death worldwide. Commonly used cancer treatments, including chemotherapy and radiation therapy, often have side effects and a complete cure is sometimes impossible. Therefore, prevention, suppression, and/or delaying the onset of the disease are important. The onset of gastroenterological cancers is closely associated with an individual's lifestyle. Thus, changing lifestyle, specifically the consumption of fruits and vegetables, can help to protect against the development of gastroenterological cancers. In particular, naturally occurring bioactive compounds, including curcumin, resveratrol, isothiocyanates, (-)-epigallocatechin gallate and sulforaphane, are regarded as promising chemopreventive agents. Hence, regular consumption of these natural bioactive compounds found in foods can contribute to prevention, suppression, and/or delay of gastroenterological cancer development. In this review, we will summarize natural phytochemicals possessing potential antioxidant and/or anti-inflammatory and anti-carcinogenic activities, which are exerted by regulating or targeting specific molecules against gastroenterological cancers, including esophageal, gastric and colon cancers.

INTRODUCTION

Cancer is a leading cause of death worldwide. Surgery, chemotherapy and radiation therapy are commonly used cancer treatments. However, these can cause a number of side effects, and complete cure is often infeasible for most patients suffering from specific cancers. Epidemiological studies have suggested that regular consumption of vegetables, fruits, red wine and tea is associated with lower incidences of many chronic diseases, including cancers[1-4]. A recent review reported that natural bioactive compounds found in various foods can activate or deactivate molecular signaling cascades by targeting small molecules in cancer cells[5]. A number of natural phytochemicals, including isoflavones, gingerol, (-)-epi-

gallocatechin gallate (EGCG), quercetin, resveratrol, and curcumin have been identified to be chemopreventive and their significant health benefits are an active field of research[5]. In particular, gastroenterological cancers are closely associated with lower consumption of fruits or vegetables. Therefore, in this review, we will summarize the natural phytochemicals possessing potential antioxidant and/or anti-inflammatory and anti-carcinogenic activities, which act by regulating or targeting specific molecules against gastroenterological cancers, including esophageal, gastric and colon.

PHYTOCHEMICALS IN ESOPHAGEAL CANCER

Esophageal cancer is the eighth most common cancer and is the sixth most common cause of cancer-related deaths[6]. Due to the lack of symptoms, individuals are rarely aware of their condition until the metastatic stages of the disease[7]. Despite developments in current cancer treatments, including chemotherapy, radiation therapy, and surgery (esophagogastric resection), patients with esophageal adenocarcinoma are not often cured of the disease[8]. Statistical analysis for the past 5 years shows that Americans and Europeans with esophageal cancer have relatively low survival rates, 10%-15% and 10% respectively[9]. Moreover, this suggests that the esophageal tumors are resistant to regular therapies and, thus, alternative strategies for the treatment and/or prevention of esophageal cancer are required.

Major risk factors for esophageal cancer are chewing and smoking tobacco, drinking alcoholic beverages[10], low consumption of fruits and vegetables[1] and consumption of salt-cured, salt-pickled, and moldy foods[11]. Therefore, quitting cigarette smoking, reducing alcohol consumption, increasing fruit and vegetable consumption, and avoiding foods containing nitrosamines and nitrosamine precursors are critical for the prevention of this disease. In addition to such lifestyle changes, identifying foods or food constituents that can help to prevent, suppress, and/or delay the onset of esophageal cancer is essential[12,13]. Recent attention has focused on the beneficial actions of natural phytochemicals, such as isothiocyanates, curcumin, and resveratrol, against esophageal cancer (Table 1). Although the underlying molecular mechanisms have not been fully understood, such natural chemicals are known to protect against disease progression by targeting specific proteins.

Isothiocyanates

Isothiocyanates are naturally occurring phytochemicals in cruciferous vegetables, including Chinese watercress, cabbage, Brussels sprouts, turnips and cauliflower[14]. In the gastrointestinal tract, isothiocyanates are released from their precursor *via* hydrolysis catalyzed by myrosinase. Of its metabolites, phenethyl isothiocyanate (PEITC) has been reported to be rapidly absorbed and distributed in mice following oral administration[15]. Studies have demonstrated that PEITC (> 1.0 μmol/g diet) protects against esophageal cancer by inhibiting tumor incidence and multiplicity in rats treated with N-nitrosobenzylmethylanime (NMBA), the most potent inducer of esophageal tumors and is commonly used to study the pathogenesis of esophageal cancer[16].

Several studies of the molecular mechanism whereby PEITC inhibits NMBA-induced esophageal tumorigenesis have revealed that PEITC suppresses the activity of cytochrome P450 enzymes in rats with NMBA-induced esophageal cancer[11,17,18], and also inhibits DNA methylation by inhibiting the formation of the pro-mutagenic adduct O^6-methylguanine in rat esophageal DNA[16]. Significant correlations between DNA adduct formation and tumor multiplicity have been observed in rat lungs as well as esophagi[18], indicating that DNA adduct formation probably contributes to tumor incidence and multiplicity. Collectively, PEITC is likely to have anti-carcinogenic activity *via* regulation of P450 enzyme activity and inhibition of DNA damage, contributing to the prevention of esophageal cancer. However, no direct target has been identified. Hence, future investigation is needed to elucidate the molecular target(s) of isothiocyanates or their metabolites in the prevention and/or treatment of esophageal cancer.

EGCG

Polyphenols are major components of tea. One-third of the dry weight of green or black tea is composed of polyphenols, which have powerful antioxidant and anti-inflammatory potential[19]. Wang *et al*[20] reported that both decaffeinated green and black tea consumption reduced esophageal tumorigenesis and molecular events in rats treated with N-nitrosomethylbenzylamine, which is probably due to the suppression of tumor incidence and multiplicity[21]. EGCG is the most abundant and active constituent among tea polyphenols. In general, the anti-carcinogenic activities of EGCG are mediated *via* multiple mechanisms, including the inhibition of mitogen activation protein kinases (MAPK), activator protein-1 and cell transformation[22-24], inhibition of epidermal growth factor receptor (EGFR) phosphorylation[25], induction of cell cycle arrest (G0/G1)[26,27] and apoptosis[28], and inhibition of DNA methyltransferase (DNMT) activity[29].

EGCG also regulates multiple targets and mechanisms in protecting against esophageal cancer. EGCG (40 μmol/L) inhibits phosphorylation of ERK1/2, c-Jun, and cyclooxygenase-2 (COX-2), which are increased in the human esophageal cancer cell lines SKGT-4 and TE-8 as well as in esophageal tissue specimens obtained from patients[30]. *In vivo* analysis using nude mouse xenograft models also confirmed that lower tumor formation and growth are associated with the decreased expression levels of phosphorylated extracellular-signal-regulated kinase (ERK) and COX-2 induced by EGCG treatment(50 μg/kg per day)[30]. Together these suggest that EGCG may protect against esophageal cancer by reducing pro-inflammatory mediators, including ERK, c-Jun

Table 1 Chemopreventive phytochemicals and their actions and targets/mechanisms during the development of esophageal cancer, gastric cancer and colon cancer

	Natural phytochemical	Chemopreventive action	Targets/mechanisms	Ref.
Esophageal cancer	Isothiocyanate	Inhibition of DNA damage	Inhibition of DNA methylation	[17]
		Inhibition of tumorigenesis	Inhibition of cytochrome P450 enzymes activity	[11,18]
	EGCG	Anti-inflammation	Inhibition of phosphorylated ERK1/2, c-Jun and COX-2 expressions	[30]
			Decreased COX-2 expression and PGE_2 production	[32]
		Growth inhibition	Inhibition of EGFR phosphorylation	[31]
		Induction of cell cycle arrest	Inhibition of cyclin D1	[32]
		DNA damage	Inhibition of DNA methyltransferase activity	[29]
	Curcumin	Antioxidant	Induction of SOD-1	[46]
		Anti-inflammation	Inhibition of COX-2	[46]
			Inhibition of NF-κB activity	[50-52]
			Inhibition of IL-8 mRNA expression	[52]
		Apoptosis and cell cycle arrest	Inhibition of Notch signaling	[57]
Gastric cancer	Curcumin	Chemoresistance	Downregulation of NF-κB	[61]
			Induction of apoptotic genes *Bcl-2* and *Bcl-xL*	[61]
		Suppression of cell proliferation and invasion	Downregulation of EGFR-PAK1	[62]
			Reduction of cyclin D1 expression	[62]
	Resveratrol	Inhibition of cell cycle progression	Inhibition of PKC	[72,73]
			MEK1/2-ERK1/2-c-Jun	[74]
		Induction of apoptosis	Reduction in Bcl-2, enhancing *Bax* gene	[76,77]
	Sulforaphane	Protection against oxidative stress	Stimulation of Nrf2	[78-80]
			Enhancement of GST and glutathione levels	[78,81]
		Anti-bacterial activity	Decrease in gastric bacterial colonization	[82]
			Reduction in the expression of TNF-α and IL-1β	[82]
Colon cancer	Curcumin	Growth inhibition	EGFR/IGFR	[102]
			ERK/Egr-1/EGFR	[87,96]
		Suppression of tumorigenesis	AMPK-COX-2	[101]
			Wnt/β-catenin	[102,106]
	Resveratrol	Anti-proliferation Apoptosis	IGF-1, p53	[108]
			PPP-FAK signaling	[109]
		Apoptosis growth inhibition	AMPK	[110]

ERK: Extracellular-signal-regulated kinase; COX-2: Cyclooxygenase-2; PGE_2: Prostaglandin E2; EGFR: Epidermal growth factor receptor; EGCG: Epigallocatechin gallate; SOD: Superoxide dismutase; NF-κB: Nuclear factor κB; IL-8: Interleukin-8; PKC: Protein kinase C; MEK: Mitogen-activated protein kinase; Bcl-2: B-cell lymphoma 2; GST: Glutathione S-transferase; TNF: Tumor necrosis factor; IGFR: Insulin-like growth factor receptor; PPP: Pentose phosphate pathway; FAK: Focal adhesion kinase; AMPK: Adenosine monophosphate-activated potein kinase.

and COX-2 in *in vitro* carcinogenesis and *in vivo* tumorigenesis models, and cancer patients.

EGCG inhibits phosphorylation of EGFR and HER-2/neu in KYSE 150 esophageal squamous cell carcinoma, leading to the inhibition of growth factor receptor and, thus, exerting anti-carcinogenic activity[31]. Another study demonstrated that EGCG (4 mg/kg *i.p.*) attenuates cyclin D1 and *COX-2* gene expression, thereby reducing the production of prostaglandin E2 (PGE_2) in rats treated with NMBA[32]. This suggests that cyclin D1 and COX-2 may act as partial targets of EGCG. EGCG-mediated decrease in PGE_2 production following NMBA treatment was further supported by another study using F344 rats[33]. Lastly, EGCG also inhibits DNA methylation, thereby suppressing the onset of esophageal cancer. Indeed, hypermethylation of DNA is associated with critical events during cancer progression, such as cell cycle regulation, DNA repair, and apoptosis[34-36]. In particular, methylation of CpG by DNMT is known to cause chromosome condensation and transcription repression[37,38]. The importance of DNA demethylation has been emphasized in strategies to develop cancer therapies and was further supported by studies using DNMT inhibitors. Treatment with DNMT inhibitors leads to the inhibition of cancer cell growth, induction of cancer cell apoptosis, and attenuation of tumor volume in mice[39-42]. In fact, Fang *et al*[29] demonstrated that EGCG acts as a potent DNA methylation inhibitor by suppressing DNMT activity, leading to the demethylation of CpG and reactivation of methylation-silenced genes in the human esophageal cancer cell line KYSE 510.

Curcumin

Curcumin is a yellow pigment derived from turmeric, the powdered rhizome of Curcuma longa Linn. Accumulating evidence suggests numerous health benefits of curcumin, including antioxidant, anti-inflammatory, and anti-carcinogenic properties[43,44], which are probably mediated by regulation of multiple intracellular targets[5]. Multiple molecular targets have been identified using various cancer cell lines and xenograft animal models of esophageal cancer.

Curcumin is a well-known antioxidant[43]. Excess amounts of reactive oxygen species (ROS) lead to the initiation, progression, and promotion of various cancers[45]. Therefore, the role of antioxidants is critical dur-

ing the development of cancers. In fact, treatment with curcumin (10-100 μmol/L) reversed suppression of the powerful antioxidant superoxide dismutase (SOD)-1 and induction of *COX-2* gene expression following treatment with bile acid in an esophageal epithelial cell line (HET-1A)[46]. This suggests that the antioxidant capacity of curcumin contributes to the prevention of esophageal cancer by increasing the activity and/or expression levels of antioxidant enzymes, including SOD, and reducing pro-oxidant enzymes, such as COX-2.

In addition to its antioxidant capacity, curcumin exerts its anti-cancer activities *via* its anti-inflammatory activity. Nuclear factor κB (NF-κB) is a well-known pro-inflammatory transcription factor involved in the initiation, promotion and progression of cancers[47]. It is also known that increased NF-κB activity is associated with greater cell proliferation, invasion, angiogenesis, metastasis, suppression of apoptosis, and chemoresistance in various types of cancer[48,49]. Several studies have demonstrated that curcumin inhibits NF-κB activity in esophageal adenocarcinoma[50,51]. Rawat *et al*[52] reported that curcumin (50 μmol/L) protects against bile acid-induced enhanced NF-κB activity in an esophageal cell line (OE33), which in turn reduces the expression levels of NF-κB target genes, including interleukin (IL)-8. In addition, patients with Barrett's esophagus supplemented with curcumin (a 500 mg curcumin tablet daily for 7 d) showed decreased IL-8 mRNA expression, suggesting that curcumin can act as a potential chemopreventive agent against esophageal cancer[52].

Recently, it was demonstrated that curcumin induces cell death (apoptosis) and cell cycle arrest by blocking Notch signaling pathways. Notch signaling was recently found to be upregulated in esophageal cancer and is as a therapeutic target for esophageal cancer due to its critical roles in tumor cell proliferation, apoptosis and stem cell maintenance and renewal[53-56]. Inhibition of Notch signaling in oral squamous carcinoma cells by curcumin also contributes to downregulation of NF-κB, which in turn reduces the expression of target genes of NF-κB, including Bcl-2, cyclin D1, vascular endothelial growth factor, and matrix metalloproteinase-9[57].

PHYTOCHEMICALS IN GASTRIC CANCER

Gastric cancer is the seventh most common cause of cancer-related mortality in the world. Exposure to chemical carcinogens or *Helicobacter pylori* (*H. pylori*) infection causes several events which may lead to the development of gastric cancer[58]. In particular, *H. pylori* infection results in infiltration of neutrophils and macrophages into the gastric mucosa. Infiltration of neutrophils and macrophages leads to the production of free radicals, including superoxide and nitric oxide. ROS-mediated stress responses result in gastric mucosal injury, ulcers, and ultimately gastric cancer[59]. Therefore, agents that have powerful antioxidant potential *via* scavenging ROS or enhancing antioxidant capacity may help to protect against gastric cancer development (Table 1).

Curcumin

It has been suggested that curcumin inhibits *H. pylori* infection in mice by reducing its growth[60]. The mechanisms of cellular growth and potential therapeutic capacity of curcumin have been further investigated by *in vitro* studies using multiple gastric cancer cell lines. Curcumin protects against chemoresistance in human gastric cancer cells by downregulating NF-κB and subsequent NF-κB-mediated anti-apoptotic genes, such as Bcl-2 and Bcl-xL in the human gastric cancer SGC 7901 cell line[61].

In addition, curcumin reduces EGFR expression and the activity of p21-activated kinase (PAK)1, a downstream regulator of EGFR. Curcumin also reduces NF-κB activity, regulated by PAK1, leading to decreases in cell proliferation by reducing the mRNA and protein expression of cyclin D1 and suppresses cell cycle progression from the G1 to S phases. Therefore, curcumin inhibits the proliferation and invasion of various gastric cancer cells[62].

Resveratrol

Resveratrol is a highly abundant polyphenol found in red grapes and red wine. Epidemiological studies have revealed an inverse relationship between red wine consumption and the incidence of cardiovascular disease[63,64]. The cardioprotective effect of red wine was attributed to resveratrol[65]. During the last two decades, extensive research has focused on the antioxidant, anti-inflammatory and anti-carcinogenic health benefits of resveratrol[66]. Specifically, resveratrol was found to have antibacterial effects[67] by inhibiting the growth of multiple *H. pylori* strains[68-70]. Increased expression of IL-8 and increased production of ROS were detected in the gastric mucosa following exposure to *H. pylori*. Furthermore, *H. pylori*-mediated infection increases motility and leads to morphological changes in co-cultured cells, known as the hummingbird phenomenon. Treatment with resveratrol (1-100 μmol/L) significantly attenuated IL-8 secretion, ROS formation, and markedly inhibited morphological changes in cells infected with *H. pylori*[71]. Hence, resveratrol is a candidate therapeutic agent against gastric cancer.

Resveratrol inhibits cell cycle progression of nitrosamine-stimulated KATO-Ⅲ and RF-1 cells by inducing cell cycle arrest in the G0/G1 phase through inhibiting kinase C-mediated mechanisms and induces apoptotic cell death in various gastric adenocarcinoma cell lines[72,73]. Another mechanism by which resveratrol regulates cell proliferation is associated with the MEK1/2-ERK1/2-c-Jun signaling cascade, a critical signaling pathway in the proliferation and growth of human adenocarcinoma gastric cells. Resveratrol was found to suppress the phosphorylation of MEK1/2-ERK1/2, which subsequently inhibits translocation of c-Jun into the nuclear compartment, leading to inhibition of cell proliferation[74].

In addition to the inhibition of cell proliferation, resveratrol (50-200 μmol/L) induces apoptosis in human gastric cancer SGC7901 cells by producing ROS, which can be reversed by treatment of cells with SOD or catalase, leading to the attenuation of resveratrol-mediated

cellular apoptosis[75]. Resveratrol induces apoptosis in esophageal carcinoma (EC-9706) cells, mediated by reducing the expression of Bcl-2 and enhancing that of the pro-apoptotic gene Bax[76]. Resveratrol can induce apoptosis of transplanted tumor cells, probably mediated by downregulation of the anti-apoptotic gene bcl-2 and upregulation of the apoptotic gene Bax by resveratrol in implanted primary human gastric cancer cells in nude mice[77].

Sulforaphane

The natural chemical compound sulforaphane is an isothiocyanate and is abundant in cruciferous vegetables, especially broccoli[59]. Sulforaphane is present as sulforaphane glucosinolates (SGS), which is biologically inactive. SGS is hydrolyzed by the action of myrosinase in the oral cavity and small intestine to produce sulforaphane. Biologically active sulforaphane is ultimately absorbed into the systemic circulation, where it exerts various activities[59]. Although sulforaphane is not itself an antioxidant, it exerts antioxidant activity by stimulating Nrf2-depedent antioxidant enzymes, such as glutathione S-transferase (GST), thereby protecting cells against oxidative stress[78-80]. Compared to other strong antioxidants, such as vitamin C or polyphenols, sulforaphane maintains the activities of antioxidant enzymes, including NAD(P)H: quinone oxidoreductase (NQO1) and GST in the gastric mucosa of Nrf2-/- mice infected with *H. pylori* and fed a high salt diet[59]. This renders sulforaphane a more potent antioxidant substance and mediates its protection of the gastric mucosa against oxidative stress.

Sulforaphane increases detoxification as well as antioxidant enzymes in a Nrf2-dependent manner. Fahey *et al*[78] demonstrated that sulforaphane suppresses benzo-[a]pyrene-evoked forestomach tumors in ICR mice. This is probably mediated by inducing phase 2 detoxification enzymes, including NQO1 and GST, and upregulating antioxidant enzymes, which are abrogated in mice without the *Nrf2* gene[78]. In patients with *H. pylori*-associated gastritis, *H. pylori* eradication increased or restored the activity of GST and glutathione levels in the antral mucosa[81]. This further emphasizes the importance of antioxidants during the development of gastric cancers associated with *H. pylori* infection.

In addition to its antioxidant capacity, sulforaphane exerts chemoprotective effects which are attributed to its *in vitro* anti-bacterial activity[59]. In a clinical study of *H. pylori*-infected patients (n = 48), the group that consumed broccoli (70 g/d; containing 420 μmol/L sulforaphane precursor) for 8 wk showed decreased levels of markers of *H. pylori* colonization (*i.e.*, urease level and *H. pylori* stool antigen) and markers of gastric inflammation (*i.e.*, serum pepsinogens Ⅰ and Ⅱ) compared to the placebo group[82]. An *in vivo* study using C57BL/6 female mice infected with *H. pylori* Sydney strain 1 and maintained on a high-salt (7.5% NaCl) diet confirmed the anti-bacterial activity of sulforaphane. Mice treated with broccoli rich in sulforaphane showed decreased gastric bacterial colonization as well as reduced expression of tumor necrosis factor (TNF)-α and IL-1β in the gastric mucosa, contributing to amelioration of inflammation and, thus, prevention of high salt-induced gastric corpus atrophy[82]. Interestingly, the anti-bacterial and anti-inflammatory activities of sulforaphane were not observed in mice with *Nrf2* gene depletion, suggesting that sulforaphane exerts its effect *via* Nrf2[82].

PHYTOCHEMICALS IN COLORECTAL CANCER

Colorectal cancer is one of the most commonly diagnosed cancers in both males and females[83]. The mortality rate of males with colon and rectal cancer was the third highest for cancers in the United States between 1930 and 2007[84]. Consumption of a high-calorie diet that is high in fat leads to obesity. Many studies have investigated the contribution of obesity to colorectal diseases[85-88]. The colon is one of the first organs to encounter various factors in foods and, thus, the effects of natural bioactive compounds in the diet on colorectal tissue are the subject of extensive investigation.

The Wnt signaling pathway is a primary factor in colorectal cancer. Among several Wnt signaling proteins, β-catenin is a key regulator, which turns on and off cell proliferation proteins. In the normal state, the "destruction" complex comprising axin, APC, and glycogen synthase kinase-3β, phosphorylates β-catenin, which subsequently becomes degraded[89]. However, after activation of the Wnt signaling pathway, the "destruction" complex is suppressed and β-catenin is not degraded by ubiquitination. Accumulated β-catenin then translocates into the nucleus and binds directly to the T-cell factor (TCF)/lymphoid enhancer factor (LEF) family molecules. These interactions stimulate TCF/LEF target genes involved in cellular proliferation, such as c-myc and cyclin D1[90,91].

More importantly, the Wnt signaling pathway is stimulated by obesity[92] and is a secondary factor in the development of colon cancers[93,94]. Obesity is associated with chronic inflammation[85]. In obesity-related cancers, phosphoinositide-3-kinase (PI3K)/Akt, MAPK, and their downstream signaling proteins, including mammalian target of rapamycin (mTOR), are activated as the severity of obesity increases[95]. Overall, it is commonly accepted that suppression of the inflammatory signaling pathway may represent an important strategy for inhibition of both Wnt- and obesity-related colon cancers. Several lines of evidence have reported the anti-colon carcinogenic effects of natural compounds, which act as small molecule inhibitors of the inflammatory signaling pathway. Among them, curcumin and resveratrol are the most significant anti-carcinogenic compounds (Table 1).

Curcumin

Curcumin is the yellow pigment of turmeric and numerous studies using various carcinogenesis models have

shown its chemopreventive effects. One clinical study reported that curcumin has anti-colon carcinogenic effects. Indeed, oral intake of curcumin (4 g for 30 d) decreased the number of aberrant crypto foci in the colon in this Phase Ⅱ a clinical trial of curcumin for the prevention of colorectal neoplasia.

A number of studies have investigated the mechanisms underlying the inhibition of colon cancer development by curcumin. The major targets of the signaling pathways regulated by curcumin are EGFR[96,97], AMPK-COX-2[98], MAPK[99] and Wnt/β-catenin[100]. EGFR is one of four family erbB receptors and is involved in many malignancies, including colorectal cancer[97], by modulating multiple signaling pathways. Specifically, ligand-activated EGFRs are autophosphorylated and activate Ras and other signaling pathways, which in turn increase the expression of EGFR target genes. Indeed, increased levels and function of EGFR are closely associated with the metastatic potential of human colon carcinoma cells. Chen *et al*[96] reported that curcumin inhibits colon cancer cell growth by reducing the ERK/Egr-1/EGFR signaling pathway and decreasing the expression of EGFR. Curcumin was also demonstrated to prevent the emergence of chemoresistant colon cancer cells *via* inhibition of EGFR and insulin-like growth factor (IGF)-1R.

AMPK is a highly conserved kinase in eukaryotes. Although its main function is in maintenance of energy homeostasis, novel roles for AMPK were discovered recently. The AMPK-COX-2 cascade is an important pathway associated with cancer growth. Previous studies demonstrated that a signaling cascade involving AMPK, pAkt and COX-2 is a promising target as it is regulated by curcumin during cancer cell growth. Over 80% of colonic adenomas and carcinomas exhibit mutations in the *APC* gene and constitutive activation of Wnt signaling[101]. Thus, Wnt/β-catenin signaling has been targeted for the development of novel anti-colorectal cancer drugs. Curcumin also inhibits the Wnt/β-catenin signaling pathway[102]. Curcumin impairs Wnt signaling and cell-cell adhesion pathways, subsequently inducing G_2/M phase and apoptosis in colon cancer cells.

Resveratrol

Resveratrol is a naturally occurring phenolic phytochemical, which is present in red grapes. Resveratrol exerts its chemopreventive and chemotherapeutic effects by modulating multiple biological activities. Daily *p.o.* doses of 0.5 g or 10 g resveratrol for 8 d inhibited tumor cell proliferation by 5% with no resveratrol-related adverse effects in patients with resectable colorectal cancer (n = 90)[103]. Another clinical study demonstrated that ingestion of grape powder suppresses the expression of Wnt target genes, including cyclin D1 and axin Ⅱ, in normal colonic mucosa. This suggests that dietary supplementation with resveratrol-containing products is a potential colon cancer preventive strategy and that Wnt/β-catenin is a potential target for resveratrol in normal colonic mucosa[104]. The anti-colonic tumor effects of resveratrol have been investigated in various *in vivo* studies[105-107]. Resveratrol (300 ppm) supplementation reduced levels of markers of DSS-mediated colitis inflammation, such as iNOS, COX-2 and TNF-α, in mice[105]. Resveratrol also inhibited the 1,2-dimethylhydrazine-induced tumor burden per animal, per group and over the three regimens of colon carcinogenesis (initiation, post-initiation and entire period)[107].

Resveratrol suppresses IGF-1-induced human colon cancer cell proliferation by activating p53 signaling pathways. Because the IGF signaling pathway is closely related to obesity-mediated colorectal carcinogenesis[108], resveratrol may be useful for suppressing obesity-induced colorectal cancers. Additionally, resveratrol inhibits human colon cancer cell proliferation and promotes apoptosis by suppressing the pentose phosphate pathway and focal adhesion kinase, a critical protein for cell-extracellular matrix communication. This supports the anti-colon-carcinogenic effect of resveratrol in obese individuals[109].

Furthermore, resveratrol exerts synergistic anti-cancer effects on chemoresistant cancer cells by regulating the AMPK signaling pathway. The HT-29 cell line has been used to develop anti-cancer drugs intended to overcome chemoresistance[110]. Although 100 μmol/L etoposide, an anti-cancer agent, did not inhibit the proliferation of HT-29 cells, pretreatment with resveratrol (50-400 μmol/L) induced cytotoxicity under 100 μmol/L etoposide[110]. Additionally, the phosphorylation level of acetyl-CoA carboxylase (ACC), the downstream molecule of AMPK, was increased by co-treatment with resveratrol and etoposide and increased phospho-ACC and pAMPK inhibition of cell viability. Compound C, an AMPK inhibitor, reduced resveratrol/etoposide-induced cytotoxicity on HT-29 cells[110].

CONCLUSION

Gastroenterological cancers, including those of the esophagus, stomach and colon, are closely associated with lifestyle factors, especially diet. Patients suffering from gastroenterological cancers often cannot be completely cured with regular chemopreventive strategies and, thus, prevention, suppression, and/or delaying the onset of these cancers are critical. A number of natural phytochemicals, including curcumin, resveratrol, isothiocyanates, EGCG, and sulforaphane have been shown to have anti-carcinogenic, anti-inflammatory, and antioxidant activities by targeting small molecules or regulating signaling cascades, thereby protecting against the development of gastroenterological cancers. Although most phytochemicals act as small molecule inhibitors, they often have low bioavailability following oral administration. Indeed, the concentration of resveratrol is lower than its major metabolite resveratrol sulfate glucuronide after daily administration of 0.5 g resveratrol for 8 d to colorectal cancer patients[103]. The majority of the phytochemicals are readily converted to their metabolites in the gastrointestinal tract. These metabolites may have similar or better effects than their parent compounds and, thus, may also represent primary therapeutic agents.

Abstract

Ulcerative colitis (UC) is an inflammation-associated disease of the colon and rectum. The onset and progress of the disease are directly influenced by the nature of the intestinal microflora, the intestinal barrier function, and the immunological responses of the host. The epithelial invasion of pathogenic bacteria due to excess contact and/or barrier dysfunction is related to inflammation mediated by intestinal immune responses. Although the etiology of UC is not clearly understood, recent studies have shown a rising incidence of UC worldwide, and this phenomenon is more prominent in Asian countries and in Asian immigrants in Western countries. The increased prevalence of UC also contributes to an increased risk of developing colorectal cancer. Environmental factors, including changes in dietary habits, have been suggested as major risk factors of UC. A systematic review showed a negative association between UC risk and vegetable intake, whereas total fat, omega-6 fatty acids and meat intake were positively associated with an increased risk of UC. Individual dietary factors and energy balance have been suggested as having important roles in inducing changes in the microbial population and intestinal barrier integrity and in regulating inflammatory immune responses, directly or indirectly. Excess energy intake is now known to increase pathogenic microbial populations. Likewise, the application of appropriate probiotics may reverse the pathogenic progression of the disease. In the meantime, dietary anti-inflammatory compounds, including omega-3 fatty acids and other phytochemicals, may directly suppress inflammatory responses in the course of UC development. In this review, the increased prevalence of UC and its management are interpreted from the standpoint of nutritional modulation to regulate the intestinal microflora population, intestinal epithelium permeability, and inflammatory responses.

INTRODUCTION

Ulcerative colitis (UC) is a major type of inflammatory bowel disease (IBD) characterized by chronic inflammation in the colon and rectum. It progresses by extensive epithelial apoptosis and ulceration due to chronic inflammation induced by T-helper (Th) 2 cytokines[1]. Recent studies have also indicated that a balance between proinflammatory Th17 cells and immunsuppressive Treg cells play a crucial role in the development of

UC[2]. Although the etiology of UC has not been clearly determined, environmental factors are thought to stimulate overt immune responses to bacterial components in individuals with high genetic susceptibility. A recent report on the incidence of IBD in Asia indicated that the prevalence of UC is growing rapidly in Japan, Hong Kong, and South Korea[3-5], countries where IBD used to be rare. The most recent reports on UC prevalence in Japan and South Korea provided figures of 63.6 and 30.9 per 100 000 people, respectively[4,5]. UC reportedly affects 0.24% of the United States population[6], and the prevalence in Northern European countries ranges from 40 to 240 per 100 000 people[7].

Lifestyle changes, as well as increased awareness of the disease and improved diagnosis, may have contributed to the increased incidence. Dietary habits in Asian countries have changed, resulting in a Western-style diet with fewer plant-based and more processed foods. A recent systematic review of 19 studies reported a negative association between UC risk and vegetable intake, whereas total fat, omega-6 fatty acids, and meat intake were positively associated with increased UC risk[8]. Information is limited, however, on the role of individual dietary components in UC development, and most nutritional modulation studies have focused on delaying relapses of UC, efforts that involve secondary rather than primary prevention. The cumulative incidence of relapse in UC are 30%, 72%, and 88% after 1, 5, and 10 years following the initial diagnosis[9]. Patients younger than 40 years have been shown to present with more severe disease at the time of diagnosis compared with older patients[10]. Importantly, the increased incidence of UC may be closely related to an increase in the prevalence of colorectal cancer (CRC). A subset study population with UC from the Kaiser Permanente Medical Care Program was analyzed for CRC incidence and mortality, and the standardized mortality ratio for CRC among UC patients was 2.0 (95%CI 1.3-2.7)[11]. Chronic inflammation mediates a wide range of signaling cascades that possibly facilitate colorectal carcinogenesis, and UC remission may reduce the risk of CRC. In this review, the pathophysiology of UC is summarized to allow understanding of the molecular mechanisms involved in the action of dietary components. Major dietary components reported to regulate, directly or indirectly, inflammatory responses in UC are discussed, with a focus on human studies where available. Genetic factors and therapeutic measures, while important to consider, fall outside the scope of this review.

INTESTINAL BARRIER FUNCTIONS AND INFLAMMATION IN UC

The human large intestine contains a concentration of approximately 10^{11}-10^{12} microorganisms per gram of luminal content. These microbes can be either beneficial or harmful to the intestinal epithelium. Under normal circumstances, multiple mechanisms protect the intestinal epithelium from microbial invasion, but environmental stimuli in combination with genetic factors can facilitate overgrowth of harmful microflora and induce abnormal immune responses that disrupt the mucosal barrier, causing inflammation (Figure 1).

The luminal side of the intestinal membrane is in constant contact with intestinal microflora. The most evident characteristic of pathogenic bacteria are their invasiveness and induction of inflammatory responses in the intestinal epithelium[12]. The host system, in other words, is able to recognize and differentiate pathogens from the commensals. To protect the host from pathogenic bacteria, the intestinal epithelium is equipped with multiple defense systems. Intestinal epithelial cells (IECs), which are layered by glycoproteins such as mucin, form the first line of immune defense. Tight junction (TJ) proteins seal the space between IECs. The layer below the IECs is the sub-epithelial dome, containing antigen-presenting cells, and underneath are Payer's patches, where B-cell follicles and T-cells reside.

Bacterial invasion is recognized by receptors called pattern recognition receptors (PRRs) in the IEC membrane, and the primary PRRs are toll-like receptors (TLRs). There are 10 different classes of TLRs expressed throughout the whole human gastrointestinal tract. The recognition of bacteria is carried out by means of communication between PRRs and microbial components such as lipopolysaccharide (LPS), and this is followed by immune responses to destroy the invading pathogens. Microbiota and viral-associated ligands use different types of TLRs depending on molecular patterns. For example, TLR2 recognizes lipopeptides, TLR 3 recognizes viral-derived dsRNA, and TLR4 recognizes LPSs[13]. Constant immune responses provoke chronic inflammation, which is mediated by pro-inflammatory cytokines and chemokines. The inflammation not only contributes to clinical features of inflammatory disease, but also exacerbates the penetration of pathogenic bacteria by increasing the membrane permeability, creating a vicious cycle. The ability of the intestinal epithelium to distinguish commensal from pathogenic bacteria is important because the intestine requires a symbiotic relationship with commensals without immune responses. Several explanations exist for the intestinal epithelium's ability to discriminate harmful bacteria from commensals[14]. In brief, pathogenic bacteria possesses virulence factors to stimulate the innate immune responses while commensals mutate their molecular patterns, escaping recognition by TLRs, and attenuate the nuclear factor (NF)-κB pathway. Also, the hyporesponsiveness to commensals has been explained by the anti-inflammatory nature of the gut mucosa including reduced expression of PRRs and reduced inflammatory nature of intestinal immune cells.

DIETARY FACTORS MODULATING INTESTINAL BARRIER FUNCTIONS IN UC

Excess energy (obesity)

Obesity is the most convincing risk factor in the devel-

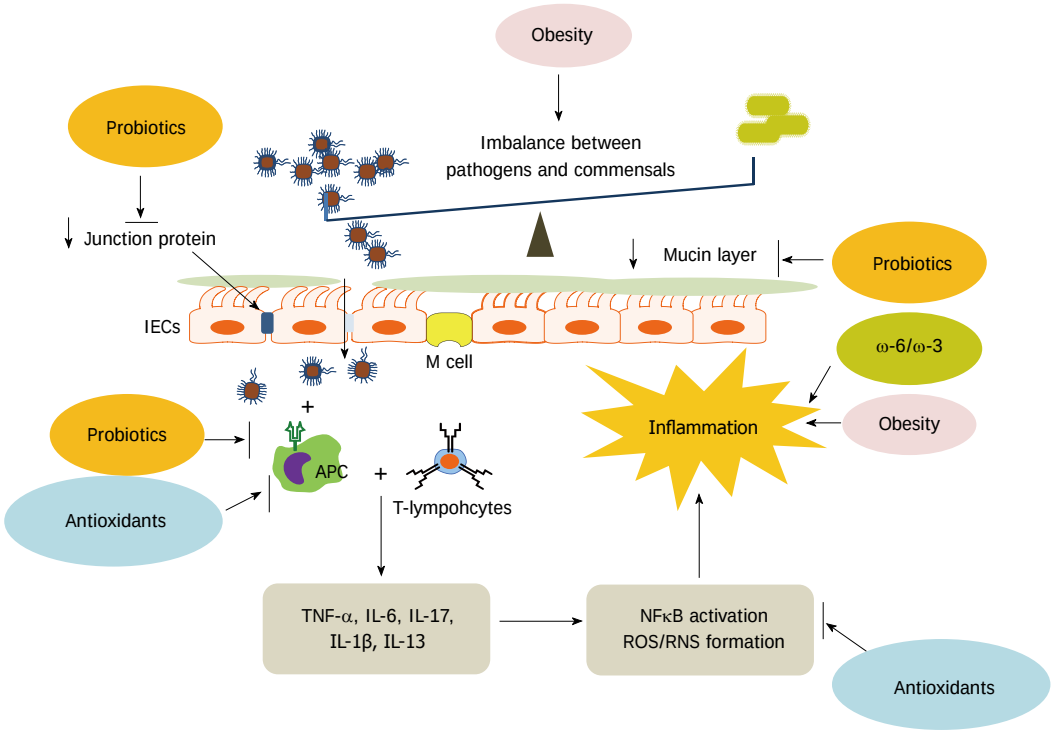

Figure 1 Disrupted intestinal homeostasis in ulcerative colitis and the role of nutritional factors. Ulcerative colitis is a chronic inflammatory disease of the colon and rectum. Inflammatory responses are induced by the penetration of excessive pathogenic bacteria due to the increased population of pathogenic bacteria, the loss of junction proteins and thin mucin layer. Once pathogens are recognized by antigen-presenting cells (APC), T-lymphocytes produce pro-inflammatory cytokines activating inflammation-inducing nuclear transcription factor, nuclear factor (NF)-κB and generating reactive oxygen species (ROS) and reactive nitrogen species (RNS) which result in the inflamed intestine. Obesity is known to cause imbalances between pathogens and commensals as well as chronic inflammation. The increased ω-6 to ω-3 fatty acid ratio in the diet also accelerates inflammatory responses. Probiotics supplementation helps to maintain gut health by retaining tight junctions and mucin layer. Probiotics and antioxidants suppress immoderate immune responses, and ROS-induced inflammatory responses are moderated by antioxidants. TNF-α: Tumor necrosis factor-α; IL-1β: Interleukin-1β; IECs: Intestinal epithelial cells.

opment of many noncommunicable diseases, including type 2 diabetes, cardiovascular diseases, non-alcoholic fatty liver disease, and selected types of cancer. World Health Organization statistics stated that physical inactivity and being overweight or obese contributed, respectively, to 5% and 6% of deaths[15]. The estimated prevalence of overweight [body mass index (BMI) $\geqslant$ 25 kg/m^2] and obese (BMI $\geqslant$ 30 kg/m^2) males and females aged 15 or older was $\geqslant$ 80% in the United States, $\geqslant$ 65% in Canada, Mexico, Argentina, Australia, the United Kingdom, and Germany, and $\geqslant$ 35% in all other countries, except for several African countries, India, and South East Asian countries[16].

Obesity and abdominal obesity have been specifically identified as the most convincing risk factors for the development of CRC[17]. In many studies, obesity-related inflammatory biomarkers were shown to be associated with disease activity. Among adipokines, resistin was considered to have a positive relationship with disease activity[18,19]. In a multicenter registry of children with IBD, 1 in 3 children with UC were overweight or obese, which is comparable to the rate in the general population[20]. However, prior IBD-related surgery was positively associated with being overweight or obese, which implies that obesity may provoke a more severe disease course. CRP was found to be a marker predictive of disease progression in a population-based prospective study[21]. CRP concentrations above 23 mg/L at diagnosis showed an odds ratio (OR) of 4.8 (95%CI, 1.5-15.1) in the prediction of surgery in UC patients. These results suggest that systemic inflammation worsens disease activity, and therefore the suppression of inflammatory events may be critical for the management of UC.

Mechanistic explanations have not been provided regarding the relationship between obesity and intestinal inflammation in patients. However, a number of rodent model studies have indicated that intestinal inflammation is mediated through obesity-related factors. Leptin was shown to act as a critical mediator in colitis development[22]. Leptin-deficient (*ob*/*ob*) mice were shown to be resistant to chemically-induced colitis, indicating that leptin is a critical regulator. Adiponectin, on the other hand, was shown to be a negative regulator in the development of dextran sulfate sodium (DSS)-induced colitis through the suppression of pro-inflammatory cytokine and chemokine production[23]. In a recent study, the effects of high-fat diet-induced obesity and chemically-induced colitis were compared in the development of UC[24]. A high-fat diet alone did not induce characteristic histopathological features of UC, indicating UC development is accelerated through inflammatory infiltration in the colon tissue of chemically-induced colitis. It is also interesting to note that the inflamed intestines of mice with chemically-induced colitis exhibited higher

inflammatory activities in the mesenteric fat compared with obese mice, which implies that intestinal inflammation may precede systemic inflammation[25]. These results suggest that obesity may not be an independent risk factor for UC development, although it may aggravate disease progression.

There are several reports showing evidence of obesity-associated changes in the intestinal microbiota. However, there is no clear explanation if this is due to adiposity or dietary composition[26]. Therefore, the altered microbial population is either a cause or a consequences of obesity. A recent report suggested that diets high in saturated fat promote taurine-conjugated bile acid formation, altering microbial composition towards the overgrowth of a sulfite-reducing pathobiont, *Bilophilla wadsworthia*. This accelerated the development of colitis in interleukin (IL)-10 -/- mice[27], providing evidence of a direct contribution from increased dietary fat. High-saturated fat diets altered microbial composition, resulting in a significantly higher ratio of *Firmicutes* to *Bacteroidetes*[28]. A decreased proportion of *Bacteroidetes*[29] was also observed in IBD, suggesting a possible mediating effect of these bacteria in obesity-related pathogenic changes in the intestinal epithelium. Others have reported that changes in the gut microbiota directly contribute to the development of obesity and related metabolic disturbances[30,31], which requires further investigation.

Fatty acids

The intakes of pro-inflammatory omega-6 fatty acids and anti-inflammatory omega-3 fatty acids have been suggested as important regulators in UC disease activity. A recent systematic review concluded that available randomized controlled trials do not indicate that omega-3 fatty acids are useful to alleviate IBD[32].

Epidemiological studies have been conducted to investigate the association between UC and nutrients. A total of 139 UC patients were identified as a subgroup of the population participating in a large prospective cohort study, the European Prospective Investigation into Cancer and Nutrition (EPIC)[33]. Results indicated that there is a marginally significant association between UC and an increasing percentage intake of energy from total polyunsaturated fatty acids (OR, 1.19; 95%CI, 0.99-1.14, $P = 0.07$). In another EPIC sub-cohort report, the highest quartile of intake of linoleic acid was positively associated with UC risk (OR, 2.49; 95%CI, 1.23-5.07)[34]. A nested United Kingdom cohort study analyzed the effect of total and specific dietary omega-3 fatty acids intake on the risk of UC[35]. Docosahexaenoic acid (DHA) was found to have a statistically significant protective OR of 0.43 (95%CI, 0.22-0.86), while total omega-3 fatty acids and eicosapentaenoic acid (EPA) showed marginally negative values.

Few studies have reported fatty acid composition markers of UC in human biospecimens. In accordance with the above mentioned epidemiological evidence, one study showed that the erythrocyte membrane content of linoleic acid, the most abundant dietary polyunsaturated acid present in plant seed oil was significantly higher in IBD patients (29 UC and 20 CD patients) compared with control subjects ($n = 31$)[36]. In the same study, UC patients showed a significantly higher ratio of arachidonic acid (AA) to EPA compared with control subjects. Leukotrienes (LTs) are pro-inflammatory lipid mediators involved in the progression of UC. The 5-lipoxygenase pathway (5-LOX) catalyzes the formation of LTs from AA, and the deletion of the gene encoding 5-LOX in an animal model prevented the development of chemically-induced colitis[37]. In a prospective case-control study, UC patients had significantly higher urinary LTE4 excretion compared with controls[38]. A subpopulation of the EPIC prospective cohort study showed that subjects in the highest quartile for adipose tissue AA concentration had a relative risk for UC of 4.16 (95%CI, 1.38-2.27)[39].

Experimental animal model studies have investigated the effects on UC development of omega-3 fatty acid supplementation or an increased ratio of omega-3 to omega-6 fatty acid in the diet[41-43]. Possible mechanistic explanations include: (1) the restoration of membrane TJ protein expression and distribution; or (2) the activation of peroxisome proliferator-activated receptor-γ, possibly inhibiting NFκB transcriptional activity. However, Varnalidis *et al*[42] suggested that the ameliorating effects of omega-3 fatty acids are accompanied by increased colonic neutrophil infiltration, and needs further clarification. Matsunaga *et al*[41] reported that feeding fish oil (8% w/w) exacerbates DSS-induced colitis in mice by suppressing the expression of adiponectin in myofibroblasts of the intestinal epithelium.

Apart from omega-6 and omega-3 fatty acids, short chain fatty acids have been suggested to suppress intestinal inflammation through G-protein-coupled receptor 43 (GPR-43)[44]. Acetate supplementation suppressed DSS-induced colonic inflammation in wild-type mice, while GPR-43 $^{-/-}$ mice did not respond to acetate. These results explain the role that intestinal microbiota play in producing short chain fatty acids from dietary fiber in the maintenance of a healthy gut.

The efficacy and safety of fish oil in the remission of IBD [Crohn's disease (CD) or UC] have been investigated in clinical trials. A recent meta-analysis retrieved 9 randomized, placebo-controlled trial of fish oil administered for at least 6 mo[45]. A total of 1.8-6.2 g/d of DHA + EPA or total omega-3 fatty acids were provided during the study period, and the primary outcome was relapse rate. A meta-analysis indicated that there was no significant reduction in the relative risk of UC, while the pooled relative risk of CD relapse was 0.77 (95%CI, 0.61-0.98). A clinical trial based on n-3 polyunsaturated diet therapy (n-6 to n-3 fatty acid ratio of approximately 1) reported that subjects exhibiting disease remission after a n-3 PUFA diet had a higher ratio of n-3/n-6 fatty acids in the red cell membrane compared with the relapse group[46].

Probiotics

Probiotics are live, nonpathogenic microorganisms that

contribute to the improvement of epithelial and mucosal barrier function through various mechanisms, including reduced intestinal pH, inhibition of pathogenic bacteria, and modulation of the intestinal mucosa immune responses[47-49]. Although there is a growing body of evidence from *in vivo* studies on the beneficial effects of probiotics in UC, reliable clinical trials are limited in number. The aim of this chapter is to review randomized, double-blind, placebo-controlled clinical trials which suggest that probiotics are effective in UC.

The probiotic *Escherichia Coli* strain Nissle 1917 (EcN) is non-pathogenic and one of the best characterized strains used as a probiotic drug[50]. The clinical effectiveness of EcN in adult UC patients seems to be promising[51]. Patients with moderate distal active UC were assigned to treatment with either 10, 20, or 40 mL of EcN enema (n = 23, 23, 24) containing 10^8 CFU/mL or placebo once a day for at least 2 wk. If there was no disease activity index (DAI) improvement after 2 wk, patients were classified as non-responders and discontinued therapy. Those classified as responders could receive the treatment for 4 or 8 wk. Although the number of responders was not significantly higher in the EcN group than in the placebo group, the efficacy of rectal EcN treatment was dose-dependent and significant in the per-protocol analysis. This Phase Ⅱ study showed that EcN is an effective and well-tolerated alternative or supplementary treatment in mild-to-moderate distal UC patients.

The induction of remission in patients with mild-to-moderate UC was also demonstrated with VSL3™ treatment. VSL3 is a high-concentration probiotic mixture, which combines 8 different bacterial species including *Bifidobacterium* (*B.*) *longum, B. breve, B. infantis, Lactobacillus* (*L.*) *casei, L. plantarum, L. acidophilus, L. Bulgaricus,* and *Streptococcus thermophilus*[52]. In a multicenter, randomized, double-blind, placebo-controlled trial, subjects received either VSL3 (n = 77) containing 3.6×10^{12} CFU or placebo (n = 70) twice per day for 12 wk[53]. VSL3 led to a 50% improvement in DAI at 6 wk and clinical remission was shown in 33 patients given VSL3 (42.9%) compared with 11 patients given placebo (15.7%) at 12 wk.

A single-center, randomized, double-blind, placebo-controlled trial of the efficacy of symbiotic treatment was performed using 18 patients with active UC[54]. Participants were given either 2×10^{11} *B. longum and* 6 g of prebiotic fructo-oligosaccharide/inulin mix (n = 9) or placebo (n = 9) twice a day for 4 wk. The results showed that consumption of symbiotic treatment over 4 wk significantly ameliorated mucosal mRNA levels of human beta-defensins 2, 3, and 4, which are strongly upregulated in active UC. In addition, mucosal mRNA levels of tumor necrosis factor-α (TNF-α) and IL-1α were significantly decreased in the symbiotic group, with remission of sigmoidoscopy scores. This small trial provided the potential efficacy of symbiotic therapy for patients with active UC. The effect of *L. acidophilus* La-5 and *B. lactis* BB-12 (Probio-Tec AB-25) was investigated in a randomized, double-blind, placebo-controlled trial[55]. Patients with left-side UC were given either Probio-Tec AB-25 (n = 20) or placebo (n = 12) for 52 wk, and clinical, endoscopic, and histological parameters were analyzed at entry and in case of relapse. In this study, there was no statistical difference in remission rate and the median time to relapse between the two groups after 1 year of treatment. The authors concluded that Probio-Tec AB-25 was well tolerated by study participants and that a failure to prove efficacy in remission rate may be due to the small sample size.

The use of probiotics as maintenance therapy in UC patients seems promising. Two randomized, double blind, double-dummy clinical trials to determine the efficacy of EcN were conducted. In the preliminary study, 120 patients with inactive UC were treated with either an oral preparation of EcN containing 25×10^9 bacteria daily or mesalazine 1500 mg daily for 12 wk. The start and end DAI scores demonstrated no significant difference between the two groups. The relapse rate was 16.0% in EcN group and 11.3% among those taking mesalazine[56]. The same authors investigated the effectiveness of EcN in 327 patients with UC. Subjects received either probiotics containing 5×10^{10} bacteria or mesalazine 1500 mg daily (n = 162, 165) for 12 mo. According to the per protocol analysis, 36.4% of patients in the EcN group experienced a relapse, compared with 33.9% of patients in the mesalazine group. The investigators concluded that EcN is efficient and safe in maintaining remission, and equivalent to the standard mesalazine[57]. Another study also confirmed that the administration of EcN was as effective as mesalazine in the maintenance of remission in patients with UC[58]. Patients with active UC were randomized to EcN treatment of 5×10^{10} probiotics/d (n = 57) or mesalazine treatment (1200 mg/d, n = 59) for 12 mo. In the intention-to-treat analysis, the health conditions were improved in 39 (68.4%) subjects in the EcN group and 44 (74.5%) subjects in the mesalazine group. The mean time of remission was 42 d (median 37 d) in the EcN group and 44 d (mean 42 d) in the mesalazine group. These results support the conclusion that EcN treatment has an equivalent effect to mesalazine in maintaining remission of UC.

The efficacy of VSL3 on induction and maintenance of remission in patients with active UC was studied in a long-term, randomized, double-blind, placebo-controlled trial[59]. In this study, subjects were children (mean age: 9.8 years; range: 1.7-16.1 years) and they were received either VSL3 containing 4.5-18 $\times 10^{11}$ bacteria/d (n = 14) or placebo (n = 15) for 1 year. All of the 29 patients were also treated with mesalazine during this trial period. Three of the 14 (21.4%) subjects in the VSL3 group and 11 of the 15 (73.3%) subjects in the placebo group relapsed within 1 year of follow-up. At 6 mo, 12 mo, or at time of relapse, endoscopic and histological scores were significantly lower in the VSL3 group compared with the patients in the placebo group. No adverse effect related to VSL3 was observed. Although the sample size of this

study was small, it provided evidence for the efficacy and safety of VSL3 in pediatric UC patients receiving conventional IBD therapy.

Another study evaluated the efficacy of VSL3 supplementation in patients with mild-to-moderate UC who were already being treated with 5-aminosalicylic acid (5-ASA) and/or immunosuppressants[60]. The patients were randomly treated with either VSL3 (n = 65) including 3600 × 10^9 CFU/d or placebo (n = 66) for 8 wk. After 8 wk, decreases in DAI scores of 50% or more were significantly higher in the VSL3 group than in the placebo group. However, there was no significant difference in stool frequency, physician rating of disease, and endoscopic scores between the two groups. Although the mechanism(s) of VSL3 treatment in IBD therapy is unclear, these two randomized, double-blind, placebo-controlled clinical trials showed the potential synergistic activity of probiotics.

A large number of animal model studies have reported protective effects of probiotics, and these results are summarized elsewhere[61]. Most of the studies used DSS mouse[62-64], trinitrobenzene sulfonic acid (TNBS) mouse[65-67] and IL-$10^{-/-}$ mouse[68-70]. The most frequently used probiotics were VSL3, *Lactobacillus, Bifidobacterium*, and *Saccharomyces*. The proposed mechanisms of action were as follows: (1) reduction of inflammatory cytokine and chemokine levels; (2) downregulation of TLR signaling followed by immune suppression; (3) increase in epithelium gap junction protein expressions; (4) prevention of pathogen growth and/or attachment; (5) increase in mucin production; (6) decrease in leukotriene B4 production; and (7) increase in short-chain fatty acid production. The reduced level of inflammatory cytokines and chemokines were thought to be mediated through signal transducer and activator of transcriptions-3 signaling[71,72] and/or NF-κB activation[73,74].

Although the specific mechanisms of action of probiotics are unknown, their therapeutic effects may be related to modulation of antigen-presenting cells. Local T cell immunity is an important factor involved in the specific intestinal immune system and its activation is programmed by dendritic cells (DCs) that help maintain mucosal tolerance and contribute to the development of chronic intestinal inflammation as key initiators of innate and adaptive immune responses in the gut[75-77]. However, the immunological mechanisms of certain probiotics are still poorly understood while several studies have demonstrated that anti-inflammatory activity of probiotics is due to modulation of DC and regulatory T cell (Treg) phenotype function. It was reported that the therapeutic effect of VSL3 was due to regulation mucosal CD4+ T cell responses in a colitis-associated CRC model[78]. VSL3 administration in UC patients significantly decreased TLR-2 expression on colonic DC[79]. Also, VSL3 supplementation increased IL-10 production and decreased IL-12p40 production by colonic DC[76]. VSL3 administration induced a significant expansion of mucosal Treg cells in UC patients[80]. *L. rhamnosus* induced maturation of monocyte-derived DC and induced both lower IL-12 and IL-18 production and development of T cells without a typical Th phenotype[81]. A probiotic mixture containing *L. helveticus* and *L. rhamnosus* increased follicular Treg cells in *Citrobacter rodentium*-induced colitis[82]. *L. casei* inhibited TNF-induced secretion of the T-cell chemokine interferon-inducible protein 10 (IP-10) in IECs by blocking IP-10 protein secretion and IP-10-mediated T-cell transmigration[83]. *L. casei* lysate DN-114 001 treatment increased the numbers of CD4(+)FoxP3(+)Treg cells in mesenteric lymph nodes, decreased the production of TNF-α, interferon-γ, and IL-10 in Peyer's patches and large intestine, and changed the gut microbiota composition in a DSS-induced colitis model[84]. *L*-peptidoglycan purified from Ls33 also ameliorated TNBS-induced colitis by development of CD103(+) DCs and CD4(+)Foxp3(+) Treg cells[85]. Thomas *et al*[86] showed that *Saccharomyces bourladii*, a probiotic yeast preparation, reduced IL-6 and TNF-α and decreased the expression of co-stimulated surface markers CD40, CD80, and the migration marker CD197 (CCR7) on LPS-stimulated human 92 induced apoptosis of antigen-stimulated T cells. These data suggest that each strain exhibits a different ability to modulate DC and Treg functions and explain various potential mechanism(s) of bacterial strains.

Current evidence suggests that probiotics are good complementary and alternative medicine candidates to maintain remission and prevent relapse of UC. However, the clinical efficacy results are limited, and strain-specific mechanistic explanations are insufficient. Additional large-scale clinical trials are required to shed light on optimal doses and treatment periods.

Antioxidant vitamins and phytochemicals

Oxidative stress is known as a potential etiological and/or triggering factor in the initiation and preservation of UC[47,87-89]. Inflammation augments oxidative stress by activating reactive oxygen and/or reactive nitrogen, generating enzymes such as NAD(P)H oxidase, inducible nitric oxide synthase, and myeloperoxidase[89,90]. A group of antioxidants has been used to ameliorate the clinical condition of UC patients. In addition, several studies have shown that patients with UC often have antioxidant nutrient deficiencies at the time of diagnosis[91-93]. Although the important role of antioxidants in UC has been seen in several studies, few clinical trials have been conducted. A randomized, controlled trial evaluated the efficacy of a nutritionally balanced oral supplement including fish oil, fructo-oligosaccharides, gum arabic, vitamin E, vitamin C, and selenium in 121 patients with mild-to-moderate UC[93]. Patients consumed either 510.3 g of the oral supplement or placebo each day for 6 mo. Compared with the placebo group, both intent-to-treat and completer patients given the oral supplement showed a significant decrease in the dose of prednisone required to control clinical symptoms over 6 mo. Mirbagheri *et al*[94] performed an open-label, preliminary trial for the efficacy of D-α-tocopherol using 14 patients who were receiving concomitant therapy with 5-ASA and/or immunosuppressants. Patients received a D-α-

Table 1 Action targets of major beneficial dietary components in ulcerative colitis

tocopherol enema (8000 U/d) for 12 wk. At the end of 12 wk, the DAI score had statistically decreased from the beginning of the study, all 14 patients responded clinically to the therapy, and remission was induced in 9 patients (64%) without adverse events.

In recent years, several studies have investigated the efficacy of curcumin, a polyphenolic antioxidant in *Curcuma longa L.*, in experimental models of UC. These studies have showed a strong antioxidant effect, as well as an anti-inflammatory effect, of curcumin in this model. A small, open-label, pilot clinical trial of the effect of curcumin in patients with IBD (5 UC, 5 CD) receiving IBD medication (5-ASA or corticosteroids) was conducted[95]. The patients were given curcumin 1100 mg/d for 1 mo and 1650 mg/d for an additional 2 mo. All 5 patients with UC had significant improvement in their medication, as follows: two patients stopped taking 5-ASA, two reduced 5-ASA dosage, and one stopped corticosteroids entirely. This encouraging pilot study showed the strong potential efficacy of curcumin in UC patients.

In a multicenter, randomized, double-blind, placebo-controlled trial, the efficacy of curcumin in 89 patients with quiescent UC was evaluated[96]. In addition to their usual medication (sulfasalazine or mesalamine), participants received either curcumin (2 g/d) or placebo (n = 45, 44) for 6 mo. DAI and endoscopic scores were determined at entry, every 2 mo (DAI), at the conclusion of the 6-mo trial, and after a 6-mo follow-up. The relapse rate was significantly lower in the curcumin group than in the placebo group and the recurrence rate was significantly reduced in the curcumin group compared with the placebo group. Both the DAI and endoscopic score were also improved in the curcumin group without any adverse effects. Although only two clinical trials have been performed, the potential therapeutic capability of curcumin in UC patients has been shown, possibly resulting from its antioxidant and anti-inflammatory effects. However, large-scale, randomized, double-blind, placebo-controlled clinical trials are required to achieve convincing evidence for the routine use of antioxidants in patients with UC.

Many studies have reported that antioxidant supplementation has therapeutic efficacy in animal models, and these results were summarized in a recent review[97]. Mechanisms of action include: (1) direct scavenging of reactive oxygen species; (2) suppression of proinflammatory protein expression by downregulating related enzymes or transcription factors; and (3) alteration of leukocyte cell surface molecules.

UC is associated with increased gastrointestinal permeability[98,99]. Although the causes of increased permeability are not completely understood, an inflammation-associated increase in permeability has been shown to result in bacterial translocation into the lamina propria, which exacerbates the loss of barrier function. We have previously reported that aloe anthraquinones and chromone ameliorate colonic inflammatory responses in a DSS-induced UC model; aloesin, an aloe chromone, showed the most drastic results[100]. Additionally, we studied whether aloesin modulates mucosal permeability and found that this phytochemical recovered the gene expression levels of apical junctional complex proteins, which regulate gut permeability and barrier function (unpublished data). These results suggest that the anti-inflammatory property of aloesin is partly based on regulation of gut permeability, although human studies of clinical use are required.

Over the last few decades, phytochemical-based complementary and alternative treatments have emerged as relatively effective and safe therapeutic strategies for UC. Although a significant number of animal studies have established the potential beneficial effects on UC of phytochemicals and bioactive components of other natural sources, the exact mechanisms and/or molecular targets of their anti-inflammatory actions are not fully understood. Further studies are needed to evaluate their safety, targets, phytochemical-drug interactions, and pharmacokinetic information. Understanding these issues through well-designed clinical trials will enable us to choose reliable complementary and alternative therapies for patients with UC.

CONCLUSION

Because the increased prevalence of UC is potentially due to changes in dietary habits, especially in Eastern countries, it is now considered a lifestyle-related disease. It has been proposed that UC onset and progress are modulated by dietary factors such as excess energy intake, saturated fat intake, fatty acid ratio in the diet, and antioxidant intake. However, well-controlled human intervention trials are required to clarify the effect of nutritional factors on UC development. As understanding of the mechanisms involved in UC improves, a target-oriented search for compounds possessing therapeutic or complementary value becomes possible (Table 1). Nutritional modulation that aims to not only prevent the onset and relapse of the disease but also maintain remission will contribute to the successful management of UC.

Abstract

Colorectal cancer remains the third most common cancer in both women and men worldwide. Identifying modifiable dietary factors is crucial in developing primary prevention strategies. Vitamin B6 is involved in more than 100 coenzyme reactions, and may influence colorectal cancer risk in multiple ways including through its role in one-carbon metabolism related DNA synthesis and methylation and by reducing inflammation, cell proliferation, and oxidative stress. Observational studies of dietary or dietary plus supplementary intake of vitamin B6 and colorectal cancer risk have been inconsistent with most studies reporting non-significant positive or inverse associations. However, published studies of plasma pyridoxal 5'-phosphate (the active form of vitamin B6) levels consistently support an approximately 30%-50% reduction in risk of colorectal cancer comparing high with low concentrations. The reasons for the discrepancy in the results between dietary-based and plasma-based studies remain unresolved. Other unresolved questions include the effects of vitamin B6 intake in early life (*i.e.*, childhood or adolescence) and of suboptimal vitamin B6 status on colorectal cancer risk, whether the associations with vitamin B6 differ across molecular subtypes of colorectal cancer, and whether the vitamin B6-colorectal cancer association is modified by genetic variants of one-carbon metabolism.

INTRODUCTION

Colorectal cancer is the third most common cancer worldwide[1]. In the United States, colorectal cancer will account for approximately 143 460 new cases in 2012[2]. The wide variation in age-adjusted incidence rates for colorectal cancer between countries suggests a role of environmental factors such as diet in colorectal carcinogenesis. However, as summarized in several recent reviews[3-5], the effect of dietary factors on colorectal cancer remains largely inconclusive. For example, based on a comprehensive review of published studies, the 2011 World Cancer Research Foundation and American Institute for Cancer Research report on diet and colorectal

cancer identified that there was convincing evidence only for red meat, processed meat, and alcoholic drinks (in men) as risk factors and for dietary fiber as a protective factor for colorectal cancer[3]. The effect of other dietary factors such as vitamin B6 on colorectal cancer remains to be elucidated. Vitamin B6, a one-carbon metabolism related nutrient, may have a potential role in colorectal carcinogenesis. The current epidemiologic studies examining vitamin B6 and risk of sporadic colorectal cancer and adenomas are briefly summarized here. Although the possible effect of vitamin B6 may differ by molecular subtype of colorectal cancer or be mediated by genetic variants in one-carbon metabolism, few data are available to date[6-11] and thus are not reviewed here.

Vitamin B6 is a water-soluble vitamin that participates in more than 100 coenzyme reactions involved in the metabolism of protein, carbohydrates, and lipids[12]. In the United States, the major food sources for vitamin B6 include fortified cereals, starchy vegetables, beef, and poultry[12]. The recommended daily allowance (RDA) for vitamin B6 intake is 1.7 mg/d for men and 1.5 mg/d for women aged 51 years or older[12] although some subgroups of the population including smokers, blacks, seniors, and current and former oral contraceptive users require higher intakes[13]. Plasma pyridoxal 5'-phosphate (PLP) is the active form of vitamin B6 and is most commonly used to measure vitamin B6 status. A PLP level of more than 20 nmol/L is an indicator of adequate vitamin B6 status in adults[12]. The 2003-2006 national health and nutrition examination survey found that 11% of vitamin B6 supplement users (approximately 20%-30% of United States adults[14]) and 24% of people in the United States who do not take supplements containing vitamin B6 have suboptimal plasma PLP concentrations (< 20 nmol/L)[13].

VITAMIN B6 AND POTENTIAL MECHANISMS RELATED TO COLORECTAL CARCINOGENESIS

Vitamin B6 may influence colorectal carcinogenesis through its role in DNA synthesis and methylation[15], both of which are potentially involved in colorectal carcinogenesis. In addition, animal models have demonstrated that supplemental vitamin B6 suppressed cell proliferation and reduced the number of tumors in the colon[16,17]. Moreover, vitamin B6 has been shown to inhibit angiogenesis[18], suppress nitric oxide[16], and reduce oxidative stress[19], all of which are associated with preventing carcinogenesis. Further, low vitamin B6 status may link to chronic inflammation[20], a potential risk factor for colorectal cancer[21], based on significantly lower PLP concentrations observed among patients with inflammatory bowel diseases[22] and rheumatoid arthritis[23,24] compared to generally healthy populations. Other evidence of the link between vitamin B6 and inflammation includes the inverse relation of plasma PLP with cardiovascular disease[25,26], C-reactive protein[23,27], and tumor necrosis factor alpha[24].

OBSERVATIONAL STUDIES OF VITAMIN B6 INTAKE AND COLORECTAL CANCER RISK

Despite potential mechanisms supporting the hypothesis that vitamin B6 may reduce colorectal cancer risk, epidemiologic evidence examining vitamin B6 intake and colorectal cancer risk has been inconclusive. At least 9 case-control studies have examined the relation between vitamin B6 intake and colorectal cancer risk. The majority of the case-control studies reported a modest significant inverse association for comparisons of the highest with the lowest vitamin B6 intake categories. For example, a quantitative review of six case-control studies published in 2008 reported a summary multivariable relative risk (RR) of 0.67 (95%CI: 0.60-0.75) comparing high with low vitamin B6 intake[28]. However, there was borderline significant heterogeneity among these case-control studies (*P* value for heterogeneity = 0.09) with risk estimates ranging from 0.51 to 1.00. In addition, a meta-analysis of nine cohort studies that included eleven risk estimates (3 studies analyzed men and women separately) found no substantial effect of vitamin B6 intake on colorectal cancer risk (high *vs* low intake categories, summary RR = 0.90, 95%CI: 0.75-1.07). However, there was statistically significant heterogeneity in the results from the cohort studies (*P* value for heterogeneity = 0.01) with 6 cohort studies reporting 18%-39% lower risks of colorectal cancer comparing the highest *vs* lowest categories (the associations in three studies were statistically significant) and 5 studies reporting nonsignificant positive associations[29]. In the meta-analysis, only two cohort studies had evaluated associations with total vitamin B6 intake and a nonsignificant association was observed (summary RR = 0.90, 95%CI: 0.73-1.11)[29]. The only subsequently published study of two cohorts examined potential latency effects of vitamin B6 intake on colorectal cancer risk and found no difference for intakes measured 0-4 years before diagnosis compared to intakes measured 12-16 years before diagnosis[30]. Of note, the study populations in these studies were relatively well nourished, with a low prevalence (*i.e.*, 5%-10%) of individuals below the RDA levels of vitamin B6 intake, limiting the ability to test the potential effect of suboptimal vitamin B6 status on colorectal cancer risk.

NESTED CASE-CONTROL STUDIES OF PLASMA PLP CONCENTRATIONS AND COLORECTAL CANCER RISK

Four out of five nested case-control studies conducted to date have shown that higher pre-diagnostic plasma PLP concentrations were statistically significantly associated with a 30%-50% lower risk of colorectal cancer[29]. The first study was from the United States (*n* = 188 cases, highest *vs* lowest quartile, RR = 0.48, 95%CI: 0.25-0.92, *P* value for trend = 0.03)[31]. The second study conducted

in Finland found that men in the highest quartile of PLP concentrations had non-significant lower risk of colorectal cancer (n = 275 cases, RR = 0.61, 95%CI: 0.32-1.14, P value for trend = 0.08)[32]. Similar magnitudes of inverse associations were also observed in subsequent analyses using data from the Multiethnic Cohort study (n = 223 cases, RR = 0.52, 95%CI: 0.29-0.92, P value for trend = 0.03)[33] and the Physicians' Heath Study (n = 197 cases, RR = 0.49, 95%CI: 0.26-0.92, P value for trend = 0.01)[34]. Likewise, in the largest and most recent analysis to date (n = 1365 cases), the RR comparing the highest to lowest quintile was 0.68 (95%CI: 0.53-0.87, P value for trend < 0.001) in the European Prospective Investigation into Cancer and Nutrition cohort[9]. As shown in the meta-analysis of these studies[29], the pooled RR of colorectal cancer for the highest *vs* lowest categories of PLP levels was 0.52 (95%CI: 0.38-0.71).

CLINICAL TRIALS OF VITAMIN B6 SUPPLEMENT AND COLORECTAL CANCER

The effect of treatment with vitamin B6 supplements (40 mg/d) on colorectal cancer incidence and mortality has been evaluated, to the best of our knowledge, in only two randomized double-blind, placebo-controlled trials, the Norwegian Vitamin Trial[35] and the Western Norway B Vitamin Intervention Trial[36]. These studies were not primarily designed to examine cancer outcomes and included 6837 participants with ischemic heart disease after a median of 39 mo of treatment and an additional 38 mo of post-trial observational follow-up[37]. In both trials, participants were randomized into one of four groups: (1) folic acid (0.8 mg/d), vitamin B12 (0.4 mg/d), and vitamin B6 (40 mg/d); (2) folic acid (0.8 mg/d) and vitamin B12 (0.4 mg/d); (3) vitamin B6 alone (40 mg/d); or (4) placebo. The pooled analysis of data from these two trials showed no benefit of vitamin B6 supplementation on incident colorectal cancer or fatal colorectal cancer. Of note, only a limited number of colorectal cancer cases and deaths were included in the analysis. A total of 26 participants (1.5%) who received vitamin B6 and 22 (1.3%) participants in the placebo group were diagnosed with incident colorectal cancer during the trial (vitamin B6 *vs* non-vitamin B6 group, RR = 1.18, 95%CI: 0.69-2.00)[37]. Furthermore, there were only 5 deaths due to colorectal cancer in the vitamin B6 group and 7 in the placebo group (vitamin B6 *vs* non-vitamin B6 group, RR = 0.51, 95%CI: 0.17-1.55)[37].

VITAMIN B6 INTAKE, PLASMA PLP CONCENTRATIONS AND COLORECTAL ADENOMAS

The evidence for the association between vitamin B6 intake or plasma PLP concentrations and risk of colorectal adenoma, precursors of colorectal cancer, is less consistent than observed for colorectal cancer, with only a small number of studies published[10,11,31,38]. Specifically, the first study found a suggestive inverse association between plasma PLP concentration and advanced (≥ 1 cm in size, or villous or tubulovillous) distal colorectal adenoma (n = 408 cases, RR = 0.65, 95%CI: 0.37-1.11, P value for trend = 0.08), but a weaker association with low risk of (small and tubulous) adenoma (n = 210 cases, RR = 0.85, 95%CI: 0.52-1.38, P value for trend = 0.52)[31]. The other cohort study showed that high plasma levels of PLP were inversely associated with risk of colorectal adenoma (n = 210 cases, highest *vs* lowest tertile, RR = 0.44, 95%CI: 0.26-0.74, P value for trend = 0.002)[10]. Among 2 studies that evaluated the effect of vitamin B6 and adenoma recurrence, the first study from the Wheat Bran Fiber intervention trial showed a lower odds of adenoma recurrence for higher vitamin B6 intake (n = 495 recurrences, highest *vs* lowest quartile, OR = 0.65, 95%CI: 0.45-0.94, P value for trend = 0.03)[38]. The Aspirin/Folate Polyp Prevention Study, a trial of folic acid supplementation, found a borderline significant inverse association with plasma PLP concentrations and risk of adenoma recurrence (n = 430 recurrences, highest *vs* lowest quartile, RR = 0.78, 95%CI: 0.61-1.00, P value for trend = 0.08)[11].

DISCUSSION

Overall, based on a meta-analysis of nine cohort studies a substantial effect of vitamin B6 intake in adulthood and colorectal cancer risk was not evident although the study-specific results were inconsistent. In contrast, all five studies of circulating PLP levels found that participants with higher plasma PLP levels had a 30%-50% lower risk of colorectal cancer with the associations being statistically significant in four of the studies. Of note, only two nested case-control studies[31,33] have examined associations with both vitamin B6 intake and PLP levels and colorectal cancer risk and in these two studies inverse associations of similar magnitude were observed for vitamin B6 intake and plasma PLP concentrations and colorectal cancer risk. Several issues related to examining associations between vitamin B6 and colorectal cancer risk are discussed below.

Confounding by other factors?

Vitamin B6 intake is an important determinant of PLP levels[39]. However, individuals with high vitamin B6 intake tend to have healthy behaviors such as higher physical activity, less smoking, and higher intakes of folate, calcium, and vitamin D compared to individuals with lower vitamin B6 intake[30,40-42]. Because being physically active, not smoking, and having higher intakes of folate, calcium and vitamin D may reduce the risk of colorectal cancer[3,5,43,44], the inverse associations observed with higher PLP concentrations might be simply due to the correlations between vitamin B6 intake and these healthy behaviors. Although previous studies have adjusted for these potential confounding factors[29,30], residual confounding may still exist. Further, it is challenging to tease

out the independent effect of vitamin B6 from certain other nutrients such as folate, calcium, and vitamin D given that their intakes are positively correlated, particularly for intakes from food and supplemental sources combined. In addition, variation in plasma PLP could possibly reflect metabolic states such as chronic inflammation[22-24,27,45], a risk factor for colorectal cancer[21]. Studies have shown that patients with inflammatory bowel diseases[22] and rheumatoid arthritis[23,24] have significantly lower plasma PLP concentrations than healthy individuals. Although the data are not in full agreement[46], plasma PLP concentrations also have been found to be inversely correlated with C-reactive protein levels[23,27], and tumor necrosis factor alpha levels[24], both of which are markers of inflammation and possible risk factors for colorectal cancer[47]. Possibly, lower PLP levels could reflect a patho-physiologic state such as inflammation, which may be associated with higher risk of colorectal cancer, but increasing plasma PLP concentrations through increased intake may not necessarily lead to lower colorectal cancer risk. However, one study found that the inverse association with higher plasma PLP concentrations did not change even after adjustment for plasma concentrations of homocysteine, C-reactive protein, tumor necrosis factor alpha, and interleukin-6[34]. Nonetheless, it is unclear whether plasma PLP levels *per se* or the healthy behaviors or physiologic states associated with plasma PLP levels conferred the benefits observed in the studies of PLP concentrations and colorectal cancer risk.

Measurement error in assessment of vitamin B6?

Measurement error may have occurred in estimated vitamin B6 intake assessed using food frequency questionnaires (FFQs). However, the relatively high correlations (ranged from 0.4 to 0.8) observed between vitamin B6 intake assessed by FFQs and intake assessed using a reference methods (*i.e.*, dietary records)[6,30,40-42,48,49] reduce the possibility of missing a strong association between vitamin B6 intake and colorectal cancer risk in cohort studies. Moreover, total vitamin B6 intake (from food and supplemental sources combined) appears to be a good predictor of plasma PLP concentrations. For example, among representative random samples from the Nurses' Health Study (n = 381 women) and the Health Professionals Follow-up Study (n = 345 men) who had provided blood samples and served as controls in a nested case-control study of colorectal cancer[30], an approximately 3-fold difference was observed in mean plasma PLP concentrations comparing the top *vs* bottom quintiles of total vitamin B6 intake. Specifically, for the top and bottom quintile categories of total vitamin B6 intake, the mean plasma PLP concentrations were 98.3 nmol/L and 38.9 nmol/L in women and 183.2 nmol/L and 66.0 nmol/L in men. In addition, the Spearman correlation coefficients between total vitamin B6 intake and plasma PLP concentrations were 0.52 in women and 0.54 in men[30]. Thus, the ability of FFQs to predict an almost 3-fold difference in plasma PLP levels argues against measurement error in vitamin B6 intake masking detection of a strong association between vitamin B6 intake and colorectal cancer risk. Misclassification of vitamin B6 status also may occur in studies of PLP levels and colorectal cancer risk given that the studies published to date have only used one blood sample to measure PLP levels which may not reflect long term vitamin B6 status.

Interaction with other factors?

Inconsistent results might also result from differences in distributions of potential effect modifiers of the association between vitamin B6 and colorectal cancer risk. Given that alcohol consumption may decrease vitamin B6 levels[50,51], any effect of vitamin B6 on colorectal cancer risk might therefore be stronger among heavy drinkers. To date, results have been conflicting among the six studies we identified. A non-significant interaction between vitamin B6 and total alcohol consumption including wine, beer, spirits was observed in three studies of vitamin B6 intakes[30,52] and one study of plasma PLP levels[31]. In contrast, a stronger inverse association with plasma PLP concentrations[9] or vitamin B6 intake[41] has been reported among alcohol drinkers compared to nondrinkers. In addition, if vitamin B6 influences the development of colorectal cancer through the one-carbon metabolism pathway, the potential benefit of vitamin B6 might be stronger among individuals with low intake of other one-carbon metabolism related nutrients such as folate, riboflavin, methionine, and vitamin B12. However, current studies are limited and found no evident pattern[30,31]. With respect to adenomas, studies are limited and results have also been mixed. Results from the Multiethnic Cohort Study showed a non-significant interaction between plasma PLP and alcohol consumption[10] and the Aspirin/Folate Polyp Prevention Study found that the inverse association with plasma PLP was evident only among nondrinkers (P value for interaction = 0.03)[11].

Timing of intake is important?

Because most cohort studies conducted to date have only a single assessment of vitamin B6 intake[29,30], it is uncertain when in the natural history vitamin B6 intake may influence colorectal cancer risk. However, a recent study that specifically evaluated the timing using time lagged analyses found no clear pattern[30]. In contrast, when potential latency effects of total folate intake (another one-carbon metabolism related nutrient) were examined, only total folate intake measured 12-16 years prior to diagnosis of colorectal cancer was significantly associated with a lower risk of colorectal cancer, consistent with the only prior study examining the timing of folate intake on colorectal cancer risk[53]. When total folate and total vitamin B6 intakes measured 12-16 years prior to diagnosis were simultaneously included in the multivariate model, a statistically significant inverse association continued to be observed for total folate intake while a weak, nonsignificant association was observed for total vitamin B6 intake. However, it is unknown whether vitamin B6 intake in childhood, adolescence, or early adulthood might be important in colorectal carcinogenesis because dietary

habits experienced early in development may play an important role in adult disease[54,55]. The previous observational studies that we identified have focused on vitamin B6 intake in adulthood[30].

CONCLUSION

In contrast to the inverse associations observed in most studies of plasma PLP concentrations, the results from cohort studies of vitamin B6 intake in adulthood and colorectal cancer risk in relatively nourished populations have been inconsistent. The reason for this discrepancy between dietary-based and plasma-based studies remains unresolved and a better understanding is needed of the determinants of plasma PLP concentrations. Future studies should focus on early life intake (*i.e.*, childhood or adolescence), the effects of suboptimal vitamin B6 status, molecular subtypes of colorectal cancer, and effect modification by genetic variants of one-carbon metabolism.

Abstract

Stomach and colorectal cancers are common cancers and leading causes of cancer deaths. Because the alimentary tract can interact directly with dietary components, stomach and colorectal cancer may be closely related to dietary intake. We systematically searched published literature written in English *via* PubMed by searching for terms related to stomach and colorectal cancer risk and dietary flavonoids up to June 30, 2012. Twenty-three studies out of 209 identified articles were finally selected for the analysis. Log point effect estimates and the corresponding standard errors were calculated using covariate-adjusted point effect estimates and 95%CIs from the selected studies. Total dietary flavonoid intake was not associated with a reduced risk of colorectal or stomach cancer [odds ratio (OR) (95%CI) = 1.00 (0.90-1.11) and 1.07 (0.70-1.61), respectively]. Among flavonoid subclasses, the intake of flavonols, flavan-3-ols, anthocyanidins, and proanthocyanidins showed a significant inverse association with colorectal cancer risk [OR (95%CI) = 0.71 (0.63-0.81), 0.88 (0.79-0.97), 0.68 (0.56-0.82), and 0.72 (0.61-0.85), respectively]. A significant association was found only between flavonols and stomach cancer risk based on a limited number of selected studies [OR (95%CI) = 0.68 (0.46-0.99)]. In the summary estimates from case-control studies, all flavonoid subclasses except flavones and flavanones were inversely associated with colorectal cancer risk, whereas neither total flavonoids nor any subclasses of flavonoids were associated with colorectal cancer risk in the summary estimates based on the cohort studies. The significant association between flavonoid subclasses and cancer risk might be closely related to bias derived from the case-control design. There was no clear evidence that dietary flavonoids are associated with reduced risk of stomach and colorectal cancer.

INTRODUCTION

Stomach and colorectal cancer are common cancers and leading causes of cancer deaths[1]. Because the alimentary tract can interact directly with dietary components, stomach and colorectal cancer may be closely related to dietary intake. The consumption of meat, especially of red and processed meats that produce N-nitrosamine, was positively associated with stomach and colorectal cancer risk in a previous meta-analyses[2-4]. However, fruit and vegetable intakes were inversely associated with

colorectal cancer risk in people with high intakes of red and processed meat[5], and inverse association between vitamin C intake and stomach cancer risk was stronger in high red and processed meat intake group[6]. High fruit and vegetable intakes are associated with beneficial health effects, and these effects have been partly attributed to the high flavonoid content of these foods. Flavonoids are polyphenolic compounds that are abundant in fruits and vegetables. The beneficial health effects of flavonoids have been attributed to their free radical scavenging properties. In addition to their antioxidant properties, flavonoids have antiviral, antiallergic, antiinflammatory, and antitumor activities[7,8]. Flavonoids are generally classified as flavonols, flavones, flavanones, flavanols, isoflavones or anthocyanidins based on their chemical structure[9-11]. The antioxidant activities of the dietary flavonoids and their subclasses vary due to the differences in their chemical structures. Flavonols, the most common flavonoids in foods, include kaempferol, myricetin, quercetin, and isorhamnetin. Among them, quercetin is abundant in onions and apples, and has been studied extensively due to its high bioavailability and strong antioxidant effects. Flavones, such as apigenin and luteolin, are abundant in green leafy spices (*e.g.*, parsley, thyme, and celery), and the flavanones naringenin, hesperetin, and eriodictyol are found in citrus fruits. Flavanols, often referred to as flavan-3-ols, include catechin, gallocatechin, and epicatechin, which are abundant in teas, red wine, and apples. Isoflavones, especially genistein, are found in soy foods and have been studied widely due to their antitumor properties. Anthocyanidins are found in cherries, strawberries, and red wine.

A reduced risk of cardiovascular disease associated with flavonoid intake has been observed in many epidemiological studies[12,13]. Flavonoids have been suggested to reduce the risk of cardiovascular disease by modulating various mechanisms[14]. However, the association between cancer risk and dietary flavonoid intake has less supportive evidence from epidemiological studies, and the results have been inconsistent. To date, meta-analyses have focused mainly on dietary flavonoids and cardiovascular disease[12,13] or tea flavonoids and lung cancer[15,16]. Thus, we performed a meta-analysis of summary data to calculate the effect estimates of dietary flavonoid intake, including individual subclasses of flavonoids, on stomach and colorectal cancer risk.

DIETARY FLAVONOID INTAKE AND RISK OF STOMACH AND COLORECTAL CANCER

English-language studies were systemically searched using PubMed with the phrase "cancer risk and (stomach or gastric or colorectal or colon or bowel or rectal) and (flavonoid or flavonol or quercetin or kaempferol or myricetin or isorhamnetin or flavone or luteolin or apigenin or flavanone or eriodictyol or hesperetin or naringenin or flavan-3-ol or catechin or epicatechin or theaflavin or anthocyanidin or cyanidin or delphinidin or malvidin or pelargonidin or peonidin or petunidin or proanthocyanidin or isoflavone)" up to June 30, 2012. The inclusion criteria were as follows: (1) original articles with a case-control or cohort design; (2) articles reporting intake of either total flavonoids or subclasses of flavonoids and stomach or colorectal cancer; (3) articles with at least 3 categories of dietary flavonoid intake; and (4) studies reporting adjusted odds ratios (OR) or relative risks (RR) with 95%CIs for the risk of stomach or colorectal cancer in subjects with the highest dietary flavonoid intake compared with those with the lowest intake of dietary flavonoids.

The retrieved studies were reviewed independently by two investigators (Woo HD and Kim J). Data on authors, publication year, types of flavonoids, cancer sites, country in which the study was performed, number of cases and controls, categories of flavonoids or subclasses of flavonoids, subclasses included in the calculation of total flavonoids, and adjusted OR/RR and 95%CI were collected for the meta-analysis. The multivariate-adjusted values for OR/RR and 95%CI were selected for the meta-analysis to reduce the effects of potential confounding variables. If there was additional adjustment for fruit and vegetable intake, the adjusted values were selected.

All statistical analyses were performed using the STATA software package (version 10; Stata Corp, College Station, TX, United States). Log point effect estimates and the corresponding standard errors were calculated using the covariate-adjusted point effect estimates and 95%CI from selected studies and weighted by the inverse variance to calculate the summary estimates[17]. The heterogeneity across studies was measured using the Q-test based on the χ^2 statistic. Heterogeneity was considered statistically significant when $P < 0.1$ for the Q-test and was quantified using the I^2 test as described by Higgins *et al*[18]. Based on the heterogeneity of the included studies, fixed or random effects models were selected to calculate the pooled effect measures. Sensitivity analyses were performed to test the robustness of the results of the combined effects.

A total of 209 studies were identified, and 160 studies were excluded based on the titles and abstracts. The full texts of the remaining 49 studies were reviewed, and 25 studies were excluded for the following reasons: 7 studies were not related to dietary flavonoid intake or any of the flavonoid subclasses; 5 studies presented only recurrence or survival analysis data; 5 studies were not related to stomach or colorectal cancer: 4 studies did not report cancer risk; 2 studies were review articles; and 2 studies reported plasma concentrations instead of dietary flavonoid intake.

Sensitivity tests were conducted for the remaining 24 studies of total flavonoids and each subclass of flavonoids. One study showing substantial influence on the summary estimates in the sensitivity tests was excluded[19]. Thus, 23 studies, comprising 13 case-control

studies and 10 cohort studies, were finally selected to estimate the overall effects of total dietary flavonoid or flavonoid subclass intake on stomach and colorectal cancer risk (Table 1)[20-42]. Begg's funnel plot and Egger's test were used to evaluate the publication bias in studies of total flavonoids and each subclass of flavonoids. Egger's test showed no significant bias.

The summary estimates for the risk of cancer in subjects with the highest dietary flavonoid intake, compared with that in subjects with the lowest flavonoid intake, are presented in Table 2. The heterogeneity was low in the overall results, but heterogeneity was found in several summary estimates of the studies that included mostly case-control design. Total dietary flavonoids were not associated with a reduced risk of colorectal or stomach cancer [OR (95%CI) = 1.00 (0.90-1.11) and 1.07 (0.70-1.61), respectively]. However, flavonol, flavan-3-ol, anthocyanidin, and proanthocyanidin intakes showed a significant inverse association with colorectal cancer risk among flavonoid subclasses [OR (95%CI) = 0.71 (0.63-0.81), 0.88 (0.79-0.97), 0.68 (0.56-0.82), and 0.72 (0.61-0.85), respectively]. A significant association was found only for flavonol intake and stomach cancer risk in a limited number of selected studies [OR (95%CI) = 0.68 (0.46-0.99)].

Subgroup analyses by study design or sex were conducted for each subclass of flavonoids. In case-control studies, all flavonoid subclasses except flavones and flavanones were inversely associated with colorectal cancer risk. However, neither total flavonoids nor any subclasses of flavonoids were associated with colorectal cancer risk in the cohort studies. Colorectal cancer showed a statistically significant association for the summary estimate of flavonols in both female and male subjects [OR (95%CI) = 0.84 (0.75-0.93) and 0.87 (0.79-0.96), respectively] and isoflavones in male subjects [OR (95%CI) = 0.90 (0.83-0.99)]. A reduced risk of colorectal cancer was not observed for the subclasses of flavonols.

The preventative effects of flavonoids on stomach and colorectal cancer risk were estimated by pooling the estimates based on the published observational studies. Total dietary flavonoid intake was not associated with a reduced risk of stomach and colorectal cancer, but several subclasses of flavonoids, mostly in case-control studies, showed protective effects against stomach and colorectal cancer risk.

Flavonoids could affect cancer risk through their antiinflammatory and antitumor activities. Flavonoids exert their antiinflammatory activities by inhibiting cycloxygenase-2 (COX2) in colon cancer cells, and this is associated with a reduced risk of colorectal cancer[43]. Plant flavonoids induce apoptosis and suppress the growth of colon cancer cells by inhibiting the COX2- and Wnt/epidermal growth factor receptor/nuclear factor-κB-signaling pathways, which play crucial roles in colorectal cancer[44]. Quercetin inhibits tyrosine kinase activity, thus downregulating cell proliferation[45]. The antitumor effects of flavonoids have not been demonstrated conclusively, but it has been suggested that the free radical scavenging properties of flavonoids are closely related to beneficial effects on cancer risk, as flavonoids are more effective antioxidants than vitamin C, vitamin E and carotenoids[46]. Hydroxylation at the 3-position on the C ring, the increased number of hydroxyl groups in ring B, and a saturated 2-3 bond on the C ring showed enhanced scavenging activities[47,48].

Reduced risks of colorectal cancer were observed in the summary estimates for flavonols, flavan-3-ols, anthocyanidins, and proanthocyanidins in the present study, as well as in subgroup analyses. The intake of total dietary flavonols and dietary quercetin were associated with a significant reduction of stomach cancer risk. These results might be attributed to the antiinflammatory and antitumor effects of those nutrients. However, no reduced risk of stomach and colorectal cancer was observed in the summary estimates of total dietary flavonoids, including the subgroup analyses by sex and study design, in the present meta-analysis. The subclasses of flavonoids included in the calculations of total flavonoids were different across studies, as shown in Table 1. All studies included flavonols and flavones among the total dietary flavonoids, but flavan-3-ols, proanthocyanidins, which can contribute a considerable proportion of the total flavonoid intake, were not considered in most studies. These discrepancies can lead to highly heterogeneous results. However, the overall results were homogenous in terms of the effects of total flavonoids, except for the summary estimate of case-control studies, which showed moderate heterogeneity. Thus, dietary flavonoid intake might not be truly associated with stomach or colorectal cancer risk. Furthermore, dietary intake of quercetin, kaempferol, and myricetin showed no significant association with colorectal cancer risk, whereas total dietary flavonols showed statistically significant results for both cancer types. These results might be closely related to the design of the selected studies. The studies that investigated total flavonoids as well as the flavonols quercetin, kaempferol and myricetin were mostly cohort designs, while the studies that investigated total flavonols were mostly case-control designs. Case-control studies are more subject to recall bias, resulting in either an underestimate or overestimate of the risk estimates. Especially in stomach and colorectal cancer, patients might have intestinal discomfort prior to diagnosis, resulting in changes in dietary habits. Similar results were found in a meta-analysis of fruit and vegetable consumption[49]. A statistically significant association between the risk of stomach and colorectal cancer and fruit and vegetable consumption was observed only in the summary estimate of case-control studies. This summary risk estimate was highly heterogeneous, unlike that of the cohort studies, suggesting that bias might be introduced in case-control studies. Another explanation for the lack of association in cohort studies is the typically short follow-up times. In a meta-analysis of association between fruit and vegetable consumption and gastric cancer risk[50], a

[a]Selected study numbers; [b]*P* values for heterogeneity from *Q*-test; [c]Random effects model was used if $P < 0.1$. RR: Relative risk.

significant association was observed only in the meta-analyses of studies with more than 10 years of follow-up. Meta-regression also revealed that longer follow-up time was associated with lower risk of gastric cancer. The mean follow-up times were more than 10 years for all cohort studies reporting total dietary flavonoid intake in our study, except for Hirvonen *et al*[35]. A meta-analysis performed after excluding this study did not change the results. Thus, the hypothesis of an inverse association between dietary flavonoids and risk of stomach and colorectal cancer cannot be supported by our results.

Although this meta-analysis provided little evidence of an inverse association between stomach and colorectal cancer risk and flavonoid intake, several mechanisms supported by *in vitro* and animal studies remain biologically plausible. Antitumor effects were shown for quercetin, luteolin, and myricetin[51-54], and polyphenols extracted from apple and olive oil had a chemopreven-

tive effect in colon cancer cell lines or mice[55-57] and antioxidant activities in gastric mucosa[58,59]. Most subclasses of flavonoids were inversely associated in the present meta-analyses, although some bias might have been introduced. Thus, it is thought that dietary flavonoids are inversely associated with stomach or colorectal cancer risk, but this association is very small, making it difficult to detect. The United States Department of Agriculture (USDA) database for food flavonoids has been updated several times since 2003[60]. Most total dietary flavonoids are flavan-3-ols (82.5%), as estimated by USDA database and 24 h dietary records provided by United States adults[61]. The second greatest contributor was flavanones (7.6%), followed by flavonols (6.8%), anthocyanidins (1.6%), flavones (0.8%), and isoflavones (0.6%). However, the bioavailability of these compounds might be different. For example, tea flavonoids showed low absorption rates, whereas quercetin and isoflavones showed strong bioavailability. The main source of dietary flavonoid subclasses in Scotland in a database by Kyle *et al*[62] was tea[24], whereas the main sources of total flavonoids in Spain[31], calculated using the USDA database[60], were fruits (65.1%), followed by wine (14.4%), legumes (6.3%), and vegetables (4.2%). The methods used to estimate total flavonoids from dietary intake are poorly established[61]. Levels of exact individual flavonoid intake from food should be determined to confirm the true association between flavonoids and stomach and colorectal cancer risk.

The main limitation of this study is the small number of publications included. Especially in the case of stomach cancer, summary estimates could not be calculated in several subgroup analyses due to the limited number of studies. Because a significant association was found in the analyses of case-control studies which were subject to bias, the inverse association between subclasses of dietary flavonoid intake and cancer risk may be overestimated.

CONCLUSION

There was no clear evidence that dietary flavonoids are associated with reduced risk of stomach and colorectal cancer in the present meta-analysis. However, there is a possibility that there may be a weak association with stomach and colorectal cancer based on consistent associations for subclasses of flavonoids. The association of flavonoids with stomach and colorectal cancer could be relatively small and thus might only be detected with better methods of estimating true dietary flavonoid intake.

Abstract

To summarize the evidence about the association between red and processed meat intake and the risk of esophageal cancer, we systematically searched the PubMed and EMBASE databases up to May 2012, with a restriction to English publications, and the references of the retrieved articles. We combined the study-specific relative risks (RRs) and 95%CI, comparing the highest with the lowest categories of consumption by using a random-effects model. A total of 4 cohort studies and 23 case-control studies were included in the meta-analysis. The combined RRs (95%CI) of the cohort studies comparing the highest and lowest categories were 1.26 (1.00-1.59) for red meat and 1.25 (0.83-1.86) for processed meat. For the case-control studies, the combined RRs (95%CI) comparing the highest and lowest categories were 1.44 (1.16-1.80) for red meat and 1.36 (1.07-1.74) for processed meat. Findings from this meta-analysis suggest that a higher consumption of red meat was associated with a greater risk of esophageal cancer.

Choi Y, Song S, Song Y, Lee JE. Consumption of red and processed meat and esophageal cancer risk: Meta-analysis. *World J Gastroenterol* 2013; 19(7): 1020-1029 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1020.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1020

INTRODUCTION

The incidence rate of esophageal cancer ranked eighth worldwide, accounting for 3.8% of all new cancers, and its mortality rate ranked sixth, accounting for 5.4% of all cancer deaths in 2008[1]. The most predominant histological types of esophageal cancer are esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC), representing distinct characteristics in patterns of cancer development and risk factors[2].

Given that mutagenic compounds such as heterocyclic amines (HCAs), polycyclic aromatic hydrocarbons (PAHs), and N-nitroso compounds (NOCs) generated from red and processed meats were associated with cancer development[3], concerns about a high incidence of esophageal cancer related to a high consumption of red and processed meats have been increasing. In 2007, a consensus report of experts assembled by the World Cancer Research Fund (WCRF) and the American Institute for Cancer Research (AICR)[4] concluded through review of studies published up to 2004 that there were suggestive but inconclusive associations between red and processed meat consumption

and esophageal cancer risk. The WCRF/AICR expert report also indicated that the lack of consistent results may be because of insufficient data, especially from prospective cohort studies. Another review of studies published up to 2005[5] suggested a possible increased risk of esophageal cancer with processed meat (9 case-control studies) and combined white and red meat (2 cohort and 18 case-control studies); however, this study concluded that more prospective data involving a larger number of cases would be needed to determine the association between meat consumption and the risk of esophageal cancer.

Since the completion of the two reviews, the results of the large prospective studies as well as new or updated case-control studies that examined association between red and processed meats and esophageal cancer risk have been published, but no meta-analysis of the prospective cohort studies has been reported. We, therefore, performed a meta-analysis of large prospective cohort and case-control studies to summarize the association between red and processed meat intake and the risk of esophageal cancer. We also quantified the dose-response relationships in the analysis of the cohort studies.

SEARCH STRATEGY

Two authors (Choi Y, Song S) independently performed a systematic search of published articles using the PubMed and EMBASE databases up to May 2012[6]. We used the following search terms: "oesophageal or esophageal or esophagus or oesophagus" and "cancer or neoplasm or carcinoma" and "cohort or prospective or case-control" and "food or diet or meat". We also reviewed the reference lists from the retrieved articles and those from previous review studies to identify additional relevant studies that may not have been identified by our database searches.

INCLUSION CRITERIA

Studies were included in our meta-analysis if they met the following criteria: (1) either a cohort or case-control design was used; (2) relative risk (RR) estimates and the 95%CI were provided for the association between red and/or processed meat intake and esophageal cancer; (3) the outcomes of interest were either the overall incidence of esophageal cancer or the two main histological subtypes, ESCC or EAC; and (4) the study was published in English. We included studies that reported the associations of esophageal cancer with exposures identified as "red meat" or "processed meat" and individual food items within the two groups. Studies generally included beef, pork, minced meat, lamb, veal, and offal (*e.g.*, liver, kidney) for unprocessed red meat and sausage, ham, bacon, salami, luncheon meat, or frankfurters, and any types of meat that were processed by smoking, curing, salting, or the addition of preservatives for processed meat. We excluded studies providing no apparent classification of meat or studies reporting a combination of red and white meat (*e.g.*, poultry). If data were duplicated in more than 1 study, the latest studies were included.

DATA EXTRACTION

We independently extracted the following data from each study, according to the meta-analysis of observational studies in epidemiology guidelines[6], and any discrepancies were resolved by discussion: the first author's last name, the publication year, the country where the study was conducted, the study period, the age range of the subjects, the number of cases and controls or the cohort size, the measures and comparison levels of the exposures, the multivariate adjusted RRs with corresponding 95%CI for the highest *vs* lowest categories of red or processed meat intake, and the variables that were adjusted for in the analysis. For each study, we used the most fully adjusted RRs in the multivariate model. Any disagreements were resolved through consensus. The same two authors assessed the quality of the studies based on the Newcastle-Ottawa Scale, which ranged from 1 to 9 stars[7]. The average score for each study was used in the analysis.

STATISTICAL ANALYSIS

We conducted separate meta-analyses for case-control and cohort studies, using results that compared red and processed meat intake as well as those that assessed each type individually. We also performed a meta-analysis combining both case-control and cohort studies. Using a random-effects model that considered both within and between study variation[8], we combined the study-specific multivariate RRs and 95%CI, comparing the highest and the lowest categories of red and processed meat intake.

We assessed the statistical heterogeneity among the studies by using Q and I^2 statistics[9], where significance was reached at $P < 0.1$. Publication bias was evaluated by using the Egger asymmetry test[10], with significant level at $P < 0.05$. We investigated the potential sources of heterogeneity among the studies by conducting subgroup and meta-regression analyses for histological subtype (ESCC and EAC), sex (males, females, and both sexes), study location (Asia, Europe, North America, and South America), study quality, and confounders adjusted for in the analysis [alcohol, smoking, body mass index (BMI), and fruit and/or vegetable]. We also conducted the sensitivity analysis for case-control and cohort studies separately, omitting each study individually to evaluate whether the results could have been affected substantially by any one study.

In a sensitivity analysis, we estimated a dose-response for combined RRs for 100 g/d increments of red or processed meats for 3 cohort studies[11-13], which are less prone to selection or recall bias than case-control studies. We did not include one study (Yu *et al*[14]), that presented binary categories of exposure for a dose-response analysis. For two studies[11,13], the estimates were rescaled into 100 g/d increments. All statistical analyses were performed with Stata software, version 11 (Stata Corp., College Station, TX, United States). $P < 0.05$ considered statistically significant.

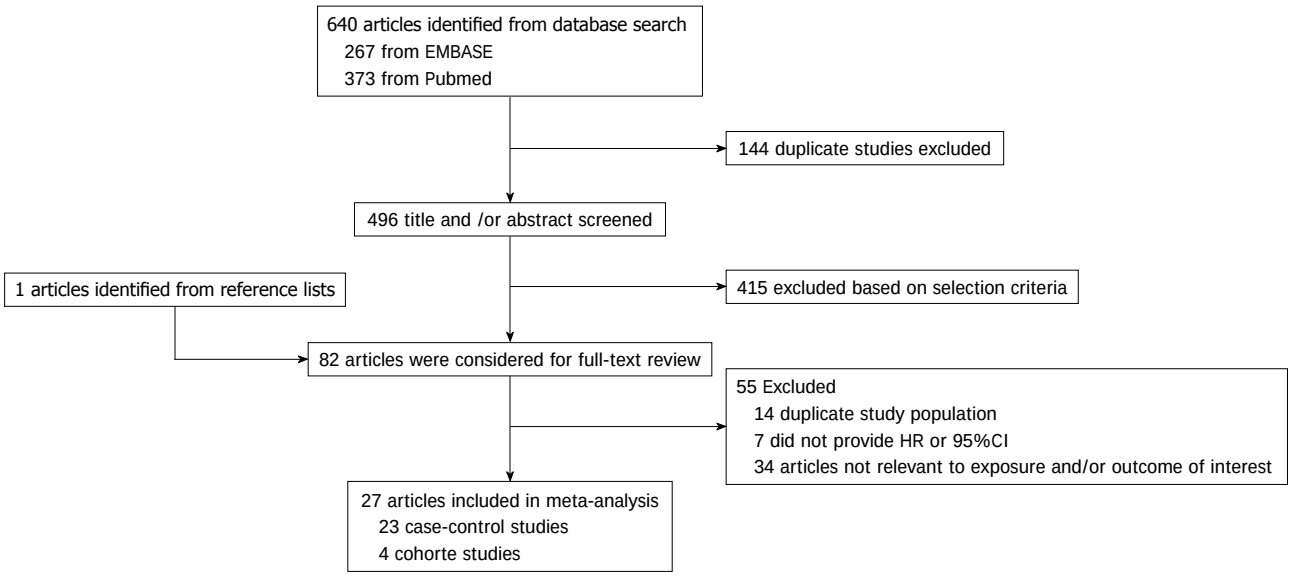

Figure 1 Selection of studies included in meta-analysis.

LITERATURE SEARCH

The preliminary literature search yielded 640 articles. Of these, 81 articles and 1 additional article identified from the reference lists were considered for further review (Figure 1). After the full-text review, 7 articles that did not provide RRs or 95%CI, 14 articles that used duplicated study populations, and 34 articles that were unrelated to exposure or outcomes of interest were excluded. A total of 27 articles were included in the meta-analysis; 22 articles (4 cohort and 18 case-control studies) that reported findings on red meat and 18 articles (3 cohorts and 15 case-controls) that reported findings on processed meat were included in the meta-analysis.

RED MEAT INTAKE

We identified 4 cohorts studies[11-14] involving 2324 cases and 1 149 981 participants and 18 case-control studies[15-32] involving 5165 cases and 26 350 control subjects (Table 1). Two of the 22 studies reported results for both ESCC and EAC, 16 studies reported the results for either EAC or ESCC, and 6 reported results for overall esophageal cancer without the histological subtypes. Six studies were conducted in Asia, 6 in Europe, 7 in United States, and 3 in South America. The studies used either a food frequency questionnaire (FFQ) or a structured questionnaire form to measure red meat intake. Fifteen studies provided RR estimates that were adjusted for alcohol intake, 16 for smoking habit, 12 for BMI, and 7 for fruit and/or vegetable intake. Eight studies were given a score of 7 stars or above, representing a high quality of studies[7]. The combined RRs (95%CI) comparing the highest and lowest categories of red meat intake were 1.26 (1.00-1.59) for the 4 cohort studies and 1.44 (1.16-1.80) for the 18 case-control studies (Figure 2A). There was no evidence of heterogeneity among the cohort studies ($P = 0.15$, $I^2 = 35.3\%$), but there was a heterogeneity among the case-control studies ($P < 0.01$, $I^2 = 72.8\%$). Combining the two types of study design resulted in an overall combined RR of 1.38 (95%CI: 1.17-1.64; P for heterogeneity: $P < 0.01$, $I^2 = 67.1\%$). Excluding a single study did not substantially influence the combined estimates of the cohort or case-control studies. There was no statistical evidence of publication bias according to the Egger asymmetry test ($P = 0.79$ for cohort studies and $P = 0.34$ for case-control studies). Dose-response associations were examined in 3[11-13] of 4 cohort studies, showing the combined RRs of 1.05 (95%CI: 0.91-1.21; P for heterogeneity = 0.42, $I^2 = 0.2\%$) for every 100 g/d increment of red meat intake. The associations did not vary significantly by histological subtypes, study location, sex, and study quality (Table 2). In addition, the associations did not differ by adjusted confounding factors including alcohol, smoking, BMI, and fruit and vegetable intakes (data not shown).

PROCESSED MEAT INTAKE

We conducted a meta-analysis of 3 cohort studies[11-13], which included 1162 cases and 1 137 288 participants and 15 case-control studies[15,16,19-21,24,25,27,30,32-37], which included 3851 cases and 10 064 controls (Table 1). Two of the 18 studies examined both ESCC and EAC as the primary endpoints, 13 studies reported the results for either EAC or ESCC and 5 did not differentiate between histological subtypes. Five studies were conducted in Asia, 7 in Europe, 5 in United States, and 1 in South America. The studies used either a FFQ or a structured questionnaire form to measure processed meat intake. Fourteen studies provided RR estimates that were adjusted for alcohol intake, 15 for smoking habit, 10 for BMI, and 8 for fruit and/or vegetable intake. Six studies were given a score of 7 or greater, indicating a high methodological quality[7].

A

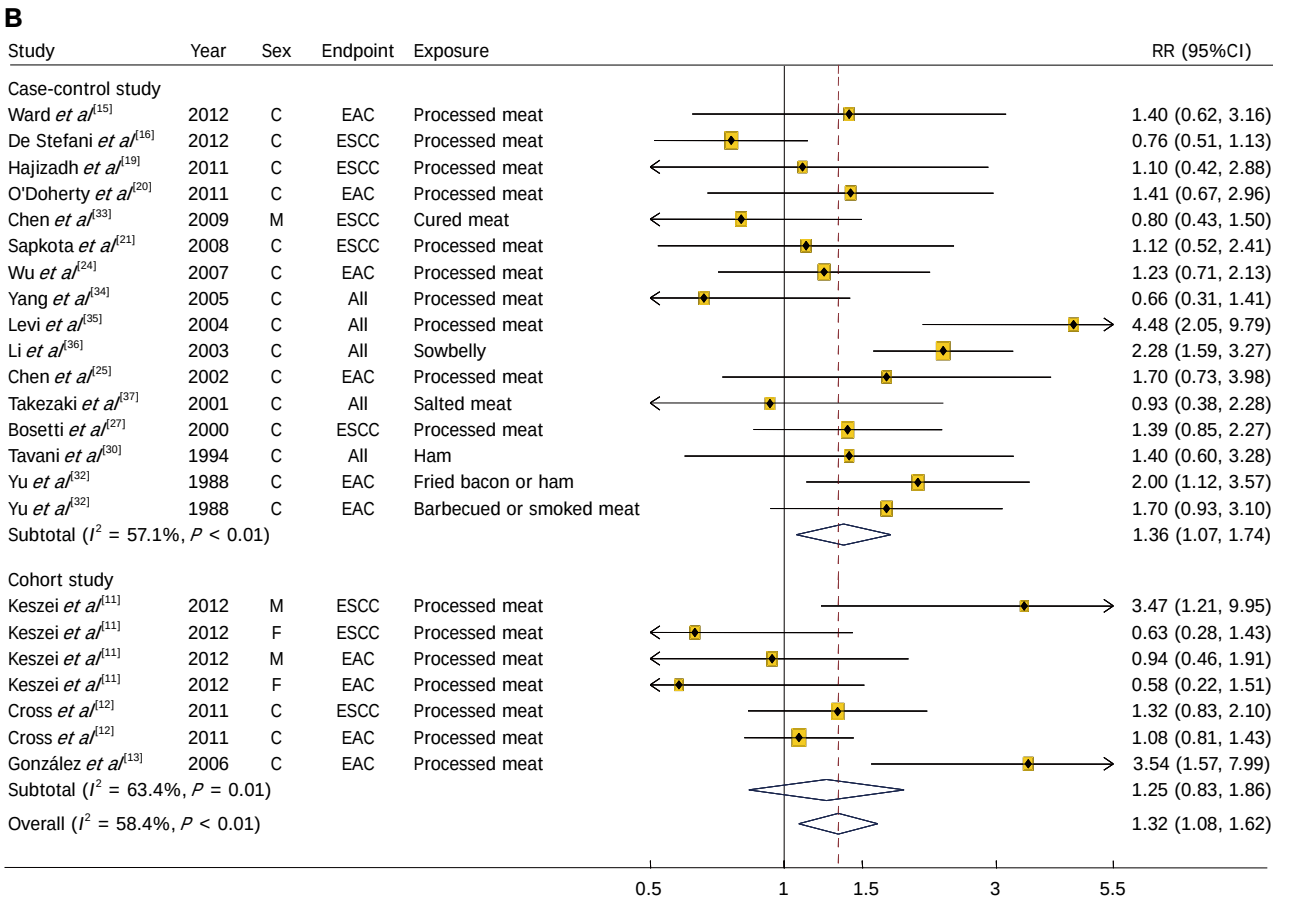

Figure 2 The combined relative risks and 95%CI of esophageal cancer risk for the highest *vs* lowest categories of red meat (A) and processed meat (B). M: Male; F: Female; C: Combined males and females; ESCC: Esophageal squamous cell carcinoma; EAC: Esophageal adenocarcinoma.

In a meta-analysis of the 15 case-control studies, we found that the highest categories of processed meat intake were associated with a 36% increase in esophageal cancer risk when compared with the lowest categories (95%CI: 1.07-1.74; Figure 2B); however, we found a non-significant, positive association when we examined only the cohort studies (RR: 1.25; 95%CI: 0.83-1.86). When we examined whether an individual study was the source of heterogeneity among either the cohort or case-control studies, there were heterogeneities between the case-control studies (P < 0.01, I^2 = 57.1%) and the cohort studies (P = 0.01, I^2 = 63.4%). When the results from the cohort and case-control studies were combined, the overall combined RR comparing the highest and the lowest category of processed meat was 1.32 (95%CI: 1.08-1.62; P for heterogeneity: P < 0.01, I^2 = 58.4%). The heterogeneity observed between the prospective studies of processed meat intake and esophageal cancer risk was no longer significant (P = 0.12) after excluding a study by González *et al*[13]. However, excluding any one case-control study from the analysis did not influence the heterogeneity findings observed among case-control studies.

No publication bias was found for either the cohort or case-control studies (P = 0.65 for the cohort studies and P = 0.80 for the case-control studies). In a dose-response meta-analysis of 3 cohort studies, we found that each 100 g/d increase in processed meat intake was positively, but not significantly, associated with esophageal cancer risk (RR: 1.37; 95%CI: 0.88-2.13). There was no evidence of heterogeneity (P = 0.17, I^2 = 33.5%).

When stratifying the analyses by histological subtypes, study location, sex, and study quality, we found no significant differences in the associations, although the magnitude of the associations differed slightly in these subgroups (Table 2). The associations also did not vary by adjusted confounding factors including alcohol, smoking, BMI, and fruit and vegetable intakes (data not shown).

DISCUSSION

To our knowledge, this is the first systematic meta-analysis of cohort and case-control studies to summarize the evidence regarding the association between red or processed meat intake and the risk of esophageal cancer. High red meat consumption was associated with a 38% higher risk of esophageal cancer compared to low consumption in a meta-analysis of both case-control and cohort studies. A 26% higher risk of esophageal cancer was observed among those who had high red meat intake compared to those with low intake in a meta-analysis of 4 cohort studies. With regard to processed meat, we found a higher risk of esophageal cancer with high processed

meat intake compared to low intake in a meta-analysis of case-control studies, but the combined estimate of cohort studies did not reach statistical significance. Prospective cohort studies are less prone to selection or recall bias compared to case-control studies, which is critical in research of diet and cancer etiology. Therefore, a significant association in only the case-control studies and not in the meta-analysis of the 3 cohort studies could not provide adequate supportive evidence of an increased risk associated with processed meat consumption. However, the results for more prospective cohort studies need to be reported to obtain a clearer conclusion.

There are possible underlying mechanisms linking the consumption of red and processed meats and the incidence of cancer. HCAs and PAHs are chemical compounds with mutagenic potential that are formed when meat is boiled, fried, or grilled at high temperatures[3]. Animal studies have suggested that these two mutagenic compounds may induce changes in DNA, possibly promoting carcinogenesis[3,38]. Another class of meat-related mutagen is NOCs, the majority of which are potent carcinogens[39] formed either endogenously or exogenously. Processed meat is typically preserved by adding nitrate or nitrite, which increases the formation of NOCs[3]. Heme iron, largely derived from red meat sources, has been suggested to promote the endogenous formation of NOCs[40]. There is only limited epidemiological evidence, however, to suggest that the dietary intake of nitrite or nitrosamine is positively associated with the risk of esophageal cancer[5]. The esophagus is frequently exposed to these dietary mutagenic and/or carcinogenic compounds as stomach and colon, permitting food to pass from the esophagus into the stomach. While the specific mechanism by which meat causes esophageal cancer has not been fully elucidated, one likely reason may involve the potential for increase the susceptibility to carcinogenesis by repeated exposure of esophagus to the mutagenic and/or carcinogenic compounds, given their effects on carcinogenesis in animal models[3,38,39].

The results from the subgroup and meta-regression analysis could not completely explain the potential sources of between-study heterogeneity because we did not observe statistically significant differences by histological subtype, study location, sex, or study quality. For red meat intake, it appeared that a single study did not substantially influence the overall combined RR, whereas, the observed heterogeneity among the prospective studies of processed meat intake and esophageal cancer risk disappeared when the study by González *et al*[13] was excluded. However, the observed heterogeneity among the case-control studies of processed meat intake and esophageal cancer risk was not martially altered in sensitivity analyses excluding one study at a time.

Our meta-analysis had some limitations. Although the majority of the studies adjusted for known potential confounding factors, there may be a possibility that unidentified or residual confounding factors remained that were not adjusted for in the multivariate analysis or by covariates inadequately measured. Most studies, however, adjusted for alcohol and smoking, both of which are established risk factors for esophageal cancer. Additionally, we found an increased risk of esophageal cancer with high red meat intake in a meta-analysis of well-scored studies, which were relatively recent and adjusted for various potential confounding factors. The random measurement error of meat consumption that occurred during dietary assessment or the systematic error resulting from recall or selection bias in the case-control studies may have influenced our findings; however, we found a statistically significant association between red meat intake and esophageal cancer risk in a meta-analysis of prospective studies, which supports the hypothesis that red meat intake increases the risk of esophageal cancer.

Our meta-analysis also included several strengths. Our meta-analysis updated the recent large prospective and case-control studies with a larger number of cases that were not included in previous reviews. In particular, the inclusion of new data from large cohort studies, which were unavailable when earlier conclusions of these associations were made by the WCRF/AICR expert panel[4] or by a review study[5], enabled us to provide more unbiased evidence compared to the review that included only case-control studies. The findings from this meta-analysis were not subject to publication bias, indicating that the probability of publishing a study did not rely on the strength and direction of the associations.

CONCLUSION

The findings from our meta-analysis of either prospective cohort or case-control studies suggest that a high consumption of red meat may increase the risk of esophageal cancer. Although we found an increased risk in a meta-analysis of the case-control studies for processed meat intake in relation to esophageal cancer risk, the prospective cohort studies did not strongly support this evidence. There is a need for further large scale prospective studies to determine whether processed meat intake increases the risk of esophageal cancer. Moreover, further studies evaluating the effect of red or processed meat intake on individual histological subtypes of esophageal cancer are warranted.

ACKNOWLEDGMENTS

We thank Dr. Cross for data provision for our dose-response meta-analysis part.

Abstract

Current progress in epigenetic research supports the view that diet and dietary components are important in cancer etiology by enhancing or inhibiting carcinogenesis. Since diet and dietary factors may significantly contribute to the causation and progression of many cancers, it is important to find the molecular mechanisms of action of such dietary factors for cancer prevention and treatment. Recently, the role of epigenetic mechanisms in the cancer development and progression has attracted more attention as additional evidence along with traditional DNA sequence based mechanisms such as mutations and structural re-arrangements. Such an increasing interest in cancer epigenetics has also accelerated the development and application of molecular assays and tools for DNA methylation detection and histone modification enrichment analysis. In this paper, key assays and methods for epigenetic research are reviewed and discussed in terms of their utility and usability. In addition, more advanced methods for genome-wide analysis are introduced as part of upcoming research trends and directions.

INTRODUCTION

Diet and dietary factors play an important role in many biological processes and are also involved in the regulation of pathological progressions including cancers. Several epidemiological and preclinical studies suggested that increased intake of bioactive dietary components may modulate cancer risk. Many studies provide compelling evidence that part of the anti-cancer properties contributed to several bioactive dietary components may relate to modulation of epigenetic process including DNA methylation and histone protein modifications. Here, we provide a brief overview of dietary modulation of DNA methylation and histone modifications and its potential role in cancer prevention. Also, we will discuss several new epigenetic methods to help understand the effect of dietary factors on epigenetic modifications.

EPIGENETICS AND CANCER

The growing interest in the role of epigenetics in cancer came from the demonstration that epigenetic modifications are involved in tumor development and progression. Epigenetics can be defined as phenomena that alter the expression of the information in the genome at the transcriptional, translational, or posttranslational

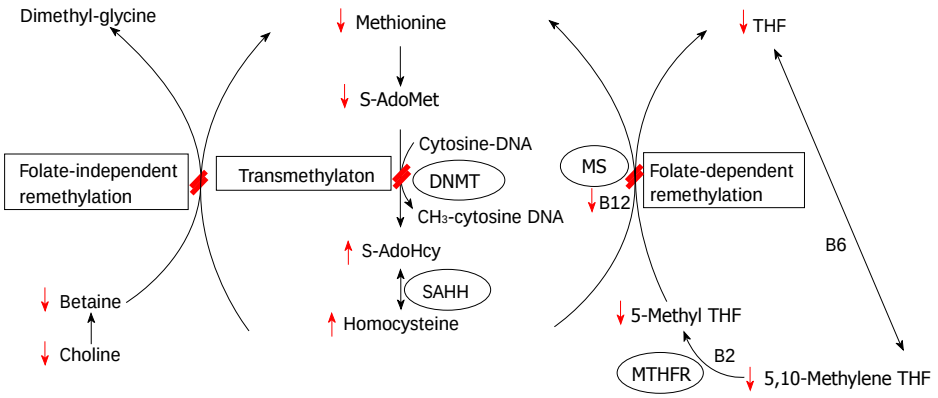

Figure 1 Effect of methyl-deficiency on biological methylation pathway. S-AdoMet: S-adenosylmethionine; S-AdoHcy: S-adensylhomocysteine; DNMT: DNA methyltransferase; SAHH: S-adenosylhomocysteine hydrolase; MS: Methionine synthase; THF: Tetrahydrofolate; MTHFR: Methylenetetrahydrofolate reductase.

level without change in DNA sequence[1,2]. Epigenetic information is maintained to preserve cellular identity in normal cells, while cancer cells are characterized by profound alteration of epigenetic regulation[3-7]. The overall disruption of epigenetic phenomena is a common feature of all human tumors and includes alteration of DNA methylation and histone modification patterns[8]. DNA methylation patterns of neoplastic cells have been recognized as being substantially altered compared with normal cells[3,4]. Two types of changes in the DNA methylation pattern can occur in cancer: global DNA hypomethylation and hypermethylation of CpG islands which are associated with gene silencing[3,4,7]. DNA in eukaryotic cells is intimately associated with a family of small, basic histone proteins forming a highly ordered and condensed DNA-protein complex termed chromatin. Because of this chromatin structure, changes in DNA methylation in cancer cells are not isolated events; they occur in the context of more complex epigenetic deregulation[9]. Chromatin is the physiological template of the genetic information and is composed of DNA, histones, and other chromosomal proteins. The fundamental repeating unit of chromatin is the nucleosome octamer, which consists of 147 base pairs of DNA wrapped around 2 copies each of histones H2A, H2B, H3 and H4[10]. The amino-terminal tails of histones are subject to posttranslational modifications, including acetylation, methylation, phosphorylation, ubiquitination, SUMOylation, and ADP-ribosylation[11], and multiple histone modifications may occur on a given histone tail[12]. Histone modifications patterns distinguish the structure of chromatin status, in particular, acetylation of histone H3 and H4 is associated with active gene expression with open chromatin structure. Histone acetylation is regulated by several enzymes such as histone acetyltransferase and histone deacetylases activity. Aberrations in post-translational modifications of histones have been shown to occur in cancer cells. Although alterations in global histone modification patterns in cancer cells have remained unknown, recent studies on global histone modifications at specific amino acids have been suggested as predictive clinical outcomes for various cancers[13-15]. Additionally, a number of studies have been focused only on changes of a particular histone modification at individual gene promoters in cancer cells.

DNA METHYLATION

Methyl-deficient diet induced hepatocarcinogenesis

In last 4 decades, researchers have developed various tools for exploring DNA methylation, and started to apply those new technologies to the field of nutrition science. The methyl-deficient model of endogenous hepatocarcinogenesis is one of which in DNA methylation has been extensively studied. This animal model is unique in that dietary omission rather than chemical carcinogens addition can lead to tumor formation[16]. Specifically, deficiency of the major dietary sources of methyl groups - methionine, choline, folic acid and vitamin B12 - leads to the development of liver cancers in rats and certain mouse strains[17-19]. From early 1990, these animal models have shown that the methyl-deficiency is associated with several defects, including genome-wide DNA hypomethylation and gene-specific hypermethylation[20-22]. Importantly, the aberrant epigenetic alterations imposed by this diet have been hypothesized to be the primary mechanism responsible for malignant transformation of rat liver cells[15,20,22,23]. Figure 1 displays a simplified version of biological methylation pathway from one-carbon metabolism, emphasizing that various dietary methyl sources (methionine, choline, various coenzymatic forms of folate and vitamin B2, B6 and B12) play an important roles in DNA methylation. Methyl source deficiency has marked effects on the flow of one-carbon units through this web of reactions as the effect of methyl source deficiency are highlighted in red. The major effect observed in methyl deficiency models is a rapid decrease in hepatic S-adenosylmethionine (SAdoMet) levels and genomic DNA hypomethylation. In other recent studies examining the early stages of hepatocarcinogenesis induced by methyl deficiency in rats, substantial alterations in other aspects of the epigenetic machinery have been observed, including aberrant expression of DNA methyltransferases and methyl-CpG

Table 1 DNA methylation analyses used in methyl-deficient model of hepatocarcinogenesis in rodents

Dietary component	Model	Observations	Methylation assay	Ref.
Amino acid-defined diet lacking choline, methionine, folic acid and vitamin B12	Rat	Depletion of SAdoMet and DNA hypomethylation	Liver DNA methyltransferase activity assay with labeled SAdoMet	[20]
Amino acid-defined diet lacking choline, methionine, folic acid and vitamin B12	Rat	Hypomethylation of CCGG site of c-myc, c-fos and c-Ha-ras	Enzyme digestion by *Hpa* Ⅱ/*Msp* Ⅰ	[21]
Diet low in methionine lacking in choline and folic acid	Rat	Hypermethylation of $p16^{INK4A}$	MS-PCR	[94]
Diet low in methionine lacking in choline and folic acid	Rat	Decrease in the total percent of methylated CCGG sites in DNA	*Hpa* Ⅱ/*Msp* Ⅰ-based cytosine extension assay	[22]
Diet low in methionine lacking in choline and folic acid	Rat	Depletion of S-AdoMet, decrease in S-AdoMet/S-AdoHcy and global DNA hypomethylation	*Hpa* Ⅱ/*Msp* Ⅰ-based cytosine extension assay	[23]
Diet low in methionine lacking in choline and folic acid	Rat	Hypomethylation of ID element and LINE-1 in preneoplastic livers and liver tumors; Decrease in histone H4-Lys20 trimethylation and increase in histone H3-Lys9 trimethylation; Decrease in histone H4-Lys20 trimethylation at the LINE-1 regulatory region	ID methylation by methylation-sensitive McrBC-PCR array; LINE-1 methylation by COBRA-assay; global histone methylation by Western blotting; LINE-1-associated histone methylation by ChIP	[15]
Diet deficient in methionine lacking in choline and folic acid	Rat	Changes in the DNA methylation machinery	Indirect methods by DNA methyltransferases and Methyl CpG binding proteins	[24]
Amino acid-defined diet lacking choline	Rat	Hypermethylation of upstream of E-cadherin and Cx26	Bisulfite sequencing	[95]
Diet deficient in methionine lacking in choline and folic acid	Rat	global loss of DNA methylation; hypermethylation of CpG islands	Global DNA methylation by cytosine extension assay and [^{3}H-methyl] incorporation; CpG island methylation by [^{32}P]dGTP incorporation	[30]
Diet deficient in methionine lacking in choline and folic acid	Mouse	Global DNA hypomethylation; substantial loss of repetitive sequences (LINE-1, SINES, IAP elements) cytosine methylation. Increase in histone H3-Lys9 trimethylation and decrease in histone H4-Lys20 trimethylation	Global DNA methylation by cytosine extension assay; methylation-sensitive McrBC-qPCR assay; global histone modifications by Western blot	[96]
Diet deficient in methionine lacking in choline and folic acid	Mouse	Detection of CpG island methylation profiles	MeDIP	[97]

S-AdoMet: S-adenosylmethionine; ID: Identifier; LINE-1: Long interspersed nucleotide elements; SINES: Short interspersed nuclear elements; IAP: Intracisternal A-particle; MS-PCR: Methylation-specific polymerase chain reaction; ChIP: Chromatin immunoprecipitation; MeDIP: Methylated DNA immunoprecipitation.

binding proteins[24], defects in histone methyltransferase protein expression and histone posttranslational modifications[15]. In Table 1, various DNA methylation assays were summarized in methyl-deficient model of hepatocarcinogenesis in rodents.

Genomic DNA methylation assays

One of widely used methods for global DNA methylation assay is a radioassay that utilizes the enzyme *Sss* I DNA methyltransferase to catalyze the *de novo* methylation of the CpG sites with radiolabeled [^{3}H]-SAdoMet, a universal methyl donor *in vitro*[20,25-28]. And another method was developed thanks to the discovery of methylation-sensitive restriction endonucleases. In 1999, Pogribny *et al*[29] developed a new method based on methylation-sensitive endonucleases followed by single nucleotide extension with radiolabeled [^{3}H]-dCTP. This cytosine extension assay was used in various studies of methyl-deficient model of hepatocarcinogenesis for genomic DNA methylation[22,23,29,30]. These enzyme based methods have wide variations in precision as a result of inconsistency in the activity of methyl-sensitive endonucleases and the instability of methyltransferase activity[31]. In 2002, Friso *et al*[32] developed a method for quantitative determination of 5-methyl-2'deoxycytidine using liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS). This method allows accurate measurement of the absolute amount of 5-methyl-2'deoxycytidine relative to the total amount of cytosine residues, furthermore, it requires relatively lower amount of DNA and has a shorter run time for each sample than other high-performance liquid chromatography-based methods[33-35]. DNA methylation assay by LC/ESI/MS has been widely used for quantitative DNA methylation in animal studies and population-based studies in the light of its greater reproducibility and precision in large number of samples[32,36-40].

Gene-specific DNA methylation measurements

DNA methylation has long been recognized as an important factor on the silencing of genes, therefore it has become important to know the methylation status of individual CpG site. The first generation of DNA methylation detection assay is Southern blot or polymerase chain reaction (PCR) amplification that follows the enzyme digestion with methylation-sensitive restriction endonucleases[41-46]. Currently, the most commonly used methods for gene-specific DNA methylation can be categorized into three major methods.

Bisulfite DNA sequencing and methylation-specific

PCR: Treatment of DNA with bisulfite converts cytosine residue to uracil, but leaves 5-methylcytosine residue unaffected. Bisulfite sequencing involves chemical conversion of cytosine to uracil, followed by PCR, and DNA sequencing[47]. While providing single-base resolution, the high cost and labor-intensive steps limit the use of this method for high-throughput analyses[48]. Methylation-specific-PCR also employs bisulfite conversion, but avoids the need to sequence the area of interest. Instead, methyl-specific and unmethyl-specific primer sets are designed, to distinguish methylated from unmethylated DNA in bisulfate-converted DNA[49]. This method is powerful to explore CpG islands with high methylation density, as increased numbers of CpG in the primer increase the specificity of the assay. However, these two methods using bisulfite conversion are not currently suitable for whole-genome analysis on multiple samples but commonly used for data validation from array-based methods.

Methods that focus specific single-CpG: These include Combined Bisulfite Restriction Analysis (COBRA)[50], MethyLight[51], and bisulfite pyrosequencing[52]. In COBRA, the combination of bisulfite conversion and PCR amplification is used, therefore it results in sequence conversion (unmethylated cytosine residue to thymidine and methylated cytosine to cytosine) which can lead to new methylation-dependent restriction enzyme sites. The following digestion of the PCR product with at least one CpG site in the recognition sequence only proceeds if the CpG site is protected from bisulfite conversion by methylation. For this reason, the signal ratio of restriction products indicating methylation to undigested PCR product representing unmethylated sequences can be used as a measure for the methylation level of this specific CpG. MethyLight is a bisulfite-dependent, fluorescence-based, quantitative real-time PCR method for DNA methylation. MethyLight relies on methylation-specific priming combined with methylation-specific fluorescent probing. This combination of methylation-specific detection principles results in a highly methylation-specific detection technology, with an accompanying ability to sensitively detect very low frequencies of hypermethylated alleles. Bisulfite pyrosequencing has been used to analyze bisulfite-converted DNA without using methylation-specific PCR. Following PCR amplification of the region of interest, pyrosequencing is used to determine the bisulfite-converted sequence of specific CpG sites in the region. The ratio of cytosine to thymidine at individual sites can be determined quantitatively based on the amount of cytosine and thymidine incorporation during the sequence extension. While the methods mentioned above are sensitive, specific, and relatively inexpensive, none of these methods is suitable for analysis of the whole genome, which includes about 28 million CpGs.

Microarray-based methods: These enable to interrogate larger numbers of CpG, there are three major types of microarray-based methylation analysis. Direct hybridization to CpG island arrays is the first high-throughput approach capable of detecting DNA methylaion in genes across several CpG sites. Based on the bisulfite modification of DNA, this method utilizes methylation-specific oligonucleotides arrayed on glass slides for detection of all possible methylation in target DNA[53]. Methylated DNA immunoprecipitation (MeDIP) is also a large-scale, genome-wide purification method that is used to enrich for methylated DNA sequence using antibody raised against 5-methylcytosine[54]. DNA from MeDIP can be used for either array-based hybridization (MeDIP-chip) or high-throughput sequencing (MeDIP-seq). Although MeDIP helps generate comprehensive DNA methylation profiles, both applications have their typical limitation of array-based technology, restricted resolution. The HELP assay (*Hpa*Ⅱ tiny fragment enrichment by ligation-mediated PCR) is comparative isoschizomer profiling of DNA methylation[55]. DNA is digested by *Hpa*Ⅱ in parallel with *Msp* Ⅰ (resistant to DNA methylation), and then the *Hpa*Ⅱ and *Msp* Ⅰ products are either amplified by ligation-mediated PCR and hybridized using separate fluorochromes to a customized array, or directly sequenced[56]. These high-throughput array-based approaches for DNA methylation are relatively inexpensive tool suitable for genome-wide analysis, therefore, help to target aberrant methylation patterns in various cancer models. Furthermore, methylation profiling achieved from high throughput methods will offer differentially methylated regions to understand the effect of dietary factors on epigenetic modifications in cancer, subsequently, provide insight in prevention strategies to reduce the burden of cancer.

HISTONE MODIFICATION

Histone deacetylase inhibition by butyrate

In addition to the effects on DNA methylation, dietary components can affect posttranslational modifications of histones. The dietary agent best studied in histone modifications is the short chain fatty acid butyrate which is generated in the colon as a result of bacterial fermentation of dietary fiber. Higher intake of dietary fiber is associated with reduced risk of colorectal cancer[57,58]. The molecular mechanisms underlying this anti-cancer effect of dietary fiber are poorly understood, however, the strongest evidence is based on the anti-carcinogenic actions of butyrate. Butyrate can be found at millimolar concentrations in the lumen of the colon[59], and has inhibitory effects on types Ⅰ and Ⅱ histone deacetylase enzymes. Butyrate-induced alterations in histone marks, especially acetylation at histone H3 and/or H4, have been associated with several processes, including cellular differentiation[60,61], cell cycle arrest[62-64], apoptosis[65-67], and inhibition of invasion[68] in a number of cancer cell studies. Table 2 summarized some of evidence of the effects of butyrate on histone acetylation. Although butyrate has strong marks

Table 2 A summary of selected evidence for effects of butyrate in histone modification and histone modification assays in cancer cell culture models

Dietary component	Cell culture model	Observations	Histone modification assay	Ref.
Sodium butyrate	SW620 human colon carcinoma cells	Increased global histone H4 acetylation	Western blot	[70]
Sodium butyrate	A375 human melanoma and S91 mouse melanoma	Increased global histone H4 acetylation	Western blot	[98]
Sodium butyrate	Colo-320 human colon cancer cells	Increased acetylation of histone H3 and H4 within CDKN1A promoter site	ChIP	[64]
Sodium butyrate	EBC-1 human lung epithelial cells	Increased histone H3 and H4 acetylation associated with promoter of cathelicidin	ChIP	[99]
Sodium butyrate	HepG2 human hepatocarcinoma	Increased global histone H3 and H4 acetylation; Genome-wide changes in acetylation of DNA-bound histones	Western blot; ChIP-chip (ChIP and microarray hybridization)	[100]

CDKN1A: Cyclin-dependent kinase inhibitor 1A; ChIP: Chromatin immunoprecipitation.

on histone acetylation, a small fraction of cellular genes is regulated in response to butyrate[69-71]. Therefore, it should be noted that site-specific approach by chromatin immunoprecipitation (ChIP) based experimental tools will provide a better understanding on the chemopreventive effects of butyrate, showing gene-specific histone acetylation and its associated gene expression.

Global histone acetylation assays

The first estimates for the rate of acetylation turnover were measured by pulse, pulse-chase, and steady-state acetylation labeling in hepatoma tissue culture cells in 1975[72]. Boffa *et al*[73] showed that sodium butyrate suppressed histone deacetylation *in vivo* and *in vitro* by measuring the kinetics of [^{3}H] acetate release from histone proteins. Since specific antibodies to modified histones were developed, Western blot has been used to detect histone modifications. As shown in Table 2, butyrate-induced histone acetylation was confirmed by Western blot in many studies.

Gene-specific histone acetylation measurements

ChIP: The antibodies to acetylated histone H3 and H4 have been used for ChIP to determine histone acetylation in specific regions of gene promoter and other regulatory regions. ChIP is a specialized immunoprecipitation used to detect the covalent interaction between the DNA sequence and DNA-binding proteins such as transcription factors or histone proteins. ChIP using histone antibodies is able to determine the specific location in the genome that various histone modifications are associated with, indicating the target of the histone modifiers[74]. For example, ChIP experiment unveiled that butyrate induced an increase in histone H3 and H4 acetylation within the CDKN1A promoter, which regulates the p21 protein, in Colo-320 human colon cancer cells[64]. Due to its ability to precisely detect the DNA binding of modified histones, transcription factors, and non-histone chromosomal proteins, ChIP has been widely used to generate and test numerous hypotheses regarding transcriptional and epigenetic regulations. However, it remains to be still challenging to conduct ChIP on an "epigenome" level, since ensuring an antibody of high specificity is often laborious and time-consuming. Another important concern with ChIP scalability is the maximum range of target regions that can be investigated by a single assay. For instance, a typical experiment of ChIP coupled with qPCR is designed to measure the enrichment levels of a DNA binding protein at a handful of sites (*e.g.*, gene promoters). However, in general, even a single epigenetic event in the cell pervasively occurs over a wide range of genomic regions, often involving thousands of genes and their associated regulatory elements. Thus, it becomes more important to have an ability to run the assay on a genome-wide scale for having a more balanced and unbiased perspective on the underlying mechanisms. Coupled with genomic profiling technologies such as tiling arrays or next generation sequencing (NGS), ChIP can be extended over the whole genome. In the following sections, we will introduce two major methods coupled with ChIP that enable epigenome-scale research of histone marks and transcription factors.

ChIP-chip: ChIP-chip is based on the combination of ChIP and a genomic tiling array technology (*i.e.*, chip), in which DNA sequences extracted after ChIP hybridize with probes that are designed to cover the whole genome or specific regions of interest such as promoter[75,76]. Due to bias in microarray hybridization, a control experiment using chromatin input or DNA from non-specific immunoprecipitation (IP) (*e.g.*, IP against immunoglobulin G) is often recommended. Most algorithms for ChIP-chip are designed to compute the normalized ratio between the hybridizations of ChIP and control after removing random and/or systemic noise. Then, they call binding sites as those significantly enriched in ChIP over control[77-79]. Since its emergence in the early and mid 2000s, ChIP-chip has been widely adopted in many transcriptional and epigenetic regulation studies, assisting scientists to more understand the role of each histone mark in physiological and pathological processes[80-83]. However, the utility of ChIP-chip is heavily restricted by a tiling array probe design, which determines the resolution of

the measurement (*i.e.*, intervals between adjacent probes) and the regions that can be explored (*e.g.*, omission of repetitive sequence areas). These weaknesses of ChIP-chip have accelerated the major platform shift to NGS.

ChIP-Seq: In ChIP-Seq, the extracted DNA sequences are directly sequenced using a NGS technology instead of being hybridized onto tiling arrays. NGS refers to sequencing technologies that newly emerged since the mid 2000s as an alternative to the traditional automated Sanger sequencing. NGS is characterized as massive parallel sequencing of template DNA or RNA (cDNA) molecules by a relatively short length ranging over 50-400 bp[84]. One advantage of ChIP-Seq over ChIP-chip is that ChIP-Seq does not require any predefined array design, which allows a more unbiased assay at a much higher resolution (100-1000 bp in ChIP-chip *vs* 10-100 bp in ChIP-Seq). Since NGS generally produces a notoriously large amount of data than array-based methods, more powerful bioinformatics support is essential for data processing and analysis[85,86]. Bioinformatics analysis for ChIP-Seq in epigenetic research includes the pre-processing for sequence data such as quality control and read mapping, the identification of candidate sites enriched by the target histone mark, and further down-stream analysis for revealing biological implications of the observations from the precedent steps[85,86].

In cancer studies, the down-stream analysis is focused on finding the most associated genes or regulatory elements (*e.g.*, promoters or enhancers) with the histone mark of interest and investigating how these genes and regulatory elements can be understood in the context of biological pathways. Since Barski *et al*[87] and Wang *et al*[88] studies on 19 histone methylations and 18 histone acetylations using the human CD4+ T cell, many studies have been done to understand the biological implications of histone marks in normal conditions[80-82]. However, due to the plasticity of epigenome and heterogeneity of cancer, cancer epigenetics of examining histone modifications on a genome scale still remains in its beginning stage. For this reason, most of currently on-going efforts in cancer epigenetics still largely target DNA methylation (*e.g.*, The Cancer Genome Atlas, http://cancergenome.nih.gov/)[89]. Therefore, it will be a long-term goal to accumulate the knowledge on cancer epigenetics from histone modifications and use it for cancer studies, which will require a great amount of public and private investments. Another interesting research direction is an attempt to comprehend how genetic variations lead to epigenetic changes in cancer. In 2011, several studies have been published about the possibility of multiple chromatin remodelers and histone enzymes as potential oncogenes or tumor suppressor genes[90-93]. These studies suggest that the disruption of chromatin remodelers and histone enzymes due to driving somatic mutations in their coding regions may cause aberrant epigenetic changes, which eventually lead to cancer development or evolution in at least several cancer indications. Such approach is particularly interesting because it may be able to provide a genuine perspective on the target histone mark by observing somatic mutations in several key chromatin remodelers and histone enzymes.

CONCLUSION

In conclusion, a number of aberrant epigenetic modifications have been found in cancer cells, and diet and dietary factors play an important role to prevent cancer as well as to stimulate carcinogenesis. The use of epigenetic technology offers significant advantages to study the epigenetic mechanisms of cancer development and progression. Also, the newly developed technologies for epigenetic study expand the scope of nutrition study in the field of cancer research by helping monitor and pin down specific epigenetic pathways in diet-related cancers.

Abstract

The use of thiopurines as immunosuppression for the treatment of refractory or chronic active inflammatory bowel disease is established for both Crohn's disease and ulcerative colitis. Nevertheless, many questions remain concerning the optimal treatment regimens of azathioprine, 6-mercaptopurine and thioguanine. We will briefly summarize dose recommendations, indications for thiopurine therapy and side effects which are relevant in clinical practice. We discuss some currently debated topics, including the combination of azathioprine and allopurinol, switching of thiopurine therapy in case of side effects, the use of azathioprine in pregnancy, the infection risk using thiopurines and the evidence when to stop thiopurines. Excellent reviews have been published on the thiopurine metabolic pathway which will not be discussed here in detail.

DOSING AND MONITORING OF THIOPURINES

Thiopurines used for inflammatory bowel disease (IBD) treatment are azathioprine (AZA), 6-mercaptopurine (6-MP) and occasionally also 6-thioguanine (6-TG). The most commonly used thiopurine is AZA. The hepatic enzyme glutathione-S-transferase rapidly cleaves the prodrug AZA to 6-MP[1], which is then metabolized in both liver and gut by several enzymes: (1) thiopurine-s-methyltransferase (TPMT) catalysing 6-MP to 6-methyl-MP (6-MMP); (2) xanthine oxidase catalyzing 6-MP to thiourea; and (3) hypoxanthine-guanine-phosphoribosyltransferase converting 6-MP to 6-thioguanine nucleotides (6-TGN). 6-TG is the final effector-metabolite[2] which slowly accumulates in cells, and this metabolite is probably responsible for the delayed onset of action after 10-12 wk[3].

Dose recommendations for AZA and 6-MP vary slightly between Western guidelines, with a daily dose of 2-3 mg/kg AZA and 1-1.5 mg/kg 6-MP recommended by the AGA[4], and a daily dose of 1.5-2.5 mg/kg AZA and 0.75-1.5 mg/kg 6-MP recommended by the European Crohn's and Colitis Organisation (ECCO)[5]. However, these recommendations do not necessarily hold true for other ethnicities. Several Japanese studies showed that Japanese IBD patients might reach sufficient 6-TGN values with substantially lower AZA and 6-MP dosages in adults[6,7], children and adolescents[8]. If 6-TG is exceptionally used, it should be started at a much lower dosage of approximately 20 mg per day and should not exceed

25 mg daily[9]. However, it has to be strengthened that there are limited indications for use of 6-TG in IBD. 6-TG can be used in IBD patients who need a thiopurine for maintenance therapy but who are intolerant (or resistant) to 5-aminosalicylic acid (5-ASA) [in ulcerative colitis (UC)], AZA, 6-MP and methotrexate [in Crohn's disease (CD)], and who do not have an option for surgery[9]. Biological therapy could be considered as an alternative to 6-TG in this setting. The ECCO guidelines[5] concluded in 2006 that thioguanine cannot currently be recommended for maintenance of CD due to a high frequency of liver abnormalities (mainly nodular regenerative hyperplasia). According to the current literature, this might, however, be explained by the use of too high dosages of 6-TG resulting in 6-TGN levels exceeding 1000 pmol/8 × 10^8 erythrocytes which is much more than the target levels of 250-500 pmol/8 × 10^8 erythrocytes usually recommended when using AZA or 6-MP[10-12]. Thus, if 6-TG is used as therapy for selected IBD patients, the 6-TGN levels should be controlled regularly combined with close monitoring of liver values[13], hematology and especially liver biopsy after one, three and then every three years[9]. However, the histopathological diagnosis of nodular regenerative hyperplasia is difficult with a very poor inter-observer agreement, even among experts[14]. Alternatively, non-invasive monitoring such as magnetic resonance imaging may be considered[15].

The dose recommendations as mentioned above are based on "Western" or "Caucasian" guidelines/evidence and are linked to the assumption that the TPMT pathway is "normal". A diminished TPMT activity due to mutations of the *TPMT* gene leads to toxic levels of 6-TGN, which is a risk factor for drug-induced myelosuppression[16]. TPMT mutations are not uncommon in Caucasian populations (mutation prevalence approximately 10%), but rarer in *e.g.*, Chinese patients (5%) or even very rare in Japanese patients (1%)[17], which questions the usefulness of routine TPMT monitoring in these patients. The role of pharmacogenetics has recently been addressed in an excellent review by Chouchana *et al*[18] and is shortly summarized below.

To achieve an optimal therapy, it seems crucial to find the correct concentration of intracellular 6-TGN (serum levels are of no value). Concentrations that are too high lead to myelosuppression, whereas concentrations that are too low result in a lack of efficacy in IBD[16,19]. TGN-levels can be measured irrespective of the time of intake of thiopurines. The commonly recommended 6-TGN concentration is 235-500 pmol/8 × 10^8 erythrocytes. In a meta-analysis[20], patients with 6-TGN levels above the threshold value of 235 were more likely to be in remission than those below the threshold value (62% *vs* 36%, $P < 0.001$). The usefulness of therapeutic drug monitoring has recently been supported in a Dutch study[21]. However, the minimum effective dose is unknown. No dose-response study has ever been carried out, but at least one study showed that an increase in AZA dosage (2.02-2.72 mg/kg daily) can induce response in some patients[22]. Since there is only a very weak correlation between thiopurine dosage and 6-TGN levels[20] and some ethnic variability[6,7], the authors believe that 6-TGN levels should be regularly measured. Measuring the 6-TGN levels alleviates uncertainties when AZA therapy is combined with 5-ASA in UC[23]. In a recent and well-performed prospective study, the addition of 2 g of 5-ASA increased the total amount of 6-TGN by 50%, and methylmercaptopurine ribonucleotide levels were reduced after adding 4 g of 5-ASA[24]. Further studies are needed to show whether 6-TGN measurements might be useful to improve thiopurine therapy.

TPMT MONITORING

Beside the above mentioned measurement of thiopurine metabolites, TPMT genotyping (analysis of single nucleotide polymorphisms which influence the TPMT activity) and phenotyping (measuring the TMPT activity) can be applied before therapy with AZA or 6-MP is initiated. A recent study concluded that genotyping should be favoured for pre-treatment TPMT function since it is the more reliable test[25]. This evaluation may help to identify slow metabolizers which are at risk of toxicity[4]. Nevertheless, a recently meta-analysis stated that there is not yet enough evidence to advocate for routine TPMT testing[26]. The United States Food and Drug Administration (FDA), but not the ECCO, recommends TPMT monitoring before the initiation of thiopurine therapy. In 2011, the first guideline for a thiopurine starting dose according to TPMT phenotype/genotype was developed[27]. A reduction to 30%-70% of the full dose is recommended in patients with an intermediate activity (heterozygote). In patients with low/absent activity (homozygous mutant or compound heterozygote), an alternative drug should be considered or AZA starting dose must be reduced by a 10-fold, administered thrice weekly, and under close monitoring. For patients with intermediate and low/absent TPMT activity, a therapeutic drug monitoring is recommended four weeks after treatment initiation. Patients with a very high activity might benefit from an increase in AZA dosage up to 3.0 mg/kg per day[18]. Nevertheless, it is important to note that TPMT testing does not predict the long-term risk of myelosuppression or idiosyncratic adverse events such as fever, arthralgias, hepatitis or pancreatitis[28]. Regular hematologic monitoring remains necessary[26], initially at least every second week until the patient has been on a stable dose for a month; in the later course at least every third month[29,30], including a complete blood count including a differential count, especially to check the lymphocyte level but also platelets as well as amylase, and liver enzyme levels[4,30,31].

INDICATIONS FOR AZATHIOPRINE OR 6-MERCAPTOPURINE

No evidence for induction of remission in active IBD

There is not enough evidence to recommend thiopurines

for inducing remission in active IBD[32] based on five randomized controlled trials (RCTs) in active CD[33-37] and on two RCTs in active UC[38,39].

Prevention of relapse in quiescent IBD

In quiescent CD, AZA and 6-MP are effective at preventing a relapse based on two RCTs comparing AZA with placebo[33,37], and three RCTs comparing continued AZA *vs* withdrawal in patients who had been successfully maintained on AZA[40-42]. These studies showed a significantly higher relapse rate in the placebo groups as compared with the active treatment[32]. Additionally, a RCT evaluating glucocorticoid-dependent CD patients suggested that AZA was better than placebo at reducing the need for glucocorticoids[43].

In quiescent UC, AZA and 6-MP are effective at preventing a relapse based on three RCTs comparing AZA with placebo[38,39,44]. Overall, 60% of patients can be kept in remission if AZA is continued for 9-12 mo[32]. Similarly, another RCT which evaluated AZA withdrawal in 79 patients, who had been maintained on this drug for a minimum of 6 mo, showed a significant reduction on the relapse rate on AZA *vs* placebo after one year (36% *vs* 59%)[45] .

Post-operative treatment of CD with thiopurines

Two RCTs in postoperative CD suggest that AZA or 6-MP is superior to placebo at preventing recurrence after surgery[46,47]. Furthermore, thiopurines administered postoperatively significantly reduced the clinical recurrence rates in population-based cohorts[48,49]. Thus, thiopurines might be a useful strategy, although anti-tumour necrosis factors (anti-TNFs) might be more efficient in preventing CD relapses postoperatively[50,51], especially among high risk patients (smokers, perforating disease or $\geqslant$ second operation)[50].

Treatment of fistulising CD with thiopurines

A meta-analysis in fistulizing CD demonstrates a significantly higher response rate to AZA and 6-MP as compared to placebo (54% *vs* 21%)[52]. The analyzed studies included patients with perianal, enterocutaneous, enteroenteric and rectovaginal fistulas. However, only in a minority of patients, AZA and 6-MP will lead to a complete fistula closure, but symptoms such as inflammation, discharge and discomfort are often substantially reduced. Since response of fistulas to these drugs will need several months, immunosuppression will be reasonable only as second-line treatment if fistulas don't necessitate immediate surgery. Antibiotics are commonly used as first-line treatment and need to be started in parallel[53].

An overview of indications for thiopurines in IBD is given in Table 1.

ADVERSE EVENTS

AZA and 6-MP have similar side effects leading to discontinuation of therapy in 39% of patients in a large Dutch cohort[54], however, rates of intolerance are usually far lower. Most adverse events occur within the first 3 mo[55]. More than 50% of AZA intolerant patients tolerate 6-MP long-term[56]. Common side effects can be divided into dose-dependent and idiosyncratic side effects.

The major dose-dependent side effect of thiopurines is drug-induced myelosuppression which is observed in 2%-5% of Caucasian patients[57,58]. It can occur at any time with 25% of cases appearing beyond the first year[55]. Asian (or at least Japanese patients[6,7]) have a higher risk of myelotoxicity. It has been speculated that viral infections might contribute to myelosuppression, however, clear evidence is missing. Determining TPMT activity before starting thiopurines might avoid early myelosuppression, but regular haematological monitoring remains necessary in every patient.

Infectious complications are mostly dose-dependent, but sometimes idiosyncratic side effects. Infectious complications during thiopurine therapy can occur even in the absence of a dose-dependent leukopenia[4,59,60], especially when using a combination of thiopurines with corticosteroids which may induce a dose-dependent lymphocyte depletion. We recommend avoiding a lymphopenia of $< 600/\mu L$ based on data from a rheumatological study[31]. Doing this, severe immunodeficiency is likely to be avoided[31] Hepatotoxicity can manifest as early drug-induced hepatitis, nodular regenerative hyperplasia after years of therapy, sinusoidal dilatation or fibrosis[61]. It is important to note that IBD *per se* is a risk factor for nodular regenerative hyperplasia[62]. Hepatotoxicity induced by thiopurines seems more often dose dependent than idiosyncratic. In many patients, elevated transaminases respond to dose reduction. In a prospective monocentric cohort, 21 of 123 patients showed a transient or constant elevation of alanine aminotransferase levels[63]. If liver enzymes are repeatedly elevated, thiopurines need to be discontinued.

The most frequent idiosyncratic side effects are nausea, vomiting, and malaise in up to 15% of all patients[64]. Some advocate to slowly increase the dosage when thiopurine therapy is started, or to take it before nighttime. However, the best way to start thiopurine therapy still has to be determined[4]. Other common side effects are headache, fatigue, anorexia, weight loss, stomatitis, alopecia, arthralgia, muscular weakness and rash, which may occur in more than 10% of patients. If these side effects are reported, it should be determined whether they disappear after dose reduction[4,59,60,65,66]. In case of arthralgias/myalgias upon AZA, a switch to 6-MP can be explored[55].

Pancreatitis is an important idiosyncratic side effect and occurs in up to 4% of the patients[4,60], especially during the first weeks of treatment[67]. A minor and asymptomatic increase in serum amylase ("pancreatic hyperenzymemia") is frequently observed, but only poorly understood and not discussed in current guidelines. Some authors prefer to reduce dosing, or stop treatment

Table 1 Indications for thiopurines in inflammatory bowel disease

	Indication	No indication
Crohn's disease	Maintaining remission in moderate (to severe) CD (any site of disease especially for extensive disease) Maintaining remission in CD with early relapse (< 3 mo after the last flare) or frequent flares (more than two per year) Fistulizing CD (in combination with antibiotics, if no early start of anti-TNF or surgery necessary) Postoperative prevention of CD recurrence (unless high-risk situation such as repeated surgery or current smoker) In combination with anti-TNFs in case of severe CD (rapid step-up or top-down)	Induction of remission (as a sole therapy in active disease)
Ulcerative colitis (treated with 5-ASA at optimal dose unless intolerant)	Maintaining remission in steroid-dependent UC Maintaining remission in UC with early relapse requiring steroids Maintaining remission in UC with frequent flares requiring steroids Maintaining remission in UC after induction of remission by ciclosporin, tacrolimus, or *i.v.* steroids Acute or chronic refractory pouchitis	Induction of remission (as a sole therapy in active disease)

CD: Crohn's disease; UC: Ulcerative colitis; TNF: Tumour necrosis factor; 5-ASA: 5-aminosalicylic acid.

in case of lack of biochemical response[68]. Thiopurines must be discontinued if amylase increase is associated with typical pain symptoms (*i.e.*, toxic pancreatitis). After AZA-induced pancreatitis, a switch to 6-MP is not recommended since these patients are less likely to tolerate 6-MP[64]; However, evidence against the use of 6-MP in AZA-induced pancreatitis is weak. As earlier outlined, 6-TG is a debated alternative to AZA and 6-MP in case of intolerance[9], which is, however, not recommended by some authors[69,70].

WHEN AND HOW TO CHANGE THIOPURINE THERAPY IN CASE OF SIDE EFFECTS?

In the case of idiosyncratic side effects, it might be reasonable to change from AZA to 6-MP, as discussed above. Furthermore, in so-called preferential 6-MMP metabolizers which achieve only low 6-TGN levels due to high 6-MMP levels with associated hepatotoxicity, adding low-dose allopurinol as a XO inhibitor to dose-decreased AZA (25%-33% of intended dose[71], might switch the AZA metabolism to 6-TGN instead of 6MMP. Close monitoring of 6-TGN metabolites and hematology is in such cases necessary (weekly during the first month, then every other week for the next month)[69]. This strategy often allows to reach therapeutic levels of 6-TGN and clinical remission, but may also to reduce or even alleviate nausea as one of the major early side effects in more than 80% of patients[72]. Interestingly it seems possible to achieve higher 6-TGN and lower 6-MMP levels in preferential 6-MMP metabolizers by simply splitting the daily thiopurine dose[73] or by switching to 6-MP.

MALIGNANT COMPLICATIONS

Treatment with AZA/6-MP is associated with a potential risk of developing lymphoma[74], including hepatosplenic T-cell lymphoma (HSTCL)[75]. Although the relative risk of lymphoma is increased four to five-fold[74,76], the absolute risk still remains rather small, and currently available data show that the benefits of thiopurines used in IBD greatly outweigh its risks[77]. The same holds true for non-melanoma skin cancer[78-80], which in a large cohort of 108.518 IBD patients collected from 1997 to 2009 was shown to occur significantly more often in IBD patients on thiopurines especially among those with CD than controls[79], correlating with the length of receiving thiopurines. Of 32 cases of nonmelanoma skin cancer in a large cohort[80], only 5 cancers occurred in immunomodulator-naïve patients, but 9 and 18 cancers occurred in patients who had previously taken or were currently on thiopurine therapy. Based on these studies, a dermatologic exam should be considered before and regularly during immunomodulator therapy; especially in elderly patients. It should in this context be mentioned that skin protection is rather crucial.

WHEN SHOULD THIOPURINE MONOTHERAPY BE STOPPED?

When to stop a successful immunosuppression is one of the most difficult decisions in IBD therapy. Five studies focussing on this question were recently reviewed by Clarke and Regueiro[81]. According to a randomized, controlled study from 2005, even CD patients who were in remission on AZA for at least 3.5 year profited from prolonged AZA therapy (relapse risk 8% *vs* 21% on placebo)[40]. Similar results have been gained from other studies[82]. Five years after stopping AZA, 3/4 of patients suffer from relapse. Nevertheless, a treatment stop seems justified since almost all patients re-treated with thiopurines were able to regain remission (23 of 24 patients; many with a combined short course of glucocorticoids)[83]. Independent predictors for a flare are a C-reactive protein-level of > 20 mg/L, a haemoglobin-level < 12 mg/dL, and an absolute neutrophil count of > 4×10^9/L at baseline. Since more than half of the patients with risk factors experienced a clinical flare-up within 24 mo (compared to only 15% of patients without negative predictors), a continuous course of thiopurine therapy is recommended for these patients.

In UC, several studies have shown that a prolonged AZA therapy helps to reduce the risk of relapse. Six months is certainly the minimum length of immunosuppression (with at least 3 mo disease-free interval off glu-

cocorticoids)[84,85], but other studies showed that 18 mo is significantly better than 6 mo[81].

In clinical practice, decision on the length of immunosuppressive therapy means weighing benefits of immunosuppression on IBD and risk of malignancies and other complications. The risk factors should be analysed before immunosuppression is stopped. Best candidates for stopping immunosuppression will probably be IBD patients in deep, prolonged remission with a short duration of time between diagnosis and immunomodulator treatment[81]. Nonetheless, prospective RCTs are needed for the development of evidence-based tapering schemes regarding AZA and 6-MP treatment, both in CD as well as in UC.

IMMUNOMODULATORS AND BIOLOGIC THERAPY

Many experts in the field currently advocate a "top down" approach with early combination therapy for moderate to severe CD based on evidence from three infliximab and azathioprine studies in CD[86-88], including the famous SONIC trial[86]. Nevertheless caution is advised as the number needed to treat for the combination therapy is 8, meaning that only one out of 8 patients will definitely benefit from the combination. For the combination of AZA and adalimumab, there are only retrospective and hardly convincing data[89]. Future trials need to determine whether it is crucial to start with anti-TNFs and thiopurines at the same time, or whether a sequential addition of thiopurines to anti-TNFs will have the same effect in the patients experiencing a benefit from this combination.

Furthermore, there are not enough available data on how long the concomitant use of immunomodulators should be maintained in patients receiving infliximab. There are no studies which documented a sustained efficacy of concomitant use of immunomodulators beyond 6-12 mo[90,91]. If therapy should be reduced, then AZA and not infliximab may be stopped. In the recently published prospective STORI (Stop Infliximab in Patients With Crohn's Disease) study on infliximab stop in patients in remission under combined immunosuppression, nearly half of all patients suffered from relapse within 1 year when infliximab was stopped despite continuing azathioprine[92]. In contrary, the risk of relapse after stopping AZA seems lower than after stopping infliximab. Thus, in a single referral center observational study on CD patients who stopped AZA after being in remission under combined AZA and infliximab for at least 6 mo, 15% of patients relapsed after 1 year[93].

THIOPURINES IN PREGNANCY AND LACTATION

Even though thiopurines belong to FDA pregnancy category D, the risk seems minimal. Two studies[94,95] did not find any evidence for an increased risk of pregnancy-related complications. Probably, the only major side effect of thiopurines is the risk of preterm birth[95-97], which, however, might be simply a disease effect. Furthermore, thiopurine levels in breast milk of mothers treated with AZA seem harmless[98] and without any long-term effects in these babies. Thus, it can be concluded that thiopurines can be administered safely to women with IBD, prior to and at the time at conception, as well as during pregnancy and lactation. Indeed, in a recent survey among gastroenterologists showed that more than 90% would recommend continuous thiopurine treatment[99].

CONCLUSION

Indications for use of thiopurines in IBD and ways to monitor therapy have been well established. In clinical practice, the possibility of 6-TGN measurement to monitor therapy seems underused. It is likely that broader use of TGN monitoring, and a combination of thiopurines with low dose allopurinol in case of inefficiency or side effects allows to (achieve or) maintain clinical remission in more patients. For the thiopurine/allopurinol combination, but also for 6-TG therapy, prospective trials to document the benefit (and risk) are urgently needed. Furthermore, more trials are needed to elucidate whether an early "top down" approach for combination of thiopurines with anti-TNF will bring a long-term benefit for patients as compared to a step-up approach in case of a non-response to thiopurines. Criteria when a successful thiopurine therapy for maintenance of remission can be stopped also need to be elucidated in future prospective trials. Risk communication with patients, but also referring physicians, about benefit, side effects and the above mentioned uncertainties remain challenging. Benefits are the quality of life gained by medically maintained remission; the avoidance of surgery (in CD and UC) and avoidance of colorectal cancer through efficient anti-inflammatory therapy. Risks are, however, (opportunistic) infections, lymphomas such as HSTCL and side-effects such as pancreatitis.

Accordingly, thiopurine therapy remains a hot topic in IBD.

Abstract

The performance of hepatic surgery without a parenchyma-sparing strategy carries significant risks for patient survival because of the not negligible occurrence of postoperative liver failure. The key factor of modern hepatic surgery is the use of the intraoperative ultrasound (IOUS), not only to stage the disease, but more importantly to guide resection with the specific aim to maximize the sparing of the functional parenchyma. Whether in patients with hepatocellular carcinoma and underlying liver cirrhosis, or in patients with colorectal liver metastasis, IOUS allows the performance of the so-called "radical but conservative surgery", which is the pivotal factor to offer a chance of cure to an increasing proportion of patients, who until few years ago were considered only for palliative care. Using some new IOUS-guided surgical maneuvers, which are based on the liver inflow and outflow modulations, more precise anatomically subsegmental- and segmental-oriented resections can be effectively performed. The present work describes the rationale and the surgical technique for a precise tailoring of the area of hepatic resection using the most recent attainments in IOUS. Such important technical achievements should be a fundamental part of the surgical armamentarium of the modern liver surgeon.

INTRODUCTION

The performance of hepatic surgery without a parenchyma-sparing strategy carries significant risks for patient survival because of the not negligible occurrence of postoperative liver failure, which is definitely related to the amount of the sacrificed parenchyma[1,2]. Indeed, major or extended hepatic resections are independent negative prognostic factors with regard to short- and long-term outcomes[2-7]. The key factor of modern hepatic surgery is the use of the intraoperative ultrasound (IOUS) not only to stage the disease, but more importantly to guide resection, with the specific aim of maximizing parenchyma-sparing, removing only the tumoral tissue[8]. Whether in patients with hepatocellular carcinoma (HCC) or in patients with colorectal liver metastasis (CLM), IOUS allows the performance of the so-called "conservative but radical surgery"[9], which is the pivotal factor to offer a chance of cure to an increasing proportion of patients, who until few years ago were considered only for palliative care. Indeed, in cases of HCC with cirrhosis the underlying liver function is generally marginal, and the prognosis of the patient might be more related to the residual liver function rather than to the pres-

ence of HCC. In such patients, the hepatectomy should always be tailored on the basis of both tumoral features and functional liver reserve. Similarly, in cases of CLM the rationale of the surgical approach described here is based on the need to minimize the rate of major or extended resections with the aim of reducing operative risk, and at the same time preserving the liver parenchyma, which could be the site for future hepatic recurrence potentially re-treated with curative intent.

OPERATIVE TECHNIQUE

The J-shaped laparotomy is the preferred incision for liver surgery, and the access into the right thoracic cavity following the 9th intercostal space is carried out to control the hepatocaval confluence. In particular, the thoracoabdominal approach is selected in obese patients, in patients with a deep chest, and during complex reoperations. Thus, the liver is partially mobilized by dividing the round and the falciform ligaments. Sometimes the coronary and triangular ligaments are also divided early to obtain enough space for IOUS. This should in fact be performed before complete mobilization of the liver to avoid any artifact made by the surgical maneuvers.

INTRAOPERATIVE ULTRASOUND

IOUS is the procedure of choice to stage disease in patients with liver tumors. It should be fully performed by the surgeon in charge for the operation rather than by the assistants, radiologists or technicians. This is because the information gathered during the exploration requires interpretation to have most impact on the surgical strategy. Thus, IOUS is mainly performed to plan the surgical strategy rather than to locate the lesions. Generally, high frequency probes (7.5-10 MHz) are recommended for IOUS, since they allow for a higher spatial resolution than those working at lower frequencies (3.5-5 MHz). However, those latter probes are very useful for the initial exploration providing a better panoramic view. Lower frequency probes are also useful for allowing contrast-enhanced IOUS. Different shapes of probes are available for intraoperative use: the linear T-shaped, the inter-digital, and micro-convex probes. The best probe is the one that ensures the optimal compromise between the volume of the probe itself, which should be minimal, the scanning windows, which should be the largest, and the stability once in contact with the liver surface. In this sense, a new micro-linear probe with trapezoid scanning windows probably represents the best compromise among all the aforementioned requirements; this probe is furthermore designed to meet the requirements for those surgical maneuvers discussed here (Figure 1). Of note, the performance of IOUS may take time, and it requires experience to be effective and beneficial[10].

RESECTION GUIDANCE

Apart from staging, IOUS is essential to guide resection. It is almost impossible to correctly define the hepatic segmental boundaries without IOUS, nor the boundaries of the tumor itself because of the existing wide variations in anatomy. The main advantage of IOUS-guided resection is modification of the traditional approach to liver tissue dissection, which involves dissection in vertical planes to avoid tumor exposure on the cut surface. With IOUS, the relationship between the dissection plane and the tumor edges can be followed in real time, and the direction of the dissection plane can be modified when needed. Versatile dissection planes around the tumors can avoid tumor exposure while sparing important vascular structures, thus sparing vital liver parenchyma. This approach has been recently redefined by the authors as the "radical but conservative approach", and should be applied in liver surgery to maximize the results[9]. Also, in patients in whom major resections should be required, IOUS allows better design of the dissection plane, leading to conservative surgery even in patients with complex tumoral presentations[11]. Specific, and original IOUS techniques have already been developed to help the surgeon during the operation[12-15]. The following paragraphs will focus on two crucial techniques for defining the area of resection using IOUS findings.

PLANNING OF THE SURGICAL STRATEGY

The information achieved from the preoperative imaging workup, which has an essential role in staging intra- and extra-hepatic disease, should be used to plan the surgical strategy. However, the surgical strategy should be intraoperatively defined only after IOUS exploration. The impact of IOUS on the operative decision-making, when compared with that of preoperative imaging techniques, is reported to be around 4%-7%[16,17]. These relatively low rates may be explained because of the different surgical policies applied by the different centers as well as the different tumor types considered. Indeed, IOUS, when used in a systematic and extensive way to map the tumor nodules, allows a 3-dimensional reconstruction of the relationships between the tumor and the main intrahepatic vascular structures [glissonian pedicles and hepatic veins (HVs)], which is pivotal in planning the individualized surgical strategy for each patient. Indeed, some experienced authors reported better results in terms of IOUS accuracy[18-21]. Some important tumor-vessel relationship rules have been developed by the authors, both for HCC and for CLM, with the aim of providing an intraoperative guide to individualize the surgical strategy and minimize parenchyma sacrifice.

Tumor in contact with a glissonian pedicle

The glissonian pedicle may be spared when in contact with an encapsulated HCC or with a CLM once the integrity of the vessel wall is confirmed at IOUS, without any sign of distal bile duct dilation. For CLM, the contact should extend for less than one-third of the pedicle circumference. In the presence of bile duct dilation, tu-

mor thrombus, or invasion of the vessel wall, the pedicle must be divided[9].

Tumor in contact with a HV

The HV may be spared when in contact with an encapsulated HCC or with CLM once the integrity of the vessel wall is confirmed at IOUS. For CLM, the contact should extent for less than two-thirds of the vessel circumference. Thus, in the presence of a tumor thrombus, invasion of the vessel wall, and wider contact the HV must be divided[15]. However, as described below, the extension of the hepatectomy to the portion of the liver theoretically drained by the resected HV is not systematically performed, but only when accessory HVs and/or communicating veins are missing or when inversion of the portal flow is demonstrated by IOUS[22].

INFLOW MODULATION

Initially used for tumors located in the left hemiliver[14], the inflow modulation technique has more recently been successfully extended to any liver segment[23], including segment 8, and even to sectional portions of the liver[24]. Once the feeding portal branch is identified at IOUS, it can be compressed using the IOUS probe by one side of the liver, and by the finger in the opposite side with the aim to induce a transient ischemia of the portion of the liver distal to the compression site. This portion can then be marked with the electrocautery, and when released, resection can be performed. This technique is simple, fast, non-invasive, and reversible. Also, the possibility of modifying the site of the compression, and then the corresponding resection volume allows tailoring of the resection according to tumor features, and more importantly to the status of the background liver. This is of paramount importance in patients with HCC and cirrhosis, in which the functional liver reserve may be marginal. Such a technique allows for precise anatomical resection of a subsegment, segment or section of the liver. As is well-established, anatomical resection of HCC is recommended to offer a higher chance of cure[25-29]. For segments such as segment 1 and 4 superior, for which direct compression of the feeding portal branch may not be feasible, the compression of the adjacent segmental branches allows definition of their segmental margins. Indeed, our technique can be used in a counter-compression perspective similar to the counter-staining technique reported by Takayama *et al*[30]. Figure 2 illustrates the layout of the liver with the compression technique applied to delineate the right posterior section, while Figures 3 and 4 show an actual case.

OUTFLOW MODULATION

The area of resection may be tailored not only using US-guided finger compression of the portal branch as described above, but also using IOUS outflow modulation. Indeed, we have already showed how to minimize

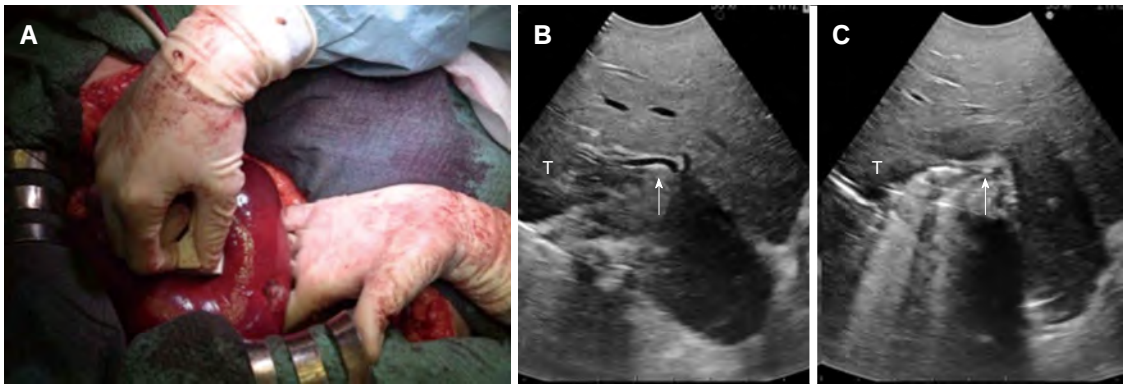

Figure 3 A case of intraoperative ultrasound-guided finger compression of segment 6. A: The portal pedicle for segment 6 is compressed by the probe in the right hand and by the finger in the left hand; B: Intraoperative ultrasound (IOUS) focused on the portal pedicle (arrow) for segment 6 before the compression; C: IOUS focused on the portal pedicle (arrow) for segment 6 during the compression. T: Tumor.

the sacrifice of liver parenchyma even in those patients with a tumor at the hepatocaval confluence, for which a standard major or extended hepatectomy should be indicated based on traditional criteria. In addition, we have introduced some new operations, such as mini-mesohepatectomy, and systematic extended right posterior sectionectomy[22-31], which simultaneously limit the need for formal major resection, and improve the chances of resection for those patients with complex tumoral presentation. The definition of the resection area using the outflow control is based on the extensive use of IOUS flow analyses, with the aim of checking the outflow modifications once the HV that should be resected is clamped. For this purpose rather than the direct closure of the vein by a vessel loop, the US-guided fingertip compression at the caval confluence might be adequate[32]. Certainly, the HV may already be closed by the tumor. At that case, the search is focused on at least one of the following criteria: reversal of flow direction in the peripheral portion of the compressed HV, which suggests drainage through the collateral circulation in adjacent HVs or inferior vena cava (IVC); direct detection of collaterals between the compressed HV and adjacent HV or IVC; or persistence of hepatopetal flow in the portal branches corresponding to the area drained by the compressed HV. In particular, in the case of hepatofugal flow direction in the portal branches, the resection should not be minimal but extended to the parenchyma fed by those portal branches. The presence of hepatofugal flow in the portal branches is a clear signal of insufficient drainage of the corresponding HV. Once at least one of the aforementioned criteria has been satisfied, full mobilization of the right and left hemiliver is performed, preserving most of the posterior short HVs to minimize the risk of congestion of the residual liver. Thus, the area of resection may be marked on the liver surface using electrocautery and IOUS to define the caudal, medial and lateral limits of the parenchyma to be removed, while the surgeon's left fingertip is visualized in the most cranial portion, and it is used to mark the dissection area. Parenchyma transection is then carried out with the surgeon's left hand behind the right hemiliver with the aim of guiding resection by the right hand in real time. Figure 5 illustrates the layout of the liver with the outflow modulation technique, while Figure 6 shows an actual case.

PROBLEM OF THE SURGICAL MARGIN

One of the main criticisms of this surgical approach is the problem of the surgical margin. Both for HCC and CLM the detachment of the tumor from a spared vessel

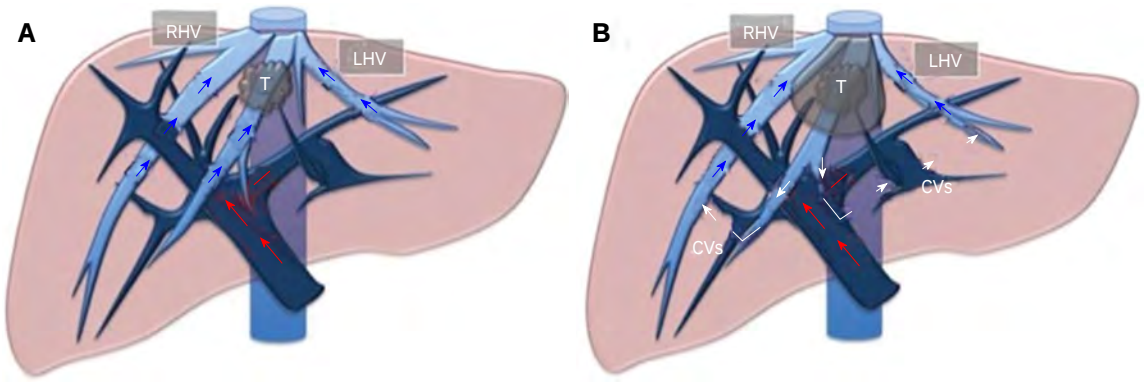

Figure 5 Layout of the liver for outflow modulation. A: A tumor in contact with the middle hepatic vein at the caval confluence; B: Once that vein is infiltrated and/or compressed, some collateral veins (CVs) shunting the flow from the middle hepatic vein territory to right hepatic vein (RHV) and/or left hepatic vein (LHV) territories can be detected. T: Tumor.

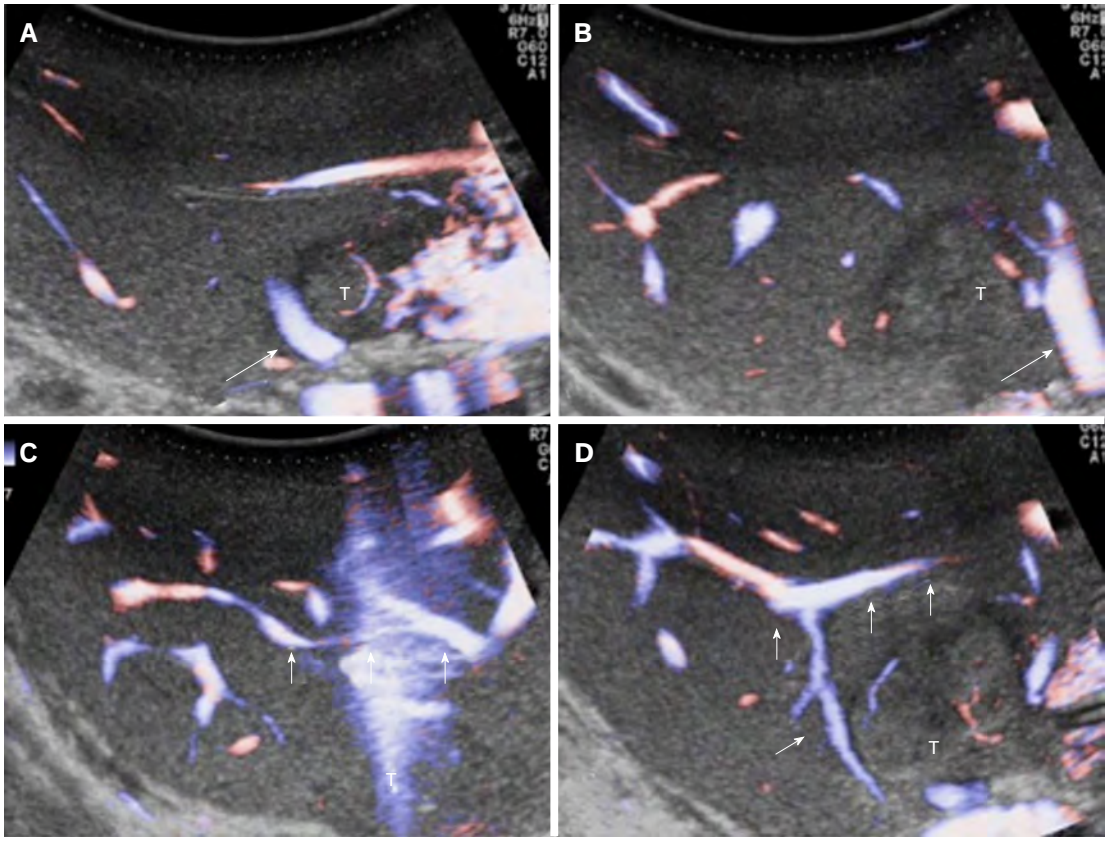

Figure 6 Intraoperative ultrasound study of communicating veins. A: A tumour located between the middle hepatic vein (MHV) (arrow) and the left hepatic vein (LHV) at their confluence into the inferior vena cava; B: The arrow indicates the LHV; C, D: Evidence of communicating veins (arrows) between the LHV and the MHV. T: Tumor.

may mean zero millimeters surgical margin, which traditionally is classified as R1 resection by the pathologist. Indeed, exposure of the tumor on the dissection plane is sometimes required to spare intrahepatic major vascular structures, which is the mainstay of our surgical policy. However, the effect of surgical margin status on survival of patients with HCC and CLM has been studied, but controversy still remains among surgeons. There is still debate about the real impact of the extent of the surgical margin once tumoral tissue is removed from the cut surface. For HCC, some authors reported that a margin smaller than 1 cm and even 2 cm plays a negative role in terms of long-term survival, while others authors found that a 0 mm margin is acceptable[33-37]. Also for CLM, there is no definitive agreement on the surgical margin[38,39]. It is well known that a positive margin is associated with increased risk of recurrence, but its width does not affect survival[40,41]. Moreover, it has been shown that patients with complex tumoral presentation treated with R1 resection may have the same long-term

survival of patients treated with R0 resection if aggressively treated with modern chemotherapy and repeated surgery[42]. Therefore, an anticipated minimal negative surgical margin should not be used as exclusion criterion for resection of HCC or CLM. The keystone is the performance of IOUS to guide the resection with the aim of achieving complete tumor clearance to minimize the risk of non-curative surgery.

In conclusions, IOUS is the best method for staging a liver tumor, and it is certainly the best method for the surgeon to understand in real-time the liver anatomy, and the relationships between tumors and intrahepatic vessels, thus allowing effective surgical operations. IOUS guidance allows for expanding indications offering the chance of cure to a greater proportion of patients, who would otherwise be excluded from the surgical program or submitted to more traditional but more risky operations. A precise tailoring of the area of hepatic resection using inflow and outflow modulation should be part of the surgical armamentarium of the modern liver surgeon.

Abstract

AIM: To characterize oxidase- and urease-producing bacterial isolates, grown aerobically, that originated from antral biopsies of patients suffering from acid peptic diseases.

METHODS: A total of 258 antral biopsy specimens were subjected to isolation of bacteria followed by tests for oxidase and urease production, acid tolerance and aerobic growth. The selected isolates were further characterized by molecular techniques *viz.* amplifications for 16S rRNA using universal eubacterial and *HSP60* gene specific primers. The amplicons were subjected to restriction analysis and partial sequencing. A phylogenetic tree was generated using unweighted pair group method with arithmetic mean (UPGMA) from evolutionary distance computed with bootstrap test of phylogeny. Assessment of acidity tolerance of bacteria isolated from antrum was performed using hydrochloric acid from 10^{-7} mol/L to 10^{-1} mol/L.

RESULTS: Of the 258 antral biopsy specimens collected from patients, 179 (69.4%) were positive for urease production by rapid urease test and 31% (80/258) yielded typical *Helicobacter pylori* (*H. pylori*) after 5-7 d of incubation under a microaerophilic environment. A total of 240 (93%) antral biopsies yielded homogeneous semi-translucent and small colonies after overnight incubation. The partial 16S rRNA sequences revealed that the isolates had 99% similarity with *Pseudomonas* species. A phylogenetic tree on the basis of 16S rRNA sequences denoted that JQ927226 and JQ927227 were likely to be related to *Pseudomonas fluorescens* (*P. fluorescens*). On the basis of *HSP60* sequences applied to the UPGMA phylogenetic tree, it was observed that isolated strains in an aerobic environment were likely to be *P. fluorescens*, and *HSP60* sequences had more discriminatory potential rather than 16S rRNA sequences. Interestingly, this bacterium was acid tolerant for hours at low pH. Further, a total of 250 (96.9%) genomic DNA samples of 258 biopsy specimens and DNA from 240 bacterial isolates were positive for the 613 bp amplicons by targeting *P. fluorescens*-specific conserved putative outer membrane protein gene sequences.

CONCLUSION: This study indicates that bacterial isolates from antral biopsies grown aerobically were *P. fluorescens*, and thus acid-tolerant bacteria other than *H. pylori* can also colonize the stomach and may be implicated in pathogenesis/protection.

Patel SK, Pratap CB, Verma AK, Jain AK, Dixit VK, Nath G. *Pseudomonas fluorescens*-like bacteria from the stomach: A microbiological and molecular study. *World J Gastroenterol* 2013; 19(7): 1056-1067 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1056.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1056

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a gram-negative, microaerophilic bacterium found primarily in the stomach. It has been implicated in chronic gastritis, gastric ulcers, duodenal ulcers and stomach cancers that were previously believed to be of non-microbial origin[1-3]. There was a misconception that no bacteria could live in the stomach because of its highly acidic environment. For the first time, Steer and Colin-Jones[4] published their results regarding the presence of gram-negative, oxidase- and urease-producing bacteria, but they proposed that it was *Pseudomonas* (*P.*), a contaminant and not related to peptic ulcer. In an effort to grow *H. pylori* from an antral biopsy, we could see that a peculiar type of bacterial colony was growing consistently after overnight incubation while *H. pylori* was taking 3-5 d to grow. These colonies were also oxidase and urease producers, but growing in an aerobic environment. There are reports that show the presence of a variety of bacteria in the stomach by isolation, DNA profiling and polymerase chain reaction (PCR)-based analysis, and some of them are urease producers hindering the specificity of the urea breath test[5-7]. Therefore, we aimed to characterize this type of bacterial isolate and to analyze whether they are colonizers or contaminants.

MATERIALS AND METHODS

Collection of specimens

The study subjects were patients attending inpatient services of the Department of Gastroenterology, University Hospital of Banaras Hindu University, Varanasi, Uttar Pradesh, India. This hospital provides tertiary-level health services for the eastern part of Northern India. The culture isolation, phenotypic and molecular characterizations were carried out in the Department of Microbiology, Institute of Medical Sciences.

Patients and samples

A total of 258 patients suffering from upper gastrointestinal (UGI) diseases like non-ulcer dyspepsia (NUD), peptic ulcer diseases (PUD) including gastric ulcer and duodenal ulcer, and gastric carcinoma were enrolled during a period of 3 years (2007-2010) and three antral biopsy pieces from each patient were collected. Before taking a biopsy, the endoscope was rinsed with detergent followed by water, and disinfected with 2% alkaline glutaraldehyde for 30 min then rinsed with sterile water. In a similar way, biopsy forceps were washed and sterilized and one biopsy forceps was used for one patient exclusively. The biopsy specimens were collected by endoscopic forceps from each individual with full aseptic precautions after taking well-informed consent. The work was approved by the Ethics Committee of the Institute of Medical Sciences, Banaras Hindu University. Patients with mucosal breaks greater than 5 mm in size with apparent depth were diagnosed as having ulcer and those with ulcerato-infiltrative lesions with positive histology/brush cytology were considered as having stomach carcinoma. The patients not having ulcerative lesions but suffering from dyspeptic symptoms were diagnosed as NUD. Individuals with normal endoscopic findings without gastroduodenal symptoms but having other gut problems were treated as healthy controls. In the present study, those patients were excluded who had a history of previous gastric surgery, active UGI bleeding, chronic alcoholism, intake of antibiotics and proton pump inhibitors during the last 4 wk or those taking non-steroidal anti-inflammatory drugs. Further individuals less than 18 years of age, pregnant or lactating mothers or those having illnesses like cirrhosis, chronic renal failure or ischemic heart disease were also excluded.

Microbiological processing

The three biopsy pieces were pooled and homogenized into phosphate saline buffer together in an all glass disposable homogenizer and were divided into three aliquots. The first aliquot of the tissue homogenate was transferred immediately into a rapid urease test (RUT) medium and the second was plated within 30 min of collection onto the media used for bacterial culture [Mueller Hinton agar without supplement and media containing brain heart infusion agar (Difco, Becton Dickinson, Sparks, MD, United States), supplemented with 7% sheep blood, 0.4% IsoVitaleX, and Skirrow selective supplement (vancomycin 10 μg/mL; polymixin B sulfate 2.5 IU/mL; trimethoprim lactate 5 μg/mL) (Difco, Becton Dickinson, Sparks, MD, United States)]. The non-enriched plate was incubated at 37 ℃ in an aerobic atmosphere while the other was incubated in the presence of 5% O_2, 10% CO_2, and 85% N_2 for 3-7 d. Several small colonies could be seen after overnight incubation in the first plate. The other plate was examined every alternate day after 3-7 d to see if colonies other than those observed after overnight incubation developed. Small translucent colonies developed after 5-7 d of incubation other than those originally after observed overnight incubation on non-enriched nonselective medium. These colonies were further subjected to morphological and biochemical tests *viz.* motility, oxidase, catalase, and urease. All the isolates were divided into two groups on the basis of the incubation period, *i.e.*, those isolates obtained after overnight incubation designated as group A and the other group B possessing those strains isolated after 5-7 d of incubation. The third aliquot was subjected to genomic DNA extraction.

Table 1 Primers used to study *Helicobacter pylori* and *Pseudomonas fluorescens* isolates

Target gene	Primer name	Primer sequence (5′-3′)	PCR condition (number of cycles, size of product)

PCR: Polymerase chain reaction.

RUT

For the RUT, biopsy specimens were inoculated into 1 mL of 10% urea in deionized water (pH 6.8), to which two drops of 1% phenol red solution was added, and incubated at 37 ℃ for 24 h. A positive result was recorded when the color changed from yellow to pink within 30 min. If there was mild color change within 30 min, the RUT tubes were incubated for a further 24 h.

Subculture at different temperatures

The organisms which appeared after overnight incubation were tested for growth at 4 ℃, 35 ℃ and 42 ℃ onto Muller Hinton agar; incubation was maintained for 14 d to distinguish *Pseudomonas* spp.[8,9]. Those organisms showing growth at 4 ℃ were sub cultured twice and incubated at the appropriate temperature for more than 10 d each time.

Assessment of acidity tolerance of bacteria isolated from gastric niche

Five isolates were suspended into different molar concentrations of hydrochloric acid (10^{-1} to 10^{-7} mol/L corresponding to pH 1.0 to 7.0) and a CFU was maintained as 10^6 CFU/mL. After the intervals of 0 min, 5 min, 10 min, 20 min, 30 min and 60 min, 100 μL acidic suspension (10^5 CFU) were transferred into 3 mL BHI broth. After overnight incubation optical density was recorded with the help of a spectrophotometer at 600 nm wavelength and bacterial count was expressed in CFU/mL. This experiment was repeated twice.

Preparation of genomic DNA for PCR assay

Extraction of genomic DNA from both types of bacterial isolates (A total of 320 strains including groups A + B) as well as from tissue homogenate was performed using a standard proteinase K and phenol-chloroform method[10]. To exclude the possibility of cross contamination of DNA during DNA extraction, one set of double distilled was included in each batch of DNA extraction.

Detection of H. pylori by nested PCR

Confirmation of *H. pylori* was done at a molecular level by nested PCR targeting the conserved *HSP60* gene and its restriction fragment length polymorphism. The reaction was performed in 25 μL final volume containing 10 ng of DNA, 1 U of Taq polymerase (Bangalore Genie, India), 200 mmol/L (each) deoxynucleotide triphosphate (MBI, Fermentas) and 1.5 mmol/L $MgCl_2$ in standard PCR buffer and 10 pmol of each primer as described by Singh *et al*[11]. Primer sequences and PCR conditions are displayed in Table 1. For the internal amplification, the PCR product from the primary cycle was diluted 1/50 and 1 μL was used as the template in the nested PCR. The conditions for the PCR amplification, first and nested reactions were the same. DNA from *H. pylori* reference J99 and a tube containing water in place of DNA were assayed in each PCR run as positive and negative controls, respectively.

After amplification, the PCR products (501 bp) were precipitated with 2.5 volumes of ethanol. The pellets were washed twice with 70% ethanol and dissolved in Tris-EDTA buffer (pH 8.0). A 10 μL precipitated amplified DNA sample was then digested with 10 U of restriction enzyme *Hind*Ⅲ in appropriate buffered solution recommended by the manufacturer (Bangalore Genie, India) and incubated for 3 h at 37 ℃. The digested DNA fragments were analyzed by electrophoresis on 2% agarose gels (Bangalore Genie, India) containing 0.5 μg of ethidium bromide per mL. The gel was run at 70 V with TBE (Tris Boric acid EDTA) buffer for 3 h and was examined by a transilluminator and photographed. The sizes of digested DNA fragments were estimated from distances of molecular weight standards and compared with in silico restriction digestion.

Amplified rDNA restriction analysis

For each group of isolates, the 16S rRNA from 8 randomly selected isolates was amplified using forward primer-16SF and reverse primer-16SR[12]. PCR amplification was performed in a thermocycler (Biometra, Germany) according to standard procedures (Table 1). After amplification by universal eubacterial primers, the PCR products (1155 bp) were precipitated with 2.5 volumes of ethanol. The pellets were washed twice with 70% ethanol and dissolved in Tris-EDTA buffer (pH 8.0). A 10 μL precipitated amplified DNA sample was then digested with 10 U of restriction enzyme *Eco*R1, in appropriate buffered solution recommended by the manufacturer (Bangalore Genie) and incubated for 3 h at 37 ℃. The visualization of the restriction fragment was done by the same method as described in the previous paragraph.

Sequencing

The amplified PCR products were purified from salts and primers using QIA quick PCR purification kit (Qiagen, United States). A total of 8 purified amplicons generated targeting *HSP60* and 2 amplicon 16S rRNA genes were outsourced for partial sequencing to Bangalore Genei, India. Sequences were analyzed using BLASTN (http://www.ncbi.nlm.nih.gov/BLAST) to verify the identity of the sequences: whether *H. pylori* or some other microorganism.

Sequence analyses

Reference sequences of *Pseudomonas* group and other enteric pathogens used for phylogenetic analyses were retrieved from Genbank. The partial 16S rRNA sequences and HSP60 sequence for the strains were aligned with reference sequences using Clustal X version 1.81, with default parameters[13]. Phylogenetic and molecular evolutionary analyses were performed using *MEGA* version 4[14]. The phylogenetic tree was generated using the unweighted pair group method with arithmetic mean (UPGMA) from evolutionary distance computed with bootstrap test of phylogeny. The degree of statistical support for branches was determined with 500 bootstrap replicates.

Primers designed for Pseudomonas fluorescens targeting putative membrane-bound protein

The putative membrane-bound protein coding gene present in all the strains of *P. fluorescens* is available in NCBI Genbank. Due to a similarity of sequences of about 55% in *P. fluorescens,* we therefore planned to design nested degenerate primers to amplify the partial sequence of putative membrane bound protein so that it was able to amplify all strains of *P. fluorescens*. Forward and reverse oligo-nucleotide degenerate primers derived from the region located between bases 92072 and 92775 of the *Pseudomonas fluorescens* (*Pseudomonas fluorescens* Pf0-1; GenBank Accession number CP000094.2 and GI: 253992019) were synthesized. Internal primers were derived from the region between bases 92114-92726 for nested PCR. DNA extracted from *P. putida* and *P. aeruginosa* was used to monitor sensitivity against *P. putida* and *P. aeruginosa*. During the PCR assay in each batch, Mili Q water was used as a template to ensure that there was no contamination by water and PCR reagent[15].

Pseudomonas fluorescens NCIMB 10586 mupirocin biosynthetic gene

Forward and reverse oligonucleotides were derived from the conserved region located between bases 68101 and 68822 of the mupirocin biosynthetic gene cluster of *Pseudomonas fluorescens* (NCIMB 10586). An internal primer was derived from the region between bases 68796 and 68796 (GenBank Accession number AF318063.2; gene GI: 20150006). PCR amplification was similar to amplification of *HSP60* gene and conditions are described in Table 1.

Randomly amplified polymorphic DNA PCR

Fingerprinting of 71 randomly selected strains from group A was performed based on randomly amplified polymorphic DNA (RAPD) PCR methods by using primers RAPD3 5'-TACAGCTCG-3'and RAPD5 5'AGCACTGCCT-3' (this study). PCR was carried out in 25 μL volume using 10 ng of genomic DNA, 1 U of Taq polymerase (Bangalore Genie, India), and 15 pmol of each primer (Bangalore Genie), 200 mmol/L (each) deoxynucleotide triphosphate (Bangalore Genie, India) and 2 mmol/L $MgCl_2$ in standard PCR buffer. Amplification reactions were carried out in a thermal cycler (Biometra, Goettingen, Germany).

The gel images were analyzed under ultraviolet light in a gel documentation system (Alpha Innotech, United States). Cluster analysis of all the isolates was done on the basis of the fingerprint generated. Based on the presence or absence of different DNA fragments in the fingerprints of the *P. fluorescens* strains, a binary data matrix was created. Overall similarity between the pair of strains was calculated from the binary data matrix using the simple matching-dice coefficient. The resulting similarity matrix was used as the input data for cluster analysis by NTSYS pc2.0 programme of UPGMA[16].

Statistical analysis

The level of significance between the two proportions, *i.e.*, culture rates and molecular detection rates, was calculated by Fischer's Exact Probability test.

RESULTS

Bacteriological findings

Of the 258 antral biopsy specimens collected from patients, 69.4% (179/258) were found to be positive by RUT and 31% (80/258) by culture for typical *H. pylori,* after 5-7 d of incubation under a microaerophilic environment; these were gram-negative curved rods and were positive for oxidase, catalase and urease. However, 258 antral biopsies yielded 240 (93%) homogeneous semi-translucent and small colonies after overnight incubation. These isolates also grew aerobically but the colonies had

[1]$P < 0.001$ between *Helicobacter pylori* (*H. pylori*) and nested polymerase chain reaction (PCR); [2]$P < 0.001$ between *H. pylori* and *Pseudomonas fluorescens* (*P. fluorescens*); [3]$P < 0.001$ between colonies appearing after overnight incubation group (group A) and colonies appearing after 3-7 d of incubation group (group B). Group A: Non-ulcer dyspepsia (NUD) *vs* gastric carcinoma (CA), $P = 0.02$; NUD *vs* normal, $P < 0.02$; *H. pylori*: Peptic ulcer diseases (PUD) *vs* CA, $P < 0.001$; NUD *vs* CA, $P < 0.001$; CA *vs* Normal, $P = 0.001$; Overall: Culture of *P. fluorescens* *vs* nested PCR, $P < 0.001$. Normal: Patients whose endoscopic findings were normal; RUT: Rapid urease test; RUT: Rapid urease test.

an opaque, small character contrary to the translucent one which is typical for *H. pylori* (Table 2).

Biochemical characterization

A total of 100 isolates randomly selected from group A were subjected to extensive phenotypic characterization. All of them were gram-negative, oxidase-, catalase- and urease-positive. All were non-fermenters, showed variable nitrate reduction and failed to utilize simple sugars (glucose, lactose, sucrose, mannitol and maltose). Citrate was utilized by all of them. All the tested strains were Methyl Red negative and Voges-Praskauer negative or equivocal. All the strains were oxidase- and catalase-positive. Indole test was negative but on mixing with the Kovac's reagent a typical greenish color developed. All these isolates were able to multiply at 4 ℃. These findings intimated that those isolates which appeared after overnight incubation were *P. fluorescens*.

Acid tolerance assay

The bacterial count of *P. fluorescens* was 7.3×10^8, 6.9×10^8, 7×10^8, 6.1×10^8, 7.6×10^8, 6.5×10^8 and 9.8×10^8 CFU/mL for 0 min, 5 min, 10 min, 15 min, 20 min, 30 min and 60 min after acid exposure (pH 1.0). Average bacterial counts were 9.3×10^8, 9.8×10^8, 1.0×10^9, 9.5×10^8 and 9.8×10^8 CFU/mL for acid tolerance of low pH 2, pH 3, pH 4, pH 5, pH 6 and pH 7, respectively, for different time intervals (0 min, 5 min, 10 min, 15 min, 20 min, 30 min and 60 min). Similarly, bacterial growth was approximately the same in control experiments where acidic solution was replaced by LB Broth. The exposure to acidic pH showed that *P. fluorescens* growth was not killed by exposure to lower pH 1.0 for an hour.

Amplification and RLFP of HSP60 gene

Isolates from group B, which grew under microaerophilic environment, were subjected to amplification by primers specific for *HSP60* gene of *H. pylori*. All the 80 isolates from 258 patients were positive for the 501 bp of amplicon for the corresponding gene. However, 211 (81.8%) of 258 antral biopsies were positive for *H. pylori* DNA as the 501 bp amplicon was produced by nested PCR. All nested amplicons of 501 bp were restricted into two fragments of 310 bp and 191 bp by the *Hind*Ⅲ restriction enzyme (Figures 1 and 2). Although colonies grown after overnight incubation could give amplification with first round of PCR primers, nested PCR did not generate 501 bp amplicon specific to *H. pylori*. Similarly, 240 aerobic isolates could not amplify in second round PCR.

16S rRNA amplified rDNA restriction analysis

The isolates analyzed by using *Eco*R1 restriction endonuclease enzyme on amplicons generated by 16S rRNA specific primers fell into two groups: group A isolates could not be restricted, while group B isolates which were restricted into two fragments of 635 bp and 520 bp which were similar to *in silico* restriction of *H. pylori* J99 (Figure 3).

Identification on the basis of 16S rRNA and HSP60 gene sequence

The partial nucleotide sequence of 16S rRNA of 2 isolates (GenBank accession number JQ927226 and JQ927227) from group A represented no restriction site for *Eco*R1 restriction enzyme, and comparison of the nucleotide sequences with the NCBI database showed similarity of 99% with *P. fluorescens*. Similarly, partial nucleotide sequence of unrestricted amplified *HSP60* gene (590 bp) of the isolates that grew after overnight incubation aerobically also showed 96% similarity with *P. fluorescens*.

Phylogenetic sequence analysis

The partial sequence of the 16S rRNA gene of two *P. fluorescens*-like isolated strains and sequences of *16S rRNA* gene from 34 reference strains representative of the principal *Pseudomonas* phyla and 12 other bacterial pathogens were used for comparison of a phylogenetic tree. Similarly, a partial sequence of *HSP60* gene of 8 *P. fluorescens*-like isolates and sequence of *HSP60* gene of 5 *P. fluorescens* reference strains and 6 other reference strains representative of the principal *Pseudomonas* phyla and 11 other clinical pathogens were used to prepare a phylogenetic tree. To simplify the comparisons for the resulting phylogenetic tree by the UPGMA method, we named clusters based on *16S rRNA* gene data, r-clusters, and those based on

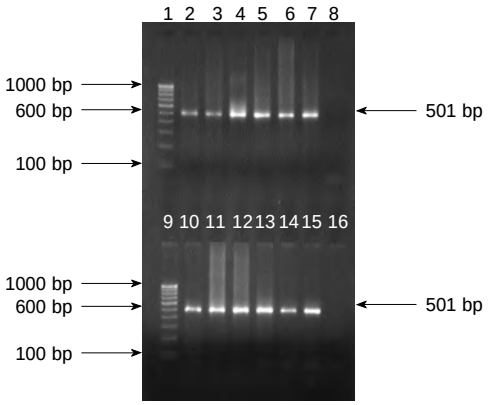

Figure 1 Amplification of partial 501 bp *HSP60* gene with specific nested primer for *Helicobacter pylori* in antral biopsies and culture isolates. Lanes 1 and 9: Molecular marker (100 bp); Lane 2: Positive control; Lanes 3 to 7: gDNA from antral biopsies; Lanes 8 and 16: Negative control; and Lanes 10 to 15: Bacterial gDNA from culture isolates.

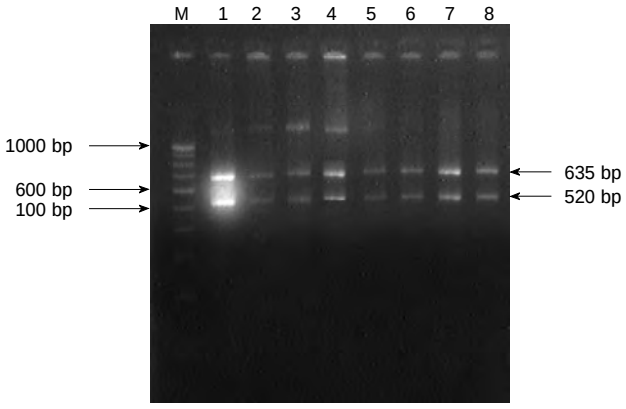

Figure 3 Gel picture of amplified rDNA restriction analysis. Lane M: 100 bp molecular marker; Lanes 1 to 8: Digested 1155 bp 16S rRNA amplicon into two fragments (635 bp and 520 bp) of culture isolates of *Helicobacter pylori*.

HSP60 data, h-clusters. The tree showed, on the basis of 16S rRNA sequences, it can be grouped clearly into three r-clusters on the basis of number of bootstraps *i.e.*, 90, 78 and 60. Cluster r-1 represents a fluorescens group along with two sequences submitted to gene bank (accession number as JQ927226 and JQ927227 for RCa25 and RCa24 respectively). Cluster r-2 represents *Pseudomonas aeruginosa, Pseudomonas syringae, Pseudomonas stuzeri, Pseudomonas chlororaphis, Pseudomonas putida, Pseudomonas pertucinogena* group and 4 *P. fluorescens* reference strains, and r-3 cluster represents other microbes and enteric pathogens rather than non-*Pseudomonas* spp. From cluster analysis it is clear that JQ927226 and JQ927227 are related to *P. fluorescens* (Figure 4).

The tree shows that, on the basis of *HSP60* sequences, three h-clusters could be observed (bootstraps number, 99, 63 and 71): the sequences of seven isolated strains from the gastric niche could be grouped in h-cluster I along with *P. fluorescens* strains while cluster II represents non-fluorescens pseudomonas species with the exception of *P. fluorescens* F113 (CP003150). The h-cluster III grouped non-*Pseudomonas* sp. including enteric pathogens along with *H. pylori*.

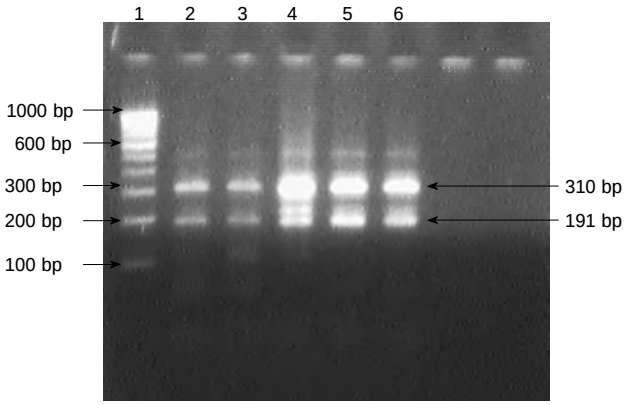

Figure 2 Electrophotograph of restriction digestion of *HSP60* gene of *Helicobacter pylori* isolates with *Hind*Ⅲ. Lane 1: 100 bp molecular marker; Lanes 2 to 6: Restricted 501 bp *HSP60* gene amplicon into two fragments (310 and 191 bp) of culture isolates of *Helicobacter pylori*.

Interestingly, one strain of *P. fluorescens* RCa 24 fell into this III cluster with closeness to *Stenotrophomonas maltophilia* and *Bordetella pertusis* (Figure 5).

Pseudomonas fluorescens specific PCR

One specific pair of primers targeting putative outer membrane protein was used to identify *P. fluorescens*. The other specific primers targeting mupirocin biosynthetic gene were used to screened out whether any *P. fluorescens*-like isolate was producing mupirocin. Genomic DNA extracted from group-A isolates and all biopsies was used as template for PCR amplification. A total of 250 (96.9%) out of 258 biopsy specimen genomic DNA samples and 240 bacterial isolates were positive for the amplification of the corresponding gene, *i.e.*, the putative outer membrane protein gene sequences (Table 2 and Figure 6). Although putative outer membrane protein gene targeting primers were degenerate, they were unable to produce the 613 bp amplicon from *Pseudomonas aeruginosa* and *Pseudomonas putida* at similar PCR conditions. The mupirocin biosynthetic gene targeting primers were unable to produce amplification of the 722 bp or 611 bp amplicon either in primary or secondary round PCR, respectively, from any of the isolates (data not shown).

RAPD

All the 71 strains tested from group-A yielded significant PCR products with RAPD primers. The strains generated approximately 3-13 well-defined bands between 150 bp to 2.5 kb sizes (9 bands on average) with each isolate yielding a unique profile of products. Cluster analysis with a RAPD-PCR based method showed that only a few isolates exhibited an identical profile. Nearly all the isolates appeared as dissimilar from each strain, but 5 strains isolated from cancer patients showed similar banding pattern at 0.0 coefficient (Figures 7 and 8).

DISCUSSION

Traditionally, the human stomach has been viewed as an

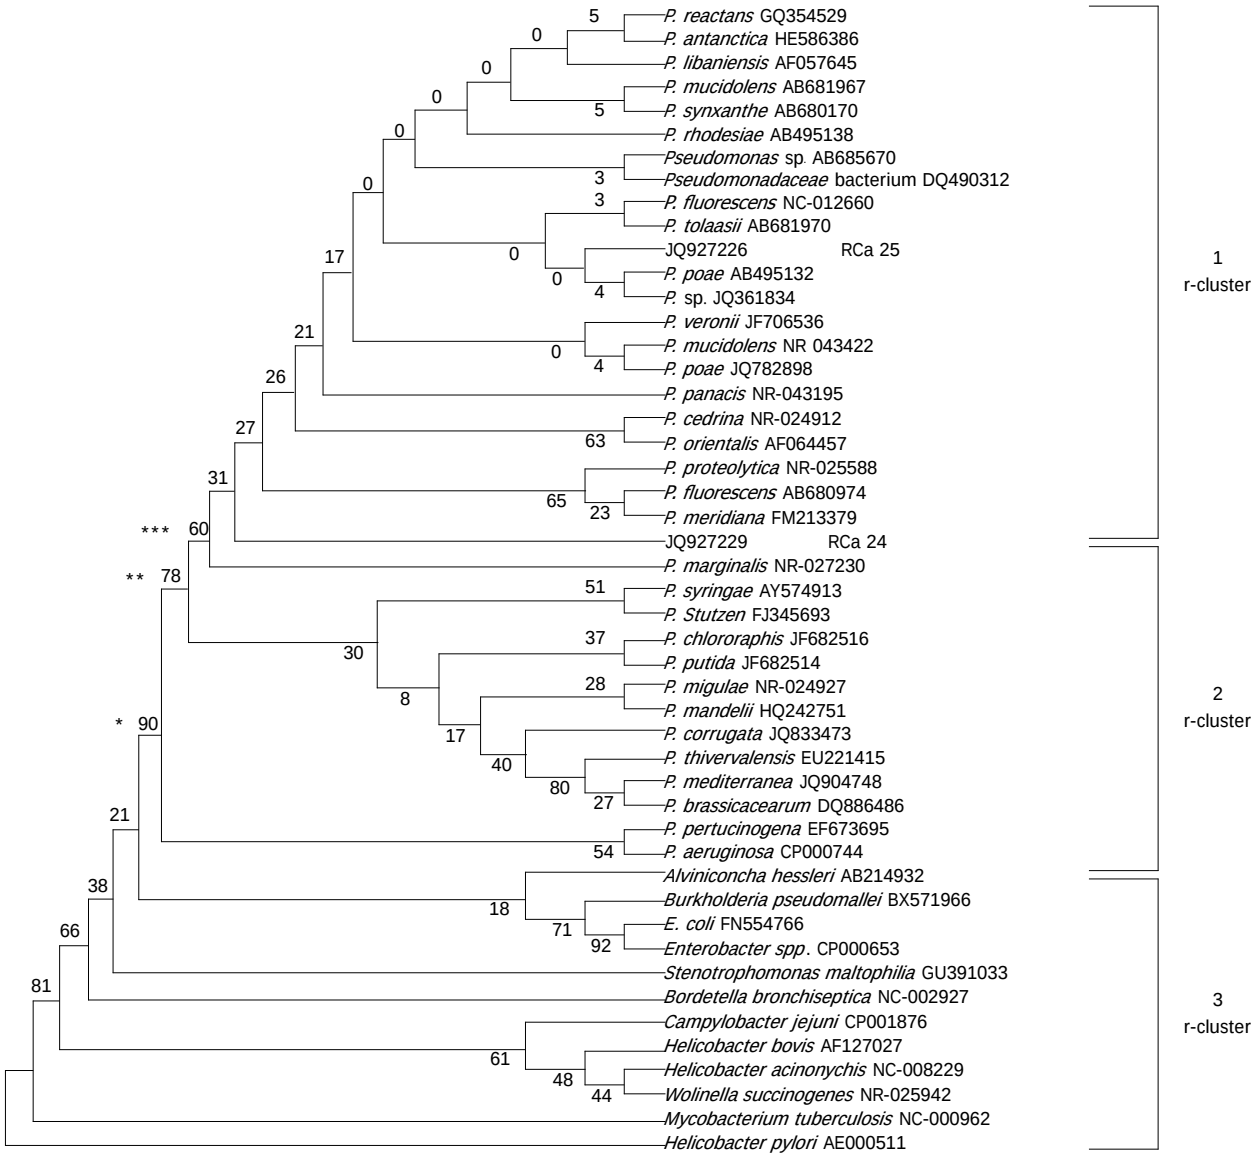

Figure 4 Phylogenetic affiliation of the *Pseudomonas fluorescens*-like isolates (*n* = 2; JQ927226 and JQ927227). The unrooted tree was generated using unweighted pair group method with arithmetic mean from evolutionary distance computed with bootstrap test of phylogeny using *MEGA* version 4 by aligning published sequences from Genbank of *16S rRNA* genes from 34 reference strains representative of the principal *Pseudomonas* (*P.*) *phyla* (accession number followed by species name in parentheses). For checking relatedness with other genera, we included *16S rRNA* gene sequences from GenBank of 12 bacterial pathogens namely *Stenotrophomonas maltophilia*, *Bordetella bronchiseptica*, *Wolinella succinogenes*, *Helicobacter pylori*, *Helicobacter acinonychis*, *Escherichia coli* (*E. coli*), *Enterobacter* spp., *Campylobacter jejuni*, *Burkholderia pseudomallei*, *Alviniconcha hessleri*, *Helicobacter bovis* and *Mycobacterium tuberculosis*. Branches found by maximum likelihood are labeled with asterisks: one asterisk if bootstrap values = 90%, two asterisks if = 78% and three asterisks if = 60%.

inhospitable environment for microorganisms because of its acidic environment along with several other antimicrobial factors. With the discovery of *H. pylori* and other gastric helicobacters, and subsequent insight into the mechanisms by which these organisms adapt to the gastric environment[17], the existence of a bacterial community adapted to this human niche seems quite plausible. This is the first report of its kind showing the presence of a *P. fluorescens*-like bacterium in the human stomach. We isolated the bacteria from NUD, gastric ulcer, duodenal ulcer and gastric carcinoma patients with the belief that only *H. pylori* is associated with acid peptic diseases. However, *P. fluorescens* grew on a simple medium like Mueller-Hinton agar without an antibiotic supplement. The small white colonies had Gram-negative slightly curved rods and produced oxidase, urease and catalase enzymes. These colonies appeared after overnight incubation in an aerobic environment. These isolates exhibited growth at 4 ℃, which is one of the key characteristics of *P. fluorescens*[9]. When these isolates were exposed to acidic pH as low as pH 1.0 for 1 h, the subsequent growth of the bacteria was not affected, indicating that they were acid tolerant. However, due to deviation from the classical *H. pylori* growth characteristics, we were prompted to consider them as non-*H. pylori* and submit them for further characterization. For the purpose, *H. pylori* specific primers for amplifying *HSP60* gene-specific sequences were applied[11]. However, an approximate 600 bp sized amplicon

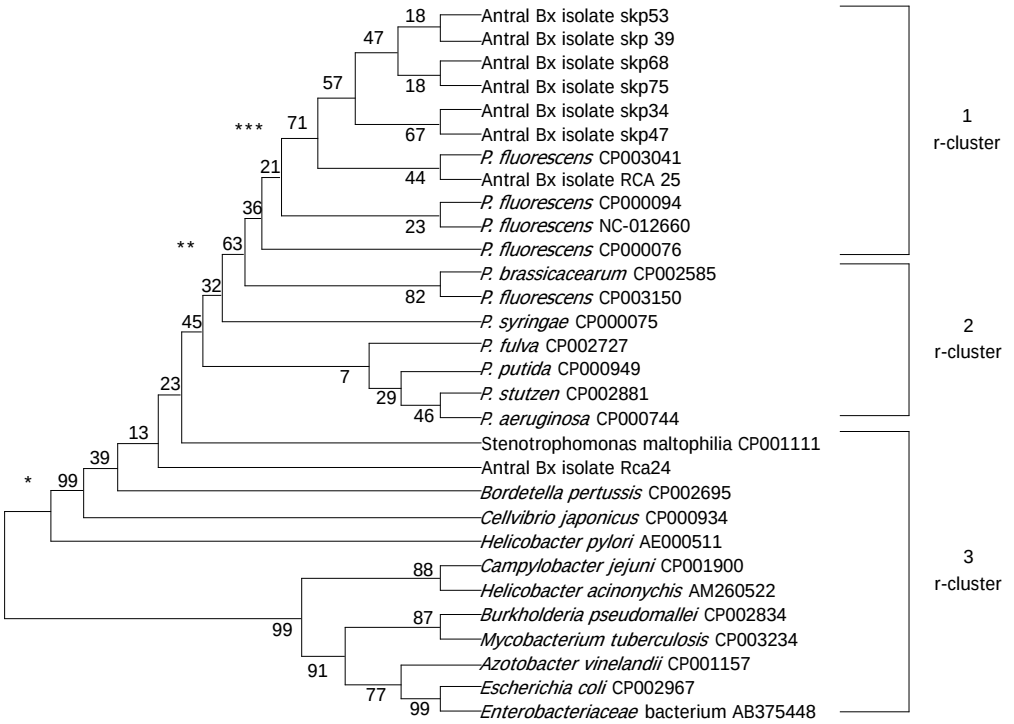

Figure 5 Phylogenetic affiliation of the *Pseudomonas fluorescens*-like isolates (*n* = 8; partial sequences of *HSP60*) on the basis of *HSP60* gene sequences. The unrooted tree was generated using unweighted pair group method with arithmetic mean from evolutionary distance computed with bootstrap test of phylogeny using *MEGA* version 4 by aligning published sequences from Genbank of heat shock protein (*HSP60*) genes from 5 reference strains of *Pseudomonas fluorescens* (*P. fluorescens*), 6 other reference strains representative of the principal *Pseudomonas phyla* (accession number followed by species name in parentheses). For checking relatedness with other genera, we included *HSP60* gene sequences from GenBank of 11 bacterial pathogens, namely *Helicobacter pylori*, *Helicobacter acinonychis*, *Campylobacter jejuni*, *Enterobacter* spp., *Escherichia coli*, *Bordetella pertussis*, *Burkholderia pseudomallei*, *Stenotrophomonas maltophilia*, *Cellvibrio japonicus*, *Azotobacter vinelandii* and *Mycobacterium tuberculosis*. Branches found by maximum likelihood are labeled with asterisks: one asterisk if bootstrap values = 99%, two asterisks if = 63% and three asterisks if = 71%.

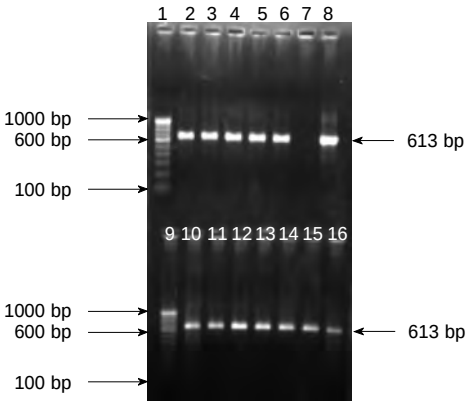

Figure 6 Amplification of putative outer membrane protein gene with specific nested primer generating 613 bp amplicon for *Pseudomonas fluorescens* of antral biopsies and culture isolates. Lanes 1 and 9: Molecular marker (100 bp); Lanes 2 to 6: gDNA from antral biopsy specimens; Lane 7: Negative control; Lane 8: Positive control; and Lanes 10 to 16: Bacterial gDNA from culture isolates.

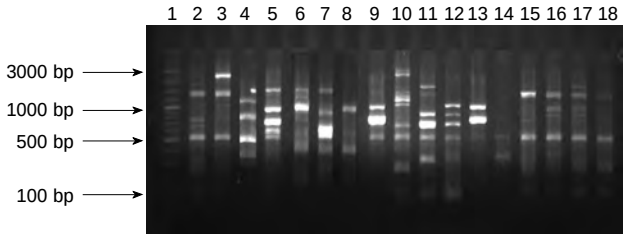

Figure 7 Representative gel showing amplification of *Pseudomonas fluorescens* genomic sequences by randomly amplified polymorphic DNA primers. Randomly amplified polymorphic DNA (RAPD) 3 5'-TACAGCTCG-3' and RAPD5 5'-AGCACTGCCT-3'. Lane 1: 100 bp molecular marker; Lanes 2 to 18: *Pseudomonas fluorescens* isolates isolated from stomach.

was produced by the first round of PCR, but a restriction site specific for *H. pylori* for *Hind*Ⅲ enzyme was absent in these amplicons. Further, none of these isolates could yield a 501 bp amplicon for *H. pylori* by nested PCR primers. Thus, the possibility of these isolates being *H. pylori* was excluded. On the other hand, the typical *H. pylori* isolates which grew after 5-7 d of incubation yielded 501 bp amplicon by nested PCR protocol targeting the *HSP60* gene.

Identification based on partial nucleotide sequencing of 16S rRNA of the representative isolates showed 99% sequence similarity with γ-*protobacteria*. On the basis of enzyme restriction analysis as well as partial nucleotide sequencing of 16S rRNA, the strains isolated from the acidic environment of the stomach either could be grouped in the genus *Pseudomonas* or with a closely related new genus. Further, on the basis of blasting of partial nucleotide sequences of *HSP60* gene sequences on the NCBI gene data bank, isolated strains could be grouped with *P. fluorescens*. On the basis of h cluster based on the

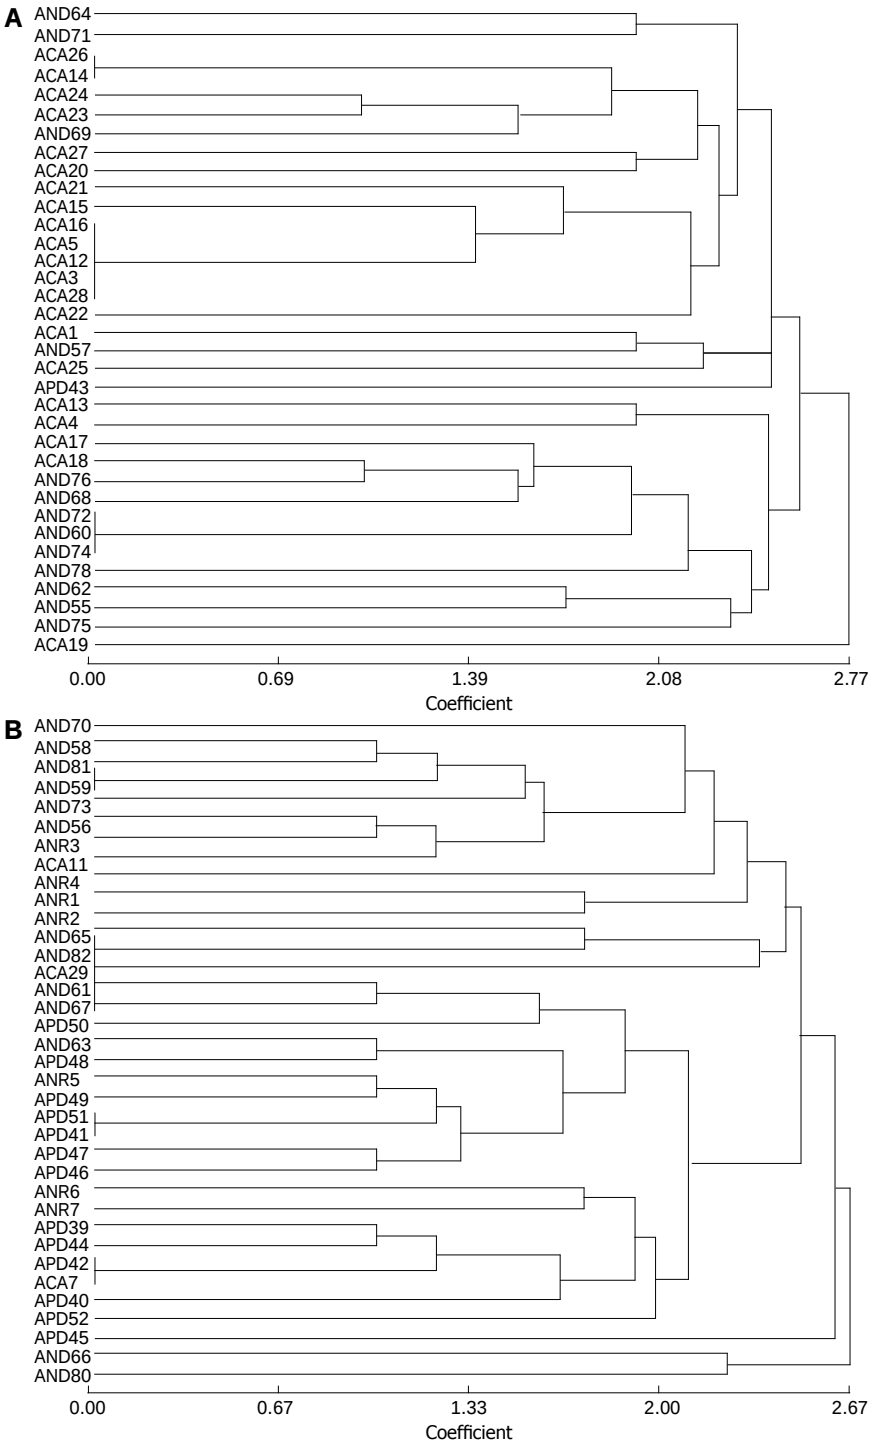

Figure 8 Dendrogram generated by unweighted pair-group method, arithmetic mean on basis of banding pattern of randomly amplified polymorphic DNA for *Pseudomonas fluorescens*. A: 1-35 out of 71 randomly selected isolates of *Pseudomonas fluorescens* from group A (n = 35); B: 36-71 out of 71 randomly selected isolates of *Pseudomonas fluorescens* from group A (n = 36).

UPGMA phylogenetic tree, it may be concluded that the *HSP60* gene sequence has better discriminatory power than 16S rRNA. Further, as one of the isolates could be grouped with *Stenotrophomonas maltophilia* and *Bordetella pertusis,* the possibility of the presence of bacteria other than *P. fluorescens* may not be denied.

The relatively conserved *16S rRNA* gene of *P. fluorescens* has been targeted for PCR-based amplification in culture isolates, but with variable specificity[18]. Therefore, we decided to target a conserved putative membrane-bound protein gene of *P. fluorescens*. The putative membrane-bound protein specific primer screened in the present study was found to be specific for *P. fluorescens* and it yielded an amplicon of 613 bp, confirming the isolates as being *P. fluorescens*. Mupirocin is known for its antibacterial activity and has been reported in only one strain of *P. fluorescens* (NCIMB 10586). A mupirocin-producing gene cluster could not be traced in any of the *P. fluorescens*

isolates despite confirmation by 3 genes, *i.e.*, 16S rRNA, *HSP60* and putative membrane bound protein genes. None of our isolates showed the presence of *mup*V (mupirocin). It is quite possible that this gene might be either absent in all the strains or have too much polymorphism at the loci of primer annealing[19]. We could isolate the *P. fluorescens* strain from 93% of antral biopsies of the patients suffering from gastric diseases. These isolates were further confirmed by PCR-based amplification targeting 3 conserved genes. In DNA of antral biopsy tissue also, 98.4% of NUD and 93.9% of gastric cancer patients were found to be positive for the *P. fluorescens* DNA by nested PCR, while 95.2% of normal stomach had *P. fluorescens* and 96.9% of patients with PUD were found to have the bacterium. Thus our observation indicates a high prevalence and density of these non-*H. pylori* bacteria in the gastric mucosa of patients. Further, to ascertain that the isolated *P. fluorescens* were not contaminants, we carried out whole genome fingerprinting of the 71 randomly selected isolates by using RAPD[20,21] with two RAPD primers. Cluster analysis indicated that almost all the strains had different banding patterns with only a few exceptions, confirming that the isolates were of different clones and thus ruling out the possibility of cross contamination. Moreover, from time to time, we did specific PCR amplification for the *P. fluorescens* on DNA extracted from samples of tap water and washouts of the endoscope, which never yielded the required amplicon even by nested protocol for putative outer membrane protein.

It is interesting to mention that before the implication of *H. pylori* in acid peptic diseases and stomach cancer, Steer and Collin-Jones[4] reported that 80% of antral biopsies have *Pseudomonas* spp. There are reports showing the presence of non-*Helicobacter* bacteria in gastric biopsies of patients suffering from gastric atrophy[22,23]. In cases of reduced gastric acidity due to antacids, it also has been reported that there is presence of several other bacteria[24-26]. Two more studies based on profiling of bacterial flora by temperature gradient gel electrophoresis, 16S rRNA sequence analysis[7] and molecular analysis of the bacterial microbiota[27] have shown presence of several bacterial species including *Pseudomonas* in the stomach. This bacterium seems to be able to colonize the stomach due to its ability to produce urease enzyme. Similarly, it was reported that a non-*H. pylori* bacterium, *Ochrobacrum anthropi,* could be implicated in causation of gastritis in the Squirrel monkey[6].

Such a high prevalence of *P. fluorescens* in human stomach raises many questions: Is it prevalent in the stomach of patients of other subcontinents and continents? Does it have any pathogenic role? Does it have some protective role? Is it simply a part of commensal flora of human stomach? There is a study from Venezuela[5] reporting that *Pseudomonas* strains may interfere with the identification of *H. pylori*. They suggested that one should not rely on rapid urease, catalase and oxidase tests for identification of *H. pylori*. However, studies are needed to observe and identify the presence of *P. fluorescens* in other parts of the world also. With regard to its pathogenic potential, *P. fluorescens* is known as an unusual pathogen of humans. It has been reported as causing septicemia in humans, especially associated with transfusion and cancer[28-30]. Moreover, there is a report indicating that *P. fluorescens* encodes the Crohn's disease-associated I^2 sequence and T cell super antigen, thus implicating it in the pathogenesis of Crohn's disease[31].

However, its commensal state in the stomach may be speculated strongly due to its prevalence in stomach at such a high level and density (it could be isolated in the majority of the antral biopsy). Assumptions may be made that *P. fluorescens* might be producing some antibacterial substances, such as is produced by *P. aeruginosa*, *P. aeruginosa* is known for producing 4-hydroxy-2-alkylquinoline which is inhibitory *in vitro* to *H. pylori*[32]. Moreover, one of the *P. fluorescens* strains is already known for production of mupirocin which is very effective against methicillin-resistant *Staphylococcus aureus*. This bacterium has been stated to have a probiotic role in the gills of fish[33]. Furthermore, low isolation of *H. pylori* and fewer incidences of acid peptic diseases including gastric cancer in North Indians may also be speculated on the basis of the probiotic activity of *P. fluorescens* in the stomach. In addition, there are reports of the unique property of *P. fluorescens* to inhibit the growth of other bacteria, fungi and nematodes causing plant pathology[34-40].

In view of the suggestions made by previous studies[41-43], there is a strong need to explore the exact role of *H. pylori* in stomach diseases because the commensal role of *H. pylori* cannot be rejected outright. In a similar way, the observations made in the present study strongly indicate that further exploration of the different aspects of associations of *P. fluorescens* with human disease and health should be carried out. The pathogenic potential may be explored in animal models like gerbils.

This study concludes that *P. fluorescens* is as common as *H. pylori* in the stomach of humans. Colonies that appeared on enriched BHI agar after 72 h of strictly microaerophilic incubation were *H. pylori* while those growing faster in an aerobic atmosphere were different. These different growths could be identified as *P. fluorescens*. The activity of *P. fluorescens* in the stomach may be speculated to be either pathogenic or probiotic.

COMMENTS

Background

Although *Helicobacter pylori* (*H. pylori*) has been implicated in acid peptic diseases along with stomach cancer, there are reports indicating the presence of several other bacterial species in the stomach. Antral biopsies from North Indian subjects frequently yielded a bacterial growth on selective, non-enriched simple medium in an aerobic environment at 37 ℃ of small, low convex, and pinhead-size translucent colonies. Presence of these types of growth provoked questions about its characterization and its status: whether it was a contaminant from the environment during antral biopsy collection.

Research frontiers

The big question to be answered is further characterization of these isolates and to ensure that they are actual colonizers of the stomach. Do these acid tolerant isolates have pathogenic potential if they are real colonizers?

Innovations and breakthroughs

Pseudomonas fluorescens (*P. fluorescens*)-like bacteria colonize the stomach quite frequently of North Indian patients at high density, as polymerase chain reaction (PCR)-based detection and isolation rates were both comparable. In contrast, the density of *H. pylori* seems to be quite low as nested PCR-based detection is significantly high as compared to the isolation rate of the bacterium. *P. fluorescens* isolates are urease producers and acid tolerant. Although the mupirocin gene could not be detected in any of the *P. fluorescens* isolates, the probiotic (inhibitory to *H. pylori*) role of the bacterium in the stomach may be speculated.

Applications

The potential of *P. fluorescens* as a probiotic may be explored because despite very high prevalence of *H.pylori* in India the incidences of acid peptic diseases and stomach cancer are quite low.

Terminology

Nested polymerase chain reaction is a modified technique of PCR intended to increase sensitivity and specificity of primer and to reduce the contamination in amplicons due to the amplification of undesired primer annealing sites. Phylogenetics is the study of evolutionary relations among groups of organisms such as strains or species, which are based on molecular sequencing data matrices. Probiotics are live microorganisms which when administered in adequate amounts confer a health benefit on the host, *e.g.*, lactic acid bacteria.

Peer review

The study is well carried out from the methodological perspective. This manuscript characterized the bacterial isolates growing aerobically from antral biopsies were *P. fluorescens*, which was the acid tolerant bacteria other than *H. pylori*. On the basis of 16S rRNA and HSP60 sequence and from phylogenetic sequence analysis these organisms were closely related to *P. fluorescens*. The authors also reconfirmed this unknown bacterium as *P. fluorescens* by PCR positivity of *P. fluorescens* specific conserved putative outer membrane protein gene. Finally, the authors concluded that *P. fluorescens* is as common as *H. pylori* in the human stomach.

Abstract

AIM: To clarify the specific roles and mechanisms of long interspersed nuclear element-1 ORF-1 protein [human long interspersed nuclear element-1 (LINE-1), ORF-1p] in chemotherapeutic drug resistance and cell proliferation regulation in hepatocellular carcinoma (HCC) cells.

METHODS: MTT assays were performed to identify the effect of the chemotherapeutic drug toxicity on HepG2 cells. Cell proliferation inhibition and the IC_{50} were calculated by the Origin 8.0 software. Western blotting assays were performed to investigate whether LINE-1 ORF-1p modulates the expression of some important genes, including *p53*, *p27*, *p15*, *Bcl-2*, *mdr*, and *p-gp*. To corroborate the proliferation and anchor-independent growth results, the HepG2 cells were analyzed by flow cytometry to investigate the effect of LINE-1 ORF-1p on the apoptosis regulation.

RESULTS: LINE-1 ORF-1p contributed to the resistance to several chemotherapeutic drugs (cisplatin and epirubicin) in HepG2 cells. The IC_{50} of the epirubicin and cisplatin increased from 36.04 nmol/L to 59.11 nmol/L or from 37.94 nmol/L to 119.32 nmol/L. Repression of LINE-1 ORF-1p expression by the siRNA could markedly enhance the response of HepG2 cells to the epirubicin and cisplatin. The IC_{50} correspondingly decreased from 28.06 nmol/L to 3.83 nmol/L or from 32.04 nmol/L to 2.89 nmol/L. Interestingly, down-regulation of LINE-1 ORF-1p level by siRNA could promote the response of HepG2 cells to the paclitaxel. The IC_{50} decreased from 35.90 nmol/L to 7.36 nmol/L. However, overexpression of LINE-1 ORF-1p did not modulate the paclitaxel toxicity in HepG2 cells. Further Western blotting revealed that LINE-1 ORF-1p enhanced *mdr* and *p-gp* gene expression. As a protein arrested in the nucleus, LINE-1 ORF-1p may function through modulating transcriptional activity of some important transcription factors. Indeed, LINE-1 ORF-1p promoted HepG2 cell prolifera-

tion, anchor-independent growth and protected the cells against apoptosis through modulating the expression of *p15*, *p21*, *p53*, and *Bcl-2* genes.

CONCLUSION: LINE-1 ORF-1p promotes HepG2 cell proliferation and plays an important role in the resistance of chemotherapeutic drugs. By establishing novel roles and defining the mechanisms of LINE-1 ORF-1p in HCC chemotherapeutic drug resistance and cell proliferation regulation, this study indicates that LINE-1 ORF-1p is a potential target for overcoming HCC chemotherapeutic resistance.

Feng F, Lu YY, Zhang F, Gao XD, Zhang CF, Meredith A, Xu ZX, Yang YT, Chang XJ, Wang H, Qu JH, Zeng Z, Yang JL, Wang CP, Zhu YF, Cui JJ, Yang YP. Long interspersed nuclear element ORF-1 protein promotes proliferation and resistance to chemotherapy in hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(7): 1068-1078 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1068.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1068

INTRODUCTION

Hepatocellular carcinoma (HCC) which is the most common tumor worldwide, and the third most common cause of cancer death, is often accompanied by a poor prognosis[1]. The majority of HCC patients are unresectable at the time of first diagnosis, and even in patients who are suitable for surgery, the risk of recurrence is high. Consequently, chemotherapy is an important alternative strategy for most HCC patients[2]. Cisplatin, paclitaxel and epirubicin are common chemotherapeutic agents used in the treatment of HCC. However, chemotherapy is often ineffective in HCC patients due to potent multidrug resistance (MDR)[3]. Many studies have indicated that alterations in target gene expression are correlated with drug resistance and may provide a new strategy for sensitizing cancer cells to chemotherapeutic drugs and to reverse MDR in cancer cells.

The human long interspersed nuclear element-1 (*LINE-1*) gene encodes two proteins: LINE-1 ORF-1p and LINE-1 ORF-2p[4]. It is reported that LINE-1 ORF-2p is mainly involved in the retrotransposition process through its endonuclease activity[4]. In human cancer cells, LINE-1 ORF-2p can be regulated by LINE-1 ORF-1p[4,5]. The expression of the LINE-1 ORF-1 protein is almost 1000-fold greater than the LINE-1 ORF-2 protein[5], which indicates that LINE-1 ORF-1p has many roles. Our previous results suggested that LINE-1 ORF-1p enhances the proliferation of several cancer cell lines[6]. LINE-1 ORF-1p also increased the proliferation of hepatocellular carcinoma cells Bel-7402, SMMC-7721, HepG2, and LO2 cells and was associated with a significant risk of HCC progression[7]. However, the detailed mechanisms and roles of LINE-1 ORF-1p in HCC development are still largely unknown.

Based on our previous study[7], we hypothesized that LINE-1 ORF-1p might also be involved in HCC development and chemotherapy resistance regulation. To address this hypothesis, we performed MTT assays and found that LINE-1 ORF-1p protects HepG2 cells against chemotherapy. More importantly, we also found that LINE-1 ORF-1p enhances HepG2 cell proliferation through the modulation of genes involved in cell proliferation and apoptosis such as *p53* and *Bcl-2*.

MATERIALS AND METHODS

Plasmids

The full length of LINE-1 ORF-1p cDNA was cloned into a pcDNA3.1 vector linked with fludarabine + high-dose cytarabine + G-CSF (FLAG) at the amino terminus by polymerase chain reaction using a cDNA library as the template[6,7]. The siRNA targeted to LINE-1 ORF-1p was cloned into the psilencer-2.1-U6 (neo) vector (Ambion). The sequence of siRNA is AAGGAGGTGCACTATA-AGAAC[6,7]. The luciferase reporters, Luc-p21 (containing p53 binding element), Luc-Smad4 binding element (SBE), Luc-SP1 and Luc-androgen response element (ARE) were gifts from Dr. Cui JJ and Yang YT.

Antibodies

Antibodies against *p27*, *p53*, *Bcl-2*, and *p15* were from Santa Cruz Biotechnology Inc., United States, and antibodies against MDR, p-gp and GAPDH were from Sigma-Aldrich, St. Louis, United States. The antibody against LINE-1 ORF-1p was described previously[6,7]. Polyclonal anti-rabbit IgG was from Qiagen, Beijing, China.

Chemotherapeutic agents and cell culture

Epirubicin (Pfizer, NY, United States), Cisplatin (QILU Pharmaceutical Co., Jinan, China), paclitaxel (Roche, Basel, Swiss), Lipofectamine 2000 (Invitrogen, Carlsbad, CA, United States) and other agents (*Amersham Biosciences*, Piscataway, NJ, United States) were used in this study. HepG2 cells (American Type Culture Collection, ATCC) were cultured in DMEM (GIBCO, Grand Island, NY, United States) medium containing 10% FBS.

Cell proliferation assays

HepG2 cells were transfected with FLAG-LINE-1 ORF-1p or siRNA plasmid, and cultured for 24 h at 37 ℃ and 5% CO_2. Then, 10 μL CCK-8 reagent was added to each well and cultured at 37 ℃ and 5% CO_2 for 4 h. The absorbance of the inhibition rate was measured using a multifunctional microplate reader at 490 nm. The inhibition rate = (*A* control group - *A* administration group)/(*A* control group - *A* blank group) × 100%. The assays were performed three times with similar results.

Table 1 Effect of long interspersed nuclear element ORF-1 protein on the cytotoxic activity of chemotherapeutic drugs *in vitro*

Drugs	IC_{50} (nmol/L)			
	FLAG	FLAG-ORF-1p	Control	siRNA
Epirubicin	36.04 ± 4.48	59.11 ± 3.37	28.06 ± 5.31	3.84 ± 0.48
Cisplatin	37.94 ± 2.90	119.32 ± 21.99	32.04 ± 3.71	2.89 ± 0.44
Paclitaxel	27.01 ± 3.91	29.01 ± 2.95	35.90 ± 7.03	7.36 ± 0.69

FLAG: Fludarabine + high-dose cytarabine + G-CSF; siRNA: Small interfering RNA.

Anchorage-independent growth assay

HepG2 cells which stably expressed FLAG-LINE-1 ORF-1p or siRNA were placed in 6-well plates, with a bottom layer of 0.7% low-melting-temperature agar in DMEM and a top layer of 0.25% agar in DMEM. Colonies were scored after 3 wk of growth. The assays were performed in three independent experiments with similar results.

Luciferase assay

HepG2 cells were seeded in 24-well plates. After 24 h, the cells were transfected with FLAG-LINE-1 ORF-1p and the indicated reporter gene using Lipofectamine 2000 (Invitrogen). Twenty-four hours later, the cells were harvested and analyzed for luciferase following the manual protocol (Promega Corp., Madison, WI, United States).

Flow cytometry and apoptosis analysis

Assays were performed following the protocol provided by the apoptosis assay kit (Qiagen, Beijing, China). In brief, cells were treated with dehydrated alcohol for flow cytometry analysis. Before analysis, cells were treated with 0.5% RNase at 65 ℃ for 30 min. The assays were performed three times with similar results.

Cell transfection and stable transfection

Plasmids were transfected into HepG2 cells using Lipofectamine 2000 (Invitrogen). Forty-eight hours later, transfected cells were cultured in 500 μg/mL G418 (Invitrogen) for approximately 2 mo. Individual clones were screened by Western blotting using anti-FLAG or anti-LINE-1 ORF-1p antibodies. Similar results were observed with stable transfection or transient transfection with individual clones or pool clones.

Immunoblotting analysis

Total protein in the samples was measured by SDS-PAGE and trans-printed to a nitrocellulose (NC) membrane. The NC membranes were blocked with 5% BSA in TBST buffer and incubated with the antibodies. The membranes were then incubated with horseradish peroxidase-conjugated secondary antibodies after washing with TBST buffer. Membranes were visualized using the appropriate kit (Qiagen).

RESULTS

LINE ORF-1 protein modulates the cytotoxic effects of chemotherapeutic agents

To determine whether LINE-1 ORF-1p modulates the cytotoxic effects of chemotherapeutic agents, MTT assays were performed. The results showed that overexpression of LINE-1 ORF-1p significantly reduced the cytotoxicity of epirubicin and cisplatin on HepG2 cells (Figure 1) and the corresponding IC_{50} values increased significantly (Table 1). Reduction of LINE-1 ORF-1p expression by siRNA markedly promoted the sensitivity of HepG2 cells to epirubicin and cisplatin (Figure 1). The IC_{50} values correspondingly decreased significantly (Table 1).

Interestingly, our data also showed that neither overexpression of LINE-1 ORF-1p plasmids nor the empty vector protected HepG2 cells from the cytotoxicity of paclitaxel (Figure 1E). Knockdown of LINE-1 ORF-1p increased the cytotoxic effect of paclitaxel on HepG2 cells (Figure 1F). The IC_{50} values correspondingly decreased from 35.90 nmol/L to 7.36 nmol/L (Table 1). Taken together, these results suggest that LINE-1 ORF-1p mediates chemotherapeutic drug resistance in HepG2 cells.

LINE ORF-1 protein promotes HepG2 cell proliferation

To determine whether LINE-1 ORF-1p affected HepG2 cell proliferation, MTT assays were performed. HepG2 cells transfected with FLAG-LINE-1 ORF1-p had an increased proliferation rate compared with those transfected with FLAG empty vector (Figure 2A); whereas cells transfected with LINE-1 ORF-1p siRNA, grew more slowly than those transfected with the control siRNA (Figure 2B). In addition, LINE-1 ORF-1p also promoted HCC SMMC-7721 (Figure 2C and D) and BEL-7402 cell growth (Figure 2E and F). These results indicated that LINE-1 ORF-1p affects HCC cell proliferation.

LINE ORF-1 protein protects HepG2 cells against apoptosis

To investigate the role of LINE-1 ORF-1p in HepG2 cell apoptosis, apoptosis assays were performed. Overexpression of LINE-1 ORF-1p protected HepG2 cells from apoptosis (Figure 3), whereas knockdown of LINE-1 ORF-1p significantly promoted the apoptosis of HepG2 cells (Figure 3).

LINE ORF-1 protein increases HepG2 anchor-independent growth

The effects of LINE-1 ORF1-p on anchorage-independent growth were tested in stable HepG2 cell lines expressing either FLAG-LINE-1 ORF1-p or siRNA. Overexpression of LINE-1 ORF-1p significantly increased the anchorage-independent growth of HepG2 cells (Figure 3); whereas knockdown of endogenous LINE-1 ORF1-p decreased anchorage-independent growth of HepG2 cells (Figure 3). These results suggest that LINE-1 ORF-1p also strongly promotes HCC cell growth.

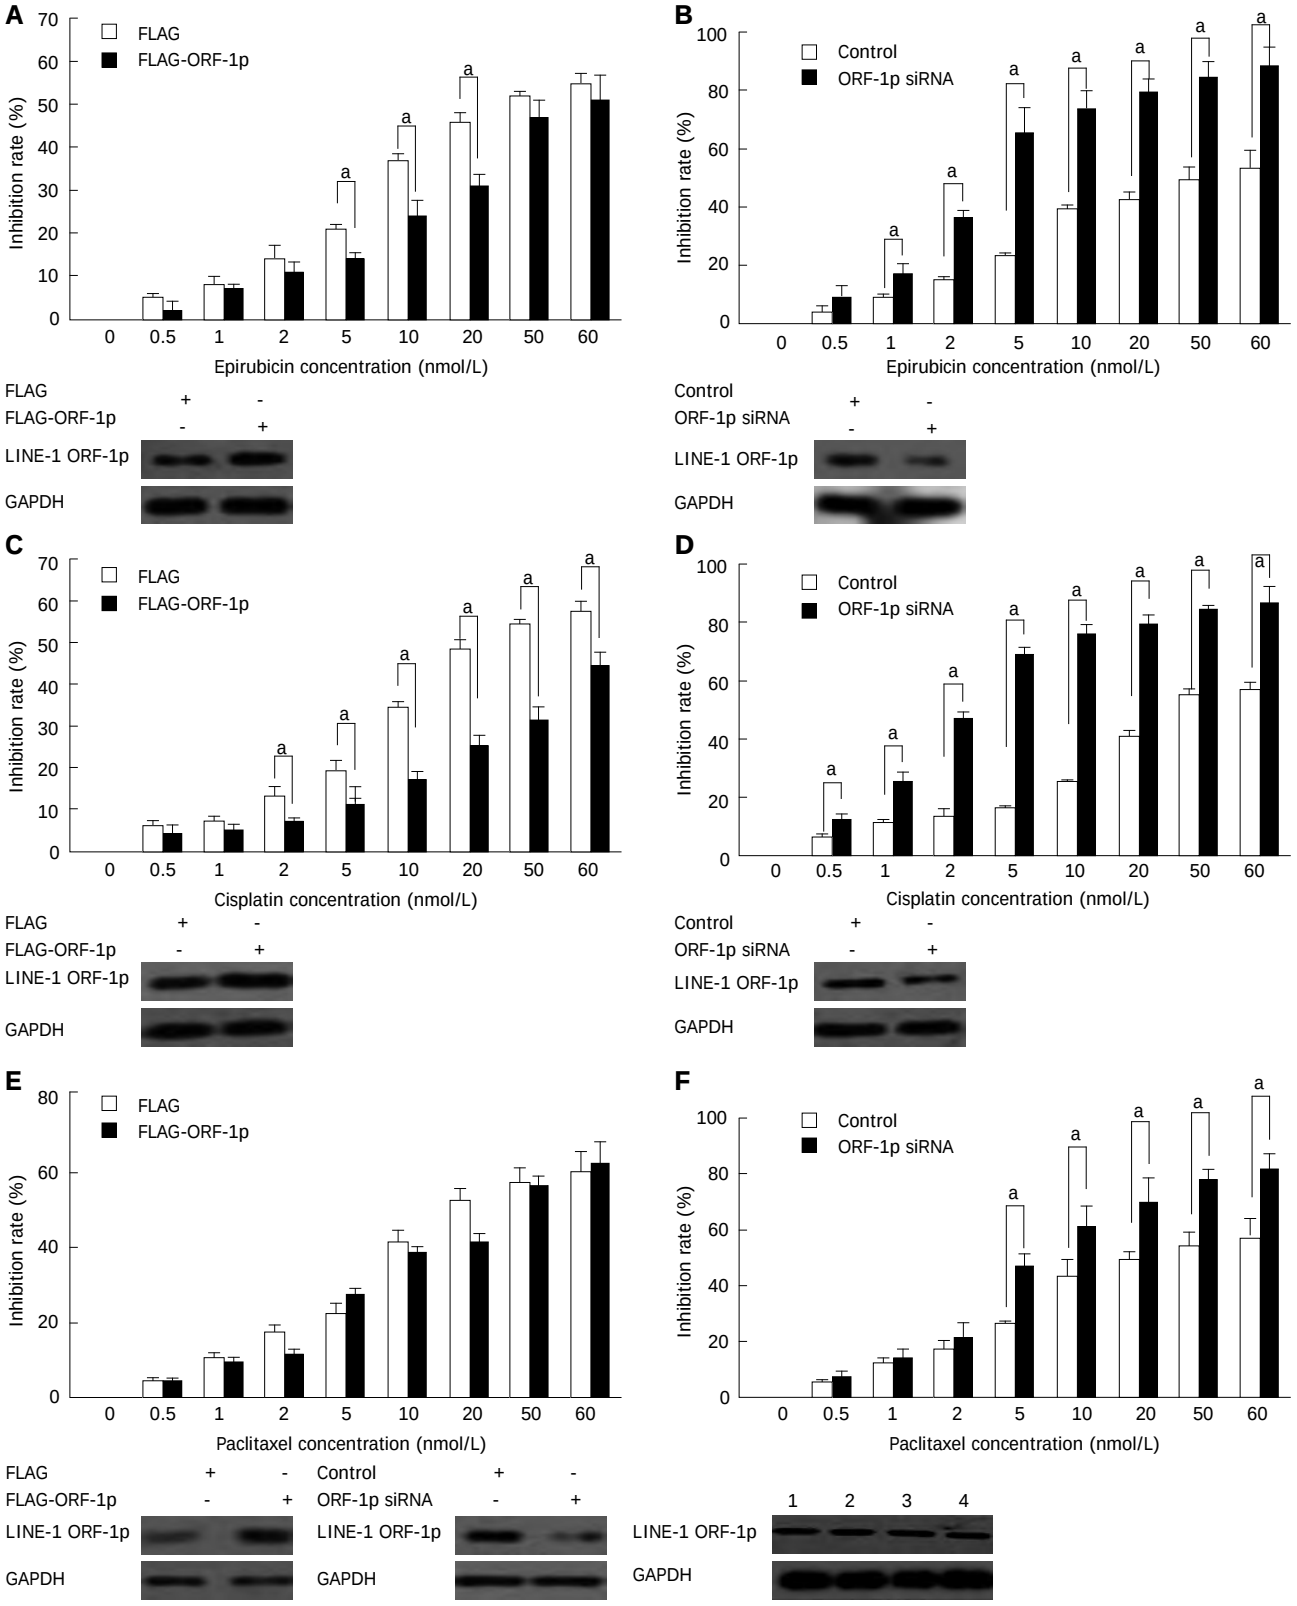

Figure 1 Effect of long interspersed nuclear element ORF-1 protein on epirubicin, cisplatin and paclitaxel cytotoxicity. HepG2 cells were treated with the indicated amounts of epirubicin (A, B), cisplatin (C, D) or paclitaxel (E, F): 0 nmol/L, 0.5 nmol/L, 1 nmol/L, 2 nmol/L, 5 nmol/L, 10 nmol/L, 20 nmol/L, 50 nmol/L, 60 nmol/L. A: HepG2 cells were transfected with the fludarabine + high-dose cytarabine + G-CSF human long interspersed nuclear element-1 (FLAG-LINE-1) ORF-1p expression vector, or the empty vector; B: HepG2 cells were transfected with the control siRNA vector or the LINE-1 ORF-1p siRNA vector; C: HepG2 cells were transfected with the FLAG-LINE-1 ORF-1p expression vector, or the empty vector; D: HepG2 cells were transfected with the control siRNA vector or the LINE-1 ORF-1p siRNA vector; E: HepG2 cells were transfected with the FLAG-LINE-1 ORF-1p expression vector, or the empty vector; F: HepG2 cells were transfected with the control siRNA vector or the LINE-1 ORF-1p siRNA vector. The assays were performed three times with similar results. $^{a}P < 0.05$ *vs* control. 1: Control; 2: Epirubicin; 3: Cisplatin; 4: Paclitaxel. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

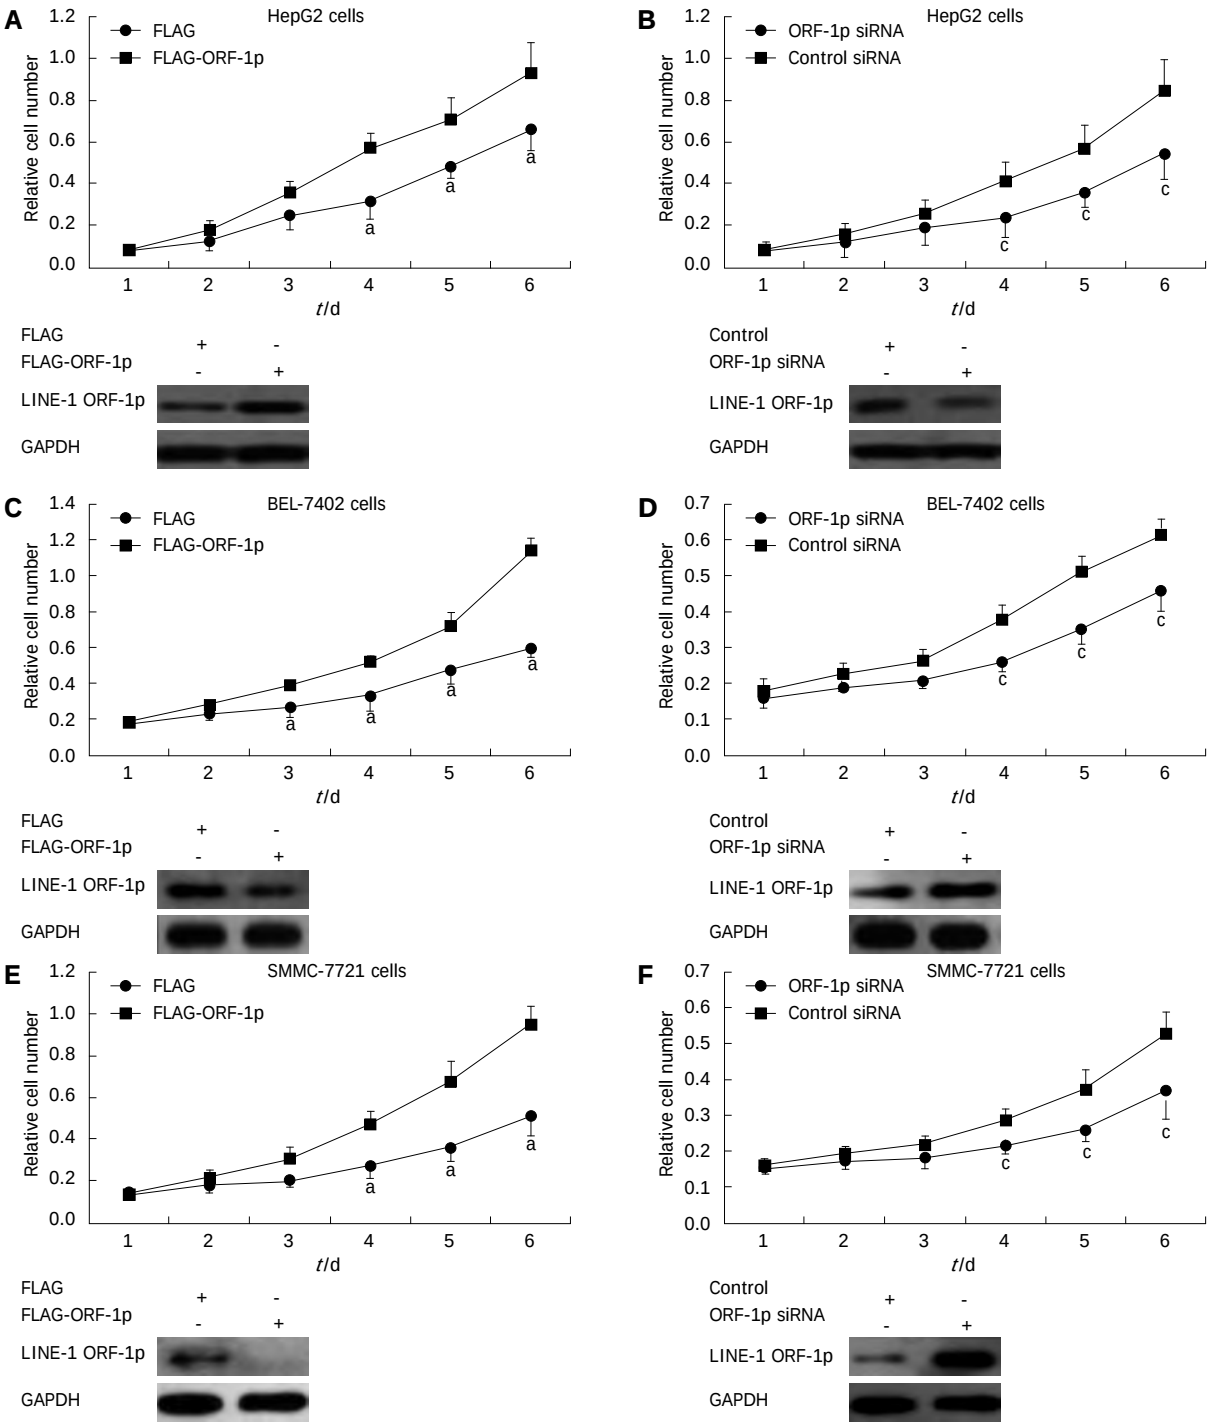

Figure 2 Long interspersed nuclear element ORF-1 protein promotes the proliferation of hepatocellular carcinoma cells. A: HepG2 cells were stably transfected with the fludarabine + high-dose cytarabine + G-CSF human long interspersed nuclear element-1 (FLAG-LINE-1) ORF-1p or the empty vector; B: HepG2 cells were stably transfected with the control siRNA or LINE-1 ORF-1p siRNA; C: BEL-7402 cells were stably transfected with the FLAG-LINE-1 ORF-1p or the empty vector; D: BEL-7402 cells were stably transfected with the control siRNA or LINE-1 ORF-1p siRNA; E: SMMC-7721 cells were stably transfected with the FLAG-LINE-1 ORF-1p or the empty vector; F: SMMC-7721 cells were stably transfected with the control siRNA or LINE-1 ORF-1p siRNA. The relative cell numbers ($A_{490\,nm}$) were determined by MTT assays, relative cell numbers (A, B) with mean ± SD (n = 3). $^{a}P < 0.05$ *vs* FLAG; $^{c}P < 0.05$ *vs* control siRNA. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

LINE ORF-1 protein regulates the reporter gene activities of p21, SBE and Sp1

To determine the mechanism of LINE-1 ORF1-p, luciferase assays were performed. The results showed that overexpression of LINE-1 ORF-1p decreased Luc-p21, Luc-SBE and Luc-Sp1 activity. Knock-down of LINE-1 ORF-1p expression enhanced the activities of Luc-p21 (Figure 4A), Luc-SBE (Figure 4B) and Luc-Sp1 (Figure 4C).

In addition, overexpression of LINE-1 ORF-1p promoted the transcription of Luc-ARE reporter (Figure 4D). Down-regulation of LINE-1 ORF1-p expression reduced the activity of Luc-ARE (Figure 4D). Taken to-

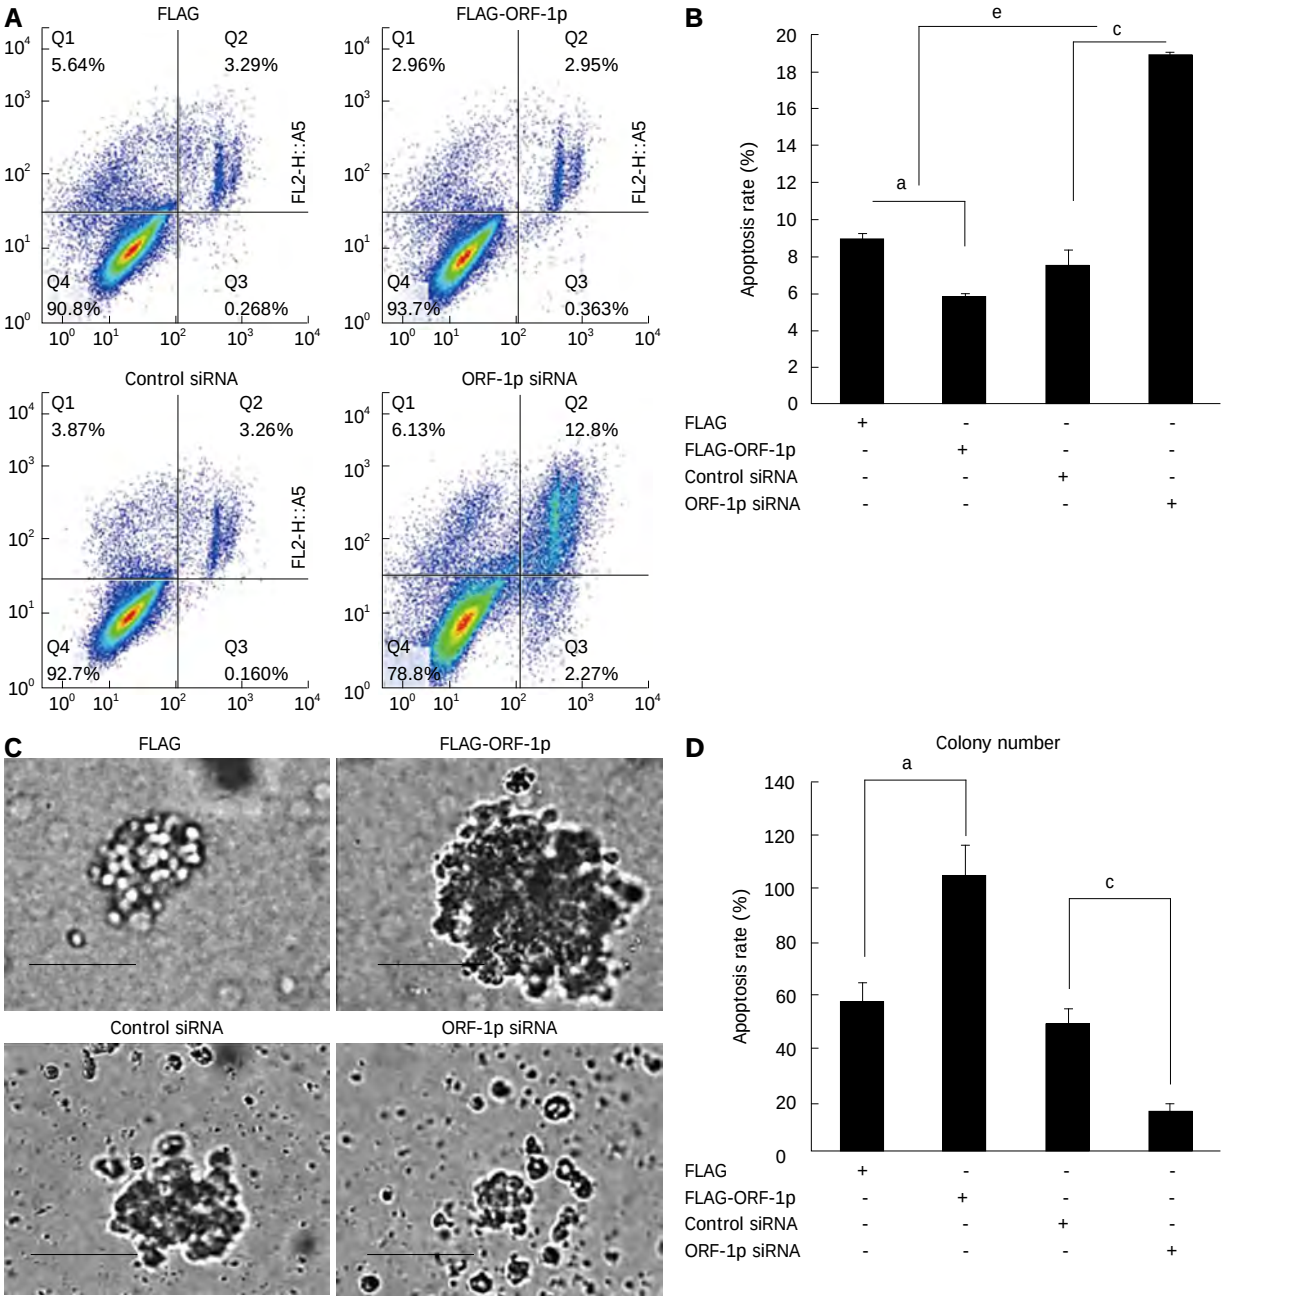

Figure 3 Long interspersed nuclear element ORF-1 protein promotes apoptosis and anchor-independent growth of HepG2 cells. HepG2 cells were transfected with the empty vector or f ludarabine + high-dose cytarabine + G-CSF human long interspersed nuclear element-1 (FLAG-LINE-1) ORF-1p, or with the control siRNA or LINE-1 ORF-1p siRNA. A, B: The rates of apoptosis are shown in the figures (A). The assays were performed three times with similar results (B); C, D: Colony numbers shown in the photographs (C), or mean ± SD (n = 3) of triplicate independent experiments (D). $^{a}P < 0.05$ *vs* FLAG; $^{c}P < 0.05$ *vs* control siRNA; $^{e}P < 0.05$ *vs* FLAG-LINE-1 ORF-1p. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

gether, these results suggest that LINE-1 ORF-1p may regulate cell proliferation by modulating the transcription activities of these genes

LINE ORF-1 protein modulates the expression of genes involved in cell proliferation and apoptosis

To corroborate the results of the luciferase assay, it is necessary to investigate whether LINE-1 ORF-1p regulates the protein levels of the genes related to cell proliferation and apoptosis. The results showed that overexpression of LINE-1 ORF-1p decreased the expression of *p15*, *p53* and *p27* genes (Figure 5A) and increased the expression of Bcl-2 (Figure 5A). However, reduction of LINE-1 ORF-1p expression with LINE-1 ORF1-p siRNA increased the protein level of *p15*, *p53* and *p27* (Figure 5B), and reduced the protein level of Bcl-2 (Figure 5B). These findings indicated that LINE-1 ORF-1p promotes cell proliferation by regulating the expression of these genes.

LINE ORF-1 protein enhances MDR and p-gp gene expression

In order to investigate the mechanism of LINE-1 ORF-1p-mediated drug resistance, the effects of LINE-1

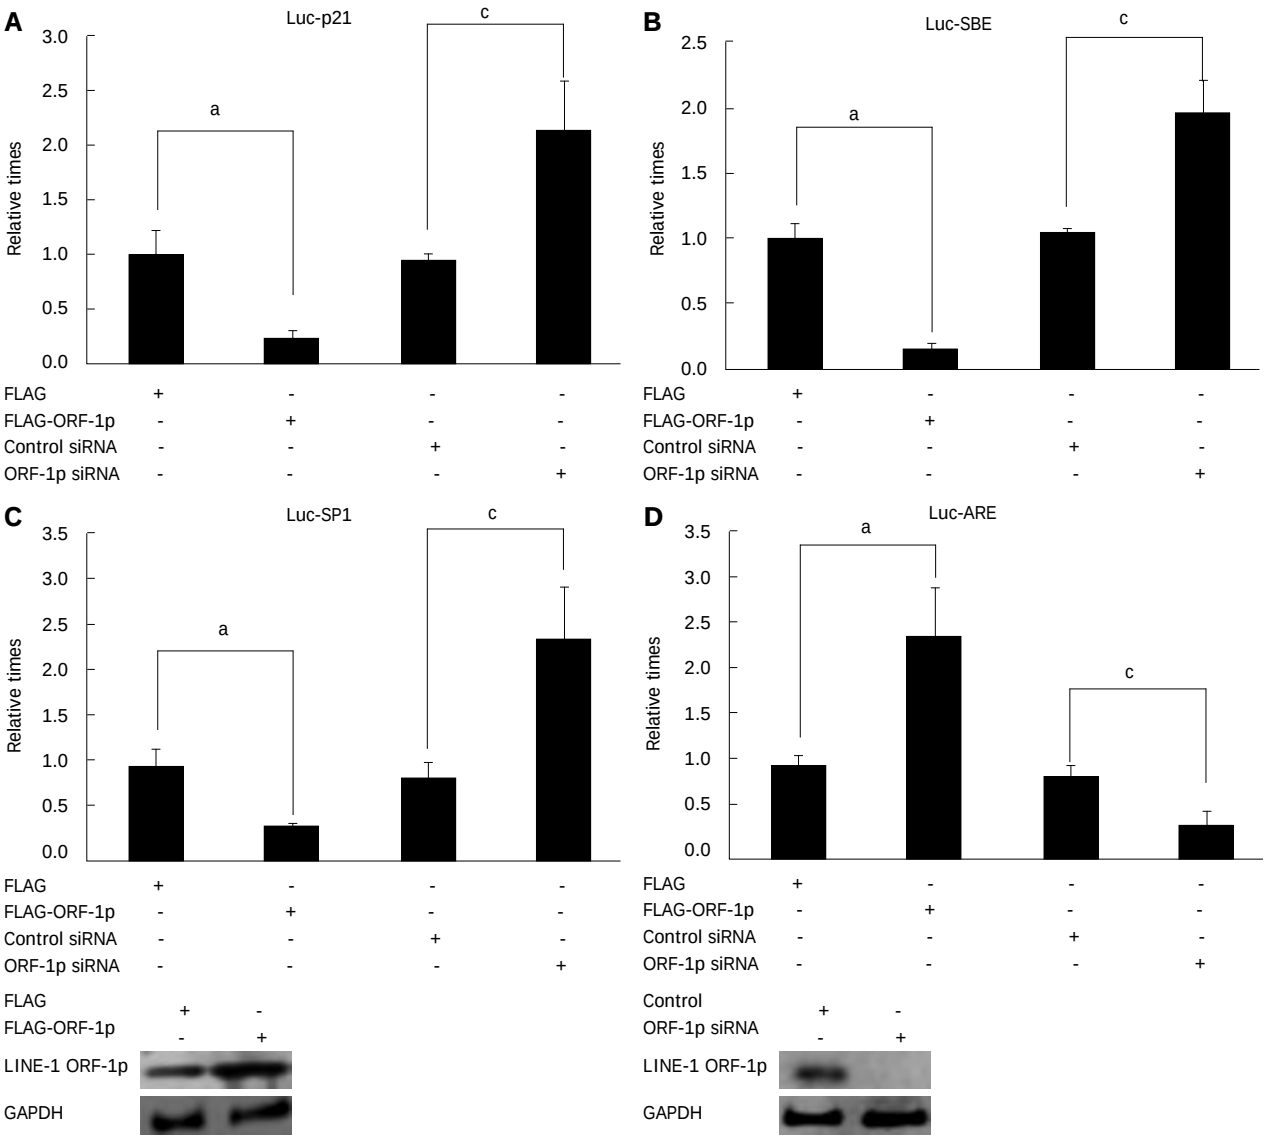

Figure 4 Long interspersed nuclear element ORF-1 protein regulates the transcription of Luciferase reporters. HepG2 cells were transfected with the fludarabine + high-dose cytarabine + G-CSF human long interspersed nuclear element-1 (FLAG-LINE-1) ORF-1p or FLAG empty vector, LINE-1 ORF-1p siRNA or control siRNA. HepG2 cells were co-transfected with Luc-p21 (A), Luc-SBE (B), Luc-Sp1 (C), or Luc-ARE (D). The assays were performed three times with similar results. [a]*P* < 0.05 *vs* FLAG; [c]*P* < 0.05 *vs* control siRNA. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

ORF-1p on the expression of genes involved in drug resistance were examined. The results showed that over-expression of LINE-1 ORF1-p increased MDR and p-gp protein levels (Figure 6A). Repression of LINE-1 ORF-1p expression through siRNA strongly reduced MDR and p-gp protein levels (Figure 6B). These results indicated that LINE-1 ORF-1p mediates drug resistance by modulating the expression of MDR and p-gp.

LINE ORF-1 protein is expressed in clinical specimens and HepG2 cells

Next, we used immunohistochemistry and immunoblot assays to detect LINE-1 ORF-1p protein expression in clinical specimens and the HepG2 cell line. In most cases, the HepG2 cell line and liver tumors expressed high protein levels of LINE-1 ORF-1p (Figure 7).

DISCUSSION

In this study, we provide evidence of the novel roles of LINE-1 ORF-1p in chemotherapeutic drug response and proliferation of HepG2 cells. The results demonstrated that over-expreesion of LINE-1 ORF-1p significantly inhibited the cytotoxic effects of epirubicin and cisplatin on HepG2 cells. However, knockdown of LINE-1 ORF-1p with epirubicin, cisplatin or paclitaxel had a synergistic effect on HepG2 cells. Moreover, LINE-1 ORF-1p regulated the proliferation and anchor-independent growth of HepG2 cells. In addition, LINE-1 ORF-1p repressed Luc-SBE, Luc-SP1, and Luc-p21 transcription, and enhanced Luc-ARE transcription. More importantly, LINE-1 ORF-1p modulated the expression of important genes: *p15*, *p27*, *p53* and *Bcl-2*, which are related to

HepG2 cell proliferation and apoptosis. Finally, LINE-1 ORF-1p also affected *mdr* and *p-gp* gene expression, which is related to chemotherapeutic drug resistance in cancer cells.

LINE-1 comprises at least 17% of the human genome sequence and may significantly affect human genome stability and chromosome structure after de-methylation. LINE-1 displays a silenced state in normal adult tissues with high methylation[8]. It is activated by the de-methylation mechanism, and then frequently retrotransposes[9]. Frequent transposition of LINE-1 may lead to significant changes in the genome, eventually inducing tumorigenesis[10]. It was reported that genome hypomethylation was significantly increased in patients with HCC. The levels of serum LINE-1 hypomethylation at initial presentation correlated significantly with tumor size, tumor number and alpha-fetoprotein level. Moreover, high serum LINE-1 hypomethylation correlates significantly with poor survival[11,12]. Therefore, it is thought that overexpression of LINE-1-associated protein promotes the progression of HCC and affects the outcome of systemic chemotherapy.

Our previous studies indicated that LINE-1 ORF-1p was involved in the regulation of transformation, devel-

opment and proliferation of several cancer cells[13,14]. We also established several tumor cell models of LINE-1 ORF-1p in human lung cancer, gastric cancer and breast cancer[15]. It is reported that LINE-1 ORF-1p interacts with its own DNA[16]. Thus, LINE-1ORF-1p may regulate important transcription factor activity by changing the structure of chromatin, and in turn promote the growth of cancer cells by modulating the expression of genes related to proliferation, cell cycling and apoptosis regulation[17-19]. LINE-1 ORF-1p may play a role in the regulation of cancer cell proliferation and chemotherapy resistance through various mechanisms.

In this study, we found that overexpression of LINE-1 ORF-1p significantly inhibited the cytotoxic effect of epirubicin and cisplatin on HepG2 cells, without affecting the role of paclitaxel, these results were expected. LINE-1 ORF-1p siRNA with epirubicin, cisplatin or paclitaxel had a synergistic effect on HepG2 cells. In HCC, the rapid growth of cells is caused by high levels of DNA replication and expression, and a high rate of metabolism. In addition, in HCC cells, chromatins are generally unfolded and not agglutinated[17-19]. Therefore, the DNA is more vulnerable than in normal somatic cells[12]. Some chemotherapeutic agents such as cisplatin and epirubicin target bio-macromolecules, such as DNA, and are naturally cytotoxic to HepG2 cells[12]. While LINE-1 ORF-1p binds to DNA, it is likely to play a protective role and act as a barrier to DNA. It is possible to protect DNA against the cytotoxic effects of epirubicin and cisplatin. Our previous study showed that LINE-1 ORF-1p promotes the cell cycling program. These previous results also confirmed the conclusions in this study. In addition, LINE-1 ORF-1p enhanced the protein level of *mdr* and *p-gp* genes[20-22]. Thus, LINE-1 ORF-1p also modulates the genes involved in multi-drug resistance.

We then found that LINE-1 ORF-1p promoted *Bcl-2* gene expression which is involved in resistance to apoptosis, and inhibited the expression of the genes, *p15*, *p27* and *p53*[13]. These genes promote apoptosis and arrest cell growth or cell cycling. These results were consistent with those from the luciferase assays. LINE-1 ORF-1p reduced the activity of Luc-p21, Luc-SBE, and Luc-Sp1 reporters and enhanced Luc-ARE reporter transcription. p53, Smad4, Sp1 and AR are important transcription factors, which modulate the transcription of many genes and play a role in the regulation of cancer progression. LINE-1 ORF-1p may interact with these transcriptional factors which are recruited to specific regulatory elements such as SP1 and p53 binding sites. They then interfere with their function through conformational alteration or by affecting their co-repressor recruitment. Further studies are required to address this hypothesis.

Paclitaxel targets microtubules. Overexpression of LINE-1 ORF-1p did not antagonize the cytotoxic effect of paclitaxel, however, knockdown of LINE-1 ORF-1p and paclitaxel had a synergistic effect and reduced its expression level and slowed cell growth by modulating *p53*, *p15*, *p27*, and *Bcl-2* expression.

Taken together, these findings suggest that LINE-1 ORF-1p may have a role in the development of HCC, and is likely to be involved in the prediction of chemotherapeutic effect. In addition, these findings significantly advance our understanding of the functions and mechanisms of LINE-1 ORF-1p in cancer cell proliferation and may provide a novel potential therapeutic target in HCC.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the commonest form of cancer worldwide, and the third most common cause of cancer death. Chemotherapy is currently the most commonly adopted strategy for treating HCC patients; however, it also has shortcomings as HCC patients can exhibit robust multidrug resistance.

Research frontiers

Long interspersed nuclear element-1 ORF-1 protein (LINE-1 ORF-1p) plays an important role in the development of several types of carcinoma. However, the involvement of LINE-1 ORF-1p in the pathogenesis of hepatocellular carcinoma and whether it is responsible for making these tumors resistant to chemotherapy has not been addressed. In this study, the authors demonstrate that the overexpression of LINE-1 ORF-1p, commonly observed in HCC patients, could be a potential mechanism for both promoting cell proliferation and for resistance to chemotherapy.

Innovations and breakthroughs

Recent reports have highlighted the importance of LINE-1 ORF-1p in different types of cancers. This is the first study to report that LINE-1 ORF-1p mediates resistance to chemotherapy in HCC patients. Furthermore, our *in vitro* studies suggest that LINE-1 ORF-1p mediates the regulation of cellular apoptotic and proliferative pathways, and aids in the metastatic progression of HCC.

Applications

By understanding the mechanism of LINE-1 ORF-1p-mediated induction of resistance to chemotherapy, this may represent a future strategy for therapeutic intervention in the treatment of patients with hepatocellular carcinoma. In addition, the expression levels of LINE-1 ORF-1p in hepatocellular carcinoma patients may serve as a predictive marker of chemotherapy outcome.

Terminology

LINE-1 is an autonomous non-LTR retrotransposon in mammals. Retrotransposition requires the function of the two L1-encoded polypeptides, ORF1p and ORF2p. LINE-1 ORF-1p, which comprises at least 17% of the human genome sequence, is silenced (non-active) in normal adult tissues. However, in cancer cells, LINE-1 ORF-1p is active and affects genomic stability and chromosome structure through its retrotransposonal activity, eventually leading to tumorigenesis.

Peer review

In this work, the authors investigated the roles of LINE-1 ORF-1p in the drug resistance and proliferation of HCC with interesting findings.

Abstract

AIM: To formally study age of diagnosis of papillary thyroid cancer (PTC) in inflammatory bowel disease (IBD) patients and evaluate the prevalence of PTC in IBD patients compared to a control population.

METHODS: We were interested in testing the hypothesis that patients with IBD are more likely to be diagnosed with PTC than a control population. A retrospective cohort analysis was performed using the University of Pennsylvania Health System's electronic database. Outpatients from 1998-2009 were included in the search, and patients in the cohort were selected based on ICD-9 codes. Inclusion criteria included the diagnosis of Crohn's disease (CD) or ulcerative colitis (UC) and the concurrent diagnosis of thyroid cancer in comparison to a control population. Using these methods 912 patients with CD and 1774 with UC were compared to 1638 diverticulitis and 19 447 asthma controls. Statistics were performed using corrected chi-square analysis. The primary outcome for this study was the diagnosis of PTC. Approval to conduct this study was obtained by the Institutional Review Board at the University of Pennsylvania.

RESULTS: The mean age was 47.5 years (range: 18-102 years) and 66% patients were female. An analysis of variance model was used to compare the age of PTC diagnosis between the CD, UC, asthma and diverticulitis groups, and a statistically significant difference in age at PTC diagnosis was noted across all groups (F = 6.35, df = 3, P = 0.0006). The age of PTC diagnosis in CD patients was statistically significantly lower than UC, asthma, and diverticulitis patients (average PTC diagnosis age for CD 25, UC 49, asthma 45, diverticulitis 63). After covarying for sex and age in 2009, the difference in age at PTC diagnosis remained statistically significant (F = 4.13, df = 3, P = 0.0089). A total of 86 patients were diagnosed with PTC. Nine patients (0.5%) with UC were diagnosed with PTC. Patients with UC were not shown to be more likely to develop PTC [odds ratio (OR): 1.544, 95%CI 0.767-3.108] compared to asthma controls. Four patients (0.4%) with CD were diagnosed with PTC. Patients with CD were not shown to be more likely to develop PTC (OR: 1.334, 95%CI 0.485-3.672) compared to a control population with asthma. Nine patients (0.5%) with a history of diverticulitis were diagnosed with PTC. Pa-

tients with diverticulitis were not shown to be more likely to develop PTC (OR: 1.673, 95%CI 0.831-3.368) compared to asthma controls. Patients with CD or UC were not less likely to develop PTC compared to those with diverticulitis (CD OR: 0.80, 95%CI 0.25-2.60; UC OR: 0.92, 95%CI 0.37-2.33). None of the patients used immunosuppressant medications prior to the diagnosis of PTC (azathioprine, 6-mercaptopurine, and methotrexate).

CONCLUSION: There is a significant difference in age of diagnosis of PTC in patients with CD compared to patients with UC and the control populations studied.

Papillary thyroid cancer and inflammatory bowel disease: Is there a relationship? *World J Gastroenterol* 2013; 19(7): 1079-1084 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1079.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1079

INTRODUCTION

Inflammatory bowel diseases (IBD), specifically Crohn's disease (CD) and ulcerative colitis (UC), are idiopathic chronic inflammatory disorders resulting from defects in the barrier function of the intestinal epithelium and inappropriate activation of the mucosal immune system. IBD is also associated with several other extra-intestinal disease states, including ankylosing spondylitis, arthritis, pyoderma gangrenosum, and uveitis[1]. Less is known about the association of IBD with diseases of the thyroid.

Early studies have suggested a relationship between thyroid abnormalities and IBD[2]. For example, CD has been associated with Graves' disease and Hashimoto' s thyroiditis[3]. However, the association with IBD and thyroid cancer has been less critically analyzed. Thyroid cancer is the most common endocrine cancer, with over 80% of all cases consisting of the papillary type. It is more common in women than in men (3:1 ratio) and is more common in whites than in African-Americans. The mean age of diagnosis is 40 years old[4]. There are several case reports of thyroid cancer in patients with IBD, two of them involving UC[5,6]. Moss *et al*[7] described five cases of papillary thyroid cancer (PTC) in patients with preexisting CD. Despite these anecdotal published findings, there have been no formal studies evaluating the relationship that exists between PTC and IBD in a population cohort study.

It is uncertain whether PTC in patients with IBD is due to an association or coincidence. Knowledge of a relationship is important in order to determine the factors that link IBD and PTC. Exposure to radiation and multivitamin intake are both considered risk factors for PTC, both of which are common in patients with IBD due to diagnostic studies and malnutrition respectively[8]. However, a recent study by Peloquin *et al*[9] concluded that the radiation exposure in an IBD population was equivalent to the average annual background radiation dose from naturally occurring sources in the United States, while a smaller subset of patients had substantially higher doses. In addition, immunosuppressants such as azathioprine and 6-mercaptopurine are commonly taken by patients with IBD to induce remission and can increase the risk of malignancy, specifically lymphoproliferative disorders[10,11]. Whether these medications increase the risk of thyroid cancer is unknown.

It is already established that an inappropriate inflammatory response results in IBD. Defects in genes involving the innate immune system and activation of inflammatory cytokines such as NOD2, autophagy-related 16-like 1, and interleukin-23 lead to intestinal inflammation[12,13]. Similarly, lymphocytic infiltration is seen in PTC, suggesting that immunologic factors may contribute to neoplastic development[14]. Thus, the inflammatory modulators involved in the pathogenesis of IBD may have an effect on PTC development.

This study addressed an important question regarding the epidemiology of IBD and PTC. The specific aim of this study was to identify any relationships between the two diseases and to determine whether patients with IBD have a higher prevalence of PTC than a control population. Knowledge of an association if present has potential to impact the management of patients with IBD, which may warrant screening for thyroid cancer through regular thyroid examinations.

MATERIALS AND METHODS

Definition of the cohort

A retrospective cohort study from within the University of Pennsylvania Health System was performed using the data from the electronic health system database (EPIC Hyperspace Summer 2009 IU 6, EPIC Systems Corporation, Verona, Wisconsin, United States). Patients who were seen as outpatients in our health system from 1998 to 2009 were included in the search. Patients with CD and UC were identified based on ICD-9 codes (ICD-9 codes for CD: 555, 550.0, 555.1, 555.9; codes for UC: 556, 556.0, 556.1, 556.2, 556.3, 556.5, 556.6, 556.8, 556.9).

Inclusion criteria included the diagnosis of CD or UC and the concurrent diagnosis of thyroid cancer. The latter diagnosis was identified using the ICD-9 code for thyroid cancer: 193. The papillary type of thyroid cancer was verified using biopsy reports or the patients' medical records. Patients who met inclusion criteria were included in the final analysis and were compared to patients with inflammatory controls with diverticulitis and asthma. Controls were identified based on a search of our electronic database using ICD-9 codes (ICD-9 code

Table 1 Concomitant diagnosis of papillary thyroid cancer

Diagnosis	No. of patients diagnosed with PTC	Unadjusted OR (95%CI) compared to asthma controls	OR (95%CI) compared to asthma controls, adjusted for sex and age in 2009
CD	4	1.334 (0.485-3.672)	1.510 (0.548-4.162)
UC	9	1.544 (0.767-3.108)	1.679 (0.832-3.389)
Diverticulitis	9	1.673 (0.831-3.368)	1.338 (0.644-2.779)
Asthma	64	NA	NA

OR: Odds ratio; PTC: Papillary thyroid cancer; NA: Not available.

for diverticulitis: 562.11, 562.13; code for asthma: 493). Approval was obtained from the Institutional Review Board at the University of Pennsylvania to perform our study.

Definition of outcome

The primary outcome for this study was a diagnosis of PTC. We did not limit our outcome definition to an incident diagnosis of PTC following a diagnosis of IBD. We were interested in testing the hypothesis that patients with IBD are more likely to be diagnosed with PTC than a control population, not that IBD in and of itself predisposes patients to PTC. As such, we searched for any diagnosis of PTC at any time in the patients' records.

Statistical analysis

All analyses were performed separately for patients with CD and UC, and then as a combined IBD group. Analyses began with descriptive statistics. Continuous variables were reported as means ± SD. Categorical variables were reported as counts and percentages. Since age was approximately normally distributed, we used analysis of variance to test for differences in the mean age at diagnosis of PTC[15]. Statistical analysis was performed at the University of Pennsylvania, Philadelphia, PA using SAS software version 9.2 (SAS Institute, Cary, NC).

To estimate the association between PTC and IBD in this cross-sectional study, we calculated the odds ratio (OR) and 95%CI using logistic regression. We considered a finding to be statistically significance when $P < 0.05$.

Sample size and power calculations

A two group continuity corrected χ^2 test with a 0.050 two-sided significance level had 80% power to detect the difference between a proportion of 0.3% in the asthma group and a proportion of 0.8% in the UC group (OR of 2.41) when the sample sizes are 19 447 and 1774, respectively (a total sample size of 21 221). A two group continuity corrected χ^2 test with a 0.050 two-sided significance level had 80% power to detect the difference between a proportion of 0.3% in the asthma group and a proportion of 1.0% in the UC group (OR of 3.02) when the sample sizes are 19 447 and 912, respectively (a total sample size of 20 359).

RESULTS

Our retrospective analysis yielded a total of 2686 patients who were diagnosed with either CD or UC. A total of 912 patients with CD and 1774 patients with UC met inclusion criteria and were included in our analysis. These patients were compared to 1638 diverticulitis and 19447 asthma controls.

The overall mean age was 47.5 years (range: 18-102 years) and 66% patients were female. Using an analysis of variance model to compare the age of thyroid diagnosis between the CD, UC, asthma and diverticulitis groups, a statistically significant difference in age at PTC diagnosis was noted across all groups ($F = 6.35$, df = 3, $P = 0.0006$). Of note, the age of PTC diagnosis in CD patients was statistically significantly lower than UC, asthma, and diverticulitis patients (average PTC diagnosis age for CD: 25 years, UC 49 years, asthma: 45 years, diverticulitis: 63 years). After covarying for sex and age in 2009, the difference in age at PTC diagnosis remained statistically significant ($F = 4.13$, df = 3, $P = 0.0089$).

A total of 86 patients were diagnosed with PTC. Nine patients (0.5%) with UC were diagnosed with PTC. Patients with UC were not shown to be more likely to develop PTC (OR: 1.544, 95%CI 0.767-3.108) compared to asthma controls. Four patients (0.4%) with CD were diagnosed with PTC. Patients with CD were not shown to be more likely to develop PTC (OR: 1.334, 95%CI 0.485-3.672) compared to a control population with asthma. Nine patients (0.5%) with a history of diverticulitis were diagnosed with PTC. Patients with diverticulitis were not shown to be more likely to develop PTC (OR: 1.673, 95%CI 0.831-3.368) compared to asthma controls (Table 1).

Patients with CD or UC were not less likely to develop PTC compared to those with diverticulitis (CD OR: 0.80, 95%CI 0.25-2.60; UC OR: 0.92, 95%CI 0.37-2.33). None of the patients used immunosuppressant medications prior to the diagnosis of PTC (azathioprine, 6-mercaptopurine, and methotrexate).

DISCUSSION

The results of our present study highlights a statistically significant difference in age of diagnosis of PTC in patients with CD compared to patients with UC and the control populations studied. Patients with CD are diagnosed with PTC at a much younger age, possibly due to a unique pathogenetic mechanism of disease occurring in this subset of patients. It is established that CD results from a variety of factors, including genetic, environmental and immunological factors. An inappropriate inflammatory reaction is a key factor in the pathogenesis of CD. Similarly, PTC involves an inflammatory reaction, in particular, a lymphocytic infiltration of thyroid tissue[14]. Thus, overlapping immunologic factors/pathways may connect these two diseases together. The inflammatory modulators involved in the pathogenesis of IBD

may have an effect on PTC development or PTC may predispose patients to developing IBD.

In addition there have been specific genetic mutations described to be present in patients with CD. The initial frameshift mutation described was in the *NOD-2* gene in 2001[16]. Data from epidemiological studies, based on concordance data in family studies via linkage analysis to genomewide association studies, highlight evidence for over 30 distinct genomic loci involved in the genetic susceptibility to CD. These loci encode genes involved in a number of homeostatic mechanisms: innate pattern recognition receptors, the differentiation of Th17-lymphocytes, autophagy, maintenance of epithelial barrier integrity, and the orchestration of the secondary immune response[17] It is perceived that recognition of these loci will help to improve our understanding of the pathophysiology of CD.

Similarly, there have been several genetic mutations described in patients with PTC, the most common involving the RET/papillary thyroid carcinomas 1 (PTC1) and RET/PTC3 rearrangements which account for more than 90% of all genetic rearrangements found in PTC, and have been found in 30%-40% of adult patients with sporadic PTC in the United States, Italy, and Canada[18]. Other genetic mutations include the neurotrophic tyrosine kinase, receptor, type 1 (NTRK1) rearrangement, Ras kinases and Raf kinases[19-23]. In addition, recent literature has incited the presence of 7 gene regions to be associated with PTC[24]. These results suggest a possible role of genes involved in maintenance of genomic integrity in relation to risk of PTC.

Several studies determined significantly higher oncogenic rearrangements of RET and NTRK1 proto-oncogenes in patients with PTC that occurred primarily in children and young adults. An analysis of 92 patients with PTC determined that patients age 4-30 years had significantly higher frequency of *RET* or *NTRK1* gene compared to those 31-80 years (57% *vs* 32%, $P = 0.019$). Further, among patients ages 4-19 years, 67% of them displayed RET gene rearrangement[25]. Studies by Jhiang *et al*[26] and Soares *et al*[27] found that patients displaying RET rearrangement in their PTC had significantly lower mean age at diagnosis than those whose PTC did not present this rearrangement (32 years *vs* 50 years, $P < 0.05$ and 28 years *vs* 45 years, $P = 0.005$, respectively)[26,27]. An assessment of spontaneous PTC in 33 young patients ages 6-21 years showed that the RET/PTC1 rearrangement was common in the sporadic form of children with PTC (53%), with the RET/PTC3 mutation more commonly seen among children with PTC secondary to radiation exposure (67%-76%) as reported in prior studies[28-31].

One limitation to this study is the small number of patients who were found to have PTC. With so few patients with both diagnoses, it was difficult to elucidate a temporal relationship between the two diseases. Some patients were diagnosed with PTC followed by a CD diagnosis, and vice versa. A larger study would help establish whether there is a diagnosis pattern. The findings on prevalence do not suggest a higher prevalence of PTC in patients with IBD compared to the control populations studied. We cannot exclude the potential for a type Ⅱ error given that our study was underpowered. A study using a much larger cohort of patients would be better-powered and would more likely lead to statistically significant results and better define a lack of relationship between the two diseases.

There were several other limitations to this study. We did not test for confounding; we did not examine other thyroid conditions including Graves disease, Hashimoto's thyroiditis, goiter, and non-papillary type thyroid cancer as potential confounder variables. The other limitation of our study is that some relevant clinical information from the past medical history of patients may not have been included in the electronic database and thus may have been potentially omitted. This is a common limitation of retrospective studies.

In summary, the results of our study suggest that patients with CD who are also diagnosed with PTC are diagnosed at a much younger age than patients with UC and other controls. This is important for cancer detection in CD patients. Currently age, gender, radiation exposure, and a low iodine diet are the only known clinical risk factors for PTC; further studies are needed to establish whether patients with CD are at increased risk of developing PTC. If there is an increased risk, then more stringent methods of cancer screening may be warranted for CD patients, including initiating screening at a younger age.

COMMENTS

Background

Inflammatory bowel diseases (IBD), specifically Crohn's disease (CD) and ulcerative colitis (UC), are idiopathic chronic inflammatory disorders resulting from defects in the barrier function of the intestinal epithelium and inappropriate activation of the mucosal immune system. Early studies have suggested a relationship between thyroid abnormalities and IBD. For example, CD has been associated with Graves' disease and Hashimoto's thyroiditis. However, the association with IBD and thyroid cancer has been less critically analyzed. The aim of this study was to formerly study the age of diagnosis of papillary thyroid cancer (PTC) in IBD patients and evaluate the prevalence of PTC in IBD patients compared to a control population.

Research frontiers

This study addressed an important question regarding the epidemiology of IBD and PTC. The results suggest that CD patients are diagnosed with PTC at a much younger age, possibly due to a unique pathogenetic mechanism of disease occurs in this subset of patients.

Innovations and breakthroughs

The researchers drew a conclusion that there is a significant difference in age of diagnosis of PTC in patients with CD compared to patients with UC and the control populations studied. Patients with CD are diagnosed with PTC at a much younger age, possibly due to a unique pathogenetic mechanism of disease occurs in this subset of patients. It is established that CD results from a variety of factors, including genetic, environmental and immunological factors. An inappropriate inflammatory reaction is a key factor in the pathogenesis of CD. Similarly, PTC involves an inflammatory reaction, in particular, a lymphocytic infiltration of thyroid tissue. Thus, overlapping immunologic factors/pathways may connect these two diseases together. The inflammatory modulators involved in the pathogenesis of IBD may have an effect on PTC development or PTC may predispose patients to developing IBD.

Applications

This study answers important questions regarding the epidemiology of PTC and IBD, and also addresses the topic of cancer detection in CD patients. Currently age, gender, radiation exposure, and a low iodine diet are the only known clinical risk factors for PTC; further studies are needed to establish whether patients with CD are at increased risk of developing PTC. If there is an increased risk, then more stringent methods of cancer screening may be warranted for CD patients, including initiating screening at a younger age.

Peer review

The paper evaluated on a retrospective cohort study prevalence of PTC in IBD patients compared to a control population. This is a very interesting subject and there are many lacunae in the literature.

Abstract

AIM: To evaluate the safety and efficacy of Chlorella in 18 patients chronically infected with hepatitis C virus (HCV) genotype 1.

METHODS: Eighteen adults with chronic infection by HCV genotype 1 received daily oral supplementation of Chlorella for 12 wk. Changes in the RNA levels of HCV, as well as those of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels were evaluated following this treatment period. Paired *t* tests were conducted to compare the means of the different variables at the beginning and end of the study. Side effects and quality of life aspects were also compared between weeks 0 and 12 of the study period.

RESULTS: A majority 84.61% of the patients had a significant decrease in their ALT levels from week 0 to week 12. Evaluation of side effects showed that Chlorella was well tolerated. Quality of life assessment showed that 76.9 of the participants reported an improvement in their energy levels and 46.1% reported an improvement in their perception of general health. Although 69.23% also showed a decrease in their AST levels, this was not statistically significant. Most patients that exhibited an improvement in their ALT and AST levels also showed a tendency toward a decreased HCV viral load. The HCV RNA levels showed a decrease in 69.23% of the patients, which along with changes in AST/ALT ratios from week 0 to week 12, these results were not statistically significant.

CONCLUSION: Chlorella supplementation was well tolerated in patients with chronic HCV and associated with a significant decrease in ALT liver enzyme levels.

INTRODUCTION

Complementary and alternative medicines to treat chronic liver diseases, including chronic hepatitis C virus (HCV) infection, are becoming increasingly popular in North America[1-5]. Infection with HCV is global in nature, infecting approximately 160 million persons worldwide or roughly 2% of the world population, with some countries documenting a rate of 15% or more[6,7]. After an initial HCV infection, close to 70% of cases develop chronic infection that may progress to liver cirrhosis and hepatocellular carcinoma if left untreated[8]. The successful treatment of chronic HCV infection is determined by a reduced HCV-RNA viral load and improved liver function and histology. The current Food and Drug

Administration approved treatment for HCV is up to 42 wk of interferon and antiviral medications. However, there are significant costs associated with these medications and side effects which limit their use thus stressing the need for novel treatment options[9,10]. In addition, subjects that fail to respond to the initial treatment are less likely to respond to retreatment[11]. Many herbal and other natural compounds have now been used for the treatment of liver diseases, including HCV infection. Silybum marianum and Lactoferrin have been associated with a decrease in serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels[12,13]. More recently, green tea catechins have been shown to inhibit HCV attachment and transmission in human liver cells *in vitro*[14]. However, the potential benefits of herbal and other natural molecules in inhibiting the progression of HCV infection are only beginning to be understood, and more controlled studies are needed in this area.

Chlorella, a fresh water unicellular alga rich in macro- and micronutrients, has been used as a food source and nutritional supplement for centuries[15]. In animals, Chlorella has been reported to improve host resistance to viral infection and tumors[16-18]. In humans, Chlorella supplementation has been shown to enhance the antibody titer after influenza immunization[19], and to improve the outcome in several chronic diseases[20,21]. Chlorella supplementation has been also associated with an improvement in liver function in animal models[22,23]. Due to the documented benefits of Chlorella treatments in liver diseases in animals and in chronic diseases in humans, we studied the effects of Chlorella in 18 patients with chronic HCV genotype 1 infection. The plasma HCV RNA levels, hematological and chemistry results, including liver enzyme levels, and the quality of life and psychological well-being were assessed in this cohort following dietary supplementations with Chlorella-derived products.

MATERIALS AND METHODS

Population

The current study trial took place at a primary care clinic in western Massachusetts. Approval was obtained from the New England Institutional Review Board (NEIRB, Wellesley, MA, United States). The study cohort comprised 18 patients with chronic HCV infection who were either unwilling or unable to receive an interferon plus antiviral therapy. The inclusion criteria were an age of 18-65 years, evidence of chronic HCV infection by reverse transcription polymerase chain reaction (PCR), and a confirmation that the infection was due to HCV genotype 1. The exclusion criteria were any acute or chronic liver disease other than chronic HCV infection, any evidence of advanced liver disease such as a history or presence of ascites, a history of bleeding esophageal varices or encephalopathy, any known existing medical condition that could interfere with participation in the current study, co-infection with hepatitis B virus and/or human immunodeficiency virus, or a history of active alcohol or drug abuse three months prior to the beginning of the trial. Some of the patients had already been treated with interferon plus ribavirin (three years or more previously) before their participation in this study and had failed to respond.

Study design

This study examined the effects of Chlorella upon the HCV viral load, and on hematological and chemical test results, including AST and ALT liver enzyme levels, in infected patients during a 12 wk treatment period. To control for factors others than Chlorella that could have affected the results of our study, only patients with a HCV genotype 1 infection were selected for this trial. The AST/ALT ratio at week 0 and after the 12 wk of Chlorella supplementation was compared among the 13 subjects in the cohort.

We also compared the safety and efficacy of orally administered Chlorella by assessing the presence of possible side effects and their impact on quality of life. The side effects assessed included constipation, diarrhea, depression, irritability, headache/body aches, and any other significant symptoms that arose during the study period. Similarly, quality of life was assessed by evaluating changes in energy levels, general health perceptions, quality of sleep and changes in appetite. Patients were interviewed about possible side effects and impact of quality of life at baseline, and at weeks 1, 2, 4, 8 and 12. The answers were coded on a 5 level scale from 1 (much worse) to 5 (much better). Scores were then compared between baseline and weeks 1, 2, 4, 8 and 12. To assess compliance, patients were instructed to return all used and unused products at each visit.

"Sun Chlorella A™" consisted of a dry pulverized Chlorella pyrenoidosa powder plus a water soluble extract ("Wakasa Gold™"; Sun Chlorella Corp, Kyoto, Japan), which contained 82 mg/mL of Chlorella. It was administered orally to each patient as follows: three 500 mg tablets were administered twice daily on days 1-7 and then three times each day thereafter. Wakasa Gold ™ was administered at a dose of 30 mL twice a day starting on day 1. Both pulverized tablets and water soluble extracts were used in the treatment given in order to administer the greatest amount of Chlorella possible. Patients were evaluated as described above during the duration of the trial. Routine hematology, chemical tests and HCV RNA levels were done at baseline and at week 12 using a PCR-based assay conducted at a local laboratory (Life Lab; Mercy Hospital, Springfield, MA, United States).

Changes in AST and ALT liver enzyme levels and the HCV viral load in our "Chlorella treat" cohort were measured after the 12 wk study period and were compared with the same laboratory test results in a control group of 26 subjects who were also chronically infected with HCV genotype 1, but did not receive Chlorella. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; HCV: Hepatitis C virus; INF: Interferon.

in the control group were randomly selected, attended the same clinic and had a similar demographic profile as the Chlorella-treated group. Changes in the hematological, liver enzyme values and HCV-RNA viral load in this control group were assessed within an 11-21 wk period as part of a standard clinical evaluation. No subjects in either the study or control groups received treatment with interferon or other anti-viral drugs during the study period. This study was conducted in accordance with the Declaration of Helsinki, Good Clinical Practices and the study protocol was reviewed and approved by the NEIRB.

Statistical analysis

Data gathered during the study was used to examine statistically significant changes in the HCV RNA levels, and in the hematological and liver enzyme (AST, ALT) levels. Side effects and quality of life aspects were also compared between weeks 0 and 12 of the study period. Paired *t* tests were conducted to compare the means of the different variables at the beginning and end of the study. *P* values < 0.05 were considered statistically significant. All data was analyzed using Statistical Package for Social Sciences version 17.0.

RESULTS

Thirteen out of 18 enrolled patients completed our 12 wk study. Of the five patients who did not complete the trial, one individual discontinued treatment due to constipation on the first two days of treatment, which resolved upon treatment withdrawal. Four subjects were excluded due to poor compliance which was unrelated to side effects or changes in their general health status.

HCVRNA titer and liver enzyme analysis

Changes in the HCV RNA levels and in the AST and ALT liver enzyme levels among our study subjects are shown in Table 1. A majority of patients experienced an improvement in their liver enzyme profiles; 84.61% (11/13) had a decrease in their ALT levels from week 0 (mean ± SD, 89.30% ± 49.36%) to week 12 (mean ± SD, 71.46% ± 31.12%). Moreover, this decrease was statistically significant ($P < 0.05$). Although 69.23% of the patients (9/13) also showed a decrease in their AST levels from week 0 (mean ± SD, 67.84% ± 37.73%) to week 12 (mean ± SD, 54.30% ± 22.63%), this was not statistically significant ($P = 0.06$). The results further showed that 69.23% (9/13) of the patients had a decrease in their HCV RNA levels, although the results of the paired *t* test also showed this was not statistically significant ($P = 0.42$). Most patients that exhibited an improvement in their AST and ALT levels also showed a tendency toward a decreased HCV viral load. An exception was patient No. 8 whose viral load increased significantly (Table 1). The changes in the AST/ALT ratio between weeks 0 and 12 among the subjects in the Chlorella cohort shown in Table 1 were not statistically significant. The values obtained from additional laboratory tests, including routine hematology (complete blood count and differential) and chemical tests, showed no statistically significant changes during the study period (data not shown). No statistically significant differences in the changes of the AST and ALT liver enzymes, AST/ALT ratio and HCV viral load was observed within a 11-21 wk period, among the control group who received not Chlorella supplementation.

Side effect profile and quality of life assessment

The main side effects associated with the Chlorella treatments in our trial included constipation and diarrhea. Four of the 13 patients (30.7%) with a previous history of constipation reported their symptoms as worse or somewhat worse during the first two weeks of treatment. However, in all of these cases, the constipation symptoms were mild to moderate and resolved within the first two weeks. These patients continued in the trial for the scheduled 12 wk. Similarly, two of the 13 patients (15.3%) who completed the study complained of mild

diarrhea at week 1, but reported that these symptoms were much improved after week 2. None of the patients reported symptoms of abdominal pain, fever, depression, headache, body ache or other complaints during the 12 wk study.

Quality of life

Four variables were tested to assess changes in quality of life; 76.9 % of the patients (10/13) reported an improvement in their energy levels during the study period whereas 23.1% (3/13) reported no change in energy levels. In addition, 46.1% (6/13) of the patients reported an improvement in their perception of general health while 53.9% (7/13) reported no change in this regard. None of the patients reported issues with sleep quality or appetite during the 12 wk study period.

DISCUSSION

In our present study, most of the subject patients with chronic HCV showed a good tolerance to Chlorella oral supplementation. This was anticipated, based on previous studies which had also shown good tolerance of similar doses of Chlorella administered in pregnant, lactating[24], and elderly subjects[19], as well as in patients with diverse chronic diseases[20,21]. In addition, a significant percentage of our subjects reported health improvements in their quality of life questionnaire: 76.9% had an increase in energy levels and 46.1 % described an improvement in their general health perception.

The most significant finding from our current study was the statistically significant decrease in ALT levels, a marker of liver inflammation, among our patient cohort after 12 wk of Chlorella treatment. The cause-effect relationship between the observed significant decrease in the ALT levels and treatment with Chlorella is further suggested by the lack of significant ALT changes within the 11-21 wk period in a control group of HCV genotype 1 infected patients who had not received Chlorella. We further found that 69.23% of our patients showed a tendency toward a decrease in both their AST and HCV RNA levels after the 12 wk Chlorella treatment period, although this was not statistically significant. The AST/ALT ratio has been widely used as an indicator of liver disease; a ratio higher of 1 is used as indicator of liver fibrosis and cirrhosis[25,26]. In our cohort only four of thirteen subjects had an AST/ALT higher than 1 and there was no significant change after the Chlorella supplementation period (Table 1).

Animal studies have shown that enhanced immunocompetence provided by oral administration of Chlorella extract is mediated by augmentation of cell mediated immunity in normal and immunocompromised hosts[16-18]. More recently Kwak *et al*[27] demonstrated enhancement of natural killer cell activity and increase interferon and other cytokines production in humans after an 8 wk period of Chlorella supplementation at doses similar to the ones used in this study. We propose that the improvements in liver function tests in our population with chronic HCV infection is most likely due to the beneficial immunostimulatory effect of Chlorella supplementation. This is consistent with the finding that in our cohort most of the subjects that had been previously treated with interferon and failed to respond, were less likely to show a decrease in ALT and HCV-RNA values during Chlorella supplementation (Previous INF Rx, Table 1). The recovery from liver inflammation in all viral and non-viral cases of hepatitis is associated with a reduction in the ALT levels[28-30]. In Chronic HCV infection, early normalization of the ALT levels is predictive of the response to interferon[9,10,30]. However, whether the significant decrease in ALT values observed in our patients after 12 wk of Chlorella administration is associated with an improvement in liver histology remains to be determined.

The strength of our hypothesis; that the benefits of Chlorella supplementation are related to the well known immunoenhancement effects of Chlorella is limited by the lower number of subjects in our cohort and the limited time of supplementation (12 wk). Nevertheless, we conclude from our present findings that the benefits of Chlorella administration in the treatment of chronic HCV infection before and/or during the administration of interferon plus antiviral drugs, as well as the effects of Chlorella upon chronic infection by other HCV genotypes, warrant further study.

COMMENTS

Background

Chronic hepatitis C viral (HCV) infection are becoming increasingly popular in North America and most cases develop chronic infection that may progress to liver cirrhosis and hepatocellular carcinoma if left untreated. Chlorella supplementation has been shown to enhance the antibody titer after influenza immunization, and to improve the outcome in several chronic diseases.

Research frontiers

Animal studies have shown that enhanced immunocompetence provided by oral administration of Chlorella extract is mediated by augmentation of cell mediated immunity in normal and immunocompromised host. More recently Kwak *et al* demonstrated enhancement of natural killer cell activity and increase interferon and other cytokines production in humans after an 8 wk period of Chlorella supplementation at doses similar to the ones used in this study.

Innovations and breakthroughs

The study suggestes that the benefits of Chlorella administration in the treatment of chronic HCV infection before and/or during the administration of interferon plus antiviral drugs, as well as the effects of Chlorella upon chronic infection by other HCV genotypes, warrant further study.

Terminology

Chlorella, a fresh water unicellular alga rich in macro- and micronutrients, has been used as a food source and nutritional supplement for centurie. In animals,

Chlorella has been reported to improve host resistance to viral infection and tumors.

Peer review

The results are interesting and suggest that most of the subject patients with chronic HCV showed a good tolerance to Chlorella oral supplementation.

Abstract

AIM: To suggest infliximab (IFX) is effective for acute severe ulcerative colitis, from real-life clinical practice.

METHODS: All patients receiving IFX for the treatment of acute severe ulcerative colitis in a single centre were included. Data were extracted from clinical records in order to assess response to IFX therapy. The primary endpoint was colectomy-free survival, and secondary outcomes included glucocorticosteroid-free remission and safety, which was evaluated by recording deaths and adverse events. Demographic and clinical characteristics of those who underwent colectomy and those who were colectomy-free, both at discharge from their index admission, and during follow-up after an initial response to IFX were compared.

RESULTS: Forty-four patients (16 females, mean age 36 years) received IFX between May 2006 and January 2012 for acute severe ulcerative colitis. The median duration of follow-up post-first infusion was 396 d (interquartile range = 173-828 d). There were 21 (47.7%) patients with < 1 year of follow-up, 10 (22.7%) with 1 years to 2 years of follow-up, and 13 (29.5%) with > 2 years of follow-up post-first infusion of IFX. Overall, 35 (79.5%) responded to IFX, avoiding colectomy during their index admission, 29 (65.9%) were colectomy-free at last point of follow-up (median follow-up 396 d), and 25 (56.8%) were in glucocorticosteroid-free remission at end of follow-up. There was one death from post-operative sepsis, 20 d after a single IFX infusion. Colectomy rates were generally lower among those "bridging" to thiopurine. Of 18 patients "bridged" to thiopurine therapy, 17 (94.4%) were colectomy-free, and 15 (83.3%) were in glucocorticosteroid-free remission at study end. No predictors of response were identified.

CONCLUSION: IFX is effective for acute severe ulcerative colitis in real-life clinical practice. Two-thirds of patients avoided colectomy, and more than 50% were in glucocorticosteroid-free remission.

Halpin SJ, Hamlin PJ, Greer DP, Warren L, Ford AC. Efficacy of infliximab in acute severe ulcerative colitis: A single-centre experience. *World J Gastroenterol* 2013; 19(7): 1091-1097 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1091.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1091

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory disorder of the gastrointestinal tract of unknown etiology, with a prevalence of between 160 and 240 per 100 000 people

in Western populations[1-3]. The condition is thought to arise from dysregulation of both the innate and adaptive immune systems, leading to an abnormal inflammatory response to commensal bacteria in a genetically susceptible individual[4].

The clinical course of UC is characterized by periods of remission and relapse, with acute inflammatory exacerbations of disease activity which, when severe, are potentially life-threatening. The standard initial management of these inflammatory exacerbations includes high dose intravenous glucocorticosteroids in the first instance, but this strategy may be unsuccessful in up to 50% of patients[5-7]. Immunomodulating drugs such as azathioprine, whilst effective in maintaining remission[8], act too slowly to be of use in the acute setting. Following the publication of a randomized controlled trial (RCT) by Lichtiger *et al*[9] in 1994, ciclosporin has been used as medical rescue therapy in acute severe UC, in order to avoid colectomy in the short-term, and to act as a "bridge" to long-term thiopurine therapy[10]. Several case series have since been published[11-14], but despite response rates in the order of 50%-70%, many patients require colectomy in the longer term.

In recent years, biological therapies have emerged as a treatment option in inflammatory bowel disease (IBD). Infliximab (IFX) (Remicade®, Centocor Ortho Biotech Inc, PA, United States), a chimeric monoclonal antibody directed against human tumor necrosis factor-alpha was the first biological therapy to be approved for use in acute severe UC. The efficacy of IFX in UC has been investigated by a limited number of RCTs[15-18]. When data from all these trials were pooled in a recent meta-analysis the number needed to treat over placebo to achieve remission in one patient with moderately or severely active UC was only 4, suggesting this is a highly efficacious therapy[19].

However, only two of these trials studied the use of IFX in acute severe UC[15,18], one of which found no significant difference in response between IFX and placebo[18]. In addition, data from RCTs do not always translate into normal clinical practice. Data from small retrospective case series' suggest that as many as one-third of patients given IFX for acute severe UC still require colectomy during the acute admission[20-23], but larger datasets, with longer follow-up, may provide more accurate insight into the efficacy of IFX in this setting. We therefore report our 6-year experience of using IFX in acute severe UC.

MATERIALS AND METHODS

Participants and setting

Patients have been treated with IFX for acute severe UC since 2006 in the Leeds Gastroenterology Institute, which operates across two large teaching hospitals serving a local population of approximately 800 000, as well as receiving tertiary referrals from the surrounding area. After their first IFX infusion of 5 mg/kg in hospital, patients attend for their second and third infusions on an outpatient basis at 2 wk and 6 wk. These are administered at a dedicated biological therapy clinic by specialist IBD nurses, who maintain a prospective database detailing demographics, response to therapy, number of infusions received, and any adverse events experienced.

All patients who received at least one dose of IFX for acute severe UC in Leeds between May 2006 and January 2012 were included. Patients were identified by cross referencing our IBD database with pharmacy records, which are accurate as all IFX infusions for in-patients are prepared in the pharmacy department. The use of IFX to treat an episode of acute severe UC was defined as need for the drug during an in-patient admission with an acute inflammatory exacerbation of disease activity. Patients receiving IFX for IBD-unclassified or pouchitis were excluded.

Data collection

Inpatient medical records, computerized outpatient clinic letters, histopathology, endoscopy, and blood results were reviewed by one investigator. Data were collected onto a Microsoft Excel spreadsheet (XP professional edition; Microsoft, Redmond, WA, United States) designed prospectively. These included demographic details, date of UC diagnosis, extent of disease according to the Montreal classification[24], drug therapy at time of admission, prior or current use of thiopurine or 5-aminosalicylate (5-ASA), physiological and biochemical parameters at day 0 and day 3 (mean number of stools per day, pulse, temperature, and C-reactive protein (CRP) level in mg/L), severity of UC on day 3 of their admission, according to the Travis criteria[25], and duration of admission (in days). Total number of infusions received, any adverse events experienced (including death), requirement for colectomy, and current drug therapies were collected at discharge from the index admission, as well as at last point of follow-up.

The primary outcome of interest was colectomy-free survival, and secondary outcomes included glucocorticosteroid-free remission and safety. Patients were judged to have had an initial response to therapy if they were discharged from their index admission colectomy-free. Recording of the patient's current drug therapy at last contact allowed assessment of the achievement of glucocorticosteroid-free remission. Safety data included deaths or adverse events during the study period that were potentially related to IFX.

Statistical analysis

The proportion of individuals who were colectomy-free at discharge from their index admission, and who were in colectomy- and glucocorticosteroid- free remission at the last point of follow-up was calculated. Demographic and clinical characteristics of those who underwent colectomy and those who were colectomy-free, both at discharge from their index admission, and during follow-up, after an initial response to IFX were compared using

Table 1 Baseline characteristics and demographics of 44 patients with acute severe ulcerative colitis receiving infliximab *n* (%)

Characteristic	All patients (*n* = 44)
Age at index admission[1]	35.7 ± 15.9
Female	16 (36.4)
Extent of disease (Montreal classification)	
E1 (limited to rectum)	2 (4.5)
E2 (distal to splenic flexure)	13 (29.5)
E3 (proximal to splenic flexure)	29 (65.9)
Current or previous smoker	18 (40.9)
Prescribed oral 5-ASA on admission	24 (54.5)
Prescribed thiopurine on admission	14 (31.8)
Median disease duration, in days, prior to first IFX infusion (IQR)	409 (16.25 to 1896.5)
First presentation of UC	12 (27.3)
Mean CRP (mg/L) on day of admission[1]	90.1 ± 81.9
CRP ≤ 5 on day of admission	6 (13.6)
Mean number of stools per day on admission[1]	12.1 ± 5.8

[1]Data are presented as mean ± SD. UC: Ulcerative colitis; IQR: Interquartile range; 5-ASA: 5-aminosalicylate; CRP: C-reactive protein; IFX: Infliximab.

an independent samples *t*-test for continuous variables, and Fisher's exact test for categorical variables. Multivariate logistic regression was performed in an attempt to identify independent risk factors for colectomy during the index admission, or during follow-up, controlling for all baseline demographic and clinical characteristics. All statistical analyses were performed using StatsDirect version 2.7.2 (StatsDirect Ltd, Sale, Cheshire, England), and SPSS for Windows version 19.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Between May 2006 and January 2012, 44 patients were treated with IFX for acute severe UC. The median duration of follow-up post-first infusion was 396 d [interquartile range (IQR) 173-828 d]. There were 21 (47.7%) patients with < 1 year of follow-up, 10 (22.7%) with 1-2 years of follow-up, and 13 (29.5%) with > 2 years of follow-up post-first infusion of IFX. The mean age at presentation with acute severe UC was 35.7 years (range: 18-78 years), and mean age at diagnosis was 32.4 years (range: 13-78 years). Of the 44 patients, 16 were female (36.4%). Baseline demographic data and disease characteristics of the included patients are detailed in Table 1. All patients had abdominal X-ray performed on admission to exclude toxic megacolon, and this was repeated at the discretion of the treating physician during intravenous glucocorticosteroids. Confirmation of mucosal disease activity was obtained by flexible sigmoidoscopy.

All 44 patients met the modified Truelove and Witt criteria[26] for acute severe UC on the day of admission. Mean CRP at time of admission was 90.1 mg/L, although this was less than 5 mg/L in 6 (13.6%) patients, and mean number of stools per day on admission was 12.1. All patients received intravenous glucocorticosteroids from the time of admission for a median of 7 d prior to IFX. There were 12 (27.3%) patients for whom the index episode of acute severe UC was their first presentation with the disease. Among the other 32 patients with an existing diagnosis of UC, 24 (75.0%) were currently receiving oral 5-ASA therapy, 14 (43.8%) were currently receiving thiopurine therapy, and a further six had previously received thiopurines but were either intolerant of them, or had experienced adverse events.

Need for colectomy during index admission

Nine patients (20.5%) underwent colectomy during their index admission, at a median of 5 d after their first IFX infusion (range: 2-18 d). The remaining 35 patients were discharged after their first IFX infusion colectomy-free. Baseline demographic data and disease characteristics of patients according to colectomy status at discharge from hospital following the index admission are reported in Table 2.

Patients who underwent colectomy during the index admission were generally older (mean age 45.6 years versus 33.2 years), and a higher proportion were admitted with a first presentation of UC (55.6%), compared with those who were discharged without colectomy (20.0%), but these differences were not statistically significant (P = 0.18, and P = 0.09 respectively). Extent of disease, according to the Montreal classification, was not associated with need for colectomy on index admission. In terms of medication use, fewer patients who underwent colectomy were receiving oral 5-ASAs or thiopurines on admission to hospital, but only the latter difference was statistically significant (P = 0.04). Those who underwent colectomy had significantly higher CRP values both on admission, and at day 3, than those who avoided colectomy (P = 0.002, and P = 0.04, respectively). All nine patients who required colectomy met the Travis criteria at day 3, compared with only 15 (42.9%) of those who did not undergo surgery at the index admission (P = 0.002). Among those who were colectomy-free at discharge 31.4% received IFX at day 5 or sooner, compared with only 11.1% of those who underwent colectomy (P = 0.41). No predictors of need for colectomy during the index admission were identified by multivariate logistic regression.

Colectomy-free survival at study end

Of the 35 patients who avoided colectomy during their index admission, 33 received standard three-dose induction with IFX. At the last point of follow-up, 29 (65.9%) of 44 patients remained colectomy-free. Thus, 82.9% (29/35) of those who responded to IFX on the index admission remained colectomy-free during follow-up. Among these 35 patients, 17 (48.6%) had < 1 year of follow-up, 8 (22.9%) had 1-2 years of follow-up, and 10 (28.6%) had > 2 years of follow-up post-first infusion of IFX. Two patients in each of these groups underwent colectomy during follow-up (χ^2 for trend, P = 0.69). The median time from first IFX infusion to colectomy for the six patients who had colectomy following an initial response to IFX therapy was 278 d (IQR 136.5-401.25 d).

Table 2 Clinical characteristics and demographics of 44 patients with acute severe ulcerative colitis receiving infliximab, according to colectomy status after index admission and at last point of follow-up *n* (%)

	Colectomy status after index admission			Colectomy status at last point of follow-up		
	Colectomy during index admission (*n* = 9)	Discharged colectomy-free (*n* = 35)	*P* value[2]	Colectomy during index admission or follow-up (*n* = 15)	Colectomy-free survival (*n* = 29)	*P* value[2]
Age at index admission[1]	45.6 ± 24.7	33.2 ± 12.1	0.18	42.2 ± 21.4	32.4 ± 11.3	0.11

Received IFX on day 5 or sooner	1 (11.1)	11 (31.4)	0.41			

[1]Data are presented as mean ± SD; [2]Independent samples *t*-test for continuous data and Fisher's exact test for categorical data; [3]χ^2 for trend. UC: Ulcerative colitis; 5-ASA: 5-aminosalicylate; CRP: C-reactive protein; IFX: Infliximab.

Demographic data and clinical characteristics of those who were colectomy-free at study end and those requiring colectomy at any point during the study are reported in Table 2.

Those who were colectomy-free at end of follow-up were generally younger, more likely to have had an established diagnosis of UC prior to their index admission, more likely to be receiving thiopurines on admission, and had lower mean CRP levels at admission, and on day 3, but none of these differences were statistically significant. Again, no predictors of need for colectomy at any point during follow-up were identified by multivariate logistic regression.

There were 18 of the 35 patients who avoided colectomy during their index admission who received IFX as a "bridge" to commencement of thiopurine therapy during, or soon after, the index admission. Of these, 17 (94.4%) were colectomy-free at the end of follow-up, compared with 12 of the 17 (70.6%) who did not commence thiopurine therapy ($P = 0.09$).

Glucocorticosteroid-free remission at study end

Of the 29 individuals who were colectomy-free at the last point of follow-up, 25 (86.2%) were in glucocorticosteroid-free remission. Therefore of the original 44 patients, 56.8% were colectomy-free and in glucocorticosteroid-free remission at the end of follow-up. Of the four patients who were colectomy-free but not in glucocorticosteroid-free remission, two had experienced a relapse of disease activity at their most recent assessment, one was receiving long-term low-dose oral glucocorticosteroids for co-existent inflammatory arthritis but was in remission clinically, and the fourth patient was still tapering the dose of glucocorticosteroids following recent index admission. Of the 18 patients who were "bridged" to thiopurine therapy during, or soon after, the index admission 15 (83.3%) were in glucocorticosteroid-free remission at the end of follow-up.

Safety and tolerability of IFX

During the study period one patient died from severe sepsis in the post-operative period, 2 d post-colectomy, and 20 d after a single IFX infusion. A total of eight other patients experienced adverse events with IFX. Five of these were minor, including skin rash in two patients, flushing in one patient, elevated transaminases in one patient, and pruritus in the fifth. All of these resolved without the need for discontinuation of IFX. In the other three patients the adverse events were intolerable and led to discontinuation of the drug. These included infusion reactions in two patients, and a delayed hypersensitivity reaction in the third. Of the three patients who discontinued IFX, one underwent colectomy and ileal pouch formation 15 mo after the initial IFX infusion, one was receiving low-dose glucocorticosteroids (2.5 mg prednisolone daily) in combination with methotrexate for co-existent inflammatory arthritis, and was in clinical remission as detailed above, whilst the third was colectomy-free and in glucocorticosteroid- free remission on azathioprine at the last point of follow-up.

DISCUSSION

This study has demonstrated that IFX is an effective rescue therapy in acute severe UC. After failure of intravenous glucocorticosteroids to control the acute severe episode, 80% of patients receiving IFX avoided the need for colectomy during the index admission. Those who met the Travis criteria on day 3 and those who were not receiving thiopurine therapy on admission were more

likely to require colectomy on their index admission. Among those who responded to IFX during their index admission, 83% remained colectomy-free and, in those who were colectomy-free, glucocorticosteroid-free remission was achieved in 86%, after a median follow-up period of 396 d. Of the total cohort of patients, 57% were colectomy-free and in glucocorticosteroid-free remission at the end of follow-up. The efficacy of IFX as a "bridge" to commencing thiopurine therapy is reinforced by the finding that over 90% of those patients "bridged" to thiopurine therapy avoided subsequent colectomy. Serious adverse events, resulting in the discontinuation of IFX were rare. However, there was one post-operative death as a result of severe sepsis.

Strengths of the study include the use of our biologics database which is maintained prospectively, allowing the inclusion of data from every patient who received IFX for acute severe UC in a large tertiary referral centre. The relatively long duration of follow-up among included individuals provides valuable, real-life data on outcomes among patients with acute severe UC receiving IFX. There are some limitations of the study. We relied on data extracted from medical records and computerized outpatient clinic letters, which may not always be accurate. We did not measure improvement of disease activity using validated indices, but instead used the dichotomous outcome measures of need for colectomy and glucocorticosteroid-free remission. As the patients included in this study are from a tertiary referral centre, the data may not be generalizable to patients in other hospitals. However, the spectrum of disease is likely to be more severe in a population such as this, which may have led to an underestimate of the efficacy of IFX in this setting. Finally, although this is one of the largest retrospective single centre experiences of the use of IFX in acute severe UC reported, the absolute number of patients involved remains small, meaning that we were unable to identify any patient demographics or clinical characteristics that were independently associated with a response to IFX therapy or avoidance of colectomy during follow-up.

The results of this study are comparable with those found in an RCT conducted in Scandinavia by Järnerot *et al*[15], in which 71% of those treated with IFX for moderately severe or severe UC avoided colectomy over 90 d. Previous retrospective studies have demonstrated similar efficacy, with between 66% and 84% of other cohorts from the United Kingdom, Denmark and Canada avoiding colectomy during their index admission[20-23]. Retrospective studies comparing IFX with ciclosporin from New Zealand and Italy found that around 80% of patients treated with IFX avoided colectomy at 3 mo, compared with 37% and 72% respectively for ciclosporin[27,28]. Recent data from the United Kingdom national IBD audit suggest that, among those who failed first line treatment with intravenous glucocorticosteroids, response rates to IFX were generally higher than those with ciclosporin[29]. One multi-centre European RCT comparing IFX to ciclosporin head-to-head in this setting has been published recently[30], and another United Kingdom-based trial is ongoing[31]. The European trial recruited 115 patients with acute severe UC. There was no significant difference detected in rates of response to therapy at 7 d, failure of therapy after 98 d, or colectomy rates, leading the authors to conclude that the two treatments were equivalent, and that the choice of which of these therapies to use should be guided by physician and centre experience[30].

In the trial reported by Järnerot *et al*[15], IFX appeared to have a more marked effect in those with less severe disease activity. Our finding that surrogate measures of severity, including a higher CRP level on day 0 and day 3, and meeting the Travis criteria at day 3, were associated with higher colectomy rates during the index admission are consistent with this. In addition, over 30% of patients who avoided colectomy during their index admission received their first IFX infusion at day 5 or sooner, compared with only 11% of those who required colectomy. Although this result did not reach statistical significance it is noteworthy, and suggests that there may be a potential benefit associated with earlier use of IFX, before the acute episode has reached its full intensity. However, these results are not supported by the findings of a multi-centre Scottish study, in which colectomy rates were higher among those treated on day 5 or sooner, compared with those treated on or after day 6[20].

All patients in our study who underwent colectomy during the index admission were thiopurine-naïve. This is in contrast to both the Scandinavian and Scottish studies, in which thiopurine use prior to admission did not appear to affect need for colectomy[15,20], although the numbers of patients receiving thiopurines at the time of admission in both these studies were smaller. Those who were "bridged" to thiopurine therapy in our study, following an initial response to IFX, appeared less likely to require colectomy during subsequent follow-up, although a large French multicentre case series of IFX in UC, which included patients with both acute severe and chronic relapsing disease, found that immunomodulator use was not predictive of the need for IFX optimization, IFX failure, or colectomy[32]. However, the role of thiopurines and IFX in this setting is still evolving, with preliminary results from the UC SUCCESS trial showing superiority of combination IFX and azathioprine therapy over either therapy alone in the setting of moderate to severe UC[33].

In conclusion, this study provides further evidence for the efficacy and safety of IFX as rescue therapy in acute severe UC, in one of the largest cohorts of patients with a longer duration of follow-up than previously available from other retrospective, real-life data. Overall, 66% of patients were colectomy-free at study end, and 57% had also achieved glucocorticosteroid free-remission. Although serious adverse events were rare, the mortality rate of 2% is a reminder for clinicians of the profound effects of biological therapy on the im-

mune system, in a group of patients who are already seriously ill. The results of this study suggest that the use of IFX as a "bridge" to thiopurine therapy in patients with acute severe UC is highly effective, but even among patients who are already receiving, or are intolerant of, thiopurines the use of three-dose induction therapy with IFX may avoid the need for colectomy in a significant number.

COMMENTS

Background

Ulcerative colitis (UC) is a chronic inflammatory condition affecting the lower gastrointestinal tract. Acute exacerbations of inflammation are managed using intravenous glucocorticosteroids initially, but if these fail biological therapies can be used in an attempt to control inflammation and avoid the need for surgery. Infliximab (IFX) is a monoclonal antibody directed against tumour necrosis factor alpha.

Research frontiers

Whilst randomised controlled trials have established the efficacy of IFX in UC, there have been only two placebo controlled trials specifically in the context of acute severe UC. Since results from clinical trials are not always replicated under normal clinical conditions and over longer durations of follow-up, results from real-life experience are essential to provide further insight into the efficacy of IFX in this setting.

Innovations and breakthroughs

This single-centre review shows that, over longer follow-up periods and in real-life clinical settings, similar outcomes can be obtained to those in the original clinical trials, with two-thirds of patients avoiding the need for surgery. It also sheds light on the role of azathioprine alongside IFX therapy.

Applications

This study will inform clinicians and patients of the likely outcomes if IFX is used as rescue therapy in acute severe UC, unresponsive to steroid treatment.

Terminology

The use of IFX to treat an episode of acute severe UC was defined as need for the drug during an in-patient admission with an acute inflammatory exacerbation of disease activity.

Peer review

This is a well-done paper dealing with IFX rescue treatment of patients with UC. The authors are completely right that observations from real life situations are of much higher importance than those obtained from an artificial setting of a randomized controlled trial.

Abstract

AIM: To study current treatment options for pediatric hepatitis C infection and their associated success rates.

METHODS: We retrospectively reviewed charts of thirty children who had been treated with combination therapy of pegylated interferon alfa plus ribavirin for chronic hepatitis C infection. Patients had been treated with ribavirin (15 mg/kg per day) and either pegylated interferon alfa 2a (180 mg/m^2 once weekly) or pegylated interferon alfa 2b (1.5 mg/kg once weekly). Patients' follow-up included subjective assessment of complaints, physical examination including weight and height, as well as laboratory evaluations for viral load [before treatment, at 12 wk, and 6 mo following treatment completion, as determined by sustained viral response (SVR)], complete blood count, liver enzymes, alkaline phosphatase, bilirubin, renal function tests, and thyroid function tests. For patients not achieving a two log decrease in viral load at treatment week 12, treatment was discontinued and the patient was considered a treatment non-responder.

RESULTS: Thirty children aged 3-18 years were included in the study. Twenty patients (11 males, 9 females) received pegylated interferon alfa 2b and ten patients (6 males, 4 females) received pegylated interferon alfa 2a. Twenty-three patients were infected with genotype 1, six patients were infected with genotype 3, and one patient was infected with genotype 2. Twenty patients (67%) achieved SVR. Treatment success rates were 90% with pegylated interferon alfa 2a *vs* 55% with pegylated interferon alfa 2b. Although a trend was noted for improved outcomes in the group receiving pegylated interferon alfa 2a, there were no statistically significant outcome differences between the two treatment groups (P = 0.1). Treatment success was 56.5% for patients infected with genotype 1 virus, compared to 100% for patients infected with other genotypes (P = 0.064). There was no difference in treatment response between males and females. A cut-off age of twelve years was used to dichotomize younger *vs* older participants; however, no difference in treatment response was observed between these groups. Using multivariate regression analysis, we could not determine predictors for achieving SVR from among the variables we examined (age, sex, and viral genotype). Although we noted a trend toward SVR with peginterferon alfa-2a, there was no statistical difference between the two peginterferons. A high incidence of adverse reactions to treatment was noted. Twenty-five patients (83%) suffered from at least one adverse reaction, but most experienced more than one adverse reaction. All patients except one became leukopenic (white blood cell count less than 5500 leukocytes/μL), six (20%) became anemic (hemoglobin less than 110 g/L), and one (3.3%) became thrombocytopenic (platelets less than 100 000/μL).

CONCLUSION: Combination therapy to treat hepatitis

C in children is as effective as in adults. There may be a benefit for treatment with pegylated interferon alfa 2a.

Rosen I, Kori M, Eshach Adiv O, Yerushalmi B, Zion N, Shaoul R. Pegylated interferon alfa and ribavirin for children with chronic hepatitis C. *World J Gastroenterol* 2013; 19(7): 1098-1103 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1098.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1098

INTRODUCTION

Hepatitis C virus (HCV) infection is relatively uncommon in the pediatric population. Populations at risk of HCV infection are infants born to infected mothers who acquire the infection vertically, and children with chronic diseases who acquire the virus through infected blood products[1]. Vertical transmission is the predominant source for new pediatric HCV infections. Estimated transmission rates are 2%-5% when the mother is viremic during pregnancy[1,2]. Mothers with greater than 10^6 copies/mL of HCV RNA are more likely to transmit the infection to their infants compared to mothers with lower levels of viremia. Chronic hepatitis C (CHC) develops in 55%-80% of infected children[2,3]. The prevalence of HCV in children in developed countries ranges from 0.1% to 0.4%[4-6]. Treatment is contraindicated for patients less than three years of age because of safety concerns and to allow for spontaneous viral clearance. After age four, spontaneous viral clearance is unlikely[7]. The rate of viral clearance in children with CHC who acquired the infection vertically is 20%[8]. Most children who clear the virus do so during the first five years of follow-up.

In most cases, HCV infection in children is asymptomatic. Histological findings are minor and severe complications are uncommon. However, chronic hepatic inflammation from HCV infection can progress to advanced liver fibrosis and cirrhosis in four percent to six percent of infected children[9,10]. The risk of developing cirrhosis is approximately 20% and the risk of developing hepatocellular carcinoma is 2%-5%[11]. Hepatocellular carcinoma has been reported in adolescents with CHC[12].

The current treatment of choice for CHC in children, as in the adult population[13,14], is combination pegylated interferon alfa plus ribavirin. We have been prescribing this treatment regimen for the last seven years. We retrospectively reviewed charts of patients who had been treated for CHC with pegylated interferon alfa plus ribavirin in several Israeli Pediatric Gastroenterology Centers.

MATERIALS AND METHODS

Patient selection

Complete data were available for a total of thirty children with chronic HCV infection who were treated between 2003 and 2010. Chronic HCV infection was diagnosed by the presence of anti-HCV antibodies and HCV RNA positivity. Additional available information included: alanine aminotransferase (ALT) levels during the three mo prior to treatment, laboratory studies during follow-up, and, for some patients, liver biopsy specimens showing evidence of CHC or Actitest and Fibrotest results.

Ten patients were treated with pegylated interferon alfa 2a (180 mg/m^2 once weekly) plus ribavirin 15 mg/kg per day and 20 patients were treated with pegylated interferon alfa 2b (1.5 mg/kg once weekly) plus ribavirin (15 mg/kg per day). The decision for which peginterferon was prescribed depended on the patient's medical insurance. Length of treatment was 24 wk for patients with genotypes 2 or 3 (seven patients) and 48 wk for patients with genotype 1 (twenty-three patients). Patient follow-up included assessment of subjective complaints, physical examination with weight and height, and laboratory workup which included viral load [before treatment, at 12 wk, and 6 mo following treatment completion, as determined by sustained viral response (SVR)], complete blood count, liver enzymes, alkaline phosphatase, bilirubin, renal function tests, and thyroid function tests. In patients not achieving a two $\log_{10}$ IU/mL decrease in their viral loads at week 12, treatment was discontinued and the patient was considered a treatment non-responder.

Statistical analysis

Statistical analysis was performed using the SPSS software package version 15 (SPSS, Chicago, IL, United States).The normality of quantitative variables was tested using the Kolmogorov-Smirnov test. Because most of the quantitative variables were not normally distributed, the Mann-Whitney *U* test was used to analyze differences between SVR groups. Fisher's exact test was used to determine the relationship between SVR groups and categorical variables (gender, treatment type, genotype). Logistic regression was performed to predict relationships between SVR groups and several independent variables. A P value < 0.05 was considered statistically significant.

RESULTS

Patient characteristics

Thirty patients (13 girls and 17 boys) aged three to eighteen years were included in this study. Patients' characteristics and results are shown in Table 1. Twelve acquired HCV vertically, eleven through blood products, one by needle stick, and six patients had no identifiable source of infection.

It should be noted that several patients had underlying comorbidities: one patient had Becker Muscular Dystrophy, one patient had proctitis, one had Congenital Adrenal Hyperplasia, one had human immunodeficiency virus infection, and one had Obstructive Sleep Apnea. Twenty-three patients were infected with HCV genotype 1 (genotype 1b in twenty patients and genotype 1a in three patients). Six patients had genotype 3a, and one

AST (U/L)[1]	43.90 ± 19.31	55.65 ± 31.39	0.54
Weight (kg)[1]	48.66 ± 23.76	51.62 ± 21.96	0.66
Median viral load	747 000	332 500	0.49

[1]Data are presented mean ± SD. SVR: Sustained virologic response; WBC: White blood cells; HGB: Hemoglobin level; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

patient had genotype 2. Viral loads prior to treatment ranged from 134 000 to 26 200 000 copies/mL. ALT levels prior to treatment ranged from 24 to 183 U/L (mean 69.93 ± 37.64 U/L).

Liver histology ranged from mild chronic portal inflammation to moderate portal inflammation with fibrous expansion. Fibrotest scores ranged from 0 to 3 and activity ranged from 0 to 3 on the Actitest. Twenty-six patients were interferon-naïve, three patients were non-responders to previous interferon monotherapy, and one patient was a non-responder to previous pegylated interferon alfa 2a therapy (and had also been treated with pegylated interferon alfa 2b).

Treatment response

Viral load at 12 wk was undetectable in twenty-two patients, slightly positive in one patient, and positive in six patients. For one patient, viral load examination was delayed and was not tested until six months after treatment initiation, at which time it was negative (Figure 1). SVR six months following treatment completion was achieved in twenty patients, for an overall treatment success rate of 67%.

Among twenty-three patients with undetectable HCV RNA [as measured by polymerase chain reaction (PCR)] following 12 wk of treatment, 19 achieved SVR. Only one of seven patients who were positive for HCV RNA at 12 wk achieved SVR. This patient's viral load had decreased greater than two $\log_{10}$ IU/mL at 12 wk compared to baseline (Figure 1).

Forty-three percent (10/23) of those with genotype 1 did not achieve SVR; of those, four responded to treatment after twelve weeks, and six were non-responders. One patient who failed to respond was non-compliant with ribavirin, and another patient stopped ribavirin due to serious headaches and rash.

Twenty patients (eleven males, nine females) received pegylated interferon alfa 2b and ten patients (six males, four females) received pegylated interferon alfa 2a. The success rate was 90% (9/10) for those receiving pegylated interferon 2a combined with ribavirin (six patients

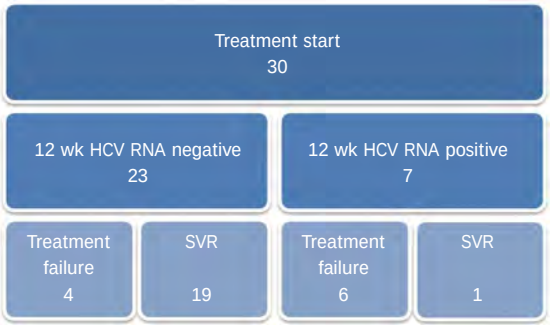

Figure 1 Hepatitis C virus RNA polymerase chain reaction results 12 wk after treatment and outcomes 6 mo after treatment completion. HCV: Hepatitis C virus; SVR: Sustained viral response.

with genotype 1b, three with genotype 1a, and one with genotype 3a). The success rate for those with genotype 1b was 83% (5/6).

Fifty-five percent (11/20) of patients receiving pegylated interferon alfa 2b and ribavirin treatment (fourteen patients with genotype 1b, five patients with genotype 3a, and one patient with genotype 2) achieved SVR. Only 36% (5/14) of patients with genotype 1b achieved SVR with this treatment. Although a trend was noted in favor of pegylated interferon alfa 2a, there were no significant differences between the two treatment groups ($P = 0.1$). The treatment success rate was 56.5% in patients infected with genotype 1 virus, compared to 100% in patients infected with non-1 genotypes ($P = 0.064$).

There was no statistical difference in response to treatment between males and females. A cut-off age of twelve years was used to compare response to treatment between younger and older patients; no statistical difference was observed. Treatment failure occurred only among those infected with genotype 1 HCV.

We could not determine predictors for achieving SVR from among the variables examined (age, sex, and viral genotype) in our multivariate regression analysis. We did observe a trend toward greater SVR when using peginterferon alfa-2a, but this difference between the two peginterferons was not statistically significant, most likely due to our small sample.

Adverse reactions

Adverse events were common, occurring in 83% of patients (25/30) and including flu-like symptoms, malaise, headaches, fever, lymphadenopathy, anorexia, weight loss, hair loss, myalgia, fat necrosis, somnolence, sleep disturbance, anemia, neutropenia, thrombocytopenia, oral aphthae and aseptic meningitis (following treatment completion). No patient experienced severe bone marrow suppression (Table 2).

Leukocyte counts before treatment ranged from 3630 to 11400 cells/μL (mean ± SD, 7540.69 ± 1950.3 cells/μL) and from 1750 to 5770 cells/μL (mean ± SD, 3335.5 ± 823 cells/μL) during treatment. The Mann-Whitney *U* test showed a significant difference between leukocyte levels before and during treatment ($P < 0.001$). Hemoglobin levels also decreased, from 116 to 169 g/L (mean ±

Table 2 Comparison of adverse reactions between those receiving peginterferon-alfa 2a and those receiving peginterferon-alfa 2b

Adverse reaction	Peginterferon-alfa 2a (n = 10)	Peginterferon-alfa 2b (n = 20)	Total
None	0	5	5

Direct hyperbilirubinemia (mg/dL)	1	0	1
Indirect hyperbilirubinemia (mg/dL)	0	1	1

GI: Gastrointestinal; HGB: Hemoglobin level.

SD, 135.3 ± 12.8 g/L) before treatment to 95 to 139 g/L (mean ± SD, 115 ± 10.2 g/L) during treatment, as determined by t-test ($P < 0.001$).

Only one patient experienced direct hyperbilirubinemia of 15 mg/L, with a total bilirubin level of 18 mg/L. Another patient had indirect hyperbilirubinemia of 26 mg/L during treatment. All patients had normal gamma-glutamyl transferase levels and renal function throughout treatment. One patient developed hypothyroidism which subsequently resolved.

DISCUSSION

Combination therapy of pegylated interferon alfa plus ribavirin for chronic HCV infection in children was found to be as effective as in adults. Fifty-seven percent of children infected with genotype 1 achieved SVR and children infected with other HCV genotypes achieved 100% SVR. The success rates are similar to success rates reported in other pediatric studies[13,15].

Treatment strategies for CHC have evolved over the years, from interferon monotherapy to combination interferon alfa plus ribavirin[16] to combination pegylated interferon alfa plus ribavirin[14,15,17,18]. This latter combination is currently the treatment of choice for CHC in children, as in adults[13,14]. Schwarz *et al*[15] reported that combination ribavirin plus peginterferon alfa is superior to peginterferon alfa and placebo for children and adolescents with CHC. Two options exist for pegylated interferon alfa therapy: pegylated interferon alfa 2a and pegylated interferon alfa 2b[19-23]. The main treatment goal is to achieve an SVR, defined as undetectable serum HCV RNA for six months following cessation of treatment. Treatment outcomes depend on HCV genotype and viral load at the beginning of treatment[13,17,24]. The genotype is a key predictor of treatment response[24]. Wirth *et al*[14] found that patients infected with genotype 1 experienced 53% SVR, compared to patients with genotypes 2 or 3 who had 93% SVR, and patients with genotype 4 who had 80% SVR. Baseline viral load is the main response predictor for patients infected with HCV genotype 1. SVR may be more likely in patients who have lower viral loads[14]. In a systematic review, Hu *et al*[13] reported that SVR rates in children with CHC ranged from 30% to 100%, comparable to those seen among adults.

Combination treatment causes high rates of adverse reactions, with almost all children suffering from transient flu-like symptoms. Other adverse reactions are diverse. In our study, 83% of patients suffered from adverse reactions, but almost all patients remained compliant with therapy. Indeed, in most studies, the treatment is tolerated and compliance is good[24,25]. The treatment protocol has been associated with significant changes in body weight, linear growth and body composition (loss of fat mass); however, these effects seem reversible[26].

In adults, HCV RNA PCR results after twelve weeks of treatment predict treatment outcomes. Failure to respond (a less than two $\log_{10}$ drop from baseline HCV RNA levels) is associated with non-response to treatment, and the therapy should be discontinued. It is unknown whether this rule applies to pediatric patients as well[13]. However, this rule does fit with our current findings.

All treatment failures in our study occurred in patients infected with genotype 1, which was also the most frequent genotype among our patients. SVR rates depend on genotype, as in the adult population, and success rates are significantly better (greater than 90%) in patients infected with genotypes 2 and 3 compared to patients infected with genotype 1 or 4 (approximately 50%)[14].

Although both pegylated interferon alfa regimens have similar safety profiles, success rates differ. In a systematic review of twelve randomized clinical trials including 5008 patients, Awad *et al*[20] concluded that peginterferon alfa-2a is associated with higher SVR than peginterferon alfa-2b. We have also noted different success rates between the two pegylated interferon alfa products, as reported in previous studies[19,20,22,23]. With caution and consideration of our small sample size, our results show the trend by which combination treatment with pegylated interferon alfa 2a may be superior to pegylated interferon alfa 2b. Such a trend has been shown previously only in adult studies[19,20,22].

The main weakness of the study is its retrospective nature and relatively small number of patients. Nevertheless, our results are consistent with previous studies in children and adults and our study is the first to compare the two pegylated interferon products in children. Further prospective studies are highly encouraged.

COMMENTS

Background

Hepatitis C virus (HCV) is a virus that chronically infects the liver. Infection by

this virus is a known risk factor for liver disease, liver failure and its complications, and even cases of liver tumors (hepatocellular carcinoma). There are limited publications about experience in treating children, recommendations for a preferred regimen, and data on treatment success rates. In this study, thirty children with chronic hepatitis C had been treated with combination therapy of peginterferon alfa plus ribavirin (as is recommended in adults). Ten of them had been given peginterferon alfa 2a, twenty of them had been given peginterferon alfa 2b, since there is no accepted preference of either of these drugs.

Research frontiers

This paper introduces the Israeli experience in treatment of children with chronic HCV infection, including success rates and adverse reactions.

Innovations and breakthroughs

The study found that success rates in children are very similar to those reported in adults. Although no significant superiority of either of the drugs was found, (most probably due to small group size), a trend for better results was noted with peginterferon alfa 2a. Even though side effects were very common during the treatment regimen, children were found to be very compliant, and most of them completed the treatment course.

Applications

The study results suggest that success rates of treatment are similar to those noted in adults, and that treatment with combination peginterferon alfa 2a plus ribavirin may be superior.

Terminology

Peginterferon alfa: A pegylated interferon drug that is given in a subcutaneous manner once a week, as opposed to previous treatment with interferon, which was given by injections 3 times a week. Treatment success: Achieving sustained viral response means that six months after treatment completion there is no detectable HCV RNA in the blood.

Peer review

Data on HCV therapy in pediatric patients are limited, thus this paper adds important information.

Abstract

AIM: To evaluate the safety and efficacy of granulocyte-colony stimulating factor (G-CSF) therapy in patients with hepatitis B virus (HBV)-associated acute-on-chronic liver failure (ACLF).

METHODS: Fifty-five patients with HBV-associated ACLF were randomized into two groups: the treatment group and the control group. Twenty-seven patients in the treatment group received G-CSF (5 μg/kg per day, six doses) treatment plus standard therapy, and 28 patients in the control group received standard therapy only. The peripheral $CD34^+$ cell count was measured consecutively by flow cytometry. Circulating white blood cell count, biochemical parameters, and other clinical data of these patients were recorded and analyzed. All patients were followed up for a period of 3 mo to evaluate the changes in liver function and survival rate.

RESULTS: The peripheral neutrophil and $CD34^+$ cell counts in the G-CSF group increased on day 3 from the onset of therapy, continued to rise on day 7, and remained elevated on day 15 compared to those of the control group. Child-Turcotte-Pugh score of patients in the treatment group was improved on day 30 from the onset of G-CSF therapy, compared to that in the controls (P = 0.041). Model for End-Stage of Liver Disease score of patients in the treatment group was improved on day 7 (P = 0.004) and remained high on day 30 from the onset of G-CSF therapy (P < 0.001) compared to that in controls. After 3 mo of follow-up observation, the survival rate in the treatment group (48.1%) was significantly higher than that in the control group (21.4%) (P = 0.0181).

CONCLUSION: G-CSF therapy promoted $CD34^+$ cell mobilization in patients with HBV-associated ACLF, and improved the liver function and the survival rate of these patients.

Granulocyte-colony stimulating factor therapy improves survival in patients with hepatitis B virus-associated acute-on-chronic liver failure. *World J Gastroenterol* 2013; 19(7): 1104-1110 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1104.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1104

INTRODUCTION

Hepatitis B virus (HBV) infection is one of the major public health problems. It is estimated that over 350 million individuals are chronically infected with HBV worldwide[1]. Some of these patients develop severe liver diseases such as acute-on-chronic liver failure (ACLF), liver cirrhosis, and hepato-cellular carcinoma[2]. The mortality rate of HBV-associated ACLF varies between 70%-80%[3,4]. Liver transplantation is the only effective treatment currently available, but its application is limited by the shortage of donors and the high cost.

In order to overcome these problems, alternative approaches have been proposed, such as an artificial liver support system[5], liver cell transplantation[6] and stem cell transplantations[7]. In particular, the great potential of stem cells to differentiate into multiple cell lineages raises the exciting hypothesis that these cells can be used in tissue repair and tissue-specific cell regeneration, when tissue-resided stem cells are not sufficient for the regeneration of a failing organ.

During liver regeneration, bone marrow-derived hematopoietic stem cells (HSC) may mobilize to the liver and, together with hepatocytes and intrahepatic stem cells, contribute to the proliferation of liver cells[8]. Hepatocytes carrying a Y chromosome were detected in the livers of female recipients who had received bone marrow transplantation from male donors[9]. Granulocyte-colony stimulating factor (G-CSF) can be used to mobilize stem cells to the periphery in patients with advanced liver disease, or to promote adequate numbers of cells for further transplantation. The safety and efficacy of this protocol has been investigated[10]. In experimental animal models, G-CSF ameliorated liver injury and improved the survival rate in rats with D-galactosamine-induced acute liver failure[11,12]. When administered to patients with severe liver cirrhosis, G-CSF boosted the numbers of peripheral leukocytes and $CD34^+$ bone marrow-derived HSCs[13]. Therefore, G-CSF therapy may be beneficial for liver regeneration in patients with different kinds of liver injuries.

Our objective in this clinical study was to evaluate the effects of G-CSF therapy on the proliferation of peripheral $CD34^+$ cells and on liver function in patients with HBV-associated ACLF. The parameters of liver function in these patients were consecutively measured. Child-Turcotte-Pugh (CTP) score, Model for End Stage of Liver Disease (MELD) score and survival rate of these patients were evaluated during a 3-mo follow-up study.

MATERIALS AND METHODS

Patients

A total of 55 patients with HBV-associated ACLF were recruited to our center from June 2009 to May 2011. HBV-associated ACLF, defined by the Asian Pacific Association for the Study of the Liver Working Party[2], is an acute hepatic insult manifested as jaundice (serum bilirubin $\geqslant$ 5 mg/dL) and coagulopathy [international normalized ratio (INR) $\geqslant$ 1.5 or prothrombin activity < 40%], with complications of ascites and/or encephalopathy within 4 wk in patients previously diagnosed or undiagnosed with chronic liver disease. Other inclusion criteria included: (1) the presence of hepatitis B surface antigen in the serum for at least 6 mo; (2) the evidence of active viral replication as indicated by detectable HBV DNA in the serum ($\geqslant 1 \times 10^4$ copies/mL); (3) flares of hepatitis, marked by increased serum alanine aminotransferase (ALT) level to more than 5-fold of the upper limit of normal value; and (4) age between 18 to 65 years.

The exclusion criteria included the following: (1) super-infection or co-infection with hepatitis A, C, D, E, Epstein-Barr virus, cytomegalovirus, or human immunodeficiency virus; (2) a previous course of any antiviral, immuno-modulator or cytotoxic/immunosuppressive therapy for chronic hepatitis within the prior 12 mo; (3) evidence of decompensated liver disease prior to the enrollment; (4) hepato-cellular carcinoma diagnosed by computed tomography or magnetic resonance imaging; (5) co-existence of any other serious medical illnesses or other liver diseases such as autoimmune hepatitis, alcoholic liver disease, drug-induced liver injury or Wilson's disease; (6) any concurrent evidence of sepsis; (7) malignant jaundice induced by obstructive jaundice and hemolytic jaundice; and (8) prolonged prothrombin time due to blood system disease.

Groups

This was a randomized, controlled, and double-blinded study. The sample size was determined as follows: Based on the hypothesis that G-CSF therapy can improve survival rate by 10% in the treatment group compared to the control group, with a power of 95% and an alpha error of 5%, the number of patients should be 25 in each group. A randomization number code was generated for each patient. Based on this code, each patient was assigned to receive G-CSF therapy plus standard medical therapy (G-CSF group), or standard medical therapy alone (control group). Both the patients and the investigators were blinded to the treatment regimen. The patients in the G-CSF treatment group received G-CSF (SL Pharm, Beijing, China) subcutaneously at the dosage of 5 μg/kg per day for six consecutive days, and were monitored with daily physical examination and laboratory tests. All patients received entecavir (0.5 mg/d, Squibb Pharmaceuticals Ltd., Shang Hai, China) and standard therapy (including reduced glutathione, glycyrrhizin, ademetionine, polyene phosphatidylcholine, alprostadil, and human serum albumin) on the day of admission. The white blood cell (WBC) counts were assessed twice per week in the first two weeks. In addition, abdominal ultrasound examination was performed on days 1 and 7 to evaluate the diameters of spleen and the hepatic portal vein.

Quantification of peripheral $CD34^+$ cells

$CD34^+$ cells in the peripheral venous blood were measured consecutively twice per week in the first two weeks

Table 1 Characteristics of patients with hepatitis B virus-associated acute-on-chronic liver failure at the time of admission

Parameters	G-CSF group	Control group	*P* value
Gender (male %)	22 (81.5)	22 (78.6)	0.755
Age (yr)	43.5 (29-63)	45.9 (22-65)	0.332
WBC (10^9/L)	5.79 ± 1.81	6.61 ± 1.71	0.443
Neutrophil (10^9/L)	3.53 ± 1.46	3.82 ± 1.17	0.114
Platelets (10^9/L)	182 (147-215)	174 (149-175)	0.680
ALT (U/L)	276 (197-801)	252 (189-1239)	0.430
AST (U/L)	246 (195-788)	251 (187-980)	0.544
Total bilirubin (μmol/L)	336 (181-519)	320.0 (174.5-519.8)	0.605
Cr (μmol/L)	83.8 ± 16.9	85.4 ± 53.87	0.475
INR	2.11 ± 0.28	2.34 ± 0.34	0.606
ALB (g/L)	29.11 ± 4.05	28.75 ± 4.63	0.596
HBV DNA (log_{10})	5.11 ± 1.37	5.55 ± 1.59	0.280
CTP score	12.17 ± 1.47	12.25 ± 1.29	0.349
MELD score	25.11 ± 3.30	26.30 ± 4.12	0.588

Values are shown as mean ± SD. WBC: White blood cell; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; Cr: Creatine; INR: International normalized ratio; ALB: Albumin; CTP: Child-Turcotte-Pugh; MELD: Model for end stage of liver disease; HBV: Hepatitis B virus; G-CSF: Granulocyte-colony stimulating factor.

in all patients. Briefly, small aliquots of peripheral blood were incubated with PE-conjugated anti-CD34 monoclonal-antibody (BD Company, United States) for 30 min on ice. Erythrocytes were lysed with ammonium chloride for 10 min at room temperature. Cells were washed with phosphate-buffered saline, and kept on ice till flow cytometric analysis.

Follow-up scheduling

All patients had daily follow-ups and physical examinations in the first month, and then at least weekly for the next 2 mo. During the 3-mo follow-up period, patients were monitored for the following parameters: the levels of serum bilirubin and albumin, prothrombin time and concentration, INR, the levels of ALT and aspartate aminotransferase, the levels of blood urea and serum creatinine, complete blood analysis, estimation of the degree of ascites, CTP score, MELD score, and hepatic encephalopathy. The survival rates were evaluated over a period of 3-mo.

Sera from patients were collected and direct polymerase chain reaction (PCR) sequencing was used to screen for HBV reverse transcriptase (RT) domain if serum HBV DNA tests were positive after patients received entecavir therapy. The *HBV* gene fragment (nt 54-1278) encompassing the complete *RT* gene (nt 130-1161) was amplified by nested PCR. The primers and reaction conditions have been described previously[14]. Substitutions at positions rt180, rt184, rt202, rt204 and rt250 were taken as resistance mutations for analysis.

Ethics

The protocol of our study is in compliance with the ethical guidelines of the 1975 Declaration of Helsinki, and was approved by the Clinical Research Ethics Committee of the Beijing 302 Hospital. All patients or their relatives in the G-CSF treatment group provided written informed consent prior to the enrollment.

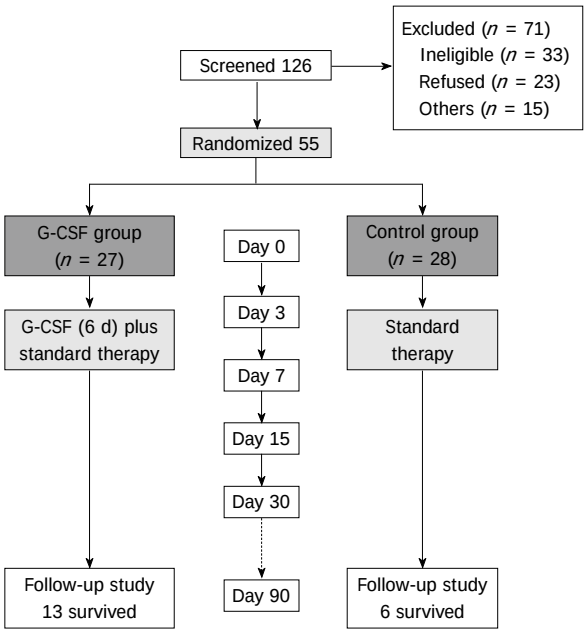

Figure 1 Study design and flow algorithm of patient selection. G-CSF: Granulocyte-colony stimulating factor.

Statistical analysis

Data were compiled using Excel XP and processed using Statistical Package for Science and Society (SPSS) version 12.0 (SPSS Inc., Chicago, IL). All quantitative variables were presented as mean ± SD. All qualitative data were described as frequency or percentage. Comparisons between groups for qualitative data were carried out using χ^2 test, Fischer's exact test, or McNemar test when appropriate. Independent sample *t* test and paired sample *t* test were used for quantitative variables with normal distribution, whereas non-parametric Mann-Whitney test and Wilcoxon signed-rank test were used for quantitative variables with non-normal distribution. In all tests, $P < 0.05$ were considered as statistically significant.

RESULTS

Baseline conditions

Of the 126 patients screened, 71 were excluded and 55 patients enrolled in our study. Among them, 27 were randomized to receive G-CSF therapy, and the other 28 were included as controls (Figure 1).

The two groups showed no statistical differences in gender, age, the baseline values of peripheral WBC, platelets, and other parameters (Table 1). All patients had a history of chronic hepatitis B, and had not received anti-viral therapy prior to the enrollment.

Peripheral neutrophil counts and CD34-positive cell counts

The baseline value of the circulating neutrophil count was compared between the G-CSF and the control groups

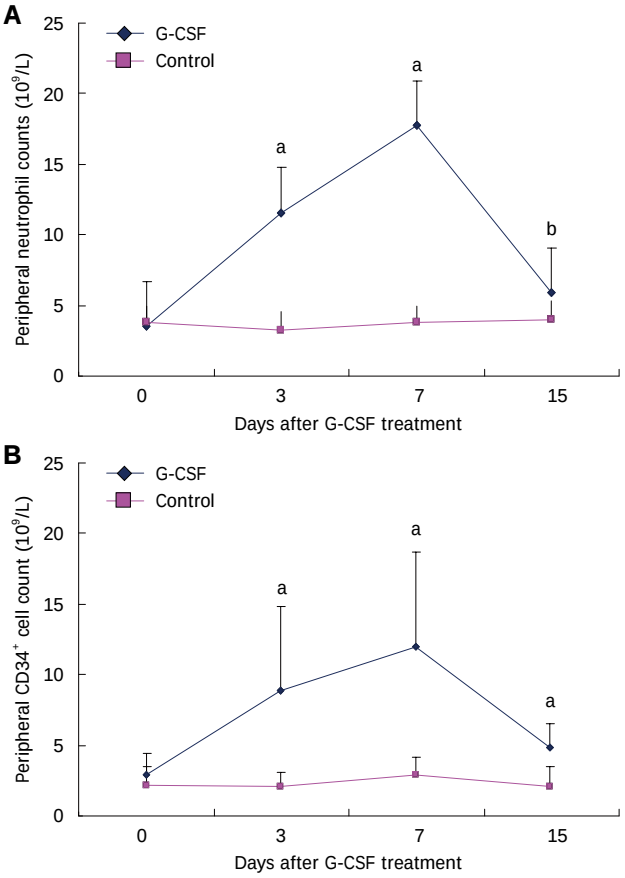

Figure 2 Kinetics of peripheral neutrophil count (A) and CD34$^+$ cell count (B) in patients treated with granulocyte-colony stimulating factor and controls. $^aP < 0.05$, $^bP < 0.01$ *vs* controls. G-CSF: Granulocyte-colony stimulating factor.

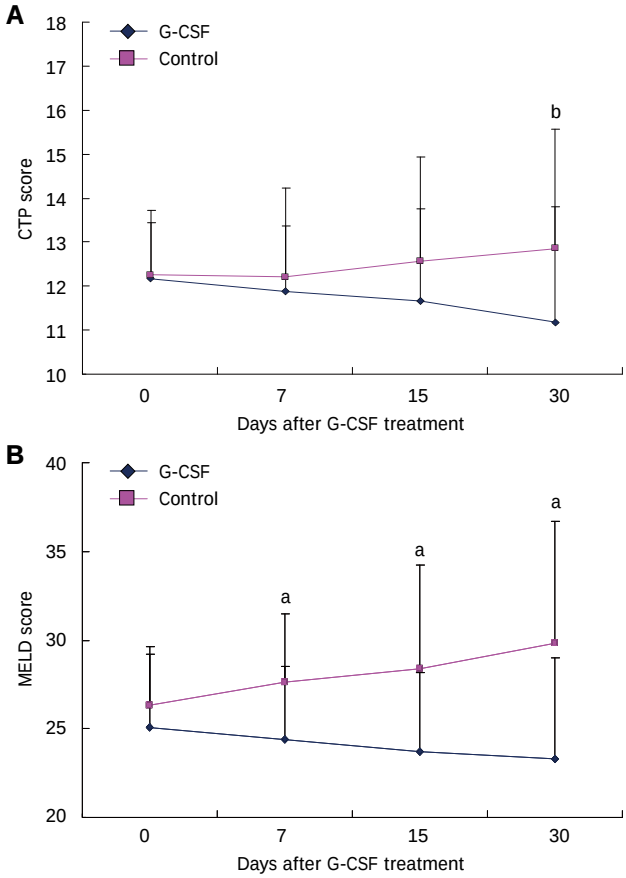

Figure 3 Changes in Child-Turcotte-Pugh score (A) and Model for End stage of Liver Disease score (B) in patients treated with granulocyte-colony stimulating factor and control groups. $^aP < 0.05$, $^bP < 0.01$ *vs* controls. G-CSF: Granulocyte-colony stimulating factor; CTP: Child-Turcotte-Pugh; MELD; Model for End Stage of Liver Disease.

(Table 1). No statistical difference was found between the baselines of the two groups ($P = 0.443$). However, on day 3 from the onset of G-CSF therapy, the peripheral neutrophil count increased to (11.59 ± 6.40) × 10^9/L, significantly higher than that of the control group (3.29 ± 1.25) × 10^9/L ($P < 0.001$). It continued to rise on day 7 to (17.76 ± 10.07) × 10^9/L in the G-CSF group, significantly higher than (3.82 ± 1.17) × 10^9/L in the control group ($P < 0.001$). On day 15, the neutrophil count decreased to (5.88 ± 3.69) × 10^9/L in the G-CSF group, but was still higher than (4.02 ± 1.33) × 10^9/L in the control group ($P = 0.032$) (Figure 2A).

Prior to G-CSF therapy, circulating CD34$^+$ cell counts were comparable in the two groups - (2.97 ± 1.52) × 10^6/L in the G-CSF group and (2.23 ± 1.29) × 10^6/L in the control group ($P = 0.085$). On day 3 of treatment, circulating CD34$^+$ cell counts in the G-CSF group increased to (8.96 ± 5.97) × 10^6/L, compared to (2.09 ± 1.02) × 10^6/L in the control group ($P < 0.001$). On day 7, the circulating CD34$^+$ cell counts continued to rise to (12.05 ± 6.70) × 10^6/L, compared to (2.97 ± 1.22) × 10^6/L in the control ($P < 0.001$). On day 15, the CD34$^+$ cell counts decreased to (4.92 ± 1.63) × 10^6/L in the G-CSF treatment group, still significantly higher than that in the control group (2.11 ± 1.39) ($P < 0.001$) (Figure 2B). On day 30, the CD34$^+$ cell counts were nearly at the same level between the two groups.

In the course of the G-CSF therapy, all patients demonstrated good tolerance. Some patients were affected by minor side effects, such as fever (8 cases), headache (5 cases), and nausea (4 cases), but all the side effects resolved within 5 d after the withdrawal of G-CSF treatment.

Changes of liver function after G-CSF therapy

Prior to the G-CSF therapy, the CTP score was 12.17 ± 1.47 in the G-CSF group, and 12.25 ± 1.29 in the control group ($P = 0.841$). The CTP score decreased gradually after the G-CSF therapy, and reached 11.17 ± 2.76 on day 30 of treatment in the G-CSF group, compared to 12.86 ± 2.63 in the control group ($P = 0.041$) (Figure 3A).

The MELD score demonstrated an early decrease in the G-CSF group (Figure 3B). On day 7 of the therapy, the MELD score decreased to 24.4 ± 3.9 in the G-CSF group, compared to 27.6 ± 4.1 in the control group ($P = 0.004$). On day 15, the MELD score was 23.7 ± 5.8 in the G-CSF group, compared to 28.4 ± 4.5 in the control group ($P < 0.001$). This trend continued during the 30-d observation period (23.3 ± 6.9 *vs* 29.8 ± 5.7) ($P < 0.001$).

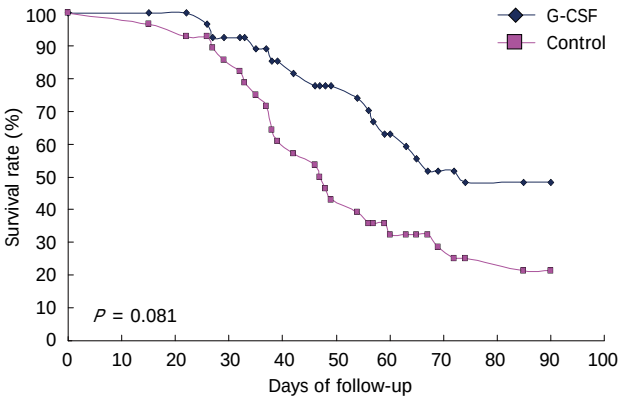

Figure 4 Survival rate of patients treated with granulocyte-colony stimulating factor and in controls. G-CSF: Granulocyte-colony stimulating factor.

Levels of serum HBV DNA and drug-resistant HBV variant monitoring

All patients enrolled in our study received entecavir antiviral treatment throughout the course of the study. After 3 mo of treatment, all the surviving patients demonstrated effective antiviral results. Of the 19 surviving patients, 16 (11 from G-CSF group, and 5 from control group) were detected negative for serum HBV DNA (below 10^2 copies/mL), and 3 (2 from G-CSF group and 1 from control group) were positive, but the concentrations of HBV DNA were all below 10^3 copies/mL. Serum HBV mutations were determined by direct sequencing methods and an entecavir-resistant mutation was not detected in these patients. No serious adverse effects of entecavir were observed in all patients.

Survival rate

The patients' survival rates were evaluated at the end of 3 mo (Figure 4). In the G-CSF group, 13 of 27 patients survived, but only 6 of 28 patients survived in the control group (χ^2 value 5.584, $P = 0.0181$). All the patients had complications of ascites and electrolyte disturbances. In the treatment group, 4 patients died of encephalopathy, 5 of gastric intestinal bleeding, 2 of hepato-renal syndrome (HRS), and 3 of sepsis. In the control group, 6 died of encephalopathy, 3 of gastric intestinal bleeding, 6 died from HRS, and 7 of sepsis. More patients in the control group died of sepsis and HRS compared to those in the G-CSF group (χ^2 value 4.863, $P = 0.027$).

DISCUSSION

In China, HBV-associated ACLF accounts for 85%-95% of all liver failure. Approximately 60% of the patients die from complications due to the lack of early liver transplantation[15,16]. Increasing evidence indicates that stem cells contribute to hepatic regeneration, which is essential for the restoration of liver function and thus the survival of the patients. Stem cells have been shown to induce the repairing process after acute liver injuries[10,12]. Therefore, G-CSF therapy may be a promising approach in the clinical treatment of patients with ACLF.

Some previous findings on the efficacy of G-CSF in patients with liver failure remain controversial. Di Campli *et al*[17] investigated the safety and efficacy of G-CSF in patients with ACLF. They found an increased number of $CD34^+$ cells in the peripheral blood, down-regulated expression of C-X-C chemokine receptor type 4, very late activation of antigen 4 and vascular endothelial growth factor receptor in the G-CSF treatment group, but they did not show the effect of G-CSF on the survival rates of these patients. Similarly, Spahr *et al*[18] investigated the efficacy of G-CSF in patients with alcoholic steatohepatitis, and observed an elevated peripheral $CD34^+$ cell count and proliferating hemopoietic cells in the liver tissues, although they failed to demonstrate the improvement of liver function. Recently Garg *et al*[19] also investigated the efficacy of G-CSF in ACLF patients with promising results. Sixteen of the 23 patients in the G-CSF group survived for 60 d, compared to merely 7 of the 24 in the control group. The discrepancies between the results by different groups may be attributable to the background of the enrolled patients. For example, Di Campli enrolled patients with alcohol liver failure, whereas Garg recruited patients with various types of liver diseases, including alcoholic-related liver diseases and HBV-associated ACLF.

In our current study we selected patients with HBV-associated ACLF for investigation. This is the first report to apply G-CSF therapy to patients with chronic HBV infection. All the patients were positive for serum HBV DNA and received entecavir antiviral treatment after enrollment. The two groups showed no statistically significant differences in gender, WBC count, CTP score and MELD score prior to the onset of the G-CSF therapy.

We observed that G-CSF therapy increased the peripheral neutrophil count and $CD34^+$ cell count in patients with HBV-associated ACLF. In addition, the G-CSF treatment group demonstrated improved liver function compared to the control group, as demonstrated by the CTP and MELD scores. Our finding on survival rate was in consistency with that of Garg *et al*[19].

It is plausible to speculate that $CD34^+$ HSC migrated from the bone marrow to the liver, and contributed to the regeneration of the liver. Future studies, such as liver biopsy or autopsy, may provide evidence for the mobilization of the stem cells. In these patients, MELD score improved sooner than CTP score after G-CSF therapy, but the mechanism is yet to be elucidated.

Currently, there are two classical pathways for stem cells to travel from the bone marrow to the liver. The first is G-CSF mobilization. Secondly, $CD34^+$ cells can be isolated from bone marrow, purified with magnetic columns, and then re-injected into the liver through the hepatic artery or the portal vein[13,20]. However, patients with ACLF often have coagulation disorders; therefore, it is risky to apply the aforementioned complicated procedures. It is a reasonable argument that the approach of G-CSF administration is probably easier and less risky to implement than the separation, purification, and autologous transplantation of bone marrow-derived HSC cells to ACLF

patients. Furthermore, it has been reported that contamination by red blood cells during $CD34^+$ cell isolation can impair the efficacy of autologous HSC therapy[21].

Antiviral therapy has been deemed as an important therapy for patients with HBV-associated ACLF[2,22]. Previously, Huang *et al*[16] reported that antiviral therapy decreased the mortality rate in patients with HBV-associated ACLF, but the patients recruited to their study had lower ALT levels and higher prothrombin activity (over 30%), which may explain the different results between these two studies. In our study, the mortality rate in the control group was higher (78.6%) than those reported in the literature. This may be attributable to several factors. Firstly, the patients in our study had larger MELD scores, of 25 to 29, indicating more serious conditions. Secondly, most patients enrolled in our study had middle-stage (PA between 20%-30%) or late-stage ACLF (PA below 20%) according to the standards of the Chinese classification system[23], which may contribute to an increased mortality rate. Thirdly, antiviral therapy can suppress HBV replication; however, there may not be enough time for HBV suppression and liver function recovery to occur due to the short life expectancy in ACLF patients. A similar phenomenon was also observed by other researchers[24]. We also consider the possibility of HBV viral breakthrough in these patients. Serum HBV DNA mutations were determined by a direct sequencing method when serum HBV DNA was positive in patients, but we did not find any entecavir-resistant mutations. Although we did not find poor compliance in these patients, we could not exclude the possibility. In our study, all the patients received antiviral therapy to help mitigate additional hepatic insult and even liver failure caused by the re-activation of HBV.

Patients treated with G-CSF not only demonstrated a significantly better 90 d survival rate, CTP and MELD scores, but were also less likely to develop HRS and sepsis compared to the controls. This could be explained by increased numbers of neutrophils in these patients. Neutrophil dysfunction has been shown to cause sepsis and further the development of HRS in patients with ACLF[25]. We did not find a correlation between $CD34^+$ cell number and liver function improvement, which means cell numbers, micro-environment of liver tissue and other possible factors may work together to improve liver function. That mechanism needs to be further investigated.

In conclusion, this randomized, controlled study clearly demonstrated the clinical safety and efficacy of G-CSF therapy in patients with HBV-associated ACLF. The convenience of administration makes G-CSF therapy readily implementable in large-scale, multi-center clinical sites, and further supports its benefits in restoring hepatic function and improving survival rate.

COMMENTS

Background

Hepatitis B virus-associated acute-on-chronic liver failure (HBV-ACLF) is associated with a high mortality. Liver transplantation could significantly improve the survival rate, but is limited by many factors, especially donor shortages. To overcome these problems, alternative approaches have been proposed. Granulocyte-colony stimulating factor (G-CSF) can be used to mobilize stem cells from bone marrow to the periphery, and then to the liver, in patients with advanced liver disease, and promote liver regeneration.

Research frontiers

In experimental animal models, G-CSF ameliorated liver injury and improved survival rate in rats with D-galactosamine-induced acute liver failure. When administered to patients with severe liver cirrhosis, G-CSF boosted the numbers of peripheral leukocytes and $CD34^+$ bone marrow-derived hematopoietic stem cells. Therefore, G-CSF therapy may be beneficial for liver regeneration in patients with different kinds of liver injuries. The safety and efficacy of a G-CSF protocol has been investigated but the efficacy is still controversial in patients with liver diseases.

Innovations and breakthroughs

In the current study, the authors selected patients with HBV-associated ACLF for investigation. This is the first randomized trial to apply G-CSF therapy to patients with chronic HBV infection. The authors observed that G-CSF therapy increased peripheral neutrophil count and $CD34^+$ cell count in patients with HBV-associated ACLF. In addition, the G-CSF treatment group demonstrated improved liver function and survival rate compared to the control group.

Applications

HBV-associated ACLF patients treated with G-CSF not only demonstrated a significantly better 90 d survival rate, and improved CTP and MELD scores, but were also less likely to develop HRS and sepsis compared to the controls. The convenience of administration makes G-CSF therapy readily implementable in large-scale, multi-center clinical sites to further support its benefits in restoring hepatic function and improving survival rate.

Terminology

HBV-associated ACLF, defined by the Asian Pacific Association for the Study of the Liver Working Party, is an acute hepatic insult manifested as jaundice (serum bilirubin $\geqslant$ 5 mg/dL) and coagulopathy (international normalized ratio $\geqslant$ 1.5 or prothrombin activity < 40%), with complications of ascites and/or encephalopathy within 4 wk in patients previously diagnosed or undiagnosed with chronic liver disease.

Peer review

This is an interesting study in patients with decompensated hepatitis B patients.

Abstract

AIM: To examine the clinical features and analyze prognostic factors in a prospective study of primary biliary cirrhosis (PBC) patients.

METHODS: From 1995 to 2010, PBC patients without hepatic decompensation seen at the Peking Union Medical College Hospital were enrolled. Clinical signs and manifestations (pruritus, persistent fatigue, jaundice and pain in the right hypochondrium), laboratory parameters (auto-antibodies for autoimmune hepatic disease, biliary and hepatic enzymes, immunoglobulin, bilirubin, and albumin) and imaging findings were recorded at entry and at specific time points during follow-up. Cox regression and Kaplan-Meier analyses, respectively, assessed the risk factors for hepatic decompensation and survival.

RESULTS: Two hundred and sixty-two PBC patients were enrolled with a median follow-up of 75.2 mo (range, 21-201 mo). The 240 patients were aged 51.5 ± 10.2 years at diagnosis and 91.6% were female. Two hundred and forty-five (93.5%) were seropositive for anti-mitochondrial antibodies. At presentation, 170 patients (64.9%) were symptomatic, while 96 patients (36.6%) had extra-hepatic autoimmune disease. During the follow-up period, 62 (23.7%) patients developed hepatic decompensation of whom four underwent liver transplantation and 17 died. The cumulative survival rate and median survival time were 83.9% and 181.7 mo, respectively. Cox regression analysis revealed that an incomplete ursodeoxycholic acid (UDCA) response or inconsistent treatment [$P < 0.001$; hazard risk (HR) 95%CI = 2.423-7.541], anti-centromere antibodies (ACA) positivity ($P < 0.001$; HR 95%CI = 2.516-7.137), alanine aminotransferase ratio (AAR) elevations ($P < 0.001$; HR 95%CI = 1.357-2.678), and histological advanced liver disease ($P = 0.006$; HR 95%CI = 1.481-10.847) were predictors of hepatic decompensation. The clinical features and survival of PBC in China are consistent with those described in Western countries.

CONCLUSION: Incomplete UDCA response or inconsistent treatment, ACA positivity, AAR elevations, and advanced histological stage are predictors of decompensation.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic autoimmune liver disease that causes lymphocytic portal hepatitis and bile duct destruction, leading to cirrhosis and liver failure[1]. The annual incidence rates range between 0.7 and 49 cases per million persons, while prevalence rates range between 6.7 and 402 cases per million[2,3]. Currently, treatment with ursodeoxycholic acid (UDCA) at a dose of 13-15 mg/kg/d is the recommended first-line therapy.

According to clinical observations, the progression and prognosis of PBC vary significantly among patients, including a relatively slow progression in some patients, while others have a more rapid progression to hepatic failure[4,5]. Therefore, knowledge of the factors affecting disease progression and prognosis would be of great value in clinical management.

Several prognostic models have been developed for PBC. The most important is the Mayo score model, which has been widely used to predict the survival of PBC patients, and assess the timing of liver transplantation[6,7]. However, some patients are asymptomatic at the time of diagnosis, which limits the application of the Mayo model; and this model was not originally developed to assess disease progression in the early stages of PBC[8]. In terms of treatment, UDCA has been reported to delay histological progression and improve long-term prognosis[9]. Previous studies have shown that anti-gp210 and anti-centromere antibodies (ACA) were associated with severe disease course and poor prognosis. Bilirubin, prothrombin time, hypoalbuminemia and serum immunoglobulin (Ig) G have also been reported as prognostic markers[10-12]. However, these studies were mainly retrospective and had small sample sizes.

We aimed to assess the clinical features and risk factors for hepatic decompensation in a large prospective cohort study in China.

MATERIALS AND METHODS

Study population and data collection

Patients with PBC seen at the Peking Union Medical College Hospital (PUMCH) from 1995 to 2010 were recruited. The ethics committee at PUMCH approved the study, and written informed consent was obtained from all participants prior to enrollment. The diagnosis of PBC was made if at least two of the following three criteria were fulfilled: (1) elevated serum alkaline phosphatase (ALP) (at least 1.5 times the upper limit of normal); (2) the presence of anti-mitochondrial antibodies (AMAs) in serum; and (3) representative histological manifestations of portal area inflammation and bile duct injury. Early PBC was defined by seropositivity for AMA, and the presence of histological manifestations, but normal liver function[4]. The liver histology was graded according to the Ludwig classification[13]. Patients with liver decompensation, autoimmune hepatitis (AIH), viral hepatitis and other causes of liver damage were excluded. Patients with PBC/AIH overlap syndrome were identified according to the criteria proposed by Chazouillères *et al*[14]. In the current study, serum antinuclear antibody (ANA), AMA, anti-smooth muscle antibody, anti-liver kidney microsomal antibody, and anti-parietal cell antibody were tested. In patients who were ANA positive, the level of alanine aminotransferase (ALT), aspartate aminotransferase (AST), IgG and autoantibodies for AIH were assessed to exclude PBC/AIH. The extra-hepatic autoimmune diseases were diagnosed according to the generally accepted criteria.

The following information was recorded: (1) demographic features, clinical signs and manifestations of liver disease including pruritus, persistent fatigue, jaundice and pain in the right hypochondrium; (2) laboratory parameters, including ANA, AMA, ACA, ALT, AST, ALP, γ-glutamyl-transferase (GGT), total bilirubin (TBil), direct bilirubin (DBil), albumin (ALB), IgG, IgA and IgM; and (3) imaging findings: liver ultrasound or CT demonstrating morphologic changes of liver and spleen, and portal vein blood flow. UDCA at the dose of 13-15 mg/kg per day was prescribed for all patients.

Follow-up

Patients were followed up in the outpatient clinic, and data were collected at 3-mo intervals during the first year, 6-mo intervals or yearly thereafter. During each visit, the clinical signs, symptoms and laboratory parameters (AST, ALT, ALP, GGT, ALB, TBil, DBil, IgG, IgA, IgM, white blood cell, hemoglobin and platelet count) were assessed. Liver ultrasound was performed annually. Gastroscopy was carried out if necessary. If the patients had symptoms of hepatic decompensation (ascites, esophageal varices, variceal bleeding, hypersplenism, coagulant function abnormality, hypoproteinemia, and hepatic encephalopathy), they were permitted to visit doctors at any time or to go to emergency departments. After treatment for one year, patients whose ALP levels decreased by more than 40% of baseline values or returned to normal were defined as UDCA responders[15].

Outcome evaluation

Two clinical outcomes were studied: hepatic decompensation, and liver-related death. Hepatic decompensation was defined as the occurrence of severe functional damage of liver and one or more complications of liver cirrhosis[16]. We investigated the following features of decompensation: hypersplenism, ascites, esophageal varices (variceal bleeding), encephalopathy, hypoproteinemia, coagulant function abnormality, and spontaneous bacterial peritonitis. Figure 1 shows a diagram of the study design.

Statistical analysis

Data were expressed as median (range) or mean ± SD. Analysis was performed using SPSS 17.0 statistical software (Chicago, IL, United States). A two-sided P-value < 0.05 was considered statistically significant. Categorical variables were compared by the χ^2 test while continuous

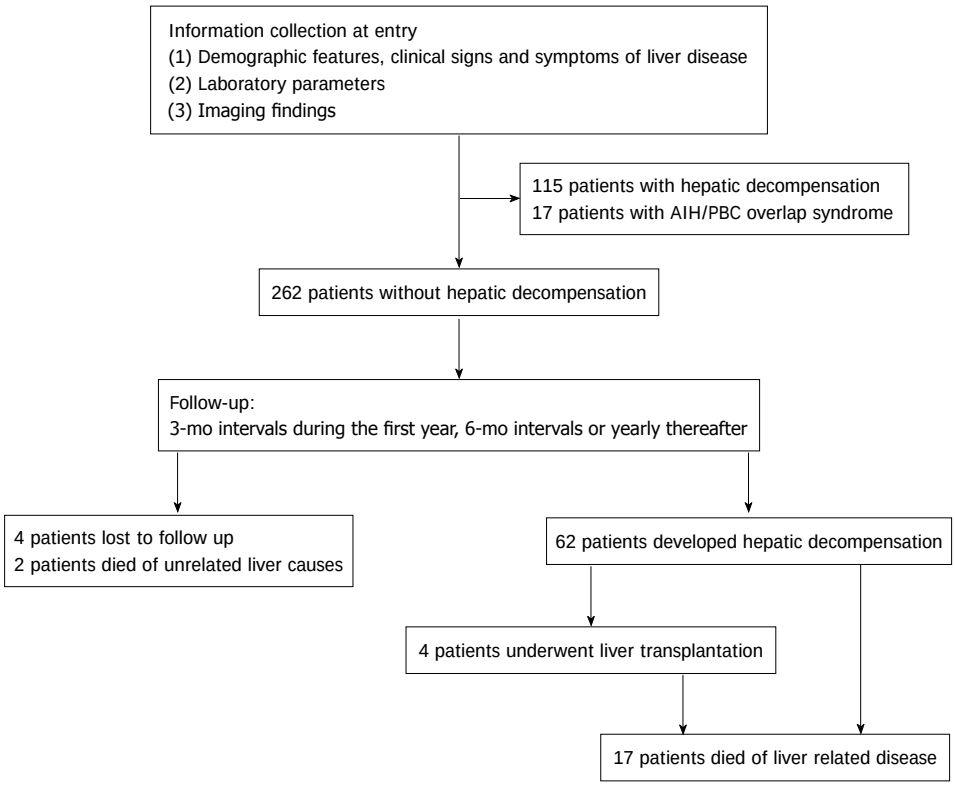

Figure 1 Diagram showing the study enrollment.

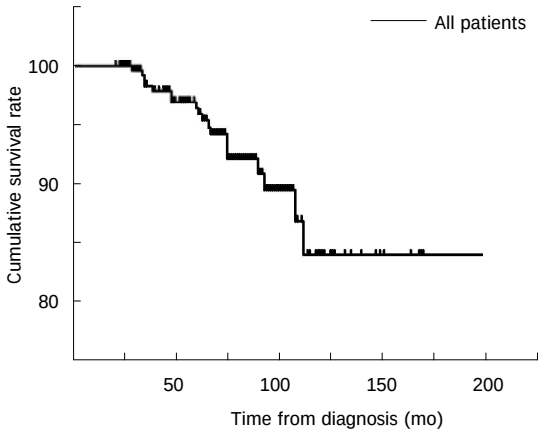

Figure 2 Survival curve of all patients in this cohort.

variables were compared by the Student's *t*-test or Mann-Whitney *U* test. Variables that were significant in univariate analysis were submitted to Cox regression analysis to predict the independent risk factors. Hazard risk (HR) and 95%CI were presented. Kaplan-Meier analysis was used to assess survival. Patients who were lost to follow-up or died of causes unrelated to liver failure were censored.

RESULTS

Clinical profiles of the study group at the entry

In this study, 262 patients with a mean age of 51.5 ± 10.2 years, including 240 (91.6%) women, were enrolled. The median duration of follow-up was 75.2 mo (range, 21-201 mo). The demographic and clinical features are shown in Tables 1 and 2.

On entry into the study, 170 (64.9%) patients presented with manifestations of liver disease, and 96 (36.6%) patients had extra-hepatic autoimmune disease. In addition, we enrolled 19 (7.3%) patients with early PBC. Two hundred and forty-five (93.5%) patients were seropositive for AMA. ANA and ACA were detected in 181 (69.1%) and 73 (27.9%) patients, respectively. Among 110 patients who underwent needle liver biopsies, 97 (88.2%) were at stages Ⅰ-Ⅱ, while 13 (11.8%) were at stages Ⅲ-Ⅳ. One hundred and ninety (72.5%) patients received UDCA regularly and responded, while 46 patients (17.6%) took UDCA consistently, but failed to respond. Of the latter, eight patients terminated treatment on their own. Others (9.9%) did not take UDCA consistently, as prescribed.

Incidence of outcomes and survival

During the study period, 62 (23.7%) patients developed adverse events, and the median duration from diagnosis to hepatic decompensation was 57.4 mo (range, 7-151 mo). Among these patients, four (1.5%) patients underwent liver transplantation at the end of follow-up or before death, and 17 (6.5%) patients died of liver failure. The median duration from diagnosis to death was 63.6 mo (range, 29-112 mo). According to Kaplan-Meier analysis, the cumulative survival rate and estimated median survival time were 83.9% and 181.7 mo, respectively (Figure 2 and Table 3).

Table 1 Demographic and clinical laboratory characteristics of primary biliary cirrhosis patients at the time of entry (*n* = 262) *n* (%)

Age (yr), mean ± SD	51.5 ± 10.2
Gender (female/male), *n*	240/22
The symptomatic	170 (64.9)
Jaundice	78 (29.8)
Pruritus	69 (26.3)
Persistent fatigue	63 (24.0)
Pain in the right hypochondrium	40 (15.3)
UDCA responders	190 (72.5)
Early PBC	19 (7.3)

Ⅲ-Ⅳ	13 (11.8)

UDCA: Ursodeoxycholic acid; PBC: Primary biliary cirrhosis; PBC: Primary biliary cirrhosis; CREST: Comprehensive overview covers symptoms, causes, treatment of this autoimmune disorder.

Risk factors for hepatic decompensation

Possible risk factors were first identified by univariate analysis. Subsequently, all variables, except histological stage, that showed statistical differences in univariate analysis were introduced into the Cox regression model. Incomplete UDCA response or inconsistent UDCA treatment ($P < 0.001$; HR 95%CI = 2.423-7.541), ACA positivity ($P < 0.001$; HR 95%CI = 2.516-7.137), alanine aminotransferase ratio (AAR) elevations ($P < 0.001$; HR 95%CI = 1.357-2.678), TBil ($P = 0.004$; HR 95%CI = 1.002-1.009), and ALP ($P = 0.008$; HR 95%CI = 1.000-1.002) showed statistical significance in the model (Figure 3 and Tables 4 and 5). Although histological stage was not introduced into the model because of limited numbers, Cox regression analysis indicated that it was also a prognostic factor ($P = 0.006$; HR 95%CI = 1.481-10.847; Figure 3).

DISCUSSION

PBC is a chronic autoimmune liver disease that has the potential to progress to cirrhosis and, eventually, hepatic failure. Although it is less common in East Asia[17], there is a rising frequency attributable to a more widespread awareness of this disease among physicians[18]. In this study, with a follow-up for 17 years, we identified the clinical profiles and risk factors for hepatic decompensation of PBC patients. To the best of our knowledge, this is the first prospective study with such a large number of patients in China.

In the current cohort, the demographic features and autoantibody profiles were consistent with those of previous studies[19]. Although PBC is an organ-specific disease, association with extra-hepatic autoimmune diseases is an important characteristic. The prevalence of such co-existing diseases was high (36.6%), the most common of which were Sjögren's syndrome (SS) (20.6%) and autoimmune thyroid diseases (9.5%). These findings were similar to the results obtained by Marasini *et al*[20] in Italy and Silveira *et al*[21] in the United States.

Table 2 Laboratory characteristics of primary biliary cirrhosis patients at the time of entry (*n* = 262)

ANA	181(69.1)
AMA	245 (93.5)
ACA	73 (27.9)
ALT (IU/L)	91.0 (9-598)
AST (IU/L)	86.2 (15-428)
AST/ALT	1.10 (0.22-4.85)
ALP (IU/L)	348.5 (21-1486)
GGT (IU/L)	428.2 (9-2614)
ALB (g/L)	40.7 (25-69)
TBil (μmol/L)	28.05 (4.90-334.40)
DBil (μmol/L)	14.39 (0.34-237.40)
IgG (g/L)	16.81 (5.12-56.60)
IgA (g/L)	3.15 (0.19-8.84)
IgM (g/L)	4.66 (0.41-22.30)

Continuous data were expressed as *n* (%) or median (range). ANA: Anti-nuclear antibody; AMA: Anti-mitochondrial antibody; ACA: Anti-centromere antibody; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: γ-glutamyl-transferase; ALB: Albumin; TBil: Total bilirubin; DBil: Direct bilirubin; Ig: Immunoglobulin.

Clinically, PBC patients can progress from an asymptomatic stage to a symptomatic stage because of liver damage[22]. In the current cohort, 64.9% patients had hepatic-related symptoms at diagnosis, which is higher than that reported by Prince *et al*[23], but lower than the results by Su *et al*[11]. In the current study, the most common manifestation was jaundice, which was different from other reports in which the most common manifestation was fatigue[22,24,25]. The median survival time for asymptomatic patients has been reported to be longer than that for symptomatic patients[26]. In addition, other studies indicated that asymptomatic patients had shorter life spans than people in the general population[26,27]. However, several studies have indicated that asymptomatic patients did not have a better prognosis[23,28].

In the current study, at the end of follow-up, sixty-tow (23.7%) patients developed hepatic decompensation. Among them, all had portal hypertension, and 17 died of liver failure. Only four patients underwent transplantation because of the enormous financial cost for patients, and limited medical resources. However, the survival rate of our patients was similar to those presented in other recent studies[29-31].

Although there has been controversy about efficacy, UDCA is currently accepted as the first-line drug for PBC. Several studies have shown that UDCA not only ameliorates laboratory indices, but also delays histological progression, and improves survival without transplantation[9,15,32-35], especially for patients at early histological stages[33]. In the current study, 72.5% patients took

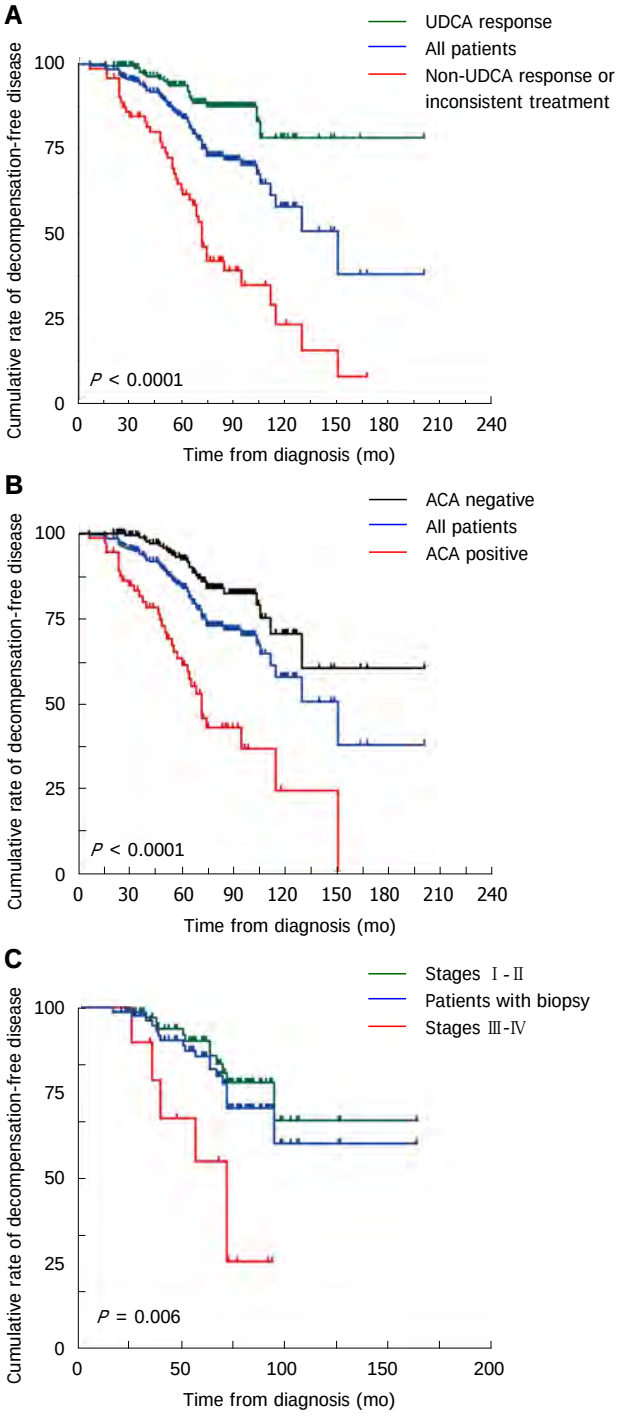

Figure 3 Cumulative rates of decompensation-free disease in primary biliary cirrhosis patients stratified by ursodeoxycholic acid treatment, anti-centromere antibody, and histological stage, respectively. A: Ursodeoxycholic acid (UDCA); B: Anti-centromere antibody (ACA); C: Histological stage.

UDCA as prescribed and responded according to the Barcelona criteria; their prognoses were significantly better than those of non-responders, which is consistent with results of a previous study[9]. Therefore, the data suggest that all PBC patients should take UDCA regularly, but novel therapeutic options are needed for patients who do not respond to UDCA.

ACA had been observed in patients with various rheumatic disorders, including CREST syndrome (comprehensive overview covers symptoms, causes, treatment of this autoimmune disorder)[36], SS[37], Raynaud's phenomenon[38], interstitial pneumonia in systemic lupus erythematosus[39], SS overlap syndrome[40] and 15%-30% PBC patients[41-44]. In the current study, ACA was detected in 27.9% patients and 56.5% of decompensated patients. It was found to be an independent prognostic factor for patients. Previous cross-sectional studies have also indicated that ACA was associated with the development of liver failure[45] and progression to portal hypertension in PBC[10]. However, Rigamonti *et al*[46] found that PBC patients with or without ACA had the same rate of liver-related death, while Parveen *et al*[47] reported that ACA was not correlated with either laboratory or histological manifestations.

Table 3 Complications of chronic liver disease in the primary biliary cirrhosis cohort (*n* = 262) *n* (%)

Hepatic decompensation	62 (23.7)
Portal hypertension	62 (23.7)
Hypersplenism	44 (16.8)
Esophageal varices	47 (17.9)
Variceal bleeding	35 (13.4)
Ascites	43 (16.4)
Encephalopathy	19 (7.3)
Coagulant function abnormality	12 (4.6)
Hypoproteinemia	35 (13.4)
Spontaneous bacterial peritonitis	3 (1.1)
Liver transplantation	4 (1.5)
Death-liver related	17 (6.5)[1]
Censor	6 (2.3)
Lost to follow-up	4 (1.5)
Death from causes unrelated to liver failure	2 (0.8)

[1]One patient who underwent liver transplantation died.

Elevation of AAR may be explained by a reduction in AST clearance, and by mitochondrial injury in severe liver disease[48]. A previous study showed that AAR exhibited modest correlations to Mayo and Child scores for evaluating the severity of PBC, and it was higher in histological stages Ⅲ-Ⅳ than Ⅰ-Ⅱ disease. Patients with an AAR of 1 or less had better prognoses than their counterparts[49]. These results are consistent with the current data.

The beneficial value of liver biopsy in patients with PBC is controversial because the pattern of cirrhosis in PBC is irregular, and sampling error may lead to misinterpretation[50]. However, several studies have indicated a relationship between histology and clinical profile. AST and bilirubin were positively related to portal fibrosis for the AMA-positive patients[51]. Prognosis was found to be correlated with the histological stages of hepatic fibrosis, cholestasis and periportal cell necrosis[52]. Cirrhosis was found to have developed within four years in 31% and 50% of patients who were initially at stage Ⅰ and stage Ⅱ, respectively[53]. Cox analysis demonstrated that histological stage was a predictor of liver decompensation.

Although TBil and ALP were included in our model, the HR approached one. Therefore, they had a relatively low correlation with survival compared with other fac-

Table 4 Univariate analysis of possible risk factors for hepatic decompensation in primary biliary cirrhosis

	Decompensation free (*n* = 196)	Decompensation (*n* = 62)	*P* value
Age at diagnosis (yr)	50.2	55.6	< 0.001
Gender (female/male)	178/18	59/3	0.275
Symptoms	60.20%	80.65%	0.003
UDCA treatment	85.20%	30.65%	< 0.001
ANA	64.80%	80.65%	0.019
AMA	92.86%	95.16%	0.731
ACA	19.39%	56.45%	< 0.001
ALT (IU/L)	89.6	96.6	0.109
AST (IU/L)	80.6	103.2	< 0.001
AST/ALT	1.05	1.27	0.013
ALP (IU/L)	311.6	454.1	< 0.001
GGT (IU/L)	395.4	524.3	0.001
ALB (g/L)	41.5	38.4	< 0.001
TBil (μmol/L)	20.92	48.84	< 0.001
DBil (μmol/L)	9.27	29.06	< 0.001
IgG (g/L)	16.61	17.43	0.386
IgA (g/L)	2.99	3.62	0.004
IgM (g/L)	4.61	4.83	0.285
Histological stage[1] (Ⅰ-Ⅱ)	92.22%	66.67%	0.008
Early PBC	9.70%	0.00%	0.023
Extra-hepatic autoimmune disease	37.24%	37.10%	0.983

[1]*n* = 108. ANA: Anti-nuclear antibody; AMA: Anti-mitochondrial antibody; ACA: Anti-centromere antibody; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: γ-glutamyl-transferase; ALB: Albumin; TBil: Total bilirubin; DBil: Direct bilirubin; UDCA: Ursodeoxycholic acid; Ig: Immunoglobulin.

tors, and their value for this purpose still needs to be confirmed by other, large long-term studies.

There are some limitations of the current study: (1) only patients without decompensation were enrolled, which resulted in the expected better survival rates compared to studies that included patients with decompensation; and (2) this was a single center study with a relatively short follow-up. Consequently, these risk factors still need to be confirmed further.

In summary, the clinical features and survival of patients with PBC in China are consistent with those described in Western countries. Incomplete UDCA response or inconsistent treatment, ACA positivity, higher AAR, and advanced histological stage are risk factors for hepatic decompensation.

ACKNOWLEDGMENTS

We thank Xu-Hua Shi and Li-Xia Gao for the collection of data and patient information.

COMMENTS

Background

Primary biliary cirrhosis (PBC) is a chronic cholestatic autoimmune liver disease with a rising frequency, attributable to a widespread awareness from physicians. The progression and prognosis of PBC vary significantly among patients. However, the clinical features and risk factors for hepatic decompensation have not yet been well-documented in a large prospective cohort study in China.

Table 5 Cox regression analysis of risk factors for hepatic decompensation in primary biliary cirrhosis (*n* = 262)

	HR	HR 95%CI	*P* value
Poor UDCA response or inconsistent treatment	4.275	2.423-7.541	< 0.001
ACA positivity	4.237	2.516-7.137	< 0.001
AAR	1.906	1.357-2.678	< 0.001
TBil	1.005	1.002-1.009	0.004
ALP	1.001	1.000-1.002	0.008

ACA: Anti-centromere antibody; ALP: Alkaline phosphatase; TBil: Total bilirubin; UDCA: Ursodeoxycholic acid; AAR: Alanine aminotransferase ratio; HR: Hazard risk.

Research frontiers

In the current study, the authors identified the clinical profiles and risk factors for hepatic decompensation of PBC patients. In the authors' view, this is the first prospective study with such a large number of patients in China.

Innovations and breakthroughs

Recent reports have highlighted the importance of ursodeoxycholic acid (UDCA) treatment for improving prognosis in patients with PBC. This is the first prospective cohort study showing that incomplete UDCA response or inconsistent treatment, anti-centromere antibodies positivity, higher alanine aminotransferase ratio, and advanced histological stage are risk factors for hepatic decompensation.

Applications

Knowledge of the factors for hepatic decompensation in PBC patients would be of great value in clinical management. Novel treatments are needed for patients with poor prognostic factors.

Terminology

PBC is an autoimmune liver disease characterized by the presence of anti-mitochondrial antibodies, and destruction of intrahepatic bile ducts, which can ultimately lead to cirrhosis and hepatic failure. Early UDCA treatment, excellent biochemical response to UDCA, and histological stages are predictors of survival.

Peer review

The authors have documented the clinical profiles and analyzed risk factors for hepatic decompensation in patients with PBC. It is a relatively large prospective study and gives important information on the prognosis of PBC patients.

Abstract

AIM: To investigate the clinical safety and efficacy of a temporary self-expanding metallic stent (SEMS) for malignant colorectal obstruction.

METHODS: From September 2007 to June 2012, 33 patients with malignant colorectal obstruction were treated with a temporary SEMS. The stent had a tubular configuration with a retrieval lasso attached inside the proximal end of the stent to facilitate its removal. The SEMS was removed one week after placement. Clinical examination, abdominal X-ray and a contrast study were prospectively performed and both initial and follow-up data before and at 1 d, 1 wk, and 1 mo, 3 mo, 6 mo and 12 mo after stent placement were obtained. Data collected on the technical and clinical success of the procedures, complications, need for re-insertion and survival were analyzed.

RESULTS: Stent placement and removal were technically successful in all patients with no procedure-related complications. Post-procedural complications included stent migration (n = 2) and anal pain (n = 2). Clinical success was achieved in 31 (93.9%) of 33 patients with resolution of bowel obstruction within 3 d of stent removal. Eleven of the 33 patients died 73.81 ± 23.66 d (range 42-121 d) after removal of the stent without colonic re-obstruction. Clinical success was achieved in another 8 patients without symptoms of obstruction during the follow-up period. Reinsertion of the stent was performed in the remaining 12 patients with re-obstruction after 84.33 ± 51.80 d of follow-up. The mean and median periods of relief of obstructive symptoms were 97.25 ± 9.56 d and 105 ± 17.43 d, respectively, using Kaplan-Meier analysis.

CONCLUSION: Temporary SEMS is a safe and effective approach in patients with malignant colorectal obstruction due to low complication rates and good medium-term outcomes.

Ding XL, Li YD, Yang RM, Li FB, Zhang MQ. A temporary self-expanding metallic stent for malignant colorectal obstruction. *World J Gastroenterol* 2013; 19(7): 1119-1123 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1119.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1119

INTRODUCTION

Over the last decade, colorectal stenting has been reported to be an effective method of relieving colonic obstruction in palliative treatment[1-5] or as a pre-operative bridge to facilitate one-stage surgical resection of primary colonic tumors[6-10]. Overall technical and clinical

success has been reported in 80%-100% of treated patients[11-15]. However, metallic stent placement has been plagued by tumor ingrowth (3%-46%) following bare stent placement[16-19], perforation (4%)[12,13,15,20], and stent migration (30%-50%)[10,21-24] following covered stent placement.

To overcome these problems, a temporary expandable colorectal stent was devised for use in patients with unresectable malignant colorectal obstruction. Our hypothesis was that the duration of placement of the self-expanding colorectal stent could be reduced to prevent perforation and stent migration. The purpose of this study was to evaluate the clinical safety and efficacy of a temporary self-expandable colorectal stent for the treatment of unresectable malignant colorectal obstruction, with a focus on preventing colonic perforation and stent migration.

MATERIALS AND METHODS

Study design

This pilot study was approved by the Institutional Review Board, and informed consent was obtained from all the patients. From September 2007 to June 2012, consecutive patients with malignant colorectal obstruction were treated with a temporary self-expanding metallic stent (Micro-Tech, Nanjing, China) in our department.

Diagnoses were established by reviewing patient histories, computed tomography (CT) imaging, colon studies and pathologic results. Patients were eligible for this procedure if the following criteria were met: (1) documented malignancy; (2) colorectal obstruction as defined by symptoms resulting in difficulty in defecation; (3) expandable metallic stent placement; and (4) life expectancy of more than 6 mo. Exclusion criteria were: (1) nonsymptomatic patients with malignant colorectal obstruction; (2) clinical evidence of perforation or peritonitis combined with multiple small-bowel obstructions; (3) extension of rectal cancer to the anal sphincter; and (4) right-sided acute obstruction (due to difficult access).

Stent

The colon stent (Micro-Tech) is woven from a single thread of highly elastic nitinol wire 0.16 mm in diameter. The stent had a tubular configuration with an elliptic structure at the proximal and distal ends. The body section was 25-30 mm in diameter when fully expanded and 70-100 mm in length. The elliptic structure at the proximal and distal ends was 5 mm wider in diameter than the body section and 10 mm in length. To facilitate removal of the stent, a retrieval lasso was attached inside the proximal end of the stent to allow removal after placement. For implantation under fluoroscopic guidance, the stent was delivered in a compressed form inside an introducer sheath with a diameter of 16 F.

Stent placement technique

The procedure was performed by one senior interventional radiologist (Yang RM), who had 18 years of experience in interventional radiology, under fluoroscopic guidance. Neither analgesia nor sedation was administered during the procedure.

Patients were initially placed in the left lateral decubitus position. Rotating the patient into the supine position allowed for a better anatomic view under fluoroscopy. The site of obstruction was established both endoscopically by direct vision and with water soluble contrast (Ultravist 300, Schering, Guangzhou, China) administered *via* a catheter passed through the endoscope and into the stricture. The procedure we used has been described elsewhere[1,6,7,10,25]. After the anal sphincter was lubricated, the distal ends of the tumors were identified by endoscopy. Then, a 0.035-inch guide wire (Radiofocus M; Terumo, Tokyo, Japan) with a 5-Fr catheter (Torcon NB; Cook, Bloomington, United States) was advanced and passed through the area of the stricture. The stricture location, length and morphology of the colon were identified by the injection of 30% diluted nonionic contrast medium (Ultravist) *via* the catheter. To avoid perforation, balloon dilation was not generally performed. After exchanging the guide wire for a 0.035-inch super-stiff guide wire (Boston Scientific/Medi-Tech, Watertown, United States), a 16-Fr delivery system (Micro-Tech) was passed over the stiff guide wire until the proximal and distal edges of the prosthesis bridged the stricture under fluoroscopic control, and the stent was then deployed by pulling back the introducer sheath. Finally, contrast medium (Ultravist) was injected through the catheter to assess correct placement and expansion of the stent.

Upon completion of the procedure, patients were transferred to the ward for observation. Once obstructive symptoms had remitted about one week after stent placement, the stent was grasped by the retrieval lasso and gently pulled out. A contrast study was performed to evaluate the patency to rule out possible concomitant lesions in the proximal and distal colon.

Postoperative outcome evaluation

Before SEMS placement, a routine workup, including CT of the abdomen and chest, as well as calculation of Karnofsky performance status, was conducted. An abdominal radiograph was taken during hospitalization 1-3 d after placement to confirm the correct deployment and expansion. After successful removal of the stent, patients were monitored in the outpatient clinic until either death, surgery was performed, patient was lost to follow-up or a complication developed. Clinical examination, abdominal X-ray and a contrast study were performed by two of our authors, who gathered both initial and follow-up data before and at 1 d, 1 wk, and 1 mo, 3 mo, 6 mo and 12 mo after stent placement. In cases where clinical exams could not be performed, data were obtained by means of telephone calls to the patient or the closest relative and by reviewing medical records. CT examination or an endoscopic procedure was performed if there was persistence or reappearance of symptoms such as abdominal pain, constipation, or rectal bleeding. Technical and clinical success of the procedure, occur-

rence and timing of complications, and the need for surgical intervention were analyzed.

Patients were considered to have incurable cancer when curative resection of metastatic disease was impossible due to extensive liver metastases or extrahepatic disease. Technical success was defined as successful placement of the SEMS, with correct deployment, positioning at the level of the stenosis, and removal of the stent determined with radiologic procedures. Clinical success was defined as complete colonic decompression and relief of obstructive symptoms as judged by clinical symptoms and radiographic observations, without intervention or device-related complications within 72 h after SEMS removal. Death was considered to be related to SEMS complications if the patient died within 7 d of insertion or removal. Major complications were events leading to surgery or reintervention or requiring admission to the intensive care unit. Perforation, stent obstruction, and migration were considered to be major complications. Mild complications were events leading to rehospitalization or prolonged hospital stay without fulfilling the major complications criteria.

Statistical analysis

Descriptive data are expressed as the mean ± SD. Categorical data are reported as numbers and percentages. Time to considered end points (occurrence of complications, surgical intervention, or death) was determined. Kaplan-Meier analysis of relief of obstructive symptoms was performed to calculate the cumulative rate of clinical success, such as sustained relief of obstruction and lack of complications. All statistical analyses were performed using the SPSS package, version 13.0 (SPSS, Chicago, Illinois, United States).

RESULTS

Patients

A total of 38 patients were included in this study initially. Five of these were excluded due to patients being lost to follow-up, thus, a total of 33 eligible patients were included (19 men, 14 women; mean age 61.55 ± 14.59 years, range 30-85 years). Stenoses were located in: the transverse colon (n = 3); left colon (n = 7); sigmoid colon (n = 12); rectum (n = 11). The mean distance of the lesion from the anus was 19.23 cm (range 5-71 cm), and the mean lesion length was 5.97 ± 2.07 cm (range 4-12 cm). The obstructions were complete (with no passage of contrast medium during contrast studies before or during stent placement) in 8 patients and incomplete in the remaining 25 patients.

Technical and initial clinical results

Stent placement in the target colon stricture was technically successful in all patients without procedure-related complications. Initially, all patients required the placement of one stent to cover the length of the obstruction. Complete expansion of the placed stent occurred within 2 d of stent placement. No patient underwent balloon dilation, either before or after stent placement. The mean procedure time was 42 min (range 30-120 min). Removal of the stents was successful in all patients.

In patients with technically successful removal of the stent, clinical success was achieved in 31 of the 33 patients within 72 h of removal, with a success rate of 93.9%. Two patients who did not achieve clinical success after removal of the stents due to paralytic ileus or extension of the tumor were retreated with the stent.

Complications

No perforations occurred following placement or removal of the stents. Stent migration occurred in 2 patients (distal partial migration in two patients), and none of these patients required a second stent placement due to improvement of the obstruction at the time of stent removal. Two patients who had a stent placed in the rectum complained of moderate rectal pain within 2 d of stent placement without requiring analgesics.

Follow-up results

Eleven of the 33 patients died 73.81 ± 23.66 d (range 42-121 d) after removal of the stent without colonic re-obstruction due to diffuse metastatic cancer, cachexia, or myocardial infarction. Clinical success was achieved in 8 patients without symptoms of obstruction. Stent reinsertion was performed in the remaining 12 patients with re-obstruction after a mean follow-up period of 84.33 ± 51.80 d (range 27-201 d). The mean and median periods of relief of obstructive symptoms were 97.25 ± 9.56 d (95%CI: 79, 116) and 105 ± 17.43 d (95%CI: 70, 139), respectively, using Kaplan-Meier analysis.

DISCUSSION

The present study was designed to test the hypothesis that a temporary self-expanding metallic colorectal stent could reduce the risk of colonic perforation and stent migration. In this uncontrolled prospective study of 33 patients with unresectable malignant colorectal obstruction, temporary self-expanding metallic colorectal stent placement was technically successful in all patients with a clinical success rate of 93.9%. There was no procedure-related mortality or perforations in this study, and all complications were managed without surgical intervention. These results suggest that a temporary self-expanding metallic colorectal stent can be considered a viable and effective treatment for patients with unresectable malignant colorectal obstruction. To date, this is the first report to describe the treatment of unresectable malignant colorectal obstruction with a temporary self-expanding metallic colorectal stent.

Colonic or rectal stent placement is associated with some complications, including stent migration, perforations, rectal bleeding, fecal impaction, abdominal pain, and tenesmus, of which stent migration and perforation are the most serious complications. In systematic reviews, migration was reported to occur in approximately 10%-12% of patients[15,20], and is usually detected on

follow-up radiographs within 1 wk of insertion. A comparatively small diameter and limited flexibility may have contributed to the more frequent occurrence of stent migration in earlier studies[26]. Although, Repici *et al*[1] and Song *et al*[6] have reported a lower migration rate (2% and 3%, respectively) with the use of the newly designed colorectal stents - WallFlex stent and dual stent (with a large diameter and flared ends) in the treatment of malignant colorectal obstruction, however, these stents may result in another serious complication - perforation[6]. Song *et al*[6] reported the lowest migration rate (0%) in the bridge-to-surgery group, but they also yielded the highest complication rate - colon perforation (22%) in 11 of the 50 patients in the same group after successful placement of the dual stent.

Perforation is found in 3.7%-4.0% of patients with a colorectal SEMS[15,20], which is lower than stent migration, but it is the most serious complication which may threaten the life of patients. Balloon dilatation of a stricture to obtain access can result in excessive manipulation of the wire through the colonic wall and anatomical sites with a comparatively high perforation risk. It is probable that stent design and long-term placement may play an important role in colonic perforation. Large diameter stents with flared ends and the stent eroding through the colonic wall during colonic peristalsis may directly result in perforation.

The ideal colorectal stent should have adequate radial expansile force and smooth edges. Enough radial expansile force is spontaneously and evenly generated, and the final diameter is reached over the course of 2-5 d, so that dilation of the stricture is gentle, as well as effective[27]. Thus, predilation is not generally necessary, and the potential for migration is reduced. A colorectal stent with smooth edges, obviating sharp hooks in the stent design, can maximally reduce the risk of perforation. The stent made by Micro-Tech has a relatively large profile and an elliptic structure to prevent stent migration, and the elliptic structure has a shrunken edge at both sides to minimize the risk of perforation and satisfies the requirements for prevention of perforation.

The significant improvement in perforation rate and stent migration during the follow-up period in the present study was predominantly attributable to the stent design and its temporary use, and demonstrated that the stent can be safely used in malignant colorectal obstruction. Our 93.9% clinical success rate in the relief of colonic obstruction following stent removal was in line with that of other researchers who reported 80%-100% relief of colonic obstruction in patients with malignant colorectal obstruction treated with SEMSs[5,9,14,15,20], and demonstrated the efficacy of the temporary stent for patients with malignant colorectal obstruction.

Our results have important clinical implications. The use of a temporary self-expanding metallic colorectal stent rather than a long-term self-expanding metallic colorectal stent in patients with unresectable malignant colorectal obstruction will substantially decrease the risk of perforation and stent migration. The findings from this study may encourage more studies on temporary self-expanding metallic colorectal stents in the palliative treatment of patients with unresectable malignant colorectal obstruction.

Our study has some limitations. The number of patients treated was relatively small with a short lifespan, and death due to rapid progression of the disease may have masked both the benefits and risks of the procedure. Secondly, we did not include a control group, therefore, future randomized trials are needed to compare the temporary self-expanding metallic colorectal stent with the long-term self-expanding metallic colorectal stent in terms of efficacy, risk of complications, and recurrent obstruction, with particular attention to stent migration, tumoral and nontumoral tissue overgrowth and perforation.

In conclusion, our preliminary study demonstrated that the temporary SEMS was a safe and effective approach for colon decompression in patients with colorectal malignant obstruction, with a low rate of complications and good medium-term outcomes. Reinsertion of the stent can be performed in patients with re-obstruction. Although the initial results are promising, longer follow-up and expanded clinical trials are needed.

COMMENTS

Background

Colorectal stenting has been reported to be an effective method of relieving colonic obstruction, however, metallic stent placement has been plagued by tumor ingrowth, perforation and migration.

Research frontiers

A temporary self-expanding metallic stent (SEMS) has been widely used for the treatment of patients with malignant esophageal stenosis, however, the use of this type of stent in patients with malignant colorectal obstruction has rarely been reported. Authors investigated the clinical safety and efficacy of a temporary self-expandable colorectal stent for malignant colorectal obstruction.

Innovations and breakthroughs

A temporary SEMS was specially devised for the management of patients with malignant colorectal obstruction associated with colonic cancer. All procedures were performed under fluoroscopic control. This is the first study to report the use of a temporary SEMS for malignant colorectal obstruction.

Applications

By determining the efficacy and safety of a temporary SEMS, this may provide a new therapeutic intervention for the treatment of patients with malignant colorectal obstruction.

Terminology

Malignant colorectal obstruction is a common presentation of colorectal cancer, accounting for about 15%-20% of initial presentations in patients with colorectal malignancy.

Peer review

The authors present a prospective study of temporary SEMS for malignant colorectal obstruction, with the aim of investigating the clinical safety and efficacy of the approach. The results reveal that the clinical success was achieved in 31 (93.9%) of 33 patients with resolution of bowel obstruction within 3 d after stent removal, as well as lower complication rates. In addition, the mean and median periods of relief of obstructive symptom were 97.25 ± 9.56 d and 105 ± 17.43 d, respectively. The results are interesting. A temporary SEMS may be a good attempt to seek the new clinical therapy for unresectable colorectal cancer patients and has a potential clinical significance.

Abstract

AIM: To conduct a meta-analysis to compare Roux-en-Y (R-Y) gastrojejunostomy with gastroduodenal Billroth Ⅰ (B-Ⅰ) anastomosis after distal gastrectomy (DG) for gastric cancer.

METHODS: A literature search was performed to identify studies comparing R-Y with B-Ⅰ after DG for gastric cancer from January 1990 to November 2012 in Medline, Embase, Science Citation Index Expanded and the Cochrane Central Register of Controlled Trials in The Cochrane Library. Pooled odds ratios (OR) or weighted mean differences (WMD) with 95%CI were calculated using either fixed or random effects model. Operative outcomes such as operation time, intraoperative blood loss and postoperative outcomes such as anastomotic leakage and stricture, bile reflux, remnant gastritis, reflux esophagitis, dumping symptoms, delayed gastric emptying and hospital stay were the main outcomes assessed. Meta-analyses were performed using RevMan 5.0 software (Cochrane library).

RESULTS: Four randomized controlled trials (RCTs) and 9 non-randomized observational clinical studies (OCS) involving 478 and 1402 patients respectively were included. Meta-analysis of RCTs revealed that R-Y reconstruction was associated with a reduced bile reflux (OR 0.04, 95%CI: 0.01, 0.14; P < 0.00 001) and remnant gastritis (OR 0.43, 95%CI: 0.28, 0.66; P = 0.0001), however needing a longer operation time (WMD 40.02, 95%CI: 13.93, 66.11; P = 0.003). Meta-analysis of OCS also revealed R-Y reconstruction had a lower incidence of bile reflux (OR 0.21, 95%CI: 0.08, 0.54; P = 0.001), remnant gastritis (OR 0.18, 95%CI: 0.11, 0.29; P < 0.00 001) and reflux esophagitis (OR 0.48, 95%CI: 0.26, 0.89; P = 0.02). However, this reconstruction method was found to be associated with a longer operation time (WMD 31.30, 95%CI: 12.99, 49.60; P = 0.0008).

CONCLUSION: This systematic review point towards some clinical advantages that are rendered by R-Y compared to B-Ⅰ reconstruction post DG. However there is a need for further adequately powered, well-designed RCTs comparing the same.

Xiong JJ, Altaf K, Javed MA, Nunes QM, Huang W, Mai G, Tan CL, Mukherjee R, Sutton R, Hu WM, Liu XB. Roux-en-Y versus Billroth Ⅰ reconstruction after distal gastrectomy for gastric cancer: A meta-analysis. *World J Gastroenterol*

2013; 19(7): 1124-1134 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1124.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1124

INTRODUCTION

Gastric cancer is one of the most common cancers worldwide with approximately 989 600 new cases and 738 000 deaths per year, accounting for about 8 percent of new cancers[1]. Surgical resection is still the only option for providing definitive treatment of this malignant disease[2]. Due to the early diagnosis of gastric cancer, there has been a significant improvement in the long-term survival of patients undergoing surgery within the past decade[3]. Surgeons have therefore focused on improving the patients' postoperative quality of life by modifying the surgical technique and the type of reconstruction performed after distal gastrectomy (DG)[4]. The three mainly used reconstruction techniques after DG are: (1) gastroduodenal anastomosis (Billroth-Ⅰ, B-Ⅰ); (2) gastrojejunal anastomosis (Billroth-Ⅱ, B-Ⅱ); and (3) Roux-en-Y (R-Y) gastrojejunostomy. Although both B-Ⅰ and R-Y anastomoses are recognized as standard reconstruction procedures after DG[5], it is yet to be established, which of these is the better of the two. The B-Ⅰ reconstruction has been commonly performed, because of its technical simplicity, with only one anastomotic site and maintaining physiological intestinal continuity[5,6]. However, gastroesophageal and duodenogastric reflux are well documented in patients who undergo this type of reconstruction following DG[7], and severe gastritis, esophagitis and gastric cancer can subsequently occur[8-11]. The aforementioned complications seriously affect postoperative quality of life of patients undergoing DG[12].

For several decades, R-Y reconstruction has been the preferred method to prevent reflux gastritis, esophagitis and decrease probability of gastric cancer recurrence[9,10,13,14]. However, the choice of surgical reconstruction is often based on personal preferences of surgeons, *e.g.*, majority of surgeons in the East favor a B-Ⅰ reconstruction, while R-Y is the procedure of choice in the West[9,15]. Although a few studies have directly compared B-Ⅰ and R-Y techniques, these studies have failed to reach a consensus and establish which method is the best choice after DG for gastric carcinoma. Thus it is difficult to choose a particular type of reconstruction, based on the current evidence base. We therefore sought to compare the perioperative outcomes and postoperative complications of patients undergoing R-Y and B-Ⅰ reconstruction after DG for gastric cancer by undertaking a meta-analysis of published data.

MATERIALS AND METHODS

Literature search

A comprehensive literature search of Medline, Embase, Science Citation Index Expanded and the Cochrane Central Register of Controlled Trials in the Cochrane Library between January 1990 and November 2012 was carried out for comparing R-Y and B-Ⅰ reconstructions after DG for gastric cancer. Medical subject headings as well as keywords "Roux-en-Y"; "Billroth-Ⅰ"; "reconstruction"; "distal gastrectomy"; "gastric cancer" and "stomach cancer" were used. All abstract supplements from published literature were searched manually. Relevant papers were also identified from the reference lists of previous papers, including those obtained through the search of abstracts and recent international meetings. Randomized controlled trials (RCTs) and non-randomized observational clinical studies (OCS) with full-text descriptions were included. Final inclusion of articles was determined by consensus; when this failed, a third author adjudicated. The results of the search strategy are shown in Figure 1.

Inclusion criteria and exclusion criteria

Two authors identified and screened the search findings for potentially eligible studies. Inclusion criteria were: (1) English language articles published in peer-reviewed journals; (2) Human trials of patients with gastric cancer undergoing DG as the main procedure; (3) Studies with at least one of the outcomes mentioned; and (4) When similar studies were reported by the same institution or author, either the better quality study or the more recent publication was included. Following studies were excluded: (1) Abstracts, letters, editorials, expert opinions, reviews and case reports; (2) Studies without available data; (3) Studies without control group; and (4) Studies including patients with benign disease.

Outcomes of interest

Perioperative outcomes and postoperative complications were evaluated. Operation time, intraoperative blood loss and hospital stay were the main perioperative outcomes to be assessed. Postoperative complications included anastomotic leakage and stricture, bile reflux, remnant gastritis, reflux esophagitis, dumping symptoms and delayed gastric emptying.

Data extraction and quality assessment

Data were extracted by two independent observers using standardized forms. RCTs were qualitatively analyzed using Jadad scoring system[16]. Non-randomized OCS were similarly evaluated using Newcastle-Ottawa scoring system[17]. The quality assessment was also carried out by two independent observers and is displayed in Tables 1 and 2. Quantitative data extracted from the selected studies including: population characteristics (study year, country, design, gender, mean age) and outcome parameters (operation time, intraoperative blood loss, hospital stay, anastomotic leakage and stricture, bile reflux, remnant gastritis, reflux esophagitis, dumping symptoms and delayed gastric emptying.

Statistical analysis

Meta-analyses were performed by using Review Man-

ager Version 5.0 software (The Cochrane Collaboration, Oxford, United Kingdom). For categorical variables, treatment effects were expressed as odds ratio (OR) with corresponding 95%CIs. For continuous variables, treatment effects were expressed as weighted mean difference (WMD) with corresponding 95%CI. Meta-analyses were performed using fixed- or random-effects model, depending on the absence or presence of significant heterogeneity. Heterogeneity was evaluated using the χ^2 test, with a $P < 0.1$ was considered significant; I^2 values were used for the evaluation of statistical heterogeneity[18]. If the test rejected the assumption of homogeneity of studies, then the random effects analysis was performed[19]. Sensitivity analyses were also performed by removing individual studies from the data set and analyzing the effect on the overall results to identify sources of significant heterogeneity. Funnel plots were constructed to evaluate potential publication bias.

RESULTS

Study characteristics

There were 399 papers relevant to the search terms. Sixteen studies[9,10,13,14,20-31] met the inclusion criteria. Four studies had previously been reported by the same institution[27-29,31]. Three studies were excluded[27-29], however, one study had some outcomes which we can include[31]. Finally, four RCTs[20,26,27,31], and 9 OCS[9,10,13,14,21-25] with 478 and 1402 patients respectively were included. All these studies have been carried out in Japan and Korea. The number of patients in the included studies ranged from 43 to 424. Characteristics of studies included in the meta-analysis are presented in Table 3.

Meta-analysis results

Included RCTs and OCS were analyzed separately to determine outcome measures in the study groups. All the results are summarized in Table 4.

RCTs comparison: To date, 4 RCTs have been under-

taken to compare R-Y with B-Ⅰ reconstruction[20,26,27,31]. However, two studies[27,31] have same study populations. All studies had a clear description of the sample size calculation and were found to be of high quality according to Jadad scoring system. The detailed results of meta-analysis are given in Figure 2.

Meta-analysis revealed that R-Y reconstruction was associated with a significant reduction in the incidence of bile reflux (OR 0.04, 95%CI: 0.01, 0.14; $P < 0.00001$) and remnant gastritis (OR 0.43, 95%CI: 0.28, 0.66; $P = 0.0001$). No significant differences were observed between the groups in terms of intraoperative blood loss (OR 26.99, 95%CI: -9.35, 63.33; $P = 0.15$), hospital stay (OR 2.96, 95%CI: -0.00, 5.93; $P = 0.05$), anastomotic leakage (OR 0.56, 95%CI: 0.12, 2.66; $P = 0.47$), stricture (OR 1.79, 95%CI: 0.52, 6.13; $P = 0.92$), reflux esopha-

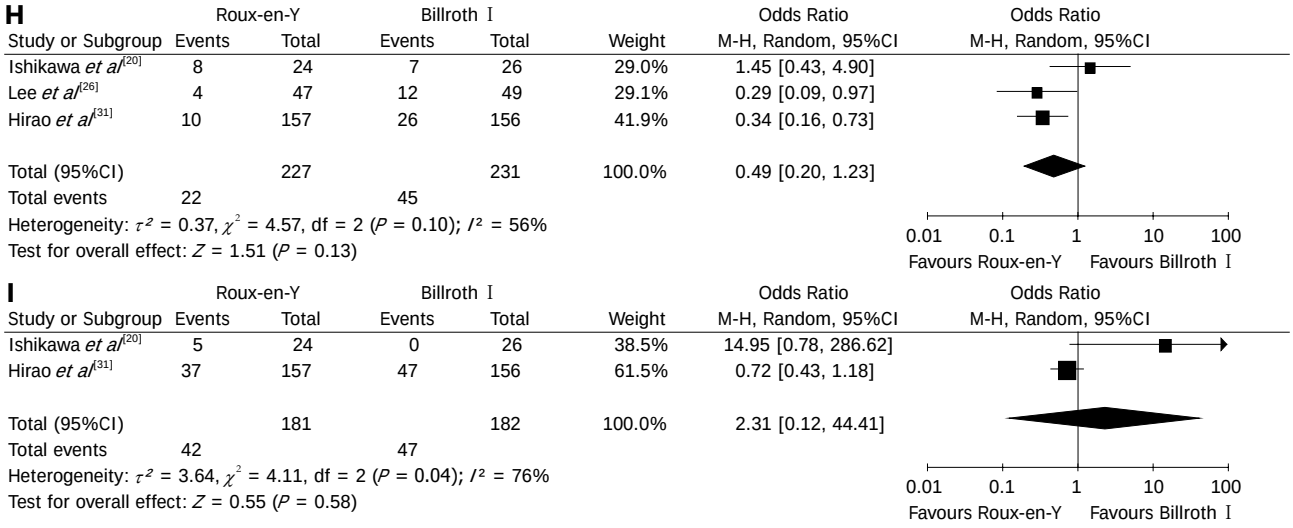

Figure 2 Roux-en-Y versus Billroth I -randomized controlled trials comparison. A: Operation time; B: Intraoperative blood loss; C: Hospital stay; D: Anastomotic leakage; E: Anastomotic stricture; F: Bile reflux; G: Remnant gastritis; H: Reflux esophagitis; I: Delayed gastric emptying. Pooled weighted mean difference (WMD) or odds ratio (OR) with 95%CI was calculated using the fixed-or random effects model.

gitis (OR 0.49, 95%CI: 0.20, 1.23; $P = 0.13$) and delayed gastric emptying (OR 2.31, 95%CI: 0.12, 44.41; $P = 0.58$). However, B- I reconstruction method took significantly less time to perform as compared to R-Y reconstruction (WMD 40.02, 95%CI: 13.93, 66.11; $P = 0.003$).

Only one study[20] reported incidence of dumping symptoms. The incidence of dumping symptoms was not significantly different between the two groups (OR 1.09, 95%CI: 0.14, 8.42; $P = 0.93$).

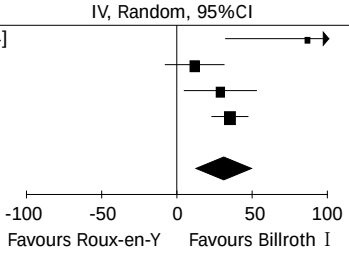
OCS comparison: Nine OCS were included[9,10,13,14,21-25]. Forest plots are illustrated in Figure 3. Results suggested that R-Y reconstruction had significantly lower incidence of bile reflux (OR 0.21, 95%CI: 0.08, 0.54; $P = 0.001$), remnant gastritis (OR 0.18, 95%CI: 0.11, 0.29; $P < 0.00\,001$) and reflux esophagitis (OR 0.48, 95%CI: 0.26, 0.89; $P = 0.02$). No significant differences were found between the two reconstructive methods in terms of intraoperative blood loss (WMD 26.90, 95%CI: -46.54, 100.34; $P = 0.47$), hospital stay (WMD 1.40, 95%CI: -0.17, 2.97; $P = 0.08$), anastomotic leakage (OR 1.26, 95%CI: 0.40, 3.97; $P = 0.70$), stricture (OR 0.94, 95%CI: 0.31, 2.89; $P = 0.91$), dumping symptoms (OR 0.59, 95%CI: 0.32, 1.12; $P = 0.11$) and delayed gastric emptying (OR 0.95, 95%CI: 0.24, 3.74; $P = 0.94$). Results also suggest that B- I reconstruction require shorter operation time (WMD 31.30, 95%CI: 12.99, 49.60; $P = 0.0008$) as compared to R-Y procedure.

Publication bias

Funnel plot analysis of the studies in the meta-analysis reporting was performed on operation time after DG in RCTs and remnant gastritis in OCS respectively. None of the studies lay outside the limits of the 95%CIs, and there was no evidence of publication bias among the studies (Figure 4).

DISCUSSION

Surgical intervention plays a vital role in the survival of patients with resectable gastric cancer. However, there seems to be lack of consensus within surgeons with regards to the choice of reconstructive procedure after DG. The ideal gastrointestinal reconstruction procedure should minimize postoperative morbidity and improve quality of life[32]. In current surgical practice, B- I and R-Y procedures are the commonly used reconstruction techniques following resection of distal stomach. To the best of our knowledge, B- I reconstruction has commonly been employed after DG for gastric cancer due to its simplicity, physiological advantage of allowing food to pass through the duodenum and ease of postoperative endoscopy allowing access to the papilla of Vater[33,34]. However, two most common drawbacks of the B- I anastomosis, remnant gastritis and reflux esophagitis, as a consequence of the absence of the pyloric sphincter which allows reflux of duodenal contents into the remnant stomach and esophagus have been well reported[35]. Furthermore, unregulated release of chyme into the duodenum results in rapid gastric emptying which manifests as dumping syndrome[36]. It is important to note that reflux of duodenal contents into the esophagus is strongly associated with Barrett's esophagus or esophageal cancer and remnant stomach cancer after gastrectomy[37-39].



Traditionally R-Y reconstruction has been the reconstruction method of choice in total gastrectomy[34] and is being increasingly used to prevent duodenogastric and gastroesophageal reflux in DG[10,14,21]. The potential advantages of improved postoperative quality of life take precedence over the possible increased risk of postoperative complications due to two gastrointestinal anastomoses and increased operating time, when considering R-Y reconstruction.

Based on our analysis, which only includes high qual-

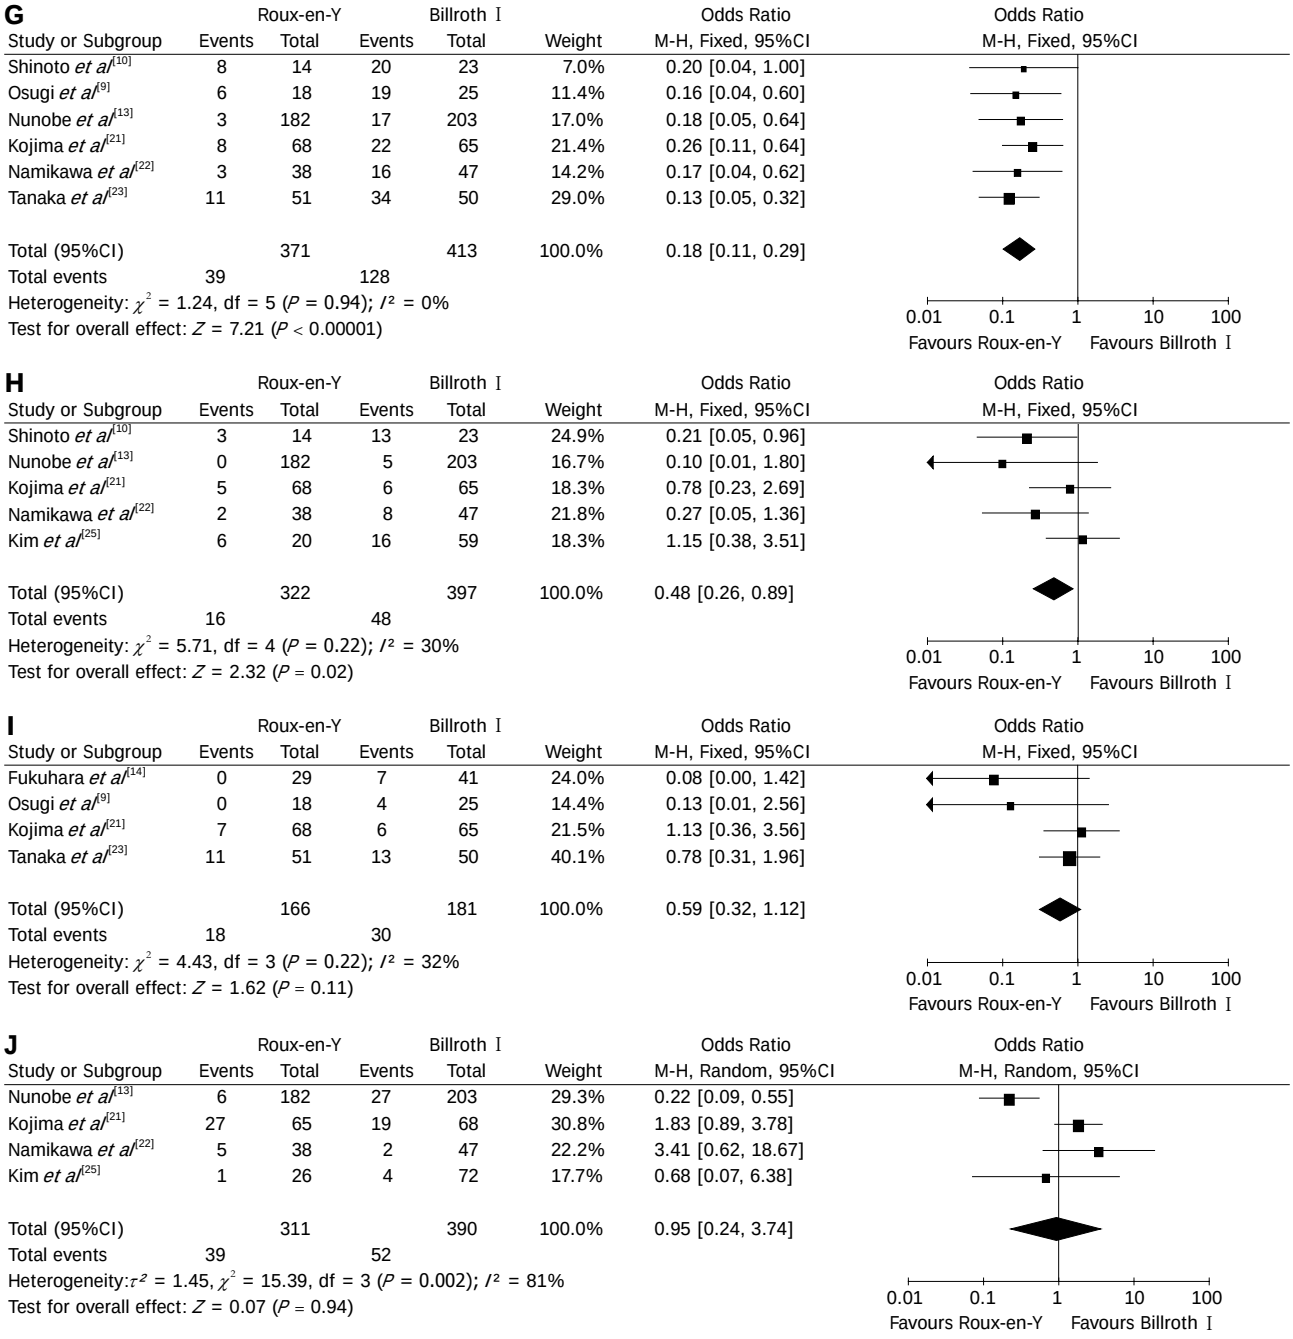

Figure 3 Roux-en-Y versus Billroth I -observational non-randomized clinical studie comparison. A: Operation time; B: Intraoperative blood loss; C: Hospital stay; D: Anastomotic leakage; E: Anastomotic stricture; F: Bile reflux; G: Remnant gastritis; H: Reflux esophagitis; I: Dumping symptoms; J: Delayed gastric emptying. Pooled weighted mean difference (WMD) or odds ratio (OR) with 95%CI was calculated using the fixed-or random effects model.

ity RCTs and OCS, we have addressed this issue, to the best of our effort, of the most appropriate gastrointestinal reconstruction following DG. It is important to note that the results come from a small number of RCTs and therefore, have to be interpreted with caution. Overall analyses for RCTs comparing R-Y with B- I reconstruction favor R-Y method in terms of preventing postoperative bile reflux and remnant gastritis, although we found no significant difference in reflux esophagitis between the two groups. The angle of His is significantly larger in patients who undergo B- I reconstruction compared to those with R-Y and this may be a factor contributing to reduced incidence of reflux symptoms in the latter group[22,28]. We may not have detected an existing difference due to the smaller sample size of the included studies. As only one RCT[20] evaluated incidences of dumping syndrome, descriptive analysis was used, and no difference was found between the two groups with regards to dumping syndrome.

The operating time was significantly shorter in B- I group compared to R-Y group, which can be explained by the additional anastomosis in R-Y reconstruction. Although it has been previously reported that anastomotic leak is higher in B- I reconstruction, possibly due to ex-

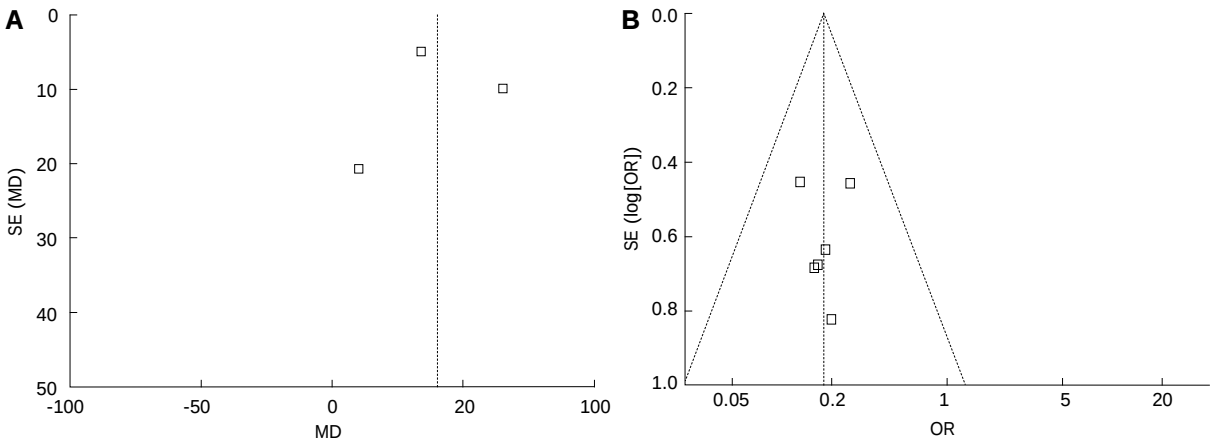

Figure 4 Funnel plot. A: Operation time-randomized controlled trial; B: Remnant gastritis-observational clinical studies. None of the studies lay outside the limits of the 95%CIs, and there was no evidence of publication bias.

cessive devascularization of duodenal stump and tension on the anastomosis[20,21,27], we found no difference in the rate of anastomotic leak within the two groups. It may be largely due to the use of gastrointestinal stapling devices and the refinement of technique.

Similarly, analysis of pooled data from the OCS, revealed a reduced incidence of bile reflux, remnant gastritis, reflux esophagitis and prolonged operative time in the R-Y reconstruction group. Consequently, based on the above findings, we can conclude that R-Y reconstruction following DG is likely to be superior to B- Ⅰ reconstruction not only in preventing bile reflux and remnant gastritis, but also reflux esophagitis (OCS analysis only), as it reduces duodenogastric and gastroesophageal reflux[13,28].

We also analyzed data regarding intraoperative bleeding and duration of hospitalization and found no significant difference in either of these parameters within the two groups, although one would expect an earlier recovery of gastrointestinal function in R-Y reconstruction group.

This review does have some limitations and hence the results should be interpreted with a degree of caution. Firstly, most data are extracted from OCS, with fewer RCT's making it difficult to make firm conclusions. In addition, several important outcomes including remnant gastritis, dumping symptoms and delayed gastric emptying have not been reported adequately in the RCTs. It is important to mention that we were unable to analyze important outcomes including quality of life and incidence of gastric carcinoma in the gastric remnant due to lack of available data. We would therefore propose well-designed RCTs with adequate follow-up and emphasis on assessing important outcomes to clarify ambiguities surrounding the use of these reconstruction methods.

In summary, our systematic review demonstrates that RY reconstruction is likely to be more effective in preventing gastroesophageal reflux or duodenogastric reflux as compared to B- Ⅰ. Furthermore, we have shown that based on results from RCTs and OCS, RY reconstruction may be used safely without increasing anastomotic leakage, anastomotic stricture and intraoperative bleeding.

In conclusion, this systematic review points towards some clinical advantages that are rendered by R-Y compared to B- Ⅰ reconstruction post DG. However there is a need for further adequately powered, well-designed RCTs comparing the same.

COMMENTS

Background

Currently, Billroth Ⅰ (B- Ⅰ) and Roux-en-Y (R-Y) reconstructions are commonly performed after distal gastrectomy for gastric cancer. However, deciding which of these reconstruction procedures is superior, remains controversial. Therefore, in order to help arrive at a possible consensus, the authors conducted a systematic review and meta-analysis to compare the clinical efficacy and safety of B- Ⅰ versus R-Y reconstruction following distal gastrectomy (DG) for gastric cancer.

Research frontiers

In order to compare the safety and effectiveness of the B- Ⅰ and R-Y reconstructions, operative outcomes including operation time, intraoperative blood loss and postoperative outcomes such as anastomotic leakage and stricture, bile reflux, remnant gastritis, reflux esophagitis, dumping symptoms, delayed gastric emptying and hospital stay were included in this study.

Innovations and breakthroughs

Although existing randomized controlled trials (RCTs) and retrospective comparative studies have concluded that R-Y reconstruction could prevent gastroesophageal and duodenogastric reflux following DG, there was a need to further assess the clinical advantages of R-Y and B- Ⅰ reconstruction based on high-level evidence. This meta-analysis reports that the R-Y reconstruction has some clinical advantages in reducing the incidence of bile reflux and remnant gastritis compared to the B- Ⅰ technique. Also, R-Y reconstruction does not significantly increase postoperative complications.

Applications

This study shows that R-Y reconstruction following DG for gastric cancer has some clinical advantages compared with B- Ⅰ reconstruction. However, taking into account the limited number of studies, further adequately powered and well-designed RCTs should be undertaken to investigate the same.

Terminology

Following distal gastrectomy, three methods, namely, (1) gastroduodenal anastomosis or B- Ⅰ; (2) gastrojejunal anastomosis or Billroth-Ⅱ; and (3) R-Y gastrojejunostomy are mainly used for gastrointestinal tract reconstruction.

Peer review

This is an interesting study, which can point out to some extent, the direction in gastrointestinal tract reconstruction for the future gastrointestinal surgeon.

Abstract

A 39-year-old male reported fevers, weight loss, watery loose stools, and decreased visual acuity in his right eye over the prior five years. He was pancytopenic, had an elevated American council on exercise level, total bilirubin, and alkaline phosphatase. Computed tomography revealed massive hepatosplenomegaly and emphysematous lung changes. Liver biopsy showed non caseating granulomas. The patient was diagnosed with extrapulmonary sarcoidosis and was treated with prednisone. The patient symptomatically improved but 5 mo later presented with abdominal pain caused by perforation of the cecum. He underwent a cecectomy and pathology revealed pneumatosis cystoides intestinalis. This represents the first reported association between pneumatosis cystoides intestinalis and sarcoidosis. The etiology of pneumatosis cystoides intestinalis in this case was likely multifactorial and involved both effects of the corticosteroids as well as the advanced nature of the gastrointestinal sarcoidosis. Furthermore this case has the unique features of emphysematous lung changes and pancytopenia which are uncommon with sarcoidosis.

Gastrointestinal sarcoidosis associated with pneumatosis cystoides intestinalis. *World J Gastroenterol* 2013; 19(7): 1135-1139 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i7/1135.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i7.1135

INTRODUCTION

Sarcoidosis is an idiopathic multisystem non-caseating granulomatous disease that has been reported to impact almost any organ. It is more common in African Americans and typically patients present with pulmonary manifestations associated with bilateral hilar adenopathy on chest X-ray. Very rarely does it present with predominantly gastrointestinal (GI) symptoms[1]. Pneumatosis intestinalis cystoides is a rare disorder defined as gaseous cysts in the bowel wall. While the etiology remains unclear, it has been associated with multiple conditions including, connective tissue disease, various drugs, colonoscopies, ileal surgeries, and chronic pulmonary disease[2,3]. Here we present a case of an individual with GI sarcoidosis who 5 mo after initial presentation was diagnosed with pneumatosis cystoides intestinalis.

CASE REPORT

A 39-year-old male presented with right lower quadrant abdominal pain that ranged between 5-9/10 severity and was diffusely located in both the right upper and lower

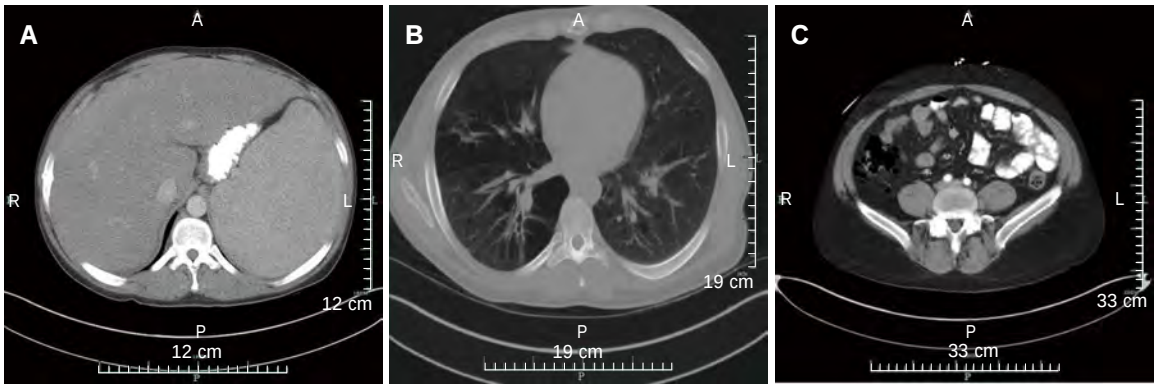

Figure 1 Computed tomography. A: Abdomen and pelvis showing massive hepatosplenomegaly at initial presentation; B: Chest at initial presentation demonstrating extensive bilateral emphysematous changes; C: Abdomen revealing pockets of free air consistent with perforation. No evidence of pneumatosis is seen on computed tomography scan. A: Anterior; P: Posterior; R: Right; L: Left.

quadrants of the abdomen. The pain begin approximately five years ago and has waxed and waned since. The week prior to admission the pain was significantly worsening. It was particularly aggravated by movement and coughing. Since the onset of symptoms five years ago, he reported watery loose bowel movements after meals, fevers up to 102F, night sweats, a 50lb unintentional weight loss, decreased visual acuity in his right eye and associated photophobia. He also described a chronic cough with occasional dark brown phlegm. He reported waking in the middle of the night coughing. He was initially evaluated multiple times at an outside hospital, but could not remember his specific diagnosis. He has a 15 pack year smoking history and denies any illicit drug use. His prior occupation involved working with copper products. His physical exam revealed severe tenderness over the right side of the abdomen. Liverspan was approximately 25 cm and spleen was easily palpable. The right eye showed an irregular opacity and photophobia.

On presentation he was pancytopenic, with an elevated alkaline phosphatase, gamma glutamyl transpeptidase, total bilirubin and angiotensin converting enzyme (ACE) level. Hemoglobin (Hgb) 13.1 g/dL [normal range (NR) 14.1-17.7 g/dL], platelet count 75 thousand/μL (NR 140-440 thousand/μL), white blood cell (WBC) 2.1 thousand/μL (NR 4.0-10 thousand/μL), alkaline phosphatase 383 IU/μL (NR 45-115 IU/μL), total bilirubin 1.7 mg/dL (NR 0.1-1.3 mg/dL), ACE was 97 U/L (NR 9-67 U/L). Anti-mitochondrial antibody, hepatitis panel, anti-nuclear antibody, human immunodeficiency virus, epstein-barr, and rapid plasma reagin serologies were negative. Tuberculin purified protein derivative and sputum acid fast smear were negative.

Abdominal computed tomography (CT) revealed a markedly enlarged liver and spleen each measuring 24 cm with distended portal and splenic veins (Figure 1A). Shotty retroperitoneal, upper abdominal and mesenteric lymphadenopathy was noted. CT chest revealed a subcentimeter enlargement of mediastinal lymphnodes that were pathological in number. Extensive bilateral centrilobular emphysematous changes were noted (Figure 1B). Bone marrow biopsy was normocellular. Immunophenotyping did not show diagnostic abnormalities of the B- or T-cells. Co-expression of abnormal antigens, antigen deletion, or light-chain clonality was not detected. Outside hospital records from 5 years prior to current admission were obtained. Full body positron emission tomography (PET) scan revealed no foci of abnormal uptake. Hgb was 13.9 g/dL, platelet count 220 thousand/μL, and WBC 4.5 thousand/μL. Alkaline phosphatase 388 IU/μL. Total bilirubin 1.2 mg/dL. Bone marrow biopsy showed hypocellular marrow with mild megaloblastic changes but no evidence of infiltrative changes.

The above findings were most consistent with a chronic inflammatory condition. Chronic inflammatory conditions that can cause hepatic noncaseating granulomas include sarcoidosis, Crohn's disease, primary biliary cirrhosis, Whipple's disease, copper poisoning, lymphomas, secondary syphilis. Given the negative full body PET scan, negative bone marrow and retroperitoneal lymph node biopsy, negative flow cytometry results, and long indolent course lymphoma was highly unlikely. While his previous occupation dealt with copper, symptoms started well before employment there and he did not demonstrate any other signs of copper poisoning. Whipple's disease is more common in European Caucasians and usually does not include ocular manifestations. However, it cannot be definitively excluded without a small bowel biopsy. Primary biliary cirrhosis and syphilis were ruled out through serologies. Crohn's disease is possible but is unlikely to cause such marked hepatosplenomegaly or pancytopenia. An extrapulmonary manifestation of sarcoidosis is the most likely explanation.

The patient was started on a 40 mg prednisone and instructed to follow up in the clinic within a mo. At subsequent follow-ups at outpatient clinic 2 wk, 2 mo, and 3 mo after presentation he was having difficult to control steroid induced diabetes requiring increasing doses of metformin and glipizide. He reported home blood sugar measurements ranged from 100-250 mg/dL. He had two separate hospitalizations for hyperglycemia 1 mo and 4 mo after presentation. At each visit his prednisone dose was being tapered. At 4 mo follow up at outpatient

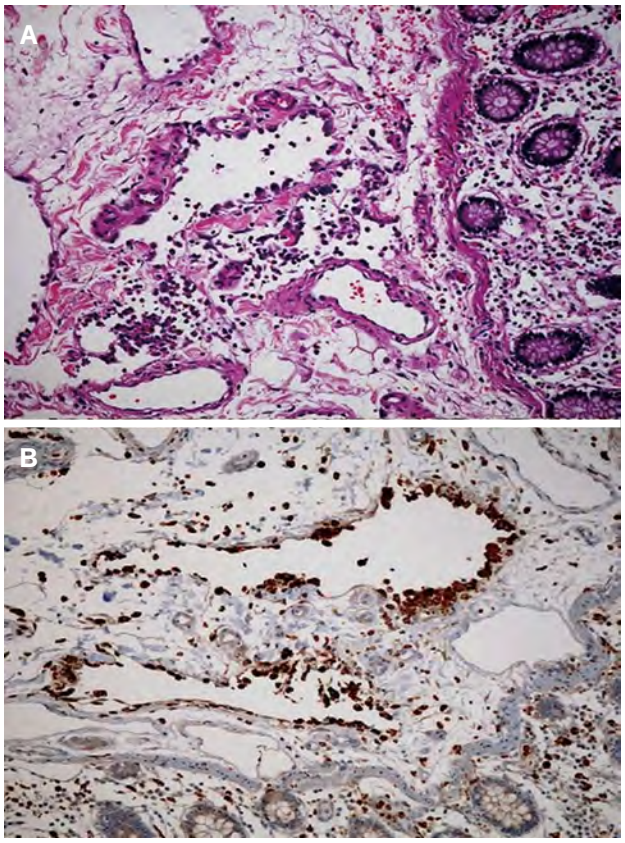

Figure 2 Pathology of the resected tissue revealed portions of large bowel with submucosal and mucosal hemorrhage and submucosa with irregular spaces lined with histiocytes (CD68 positive and CD31 negative) consistent with pneumatosis cystoides intestinalis. A: Cecum specimen stained with hematoxylin and eosin demonstrates partially endotheliolized cystic spaces in the submucosa lined by eosinophilic cells characteristic of pneumatosis intestinalis; B: Immunohistochemical staining for CD 68 which is found in cytoplasmic granules of cells within the monocyte/macrophage lineage confirms presents of histiocytes lining cystic spaces.

clinic the dose was 25 mg. The second hospitalization occurred at an outside hospital 4.5 mo after initial presentation. On discharge the patient reported he was told to increase the dose of glipizide as well as to increase his prednisone dose from 25 mg to 40 mg daily. Overall he was reporting decreased distension and abdominal discomfort. ACE level measured at outside hospital after 4 mo of steroid therapy was down to 29 U/L (97 U/L at initial presentation).

Five mo after initial presentation he came to our institution with headache, dizziness, abdominal pain, and nonbloody diarrhea 1 d. He reported the abdominal pain and discomfort were approximately baseline for him. He was afebrile and normotensive. His abdomen was tender to palpation right greater than left with guarding and rebound. Fecal occult blood was negative. He was found to have blood glucose of 623 mg/dL. Admission labs demonstrated improved pancytopenia, decreased alkaline phosphatase, but an elevated lactate [lactate 5.6 mmol/L (normal 0.5-2.2 mmol/L), Hgb (17.6 g/dL), platelets (114 thousand/μL), WBC (6.2 thousand/μL), alkaline phosphatase (223 IU/L)]. CT of the abdomen revealed pockets of free air distributed circumferentially along the cecum consistent with perforation (Figure 1C). He was taken to the OR for exploratory laparotomy requiring cecectomy and creation of ileostomy and mucous fistula. In the operating room there was no identified perforation externally, but a 2 cm × 2 cm defect within the cecum that did not penetrate the serosal surface of the bowel. The mucosa was hemorrhagic and flattened. Pathology of the resected tissue revealed portions of large bowel with submucosal and mucosal hemorrhage and submucosa with irregular spaces lined with histiocytes (CD68 positive and CD31 negative) consistent with pneumatosis cystoides intestinalis (Figure 2).

DISCUSSION

Sarcoidosis is an idiopathic multisystem non-caseating granulomatous disease that has been reported to impact almost any organ. It is more common in African Americans and typically patients present with pulmonary manifestations associated with bilateral hilar adenopathy on chest X-ray[1]. Other organs frequently involved include skin, lymph nodes, and ocular manifestations. The diagnosis is established by exclusion of other possibilities and can be supported by characteristic physical findings and biopsy showing noncaseating granulomas. ACE levels are elevated in 10% of chronic sarcoidosis and 60% of acute sarcoidosis[1].

The patient's chief complaint related to the abdominal distension and pain secondary to hepatosplenomegaly. Abdominal pain is an infrequent chief complaint in sarcoidosis however, both the liver and spleen have been reported to be involved[4]. Hepatomegaly has been reported to be as high as 21% of patients clinically and as many as 13% of patients with liver involvement had involvement independent of any typical pulmonary manifestations[4]. Splenomegaly has been reported by physical exam in 5%-14% with hypersplenism seen in 15% of those with splenic involvement[4]. While biopsy specimens from the patient presented are not available given the degree of splenomegaly and pancytopenia one could hypothesize involvement.

The patient described presented with pancytopenia likely secondary to hypersplenism. He was severely thrombocytopenic and leukopenic and mildly anemic. Cytopenias have been frequently described in sarcoidosis. However, to our knowledge significantly fewer reports describing pancytopenia. One report describes thrombocytopenia and leukopenia secondary to hypersplenism a second report notes pancytopenia with splenomegaly both were resolved with splenectomy[5,6]. This indicates a potential therapeutic role for the patient described here, but repeat CT after 5 mo on steroids revealed dramatic improvement in spleen size (Figure 3).

Pneumatosis cystoides intestinalis is a rare disorder defined as gas within the bowel wall. The presentation can range from being asymptomatic to acute abdominal pain. The mechanism of pneumatosis cystoides intestinalis is multifactorial. Current theories propose luminal gas which could be pulmonary or bacterial in origin dis-

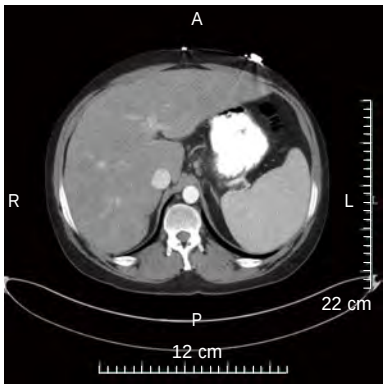

Figure 3 Computed tomography abdomen with contrast demonstrating marked reduction in spleen size and moderate reduction in hepatomegaly after 5 mo of steroid treatment. A: Anterior; P: Posterior; R: Right; L: Left.

sect through mucosa which has been compromised. Mucosa may be compromised by a number of mechanisms including immunologically or physically[7].

While typically diagnosed *via* CT scan[2] certain cases where the pneumatosis is very subtle the finding may be missed and air contrast enema may be useful[8,9]. Furthermore, when diagnosed *via* CT, the majority of patients can be managed nonoperatively as exploratory laparotomy is likely to be of benefit to only a subset of patients. Those patients include those with abdominal distension, peritonitis, and lactic acidemia[10]. The patient described here represents one of these subtle cases as he was only found to have pneumatosis on pathology. He clearly was in need of operative management given the pneumoperitoneum, abdominal distension, and elevated lactic acid.

Pneumatosis cystoides intestinalis has been linked to a number of conditions in the past. One of which is chronic obstructive lung disease[2,3]. Pulmonary function tests obtained 4 mo after presentation at an outside institution revealed moderate obstructive lung disease with abnormal diffusion capacity [forced expiratory volume in 1 second (FEV1)/forced vital capacity = 70% predicted, FEV1 = 69% predicted, single breath diffusion Dsb 38% predicted]. Typically sarcoidosis most commonly affects the lungs, but the typical radiographic presentation was absent. On chest X-ray bihilar and mediastinal lymphadenopathy (75%) and pulmonary infiltrates (50%) are the most common presentations[1]. This usually occurs in an upper lobe and nodular predominance. On CT scan typical features include bilateral perihilar opacities, bilateral symmetric hilar or mediastinal lymphadenopathy, fibrotic changes such as reticular opacities, architectural distortion, or bronchiectasis[1]. The patient presented had severe emphysematous changes which are rarely associated with sarcoidosis. Prior case reports have documented emphysema in patients with sarcoidosis though the mechanism is unclear[11,12]. While he does have a 15 pack year hx it would be unlikely all lung abnormalities are due to past tobacco at only the age of 39, though this does confound the finding.

Pneumatosis cystoides intestinalis has been very frequently linked to medications. Corticosteroids have been reported most often. Many of the other conditions, pneumatosis cystoides intestinalis has classically been linked to are treated with steroids as well, including connective tissue disease and some autoimmune conditions[2,3,13,14]. The hypothesized mechanism suggests the immunosuppressive effects of steroids results in depletion of the lymphoid tissue within the Peyer's patches, this leads to mucosal disruption allowing intraluminal gas diffusion[15,16]. One review indicates that 33% of patients with pneumatosis intestinalis had received prior steroid treatment. Another 32% had received either chemotherapy or methotrexate[15,17]. This hypothesis is supported by the fact that other immunosuppressive or cytotoxic drugs have also been associated with pneumatosis cystoides intestinalis. This includes but is not limited to sunitinib, cisplatin, irinotecan, and docetaxel, methotrexate[17-20].

Alternative mechanisms have been described for other drugs that have been implicated in pneumatosis cystoides intestinalis. The chemotherapeutic agents described above have not only been suggested to contribute to the development of pneumatosis cystoides intestinalis *via* their immunosuppressive effects but also through their apoptotic effects on rapidly dividing cells resulting in compromise of mucosal integrity. Vascular endothelial growth factor and epidermal growth factor inhibitors are hypothesized to damage the microvasculature of the intestinal wall resulting in compromise of mucosal integrity[19,21]. Alpha glucosidase inhibitors, miglitol and acarbose, inhibit the absorption of carbohydrates. It has been suggested that digestion of these carbohydrates by intestinal flora result in gas production. The increased intraluminal pressure could potentially lead to dissection through the mucosa[15,22,23].

The patient was on a steroid taper, but was increased from 25 mg to 40 mg by an outside hospital for reasons that are unclear 1 mo prior to perforation. The 5 mo course of steroids coupled with the recent increased dosage thus could have played a significant role in the pathogenesis through immunosuppression as detailed above. However, given the patients improvement in symptoms and ACE level it seems the initial course of tapering the dosage as symptoms improved was the best course of action.

The patient described here likely had a number of factors that could have additively contributed to the development of pneumatosis cystoides intestinalis. The steroid treatment coupled with his baseline pancytopenia clearly placed him in an immunosuppressed state. The massive hepatomegaly and respiratory disease may have lead to increased intraabdominal pressure producing strain on the mucosal walls. We may also speculate that the 5 year history of untreated GI sarcoidosis may have further weakened the intestinal walls through granulomatosis inflammationa nd disruption of normal architecture. Cumulatively, this created an environment where pneumatosis intestinalis could readily develop.

The described case represents a unique presentation of the difficult to recognize and diagnose GI sarcoidosis. The initial findings of pancytopenia and emphysematous

changes in the lungs are typically not found in sarcoidosis. Furthermore this is the first reported association between pneumatosis intestinalis and sarcoidosis though the exact mechanism of pneumatosis cystoides intestinalis is unclear and likely multifactorial as in many such cases.

Abstract

A pleural effusion containing chylomicrons is termed chylothorax and results from leakage of lymph fluid into the pleural cavity. We report on the case of a 59-year-old woman with severe dyspnea due to a large chylothorax. She was known to have liver cirrhosis but no ascites. There was no history of trauma, cardiac function was normal and thorough diagnostic work-up did not reveal any signs of malignancy. In summary, no other etiology of the chylothorax than portal hypertension could be found. Therapy with diuretics as well as parenteral feeding failed to relieve symptoms. After a transjugular intrahepatic portosystemic shunt (TIPS) had successfully been placed, pleural effusion decreased considerably. Eight months later, TIPS revision had to be performed because of stenosis, resulting in remission from chylothorax. This case shows that even in the absence of ascites, chylothorax might be caused by portal hypertension and that TIPS can be an effective treatment option.

INTRODUCTION

Chylothorax is defined as a pleural effusion containing chylomicrons. Triglyceride levels of at least 110 mg/dL have been found to reliably indicate chylothorax[1], originating from a lesion in the lymphatic vessels, mostly the thoracic duct. In about 40% of patients with chylothorax, these lesions are caused by trauma or surgery, whereas in about 30%, a malignant tumor is found. The remaining cases are attributed to a variety of conditions, including congenital, infectious and cardiac diseases, or are considered to be idiopathic[2]. Chylothorax rarely occurs in patients with liver cirrhosis. In such cases, concomitant ascites is usually present[3]. We report on the effective treatment of massive chylothorax in a female patient with liver cirrhosis but no ascites by placement of a transjugular intrahepatic portosystemic shunt (TIPS).

CASE REPORT

The 59-year-old woman was referred to our university hospital due to chylothorax which could not be sufficiently managed in a peripheral hospital. Since 2008, a right sided pleural effusion had to be drained occasionally despite diuretic therapy. In recent weeks, however, the pleural effusion had turned milky and had to be drained more frequently. Three weeks prior to admission, nearly 1.5 L/d had to be removed (Figure 1). The patient presented no further symptoms apart from dyspnea. Her past medical history included diagnosis of alcoholic liver cirrhosis (Child B), diabetes mellitus type Ⅱ and resection of a local ovarian carcinoma 15 years ago. The exact tumor staging was unknown. The patient had received adjuvant chemotherapy and the carcinoma has been in remission since then. One year ago, she was treated for bleeding gastric ulcer related to infection with *Helicobacter pylori*. There was no history of trauma.

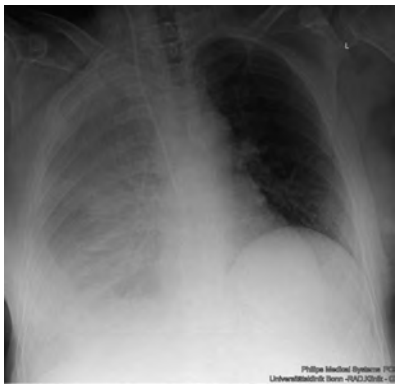

Figure 1 Chest X-ray before transjugular intrahepatic portosystemic shunt placement, showing a large right-sided pleural effusion.

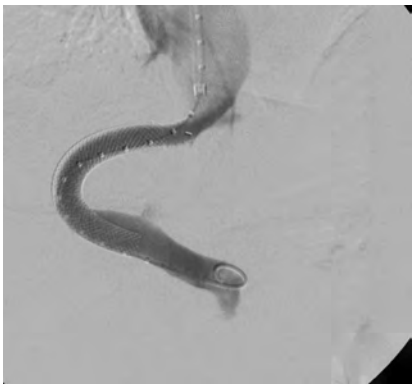

Figure 2 Angiogram after transjugular intrahepatic portosystemic shunt placement, the catheter tip is in the portal vein.

Apart from the signs of right-sided pleural effusion, some spider naevi and a small umbilical hernia, physical examination was unremarkable. Blood analysis showed slightly elevated bilirubin (1.2 mg/dL, reference range up to 1 mg/dL), increased gamma-glutamyl transferase (112 U/L, reference range up to 38 U/L), international normalized ratio (of prothrombin time) above normal (1.3) and decreased serum albumin (31 g/L, reference range 35-52 g/L). Model for End-stage Liver Disease score was 10. Mild hyperglycemia was due to diabetes mellitus. Urine analysis was unremarkable. Analysis of the pleural fluid showed 95 polymorphonuclear cells/μL, 294 mononuclear cells/μL, low albumin of 4.2 g/L, no cholesterol, but markedly increased triglycerides (386 mg/dL). Bacterial cultures were negative, microscopic examination did not reveal malignant cells. No tumor was detected in a computed tomography (CT) scan carried out at the referring hospital. Cardiac evaluation by echocardiography and transthoracic echocardiography revealed no signs of heart failure or pulmonary hypertension. Abdominal ultrasound showed a liver morphology consistent with cirrhosis and concomitant splenomegaly, but neither portal vein thrombosis nor signs of hepatocellular carcinoma nor ascites were present. To further characterize the degree of portal hypertension, we performed endoscopy of the upper gastrointestinal tract. Esophageal varices grade Ⅱ were detected.

In summary, we confirmed the diagnosis of chylothorax with a daily production of 2-4 liters. However, it was uncertain whether this was caused by liver cirrhosis. As diuretic therapy failed to drain the chylothorax, we put the patient on parenteral feeding for a total of nine days to reduce the flow in the lymphatic ducts and to promote healing of a suspected lymphatic lesion. As expected, the milky aspect of the pleural effusion vanished, but the daily amount of secretion from the pleural drainage increased even further (about 1.5-3 L/d). Since high renin blood levels are often associated with decompensated portal hypertension[4], we determined renin blood levels, revealing a value of 1680 μU/mL (reference range up to 46 μU/mL) in conjunction with an elevated level of aldosterone of 946 pg/mL (reference range up to 310 pg/mL). Thus, we proposed TIPS as treatment option and this was placed successfully in March 2010 (Figure 2). Fifteen days later, the pleural drain could be removed; another week later, the patient could be dismissed with a small, stable pleural effusion under diuretic medication. During the following months, the pleural effusion had to be drained about once per month. TIPS revision due to stenosis had to be performed by inserting a new stent in November 2010. Since then, no further pleural drainage was needed (Figure 3). After TIPS placement, the patient had several episodes of hepatic encephalopathy grade Ⅰ-Ⅱ according to the West Haven criteria, but responded to treatment with lactulose and rifaximin. Levels of bilirubin did not increase significantly after the intervention. To date, more than two years after TIPS placement, the patient is still without recurrence of chylothorax (Figure 4).

DISCUSSION

Liver cirrhosis, together with portal hypertension is a rare cause of chylothorax[3]. Diagnosis was difficult in this patient because she presented with almost normal laboratory values and without ascites. However, tiny amounts of abdominal fluid had been present in the past. Conservative management of chylothorax failed. To the best of our knowledge, TIPS as successful treatment of chylothorax in cirrhotic patients has been described before in only two cases: in one patient with traumatic injury of the thoracic duct[5] and in a second patient with concomitant refractory ascites[6]. High renin levels in our patient suggested that activation of the renin angiotensin aldosterone system (RAAS), causing sodium and fluid retention, was due to portal hypertension, complicated by the leakage of chyle in the pleural cavity. This activated RAAS argued against idiopathic etiology, which is described in 10% of patients with chylothorax. Indeed, renin values in our patient decreased considerably from 1680 to 317 μU/mL after TIPS placement, along with regression of excessive chyle formation. Other etiologies of chylothorax were not very plausible: there was no history of recent trauma or surgery and a malignant process - bearing the history of ovarian cancer in mind - was improbable due to negative CT scan and pleural fluid cytology. Furthermore, the patient developed no malignancy during the follow-up of more than two years. In the end, placement of TIPS improved the quality of life

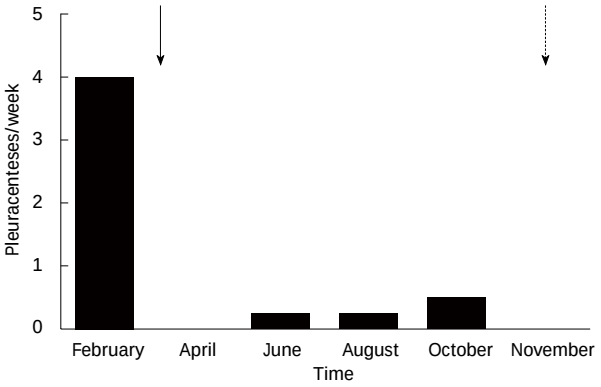

Figure 3 Need for pleurocentesis over time. There is a clear drop after transjugular intrahepatic portosystemic shunt (TIPS) placement in March (arrow) and no need for further pleurocentesis after TIPS revision in November (dotted arrow).

Figure 4 Chest X-ray during follow up without pleural effusion.

of this patient enormously. After failure of conservative treatment, the main alternative to TIPS would have been surgical procedures, such as pleurodesis or ligation/embolization of the thoracic duct[7], which, however, do not address portal hypertension as underlying disease. Fasting and parenteral nutrition have been described as effective in chylothorax particularly following surgery or trauma. In most other forms, lymphatic obstruction or increased venous pressure in the superior vena cava cause lymphangiectasia and chylothorax[7]. In these cases, parenteral feeding is not effective. Somatostatin has been used in chylothorax of various etiologies with some success[8]. Due to its characteristic contents, drainage of a chylothorax can lead to malnutrition and immunosuppression caused by loss of lipids, immunoglobulins and lymphocytes. However, this characteristic content seems to reduce the risk of infection of a pleural drain[9].

The success of the TIPS placement in our patient confirms the hepatic origin of the chylothorax. It has been suggested that in liver cirrhosis, chyle flow increases substantially due to increased formation of hepatic lymph and due to portal hypertension. Since drainage into the venous system is limited by a valve at the junction of the thoracic duct and the subclavian vein, pressure in the lymphatic vessels is increased, leading to an elevated risk of spontaneous rupture[10]. Thus, in our patient, such a spontaneous leak might have persisted as long as portal hypertension was high, maintaining the pleural effusion *via* small gaps in the diaphragm as in hepatic hydrothorax, which occurs in about 5%-12% of liver cirrhosis patients[11]. A recent review described a clinical response rate of about 70% in 198 patients with hepatic hydrothorax after TIPS placement. However, controlled studies are still missing. No case of chylothorax was described in these patients[12].

In summary, this case shows that massive chylothorax can develop in patients with otherwise well compensated liver cirrhosis and that it can be treated effectively by TIPS placement.

Abstract

The local injection of triamcinolone acetonide (TA) is effective in preventing pyloric stenosis and deformity following large endoscopic submucosal dissection (ESD). However, because of its long-acting nature, TA can induce long-term local immunosuppression and subsequent adverse events. We report a case of a cytomegalovirus (CMV) ulcer that formed only at the TA local injection site. A 68-year-old man underwent ESD to treat early gastric cancer that formed over the pylorus. The lesion extended to the duodenum, and an artificial ulcer covered more than two-thirds of the circumference of the pylorus. To prevent pyloric stenosis, TA was locally injected into the ulcer floor. On day 12, a deeper ulcer 10 mm in diameter was discovered in the center of the post-ESD ulcer. Biopsies revealed large cells with intranuclear inclusion bodies, which stained positive for the anti-CMV antibody. Local TA injections are useful, however, CMV ulcer might occur as adverse events.

INTRODUCTION

Endoscopic submucosal dissection (ESD) for early gastric cancer was developed to resect larger lesions *en bloc*[1-4]. ESD has an advantage over endoscopic mucosal resection in that it enables *en bloc* tumor removal[5-8]. However, ESD creates a large artificial ulcer that can lead to gastric stenosis[9]. In recent years, the local injection of triamcinolone acetonide (TA) has reportedly prevented post-ESD esophageal stricture, pyloric stenosis, and deformity following large ESDs because TA promotes the formation of granulation tissue at an early stage in the healing process, which leads to gastric mucosa regeneration[10-12]. However, because of its long-acting nature, TA can induce long-term local immunosuppression and can cause subsequent adverse events. We report a case of cytomegalovirus (CMV) ulcer formation that occurred only at the local TA injection site. This is the first case report of a side effect of local TA injection after treatment of an ESD ulcer floor in a non-compromised host.

CASE REPORT

A 68-year-old man underwent ESD to treat early-stage gastric cancer that was located over the pylorus (Figure

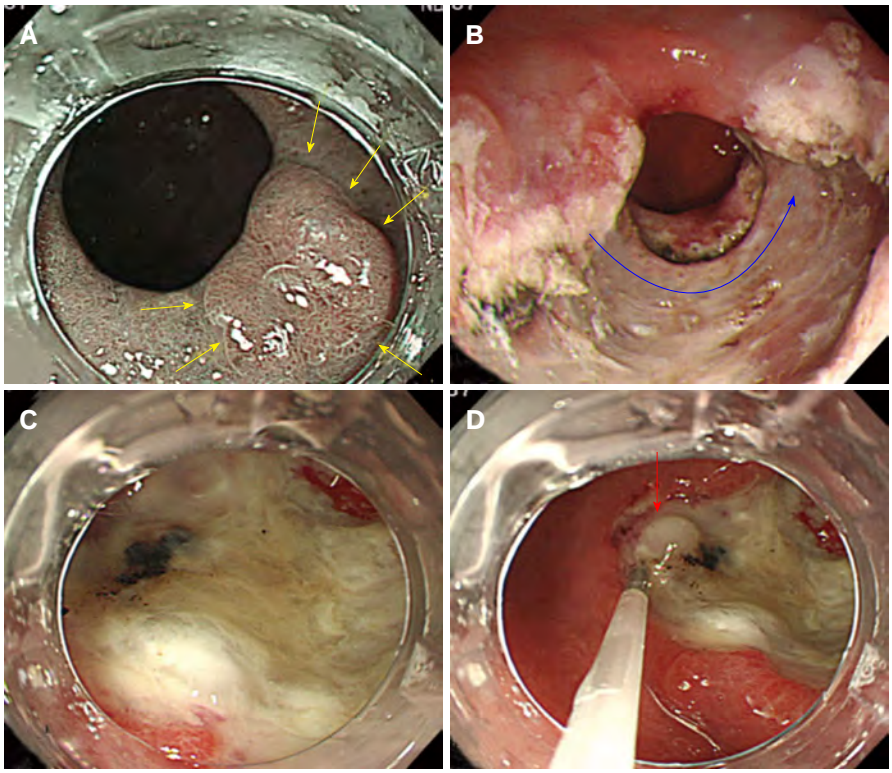

Figure 1 Endoscopic findings of tumor, post-endoscopic submucosal dissection ulcer and triamcinolone acetonide injection. A: An narrow band imaging endoscopic image reveals a flat, early gastric cancer lesion extending over the gastric outlet to the pylorus (yellow arrows); B: A post-endoscopic submucosal dissection artificial ulcer covering two-thirds of the circumference of the pylorus (blue curved arrow); C: The ulcer floor covered by a thick layer of white moss; D: Triamcinolone acetonide (2 mL) was injected locally at each site (red arrow).

1A). The lesion partially extended to the duodenum, and an artificial ulcer that formed after dissection covered over two-thirds of the pylorus circumference (Figure 1B). As routine pre-ESD examination, we conducted serology test, electrocardiogram, respiratory function test, abdominal ultrasound examination and computed tomography. These results indicated no underlying disease. To prevent pyloric stenosis, TA was locally injected into the ulcer, which was covered with white moss (Figure 1C) in 5-mm intervals [0.2 mL (2 mg)] at each site, on postoperative day 5 (Figure 1D). On day 12, abundant granulation tissue had formed over the ulcer, but another deeper ulcer approximately 10 mm in diameter was discovered centered in the post-ESD ulcer (Figure 2A). Biopsies that were conducted from the margin of the deeper ulcer revealed large cells with intranuclear inclusion bodies (Figure 2C) that stained positive for anti-CMV antibody staining (Figure 2D). As the patient wasn't a compromised host and had no other underlying disease, we thought the CMV activity of the ulcer floor was limited and focal. The CMV ulcer was occurred under focal immunosuppressive condition by TA. We considered after TA effect would subside about for 14 d, the CMV activity would decrease and the ulcer healed. We conducted frequent follow up endoscopy at POD12, 20 and 30, and confirmed negative conversion of CMV by serology test and histopathological examination. The deeper ulcer improved gradually (Figure 2B), and on day 20, the biopsies were negative for anti-CMV antibody staining. The post-ESD artificial ulcer healed without any pylorus stricture.

DISCUSSION

Some clinical studies have recommended administration of oral prednisolone[10] and local TA injection into post-ESD artificial ulcers[11] in order to prevent severe esophageal stenosis. The beneficial effects of this procedure were introduced at the Conference of Japan Gastroenterological Endoscopy in April 2009, and some clinical trials reported on the efficacy of local TA injections and oral prednisolone administration. After these reports, we reported that local TA injection into the floor of a post-ESD artificial gastric ulcer promotes the formation of granulation tissue in an early stage of the healing process, which leads to regenerated gastric mucosa without mucosal convergence or gastric deformity[12]. As our previous report, we conducted local steroid injection into post-ESD artificial ulcers to 21 patients and analyzed them according to the protocol, there were no complications. So, this case was the first case of CMV-associated ulcer development related to the side effects of local steroid injection following ESD. Pharmacologically, TA modulates the wound-healing process for post-ESD ulcers by suppressing inflammatory cell infiltration and fibrosis. This wound healing is caused by decreasing the procollagen-proline dioxygenase or prolyl hydroxylase levels. Decreasing the levels of these enzymes reduces the tissue

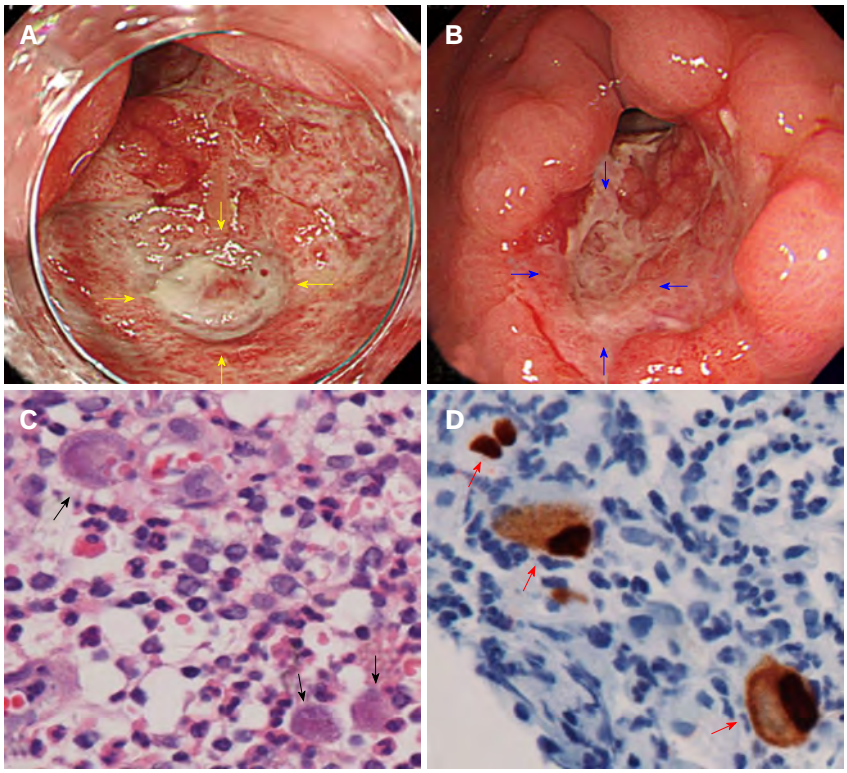

Figure 2 Endoscopic findings of cytomegalovirus associated ulcer and microscopic examination. A: Artificial ulcer on postoperative day 12, showing the formation of abundant granulation tissue and a 10-mm-deep ulcer at the center of the granulation tissue (yellow arrows); B: The healing process of the deep ulcer (blue arrows) on postoperative day 15; C: A biopsy from the deeper ulcer margin revealed large cells with intranuclear inclusion bodies (black arrow, HE staining, × 600); D: Large cells with intranuclear inclusion bodies stained positive for anti-cytomegalovirus (CMV) antibodies (red arrows, anti-CMV antibody immunohistochemical staining, × 600).

collagen component[13]; in this way, the local TA injection promoted the formation of flat and sufficient granulation tissue without fibrotic contraction. However, no infections or adverse effects were reported following local steroid injection into the post-ESD artificial esophageal or gastric ulcer floor. Subclinical CMV infection is high among Japanese infants (about 90%). Latent infection, which is established in the granulocytes and monocytes, can be reactivated by administering potent immunosuppressants, such as steroids[14]. Although the CMV ulcers generally occurred in compromised hosts, in our case, the formation of a CMV ulcer was likely caused by an inflammatory reaction in the post-ESD ulcer and reactivation of the latently infected granulocytes and monocytes, which had migrated to phagocytize the necrotic and granulation tissues on the ulcer floor. Ulcer healing occurred after 14-21 d when the TA effects had subsided. The local injection of TA is effective in preventing post-ESD esophageal stricture or pyloric stenosis; however, after the CMV is reactivated, the long-acting nature of TA may delay the healing process. CMV is recognized an important pathogen of severe infections in immunocompromised hosts, and causes CMV mononucleosis with multi-organ involvements. In general, CMV-related ulcers might make multiple and deeper lesions in digestive tract in upper gastrointestinal endoscopy[15].

In this case, the ulcer located at the center of the post-ESD artificial ulcer floor which was limited and local area under focal immunosuppressive condition by TA.

In conclusion, the local steroid injection might be an etiological factor for CMV-associated ulcers. We advise that clinicians observe the ulcer floor following TA injections and quickly treat CMV-associated ulcers with ganciclovir if needed.

Abstract

Adverse reactions to mesalamine, a treatment used to induce and maintain remission in inflammatory bowel diseases, particularly ulcerative colitis, have been described in the literature as case reports. This case illustrates an unusual adverse reaction. Our patient developed an isolated fever of unexplained etiology, which was found to be related to mesalamine treatment. A 22-year-old patient diagnosed with ulcerative colitis developed a fever with rigors and anorexia 10 d after starting oral mesalamine while his colitis was clinically resolving. Testing revealed no infection. A mesalamine-induced fever was considered, and treatment was stopped, which led to spontaneous resolution of the fever. The diagnosis was confirmed by reintroducing the mesalamine. One year later, this side effect was noticed again in the same patient after he was administered topical mesalamine. This reaction to mesalamine seems to be idiosyncratic, and the mechanism that induces fever remains unclear. Fever encountered in the course of a mesalamine treatment in ulcerative colitis must be considered a mesalamine-induced fever when it cannot be explained by the disease activity, an associated extraintestinal manifestation, or an infectious etiology.

INTRODUCTION

Mesalamine is a well-known treatment for inflammatory bowel diseases (IBDs), particularly ulcerative colitis (UC), in which it is used for remission induction and maintenance therapy. Mesalamine is considered a safe drug, but some side effects have been described in the literature. We report a case of mesalamine-induced isolated fever in a patient with UC.

CASE REPORT

A 22-year-old-man presented with a 1 wk history of apyretic acute bloody diarrhea, which was treated with 500 mg of metronidazole three times a day (TID) without clinical improvement. At this stage, flexible sigmoidoscopy showed diffuse hyperemic mucosa with few erosions. The biopsies indicated infectious colitis. The blood analysis and stool exam were normal. Treatment with 500 mg of ciprofloxacin twice a day and 500 mg of metronidazole TID was prescribed. Ten days later, the patient's clinical condition worsened, with passage of 5 stools per day with mucus and blood. A complete colonoscopy was performed, which demonstrated diffuse pancolitis with superficial ulcerations, loss of vascular

pattern and easy contact bleeding from the mucosa. The terminal ileum was normal. The colonic biopsies were consistent with UC. The blood analysis at this time was also unremarkable except for the C reactive protein (CRP) level, which was 17 mg/dL. Treatment with 4 g of pH-dependent release mesalamine (Asacol®) was started, and a significant clinical improvement was noted, with resolution of the bloody diarrhea and passage of 2 normal stools per day. Ten days later, while the patient was doing well, he presented with a 39 ℃ fever with rigor, myalgia and anorexia. Upon admission, 6 d after the fever onset, his physical examination was normal.

A blood analysis showed a hemoglobin level of 12.2 g/dL, a white blood cell count of 8600/mL (of which 77% were granulocytes), a platelet count of 264 000/mL, and a CRP level of 104 mg/dL, with normal levels of liver and pancreatic enzymes. Serologies for typhoid fever, brucellosis, parvovirus, Epstein Barr virus and cytomegalovirus were negative. Stool, blood and urine cultures were also negative. The tuberculosis skin test was normal as well as the chest X-ray and cardiac ultrasound. The mesalamine was discontinued, and the fever was treated symptomatically with paracetamol. Two days later, the patient's clinical condition improved, with the disappearance of the febrile syndrome and a decrease in the CRP level to 62 mg/dL. After discussing the matter with the patient and because a reactivation of the colitis was feared, particularly after the rapid remission that was obtained with the use of 5-aminosalicylic acid (5-ASA), we decided to reintroduce another time-dependent release mesalamine (Pentasa®) under medical surveillance. After administering the second dose, the patient presented with a 38.5 ℃ fever with rigors. Mesalamine was stopped, and the fever resolved the following day without any intervention. The diagnosis of fever related to mesalamine was confirmed. Two days later, the patient presented with bloody diarrhea, and a treatment with 40 mg of prednisone and 150 mg of azathioprine was started, with rapid improvement. The patient was discharged in good condition. Two months later, the prednisone was stopped after tapering, and the patient was maintained in clinical remission with azathioprine. Eight months later, the patient presented with a flare-up of his colitis. He consulted another gastroenterologist, who treated him with suppositories of Asacol because the rectosigmoidoscopy showed an active proctitis. Two days later, the patient presented with the same symptoms encountered with oral mesalamine (*i.e.*, fever and rigors), which spontaneously resolved after stopping the topical treatment.

DISCUSSION

The 5-ASA agents are known to be safe and remain among the first-line approaches for inducing remission and preventing relapse in UC[1]. These benefits of 5-ASA agents are less impressive in the treatment of mild to moderate Crohn's disease. Their possible role in chemoprevention of colon cancer strengthens the indication for the long-term use of 5-ASA[2].

The efficacy of sulfasalazine in UC has been known since 1940, but the use of this drug was problematic because of its side effects, either dose related or idiosyncratic reactions, such as headache, dyspepsia, nausea, hypersensitivity rash, hemolytic or aplastic anemia, and pulmonary or hepatic dysfunction[3]. The identification in sulfasalazine of the 5-ASA moiety, which is responsible for the therapeutic effects, led to the development of new drugs that delivered 5-ASA directly to the colonic mucosa with fewer side effects.

These new drugs included mesalamine or 5-ASA itself, olsalazine (Dipentum; a dimer of 5-ASA) and balsalazide (Colazal or Colazide; a pro-drug of 5-ASA). In their systematic review of the safety of 5-ASA-based agents, Loftus *et al*[3] concluded that all of these agents appeared to be safe and that the fraction of patients experiencing adverse events was similar to that seen in patients treated with placebo.

However, severe adverse events encountered with mesalamine therapy have been reported as isolated cases. A French pharmacovigilance study of mesalamine microgranules (Pentasa) reported between 6.6 and 9.0 adverse events per million treatment days over a 2-year period, including cases of pancreatitis, hepatitis, pericarditis and hematological disturbances[4,5]. Other side effects have also been reported, such as worsening colitis, renal toxicity (interstitial nephritis and nephrotic syndrome), pulmonary toxicity (interstitial lung disease and fibrosis, bronchiolitis obliterans, pulmonary granulomatosis and eosinophilic pleural effusion) hair loss and Stevens-Johnson syndrome[6]. Some of these drug-related complications must be distinguished from the extraintestinal manifestations of IBD, and they may arise independently of disease activity. The causal relationship between mesalamine administration and the occurrence of the adverse event is established by the appearance of the symptoms after the administration of the 5-ASA compound, the rapid resolution of the symptoms after discontinuation and the reoccurrence of the same symptoms if the treatment is restarted[6].

The mechanism by which mesalamine induces side effects remains unclear. In some cases, the occurrence of a complication seems to be dose related, whereas in other cases it appears to be more of an idiosyncratic reaction[7]. Moreover, the pathogenesis of the fever induced by mesalamine remains unknown.

In cases of acute pancreatitis, the suggested mechanism is an increased permeability of the pancreatic duct directly due to the effects of salicylic acid[8]. In cases of mesalamine-induced exacerbation of UC[9] or myocarditis[10], eosinophilic infiltration of the colon and the myocardium point to an allergic drug reaction.

Mesalamine-related complications are known to occur with oral and topical preparations. Some reports have claimed an absence of cross reactivity among different 5-ASA-based drugs[11].

Our patient presented with an isolated fever while his bloody diarrhea was improving. Mesalamine-induced isolated fever has been reported by Gonzalo *et al*[12] and the causal relationship was proved by a placebo-controlled challenge test and a protocol of desensitization, which was realized successfully. We realized, under medical surveillance, a challenge test with a different 5-ASA drug, and the fever reappeared earlier than the first time (1 d *vs* 10 d). On both occasions, no other causes of fever could be identified, and the fever disappeared spontaneously after stopping the drug. Moreover, reintroducing the mesalamine in suppository form one year later led to the same side effect: an isolated fever that also resolved after stopping the treatment. Although mesalamine seemed to be efficacious, we did not choose to adopt a desensitization protocol at that time because the patient feared a more severe reaction, and we needed another strategy to treat the reactivated colitis.

In conclusion, mesalamine appears to be safe and to achieve good results in IBD patients, particularly those with UC. Side effects of 5-ASA-based drugs are rare, but they should be distinguished from extraintestinal manifestations and should be suspected when the symptoms resolve with the discontinuation of the treatment and reappear with its reintroduction. An isolated fever can reappear on multiple occasions after the reintroduction of various formulations of mesalamine, as illustrated in our case report.

Abstract

Acute massive duodenal bleeding is one of the most frequent complications of peptic ulcer disease. Endoscopy is the first-line method for diagnosing and treating actively bleeding peptic ulcers because its success rate is high. Of the small group of patients whose bleeding fails to respond to endoscopic therapy, increasingly the majority is referred for embolotherapy. Indeed, advances in catheter-based techniques and newer embolic agents, as well as recognition of the effectiveness of minimally invasive treatment options, have expanded the role of interventional radiology in the management of hemorrhage from peptic ulcers over the past decade. Embolization may be effective for even the most gravely ill patients for whom surgery is not a viable option, even when extravasation is not visualized by angiography. However, it seems that careful selection of the embolic agents according to the bleeding vessel may play a role in a successful outcome. The role of the surgeon in this clinical sphere is dramatically diminishing and will certainly continue to diminish in ensuing years, surgery being typically reserved for patients whose bleeding failed to respond all previous treatments. Such a setting has become extremely rare.

TO THE EDITOR

We read with great interest the recent article by Wang *et al*[1] published in the September issue of the *World Journal of Gastroenterology* evaluating the efficacy and safety of emergency transcatheter arterial embolization (TAE) for patients with acute massive duodenal ulcer hemorrhage. We have several comments and questions.

Transcatheter embolization is now accepted as the salvage treatment of choice for acute bleeding from gastroduodenal ulcers. Many published studies have confirmed the feasibility of this approach and the high technical and clinical success rates, ranging from 91% to 100% and from 63% to 100%, respectively, in all case-series including more than 10 patients over the last decade[2,3].

First, we are surprised in the present study that 19 (65.5%) of the 29 patients had no endoscopic hemostasis prior to TAE. In our experience, endoscopic therapy remains the first treatment modality in the management of bleeding peptic ulcers, even in those presenting with massive bleeding. On the other hand, it seems that the authors performed TAE in the gastroduodenal artery territory in 3 patients who did not undergo preliminary endoscopy and for whom angiography was negative. Does it mean that TAE was carried out in these patients without neither endoscopic nor angiographic data? Could the authors clarify this point? Indeed, several pre-

vious studies found that empiric embolization based on endoscopic findings, in the absence of contrast extravasation, was helpful in achieving bleeding control, with no difference according to whether angiography identified the bleeding site[4,5]. However, accurate endoscopic localization of the bleeding site is a prerequisite to allow empiric embolization for angiographically negative upper gastrointestinal bleeding.

Second, we would like to congratulate the authors on their high clinical success rate of 93% (27 of the 29 patients). However, we are surprised that these results were obtained with the use of sponge particles as the only embolic agent. Although the influence of the type of embolic agent on the clinical outcome is controversial, several authors reported a high rate of bleeding recurrence when gelfoam was used alone[6,7], whereas the clinical success was relatively high in recent series in which glue was used as the only embolic agent[8,9]. In addition, two studies demonstrated a statistically significant association between the use of coils as the only embolic agent and greater rebleeding rates[2,10]. On the other hand, good results were reported with the combination of gelatin sponge and coils[2,11]. Based on our experience and the literature, we do not recommend the use of coils alone but in combination with gelfoam or glue, when using the sandwich technique in areas with rich collaterals like the gastroduodenal artery territory[2,10]. It allows a faster and better hemostasis, especially in patients with coagulopathy.

In addition, the normal collateral pathways after a successful embolization should be systematically checked to avoid retrograde filling through anastomoses as the inferior pancreaticoduodenal artery (IPDA) from the superior mesenteric artery in order to maximize results. Indeed, one explanation for good clinical results in this study might be the systematic use of this technique. It may be worthwhile for readers to know the number of patients in whom additional TAE of the IPDA was performed here. Another plausible explanation for high clinical success rate in this study could be the young age of the study population (36 years), without comorbidities. We know that underlying conditions can contribute to a poor outcome.

In conclusion, we agree with the authors about the safety and efficacy of TAE for the treatment of acute hemorrhage from duodenal ulcers. However, angiography should be performed only after failure of endoscopic hemostasis in such a setting. In most cases, embolization obviates the need for surgery and is associated with lower complications and mortality rates than surgical hemostasis. Although prospective studies are needed to compare these management strategies, the available data suggest that TAE is a good alternative to surgery and could be considered the salvage treatment of choice after failed endoscopic treatment. The role of the surgeon in this clinical sphere will certainly continue to diminish in ensuing years.

APPENDIX	I-VI	Instructions to authors
ABOUT COVER		Editorial Board Member of *World Journal of Gastroenterology*, Metin Basaranoglu, MD, Gastroenterology and Hepatology, Bezmialem Vakif University, Istanbul 34400, Turkey
AIMS AND SCOPE		*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries. The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.
INDEXING/ABSTRACTING		*World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

One of the main changes of the current TNM-7 is the elimination of the category MX, since it has been a source of ambiguity and misinterpretation, especially by pathologists. Therefore the ultimate staging would be better performed by the patient's clinician who can classify the disease M0 (no distant metastasis) or M1 (presence of distant metastasis), having access to the completeness of data resulting from clinical examination, imaging workup and pathology report. However this important change doesn't take into account the diagnostic value and the challenge of small indeterminate visceral lesions encountered, in particular, during radiological staging of patients with colorectal cancer. In this article the diagnosis of these lesions with multiple imaging modalities, their frequency, significance and relevance to staging and disease management are described in a multidisciplinary way. In particular the interplay between clinical, radiological and pathological staging, which are usually conducted independently, is discussed. The integrated approach shows that there are both advantages and disadvantages to abandoning the MX category. To avoid ambiguity arising both by applying and interpreting MX category for stage assigning, its abandoning seems reasonable. The recognition of the importance of small lesion characterization raises the need for applying a separate category; therefore a proposal for their categorization is put forward. By using the proposed categorization the lack of consideration for indeterminate visceral lesions with the current staging system will be overcome, also optimizing tailored follow-up.

Staging colorectal cancer with the TNM 7th: The presumption of innocence when applying the M category. *World J Gastroenterol* 2013; 19(8): 1152-1157 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1152.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1152

INTRODUCTION

Stage Ⅳ colorectal cancer (CRC) is no longer considered a single entity[1] and after several proposals for stratifying it[2,3] the current TNM-7 subdivides the M1 category into M1a (metastasis confined to one organ: liver, lung,

ovary, non-regional lymph node(s) and M1b (metastasis in more than one organ or the peritoneum): accordingly stage Ⅳ is subdivided in IVA (Any T, Any N, M1a) and IVB (Any T, Any N, M1b)[4]. Population-based studies demonstrate that the prognosis for surgically resected stage Ⅳ disease is near identical for that of patients following potentially curative surgery for stage Ⅲ disease[5].

The prognosis and treatment options (including increasingly used multimodality approaches) within the M1 stages depend largely on the extent and distribution of the metastases. Therefore, the current staging will be able to take into account improvements that have been made in surgical techniques for resectable metastases, and the impact of modern chemotherapy on rendering initially unresectable CRC liver metastases operable, while at the same time distinguishing between patients with a chance of cure at presentation and those for whom only palliative treatment is possible[3].

An other major change with the new TNM-7 is that the category "MX: Distant metastasis cannot be assessed" has been eliminated[4].

In this report, the change with the TNM-7 is discussed in a multidisciplinary setting and the diagnostic significance of small indeterminate visceral lesions encountered during radiological staging of patients with colorectal cancer is presented.

The resulting problems, in particular the ambiguities for stage assigning when applying the MX category and the risk of inaccurate staging and follow-up planning because of its elimination, are discussed. A proposal is presented for the categorization of such small, indeterminate visceral lesions.

CHANGE WITH THE TNM FROM THE PATHOLOGIST POINT OF VIEW

There are basically two reasons for MX elimination. Firstly the MX category has been a source of misinterpretation, especially by pathologists (*i.e.*, pMX) who "may assign MX, meaning that they cannot assess distant metastasis"[6]. This is a clinical, not pathological assessment. "If there are no obvious signs of metastasis, M0 or cM0 classifications are appropriate. In other words, once clinically examined, a patient is M0 until proven otherwise"[6] in analogy with the legal right Presumption of Innocence.

The second reason is that assigning the MX category prevents stage grouping by American cancer registries[6].

The elimination of MX allows only two categories, M0 (cM0): no distant metastasis and M1 (cM1 or pM1): distant metastasis[4] utilizing imaging and/or pathological assessment[7].

This goes against the TNM rule of assigning the X category, since the proper use of X is to denote the absence or uncertainty of assigning a given category[8] but importantly these are two different situations.

A similar clinical-pathological context is encountered when applying the R classification (R for residual as descriptor of "tumour remaining in the patient" after primary surgical resection): the assignment of the R classification must be performed "by a designated individual who has access to the complete data"[9].

Despite extensive clinical assessment of treatment results and careful pathologic examination, in some cases the presence of residual tumour cannot be assessed: the RX category applies[9,10].

If the pathologist hasn't access to the preoperative clinico-radiological work-up, he/she can do only a limited staging (pT and pN), in the dark about these clinical data.

As an accurate pathological examination is the prerequisite for a prognostic staging and a tailored patient treatment, the enhanced search for additional prognostic factors applies in particular cases (problems with resection margins assessment; involvement of the peritoneum and/or adjacent structures or organs; suspicion for vascular invasion; few lymph nodes recovered; pericolonic tumour deposits)[11,12].

In this setting, patient characteristics, treatment-related features and disease extension as evaluated both during surgery and preoperatively are all relevant information.

In other words, the stage grouping, as well the risk assessment of patients belonging to the same stage, are better performed in the multidisciplinary setting than considered in isolation.

RADIOLOGICAL STAGING

The major task of radiological staging is the exclusion (cM0) or detection (cM1) of metastases, particularly in the liver and/or the lung. The most frequently used imaging modalities for staging of CRC cancer patients are ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET)/CT (PET/CT)[13]. In the past 10 years, important advances have been made within all four techniques. While some (CT and PET/CT) will give patient specific information regarding abnormal masses and increased tissue metabolic activity throughout the body, others (MRI) will yield organ (liver) specific information and allow characterization of specific abnormalities to differentiate benign from malignant lesions. However, no single modality will diagnose all metastases, and the optimal imaging strategy to classify cM0 or cM1 depends on the clinical context, the organ site investigated, and the individual aims of oncologic care.

With the introduction of multidetector row CT (MDCT) scanning, CT imaging will continue to play the dominant role in the radiological staging of CRC patients[14]. Improved MDCT technologies have resulted in increased CT detection of small (< 1 cm) indeterminate lesions in the lung and/or liver (in around 10%-40% of CT CRC staging examinations)[15-20].

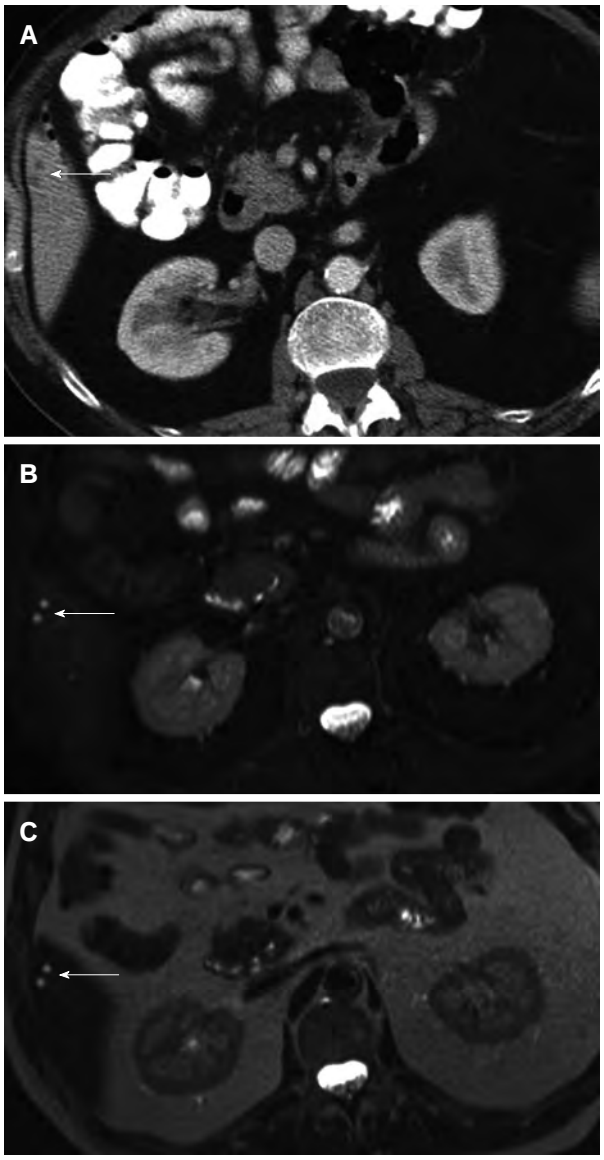

Figure 1 Example of a small lesion which proved to be benign after follow-up. A: Two small (< 10 mm) indeterminate focal liver lesions (white arrow) on contrast-enhanced computed tomography; B: Corresponding magnetic resonance imaging (MRI), images showing a T2w Turbo Spin Echo sequence with fat suppression. Two clearly hyperintense focal liver lesions (white arrow) are displayed compatible with simple liver cysts; C: Corresponding MRI images showing a T2w Turbo Spin Echo sequence without fat suppression. Two clearly hyperintense focal liver lesions (white arrow) are displayed compatible with simple liver cysts.

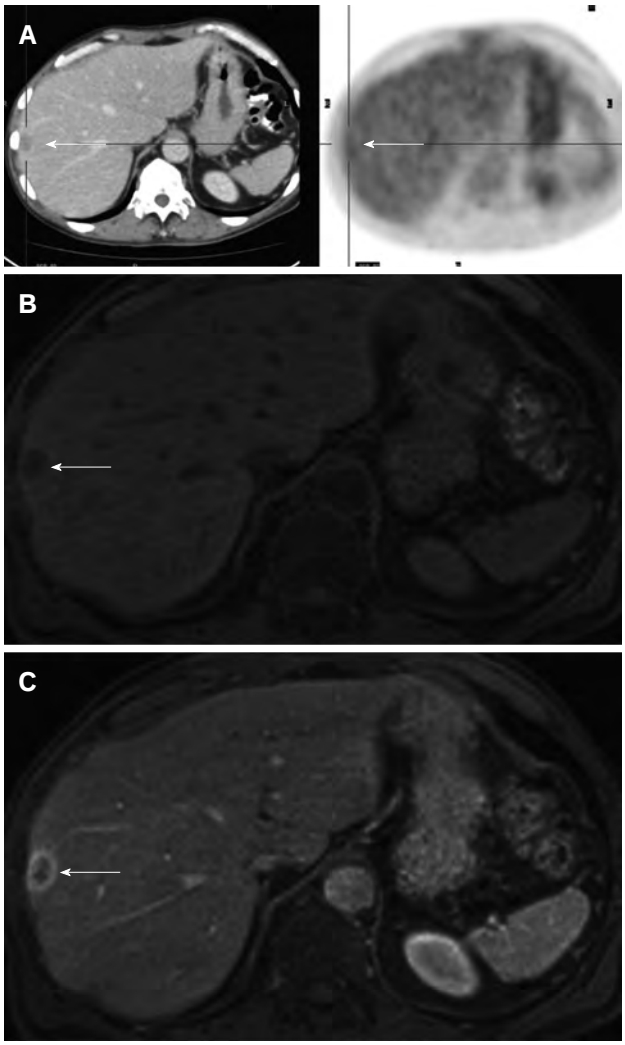

Figure 2 Example of a small lesion which proved to be malignant after follow-up. A: Positron emission tomography (PET)/computed tomography negative (PET-cold) focal liver lesion (white arrow) in a patient who received chemotherapy in the past; B: Corresponding T1w Gradient Echo magnetic resonance imaging (MRI) image before injection of contrast agent shows a rather hypo-intense focal liver lesion (white arrow); C: Corresponding T1w Gradient Echo MRI image in the venous phase after injection of contrast agent shows a hypo-intense focal liver lesion with ring-enhancement compatible with an (active) malignant focal liver lesion (colorectal cancer liver metastasis) (white arrow).

A major drawback of MDCT is that its ability to detect small lesions has outstripped its ability to characterize them. Although most tiny lung and/or liver lesions detected on CT staging of CRC patients are benign (Figure 1), 10%-20% of CT-indeterminate lung and/or liver lesions do develop into definite metastases (Figure 2)[17,18,20,21]. The M stage of CRC patients with CT-indeterminate lung and/or liver lesions, therefore, would require the category MX ("X" meaning uncertainty).

Regarding the definite diagnosis of whether or not these lesions are benign or malignant, consideration should include the T stage and the nodal status of the primary tumour and the distribution patterns of lesions as the probability of malignancy of small lung or liver lesions depends on the stage of the primary tumour (T stage) and the nodal status (N stage)[17,18].

Further evaluation with complementary imaging modalities is needed in patients with small CT-indeterminate lesions if a change of M staging would alter the treatment. In the thorax, additional PET/CT may be helpful in the differentiation of a single < 1 cm pulmonary lesion, but it may not be efficient when more than one small lesion is found on MDCT examination. In the liver, US may be the primary modality of choice in cases of advanced liver metastases, whereas contrast-enhanced US[22] MRI[23,24] and/or US-CT fusion imaging tech-

Figure 3 Restaging the liver after neoadjuvant therapy in a patient with multiple liver metastases from rectal cancer. A: On computed tomography (CT) before intravenous contrast, all the metastases disappeared except for a small lesion suspicious of residual disease (white arrow); B: Corresponding CT after intravenous contrast showing the challenging lesion (white arrow); C: Also on magnetic resonance imaging the lesion (white arrow) remains suspicious for malignancy providing indication for a liver resection.

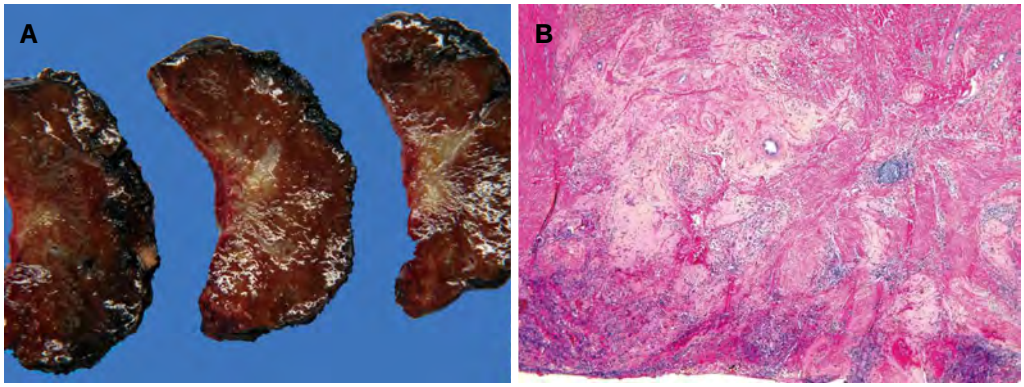

Figure 4 Pathological examination of the resected liver specimen corresponding to the lesion indicated by the white arrow in figure 3. A: Gross specimen: on cut the macroscopic examination shows a star-like whitish lesion; B: At histology (hematoxylin and eosin, x 100) only fibrosis and inflammation are seen indicating a complete response to chemotherapy.

niques[25] may complement the initial CT information in candidates for liver resection.

Follow-up CT imaging may be a reasonable approach in patients in whom a change of M staging would alter the clinical management, as malignant lesions would be expected to grow but benign lesions less so.

During restaging after neoadjuvant chemotherapy, besides the complete clinical remission (disappearance on CT, ycM0) achieved in a small number of patients with metastases (mainly in CRC lung or liver metastases), small lesions, suspected as being residual tumour may be encountered (Figure 3): the difficulties in interpreting these lesions are made harder by the response to chemotherapy which may impact on the sensitivity of preoperative imaging studies in identifying all sites of disease[26].

Either chemotherapy itself, or the fatty infiltration it commonly causes, can affect the ability of CT to effectively restage patients, resulting in both false negative and false positive results; thus, in patients with known hepatic steatosis, or in patients receiving neo-adjuvant chemotherapy, liver MRI is often recommended for staging or restaging of hepatic disease[14].

However, only pathologic examination can determine the actual nature of these lesions (Figure 4).

CONCLUSION

Advantages and disadvantages of the revised TNM classification of metastatic status

Disease management for CRC has evolved in recent years into a multidisciplinary setting and is essentially based on tumour stage.

Cancer staging represents the operational basis for choosing the most appropriate therapy and for evaluating the efficacy of different therapeutic methods; it is an essential component of patient care, cancer research, and control activities, even in light of the impressive progress that has been attained in the fields of clinical strategies and molecular medicine.

The TNM system is subjected to continuous updating through an ongoing expert review of existing data.

Proposals for changes are made in different situations, including when the classification is poorly accepted, poorly used, or criticized in the literature[27]: here comes the decision for MX category elimination[6].

As the MX category results in ambiguity (lack of information or uncertainty in assigning a given category) both in applying and in interpreting it for stage assigning, it seems reasonable to abandon it.

This is also in accord with the general rule of the

TNM system which states that, "if there is doubt concerning the correct category to which a particular patient should be allotted (T, N, or M), then the lower (*i.e.*, less advanced) category should be used"[8].

However, the increased detection of small indeterminate lesions due to improved imaging technologies, particularly with MDCT imaging[20], suggests that a separate category is needed.

This is to avoid the application of M0 category to all indeterminate/suspicious lesions, with consequent reduced diagnostic accuracy and staging errors.

Proposal

Cancer patients with small indeterminate lesions (*e.g.*, in the lung and/or liver) are at risk of developing metastases and therefore need continued follow-up with imaging. The TNM staging system uses an extensive number of prefixes and suffixes, as additional descriptors, their presence indicating cases needing separate analysis[4] and ongoing investigation. We propose to add a suffix (*e.g.*, iPUL, iHEP) to cM0 to indicate the presence of "small indeterminate lesions" considered to be benign but to be surveyed on further follow-up imaging to confirm that they are benign by their unchanged size and radiologic characteristics.

Abstract

Although much is known about how fat accumulates in the liver, much remains unknown about how this causes sustained hepatocellular injury. The consequences of injury are recognized as nonalcoholic steatohepatitis (NASH) and progressive fibrosis. The accumulation of fat within the hepatocytes sensitizes the liver to injury from a variety of causes and the regenerative capacity of a fatty liver is impaired. An additional stressor is sometimes referred to as a "second hit" in a paradigm that identifies the accumulation of fat as the "first hit". Possible candidates for the second hit include increased oxidative stress, lipid peroxidation and release of toxic products such as malondialdehyde and 4-hydroxynonenal, decreased antioxidants, adipocytokines, transforming growth factor (TGF)-β, Fas ligand, mitochondrial dysfunction, fatty acid oxidation by CYPs (CYP 2E1, 4A10 and 4A14), and peroxisomes, excess iron, small intestinal bacterial overgrowth, and the generation of gut-derived toxins such as lipopolysaccharide and ethanol. Oxidative stress is one of the most popular proposed mechanisms of hepatocellular injury. Previous studies have specifically observed increased plasma and tissue levels of oxidative stress markers and lipid peroxidation products, with reduced hepatic and plasma levels of antioxidants. There is also some indirect evidence of the benefit of antioxidants such as vitamin E, S-adenosylmethionine, betaine, phlebotomy to remove iron, and N-acetylcysteine in NASH. However, a causal relationship or a pathogenic link between NASH and oxidative stress has not been established so far. A number of sources of increased reactive oxygen species production have been established in NASH that include proinflammatory cytokines such as tumor necrosis factor (TNF)-α, iron overload, overburdened and dysfunctional mitochondria, CYPs, and peroxisomes. Briefly, the pathogenesis of NASH is multifactorial and excess intracellular fatty acids, oxidant stress, ATP depletion, and mitochondrial dysfunction are important causes of hepatocellular injury in the steatotic liver.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is one of the most prevalent forms of chronic liver disease in the United States[1]. Contributing factors to this may include the increasingly sedentary lifestyle of the population and increased consumption of a high-fat (HF) diet and high fructose corn syrup (HFCS)[2]. In the setting of excessive

central adiposity, insulin resistance is the major underlying cause of fat accumulation in the liver[3-7]. Nonalcoholic steatohepatitis (NASH), as a subgroup of NAFLD, is characterized by chronic and progressive liver pathology and may lead to advanced fibrosis, cirrhosis, end-stage liver disease, hepatocellular carcinoma and liver-related death[8-10]. One of the important and unresolved problems in NASH is the pathogenesis of hepatocyte injury. One hypothesis for the pathogenesis of NAFLD is the "two-hit" hypothesis[11]. According to this paradigm, the primary abnormality ("first hit") is most likely insulin resistance, which leads to the accumulation of triglycerides within the hepatocytes. Then, a "second hit" induces hepatocyte injury and inflammation (NASH). The mechanisms that cause hepatocyte injury in fatty liver have not been fully elucidated to date. Oxidative stress is one of the most popular proposed mechanisms of hepatocellular injury (Figure 1). It was reported that obesity correlated with systemic oxidative stress in humans and mice[12-14]. Obese adults with metabolic syndrome (MS) have higher plasma concentration of oxidative stress biomarkers than obese adults without MS. Increased reactive oxygen species (ROS) production has been selectively shown in adipose tissue of obese mice[15,16]. Previous studies also specifically observed increased plasma and tissue levels of oxidative stress markers and lipid peroxidation products with reduced hepatic and plasma levels of antioxidants in patients with NASH[2-6,12-16].

MOLECULAR SIGNAL OF DEVELOPMENT OF FATTY LIVER IN OBESITY

Obesity is associated with low-grade chronic inflammation in humans, and this chronic inflammation is a link between obesity and insulin resistance[17-19]. Indeed, obesity is strongly associated with chronic macrophage accumulation within increased adipose tissue in obese humans. Xu *et al*[16] showed that inflamed macrophages are active within white adipose tissue and this activation occurs after increased adiposity and before insulin resistance. Macrophages secrete cytokines which promote insulin resistance in adipose tissue and eventually increase adipose tissue lipolysis, which causes insulin resistance in both muscle and the liver, besides significant amount of inducible NO synthase and interleukin-6[15]. Moreover, a positive correlation between adipocyte size and the content of accumulated macrophages in adipose has been reported. Increased fatty acids or accumulated macrophages might be the reason for this increased ROS production within adipose tissue. These data indicate localized inflammation and systemic consequences such as insulin resistance and increased circulating free fatty acids. Additional evidence that this chronic inflammation causes insulin resistance comes from restoring insulin sensitivity by various anti-inflammatory agents, such as high-dose salicylates *via* IKK-β inhibition or anti-tumor necrosis factor (TNF)-α antibody infusion[20].

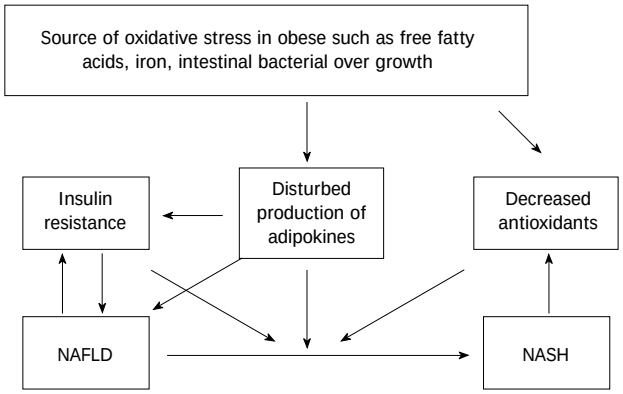

Figure 1 Oxidative stress is one of the most popular proposed mechanisms of hepatocellular injury and possible source of the oxidant stress as follows: increased free fatty acids supply, iron, intestinal bacterial over growth. NASH: Nonalcoholic steatohepatitis; NAFLD: Nonalcoholic fatty liver disease.

OXIDATIVE STRESS AND LIPID PEROXIDATION FOR DEVELOPMENT OF HEPATIC FIBROSIS

A logical and attractive hypothesis is that oxidative stress in TG-loaded hepatocytes is the cause of sustained injury with consequent NASH, fibrosis and cirrhosis[11] (Figure 2). The imbalance between the increased ROS and decreased antioxidants leads to lipid peroxidation of polyunsaturated fatty acids, cellular membranes, mitochondrial membranes, and DNA[21]. Lipid peroxidation products have longer half-lives and the capability to reach extracellular targets. Lipid peroxidation produces cytotoxic aldehydes such as malondialdehyde (MDA) and 4-hydroxynonenal. ROS and these aldehydes further contribute to oxidative stress, decreased ATP production, and increased proinflammatory cytokine release. These events promote hepatocyte injury, necroinflammation and hepatocytes apoptosis. Despite the attractiveness of this hypothesis, most clinical studies only provide correlations between the presence of NASH and elevated indices of oxidant stress, without establishing a causal relationship[22-27]. The lipid peroxidation product 4-hydroxynonenal is found more in perivenular zone (zone 3), correlating with the histological lesions of NASH that are predominantly in zone 3[21]. Lipid peroxidation is greater in patients with NASH than in patients with simple steatosis. The same study has also shown that increased 4-hydroxynonenal strongly correlates with both the grade of necroinflammation and the stage of NASH, but not with the grade of steatosis, while increased evidence of oxidant damage to DNA as measured by 8-hydroxydeoxyguanosine only correlates with the grade of necroinflammation in patients with NASH.

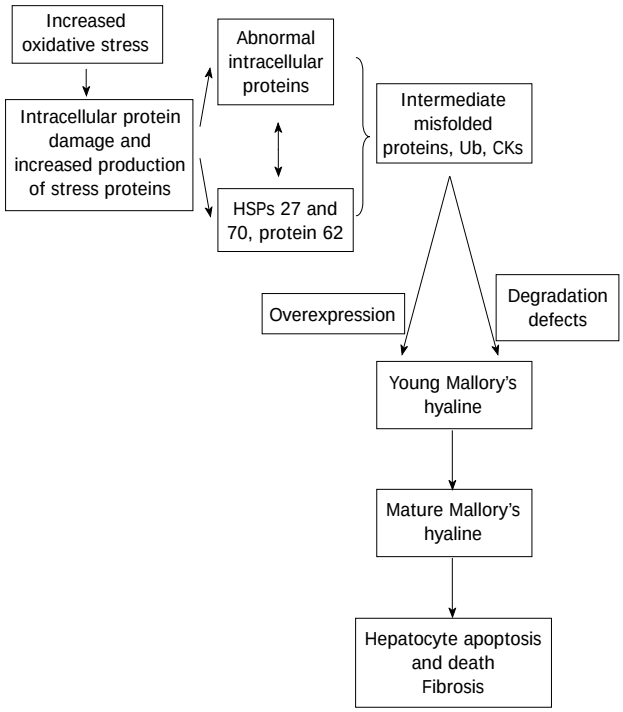

Figure 2 Logical and attractive hypothesis is that oxidative stress in TG-loaded hepatocytes is the cause of sustained injury with consequent **NASH, fibrosis and cirrhosis.** HSP: Heat shock proteins.

UNDERSTANDING THE MOLECULAR MECHANISIMS OF NASH

Oxidative stress

Oxidative stress might play a role in the pathogenesis of hepatocyte dysfunction and inflammation in NAFLD. Oxidative stress can result from either excess ROS production and/or deficient antioxidant capacity[12-15,21]. The enzyme NAD(P)H oxidase catalyzes the transfer of a single electron to molecular oxygen to produce superoxide. Upregulation of NAD(P)H oxidase can raise ROS production, and thereby contribute to the pathogenesis of oxidative stress in HF and high-sucrose-fed mice. Formation of ROS is enhanced by different mechanisms, including xanthine oxidase activation, NADH auto-oxidation, and superoxide dismutase (SOD) inactivation. Experimental evidence supports the concept of diverse ROS, such as superoxide anion, hydrogen peroxide, hydroxyl radical, nitric oxide and peroxynitrite.

Assessment of: (1) NAD(P)H oxidase (a major source of ROS) in liver; (2) downregulation of the main antioxidant enzymes, SOD, glutathione peroxidase (GPX), catalase, and heme oxygenase (HO) in liver tissue; (3) level of lipid peroxidation products, MDA + 4-hydroxyalkenals in the liver; (4) plasma concentration of 8-isoprostanes, lipoperoxides in plasma samples by measuring MDA *via* HPLC; and (5) immunoblotting to quantify NADPH oxidase, Mn SOD, Cu Zn SOD, GPX, catalase, and HO-2 levels in liver will help to understand the underlying mechanisms of oxidative stress in the pathogenesis of NASH[12,13,22-28]. A number of sources of increased ROS production have been established in NASH that include proinflammatory cytokines, such as TNF-α, iron overload, overburdened and dysfunctional mitochondria, CYPs, and peroxisomes.

Sources of oxidants

Mitochondria and mitochondrial β-oxidation: The hepatocyte is a cell rich in mitochondria. Each hepatocyte contains approximately 800 mitochondria[28]. The hepatocyte mitochondria are the main site of β-oxidation of free fatty acids. The electrons removed from free fatty acids during β-oxidation are shuttled through the mitochondrial respiratory chain (MRC), eventually leading to ATP synthesis and generation of CO_2 and water. Inherent in this process is the dissociation of partially reduced molecular oxygen in the form of superoxide, hydrogen peroxide and the hydroxyl radical, species collectively termed ROS. About 1%-5% of oxygen consumed during cellular respiration is not fully reduced to water during this process under physiological conditions, and the production of these ROS is further increased in dysfunctional mitochondria. Thus, mitochondria have been proposed to play a central role in the pathogenesis of NASH[29]. Mitochondria also increase their oxidation capacity for the increased fatty acid flux as observed in obesity and insulin resistant states in humans. However, this increase has its limits and excess free fatty acids are metabolized at other sites in hepatocytes such as peroxisomes (β-oxidation) and the smooth endoplasmic reticulum (ω-oxidation). Acyl-CoA oxidase catalyzes the initial reaction of fatty acid oxidation in peroxisomes; a process that generates hydrogen peroxide and thus may contribute to oxidant stress.

Mitochondrial β-oxidation of short-, medium- and long-chain fatty acids involves multiple steps that include entry of long-chain fatty acids into the mitochondria; a process dependent on carnitine shuttle enzymes carnitine palmitoyltransferase (CPT)-I (an outer membrane enzyme) and CPT-II, and the β-oxidation of fatty acids to form progressively shorter acyl-CoA moieties, acetyl-CoA[29]. These oxidation processes are associated with the reduction of oxidized NAD+ and FAD to NADH and $FADH_2$. Reoxidation of NADH and $FADH_2$ to NAD+ and FAD produces electrons that transfer to the MRC[29,30]. Partially reduced oxygen molecules, termed ROS, are constitutively generated during this process when the electrons of NADH and $FADH_2$ directly react with oxygen and may contribute to oxidant stress if endogenous protective mechanisms are overwhelmed[30]. Consistent with the increased flux of nonesterified fatty acid to the liver in obese patients with NAFLD, mitochondrial β-oxidation of fatty acids in the liver is also increased and as such may contribute to increased generation of ROS and oxidant stress.

Excessive fatty acids might use alternative pathways other than mitochondrial β-oxidation to be metabolized and cause mitochondrial injury. These include

peroxisomal and cytochrome P450 (microsomal CYP) oxidation systems regulated by mainly fatty acids and insulin[31]. These alternative fatty acid oxidation systems produce more ROS and thus their utilization may be a source of oxidant stress.

Peroxisomal fatty acid β-oxidation: Peroxisomal oxidation of fatty acids is the normal route of metabolism of very long chain fatty acids and dicarboxylic acids[31]. Peroxisomal oxidation is a four-step pathway in which electrons from $FADH_2$ and NADH are transferred directly to oxygen. Although this increases the production of hydrogen peroxide, peroxisomes are uniquely endowed with the enzyme catalase that eliminates this reactive oxygen molecule. Fatty acids not oxidized by mitochondria are mainly oxidized by CYP2E1; a process that further increases ROS production within the hepatocytes[32]. Increased endogenous substrate burden such as increased levels of free fatty acids and ketone bodies induce CYP2E1 expression in humans. In normal conditions, CYP2E1 oxidation produces oxygen radicals, but the balance between these ROS and the abundance of endogenous antioxidants determines the extent of resulting oxidant stress. Increased hepatic CYP2E1 expression has been demonstrated by immunostaining of paraffin-embedded liver biopsy sections in patients with NASH. In contrast, hepatic content of CYP3A was decreased in all liver sections from patients with NASH. These studies also showed that weight loss decreased hepatic CYP2E1 activity. In parallel, Leclercq *et al*[33] previously had reported that dietary sugar restriction decreased CYP2E1 activity in humans. These novel studies pointed out that insulin rather than ketone bodies, with or without glucose contribution, regulate the expression and activity of hepatic CYP2E1. These metabolic abnormalities increase hepatic CYP2E1 activity and subsequent pro-oxidant production in patients with NAFLD.

Cytochrome P450 fatty acid ω (omega)-oxidation: Fatty acids can undergo oxidation by the CYP enzymes of the smooth endoplasmic reticulum which is a relatively minor pathway. CYP2E1 and CYP4A isoforms are involved in fatty acid oxidation in conditions with substrate overload such as increased ketone bodies in type 2 diabetes mellitus. CYP4A upregulation particularly occurs in conditions with decreased CYP2E1 activity. The expression of both CYP2E1 and CYP4A mRNA and their protein levels are increased in both obese and diabetic humans[32,33]. Their hepatic activity and expression are also reported to be increased in patients with NASH due to the increased substrates, mainly fatty acids and ketone bodies, irrespective of the underlying clinical condition of diabetes or obesity. Nonetheless, the capacity of this enzyme system is very low to handle fatty acids. Oxidation reactions by the CYP enzymes can be major producers of ROS because of a low degree of coupling between substrate binding and their weak affinity to molecular oxygen, leading to the release of species such as superoxide anion radical, hydroxyl radicals, and hydrogen peroxide.

Mitochondrial dysfunction and ATP depletion: Mitochondria are the organelles primarily responsible for fatty acid β-oxidation and oxidative phosphorylation; the process responsible for the production of ATP[30]. Several observations including decreased mitochondrial enzyme activities and increased fat concentration of skeletal muscle cells in obese or diabetic patients have suggested mitochondrial dysfunction in these disorders. Such abnormalities may increase ROS production and promote both oxidative stress and lipid peroxidation within hepatocytes. Mitochondrial dysfunction is frequently due to a combination of genetic abnormalities, physical inactivity, aging, lipotoxicity (free fatty acids), lipid peroxidation (mitochondrial DNA alterations), and TNF-α[29,30,34]. Hepatic mitochondrial abnormalities have been identified in NAFLD, suggesting that mitochondria may be the source or target of injury and that ineffective mitochondrial function resulting in cellular ATP depletion may be important pathophysiological processes in NAFLD and NASH. The presence of megamitochondria, or mitochondrial swelling, is a microscopically detectable structural abnormality of hepatocyte mitochondria found in a variety of liver diseases including NAFLD[28]. Crystalline inclusions within the mitochondrial matrix have been documented by electron microscopy in patients with NASH. Hepatic mitochondrial DNA levels and the protein products of the mitochondrial genes are also decreased in patients with NASH. Impaired hepatic MRC function increases ROS production, and if ROS production exceeds antioxidant capabilities, oxidative stress and injury, lipid peroxidation of macromolecules and cellular membranes, mitochondrial DNA damage, direct damage of several mitochondrial enzymes, and further MRC dysfunction with more pro-oxidant production are observed. Mixed macro- and microvesicular steatosis due to β-oxidation defects in the mitochondria was the predominant type of steatosis in this study, and CYP 2E1 expression was upregulated, and levels of the antioxidant glutathione were decreased. Carnitine and CPT-I and CPT-II are required to transfer long-chain free fatty acids into the mitochondria for β-oxidation. Some investigators have reported the role of carnitine deficiency in NAFLD development, while others have observed normal hepatic content of total and free carnitine in patients with NASH.

Iron, oxidant stress and NASH: Iron can play a central role in promoting oxidant stress and this is proposed to be the mechanism of progressive liver disease. A large-population based study reported a correlation between elevated serum alanine aminotransferase levels and increased serum transferrin and iron concentrations[35,36]. After initial measurements, investigators in-

duced iron depletion to a level of near-iron deficiency by phlebotomy. Interestingly, they observed improvements in both insulin sensitivity and serum alanine aminotransferase activity in some of the patients, indicating that iron may play a role not only in oxidant stress but also in the initial predisposing factor of insulin resistance.

Free fatty acid toxicity: In addition to insulin resistance and hyperinsulinemia, obesity and type 2 diabetes mellitus are strongly associated with increased concentrations of free fatty acids in the circulation[24,26]. Fatty acids are involved in many important cellular events such as synthesis of cellular membranes, energy storage, and intracellular signaling pathways. However, chronically elevated free fatty acids have the capability to disturb diverse metabolic pathways and induce insulin resistance in many organ systems[37-39]. In addition to their metabolic effects, fatty acids could induce cellular apoptosis, also called lipotoxicity, in two ways: direct toxicity and an indirect effect. One proposed mechanism of fatty acid toxicity in hepatocytes is that fatty acids induce translocation of Bax (which is a mitochondrial protein and a member of the Bcl-2 family) to lysosomes and cause lysosomal destabilization, which promotes the release of cathepsin B (a specific lysosomal enzyme), from lysosomes to the cytosol. Subsequently, a cathepsin-B-dependent process induces nuclear factor (NF)-κB activation and TNF-α overexpression in the liver[26]. TNF-α might further increase lysosomal destabilization and cathepsin-B-dependent hepatocyte apoptosis. Then, cytochrome c release from dysfunctional mitochondria may occur. Mitochondrial dysfunction causes energy depletion, which activates proteolytic caspases and induces DNA fragmentation and chromatin condensation. NF-κB is a transcriptional factor and has both apoptotic and antiapoptotic effects. In healthy hepatocytes, activation of NF-κB by TNF-α induces Bcl-2 synthesis, which prevents the release of cytochrome c from the mitochondria and subsequent apoptosis. Moreover, while cathepsin B has been demonstrated in hepatocyte lysosomes of healthy control individuals, the majority of hepatocytes in patients with NAFLD show diffuse distribution of cathepsin B in the cytosol, with a positive correlation with the stage of NASH[40-44].

HEPATIC FIBROGENESIS IN NASH

Hepatic steatosis is the most frequent and initially observed morphological feature of these processes[45-53]. Steatosis, inflammation, glycogen nuclei, lipogranulomas, ballooning of hepatocytes, Mallory bodies, and fibrosis are the major features of NAFLD.

Genetic and environmental factors may affect the development of liver fibrosis in NAFLD[54-62]. Age, severity of obesity, presence of diabetes, and hyperglycemia are the major nongenetic factors. Elevated plasma glucose, free fatty acids and adipocytokines activate both Kupffer cells and hepatic stellate cells (HSCs) and stimulate fibrogenesis[63-65]. Hepatic connective tissue growth factor (CTGF) mRNA was overexpressed in all NASH patients, while hepatic CTGF mRNA and its protein were upregulated in *fa/fa* rats (obese and diabetic) compared with their lean littermates. The same study also demonstrated upregulation of both CTGF mRNA and its protein in HSCs after exposure to high concentrations of either glucose or insulin. After activation, HSCs proliferate and express α-smooth muscle actin. Activated HSCs express myogenic markers such as c-myb and myocyte enhancer factor-2, exhibit proinflammatory and profibrogenic properties, migrate and secrete extracellular matrix components (ECM) such as collagen, and regulate the degradation of ECM. Activation of HSCs is the crucial step in liver fibrogenesis. A study of NAFLD patients (16 patients with steatosis alone and 60 with NASH) demonstrated that activation of HSCs was positive in almost all cases, and markedly in two thirds of patients, and it was correlated with the degree and location of hepatic fibrosis. HSC activation and upregulation of profibrogenic genes were observed in rats on an HF diet. Lipid-peroxidation-associated inflammation and HSC activation with increased TGF-β1 mRNA expression in methionine-choline-deficient steatohepatitis models have also been reported.

Oxidative stress may also participate in the activation of HSCs and the development of fibrosis in NAFLD. The intracellular NADPH oxidase pathway produces ROS, and the disruption of NADPH oxidase protects mice from developing severe liver injury. Lipid peroxidation products enhance the production of both TGF-β and collagen.

Currently, proposed mechanisms for the transformation from NASH to NASH-associated hepatocellular carcinoma are severe and cumulative oxidative stress to the hepatocytes, production of damaged DNA, defective or inhibited DNA repair systems, chronic continued hepatocyte injury and inflammatory infiltration, impaired antioxidant systems, and increased cell cycle of hepatocytes[65-67]. Animal and human studies have also indicated that a connection between age, sex and the disease might be possible[66-70].

In conclusion, a liver with excess fat may be more vulnerable to stressors than a normal liver. The factors that play key roles in the development of NASH from NAFLD remain uncertain.

Abstract

We aimed to investigate whether increased consumption of fructose is linked to the increased prevalence of fatty liver. The prevalence of nonalcoholic steatohepatitis (NASH) is 3% and 20% in nonobese and obese subjects, respectively. Obesity is a low-grade chronic inflammatory condition and obesity-related cytokines such as interleukin-6, adiponectin, leptin, and tumor necrosis factor-α may play important roles in the development of nonalcoholic fatty liver disease (NAFLD). Additionally, the prevalence of NASH associated with both cirrhosis and hepatocellular carcinoma was reported to be high among patients with type 2 diabetes with or without obesity. Our research group previously showed that consumption of fructose is associated with adverse alterations of plasma lipid profiles and metabolic changes in mice, the American Lifestyle-Induced Obesity Syndrome model, which included consumption of a high-fructose corn syrup in amounts relevant to that consumed by some Americans. The observation reinforces the concerns about the role of fructose in the obesity epidemic. Increased availability of fructose (*e.g.*, high-fructose corn syrup) increases not only abnormal glucose flux but also fructose metabolism in the hepatocyte. Thus, the anatomic position of the liver places it in a strategic buffering position for absorbed carbohydrates and amino acids. Fructose was previously accepted as a beneficial dietary component because it does not stimulate insulin secretion. However, since insulin signaling plays an important role in central mechanisms of NAFLD, this property of fructose may be undesirable. Fructose has a selective hepatic metabolism, and provokes a hepatic stress response involving activation of c-Jun N-terminal kinases and subsequent reduced hepatic insulin signaling. As high fat diet alone produces obesity, insulin resistance, and some degree of fatty liver with minimal inflammation and no fibrosis, the fast food diet which includes fructose and fats produces a gene expression signature of increased hepatic fibrosis, inflammation, endoplasmic reticulum stress and lipoapoptosis. Hepatic *de novo* lipogenesis (fatty acid and triglyceride synthesis) is increased in patients with NAFLD. Stable-isotope studies showed that increased *de novo* lipogenesis (DNL) in patients with NAFLD contributed to fat accumulation in the liver and the development of NAFLD. Specifically, DNL was responsible for 26% of accumulated hepatic triglycerides and 15%-23% of secreted very low-density lipoprotein triglycerides in patients with NAFLD compared to an estimated less than 5% DNL in healthy subjects and 10% DNL in obese people with hyperinsulinemia. In conclusion, understanding the underlying causes of NAFLD forms the basis for rational preventive and treatment strategies of this major form of chronic liver disease.

INTRODUCTION

Excessive accumulation of triglycerides in hepatocytes in the absence of significant alcohol consumption occurs in about 20%-30% of adults[1-5]. Excessive fat in the liver, called nonalcoholic fatty liver disease (NAFLD), predisposes to the development of nonalcoholic steatohepatitis (NASH). NASH constitutes the subset of NAFLD that is most worrisome because it is a significant risk factor for developing cirrhosis and its complications, including hepatocellular carcinoma (HCC)[6-9]. Because the accumulation of excess fat in the liver is a prerequisite for the development of NASH, understanding the underlying causes of NAFLD forms the basis for rational preventive and treatment strategies of this major form of chronic liver disease.

Obesity is a low-grade chronic inflammatory condition and obesity-related cytokines such as interleukin-6 (IL-6), adiponectin, leptin, and tumor necrosis factor (TNF) α may play important roles in the development of NAFLD. The prevalence of NASH is 3% and 20% in nonobese and obese subjects, respectively. Additionally, the prevalence of NASH associated with both cirrhosis and HCC was reported to be high among patients with type-2 diabetes with or without obesity.

OBESITY EPIDEMIC

A balance exists between energy demand and intake in the human body. Obesity is one of the major abnormalities of this well preserved equilibrium. Obesity, and its consequences such as insulin resistance and the metabolic syndrome, is a growing threat to the health of people in developed nations[10]. A diet based on high cholesterol, high saturated fat, and high fructose (cafeteria or fast food type) recapitulates features of the metabolic syndrome and NASH with progressive fibrosis (Figure 1).

"FAST FOOD" OR "CAFETERIA" TYPE DIET COMPOSED OF HIGH SATURATED FATS, CHOLESTEROL, AND FRUCTOSE

The basis of the composition of "fast food" or "cafeteria" style food is high saturated fats, cholesterol, and fructose[11]. As the high fat diet produces obesity, insulin resistance, and some hepatic steatosis with minimal inflammation and no fibrosis, the fast food diet produces a gene expression signature of increased hepatic fibrosis, inflammation, endoplasmic reticulum stress and lipoapoptosis (Figure 2). Our research group previously

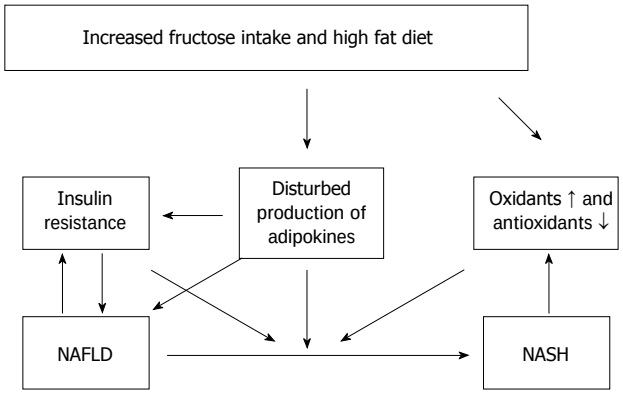

Figure 1 Diet based on high cholesterol, high saturated fat, and high fructose (cafeteria or fast food type) recapitulates features of the metabolic syndrome and nonalcoholic fatty liver disease and nonalcoholic steatohepatitis with progressive fibrosis in human and mice. NAFLD: Nonalcoholic fatty liver disease; NASH: Nonalcoholic steatohepatitis.

showed that consumption of fructose is associated with adverse alterations of plasma lipid profiles and metabolic changes in mice, the American Lifestyle-Induced Obesity Syndrome (ALIOS) model, which included consumption of a high-fructose corn syrup (HFCS) in amounts relevant to that consumed by some Americans[11]. The observation that the ALIOS mice indeed consumed a greater quantity of food beyond the additional calories consumed from the HFCS when fed HFCS compared with control water supports this observation and reinforces the concerns about the role of fructose in the obesity epidemic[12-15]. In adolescents, higher fructose consumption is associated with multiple markers of cardiometabolic risk, but it appears that these relationships are mediated by visceral obesity.

The most commonly used HFCS in soft drinks and other carbohydrate-sweetened beverages is a blend composed of 55% fructose, 41% glucose, and 4% complex polysaccharides. Fructose has increasingly been used as a sweetener since the introduction of high-fructose corn syrups in the 1960s[10-13,16] and is now an abundant source of dietary carbohydrate in the United States. The annual per capita consumption of extrinsic or added fructose was approximately 0.2 kg in 1970 to approximately 28 kg in 1997. This increased consumption has been linked to the increased prevalence of obesity, type 2 diabetes and fatty liver in the United States.

The liver is exquisitely sensitive to changes in nutrient delivery and is uniquely suited to metabolize ingested simple sugars, such as fructose and glucose[13,14]. Stress-activated protein kinases, principally the c-Jun N-terminal kinases (JNK), are activated by cell stress-inducing stimuli. Increased fructose supply provokes a hepatic stress response involving activation of JNK and subsequent reduced hepatic insulin signaling.

UNIQUE METABOLISM OF FRUCTOSE

Fructose, glucose, and galactose are the 3 major dietary

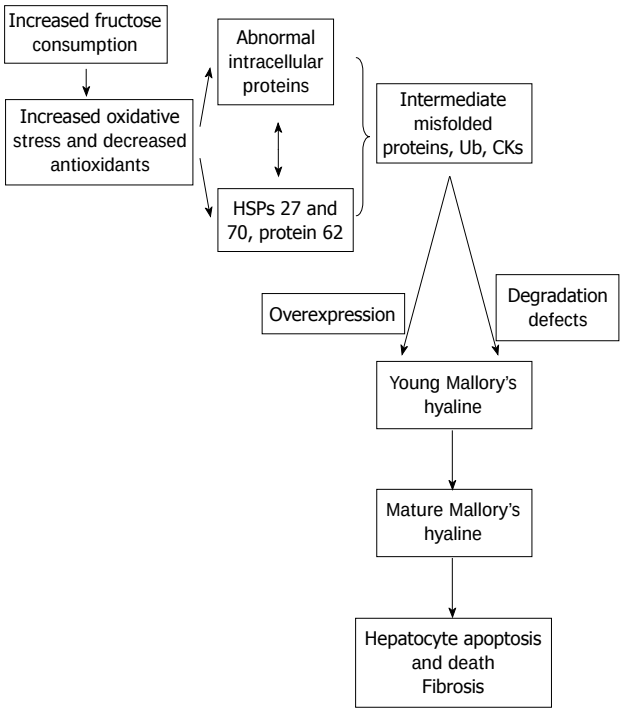

Figure 2 As the high fat diet produces obesity, insulin resistance, and some hepatic steatosis with minimal inflammation with no fibrosis, the fast food diet produces a gene expression signature of increased hepatic fibrosis, inflammation, and endoplasmic reticulum stress and lipoapoptosis. HSP: Heat shock proteins.

monosaccharides. Sucrose (glucose-fructose), lactose (glucose-galactose), and maltose (glucose-glucose) are the major disaccharides. Dietary fructose occurs in 2 forms: mono- or disaccharide. The rate of fructose absorption appears to be between that of mannose and glucose[12-15]. Fructose is absorbed by carrier-mediated facilitated diffusion, an energy-dependent process. The fructose carrier is a member of the glucose transport family and is referred to as glucose transporter 5. Sucrose is cleaved to glucose and fructose by sucrase, an enzyme located in the brush border of small intestine enterocytes.

Fructose was previously accepted as a beneficial dietary component because it does not stimulate insulin secretion. However, since insulin signaling plays an important role in the central mechanisms of NAFLD, this property of fructose may be undesirable[13-15]. Additionally, fructose may prevent suppression of ghrelin secretion, resulting in impaired satiety mechanisms[14]. In large quantities, fructose can also stress the liver by depleting hepatic energy supplies. Normal subjects and patients with NASH exhibited a similar depletion of hepatic ATP levels after an injection of fructose, but recovery of ATP levels after depletion was slower in NASH patients compared with healthy controls. A mixture of fructose and glucose might induce metabolic abnormalities that differ from sucrose, a disaccharide cleaved to fructose and glucose in the small intestine.

Phosphorylation of glucose by glucokinase is a rate-determining step in hepatic glucose metabolism. In contrast to glucose, phosphorylation of fructose in the liver occurs *via* the enzyme fructokinase. In addition, the metabolism of fructose 1-phosphate in the liver occurs independently of phosphofructokinase, a second rate-determining step in glucose metabolism[13-15]. As a result, the liver is the primary site of fructose extraction and metabolism, with extraction approaching 50% to 70% of fructose delivery. Therefore, increased availability of fructose (*e.g.*, high-fructose corn syrup) will increase not only abnormal glucose flux but also fructose metabolism in the hepatocyte. Thus, the anatomic position of the liver places it in a strategic buffering position for absorbed carbohydrates and amino acids.

Fructose extraction and metabolism by the liver are exceptionally high compared to glucose due both to the extensive amount of fructokinase that phosphorylates fructose to fructose 1-phosphate in the liver and to the subsequent metabolism of fructose 1-phosphate at the triose phosphate level, which bypasses flux control at phosphofructokinase[13-16]. Previous studies comparing the metabolism of fructose and glucose in postabsorptive humans over short intervals have shown that fructose is used faster than glucose and that more is converted to liver glycogen. Fructose oxidation represented a significant portion of fructose metabolism, accounting for 56% to 59% of the ingested fructose and approximately 33% of the infused fructose. It is likely that extrahepatic lactate oxidation subsequent to hepatic fructolysis contributed significantly to the estimated rate of fructose oxidation. Thus, increments in fructose after infusion produced immediate changes in hepatic and extrahepatic substrate metabolism, but did not induce changes in overall glucose production. An immediate fructose infusion in humans induced both hepatic and extrahepatic insulin resistance. These data are consistent with the notion that high concentrations of fructose elicit adaptations in the liver that include metabolic intermediates, gene expression, and insulin action.

SYSTEMIC AND HEPATIC INSULIN RESISTANCE IN NAFLD

While insulin receptor defects cause severe insulin resistance, most patients with insulin resistance have impaired post-receptor intracellular insulin signaling. Insulin binds α-subunits of its receptor, which is a cell surface receptor on the major insulin sensitive cells such as skeletal muscle, adipocytes, and hepatocytes, leading to autophosphorylation of the cytoplasmic domains (β-subunits) of the receptor[2-5,17]. The insulin receptor has intrinsic tyrosine kinase activity activated by insulin binding and the autophosphorylated receptor activates its substrates that include insulin receptor substrate (IRS)-1, IRS-2, Src homology collagen, and adaptor protein with a pleckstrin homology and Src homology 2 domain by tyrosine phosphorylation. These phosphory-

lated docking proteins bind and activate several downstream components of the insulin signaling pathways. Activated IRS-1 associates with phosphatidyl inositol 3-kinase, which then activates Akt. These events and insulin-dependent inhibition of hepatic glucose output maintain glucose homeostasis. Insulin also affects glucose homeostasis indirectly by its regulatory effect on lipid metabolism. Any interference in this insulin signaling pathway causes glucotoxicity, insulin resistance and, when islet beta cells are capable of responding, compensatory hyperinsulinemia.

Hepatic expression of insulin receptor protein in humans and the levels of both IRS-1 and IRS-2 in animals were decreased in chronic hyperinsulinemic states[11]. IRS-1 was more closely linked to glucose homeostasis with the regulation of glucokinase expression while IRS-2 was more closely linked to lipogenesis with the regulation of lipogenic enzymes sterol regulatory element-binding protein-1c (SREBP-1c) and fatty acid synthase[18,19]. Additional physiological roles of insulin include regulating the metabolism of macronutrients and stimulating cellular growth. Insulin activates synthesis and inhibits catabolism of lipids while shutting off the synthesis of glucose in the liver.

Adipose tissue is one of the major insulin sensitive organs in the human body and the process of differentiation of preadipocytes to adipocytes is induced by insulin[17,18]. Within the adipose tissue, insulin stimulates triglyceride synthesis and inhibits lipolysis by upregulating lipoprotein lipase activity which is the most sensitive pathway in insulin action, facilitating free fatty acid uptake and glucose transport, inhibiting hormone sensitive lipase, and increasing gene expression of lipogenic enzymes.

PROINFLAMMATORY SIGNALING IN INSULIN RESISTANCE

Protein kinase C theta (PKCθ) and inhibitor κB kinase β (IKK-β) are two proinflammatory kinases involved in insulin downstream signaling[17,18]. They are activated by lipid metabolites such as high plasma free fatty acid concentrations and there is a positive relationship between the activation of PKCθ and the concentration of intermediate fatty acid products. PKCθ activates both IKK-β and JNK, leading to increased Ser 307 phosphorylation of IRS-1 and insulin resistance. Activation or overexpression of IKK-β diminishes insulin signaling and causes insulin resistance whereas inhibition of IKK-β improves insulin sensitivity. Inhibition of IKK-β activity prevented insulin resistance due to TNF-α in cultured cells. IKK-β phosphorylates the inhibitor of nuclear factor kappa B (NF-κB), leading to the activation of NF-κB by the translocation of NF-κB to the nucleus. NF-κB is an inducible transcription factor and promotes specific gene expression in the nucleus. For example, NF-κB regulates the production of multiple inflammatory mediators, such as TNF-α and IL-6. TNF-α and reactive oxygen species could also activate NF-κB[19-22]. In contrast, antioxidants inhibit this activation. NF-κB has both apoptotic and anti-apoptotic effects. The finding that NF-κB deficient mice were protected from high-fat diet-induced insulin resistance suggests that NF-κB directly participates in processes that impair insulin signaling. High-dose salicylates also inhibit NF-κB and subsequently improve insulin sensitivity. These subsequently promote hepatic and systemic insulin resistance. The study group also showed that these results were reversed by curcumin which inhibits NF-κB activity. Curcumin also has the ability to induce antioxidant enzymes and scavenge ROS.

Suppressors of cytokine signaling (SOCS) and inducible nitric oxide synthase are two inflammatory mediators recently recognized to play a role in insulin signaling[23-25]. Induction of SOCS proteins (SOCS 1-7 and cytokine-inducible src homology 2 domain-containing protein) by proinflammatory cytokines might contribute to the cytokine-mediated insulin resistance in obese subjects[26-30]. In fact, the isoforms of SOCS are the members of a negative feedback loop of cytokine signaling, regulated by both phosphorylation and transcription events. SOCS-1, and particularly SOCS-3, are involved in the inhibition of insulin signaling either by interfering with IRS-1 and IRS-2 tyrosine phosphorylation or by the degradation of their substrates. SOCS-3 might also regulate central leptin action and play a role in the leptin resistance of obese human subjects. SOCS might be a link between leptin and insulin resistance because insulin levels are increased in leptin resistant conditions due to the diminished insulin suppression effect of leptin because of insufficient leptin levels. Moreover, SOCS proteins might involve insulin/insulin like growth factor-1 signaling. SOCS-1 knockout mice showed low glucose concentrations and increased insulin sensitivity. SREBP-1c is one of the key mediators of lipid synthesis from glucose and other precursors (*de novo* lipogenesis) in the liver. Indeed, SOCS proteins markedly induce *de novo* fatty acid synthesis in the liver by both the up-regulation of SREBP-1c and persistent insulin resistance with hyperinsulinemia which stimulates SREBP-1c-mediated gene expression. Liver is the insulin clearance organ. Thus, decreased insulin clearance in patients with NAFLD further elevates insulin levels in the circulation and *de novo* lipogenesis in the liver. SOCS-1 and SOCS-3 may exert these effects by inhibiting signal transduction and activator of transcription proteins (STAT), particularly STAT-3, *via* binding Janus tyrosine Kinase (JAK) tyrosine kinase because this binding diminishes the phosphorylation ability of JAK kinase to STAT-3. STAT-3 inhibits the activation of SREBP-1c. Specific STAT-3 knockout mice showed markedly increased expression of SREBP-1c and subsequently increased fat content in the liver. Conversely, inhibition of SOCS proteins, particularly SOCS-3, improved both insulin sensitivity and the activation of

SREBP-1c which eventually reduced liver steatosis and hypertriglyceridemia in db/db mice.

Nitric oxide synthase-2 (NOS2) or inducible nitric oxide synthase (iNOS) production are also induced by proinflammatory cytokines[31]. A high-fat diet in rats causes up-regulation of iNOS mRNA expression and increases iNOS protein activity. Increased production of NOS2 might reduce insulin action in both muscle and pancreas and decreased iNOS activity protects muscles from the high-fat diet induced insulin resistance. It was also shown that leptin deficient ob/ob mice without iNOS were more insulin sensitive than ob wild-type mice. Thus, the production of nitric oxide may be one link between inflammation and insulin resistance.

SOURCES OF LIVER FAT

Accumulation of triglycerides as fat droplets within the cytoplasm of hepatocytes is a prerequisite for subsequent events of NASH. Accumulation of excess triglyceride in hepatocytes is generally the result of increased delivery of non-esterified fatty acids (NEFAs), increased synthesis of NEFAs, impaired intracellular catabolism of NEFAs, impaired secretion as triglyceride, or a combination of these abnormalities[32]. Recent techniques, such as isotope methodologies, multiple-stable-isotope approach and gas chromatography/mass spectrometry, provided valuable information regarding the fate of fatty acids during both fasting and fed states[33] such as the relative contribution of three fatty acid sources to the accumulated fat in NAFLD: adipose tissue, *de novo* lipogenesis, and dietary fat. Additionally, these studies reported that the plasma NEFA pool is the main contributor of both hepatic triglycerides in the fasting state and very low-density lipoproteins (VLDL)-triglycerides in both fasting and fed states.

DYSREGULATED PERIPHERAL LIPOLYSIS

A study showed that adipose tissue makes a major contribution to the plasma NEFA pool, contributing 81.7% in the fasted state and 61.7% in the fed state[33]. Additionally, the contribution of dietary lipids to the plasma NEFA pool was found to be only 26.2% and 10.4% in fed and fasted states, respectively, in the same study. Finally, the contribution of newly made fatty acids (originating from the adipose tissue and liver) to the plasma NEFA pool was 7.0% and 9.4% for the fasted and fed states, respectively.

The liver takes up free fatty acids from the circulating NEFA pool and the rate of uptake depends only on the plasma free fatty acid concentrations. Hepatic NEFA uptake continues despite increased hepatic content of fatty acids and triglycerides[34]. The concentration of free fatty acids is increased in the portal circulation rapidly when lipolysis occurs in visceral adipose tissue. These products directly flux to the liver *via* the splanchnic circulation and contribute to hepatic triglyceride synthesis, NAFLD, and hepatic insulin resistance.

HEPATIC *DE NOVO* LIPOGENESIS

Hepatic *de novo* lipogenesis (fatty acid and triglyceride synthesis) is increased in patients with NAFLD[35-39]. Stable-isotope studies showed that increased *de novo* lipogenesis (DNL) in patients with NAFLD contributed to fat accumulation in the liver and the development of NAFLD[33]. Specifically, DNL was responsible for 26% of accumulated hepatic triglycerides and 15%-23% of secreted VLDL triglycerides in patients with NAFLD compared to an estimated less than 5% DNL in healthy subjects and 10% DNL in obese people with hyperinsulinemia. Interestingly, Donnelly and colleagues demonstrated the similarity between VLDL-triglycerides and hepatic-triglycerides regarding contributions of fatty acid sources (62% *vs* 59% for NEFA contribution, respectively; 23% *vs* 26% for DNL, respectively; and 15% *vs* 15% for dietary fatty acids, respectively) in NAFLD patients. Substrates used for the synthesis of newly made fatty acids by DNL are primarily glucose, fructose, and amino acids; oleic acid (18:1, a ω-6 monounsaturated fatty acid, which is relatively resistant to peroxidation) is the major end product of *de novo* fatty acid synthesis[40-42]. Moreover, simple sugars have the ability to stimulate lipogenesis[33]. Ingested carbohydrates are a major stimulus for hepatic delayed neuronal loss and are thus more likely to directly contribute to NAFLD than dietary fat intake[43-46].

In conclusion, fructose has increasingly been used as a sweetener since the introduction of high-fructose corn syrups in the 1960s and is now an abundant source of dietary carbohydrate in the United States[47-50]. The most commonly used HFCS in soft drinks and other carbohydrate-sweetened beverages is a blend composed of 55% fructose, 41% glucose, and 4% complex polysaccharides[51-55]. This increased consumption has been linked to the increased prevalence of obesity and type 2 diabetes and fatty liver in the United States by increased fructose supply, which provokes a hepatic stress response involving activation of JNK and subsequent reduced hepatic insulin signaling[56-59]. Understanding the underlying causes of NAFLD forms the basis for rational preventive and treatment strategies of this major form of chronic liver disease.

Abstract

Pancreatic cancer, although not very frequent, has an exceptionally high mortality rate, making it one of the most common causes of cancer mortality in developed countries. Pancreatic cancer is difficult to diagnose, allowing few patients to have the necessary treatment at a relatively early stage. Despite a marginal benefit in survival, the overall response of pancreatic cancer to current systemic therapy continues to be poor, and new therapies are desperately needed. Histone deacetylase (HDAC) enzymes play an important role in the development and progression of cancer and HDAC inhibitors (HDACIs) have been shown to induce differentiation and cell cycle arrest, activate the extrinsic or intrinsic pathways of apoptosis, and inhibit invasion, migration and angiogenesis in different cancer cell lines. As a result of promising preclinical data, various HDACIs are being tested as either monotherapeutic agents or in combination regimens for both solid and hematological malignancies. Vorinostat was the first HDACI approved by the Food and Drug Administration for patients with cutaneous T-cell lymphoma. The use of HDACIs in clinical trials, in pretreated and relapsed patients suffering from advanced pancreatic cancer is discussed. Unfortunately, clinical data for HDACIs in patients with pancreatic cancer are inadequate, because only a few studies have included patients suffering from this type of neoplasm and the number of pancreatic cancer patients that entered HDACIs phase Ⅱ/Ⅲ trials, among others with advanced solid tumors, is very limited. More studies recruiting patients with pancreatic cancer remain to determine the efficiency of these therapies.

Key words: Pancreatic cancer; Histone deacetylases; Histone deacetylase inhibitors; Clinical trials

Koutsounas I, Giaginis C, Theocharis S. Histone deacetylase inhibitors and pancreatic cancer: Are there any promising clinical trials? *World J Gastroenterol* 2013; 19(8): 1173-1181 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1173.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1173

INTRODUCTION

Worldwide, over 200 000 people die annually of pancreatic cancer. The incidence of pancreatic cancer varies greatly across regions, with the highest incidence and mortality rates found in developed countries, which suggests roles for lifestyle and environmental factors. Deaths from pancreatic cancer rank fourth among cancer-related deaths in the United States. Risk factors for pancreatic cancer include, among others, high-fat diet, smoking, chronic pancreatitis, primary sclerosing cholangitis, hereditary pancreatitis, family history of pancreatic cancer, and diabetes mellitus. Age seems to be a significant risk factor, with incidence increasing with age.

Due to few early illness indicators and lack of screening tests, pancreatic cancer is difficult to diagnose and often at the time of presentation, the cancer has already become advanced. The overall 5-year survival rate among

patients with pancreatic cancer is < 5%. Approximately 20% of patients present with localized, potentially curable tumors. The majority (95%) of cases of pancreatic cancer are adenocarcinomas, resembling the pancreatic ductal cell. Metastasis of this cancer can be either local, most often involving the spleen, adrenal glands and transverse colon, or distant[1,2].

TREATMENT OF ADVANCED PANCREATIC CANCER

Conventional chemotherapies

For over a decade, gemcitabine-based therapy has been considered a first-line treatment for locally advanced and metastatic pancreatic cancer. Preference for gemcitabine over 5-fluorouracil (5-FU) was established in the mid-1990s, when a phase Ⅲ trial comparing gemcitabine monotherapy to 5-FU demonstrated clinical benefit in gemcitabine-treated patients with advanced pancreatic cancer[3]. The value of radiotherapy in the management of locally advanced pancreatic cancer remains unclear[4].

Numerous attempts have been made to improve the efficacy of standard gemcitabine monotherapy in patients with advanced pancreatic cancer, but little success has been achieved. Several phase Ⅲ trials were undertaken with gemcitabine in combination with a range of chemotherapy agents. However, the combinations of gemcitabine with 5-FU[5], as well as irinotecan, oxaliplatin, pemetrexed, exatecan and cisplatin[6-10], all failed to show superiority over gemcitabine monotherapy.

Capecitabine is an orally administered fluoropyrimidine that is metabolized in both liver and tumor cells into 5-FU, resulting in high intratumoral 5-FU concentrations. Phase Ⅲ trial results on capecitabine and gemcitabine combination appeared to be contradictory. In a recent phase Ⅲ trial, the combination significantly improved objective response rate and progression-free survival (PFS), but did not show superiority in overall survival (OS) in patients with advanced pancreatic cancer[11].

In addition, folfirinox (5-FU/leucovorin, irinotecan, and oxaliplatin) treatment of metastatic pancreatic cancer patients in a randomized phase Ⅱ trial of folfirinox versus gemcitabine, indicated that response rate was more than 30%. Furthermore, the median OS was 11.1 mo in the folfirinox group as compared with 6.8 mo in the gemcitabine group, indicating that folfirinox is an option for the treatment of patients with metastatic pancreatic cancer[12].

Targeted therapies

Targeted therapies have also been investigated for advanced pancreatic cancer. The matrix metalloproteinase inhibitors (MMPIs) marimastat and talomastat (BAY 12-9566) inhibit enzymes that play a key role in extracellular matrix (ECM) degradation, and angiogenesis. In phase Ⅲ trials, neither marimastat monotherapy nor marimastat with gemcitabine, improved OS compared with gemcitabine monotherapy[13].

The farnesyl transferase enzyme Kras regulator tipifarnib in combination with gemcitabine did not improve OS compared with gemcitabine monotherapy in a phase Ⅲ trial[14].

Erlotinib is a small-molecule tyrosine kinase inhibitor (TKI) of the human epidermal growth factor receptor (EGFR). A multicenter, randomized, double-blind, placebo-controlled phase Ⅲ clinical trial of erlotinib in combination with gemcitabine, in patients with locally advanced or metastatic pancreatic adenocarcinoma met its primary endpoint, with the combination regimen being the first gemcitabine combination to demonstrate a statistically significant survival advantage over gemcitabine monotherapy and the regimen was consequently approved for metastatic disease[15].

Cetuximab, an anti-EGFR monoclonal antibody, blocks the extracellular EGFR domain, preventing ligand-dependent or independent activation and downstream signaling. An open-label, randomized phase Ⅲ trial, unfortunately, recently failed to demonstrate a clinically significant advantage of the addition of cetuximab to gemcitabine for response and OS[16].

Bevacizumab is a recombinant, humanized IgG1 monoclonal antibody that selectively binds to vascular endothelial growth factor (VEGF), inhibiting its interaction with VEGF receptor-1 and -2, on the surface of endothelial cells. Despite recently reported negative results, a number of phase Ⅱ and Ⅲ studies are underway in advanced pancreatic cancer that include bevacizumab and cetuximab in combination with other agents[17].

Finally, a wide range of molecular-targeted agents that interact with crucial pathways for cell survival in pancreatic cancer are currently being explored. These include agents that target polyADP-ribose polymerase, histone deacetylase (HDAC), Src/Abl kinases, and mammalian target of rapamycin[18].

Given the positive data observed in phase Ⅲ trials, gemcitabine, erlotinib and capecitabine are likely to form the base for future treatment strategies for advanced pancreatic cancer.

Histone acetyltransferases and HDACs

The organization of chromatin is crucial for the regulation of gene expression. Accumulating evidence suggests that the acetylation and deacetylation of histones play significant roles in transcriptional regulation of eukaryotic cells. Histone acetylation and deacetylation are catalysed by specific enzyme families, Histone acetyltransferases (HATs) and HDACs, respectively[19,20]. There are at least four groups of proteins with intrinsic HAT activity, while 18 HDACs belonging to four distinct classes have been described in mammalian cells. Eleven of the HDACs are zinc dependent, classified on the basis of homology to yeast HDACs: Class I includes HDACs 1, 2, 3 and 8; Class ⅡA includes HDACs 4, 5, 7 and 9; Class Ⅱ B, HDACs 6 and 10; and Class IV, HDAC11. Class Ⅲ HDACs, sirtuins 1-7, have an absolute requirement for NAD^+, are not zinc dependent, and generally not inhib-

ited by compounds that inhibit zinc-dependent deacetylases[21]. Apart from deacetylating histones, HDACs have also been reported to interact with non-histone proteins, involved in numerous important cell pathways including control of gene expression, regulation of cell proliferation, differentiation, migration and death. The balance between acetylation and deacetylation is an important factor in regulating gene expression and disruption of HAT or HDAC activity is possibly associated with cancer development[22,23].

HDAC inhibitors

HDAC inhibitors (HDACIs) are divided into different classes based on their chemical properties, including hydroxamic acids, such as suberoylanilide hydroxamic acid (SAHA), trichostatin A (TSA), LBH589 (panobinostat) and PXD101 (belinostat); short chain fatty acids, such as sodium butyrate (NaBu), 4-phenylbutyrate (4-PB) and valproic acid; cyclic tetrapeptides, such as trapoxin, apicidin and depsipeptide-also known as FK228 or romidepsin; benzamides, such as MS-275, CI-994 and MGCD0103, and a variety of other chemical compounds and synthetic inhibitors. HDACIs have three common structural characteristics: a Zn-binding moiety, an opposite capping group, and a straight chain alkyl, vinyl or aryl linker connecting the two[24,25].

HDAC inhibition is able to promote a variety of different anticancer mechanisms including apoptosis, cell differentiation and cell cycle inhibition. HDACIs are a new class of antineoplastic agents currently being evaluated in clinical trials. While these agents have been studied extensively in the laboratory, only recently has their mechanism of action begun to be elucidated. Several HDACIs are now in various stages of development, including clinical trials as monotherapy and in combination with other anticancer drugs and radiation[26,27].

In the present review, the available so far data regarding the different classes of HDACIs used in clinical trials including patients with pancreatic cancer are presented in Table 1.

Hydroxamic acids

SAHA (N-hydroxy-N'-phenyl-octanediamide, vorinostat) is a synthetic hydroxamic acid, which is structurally related to the natural product, TSA (7-[4-(dimethylamino)phenyl]-*N*-hydroxyl-4,6-dimethyl-7-oxo-(2*E*,4*E*,6*R*)-2,4-heptadienamide), produced by selected strains of *Streptomyces platensis*, *Streptomyces hygroscopicus* Y-50 or *Streptomyces sioyaensis*. Hydroxamic acids have a high affinity to biometals, including Fe^{3+}, Ni^{2+} and Zn^{2+}. The synthesis of SAHA and its potency to induce differentiation of murine erythroleukemia (MEL) cells was first reported in 1996. SAHA and TSA comprise a hydroxamic-acid-based metal-binding domain that coordinates the catalytic Zn^{2+} in the HDAC active site, a 5 (TSA) or 6 (SAHA)-membered carbon-based linker that mimics the Cα functional group of lysine, and a hydrophobic motif that interacts with the periphery of the HDAC binding pocket[28].

SAHA: SAHA (vorinostat) is now undergoing several clinical trials. One current phase I trial is studying the side effects and best dose of SAHA given together with flavopiridol in treating patients with advanced solid tumors. Another trial is studying SAHA in patients with metastatic or unresectable solid tumors or lymphoma and liver dysfunction. Combination with doxorubicin is also under survey for solid tumors, as well as that with bortezomib, vinorelbine, gemcitabine and other agents like paclitaxel and carboplatin, fluorouracil/leucovorin and oxaliplatin. A phase I / II trial is studying the highest tolerable dose of SAHA that can be given in combination with radiotherapy to patients with locally advanced pancreatic cancer, as well the efficacy of combined therapy. Another phase I clinical trial is now examining the safety, pharmacokinetics, pharmacodynamics and efficacy of *iv* proteasome inhibitor NPI-0052 in combination with oral SAHA in patients with non-small cell lung cancer, pancreatic cancer, melanoma or lymphoma. A phase I/ II study of SAHA in combination with radiotherapy and infusional 5-FU in patients with locally advanced adenocarcinoma of the pancreas is under way. Finally, SAHA in combination with capecitabine plus radiotherapy is also being evaluated in patients with non-metastatic pancreatic cancer. The above studies are recruiting for participants and possible patients suffering from pancreatic cancer remain to determine the efficiency of these therapies[29].

Cyclic peptides

FK228 (FR901228, depsipeptide, romidepsin): Depsipeptide (1S,4S,7Z,10S,16E,21R)-7-ethylidene-4,21-bis (1-methyletheyl)-2-oxa-12,13-dithia-5,8-,20,23-tetraazabicyclo[8.7.6]tricos-16-ene-3,6,9,19,22-pentone, is a bicyclic peptide isolated from *Chromobacterium violaceum* and has demonstrated potent *in vitro* cytotoxic activity against human tumor cell lines and *in vivo* efficacy against human tumor xenografts. Upon entering cells, FK228 is reduced to an active compound, capable of preferentially interacting with the zinc in the active site of the HDAC class I enzymes, however, it is still generally classified as a broad-spectrum inhibitor as it does inhibit class II enzymes. It was approved by the United States Food and Drug Administration (FDA) for the treatment of cutaneous T-cell lymphoma (CTCL)[30].

Among other current clinical trials for patients with advanced solid tumors, FK228 is being studied in combination with gemcitabine in patients with pancreatic cancer. This phase I / II dose escalation trial is designed to determine the maximum tolerated dose for the combination, as well as evaluate toxicities and objective disease responses. Furthermore, another phase II trial is studying the effectiveness of FK228 in patients who have locally advanced or metastatic neuroendocrine tumors; among them pancreatic islet tumors[29].

Short-chain fatty acids

Valproic acid: Valproic acid (VPA) is now an established antiepileptic drug, by affecting the function of the neu-

Table 1 Clinical studies on histone deacetylase inhibitors for treatment of patients with pancreatic cancer

HDACI	Patients total number	Patients with PC number	Time schedule	Dosage schedule (HDACI)	MTD (HDACI)	Responses (for patients with pancreatic cancer treated with HDACI)			Main toxicities	Ref.

[1]The patient with pancreatic cancer experienced grade 3 hypophosphatemia as DLT and was finally excluded from study after cycle 2 due to PD; [2]At 100 mg/m^2 one patient with advanced pancreatic cancer, developed grade 4 hyperbilirubinemia associated with febrile neutropenia on day 3. The patient developed thrombocytopenia on day 8 of treatment and anemia, necessitating platelet and blood transfusions. This was followed by an episode of atrial fibrillation on day 13 and then acute renal failure. The patient finally died on d18. PC: Pancreatic cancer; PD: Progressive disease; PR: Partial response; RPTD: Recommended dose for phase II; SD: Stable disease.

rotransmitter GABA. The finding that VPA was an effective inhibitor of HDACs arose from the observations that VPA was able to relieve transcriptional repression of a peroxisomal proliferation and activation of a glucocorticoid receptor (GR)-PPARε hybrid receptor, suggesting that it acts on a common mechanism in gene regulation, such as histone deacetylation, rather than on individual transcription factors or receptors. Consistent with this finding, it was shown that VPA causes hyperacetylation of the N-terminal tails of histones H3 and H4 *in vitro* and *in vivo*, and was found to inhibit HDAC enzymatic activity at a concentration of 0.5 mmol/L[31]. VPA has shown potent antitumor effects in a variety of *in vitro* and *in vivo* systems, by modulating multiple pathways including cell cycle arrest, apoptosis, angiogenesis, metastasis, differentiation and senescence. Most preclinical and clinical data on the anticancer effects of VPA have been generated for malignant hematological diseases[32].

A phase I clinical trial investigated the safety, toxicity and maximum-tolerated dose of VPA and the topoisomerase Ⅱ inhibitor epirubicin in solid tumors. Forty-eight patients with different malignancies were enrolled; one with pancreatic cancer. The patient suffering from pancreatic cancer experienced a partial response at 100 mg/kg VPA and 100 mg/m^2 on day 3 of the cycle, while no dose-limiting toxicities occurred. All patients with a partial response had at least a twofold increase in histone acetylation[33].

Phase I clinical trials are currently testing VPA in combination with other agents such as erlotinib, 5-FU, cyclophosphamide, bevacizumab, and azacytidine, as well as epirubicin to determine safety, tolerability and effectiveness in treating patients with advanced solid tumors. In addition, another phase Ⅱ trial is studying VPA combined with the hypomethylating factor hydralazine. A phase I clinical trial is undertaking recruitment to determine maximum tolerated doses of VPA in combination with sunitinib, sorafenib, dasatinib, erlotinib, lapatinib, or lenalidomide for the treatment of patients with advanced solid tumors, as well as to estimate the safety and treatment response[29].

4-PB: 4-PB is a short-chain fatty acid known to inhibit reversibly class I and Ⅱ HDACs. It is considered as an HDAC inhibitor of the first generation, as the HDAC inhibitory effect is not specific. Working concentrations are rather high, in the millimolar range, and the effects are pleiotropic. 4-PB is known to exert multiple effects in the cell, including the modulation of protein isoprenylation, which importantly regulates the ras proto-oncoprotein, and activation of the nuclear steroid PPAR[34]. 4-PB exerts a potent antitumor effect *in vitro* and has been shown to cause growth inhibition and differentiation in various human cancer cell lines[35].

A phase I dose escalating trial to evaluate twice daily *iv* 4-PB infusion has been undertaken. 4-PB was administered for five consecutive days for a total of 20 doses over two consecutive weeks from 60 to 360 mg/kg per day. Twenty-one patients with different malignancies, including one with pancreatic carcinoma, participated in the trial. Dose limiting toxicities were fatigue and headache, while no significant myelosuppression was seen. Three patients with brain malignancies remained stable for an average of 6 mo[36].

A current phase I clinical trial is investigating oral phenylbutyrate three times daily in patients with refractory solid tumors. Combination with azacytidine is also being studied to determine effectiveness and maximum dose in patients with advanced or metastatic solid tumors[29].

NaBu: NaBu has multiple effects on cultured mammalian cells that include inhibition of proliferation, induction of differentiation and induction or repression of gene expression. Sodium butyrate inhibits most HDACs except class Ⅲ HDAC and class Ⅱ HDAC6 and-10. Promoters of butyrate-responsive genes have butyrate response elements, and the action of butyrate is often mediated through Sp1/Sp3 binding sites[37].

In a recruiting phase I clinical trial, the butyrate prodrug tributyrin is being studied in patients with various advanced solid tumors[29].

Benzamides

MS-275: This synthetic benzamide derivative (3-pyridylmethyl-*N*-{4-[(2-aminophenyl)carbamoyl]benzyl}carbamate) has been shown to inhibit HDACs, and has antitumor activity in many preclinical models. The first clinical trial with this agent in 2005 included patients with advanced solid tumors or lymphoma. At high concentrations of MS-275, there is a marked induction of reactive oxygen species, mitochondrial damage, caspase activation and apoptosis. Treatment of sensitive tumor cell lines with MS-275 induces gelsolin, a maturation marker, and produces a change in the cell cycle distribution with a decrease in S phase and an accumulation of cells in G_1. The *in vivo* therapeutic efficacy of MS-275 has been shown in a variety of human tumor xenograft models[38].

A phase I study determined the maximum tolerated dose, the dose limiting toxicity and the pharmacokinetic or pharmacodynamic profile of MS-275 in combination with 13-cis-retinoic acid. Patients with advanced solid tumors were treated with MS-275 orally, once weekly, and 13-cis-retinoic acid orally, 1 mg/kg twice daily, for 3 wk every 4 wk. One patient suffering from pancreatic cancer remained on treatment for 6 mo and a patient with renal cell carcinoma showed a partial response in the lungs. Side effects included hyponatremia, neutropenia, anemia and fatigue[39].

Another phase I study evaluated the toxicity and pharmacokinetic profiles of MS-275 in patients with refractory solid tumors and lymphomas, including one patient suffering from metastatic pancreatic cancer, on three different schedules. The patient with metastatic pancreatic cancer developed grade 3 hypophosphatemia, thus meeting criteria for dose limiting toxicity, and was

finally removed from study due to disease progression after cycle 2. Objective responses were only observed in patients receiving the every-other-week dosing schedule, but the numbers of patients enrolled were too small to determine whether this dosing regimen was truly more efficacious[40].

CI-994: CI-994 or N-acetyldinaline [4-(acetylamino)-N-(2-amino-phenyl) benzamide] is a novel oral compound with a wide spectrum of antitumor activity in preclinical models. The mechanism of action may involve inhibition of histone deacetylation and cell cycle arrest. CI-994 is currently undergoing clinical trials. Although several changes in cellular metabolism induced by the drug have been characterized, the primary molecular mechanism of its antitumor activity remains unknown[41].

A phase Ⅱ trial of CI-994 in patients with advanced pancreatic cancer evaluated the antitumor activity and safety of CI-994. CI-994 was administered orally at 8 mg/m^2 per day. Seventeen patients were enrolled, including 15 with metastatic disease. Among patients evaluable for response, stable disease for 8 wk occurred in two patients (12%). Overall, median time to progressive disease was 6 wk and median survival was 10 wk, with one patient alive at 41 wk. Grade 3 thrombocytopenia occurred in eight patients but grade 4 in none. Most common non-hematological toxicities were generally grade 1 or 2 and included fatigue, anorexia, nausea, vomiting and bruising. According to this study, CI-994 was well tolerated but resulted in no objective responses in patients with advanced pancreatic cancer[42].

A phase 1 study in patients with solid tumors was carried out to determine the maximum tolerated daily oral dose for CI-994 administered on a chronic basis. Fifty-three patients, most of them suffering from colorectal, lung and renal malignancies, including one with pancreatic cancer, received CI-994 daily for treatment durations ranging from 2 to 10 wk. Antitumor effects were documented in four patients, including a durable partial response in one pretreated non-small cell lung cancer patient and stable disease in three patients with non-small cell lung, colon and renal cancers[43].

Another study investigated the toxicity profile, maximum tolerated dose and pharmacokinetics of CI-994 in combination with capecitabine. Fifty-four patients were treated according to three different dosing schemes in which the capecitabine dose was fixed and the CI-994 dose was escalated. In schedule C, 22 patients, including four with pancreatic cancer, were treated with capecitabine 2000 mg/m^2 per day and CI-994 for 2 of 3 wk. One partial response was achieved at the 4 mg/m^2 dose level of schedule A in a patient with colorectal cancer. Disease stabilization was seen in adenocarcinoma of unknown primary origin, appendiceal cancer, breast cancer, colorectal cancer and mesothelioma[44].

A phase I study of oral CI-994 in combination with carboplatin and paclitaxel in patients with advanced solid tumors was carried out. A total of 30 patients were entered into five treatment cohorts, including two suffering from pancreatic cancer. Five patients achieved a partial response (non-small cell lung, colon, unknown primary origin) and two patients achieved a complete response (esophageal and bladder cancer). It was observed that patients whose histone H3 acetylation in peripheral blood lymphocytes was at least 1.5-fold greater after treatment had an objective clinical response or stable disease[45].

A randomized, double-blind, placebo-controlled, multicenter study compared whether CI-994 plus gemcitabine improved OS, duration of response, time to treatment failure, and quality of life compared to gemcitabine alone. Patients had diagnosis of advanced or metastatic adenocarcinoma of the exocrine pancreas and were not considered surgical candidates. A total of 174 patients received CI-994 6 mg/m^2 per d orally on days 1-21 plus gemcitabine 1000 mg/m^2 on days 1, 8 and 15 or placebo plus gemcitabine 1000 mg/m^2 on days 1, 8 and 15 of each 28-d cycle. There was no observed difference in survival time between the two cases. The estimated median survival was 194 and 214 d and objective response rates based on investigator assessments were 12% and 14%, respectively. In addition, pain responses did not differ significantly. Treatment with CI-994 was associated with more cases of grade 3/4 thrombocytopenia, anemia and leukopenia than with placebo, while non-hematological toxicities such as nausea, vomiting, anorexia and diarrhea were identical with both treatments. Consequently, in this study, CI-994 in combination with gemcitabine did not appear to offer any benefit compared to gemcitabine as a single agent for the treatment of pancreatic cancer[46].

A randomized phase Ⅱ trial comparing the effectiveness of gemcitabine with or without CI-994 in patients with advanced pancreatic cancer is still ongoing[29].

MGCD0103: MGCD0103 is an isotype-specific aminophenylbenzamide that inhibits HDAC classes I and Ⅳ, with almost no class Ⅱ effect. MGCD0103 is well tolerated and exhibits favorable pharmacokinetic and pharmacodynamic profiles, demonstrating target inhibition and clinical responses. It induces cell death and autophagy, synergizes with proteasomal inhibitors and affects non-histone targets, such as microtubules[47].

In a phase I study MGCD0103 was given three times weekly orally to patients with advanced solid tumors to determine safety, tolerability and pharmacokinetics. Thirty-eight patients were enrolled and completed a total of 99 cycles of MGCD0103, including two with pancreatic cancer. No objective tumor responses were observed. Five patients with previously progressive colorectal, renal cell and lung cancers had stable disease for four or more cycles. Furthermore, MGCD0103 exerted dose-dependent HDAC inhibitory activity and was able to induce histone acetylation in peripheral leukocytes[48].

Oral MGCD0103 three times weekly is currently being studied in combination with gemcitabine, in patients with advanced solid tumors. In this phase Ⅰ/Ⅱ study, patients with locally advanced or metastatic pancreatic

cancer can participate. Maximum tolerated dose of MGCD0103 and objective response of patients remain to be determined[29,49].

Other HDACIs

A phase I study of LAQ824 has determined the safety, maximum tolerated dose, and pharmacokinetic-pharmacodynamic profile in patients with advanced solid tumors. Thirty-nine patients were recruited and were eligible for assessment of toxicity, including three with pancreatic cancer. At 100 mg/m^2, one patient who had advanced pancreatic cancer, developed grade 4 hyperbilirubinemia associated with febrile neutropenia on day 3. The patient finally died after an episode of atrial fibrillation and acute renal failure 18 d after the first infusion. All patients treated with LAQ824 at 12 mg/m^2 or above showed increase in histone acetylation. No objective responses were documented. One patient with hepatocellular carcinoma and two with fibrosarcoma and papillary carcinoma of the thyroid showed disease stabilization[50].

A phase I study is investigating safety, pharmacodynamic, antitumor activity, and pharmacokinetics of PXD101 (belinostat) alone and in combination with 5-FU in patients with advanced solid tumors or lymphoma[51]. Another recruiting phase I trial is studying the safety, tolerability and pharmacokinetics of orally administered PXD101 in combination with carboplatin and/or paclitaxel in patients with advanced solid tumors or lymphoma[52].

A recruiting phase I study is evaluating the pharmacokinetics and safety of oral LBH589 (panobinostat) in patients with advanced solid tumors and varying degrees of renal function. Another phase Ⅱ trial will determine tumor response, toxicity and tolerability of LBH589 in patients with gastrointestinal neuroendocrine tumors. A phase I A, dose-escalating study of *iv* LBH589 in adult patients with advanced solid tumors is ongoing. Another phase I study will evaluate the safety and tolerability of the combination of LBH589 and paclitaxel/carboplatin in patients with metastatic or locally advanced solid tumors. Finally, a phase I dose escalation trial of LBH589 and gemcitabine in patients with solid malignancies has been temporarily suspended[53,54].

Other HDACIs, such as CHR-3996, CRA-024781, SB939 and R306465, are under phase I trials for the treatment of patients with advanced solid tumors[29].

CONCLUSION

The experimental results of HDACIs led to their use in clinical trials, especially in pretreated and multiply relapsed patients at an advanced cancer stage. Additionally, HDACIs constitute a promising treatment for cancer due to their low toxicity. The first HDACIs tested in clinical trials have shown encouraging antitumor effects, at doses well tolerated by patients. Vorinostat (SAHA) was the first HDACI to be approved by the FDA for clinical use in patients with hematological malignancy (CTCL). HDACIs alone and in combination with a variety of cytotoxic or other targeted anticancer agents are now being tested. To date, at least 10 different HDACIs, including SAHA, VPA, NaBu, MS-275, CI-994, FK228, PXD101, LAQ824 and others, are in phase Ⅱ or Ⅲ clinical trials for the treatment of hematological and solid tumors.

Despite efforts in recent decades, conventional treatments such as surgery, radiation and chemotherapy, have slightly affected the course of pancreatic cancer. The development of effective systemic treatments, capable of reversing the biology of this aggressive disease, remains a critical requirement. Unfortunately, clinical data for HDACIs on patients with pancreatic cancer are inadequate (Table 1). So far, only a few studies have included patients suffering from this type of neoplasm. Additionally, the number of pancreatic cancer patients that entered HDACIs phase Ⅱ/Ⅲ trials, among others with advanced solid tumors, is very limited. Although HDACIs are recognized as some of the most promising agents, more studies recruiting candidates with pancreatic cancer remain to determine the efficacy of these therapies.

Abstract

Epigenetic alterations contribute significantly to the development and progression of gastric cancer, one of the leading causes of cancer death worldwide. Epigenetics refers to the number of modifications of the chromatin structure that affect gene expression without altering the primary sequence of DNA, and these changes lead to transcriptional activation or silencing of the gene. Over the years, the study of epigenetic processes has increased, and novel therapeutic approaches that target DNA methylation and histone modifications have emerged. A greater understanding of epigenetics and the therapeutic potential of manipulating these processes is necessary for gastric cancer treatment. Here, we review recent research on the effects of aberrant DNA and histone methylation on the onset and progression of gastric tumors and the development of compounds that target enzymes that regulate the epigenome.

INTRODUCTION

Gastric cancer (GC) is the fourth most frequent cancer and is the second leading cause of cancer-related death worldwide[1]. Histologically, gastric tumors are divided into intestinal and diffuse types according to the Lauren classification[2]. The intestinal type of GC mostly progresses through the successive steps of normal gastric mucosa, leading to acute and chronic gastritis, atrophic gastritis, intestinal metaplasia, dysplasia, and finally a gastric tumor[3]. In contrast, the sequence of events in the development of diffuse type GC is poorly understood, although a subset of diffuse type GC appears to develop independently of atrophic gastritis or intestinal metaplasia[4,5]. Differences in the clinicopathological characteristics between these two histological types indicate that development occurs through distinct molecular pathways[6-10]. Each histological type is a consequence of a progressive accumulation of different genetic and epigenetic alterations.

Epigenetics refers to a number of modifications in the chromatin structure that affect gene expression without altering the primary DNA sequence, and these changes lead to transcriptional activation or silencing of the gene. Interestingly, epigenetic modifications of DNA can also increases mutagenesis and influence the interactions between DNA and carcinogens and ultraviolet light[11]. Epigenetic modifications play a central role in gastric car-

cinogenesis[12]. Recent reports indicate that infection with *Helicobacter pylori* (*H. pylori*) or Epstein-Barr virus (EBV), pathogens with a substantial role in development of GC, are associated with elevated levels of aberrant DNA methylation in GC[13-16]. The study of epigenetic processes has increased in recent years, and novel therapeutic approaches that target DNA methylation and histone modifications have emerged. A greater understanding of epigenetics and the therapeutic potential of intervention into these processes is necessary to help GC treatment.

In this review, after a brief introduction to the methylation machinery, we focus on the roles that aberrant DNA and histone methylation play in the onset and progression of gastric tumors, and the development of compounds that target enzymes that regulate the epigenome.

METHYLATION MACHINERY

DNA methylation refers to the addition or subtraction of a methyl moiety at the 5 position of the cytosine ring within CpG dinucleotides that are usually located in CpG-rich regions or CpG islands and around the gene promoter. DNA methylation in gene promoter regions represses transcription of their downstream genes associated with the suppression of gene expression[17]. However, methylation in gene bodies does not block transcription and is sometimes associated with active transcription[18]. Methylation status is controlled by DNA methyltransferases (DNMT1, DNMT3A, and DNMT3B)[19]. DNMT1 maintains the existing methylation patterns following DNA replication, whereas DNMT3A and DNMT3B target unmethylated CpGs to initiate methylation and are highly expressed during embryogenesis and minimally expressed in adult tissues[20]. Another DNA methyltransferase family member, DNMT3L, interacts with DNMT3A and DNMT3B to facilitate methylation of retrotransposons[21]. Many studies have shown that overexpression of DNA methyltransferases is closely related to tumorigenesis, although the role of DNMT3L in cancer is still unclear (Table 1). In addition, *H. pylori* infection may increase DNA methyltransferase activity through upregulation of the epidermal growth factor and its receptor or via the release of inflammatory mediators, such as nitric oxide[22]. In particular, *DNMT1* overexpression has been associated with EBV infection in GC[23-25].

DNA methylation has also been implicated in the regulation of higher order chromatin structure, the maintenance of genome integrity, and stable patterns of gene expression. These biological effects of DNA methylation are, at least in part, mediated by proteins that preferentially bind to methylated DNA[26]. Methylated DNA is specifically recognized by a set of proteins called methyl-CpG-binding proteins (MBPs), which belong to three different structural families: methyl-CpG binding domain proteins (MBDs), Kaiso domain proteins, and SET and RING finger-associated domain (SRA) domain proteins[27,28]. MBD family proteins (MeCP2, MBD1, MBD2, MBD3 and MBD4) bind methylated CpG (5mCpG) through a conserved protein motif called the methyl-CpG binding domain[29,30]. Over the last decade, proteins that utilize different structures to recognize and bind DNA or its components have been identified. In 2001, Prokhortchouk *et al*[31] identified Kaiso proteins, which bind methylated DNA through a zinc finger motif. Other MBPs including UHRF1 and UHRF2 were identified, and these proteins use the SRA to bind 5mCpG[32,33].

In cancer, the roles of MBPs are related to their functions as transcriptional repressors or chromatin remodelers (Table 1)[34-36]. However, a few studies have reported MBPs in GC (Table 1). Mutations in *MBD4* have been found in gastric tumors in association with microsatellite instability[37,38]. *MBD4* encodes a protein that interacts with the mismatch repair protein hMLH1. Therefore, it has been postulated that mutations in *MBD4* may result in mismatch repair deficiency[30].

The processes of DNA methylation and histone modification often involve dynamic interactions that either reinforce or inhibit epigenetic changes. Thus, histone modification can also alter chromatin remodeling, and this is a possible mechanism for decreased gene expression[39-41].

The nature of the interaction between DNA and histones, which are composed of pairs of the four core proteins H2A, H2B, H3, and H4, alters the accessibility of DNA transcription sites to RNA polymerase Ⅱ and other transcription factors. The interaction between histones and DNA is thought to be under epigenetic control, because specific amino acid residues on specific histone core proteins are subjected to post-translational modifications, such as acetylation, methylation, phosphorylation, ubiquitination, sumoylation, proline isomerization, and ADP ribosylation[42,43]. Histone acetylation and methylation are the only modifications that have been clinically associated with pathological epigenetic disruption in cancer cells[44]. In this review, we focus on histone methylation modifications.

Histones can be mono-, di-, or trimethylated at lysine and arginine residues by histone methyltransferases (HMTs) or demethylated by histone demethylases (HDTs). Depending on the residue and the level of methylation, the chromatin may be transcriptionally active or inactive. In general, trimethylation at H3K4 and H3K36 or monomethylation at H3K27, H3K9, H4K20, H3K79, and H2BK5 is associated with transcriptional activation. In contrast, trimethylation at H3K27, H3K9, and H4K20 or monomethylation at H3K27, H3K9, H4K20, H3K79, and H2BK5 is associated with transcriptional repression[44].

A growing number of studies have analyzed the HMTs and HDMs in tumor cells, whereas few genes involved in histone methylation activity have been described for GC (Table 1). EZH2, an HMT that plays a role in trimethylation of H3K27 and leads to silencing of important genes in carcinogenesis, is overexpressed in several types of cancer, including GC[45,46]. Cai *et al*[47] reported that EZH2 plays an important role in the multistep process of intestinal-type GC. In addition, Fujii *et al*[48] demonstrated that silencing of *EZH2* by siRNA resulted in a lower H3K27me3 protein level in GC cells.

Table 1 Methylation machinery in gastric cancer

Gene	Function	Alteration in cancer	Ref.

DNMT: DNA methyltransferase; *EVH1*: Domain containing 1; *EZH2*: Enhancer of zest homolog2; *JARID*: Jumonji, AT-rich interactive-domain; *JHDM*: JmjC domain-containing histone demethylase 1; *JMJD*: Jumonji domain containing 2; *LSD1*: Lysine specific demethylase; *MBD*: Methyl-CpG-binding domain; *NSD2*: Nuclear receptor-binding SET-domain protein 2; *PRMT*: Protein arginine methyltransferase 1; *RIZ1*: Retinoblastoma protein-interacting zinc finger 1; *SUV39H*: Suppressor of variation 3-9 homolog.

Among the HDTs, RBP2 is a newly identified member of the JARID family of proteins, and RBP2 specifically targets tri- and dimethylated H3K4 for demethylation in cancer[49,50]. Zeng *et al*[51] reported that *RBP2* is overexpressed in GC and suggested that HDT inhibition by targeting RBP2 may be an anticancer strategy.

DNA METHYLATION

DNA methylation contributes to cancer mainly through DNA hypo- or hypermethylation. DNA hypomethylation, which refers to the loss of DNA methylation, affects chromosomal stability and increases aneuploidy[52]. DNA hypermethylation, which refers to the gain of methylation at a locus originally unmethylated, usually results in stable transcriptional silencing, which functions in regulating gene expression[53,54].

Global DNA hypomethylation is usually considered one of the hallmarks of cancer cells, because aberrant hypermethylation-vulnerable genes are overlapped by

Table 2 Aberrant DNA methylation in gastric cancer

genes targeted by hypomethylation[55,56]. Compare *et al*[57] suggested that global DNA hypomethylation may be implicated in GC associated with *H. pylori* infection at an early stage. At the individual gene level, DNA hypomethylation is often associated with activation of proto-oncogenes.

In GC, few studies have shown promoter hypomethylation associated with the activation of proto-oncogenes (Table 2). In particular, Shin *et al*[58] reported that the hypomethylation of the *MOS* promoter in GC was associated with tumor invasion, lymph node metastasis, and the diffuse type. A number of genes involved in cell cycle regulation, tumor cell invasion, DNA repair, chromatin remodeling, cell signaling, transcription, and apoptosis are known to be silenced by hypermethylation in GC (Table 2).

Multiple reports have been published regarding gene hypermethylation in both intestinal and diffuse types of GC. Interestingly, the methylation profile differs between the intestinal and diffuse types of GC[54].

The epithelial cadherin gene *CDH1*, which is a well-studied gene involved in cancer, is downregulated in gastric tumors and is hypermethylated more frequently in the diffuse type than in the intestinal type of GC. Loss of *CDH1* during tumor progression has led to the notion that this is a tumor suppressor gene[59,60]. In addition, mapping of the *CDH1* promoter has revealed a positive association between hypermethylation and older age, as well as a significant correlation between DNA hypermethylation and the A allele of the -160 C→A polymorphism. The A allele has been described to increase the risk of developing GC in association with the methylation status[61]. Unlike the *CDH1* gene, the *P16* gene is hypermethylated mainly in the intestinal type of GC[54,62,63]. This epigenetic mark was recently associated with tumor location and *H. pylori* infection in GC[64].

Other studies have also described a number of genes that are silenced by hypermethylation in association with *H. pylori* or EBV infection: *APC*, *SHP1*, *p14*, and *CDH1*[63,65-67]. According to Chan *et al*[68], the eradication of *H. pylori* infection significantly reduces the methylation index of the *CDH1* promoter. In contrast, it has been shown that a portion of the aberrant DNA methylation induced by *H. pylori* infection may persist even after the infection has disappeared[69,70]. Shin *et al*[58] observed that the methylation levels in *MOS* remained significantly increased in patients with previous *H. pylori* infection compared with *H. pylori*-negative subjects.

Moreover, hypermethylation of several gene promoters has also been observed in the premalignant stages of GC, suggesting that aberrant methylation occurs early during gastric carcinogenesis[59,71-74]. For example, the methylation levels of the catalytic subunit of the telomerase gene (*hTERT*) promoter are increased during gastric carcinogenesis. Wang *et al*[75] reported that the *hTERT* promoter was more methylated in GC than in precancerous lesions and non-neoplastic gastric tissues. Therefore, it has been suggested that the degree of methylation of the *hTERT* promoter may be useful in the early diagnosis of GC and/or may have an impact on the anti-telomerase strategy for cancer therapy. Other studies, however, showed that methylation of the *hTERT* promoter and resultant gene expression were opposite to the general model of regulation by DNA methylation, which is usually dependent on the CpG islands studied[76,77].

Recently, aberrant hypermethylation of the newly associated metastatic suppressor gene *RECK* was found to be associated with GC development and may also be useful for early diagnosis and treatment[78]. These abovementioned findings lead to the possibilities that epigenetic alterations may also occur at different stages of gastric tumorigenesis.

HISTONE METHYLATION

Histone modifications leading to gene expression alterations have been described in several cancer types, but the methylation status of chromatin is still unclear for GC. Using the ChIP-on-chip technique, Zhang *et al*[79] identified candidate genes with significant differences in H3K27me3 in GC samples compared to adjacent non-neoplastic gastric tissues. These genes included oncogenes, tumor suppressor genes, cell cycle regulators, and genes involved in cell adhesion. Moreover, these investigators demonstrated that higher levels of H3K27me3 produce gene expression changes in *MMP15*, *UNC5B,* and *SHH*.

In 2011, Kwon *et al*[80] showed that *LAMB3* and *LAMC2* were overexpressed in GC samples in comparison with non-neoplastic adjacent tissue samples. Furthermore, these researchers demonstrated that overexpression of these genes was a result of the enrichment of H3K4me3 in the gene promoter. Using immunohistochemistry, Park *et al*[81] showed that higher levels of H3K9me3, which is a repressive mark, was associated with higher T stage, lymphovascular invasion, and recurrence in gastric tumors. They also observed that the level of H3K9me3 was correlated with patient survival, because stronger methylation corresponded to a worse prognosis and intermediate methylation to an intermediate prognosis.

Taken together with results from previous studies, these results have suggested that histone methylation results in a worse prognosis by inactivating certain tumor suppressor genes[82,83]. Moreover, Li *et al*[84] used GC cell lines to demonstrate that the PRC1 member CBX7 initiated trimethylation of H3K9 at the *P16* locus through recruitment and/or activation of the HMT SUV39H2 to the target locus. This finding links two repressive epigenetic landmarks, H3K9me3 formation and PRC1 binding within the silenced domains in euchromatin, and builds up a full pathway for epigenetic inactivation of *P16* by histone modifications.

Recently, Angrisano *et al*[85] reported that *H. pylori* infection is followed by activation of *iNOS* gene expression, chromatin changes at the *iNOS* promoter (including decreased H3K9 methylation and increased H3K4 methylation), and selective release of MBD2 from the *iNOS*

promoter in a GC cell line.

METHYLATION INHIBITOR DRUGS

The silencing of cancer-related genes by DNA methylation and chromatin modification are reversible and may represent a viable epigenetic therapeutic target. In the last decade, drugs that modify chromatin or DNA methylation status have been used alone or in combination in order to affect therapeutic outcomes[86]. Specially, cytosine analogs (5-azacytidine and 5-aza-2'- deoxycytidine) are powerful mechanism-based inhibitors of DNA cytosine methylation. These cytosine analogs are incorporated into the DNA of replicating cells after the drugs have been metabolized to the appropriate dNTP. After incorporation into the DNA, the analogs interact with DNA methyltransferases to form covalent intermediates, and this interaction inhibits DNA methylation in subsequent rounds of DNA synthesis[87]. Both drugs have been approved by the US Food and Drug Administration for use in hematological malignancy treatment[88].

In GC, surgery remains the primary curative treatment for gastric tumors. Currently, adjuvant and neoadjuvant therapies are accepted[89]; however, so-called epigenetic therapy has not yet been used in treatment of GC patients.

In the past few years, epigenetic screening techniques using treatment with a demethylating agent have been developed to identify genes with epigenetic aberrations in GC cell lines. Zheng *et al*[90] treated a GC cell line with 5-aza-2'-deoxycytidine and performed DNA methylation array analysis of these cells with six normal mucosal samples from healthy patients. These results revealed 82 hypermethylated gene promoters. These authors investigated 15 candidate genes by methylation-specific PCR and confirmed five highly methylated promoters: *BX141696*, *WT1*, *CYP26B1*, *KCNA4,* and *FAM84A*. All of these, except *FAM84A*, also showed DNA hypermethylation in serum of GC patients, suggesting that serum DNA offers a readily accessible bioresource for methylation analysis.

A similar study conducted by Jee *et al*[91] described 11 selected genes and validated the genes in three GC cell lines and in non-neoplastic gastric tissue by bisulfate sequencing. Differential DNA hypermethylation was observed in *GPX1*, *IGFBP6*, *IRF7*, *GPX3*, *TFPI2,* and *DMRT1* promoter regions in GC cells but not in non-neoplastic tissues. Moreover, a poor survival rate was observed in those individuals with higher methylation status at the *TFPI2* gene. *TFPI2* is a serine protease inhibitor, which negatively regulates the enzymatic activities of trypsin, plasmin, and a tissue factor complex. Therefore, it has been proposed that this gene inactivation may be implicated in human carcinogenesis and metastasis[92].

CONCLUSION

In summary, aberrant DNA methylation and histone modification play a crucial role in gastric carcinogenesis. Thus, the recognition of the methylation machinery, genes with aberrant methylation status, and histone methylation levels in gastric carcinogenesis exemplified in this review allow us to contemplate the possibility of dealing with the aforementioned oncological issue in a new way that may have a significant impact on the therapy and management of GC.

Abstract

The incidence of hepatocellular carcinoma (HCC) is rising worldwide being currently the fifth most common cancer and third cause of cancer-related mortality. Early detection of HCC through surveillance programs have enabled the identification of small nodules with higher frequency, and nowadays account for 10%-15% of patients diagnosed in the West and almost 30% in Japan. Patients with small HCC can be candidates for potential curative treatments: liver transplantation, surgical resection and percutaneous ablation, depending on the presence of portal hypertension and co-morbidities. This review will analyze recent advancements in the clinical management of these individuals, focusing on issues related to the role of portal hypertension, the debate between resection and ablative therapies and the future impact of molecular technologies.

INTRODUCTION

The incidence of hepatocellular carcinoma (HCC) is rising worldwide being currently the fifth most common cancer and third cause of cancer-related mortality[1]. HCC accounts for more than 90% of primary liver cancers, and it usually arises in the setting of long-term underlying liver disease. In fact, HCC is now the first cause of death among cirrhotic patients[2]. According to the Barcelona Clinic Liver Cancer (BCLC) algorithm, HCC can be classified into 5 stages when considering variables related to tumor burden, liver function and health status. Additionally, this algorithm links tumor stage with a specific treatment strategy[3]. Despite recent advancements in HCC management such as the introduction of the molecular targeted agent sorafenib for advanced stages[4], the mainstream potential curative therapies in HCC are still resection, transplantation and percutaneous ablation.

HCC surveillance programs for cirrhotic patients have enabled the identification of small nodules with higher frequency[5], and nowadays account for 10%-15% of patients diagnosed in the West and almost 30% in Japan[6]. "Small HCC" is a term frequently used to define tumors less than 2 cm in diameter. This cut-off is based

on the outstanding outcomes of patients with these tumors treated with surgical resection when compared to those with larger ones[7]. However, small HCC can be two different entities in pathology: vaguely and distinctly nodular[7]. Vaguely nodular tumors are well-differentiated without local invasiveness and around 12 mm in size; whereas distinctly nodular are frequently larger (16 mm) and often show local invasiveness features such as microvascular invasion[8]. European Association for the Study of the Liver (EASL) and American Association for the Society of Liver Diseases (AASLD) guideless for HCC management enables an accurate diagnosis of tumors larger than 1 cm in cirrhotic livers when a dynamic imaging technique [computed tomographic (CT) or magnetic resonance (MR)] show the so-called "hallmark" features of HCC: uptake in the arterial phase with early wash-out in the portal phase[9]. For nodules between 1-2 cm, this criterion is still maintained particularly in referral centers with a dense experience in HCC management. In case these imaging features are absent, diagnosis still requires a biopsy. According to the BCLC algorithm, patients with small HCC can be candidates for potential curative treatments, depending on portal hypertension and co-morbidities. This short review will analyze recent advancements in the clinical management of these individuals, focusing on issues related to the role of portal hypertension, the debate between resection and ablative therapies and the future impact of molecular technologies.

TREATMENT STRATEGY OF SMALL HCC AND IMPACT OF PORTAL HYPERTENSION ON POSTOPERATIVE OUTCOME

The EASL[9] and AASLD[10] guidelines recommend three alternatives for the treatment of patients with small HCC, depending on the presence of portal hypertension and co-morbidities: liver transplantation, surgical resection and percutaneous ablation. Overall, these therapies achieve a 5-year survival rate between 60%-75% in early HCC (BCLC 0/A), even though in small HCC survival rates can even be higher. About 80% of HCC develop in patients with underlying chronic liver disease, where liver failure and portal hypertension may be present. Since different treatment options are available for patients with small HCC, allocation to a given option should rely on evidence-based criteria, considering expected outcomes rather than merely treatment feasibility[11].

As for surgical resection, peri-operative mortality has decreased to 2%-3% with current surgical techniques. On the other hand a pioneer study by our group in Barcelona[12] showed that in a series of 29 Child A cirrhotic patients and HCC less than 5 cm undergoing liver resection surgery, hepatic venous pressure gradient (HVPG) $\geqslant$ 10 mmHg was independently associated with unresolved decompensation 3 mo following surgery. In a larger series published later, post-operative survival of patients with Child A cirrhosis without clinically significant portal hypertension (CSPH) was 70% at 5 years, while it dropped to 25%-50% in patients with CSPH[3]. In addition, even small increases in bilirubin, above the 1 mg/dL cutoff, were also independently associated with increased mortality. The impact of PH-related variables on the risk of post-operative liver failure and mortality has been confirmed in many Western and in Eastern series[3,12-24] (Table 1). In these studies 3-year survival was in mean 59% (range: 45%-71%) in patients with clinical signs of portal hypertension, while it increased to 72% (62%-81%) in patients without any clinical sign of the syndrome. A similar difference is observed analyzing post-opertative liver decompensation and 5-year survival, and similar results were obtained in a Japanese cohort of resected HCC[25]. Overall these data show that even if the presence of CSPH is not an absolute contraindication for performing liver resection for HCC, it clearly increases the risk of post-operative complications and death, suggesting that other available options such as liver transplantation (see below) should be considered in this subgroup of patients. Hence, the best candidates for surgical resection are patients with solitary tumors, preserved liver function and absence of CSPH. Consequently, the European and American Associations for the study of the Liver (EASL[9] and AASLD[10]) guidelines for HCC management recommend surgical resection as the first-line option in patients with small HCC without CSPH or liver dysfunction.

A main drawback of liver resection is the risk to develop a tumor recurrence, that accounts for 70% at 5 years[26] either because of true metastasis or *de novo* HCC.

By definition, patients with small HCC are within Milan criteria for liver transplantation[27], and besides treating the tumor liver transplantation provides a solution for the underlying liver disease. However, the scarcity of donors limits its feasibility and increases time in the waiting list. Even though there are no robust data, the risk of dropout from the waiting list seems lower in patients listed with small HCC. Hence, liver transplantation is the best option for patients in BCLC stage 0/A, CSPH and absence of other medical conditions that contraindicate this procedure.

Local ablation

Local ablation is considered as a competitive alternative to resection or transplantation in patients with small HCC[28] not suitable for surgery. Both radiofrequency ablation (RFA) and percutaneous ethanol injection (PEI) are standard of care techniques for tumor ablation, being used worldwide. They are both able to induce necrosis through different mechanisms. PEI presents a higher post-treatment rate of recurrence that can reach 40% at two years in larger lesions[29,30]. RFA has shown its ability to better control the disease with a lower local recurrence rate (2%-18% at 2 years) when compared with PEI (11%-45%) in randomized control trials (RCT)[31-35]. However, differences in survival were not described. Therefore, current guidelines recommend the use of PEI in cases where RFA is not feasible for technical reasons[9]. Five-year

Bruix *et al*[12]	29	HVPG	CSPH independently associated with PLF at 3-mo
Berzigotti *et al*[13]	63	Spleen size; platelet count; platelet count/spleen diameter; liver stiffness; LSPS PH risk score	Best single predictor of CSPH: liver stiffness; combination with spleen size and platelet count improved the results (AUROC LSPS 0.852; PH risk score 0.884)
Boleslawski *et al*[14]	43	HVPG Platelet count; spleen size; esophageal varices = indirect signs of PH	CSPH independently associated with increased PLF and 90-d mortality. Indirect signs of PH showed no discriminative ability
Capussotti *et al*[15]	217	Platelet count; spleen size; esophageal varices	PH associated with lower 3-yr and 5-yr survival
Cescon *et al*[16]	90	Liver stiffness; platelet count; spleen size; esophageal varices	LS (but not other signs) independently associated with the risk of PLF
Chen *et al*[17]	190	Intraoperative measurement of PVP	PVP independently associated with PLF on multivariate analysis
Cucchetti *et al*[18]	241	Platelet count; spleen size; esophageal varices	PH associated with lower 3-yr and 5-yr survival, but not after adjusting for MELD, albumin and extent of resection no
Figueras *et al*[19]	39	HVPG	CSPH associated with increased risk of morbidity
Giuliante *et al*[20]	588	Platelet count; spleen size; esophageal varices	PH independently associated with increased mortality
Imamura *et al*[21]	532	Varices, hypersplenism or hepatofugal portal flow	PH associated with a higher risk of post-operative ascites
Ishizawa *et al*[22]	203	Platelet count	Platelet count < 100 × 10^3/mL independently associated with PLF
Kim *et al*[23]	72	Liver stiffness	LS predicted PLF with good accuracy; LS better than ICG15
Llop *et al*[24]	79	Liver stiffness	CSPH predicted with good accuracy
Ishizawa *et al*[25]	434	Platelet count; spleen size; esophageal varices	PH associated with lower 3-yr and 5-yr survival

HVPG: Hepatic venous pressure gradient; PH: Portal hypertension; LS: Liver stiffness; PVP: Portal vein pressure; PLF: Post-operative liver failure; CSPH: Clinically significant PH (HVPG ⩾ 10 mmHg); AUROC: Area under receiver operating characteristic curve; MELD: Model for end-stage liver disease.

survival with RFA reaches 70%[36,37], with the best results in patients with good liver function (Child-Pugh A) and small tumors[38]. Although resection remains the first-line option for patients without CSPH, well-preserved liver function and solitary tumors less than 2 cm, there is an increasing debate as to whether ablative therapies (particularly RFA) could be a competitive option in these patients. Theoretically, in these solitary small tumors RFA could be as effective as surgery in terms of oncological results, and avoid all the possible complications related to the surgical procedure. However, available evidence is still limited as the few RCT available evaluating face-to-face both therapeutic options show controversial results (Table 2). In addition, there are several methodological issues that preclude reaching any robust conclusion from these trials (*e.g.*, treatment allocation, patient selection criteria, trial implementation, short follow-up, *etc.*). In fact, none of them was specifically design to only include patients with HCC less than 2 cm. Replacement of resection by RFA as first line therapy in patients with early HCC cannot be recommended at this point. Further evidence will be needed to appropriately address this issue.

Tumor recurrence is the main drawback in patients treated with resection or ablation, since the risk factor for HCC development (*i.e.*, cirrhosis) is still present[39]. Early recurrence usually occurs within the 2 years after surgery and it is due to true metastatic spread. However, late recurrence appears later on, usually beyond 2 years, and it is consider as *de novo* tumor developed as a consequence of the carcinogenic effect of underlying cirrhosis (field effect)[21]. Besides clinical differences[21], these two patterns of recurrence also differ in their molecular profile[40]. A large Japanese study found that non-anatomical resection, high AFP serum levels and presence of microscopic vascular invasion were risk factors for early recurrence, whereas grade of hepatitis activity, multiplicity and gross tumor classification impacted mostly late recurrence[21].

PORTAL HYPERTENSION ASSESSMENT IN PATIENTS WITH CIRRHOSIS AND SMALL HCC

The above-mentioned data underscore the need of an accurate discrimination of the presence of portal hypertension in patients with small HCC. Portal hypertension (PH) is a clinical syndrome hemodynamically defined as an increase in the pressure gradient across the liver (between portal pressure and inferior vena cava pressure) above the normal value of 5 mmHg[41]. In patients with cirrhosis, this gradient can be estimated by its clinical equivalent-the HVPG-which is assessed at hepatic vein catheterization and avoids the need to directly puncture the portal vein[41]. An elevated HVPG between 6 to 9 mmHg defines subclinical portal hypertension, whereas an HVPG ⩾ 10 mmHg defines clinically CSPH, since all the potential complications of the syndrome (*e.g.*, varices, ascites, *etc.*) can appear above this threshold[41]. The gold standard for the diagnosis and assessment of PH is the measurement of the HVPG, which is obtained as

Table 2 Randomized controlled trials comparing surgical resection and percutaneous ablation in patients with early hepatocellular carcinoma

Ref.	Treatment allocation	Sample size (*n*)	Serum bilirubin	Tumor median size	Nodules	Median follow-up	Recurrence rate	1/3/5 yr survival

the difference between "wedged" (occluded) and "free" hepatic venous pressures. This method is safe, objective, reproducible, and accurate; and it provides prognostic information independent of liver function. It is currently the best marker to predict clinical events in patients with liver diseases within research protocols[42].

Since development of gastroesophageal varices is a direct consequence of CSPH, the presence of esophageal varices on endoscopy is a 100% specific sign of CSPH. However, approximately 50% of well compensated patients without any evident sign of portal hypertension (*e.g.*, without esophageal varices) already show CSPH on hemodynamic assessment[43]. In the specific setting of well-compensated patients without varices, CSPH independently increases the risk of developing esophageal varices, clinical decompensation and HCC during follow-up[43-45], resulting in a higher mortality. Hence, CSPH should be always assessed in patients with cirrhosis for prognostic stratification[41].

HVPG measurement has some limitations such as cost, invasiveness (even if minor) and the need for a specific training for its performance and interpretation. Since it is not available in all centers, noninvasive surrogate methods to diagnose portal hypertension are needed, and have been widely evaluated. Non-invasive markers include laboratory tests, ultrasonography and liver stiffness. Regarding routine laboratory tests, the objective components of Child-Pugh score (albumin, bilirubin, INR) correlate with HVPG[46-48] and with the prevalence and grade of esophageal varices in cirrhotic patients. Interestingly this correlation is also observed in patients with compensated cirrhosis[49] suggesting that there is a close correlation between liver structural damage and the onset of portal hypertension and hepatocellular dysfunction. Low platelet count, either alone or in combination with spleen size[50-52] is associated with CSPH and esophageal varices, and is the single most commonly reported non-invasive sign of portal hypertension. Nonetheless, there is not any established cut-off for platelet count able to accurately diagnose or exclude CSPH in patients with cirrhosis[13].

Ultrasound (US) is the first-line imaging technique used in patients with suspected cirrhosis and portal hypertension, since it is cheap, repeatable, and allows direct visualization of the anatomical changes induced by PH[53,54]. US signs of PH in cirrhosis are multiple[55,56]; overall, the sensitivity of the technique is moderate, but its specificity is above 90%. Hence, the presence of one or more US signs of PH allows to diagnose CSPH, but the absence of signs do not exclude CSPH, suggesting that it should be investigated by more sensitive techniques (*e.g.*, HVPG measurement). Splenomegaly, defined as an increase in spleen diameter above 12 cm, is among the most commonly reported signs. It is sensitive but poorly specific, while porto-collateral vessels have a low sensitivity but 100% specificity for the diagnosis of CSPH. This last sign can be therefore considered a reliable surrogate of PH if detected either on US or on CT/MR imaging.

Liver stiffness (LS) measured by transient elastography (Fibroscan®) is a well-accepted objective non-invasive method to reliably estimate liver fibrosis[57]. It has been shown that LS and HVPG show a good correlation in patients with compensated cirrhosis[13,58]. LS cut-off for the detection of CSPH varies across studies, but it is widely accepted that values above 21 kPa have a high specificity for CSPH. This has been recently confirmed by a longitudinal study using clinical endpoints that showed that HVPG ≥ 10 mmHg and LS > 21 kPa equally predict clinical decompensation in patients with compensated cirrhosis at baseline[59], making LS the most accurate method so far for predicting CSPH. Preliminary data suggests that spleen stiffness has a better correlation with HVPG than LS, but data are still limited[60].

The combination of different non-invasive methods offers potential benefits by integrating complementary information. In a recent study by our group where HVPG was used as the gold standard for diagnosing CSPH, the combination of LS, platelet count and spleen size either as LSPS[23] or as a newly calculated PH risk score improved the accuracy of LS alone for detecting CSPH, and allowed a correct diagnosis in 86% of cases[13].

The EASL[9] and AASLD[10] practice guidelines for HCC management recommend evaluation of portal hypertension prior treatment decision in HCC patients with a single tumour. For this purpose, HVPG measurement is the best available option and should be considered the standard-of-care. However, it cannot be routinely performed in all hospitals. Platelet count below 100×10^3/mL is often used to identify CSPH, especially when associated with splenomegaly[13]. In this regard, it should be underscored that both platelet count and spleen size are inaccurate for diagnosing CSPH in this specific setting[13]. Specifically, while in patients with both signs CSPH is highly probable, the absence of thrombocytopenia and/or splenomegaly cannot exclude CSPH. This has been recently confirmed in a prospective study in patients undergoing surgery for HCC including HVPG measurement[14] and reinforces the notion that more objective and accurate methods are still needed to accurately diagnose or exclude CSPH in patients with potentially resectable HCC.

Given that liver stiffness by transient elastography is currently considered the single most reliable non-invasive surrogate marker of PH, researchers from Eastern and Western countries evaluated its accuracy to predict CSPH and PH-related complication after surgery for HCC. A study including 72 patients found that LS had a good accuracy (area under receiver operating characteristic curve 0.824) in discriminating which patients would decompensate after surgery, being superior than the test usually used in Eastern countries (indocyanine green clearance at 15 min)[61]. Our group tested LS accuracy in the diagnosis of CSPH versus the gold-standard measurement of HVPG in a series of 90 patients with Child A cirrhosis and potentially resectable HCC[24]. In the 79 patients in whom LS was feasible (88% of applicability), the correlation with HVPG was lower than previously published in patients without HCC, suggesting that factors related to tumor location might interfere with LS measurements[24]. Nonetheless, results demonstrated that a cut-off of 13.6 kPa was 90% sensitive to detect CSPH, while the 21.1 kPa cutoff was highly specific. In other words, CSPH could be reasonably excluded in patients with LS < 13.6 kPa, and reliably diagnosed in those with LS ≥ 21.1 kPa. This simple rule could eventually decrease the need for HVPG measurement by half, being confined to those patients with intermediate LS levels (between 13.6-21.1 kPa) and those with unreliable measurements (*e.g.*, obesity, *etc.*). Furthermore, combination of LS with platelet count and spleen diameter has the potential of reducing the number of patients in this "grey zone", allowing to correctly diagnose CSPH in 85% of patients, although these findings need validation in independent series.

MOLECULAR PROGNOSTIC BIOMARKERS IN SMALL HCC

There is a pressing need to incorporate prognostic and predictive biomarkers in HCC management. Genome-wide expression studies have been applied in the HCC field trying to provide physicians with better tools to characterize early lesions and even to optimize patient selection for personalize therapies.

Different studies indicate that HCC can be broadly classified according to its molecular features in two major subclasses[62]. One is characterized by molecular signals of proliferation and cell cycle, usually enriched in TP53 inactivation; whereas the second subclass is characterized by *CTNNB1* mutations and enrichment in WNT target genes *GLUL*, *LGR5*, and *LECT2*. The subclass related to proliferation can be been further divided according to the activation of other cascades such as transforming growth factor-beta signaling, insulin-like growth factor[63], Notch[64], *etc.*

Besides molecular classification, a number of studies have reported gene signatures able to predict prognosis in HCC (thoroughly reviewed elsewhere[62]), not only generated from the tumor but also from the adjacent non-tumoral cirrhotic tissue. Recently an integrated prognostic model that combines genomic information from both the tumor and the adjacent tissue together with clinical-pathologic data was able to accurately predict outcome in patients with a single nodule early HCC[65]. Despite all these data from molecular profiling studies, gene signatures have not been yet incorporated clinical practice guidelines[62].

Abstract

AIM: To investigate the role of the pelvic nerve pathway in stress-induced acceleration of colorectal transit and defecation in rats.

METHODS: Surgical transection of rectal nerves (rectal branches of the pelvic nerve), vagotomy (Vag) or adrenalectomy (Adx) were performed bilaterally in rats. Number of fecal pellet output of these rats was measured during 1-h water avoidance stress (WAS). To evaluate the colonic transit, rats were given phenol red through the catheter indwelled in the proximal colon and subjected to WAS. After WAS session, entire colon and rectum were isolated and distribution of phenol red was measured. Distal colonic and rectal transit was evaluated using glass bead. Rats were inserted the glass bead into the distal colon and evacuation rate of the bead was measured. Neural activation was assessed by immunohistochemical staining of c-Fos and PGP9.5 in colonic whole-mount preparations of longitudinal muscle myenteric plexus (LMMP).

RESULTS: In the sham-operated rats (sham op), WAS significantly increased defecation and accelerated colorectal transit with marked elevation of plasma corticosterone level. Compared with sham-operated rats, increase in the excretion of fecal pellets during WAS was significantly reduced by rectal nerve transection (RNT) (sham op: 6.9 ± 0.8 *vs* RNT: 4.3 ± 0.6, $P < 0.05$) or Vag (sham op: 6.4 ± 0.8 *vs* Vag: 3.7 ± 1.1, $P < 0.05$), although corticosterone level remained elevated. Adx-rats significantly increased the defecation despite the lower corticosterone level. Distribution pattern of phenol red showed RNT inhibited distal colonic and rectal transit accelerated by WAS, while Vag inhibited proximal colonic transit. Suppression of distal colonic and rectal transit by RNT was further confirmed by the bead evacuation rate (sham op: 80.0% *vs* RNT: 53.8%). WAS significantly increased the number of c-Fos-immunoreactive neural cells in the LMMP of the proximal and distal colon, whereas c-Fos expression was decreased by RNT in the distal colon (sham op: 9.0 ± 2.0 *vs* RNT: 4.4 ± 1.0, $P < 0.05$) and decreased by Vag in the proximal colon.

CONCLUSION: Pelvic nerve conveys WAS stimuli from the brain to the distal colon, and directly activate the myenteric neurons, followed by the increase of its motility.

INTRODUCTION

Stress is a key factor in causing abnormal bowel habits, such as constipation and diarrhea, and has been known to exacerbate these symptoms[1-4]. Accumulating evidence suggests that various stressors stimulate colonic motor functions in humans and animals[5-7]. In patients with irritable bowel syndrome, psychological and physical stressors increase colonic slow-wave, contractile, and motor activities[8]. In laboratory animals, acute exposure to restraint, cold restraint, or water avoidance stress (WAS) enhances colonic motor activity (*e.g.*, colonic motility, colonic transit, and defecation)[9-11]. The stress response is a complicated process that involves the endocrine and nervous systems. Corticotropin-releasing factor (CRF) level is increased in the hypothalamic paraventricular nuclei (PVN), amygdala, and Barrington's nucleus after acute exposure to stressful stimuli[12-15]. CRF is released in the PVN, resulting in the secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary into the bloodstream. ACTH then increases the release of glucocorticoid from the cortex of the adrenal gland, which is called the hypothalamic-pituitary-adrenal axis (HPA-axis)[16]. Another endocrine system, the sympathetic-adrenal-medullary axis (SAM-axis), is activated by stress and subsequently induces the adrenal medulla to release adrenaline and noradrenaline[17]. These two major bodily pathways cause metabolic, cardiovascular, immune, and behavioral responses[18-20]. The gastrointestinal tract from the esophagus to the distal colon is innervated by parasympathetic vagal efferent fibers from the dorsal motor nucleus in the medulla oblongata[21]. Recently, it was demonstrated that vagotomy (Vag) reduced the restraint stress-induced increase in colonic transit in rats[22,23]. This evidence suggests that physical stress causes colonic dysmotility *via* parasympathetic vagal activation. On the other hand, the efferent fiber from Barrington's nucleus projects to the sacral spinal cord and terminates in the region of the preganglionic pelvic nerves[24,25]. This pelvic efferent is also classified as the parasympathetic nerve and projects to the distal colon and rectum[26]. In rats, activation of the pelvic nerve regulates distal colonic and rectal motility under physiological conditions[27], and electrical nerve stimulation elicits contractions in the rectum[28]. Million *et al*[29] demonstrated that WAS activates the sacral parasympathetic nucleus. However, it is still unclear whether activation of the pelvic nerve is involved in altered colonic and rectal motilities under stressed conditions.

In this study, we examined the role of the pelvic nerve pathway in the activation of defecation, colorectal transit, and myenteric neurons under psychological stress by surgically transecting the rectal branches of the pelvic nerve in rats. Additionally, we compared the differences between colorectal functional changes in pelvic nerve transected rats and vagotomized rats.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats (Japan SLC, Shizuoka, Japan) weighing 300-400 g were maintained under a 12-h/12-h light dark cycle (8:00-20:00) with free access to food and water. All animal experiments were approved by the ethical committee for animal experiments of Yakult Institute. All animals were kept in individual cages in a controlled environment with constant temperature (23 ℃ ± 2 ℃) for at least 1 wk before experiments.

WAS

Rats were placed on a rectangular platform (11 cm × 7 cm × 8 cm) in the center of a plastic cage (41 cm × 25 cm × 20 cm) for a 1-h or 2-h period. The cage was filled with water kept at room temperature to the height of 1 cm from the top of the platform. Control rats were placed on the same platform for 1 or 2 h in a cage without water (sham stress). After loading stress, the number of fecal pellets excreted in the cage was counted. WAS and sham stress tests were carried out between 9:00 and 12:00. The animals were placed in a plastic cage for 1 h the day before the experiments, and the rats that excreted more than 5 fecal pellets were excluded from the stress experiment. Each rat was exposed to WAS only once.

Measurement of fecal pellet output and plasma corticosterone

The number of fecal pellets found in the tank was counted and blood samples were collected into heparinized tubes from the tail vein immediately after the 1-h WAS or sham stress session. Blood samples were centrifuged and plasma was stored at -80 ℃ until measurement. The plasma corticosterone concentration was analyzed by the Correlate-EIA corticosterone enzyme immunoassay kit (Enzo Life Sciences, Farmingdale, NY, United States) according to the manufacturer's instructions.

Surgical procedure

Rectal nerve transection (RNT), subdiaphragmatic Vag, or adrenalectomy (Adx) was performed in rats that were anesthetized by intraperitoneal injection (*ip*) of pentobarbital sodium (50 mg/kg; Somnopentyl, Kyoritsu Seiyaku, Tokyo, Japan). We transected the rectal nerve branches from the pelvic plexus to avoid the impairment of the micturition reflex in the present study. A midline incision was made in the abdomen and the rectal nerves were bilaterally transected at a short distance from the major pelvic ganglion. Anterior and posterior branches of the Vag were resected above the hepatic and celiac branches, and the adrenal glands were removed bilaterally. These procedures were performed using forceps under a microscope. Sham-operated animals underwent the same procedure without the above-described resection and removal. The abdominal wall and skin were sutured after completion of surgery. Rats that did not show elevated body weight during the recovery period were excluded from the experiments. Experiments were performed 7-10 d after the surgery.

Assessment of colonic transit

Rats were anesthetized by pentobarbital sodium (50 mg/

kg, *ip*). A polyethylene catheter (PE-50, Becton, Dickinson and Company, Franklin Lakes, NJ, United States) was inserted from the cecum, and the tip was positioned in the proximal colon 1 cm distal to the cecocolonic junction. The other side of the catheter was tunneled subcutaneously to the posterior neck. Rats were given phenol red (10 mg/mL in a volume of 0.4 mL, Sigma-Aldrich, St Louis, MO, United States) through the catheter that was positioned in the proximal colon and subjected to WAS or sham stress for 1-h at 7-10 d after surgery. After the stress session, rats were euthanized with an *ip* overdose of pentobarbital sodium. The entire colon and rectum were isolated and divided into 8 equal segments, where the number of the segments from 1 to 8 was consistent with each segment that was isolated from the start of the proximal colon to the rectum. Segments 1-5 were defined as proximal colon while segments 6-8 were defined as distal colon and rectum. The number of fecal pellets in segments 6-8 was counted. Each segment was transferred into tubes and washed 3 times in phosphate buffered saline (PBS), to which followed the addition of 5 mol/L NaOH by one fifth volume. The absorbance was measured at 560 nm to calculate the volume of phenol red. The geometric center was calculated using the following equation.

Geometric center = Σ (fraction of phenol red per segment × segment number)

Assessment of transit in distal colon and rectum

The rats were fasted overnight with water ad libitum before the experiment. A single 5-mm glass bead was inserted into the distal colon (3 cm proximal to the anus). The rat was subjected to WAS or sham stress for 2-h immediately after bead insertion and the evacuation rate was monitored over a 2-h period.

Immunohistochemical analysis

Rats were euthanized with an *ip* overdose of pentobarbital sodium 1 h after the WAS or sham stress session. The proximal colon (2 cm distal to the cecocolonic junction) and distal colon (4 cm proximal to the anus) were isolated and placed in 0.01 mol/L PBS (pH 7.4). The isolated colon was opened along the mesenteric border, stretched and pinned flat on a Silicon-coated petri dish (Shin-Etsu Chemical, Tokyo, Japan), and fixed overnight in 4% paraformaldehyde in 0.1 mol/L phosphate buffer at 4 ℃. The following day, tissues were washed (3 × 10 min) in PBS, the mucosa, submucosa, and circular muscle were removed, and whole mount preparations of longitudinal muscle myenteric plexus (LMMP) were prepared. The preparations were washed (3 × 10 min) in PBS and incubated in 5% normal donkey serum (Jackson Immuno Research Laboratories, West Grove, PA, United States) in PBS containing 0.3% Triton X-100 (PBS-T) for 30 min at room temperature. The preparations were incubated with rabbit anti-c-Fos (1:10000; Ab-5; Merck Calbiochem, Darmstadt, Germany) and mouse anti-protein gene product 9.5 (PGP9.5, a marker of enteric neurons, 1:50; ab8189; Abcam, Cambridge, United Kingdom) overnight at 4 ℃. The preparations were washed (3 × 10 min) in PBS-T and incubated with donkey anti-rabbit Alexa 488 (Molecular probes, Eugene, OR, United States) and donkey anti-mouse IgG Cy3-conjugated antibody (Millipore, Billerica, MA, United States). After washing (3 × 10 min) in PBS-T, the preparations were mounted on glass slides using VECTASHIELD (Vector Laboratories, Burlingame, CA, United States) and analyzed by the Zeiss LSM 510 confocal microscope with LSM Image Browser software (Carl Zeiss, Jena, Germany). The number of c-Fos immunoreactive (IR) cells was counted in 10 randomly selected ganglia in each preparation per rat and the means of c-Fos-IR cells per rat were used to calculate the mean of each group.

Statistical analysis

All results are presented as mean ± SE. Comparisons between 2 groups were evaluated using the unpaired Student's *t* test or χ^2 test. Comparisons between the mean values of multiple groups were performed with one-way analysis of variance followed by Dunnett's multiple comparison test. *P* values of < 0.05 were considered statistically significant.

RESULTS

Effect of RNT, Vag and Adx on the WAS-induced increase in defecation

When rats were subjected to acute WAS for 1-h, the number of excreted fecal pellets was significantly increased compared to rats under sham stress (4.6 ± 1.0 *vs* 0.8 ± 0.4, $P < 0.01$). Plasma corticosterone levels markedly rose in rats just after WAS compared with those under sham stress (161.6 ± 29.5 ng/mL *vs* 24.2 ± 5.3 ng/mL, $P < 0.01$) (Figure 1A).

The sham-operated rats in RNT or Vag (Figure 1B-C) evacuated more fecal pellets and showed higher level of corticosterone in plasma after WAS treatment. The WAS-induced increase in fecal pellet output was significantly suppressed by treating RNT beforehand (sham op-WAS: 6.9 ± 0.8, RNT-WAS: 4.3 ± 0.6, $P < 0.05$), although the elevation of corticosterone was almost equally observed in RNT-rats and sham-operated rats (Figure 1B). Defecation under the condition of sham stress did not differ in RNT-rats and sham-operated rats. Similarly, Vag significantly reduced the WAS-induced increase in fecal pellet output (sham op-WAS: 6.4 ± 0.8, Vag-WAS: 3.7 ± 1.1, $P < 0.05$), but did not suppress the increase in corticosterone levels induced by WAS (Figure 1C).

On the other hand, WAS significantly increased the number of fecal pellets in Adx-rats compared with sham stress (7.4 ± 0.8 *vs* 3.6 ± 0.9). The baseline levels of plasma corticosterone were lower in Adx-rats than in sham-operated rats, and an obvious change in plasma corticosterone level was not observed after WAS in Adx-rats (Figure 1D).

Effect of RNT and Vag on WAS-induced acceleration of colonic transit

We evaluated whether the pelvic nerve pathway is in-

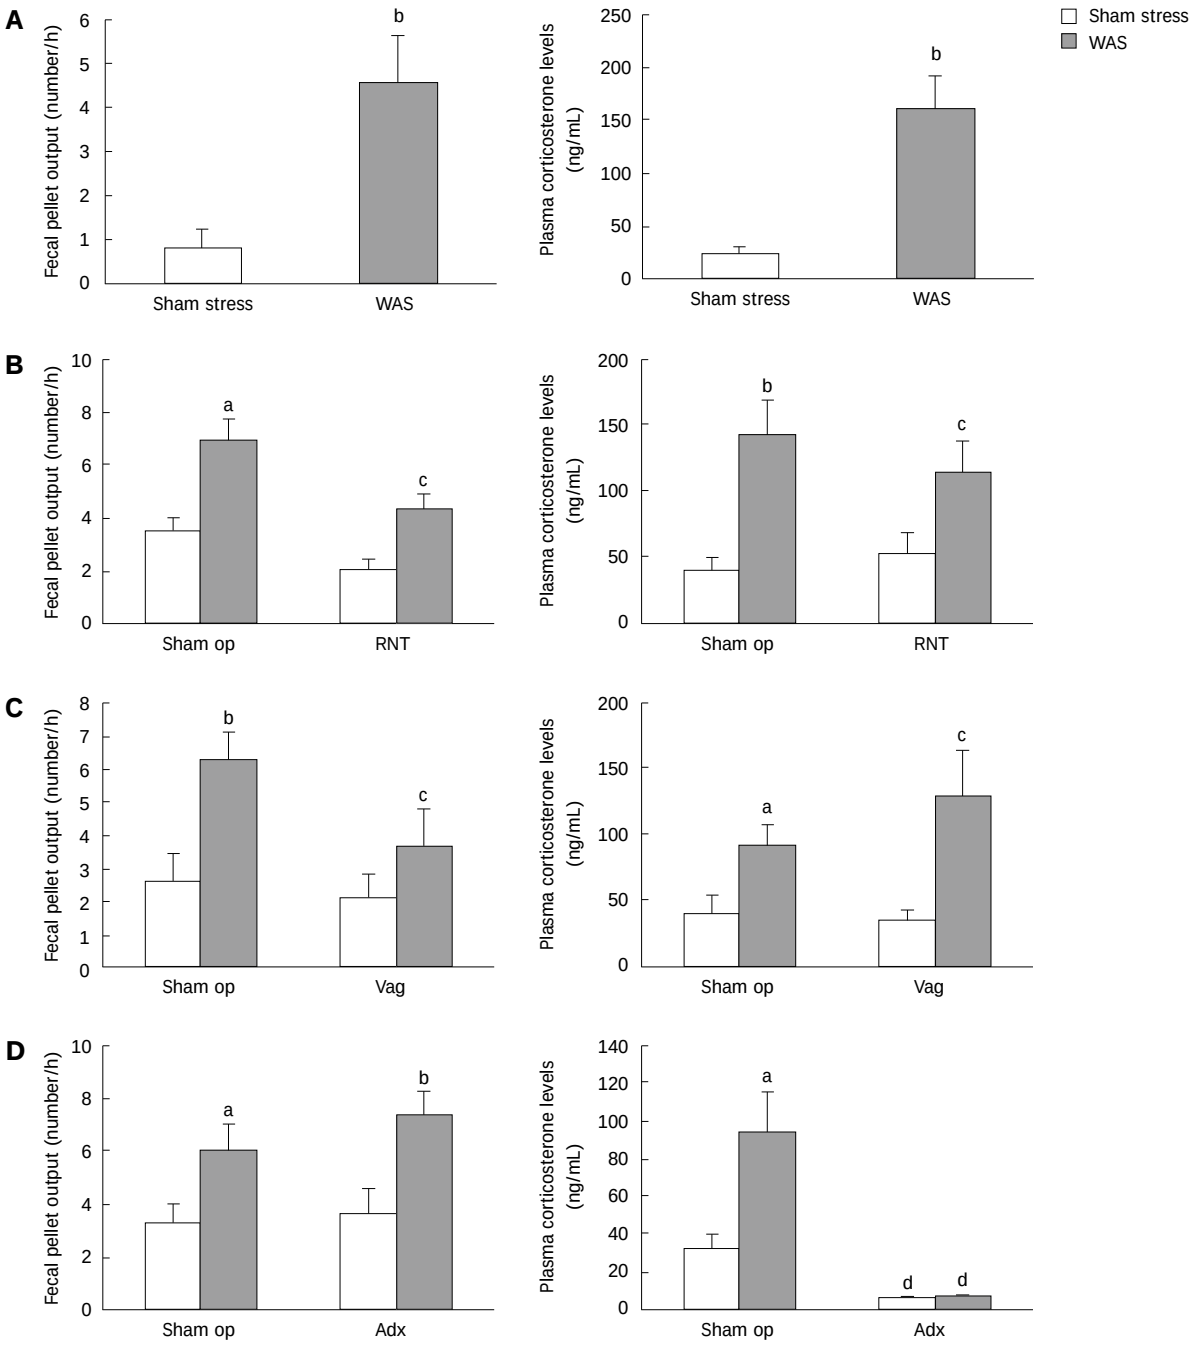

Figure 1 Involvement of parasympathetic nerves and corticosterone in the accelerated defecation induced by acute water avoidance stress. A: The naive rats showed increases in defecation and corticosterone levels after 1-h of water avoidance stress (WAS) compared with sham stress; B-D: Effects of rectal nerve transection (RNT), vagotomy (Vag) and adrenalectomy (Adx) on WAS-induced increases in defecation and plasma corticosterone in rats. Each value represents the mean ± SE (n = 6-12 per group). [a]$P < 0.05$, [b]$P < 0.01$ *vs* the response of sham stress rats; [c]$P < 0.05$, [d]$P < 0.01$ *vs* sham-operated (sham op) rats.

volved in the colonic transit during the stress session. Phenol red, a non-absorbable marker, was injected into the proximal colon *via* a catheter before stress, and geometric center was measured in the rats under the different stress conditions. In sham-operated rats, WAS significantly increased the geometric center (4.6 ± 0.4 *vs* 3.5 ± 0.1, $P < 0.05$, Figure 2A), and also RNT-rats were found to exhibit the higher geometric center after WAS treatment although the difference was not statistically significant (Figure 2A). In contrast, WAS-induced increase of geometric center was completely suppressed in Vag-rats (sham op-WAS: 5.2 ± 0.4, Vag-WAS: 3.8 ± 0.2, $P < 0.001$, Figure 2B).

In sham-stressed RNT- and Vag-rats, the phenol red was distributed over a wide range from segments 1-8 with peaks at segments 3-4. The phenol red contents decreased in segments 1-4 and increased in segments 6-8 in sham-operated rats after WAS loading compared with sham stress (Figure 2C and E). In RNT-rats, the peak of phenol red at segment 3 during sham stress shifted to segments 4-6 after WAS loading (Figure 2D). However, the distribution pattern of phenol red did not change in

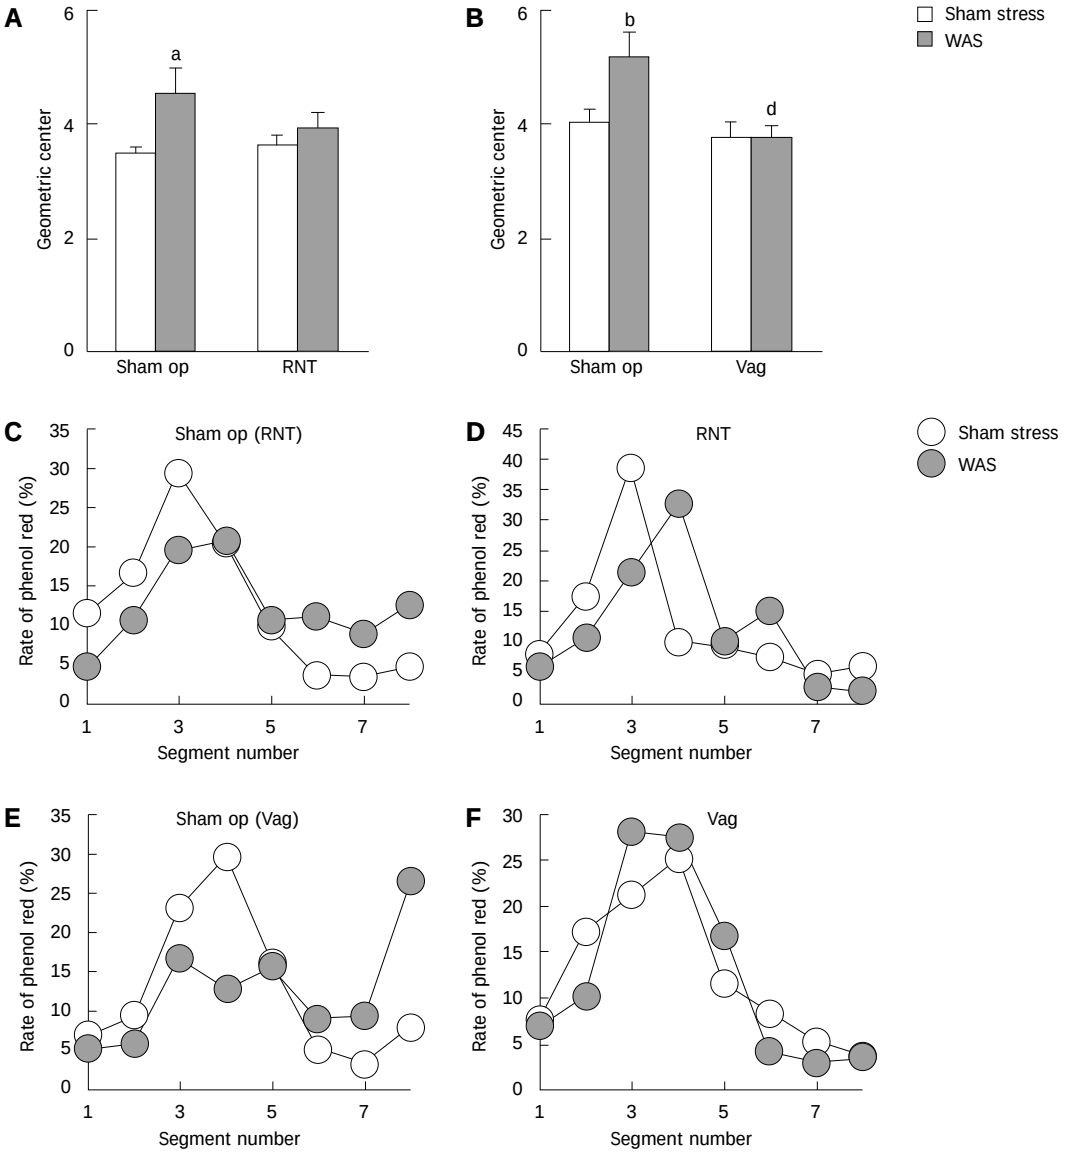

Figure 2 Involvement of parasympathetic nerves in the bowel movement. A, B: Effects of rectal nerve transection (RNT) (A) and vagotomy (Vag) (B) on the colonic transit presented by geometric center of moved phenol red; C-F: Relative distribution of phenol red through the entire colon and rectum after water avoidance stress (WAS) in sham-operated rats (C, E), RNT-rats (D) and Vag-rats (F). Each value represents the mean of 6-8 rats. [a]$P < 0.05$, [b]$P < 0.01$ *vs* the response of sham stress rats; [d]$P < 0.01$ *vs* sham-operated (sham op) rats.

Vag-rats even after WAS was treated (Figure 2F).

The number of luminal feces in the distal colon and rectum was higher in RNT-rats and Vag-rats than in sham-operated rats during sham stress (baseline values) [sham op (RNT): 2.3 ± 0.5, RNT-rats: 4.1 ± 0.4, sham op (Vag): 2.1 ± 0.4, Vag-rats: 3.0 ± 0.5, Table 1]. WAS tended to reduce luminal feces in sham-operated and Vag-rats, with differences of -0.6 and -1.8 between luminal feces in sham stress and in WAS, respectively (Table 1). The number of fecal pellets was increased by WAS in RNT-rats, but was decreased in sham op- and Vag-rats. (B)-(A) indicates the differences of the influx and efflux of fecal pellets from the distal colon and rectum. However, the difference between sham stress and WAS was 0.1 feces in RNT-rats, indicating that the luminal feces in segments 6-8 did not decrease under WAS in these rats.

Effect of RNT and Vag on WAS-induced acceleration of distal colonic and rectal transit

Preganglionic parasympathetic pelvic nerves project from the sacral spinal cord to the distal colon and rectum[26]. Thus, to investigate the effect of RNT on WAS-induced distal colonic and rectal transit, a glass bead was inserted until 3 cm depth from the anus into the distal colon, and the evacuation rate of the bead was monitored over a 2-h period.

In sham-operated rats, WAS significantly increased the rate of bead evacuation to 80% compared to 38% in sham stress, but this increase was not observed in RNT-rats subjected to WAS (Figure 3A). On the other hand, Vag did not affect the WAS-induced increase in the bead evacuation rate (Figure 3B).

Table 1 Number of luminal fecal pellets remaining in the distal colon and rectum after sham stress or water-avoidance stress

	Number of fecal pellets in the distal colon and rectum		
	Sham stress (A)	WAS (B)	(B) - (A)
Sham op (Vag)	2.1 ± 0.4	1.5 ± 0.2	-0.6
Vag	3.0 ± 0.4	1.2 ± 0.5[a]	-1.8
Sham op (RNT)	2.3 ± 0.5	1.1 ± 0.3	-1.2
RNT	4.1 ± 0.4[c]	4.3 ± 0.4[d]	0.1

Each value represents the mean ± SE (n = 6-8 per group). [a]P < 0.05 *vs* sham stress; [c]P < 0.05 , [d]P < 0.01 *vs* sham operated (sham op) rats. WAS: Water-avoidance stress; Vag: Vagotomy; RNT: Rectal nerve transection.

c-Fos expression in LMMP of RNT- and Vag-rats after WAS treatment

After rats were exposed to WAS for 1 h, the number of c-Fos-IR cells was examined in whole mount preparations of LMMP from the distal colon at 0, 1, 2 and 4 h later. The maximum increase after WAS was found at 0 h, and this number returned to a normal level within 4 h (data not shown). Therefore, we measured c-Fos expression immediately after the WAS session (1-h) in all of the following experiments using denervated rats.

The number of c-Fos-IR cells per ganglia in the LMMP of both the proximal and distal colon (Figures 4 and 5) was increased by WAS compared with sham stress. RNT significantly reduced the WAS-induced increase of c-Fos-IR cells in the LMMP by 52% in the distal colon compared with sham-operated rats (4.4 ± 1.0 *vs* 9.0 ± 2.0, P < 0.05, Figure 5B). In contrast, Vag inhibited the increase in c-Fos-IR cells after WAS in the LMMP of proximal colon but not of distal colon (1.7 ± 1.0 *vs* 5.2 ± 1.3, Figure 5C and D).

DISCUSSION

In the present study, we demonstrated the functional importance of the pelvic nerve pathway in the response to psychological stress by showing that transection of the rectal branches of the pelvic nerve (RNT) inhibited the WAS-induced increase in fecal pellet output in rats. This inhibitory effect is supported further by the observation that the RNT inhibited the increased propulsive activity of the distal colon and rectum as shown in the analysis of the colorectal excretion rate of glass beads. Therefore, it is likely that WAS accelerates distal colonic and rectal motilities *via* activation of the pelvic nerve, resulting in increased defecation in the rat. Lenz[22] and Nakade *et al*[23] showed that Vag reduced the restraint stress-induced increase in colonic motility in rats, suggesting that physical stress causes colonic dysmotility *via* parasympathetic vagal activation. Vag also suppressed the WAS-induced increase in fecal pellet output in our study, which is consistent with their results. Our study also confirmed that proximal part of the colonic transit was accelerated in RNT-rats, whereas it was inhibited in Vag-rats under stressed conditions. In fact, many hard fecal pellets remained in the distal colon and rectum of RNT-rats in spite of WAS loading. In contrast, luminal fecal pellets in the distal part of the colon and rectum were decreased in sham-operated and Vag-rats after WAS. These results suggest that pelvic nerve activation by WAS accelerates motor activities of distal colon and rectum, but not in those of proximal colon. On the other hand, Vagus nerve activation accelerates the proximal colonic transit, but not the distal colonic and rectal transit. Therefore, the difference in projection sites of the gut between the pelvic and vagal efferent nerves may be responsible for the differential actions in the gut[21,26]. The pelvic nerve innervates the distal colon and rectum, and regulates rectal motility in the physiological conditions[27]. In this study, a larger number of fecal pellets remained in the distal colon and rectum in RNT-rats without stress, compared with sham-operated rats. These observations suggest that the pelvic nerve pathway may be involved in colorectal motility in the non-stressed conditions. In addition, our findings demonstrate that acute psychological stress stimulates colorectal transit *via* the pelvic nerve pathway.

Recently, c-Fos protein expression has been used as a marker of neural cell activation[30]. c-Fos expression was significantly increased in PGP9.5-positive myenteric neurons in the proximal and distal colon after WAS. This finding is similar to that of a study by Miampamba *et al*[31], who reported increased c-Fos expression in the

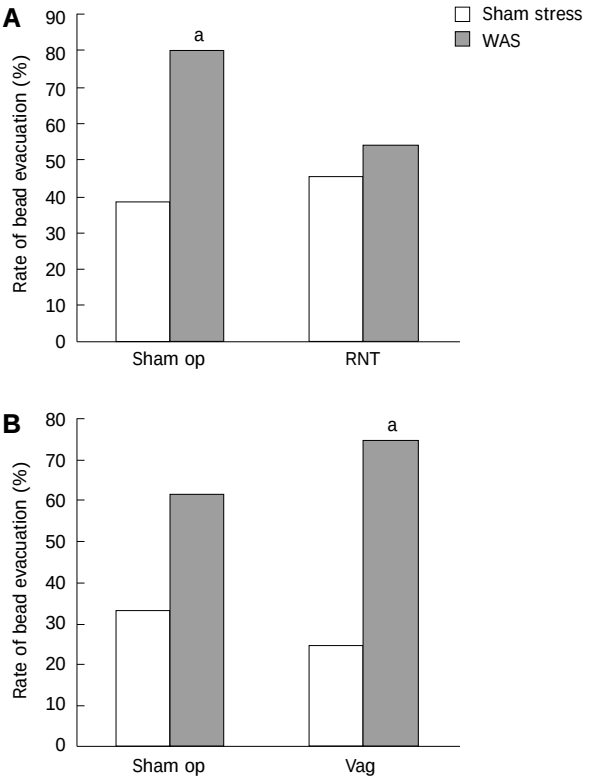

Figure 3 Involvement of parasympathetic nerves in the fecal expulsion through the distal colon. A, B: Effects of rectal nerve transection (RNT) (A) and vagotomy (Vag) (B) on the rate of bead evacuation from the distal colon during 2-h water avoidance stress (WAS). The increased rate of bead evacuation in sham-operated rats was inhibited in RNT-rats. Each value represents the mean ± SE (n = 11-15 per group). [a]P < 0.05 *vs* sham stress rats.

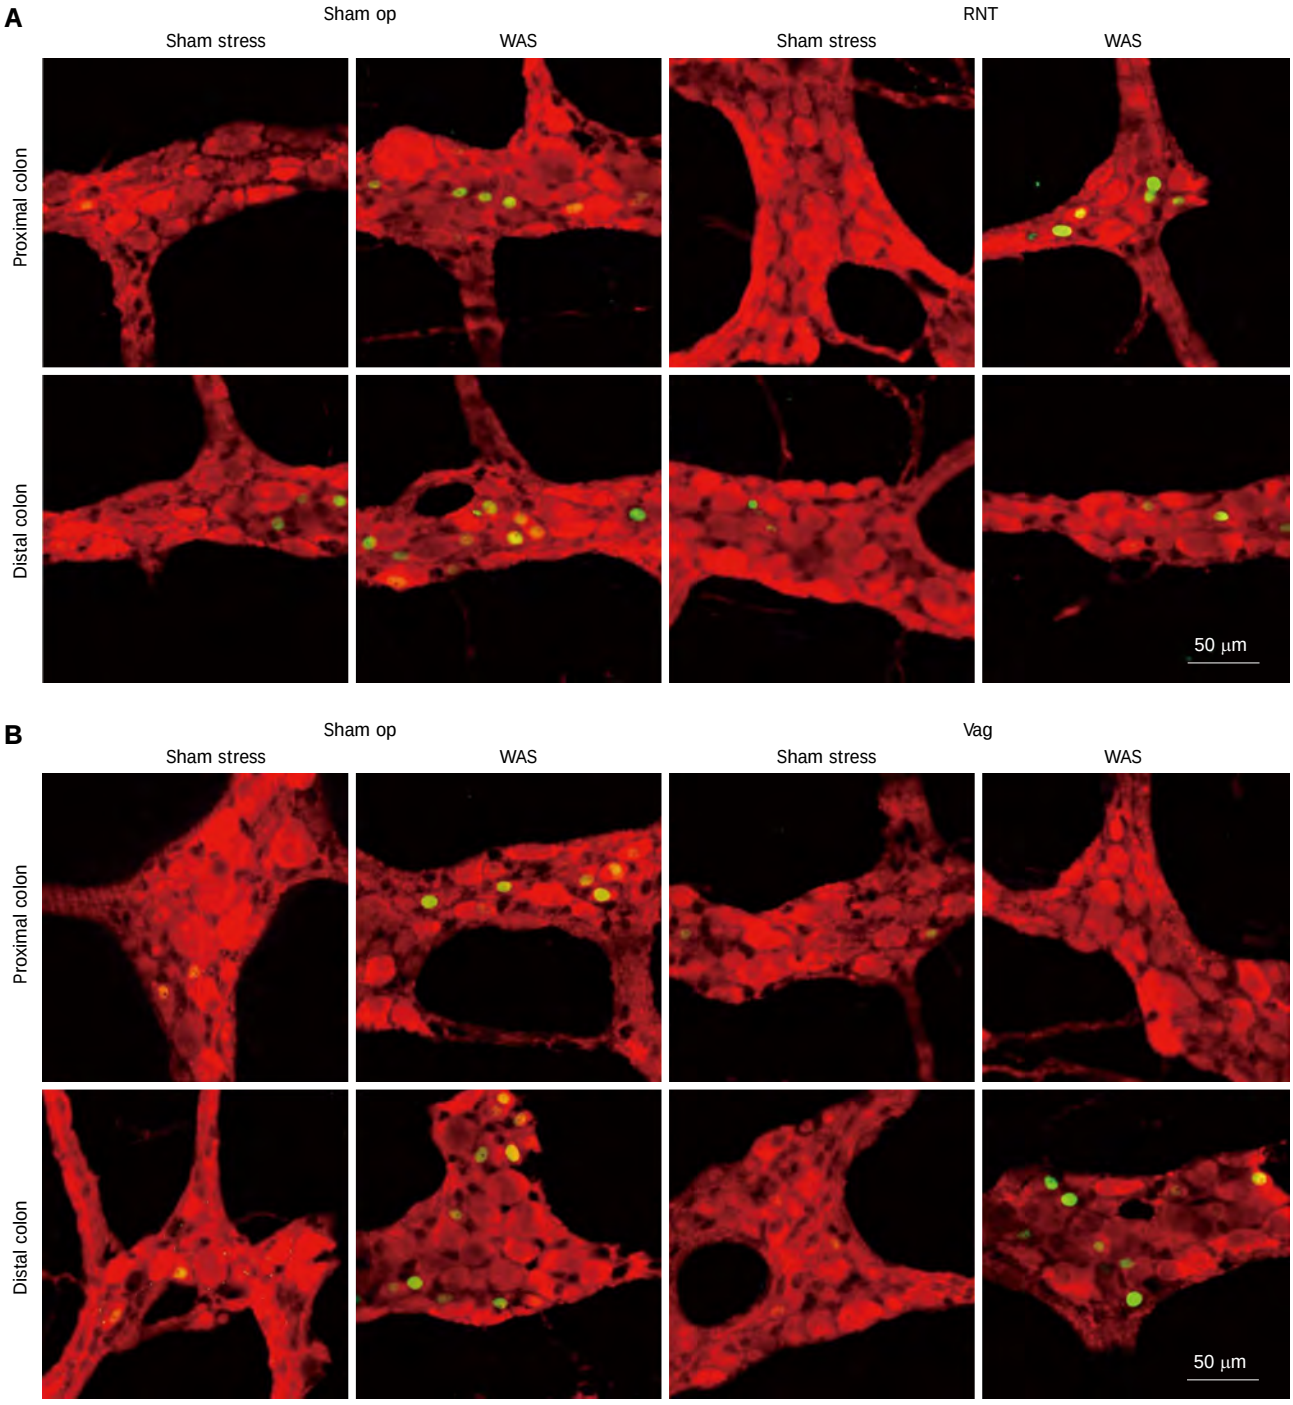

Figure 4 Induction of c-Fos expression after exposure to water avoidance stress. Confocal microscope images showing the staining of c-Fos (green) and protein gene product 9.5 (PGP9.5, red) in whole mount preparations of longitudinal muscle myenteric plexus in rectal nerve transection (RNT) (A) and vagotomy (Vag) rats (B). WAS: Water avoidance stress; Sham op: Sham-operated.

myenteric ganglia of the proximal and distal colon after WAS. Enhanced c-Fos expression was correlated with the number of fecal pellets in the rats and was significantly suppressed in the distal, but not proximal, colon by the denervation of pelvic nerve branches after WAS. On the other hand, Vag suppressed c-Fos expression in the proximal colon but had no effect in the distal colon. These results concerning c-Fos expression are consistent with the differences in the functional site of action between the vagus and pelvic nerves, as discussed above. It is yet unclear whether c-Fos expression, which was induced by WAS-loading, is a direct or indirect response to pelvic efferent nerve activation. As a direct effect, c-Fos expression could be due to inputs from the preganglionic efferent fibers to the myenteric neurons[21,26]. As indirect effect, this may be due to mechanisms such as colonic motility and secretory responses, sensory neurons and interneurons in enteric nervous systems, or the release of gastrointestinal hormones and other factors that activate myenteric neurons. Although we did not clarify the

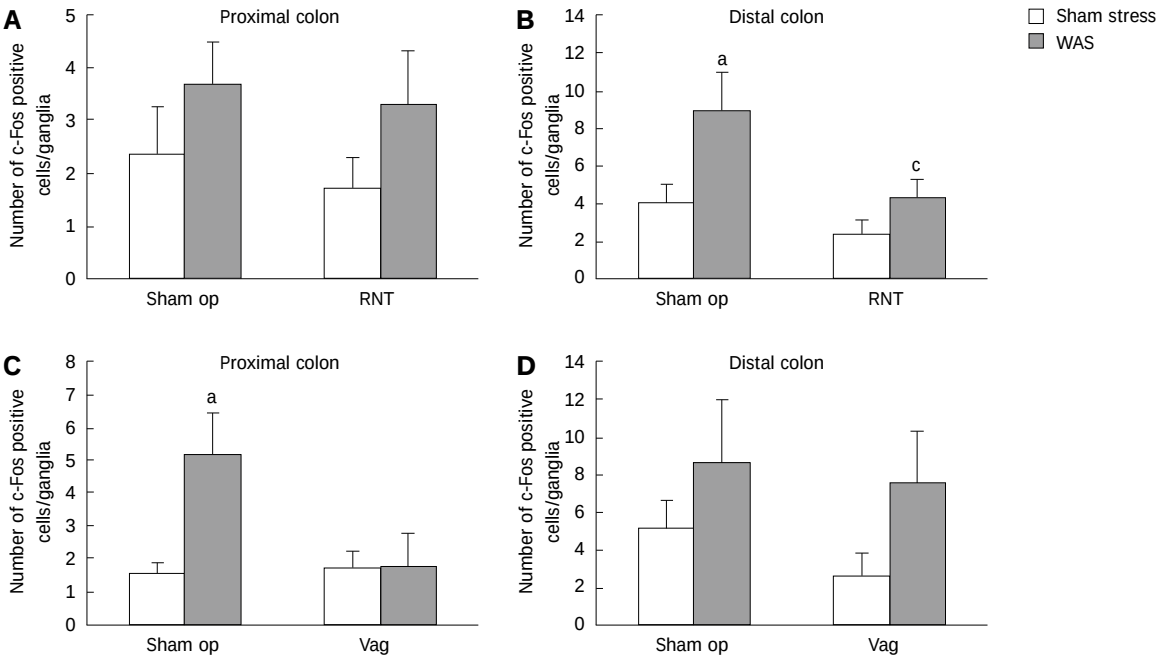

Figure 5 Effects of vagotomy and rectal nerve transection on the induction of c-Fos-expressing cells in the colon after water avoidance stress. Using whole mount preparations of longitudinal muscle myenteric plexus in the proximal (A, C) and distal colons (B, D), numbers of c-Fos immunoreactive cells per ganglia in the proximal and distal colons of rectal nerve transection (RNT) rats (A, B) and vagotomy (Vag) rats (C, D) after water avoidance stress (WAS) treatment were counted and compared to those of sham stress rats. Each value represents the mean ± SE (n = 6-12 per group). [a]$P < 0.05$ *vs* sham stress rats; [c]$P < 0.05$ *vs* sham-operated (sham op) rats.

types of neurons that expressed c-Fos protein in these experiments, myenteric neurons are generally classified as motor neurons, sensory neurons, and interneurons based on histological and morphological properties[31,32]. A double-labeling study revealed that 24%-25% of the total peripheral-choline acetyltransferase-positive neurons, which are mostly motor neurons in the myenteric plexus[32], were c-Fos positive in the proximal and distal colon after WAS[31]. Furthermore, the muscarinic receptor antagonist atropine inhibits the WAS-induced increase in fecal pellets without reducing the elevation of c-Fos-IR nuclei in the proximal and distal colonic LMMP[31,33]. Taken together, these results suggest that myenteric neurons in the distal and proximal colon are activated directly *via* the pelvic and vagal efferent, respectively, followed by acceleration of colonic transit and defecation.

The HPA-axis is also known as a key stress response pathway. HPA-axis activation ultimately induces corticosterone release from the adrenal gland[16]. In this study, the failure to release corticosterone by bilateral Adx did not affect the WAS-induced increase in fecal pellets. Furthermore, Lenz[22] showed that Adx or hypophysectomy did not alter the restraint stress-induced acceleration of colonic transit. These results indicate that the HPA-axis is not mainly involved in acute stress-induced acceleration of colorectal transit and defecation. Our results from adrenalectomized rats in this study also imply that the SAM-axis is of little importance in acute stress-induced colonic dysmotility because Adx inhibits the SAM-axis in addition to the HPA-axis[34]. It was shown recently that a corticoid-receptor antagonist inhibits chronic stress-induced defecation, indicating that the HPA-axis could be involved in the acceleration of colonic motor function by stress[35]. It is not clear why this corticoid-receptor antagonist decreased stress-induced colonic motor function, but this might be due to the different mechanisms that are involved in acute and chronic stress. In fact, it has been reported that chronic exposure of the amygdala to corticosterone delayed colorectal transit after WAS[36]. The current study has only examined the involvement of the parasympathetic nerves in stress-induced acceleration of colonic transit and defecation. The colon and rectum also receives sympathetic inputs from the lumbar colonic nerves and hypogastric nerves. It has been shown that stimulation of sympathetic nerves inhibits rectal motility in guinea pigs and cats[37-39]. Furthermore, it has been reported that sympathetic nerve denervation increased the c-Fos immunoreactivity in the LMMP[40] and the rectal motility[27]. These results suggested that sympathetic nerves may negatively regulate the colonic motor function. In the stressed-condition, however, it remains to be determined whether sympathetic nerve activity participates in the acceleration of colorectal transit and defecation induced by stress. Further experimental investigations are needed to understand the involvement of sympathetic nerves in stress-induced colonic dysmotility.

In conclusion, we have shown that WAS-induced acceleration of distal colonic transit and defecation is mediated by the parasympathetic pelvic efferent. The pelvic nerve may convey stress stimuli from the brain to the distal colon and rectum, directly activating myenteric neurons and subsequently accelerating distal colonic motility.

In contrast, WAS-induced acceleration of colonic transit and activation of myenteric neurons in proximal colon is mediated by parasympathetic vagal efferent.

COMMENTS

Background

Stress is a key factor in causing abnormal bowel habits, such as constipation and diarrhea, and has been known to exacerbate these symptoms. It has been described that various stressors stimulate colonic motor functions. Although it is reported that the activation of colonic motor function is mediated *via* the parasympathetic vagus nerve, there are few studies that have reported the involvement of the parasympathetic pelvic nerve in stress-induced gut dysmotility.

Research frontiers

The pelvic efferent projects from the sacral parasympathetic nucleus to the distal colon and rectum. It is reported that water avoidance stress (WAS) activate the sacral parasympathetic nucleus, however, it is still unclear whether activation of the pelvic nerve is involved in altered colonic and rectal motilities under stressed conditions.

Innovations and breakthroughs

This study demonstrated the importance of the pelvic nerve in the response to WAS-induced acceleration of distal colonic transit and increase of defecation. Furthermore, the results confirmed the involvement of vagus nerve to WAS-induced acceleration of proximal colonic transit. This is the first study to report the differences in the functional site of action between two nerves under stressed condition.

Applications

By understanding how stress stimuli cause the colonic dysmotility, these results would be useful for the therapeutic applications of stress-related colonic motor dysfunction, such as irritable bowel syndrome.

Terminology

Longitudinal muscle myenteric plexus (LMMP): LMMP is generally used as immunohistochemical study of the myenteric plexus; c-Fos: c-Fos protein is the product of immediate-early gene, c-fos, which is used as a marker of neural activation.

Peer review

The authors clearly demonstrated involvement of pelvic nerve in the psychological stress-induced acceleration of distal colonic transit and defecation. Additionally this study suggested that pelvic nerve directly activate the myenteric neurons and subsequently accelerating distal colonic motility. This is an interesting study, that clarify the role of the pelvic and vagus nerve in the stress-induced colonic dysmotility.

Abstract

AIM: To investigate lipopolysaccharide (LPS) related signal transduction in interstitial cells of Cajal (ICCs) from mouse small intestine.

METHODS: For this study, primary culture of ICCs was prepared from the small intestine of the mouse. LPS was treated to the cells prior to measurement of the membrane currents by using whole-cell patch clamp technique. Immunocytochemistry was used to examine the expression of the proteins in ICCs.

RESULTS: LPS suppressed the pacemaker currents of ICCs and this could be blocked by AH6809, a prostaglandin E2-EP2 receptor antagonist or NG-Nitro-L-arginine Methyl Ester, an inhibitor of nitric oxide (NO) synthase. Toll-like receptor 4, inducible NO synthase or cyclooxygenase-2 immunoreactivity by specific antibodies was detected on ICCs. Catalase (antioxidant agent) had no action on LPS-induced action in ICCs. LPS actions were blocked by nuclear factor κB (NF-κB) inhibitor, actinomycin D (a gene transcription inhibitor), PD 98059 (a p42/44 mitogen-activated protein kinases inhibitor) or SB 203580 [a p38 mitogen-activated protein kinases (MAPK) inhibitor]. SB 203580 also blocked the prostaglandin E2-induced action on pacemaker currents in ICCs but not NO.

CONCLUSION: LPS inhibit the pacemaker currents in ICCs *via* prostaglandin E2- and NO-dependent mechanism through toll-like receptor 4 and suggest that MAPK and NF-κB are implicated in these actions.

INTRODUCTION

Many morphological or functional studies have disclosed the roles of interstitial cells of Cajal (ICCs) in many organs including gastrointestinal (GI) tract. An accumulation of

evidence from these studies has revealed ICCs has the distinct role in pacemaker activity[1-3] and as mediators of enteric motor neurotransmission in GI tract[4-6]. For development and maintenance, the ICCs express the receptor tyrosine kinase Kit[1,3,7]. And, it is well known that c-Kit or ANO1 can be a selective molecular marker for researching the distribution and function of ICCs[8].

GI inflammation can be cause by inflammatory cytokines such as interleukins, chemical inflammatory mediators *etc* and lipopolysaccharide (LPS) from gram-negative bacteria is a major causative factor of GI inflammation[9]. Various *vivo* and *vitro* experiments showed LPS could play a major role in GI motility disorders[10-13]. Also, there are several reports that the morphological and functional changes of ICCs are involved in inflammation-induced GI motility[14-16]. These indicate ICCs may be important target for inflammation-induced motility disorders. Recently we reported that LPS inhibited the pacemaker currents in cultured ICCs from mouse small intestine. LPS-action was blocked by cyclooxygenase (COX)-2 inhibitor or nitric oxide (NO) synthase inhibitor, suggesting prostaglandins (PGs) and NO are involve in these actions[17], can verify this.

Generally, the stimulation of LPS rouses regulatory pathways such as the nuclear factor κB (NF-κB) pathway, as well as reactive oxygen species (ROS) signaling cascades *via* a toll like receptor-4-mediated signaling pathway[18]. Furthermore, the stimulation of LPS results in the activation of kinases including extracellular signal-regulated kinases, c-Jun N-terminal kinase (JNK) and p38 mitogen-activated protein kinases (MAPKs) critical for growth and cytokine production that induces inflammatory-related substances, such as interleukin, PGs, inducible NO synthase (iNOS) *etc*[19-21]. Our previous report suggested production of inflammatory-related substances, such as prostaglandin E2 (PGE_2) or NO are involved in LPS-induced action on ICCs[17]. However, the details of the PGs or iNOS induction in ICCs by LPS stimulation remain unclear.

In the present study, we aimed to clarify the involvement of NF-κB, ROS and MAPKs that contribute to PGs or iNOS induction in ICCs and changing of pacemaker activity in LPS-treated ICCs.

MATERIALS AND METHODS

Solutions and drugs

The cells were bathed in a solution containing 5 mmol/L KCl, 135 mmol/L NaCl, 2 mmol/L $CaCl_2$, 10 mmol/L glucose, 1.2 mmol/L $MgCl_2$, and 10 mmol/L HEPES, adjusted to pH 7.2 with Tris. NaCl was replaced with equimolar *N*-methyl-D-glucamine for making Na^+-free solution, and $CaCl_2$ was omitted in the bath solution for Ca^{2+}-free solution. The pipette solution contained 20 mmol/L K-aspartate, 120 mmol/L KCl, 5 mmol/L $MgCl_2$, 2.7 mmol/L K_2ATP, 0.1 mmol/L Na_2GTP, 2.5 mmol/L creatine phosphate disodium, 5 mmol/L 4-(2-Hydroxyethyl) piperazine-1-ethanesulfonic acid (HEPES), and 0.1 mmol/L EGTA, adjusted to pH 7.2 with Tris.

The drugs used were LPS (salmonella enteric serotype typhimurium), JNK inhibitor Ⅱ, SN-50 (NF-κB inhibitor) and catalase from Calbiochem, (San Diego, CA, United States) and the other compounds were purchased from Sigma.

Preparation of cells and tissues

Balb/C mice (3-8 d old) of either sex were anesthetized with ether and were sacrificed by cervical dislocation. The small intestines from 1 cm below the pyloric ring to the cecum were removed and opened along the mesenteric border. The luminal contents were washed away with Krebs-Ringer bicarbonate solution. The tissues were pinned to the base of a Sylgard dish and the mucosa was removed by sharp dissection. Small strips of intestinal muscle were equilibrated in Ca^{2+}-free Hank's solution containing 5.36 mmol/L KCl, 125 mmol/L NaCl, 0.34 mmol/L NaOH, 0.44 mmol/L Na_2HCO_3, 10 mmol/L glucose, 2.9 mmol/L sucrose, and 11 mmol/L HEPES for 30 min, and the cells were dispersed with an enzyme solution containing 1.3 mg/mL collagenase (Worthington Biochemical Co, Lakewood, NJ, United States), 2 mg/mL bovine serum albumin (Sigma Chemical Co., St. Louis, MO, United States), 2 mg/mL trypsin inhibitor (Sigma) and 0.27 mg/mL ATP. Cells were plated onto sterile glass coverslips coated with poly L-lysine (2.5 μg/mL, Sigma) in 35 mm culture dishes. The cells were then cultured at 37 ℃ in a 5% CO_2 incubator in SMGM (smooth muscle growth medium) (Clonetics Co., Walkersville, MD, United States) supplemented with 2% antibiotics/antimycotics (Gibco, Grand Island, NY, United States) and murine stem cell factor (SCF, 5 ng/mL, Sigma). ICCs were identified immunologically with the use of a monoclonal antibody for kit protein (ACK2) labeled with Alexa Fluor 488 (Molecular Probes, Eugene, OR, United States).

Patch clamp experiments

The whole-cell configuration of the patch clamp technique was used to record membrane currents (voltage clamp) and membrane potentials (current clamp) from cultured ICC after 2-3 d in culture. We recorded from small clusters of ICC, as spontaneous inward currents from small groups of cells are more robust and regular than from single cells. Currents or potentials were amplified by Axopatch 200B (Axon Instruments, Foster, CA, United States). A command pulse was applied using an IBM compatible personal computer and pClamp software (version 9.2; Axon Instruments). The data were filtered at 5 kHz, and the recorded data were displayed on a computer monitor saved for data analysis and future references. Results were analyzed using the Clampfit program (Axon Instruments) and Graph Pad Prism (version 2.01) software. All experiments were performed at 30 ℃.

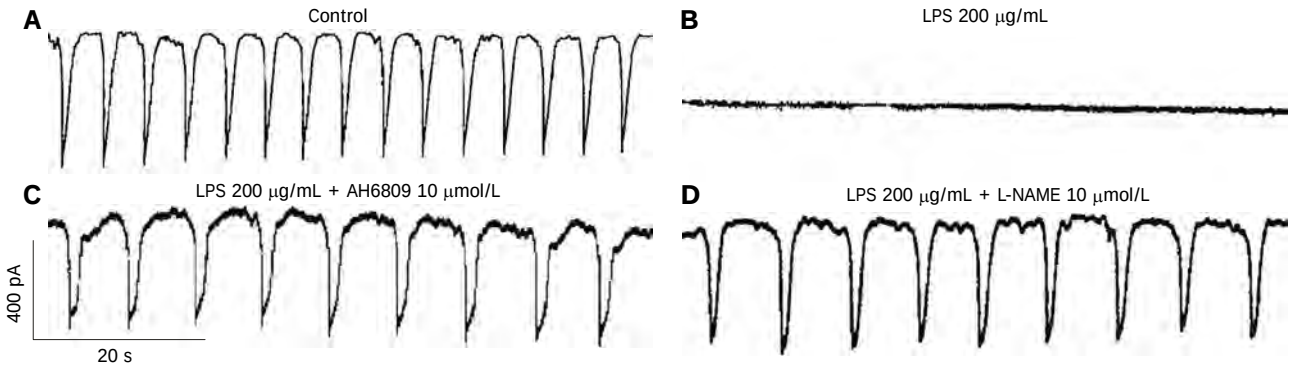

Figure 1 Effects of AH6809 or NG-Nitro-L-arginine Methyl Ester on lipopolysaccharide-induced action in interstitial cells of Cajal. A: Pacemaker currents of interstitial cells of Cajal (ICCs) at a holding potential of -70 mV in control condition; B: Pacemaker currents of ICCs incubated at 37 ℃ with 200 μg/mL of lipopolysaccharide (LPS) for 12 h; C: Pacemaker currents in ICCs pretreated with AH6809 (10 μmol/L) for 2 h prior to LPS incubation; D: Pacemaker currents in ICCs pretreated with NG-Nitro-L-arginine Methyl Ester (10 μmol/L) for 2 h prior to LPS incubation. LPS: Lipopolysaccharide; L-NAME: NG-Nitro-L-arginine Methyl Ester.

Immunocytochemistry

Cultured cells were fixed in acetone (20 ℃/5 min). Following fixation, preparations were washed for 60 min in phosphate buffered saline (PBS; 0.01 mol, pH 7.4). Cultured cells were then incubated in 10% goat serum containing 1% bovine serum albumin for 1 h at RT to reduce nonspecific antibody binding. For double immunostaining, cells were incubated overnight at 4 ℃ in a mixture of two primary antibodies raised in different species (a rat monoclonal c-Kit antibody, 1:200, Gibco-BRL, Gaithersburg, MD, United States; a goat polyclonal TLR4 antibody, 1:100, Santa Cruz Biotechnology, CA, United States; a goat polyclonal iNOS antibody, 1:100, Santa Cruz Biotechnology; a goat polyclonal COX-2 antibody, 1:100, Santa Cruz Biotechnology). The secondary antibodies were fluorescein isothiocyanate (FITC) for c-Kit and Texas Red for anti-TLR4, iNOS or COX-2, diluted 1:100 (all reagents from Vector Laboratories, Burlingame, CA). Immunoreactivity was detected using FITC-conjugated secondary antibody (FITC-anti-rat; Vector Laboratories, 1:100 in PBS, 1 h, room temperature). Control cultured ICCs were prepared in a similar manner, but, omitting ACK2 from the incubation medium. After washing with PBS, the mixture of labeled secondary antibodies was treated with FITC-conjugated donkey anti-rabbit IgG (1:100, Chemicon, Temecula, CA, United States) and Texas red-conjugated donkey anti-goat IgG (1:100, Jackson Immunoresearch Laboratories, Baltimore, PA, United States). The incubation of labeled secondary antibodies was performed for 1 h at room temperature. Cells were examined with a FV300 confocal microscope (Olympus, Tokyo, Japan) with an excitation wavelength appropriate for FITC (488 nm) and Texas Red (568 nm). Final images were constructed with Flow View Software Program (Olympus, Tokyo, Japan).

Ethics

All experiments were performed according to the Guiding Principles for the Care and Use of Animals approved by the Ethics Committee of Chosun University and the National Institute of Health Guide for the Care and Use of Laboratory Animals. Every effort was made to minimize both the number of animals used and the suffering of the animals.

Statistical analysis

Data are expressed as the mean ± SE. Differences in the data were evaluated by use of the Student's *t* test. *P* values less than 0.05 are considered a statistically significant difference. The *n* values reported in the text refer to the number of cells used in the patch clamp experiments.

RESULTS

Confirmation of prostaglandin or NO production involvement on LPS-induced action in ICCs

First, we verified inhibitory action of LPS on ICCs and the involvement of PG or NO production on LPS-induced action. Recordings were made from cells within networks that had morphologies similar to the cells that were immunopositive for c-Kit. Under voltage clamp mode at a holding potential of -70 mV, ICCs showed spontaneous inward pacemaker currents (Figure 1A) and this inhibited by 200 μg/mL LPS incubation for 12 h (Figure 1B). And inhibitory action of LPS on pacemaker activity in ICCs was blocked by 10 μmol/L AH6809 (a PGE_2-EP2 receptor antagonist) or 10 μmol/L NG-Nitro-L-arginine Methyl Ester (L-NAME) (an inhibitor of NO synthase) (n = 5, Figure 1C and D, bar graph not shown). These could make sure the involvement of PG or NO production on LPS-induced action in ICCs.

Localization of toll like receptor-4, inducible NO synthase and COX-2 in ICCs

For searching the ability that can interact with TLR4 and produce NO or PGs in ICCs, we tried immunocytochemistry with specific antibody for TLR4, iNOS and COX-2 proteins. Double staining with anti-c-Kit and anti-TLR4, anti-iNOS or anti-COX-2 antibodies revealed TLR4, iNOS and COX-2 immunoreactivity in c-Kit immune-positive ICCs (Figure 2A-C).

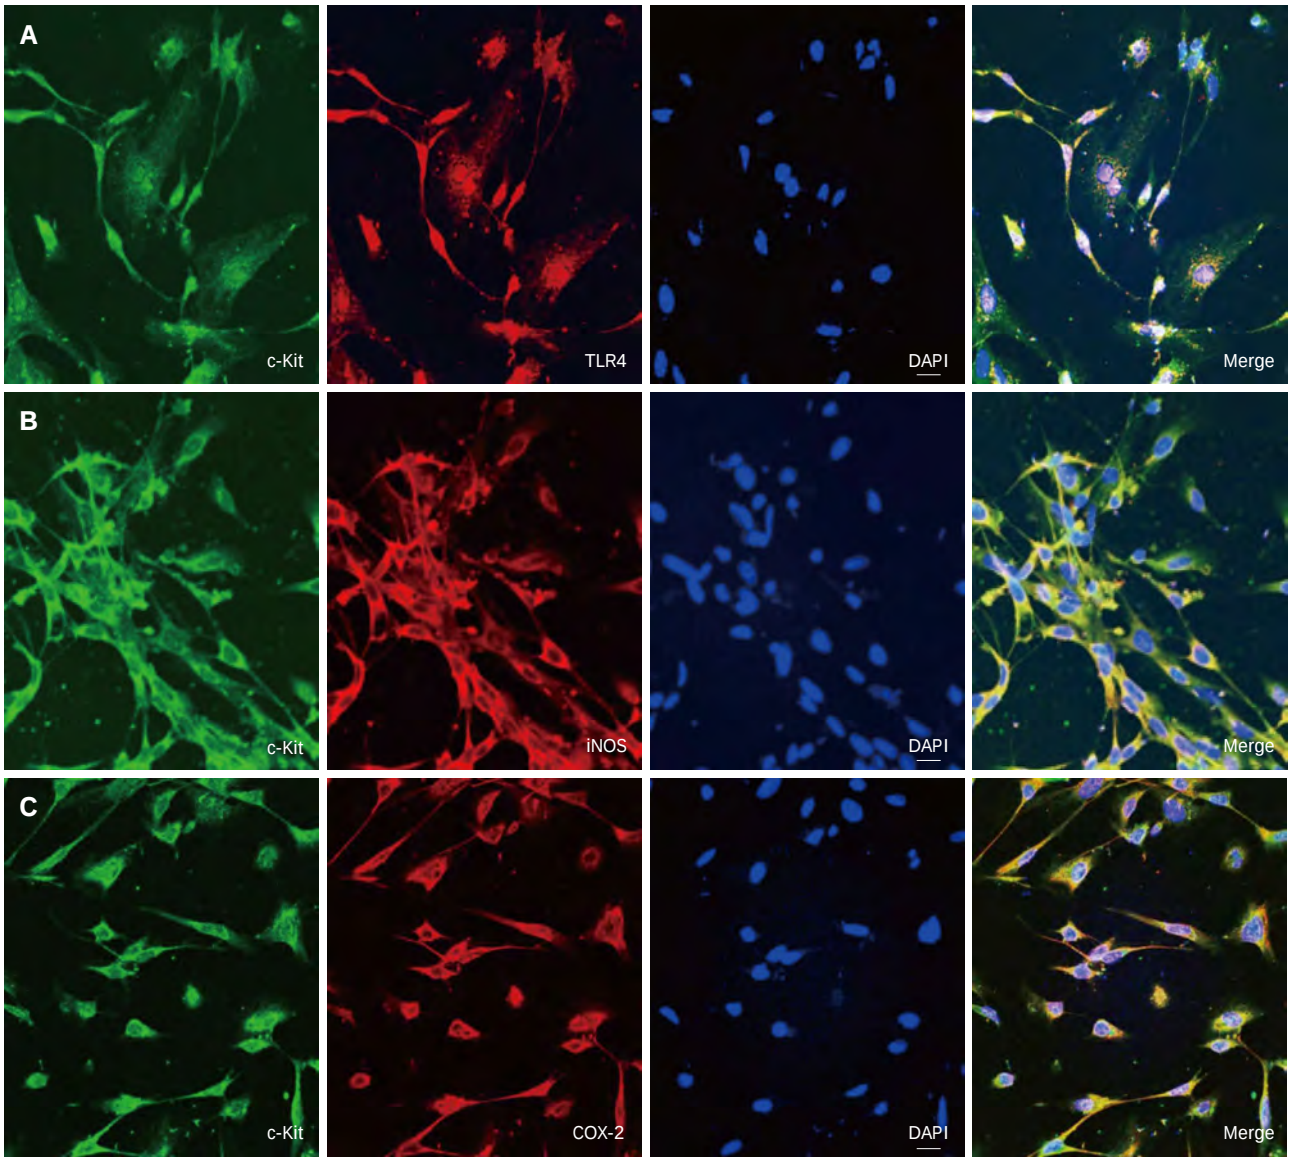

Figure 2 Expression of TLR4, iNOS and COX-2 in c-Kit positive cells. A: Double labeling of TLR4- and c-Kit-like immunoreactivity in cultured interstitial cells of Cajal (ICCs). Green (c-Kit) and red (TLR4) result in the mixed color yellow, indicating the colocalization of both peptides; B: Double labeling of iNOS and c-Kit-like immunoreactivity in ICCs. Green (c-Kit) and red (iNOS) result in the mixed color yellow, indicating the colocalization of both peptides; C: Double labeling of COX-2 and c-Kit-like immunoreactivity in ICCs. Green (c-Kit) and red (COX-2) result in the mixed color yellow, indicating the colocalization of both peptides (bar = 20 μm).

Effects of catalase on LPS-induced action in ICCs

For finding the involvement of ROS production on LPS-induced action, we used the antioxidant reagent, catalase. To investigate the effect of LPS, ICCs were incubated with 200 μg/mL LPS for 12 h and we could reconfirm the disappearance of pacemaker currents (Figure 3A). Pretreatment with catalase (3000 unit/mL) for 2 h prior to 200 μg/mL LPS incubation could not show any difference compared with LPS alone (Figure 3B). The frequency and amplitude values of pacemaker currents in catalase treatment with LPS were not significantly different compared with LPS alone (n = 4, Figure 3C and D).

Effects of SN-50 or actinomycin D on lipopolysacchardie-induced action in ICCs

For detecting the role for NF-κB or involvement of gene transcriptions on LPS-induced action, we used SN-50, the NF-κB inhibitor and actinomycin D, the gene transcription inhibitor. The incubation with LPS 200 μg/mL alone, the pacemaker currents were completely inhibited (Figure 4A). But when SN-50 (10 μmol/L) was treated for 2 h prior to LPS incubation, LPS-induced action on pacemaker currents in ICCs was blocked (Figure 4B). Also, we could find that actinomycin D (10 μmol/L) blocked the LPS-induced pacemaker currents suppression (Figure 4C). The values of frequency and amplitude induced by LPS in the presence of SN-50 or actinomycin D were significantly different from those obtained in the absence of NF-κB inhibitor (n = 5, Figure 4D and E).

Effects of MAPK inhibitors on LPS-induced action in ICCs

For understanding the involvement of MAPKs on LPS-induced action, specific MAPKs inhibitors were used. When the pretreatments of ICCs with PD 98059 (a

selective p42/44 inhibitor), SB 203580 (a selective p38 inhibitor) or JNK inhibitor Ⅱ for 2 h prior to 200 μg/mL LPS incubation, the LPS-induced inhibitory action on pacemaker currents were blocked by PD 98059 (10 μmol/L), SB 203580 (10 μmol/L) but not by JNK inhibitor Ⅱ (10 μmol/L) (Figure 5B-D). The values of frequency, amplitude and resting currents induced by LPS in the presence of PD 98059 or SB 203580 were significantly different from those obtained in the absence of these (n = 7, Figure 5E and F).

Effects of MAPK inhibitors on Prostaglandin E2-induced action in ICCs

For examining the involvement of MAPKs on PGE_2 production by LPS stimulation in ICCs, we used p42/44 inhibitor and p38 inhibitor with PGE_2. Because JNK inhibitor Ⅱ did not show any influence on LPS-induced action in ICCs, we did not test with JNK inhibitor Ⅱ in here. At first, we could see PGE_2 (5 μmol/L) itself has the inhibitory effect on pacemaker currents in ICCs (Figure 6A). Then, we examined the effects of PGE_2 on pacemaker currents in presence of PD 98059 or SB203580. The pretreatments of ICCs with PD 98059 (10 μmol/L) blocked the 5 μmol/L PGE_2-induced inhibitory action on pacemaker currents but not SB 203580 (10 μmol/L) (Figure 6B and C). The values of frequency and amplitude currents induced by PGE_2 in the presence of PD 98059 were significantly different from those obtained in the absence

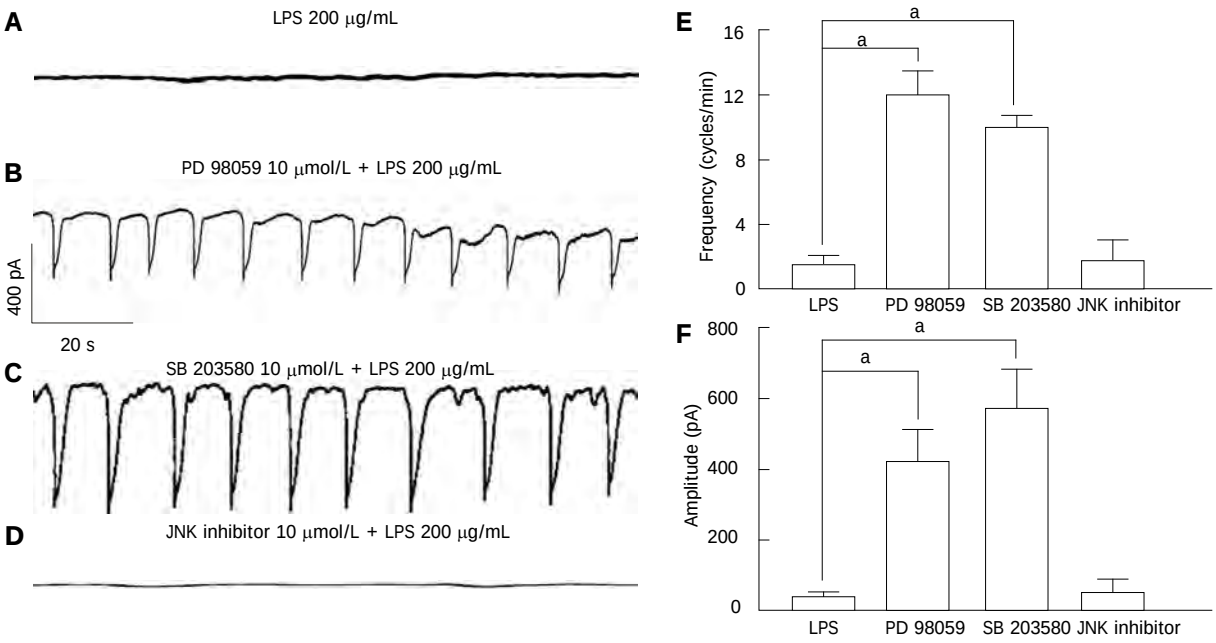

Figure 5 Effects of Mitogen-activated protein kinases inhibitors on lipopolysaccharide-induced action in interstitial cells of Cajal. A: Pacemaker currents of interstitial cells of Cajal (ICCs) incubated at 37 ℃ with 200 μg/mL of lipopolysaccharide (LPS) for 12 h at a holding potential of -70 mV; B: Pacemaker currents after pretreatment with PD 98059 (10 μmol/L) for 2 h prior to LPS incubation; C: Pacemaker currents after pretreatment with SB 203580 (10 μmol/L) for 2 h prior to LPS incubation; D: Pacemaker currents after pretreatment with c-Jun N-terminal kinase (JNK) inhibitor II (10 μmol/L) for 2 h prior to LPS incubation. The effects of mitogen-activated protein kinases inhibitors on the LPS-induced action are summarized in E and F. Bars represent mean ± SE values (n = 7 per group). $^aP < 0.05$ *vs* LPS.

of PD 98059 (n = 4, Figure 6D and E).

Effects of MAPK inhibitors on NO-induced action in ICCs

For examing the role of MAPKs on NO production by LPS stimulation in ICCs, we also used p42/44 inhibitor and p38 inhibitor with (±)-S-nitroso-N-acetylpenicillamine (SNAP), a NO donor. In our previous report[22], we already showed SNAP has inhibitory action on pacemaker currents in ICCs like as PGE_2. In here, we also could see the inhibitory action of 100 μmol/L SNAP on pacemaker currents (Figure 7A). We examined the effects of SNAP on pacemaker currents in presence of PD 98059 or SB 203580. The pretreatments of ICCs with PD 98059 (10 μmol/L) or SB 203580 (10 μmol/L) did not show any influence on 5 μmol/L SNAP-induced inhibitory action on pacemaker currents (Figure 7B and C). The values of frequency and amplitude induced by SNAP in the presence of PD 98059 or SB 203580 were not significantly different from those obtained in the absence of PD 98059 or SB 203580 (n = 5, Figure 7E and F). Furthermore, we checked the reciprocal relation between PG and NO with PGE_2 and L-NAME. In presence of 10 μmol/L L-NAME, 5 μmol/L PGE_2 still inhibited the pacemaker current (n = 4, Figure 7D, bar graph not shown).

DISCUSSION

PGE_2 and NO are inhibitory mediators on intestinal motility and produced by COX (COX-1 or 2) and NOS (nNOS/eNOS/iNOS), respectively. We have shown that LPS inhibited pacemaker currents of intestinal ICCs by activating ATP-sensitive K^+ channels through the release of PGE_2 and NO[17]. In this experiment, we further found that MAPKs are involving in LPS-induced inhibition of pacemaker currents through NF-κB-dependent mechanisms in ICCs.

The binding of TLR4 with LPS activates NF-κB through myeloid differentiation primary response gene-88 (Myd88)-dependent pathway. LPS has been shown to induce NF-κB nuclear translocation in intestinal smooth muscle and myenteric plexus cells, but not in TLR4 knockout mice[23]. The activated NF-κB then induces various transcriptional genes including COX-2 and iNOS in GI tracts. In this study, LPS-induced inhibition of pacemaker currents was blocked by COX-2 inhibitor or iNOS inhibitor. And a specific NF-κB blocker or actinomycin D, a gene transcriptional blocker, suppressed LPS-induced inhibition of pacemaker currents. Furthermore, double staining with anti-c-Kit and anti-COX-2 antibodies or anti-iNOS antibodies revealed COX-2 or iNOS immunoreactivity in c-Kit immunopositive ICCs in cultured ICCs. These results suggest that NF-κB activation is essential to induce expression of COX-2 and iNOS exposed to LPS in ICCs.

MAPKs play an important role in the mediation of cellular responses, including transcriptional responses. Three types of MAPKs (p42/44 MAPK, p38 MAPK, and JNK) are involved in LPS-induced NF-κB or JNK activator protein-1 activation in various cells[24-27]. Recently, it was reported that three types of MAPKs were

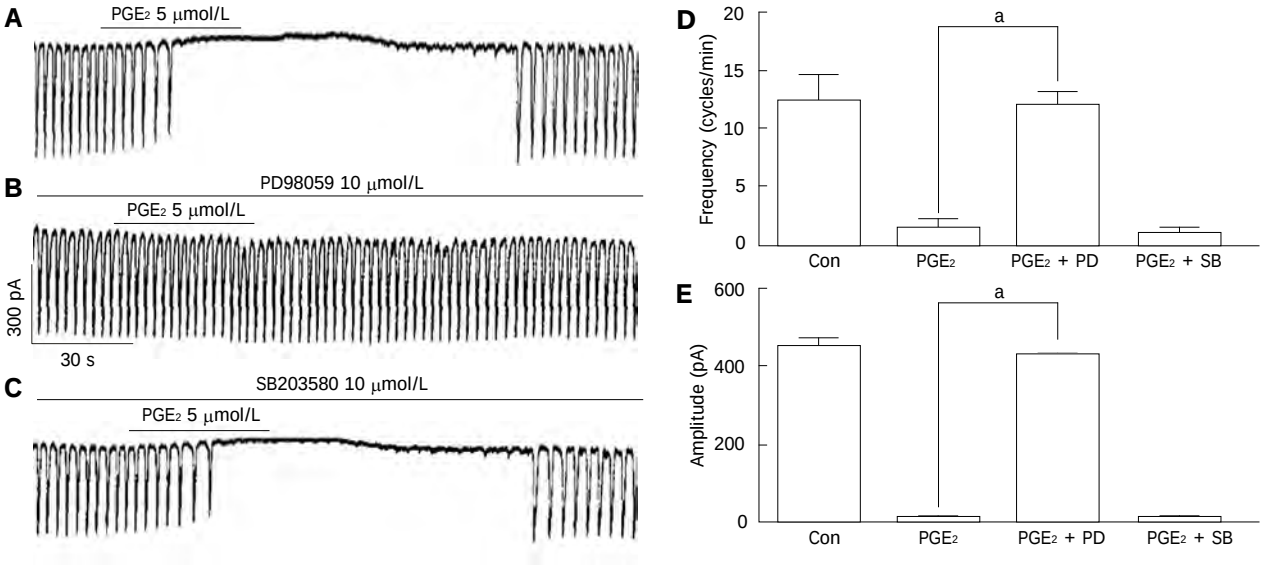

Figure 6 Effects of mitogen-activated protein kinases inhibitors on prostaglandin E2-induced action in interstitial cells of Cajal. involved in the mechanism of LPS actions in rabbit ileum and the blockade of p38, JNK or p42/44 pathways suppressed the effects of LPS on the acetylcholine-induced contractions[28]. In our study, the LPS-induced effects in ICCs were blocked by PD98059 or SB20356, but not by JNK inhibitor Ⅱ, indicating that activation of p42/44 and p38 MAPKs are involved in LPS-induced activation of NF-κB in ICCs. These results are consistent with those of others showing that p42/44 and p38 MAPKs are involved in COX-2 and iNOS induction by

LPS in tracheal smooth muscle cells[26]. However, this study showed PGE_2-induced inhibition of pacemaker currents is blocked by p42/44 MAPK inhibitor, but not by p38 MAPK inhibitor in intestinal ICCs and NO-induced inhibition of pacemaker currents was not blocked by both p42/44 MAPK inhibitor and p38 MAPK inhibitor. These results suggest that p42/44 MAPK and p38 MAPK play differential role in regulation of LPS-induced actions in ICCs. Thus, it seems that p38 MAPK may be involved in LPS-induced NF-κB activation to express COX-2 and iNOS, whereas p42/44 MAPK as a downstream pathway of NF-κB may be involved in PGE_2-induced effects in ICCs not NO signaling. Our previous study could explains the possibility that NO-induced action on pacemaker currents is *via* activating ATP-sensitive K^+ channels through cGMP-dependent mechanism in ICCs but not involvement of MAPKs[22].

LPS action was also mediated by ROS production through a nicotinamide adenine dinucleotide phosphate oxidase pathway. In rat aortic smooth muscles, LPS could induce the hydrogen peroxide signaling[29]. Also, we found that H_2O_2 inhibited pacemaker currents by activating ATP-sensitive K^+ channels in ICCs, which was mediated through COX-2-dependent PGE_2 production[30]. Therefore, in order to investigate whether H_2O_2 is involved in LPS-induced PGE_2 production, we treated catalase, a hydrogen peroxide scavenger. However, catalase did not block the LPS-induced inhibition of pacemaker currents. This result suggests that hydrogen peroxide do not involve in LPS-induced actions in intestinal ICCs.

Many reports are arguing the relation between the production of COX and NOS. NO production by NOS enzyme could stimulate or inhibit the COX enzyme induction[31,32]. And some reports suggested products by COX enzyme stimulate the NOS pathway[33,34]. In our opinion, the cross talk between NOS and COX may depend on the cell type or enzyme type. In here, we need to check whether inhibitory effect of PGE_2 on pacemaker activity is through induction of NO synthesis in ICCs. However, the proofs that PGE_2 alone could inhibit the pacemaker activity in ICCs in our previous study and L-NAME could not show any influence on PGE_2-induced action in here could establish no-interaction between the products of COX and NOS by LPS stimulation in ICCs.

In summary, the current study provides evidence that LPS inhibited pacemaker currents in cultured ICCs *via* PGE_2 and NO-dependent pathways. NF-κB and MAP kinases are involved in this inhibitory action.

COMMENTS

Background

Interstitial cells of Cajal (ICCs) are the pacemaker cells present in the gastrointestinal tract (GI) that generate the pacemaker currents that regulate the GI motility. Lipopolysaccharides (LPS) are endotoxins and pro-inflammatory agents present in the cell wall of the Gram-negative bacteria responsible for various alterations of gastrointestinal functions including intestinal dysmotility.

Innovations and breakthroughs

LPS altered GI motility through release of prostaglandins or nitric oxide (NO) by nuclear factor κB (NF-κB) dependent gene transcription. This study showed LPS inhibited pacemaker currents of ICC. Prostaglandin E2 and NO contributed to the inhibitory effects of LPS together with mitogen-activated protein kinases and NF-κB.

Applications

LPS-induced inhibitory actions on pacemaker activities of ICC may be one possible mechanism to explain LPS-induced GI dysmotility.

Terminology

ICCs refer to the several types of cells present on the musculature of the GI tract. ICCs act as pacemaker cells in gastrointestinal tracts, regulating rhythmicity by activating calcium activated chloride channel or nonselective cation channels.

Peer review

The functional regulation of ICCs is still not fully understood and this study provides novel information on the TLR 4-mediated signaling pathways on LPS–suppressed pacemaker currents of ICCs.

Abstract

AIM: To study whether the severity of liver fibrosis estimated by the nonalcoholic fatty liver disease (NAFLD) fibrosis score can predict all-cause mortality, cardiac complications, and/or liver complications of patients with NAFLD over long-term follow-up.

METHODS: A cohort of well-characterized patients with NAFLD diagnosed during the period of 1980-2000 was identified through the Rochester Epidemiology Project. The NAFLD fibrosis score (NFS) was used to separate NAFLD patients with and without advanced liver fibrosis. We used the NFS score to classify the probability of fibrosis as < -1.5 for low probability, > -1.5 to < 0.67 for intermediate probability, and > 0.67 for high probability. Primary endpoints included all-cause death and cardiovascular- and/or liver-related mortality. From the 479 patients with NAFLD assessed, 302 patients (63%) greater than 18 years old were included. All patients were followed, and medical charts were reviewed until August 31, 2009 or the date when the first primary endpoint occurred. By using a standardized case record form, we recorded a detailed history and physical examination and the use of statins and metformin during the follow-up period.

RESULTS: A total of 302/479 (63%) NAFLD patients (mean age: 47 ± 13 year) were included with a follow-up period of 12.0 ± 3.9 year. A low probability of advanced fibrosis (NFS < -1.5 at baseline) was found in 181 patients (60%), while an intermediate or high probability of advanced fibrosis (NSF > -1.5) was found in 121 patients (40%). At the end of the follow-up period, 55 patients (18%) developed primary endpoints. A total of 39 patients (13%) died during the follow-up. The leading causes of death were non-hepatic malignancy (n = 13/39; 33.3%), coronary heart disease (CHD) (n = 8/39; 20.5%), and liver-related mortality (n = 5/39; 12.8%). Thirty patients had new-onset CHD, whereas 8 of 30 patients (27%) died from CHD-related causes during the follow-up. In a multivariate analysis, a higher NFS at baseline and the presence of new-onset CHD were significantly predictive of death (OR = 2.6 and 9.2, respectively; P < 0.0001). Our study showed a significant, graded relationship between the NFS, as classified into 3 subgroups (low, intermediate and high probability of liver fibrosis), and the occurrence of primary endpoints. The use of metformin or simvastatin for at least 3 mo during the follow-up was associated with fewer deaths in patients with NAFLD (OR = 0.2 and 0.03, respectively; P < 0.05). Additionally, the rate of annual NFS change in patients with an intermediate or high probability of advanced liver fibrosis was significantly lower than those patients with a low probability of advanced liver fibrosis (0.06 *vs* 0.09, P = 0.004). The annual NFS change in patients who died was sig-

nificantly higher than those in patients who survived (0.14 *vs* 0.07, *P* = 0.03). At the end of the follow-up, we classified the patients into 3 subgroups according to the progression pattern of liver fibrosis by comparing the NFS at baseline to the NFS at the end of the follow-up period. Most patients were in the stable-fibrosis (60%) and progressive-fibrosis (37%) groups, whereas only 3% were in the regressive fibrosis.

CONCLUSION: A higher NAFLD fibrosis score at baseline and a new onset of CHD were significantly predictive of death in patients with NAFLD.

NAFLD fibrosis score: A prognostic predictor for mortality and liver complications among NAFLD patients. *World J Gastroenterol* 2013; 19(8): 1219-1229 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1219.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1219

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver disease in Western countries[1]. The prevalence of NAFLD is increasing and varies significantly with ethnicity, ranging from 24% in blacks to 33% in whites and 45% in Hispanics according to a recent study from the United States[2]. The mortality rate of NAFLD patients in the community was found to be higher than that of the general population in both the US and Sweden[3]. During an average 7.6 years of follow-up, 13% of the patients died, mainly from malignancy, coronary heart disease (CHD) and liver-related mortality[4]. Another study revealed that the survival of patients with nonalcoholic steatohepatitis (NASH) was reduced and that these patients died significantly more often from CHD and liver-related causes[3]. Patients with more advanced liver fibrosis tend to have more liver complications than those without liver fibrosis[4]. Liver biopsy is considered the gold standard for the diagnosis and assessment of fibrosis severity but has several limitations, such as sampling variability, invasiveness and expense[5]. Patients with NASH can have a significant progression of fibrosis within a few years[6-8]. Recently, a simple, noninvasive tool used for liver fibrosis assessment has been developed[9]. This new scoring system, the NAFLD fibrosis score (NFS), is a composite score of age, hyperglycemia, body mass index, platelet count, albumin, and aspartate aminotransferase and alanine aminotransferase (AST/ALT) ratio[9] and was found to independently identify NAFLD patients with and without advanced fibrosis at initial NAFLD diagnosis. Another clinical score composed of body mass index (BMI) $\geqslant$ 28 kg/m^2, AST/ALT ratio $\geqslant$ 0.8 and diabetes mellitus (the BARD score) has also been used to predict an increased chance of liver fibrosis[10]. However, the BARD score does not have the capacity to differentiate the severity of liver fibrosis among patients with a higher BMI or a higher ratio of AST/ALT, whereas the NFS takes into consideration the different ranges of BMI or AST/ALT ratios[9]. A study from Japan validated the NFS and found it to have an acceptable sensitivity, specificity, and positive and negative predictive values for advanced liver fibrosis of 100%, 83%, 63%, and 100%, respectively[11]. A longitudinal study of 103 NAFLD patients showed that the fibrosis stage progressed in 37%, remained stable in 34% and regressed in 29% of patients with a mean interval between liver biopsies of approximately 3 years[12]. The rate of fibrosis change ranged from -2.1 to 1.7 stages per year. The prognostic predictors for a higher rate of liver fibrosis were diabetes, a low initial fibrosis stage and a higher body mass index. In the current study, we aimed to determine whether the severity of liver fibrosis estimated by the NFS can predict a higher risk of overall mortality, cardiac complications, and/or liver complications among patients with NAFLD. Additionally, we aimed to determine the annual rate of the NFS change from the baseline to the end of the follow-up among NAFLD patients.

MATERIALS AND METHODS

Study subjects

In this a historical cohort study, patients residing in Olmsted County, Rochester, Minnesota, United States who had been diagnosed with NAFLD-fatty liver (HICDA Code 05710420), fatty liver hypertrophy (HICDA Code 05710421), fatty liver cirrhosis (HICDA Code 05710422), fatty liver steatohepatitis (HICDA Code 05710423) or NASH (HICDA Code 05710431), or fatty liver steatohepatitis (HICDA Code 05710-42-43) or steatosis (HICDA Code 02790-44-1) between January 1, 1980 and January 1, 2000 were drawn from the Rochester Epidemiology Project (REP) master diagnostic index. The REP index is a unique database system of medical diagnoses of the population living in Olmsted County, Minnesota[13]. Although fatty liver was recognized prior to 1980, this liver condition was better characterized in 1980[14]; therefore, we chose to identify patients after this date.

Inclusion criteria

From the 479 patients with NAFLD assessed, 302 patients (63%) greater than 18 years old were included. All of these patients were followed, and their medical charts were reviewed, until August 31, 2009 or the date when the first primary endpoint occurred. By using a standardized case record form, we recorded a detailed history and physical examination and use of statins and metformin during the follow-up period.

Exclusion criteria

We excluded NAFLD patients who lacked the data

needed for the NFS calculation, patients with pre-existing poor outcomes including overt CHD or overt liver complications at the time of NAFLD diagnosis and patients with duration of follow-up of less than 5 years. One hundred seventy-seven NAFLD patients were excluded due to missing the data needed for the NFS calculation (n = 95), overt CHD confirmed at baseline (n = 63), liver cirrhosis with complications confirmed at baseline (n = 11) and duration of follow-up of less than 5 years (n = 8).

Definitions

The diagnosis of NAFLD was based on a liver biopsy showing steatosis in at least 5% of hepatocytes or fatty infiltration of the liver confirmed by imaging study (ultrasound, computed tomography, or magnetic resonance imaging) and the exclusion of liver disease of other etiologies, including alcohol-induced liver disease (history of excessive alcohol consumption greater than 20 gm/d), drug-induced liver disease, autoimmune or viral hepatitis and cholestatic or metabolic/genetic liver disease[1]. Cirrhosis was defined based on the pathological term for the chronic liver diseases[15]. In our study, 85% of patients (n = 256) were diagnosed by liver imaging. Liver biopsy was performed in 46 patients (15% of 302 patients). The staging of fibrosis was divided into fibrosis stage 0 to stage 4 using the Brunt criteria[16]. The NAFLD patients with a histological liver fibrosis stage of 1-2 were classified as "mild liver fibrosis," and those with a histological fibrosis stage of 3-4 were classified as "advanced liver fibrosis"[16].

The primary endpoints were all-cause mortality, cardiac complications, and/or liver complications. Cardiac complications included new-onset CHD events as recorded in the medical records, defined as congestive heart failure, unstable angina, myocardial infarction, flow-limiting stenosis from angiography or angina requiring revascularization during the follow-up period and need for hospitalization[17]. Liver complications were diagnosed by clinical signs and symptoms[18], including the presence of ascites, variceal bleeding, a severe grade of hepatic encephalopathy, liver failure or hepatocellular carcinoma, that occurred during the follow-up and required hospitalization with or without death[19]. All causes of death listed on the death certificates or pathological findings (underlying, intermediate, immediate and other major conditions) were recorded using the 10th revision of the International Classification of Diseases (ICD-10). The presence of metabolic syndrome (MetS) was defined by using the 2001 National Cholesterol Education Program Adult Treatment Panel Ⅲ (NCEP-ATPⅢ) criteria and the new definition, which requires the presence of at least three of the five features[20,21]. The NFS is composed of 6 variables, including age, hyperglycemia, BMI, platelet count, albumin, and AST/ALT ratio as independent indicators of advanced liver fibrosis[9]. NAFLD fibrosis score = -1.675 + 0.037 × age (year) + 0.094 × BMI (kg/m^2) + 1.13 × IFG/diabetes (yes = 1, no = 0) + 0.99 × AST/ALT ratio - 0.013 × platelet count (×10^9/L) - 0.66 × albumin (g/dL)[9].

In this study, the NFS was used to classify advanced liver fibrosis into 2 categories[9]. NAFLD patients with a score less than -1.5 were classified as "low probability of advanced liver fibrosis," and those patients with a score of at least -1.5 were classified as "intermediate or high probability of advanced liver fibrosis"[9]. Because the information required for determination of the NFS was not always available on the same day, the scores were calculated at the time of NAFLD diagnosis using data from the medical records from visits within 3 mo of the "true" NAFLD diagnosis date and the last follow-up date. If more than one assessment for a given variable was available in the medical records during this time period, the value closest to the "true" follow-up date was used for the NFS calculation[9]. According to the 3 subgroups of low, intermediate and high probability of fibrosis, we used parameters of NFS < -1.5 for low, NFS ⩾ -1.5 to NFS < 0.67 for intermediate and NFS ⩾ 0.67 for high probability of fibrosis at baseline.

At the end of the follow-up period, we classified the patients into 3 subgroups according to the progression pattern of the liver fibrosis by comparing the NFS at baseline to the end of follow-up. The first group had stable fibrosis, defined as stability of the NFS during the follow-up. The second group had regression of fibrosis, defined as a reduction of the NFS to a milder stage of fibrosis during the follow-up. Lastly, the third group had fibrosis progression, defined as an increase of the NFS to a more advanced stage during the follow-up.

Sample-size/statistical power considerations

We assumed that the overall mortality rate in NAFLD would be 12%, with liver-related complications being observed in at least 3% and cardiac complications in 11% of patients based on results from a previous study[4]. We anticipated that at least 150 patients, or 50% of the total cohort, would be classified as "low probability of advanced liver fibrosis" using the NFS, and at least 150 would be classified as "intermediate or high probability of advanced liver fibrosis"[12]. However, a portion of patients were expected to develop new CHD events, liver complications and death. We anticipated that 15% of patients would be identified as having experienced a primary endpoint. We assumed that, at most, 10% of patients with a low probability of advanced liver fibrosis would experience events within 5 years and at least 20% of patients with an intermediate or high probability of advanced liver fibrosis would experience events within 5 years to obtain a statistical power of at least 82%.

Statistical analysis

Patients were categorized by the NFS into 2 groups of probability of advanced liver fibrosis. Differences between the primary endpoints of the two groups of low and high NFS were compared by using the χ^2 test. Differences between NAFLD patients with and without primary endpoints were tested by independent t tests for

NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: Glutamyltransferase; CHD: Coronary heart disease; NFS: NAFLD fibrosis score.

continuous variables and were tested by the χ^2 test for proportions. Continuous outcomes were presented as the mean ± SD, and categorical data were presented as numbers (percentage). Logistic regression analysis was used to identify the factors significantly associated with death among NAFLD patients. Only those variables with a *P* value < 0.1 by univariate analysis were included in multivariate analysis. To avoid overestimation of the model, we excluded those variables used as a part of the NFS calculation. We estimated receiver operating characteristics of related variables for the predicting of death to maximize the area under the curve (AUC). Two-sided *P* values < 0.05 were considered statistically significance. The rate of NFS change in each patient was calculated by the difference of NFS at the end of follow-up and at baseline divided by the duration of the follow-up time (Δ NFS/Δ time). Both phases of the study used the SPSS statistical software package (SPSS Version 15.0.1.1, Windows VISTA, July 3, 2007) for analysis. The study was approved by the Institutional Review Board (IRB) of the Mayo Clinic, Rochester, MN, United States, and all participants provided permission for their medical information to be used for research.

RESULTS

Baseline characteristic data of 302 patients with NAFLD

This study included three hundred two NAFLD patients aged 47 ± 13 year (range 21-86 year), of which 95% were white, and 44% were male. Obesity was present in 73%, and a history of diabetes mellitus type Ⅱ and hypertension was observed in 16% and 41%, respectively. Eighty-five percent of patients (*n* = 256) were diagnosed by liver imaging. Liver biopsy was performed in 46 patients (15%). Mild liver fibrosis (stage F 0-2) was found in 34 patients (74%), while advanced fibrosis (stage F 3-4) was found in 12 patients (26%). NAFLD patients who underwent a liver biopsy had a significantly lower diastolic blood pressure, a lower BMI and a higher AST level than those without a liver biopsy (*P* < 0.05). The characteristics of the 302 patients based on the degree of advanced liver fibrosis estimated by the NFS at baseline are shown in Table 1. A low probability of advanced liver fibrosis (NFS < -1.5) was found in 60% of patients, while an intermediate or high probability of advanced liver fibrosis (NFS ⩾ -1.5) was found in 40%. The mean ± SD value of NFS in patients with a low probability of advanced liver fibrosis was -2.6 ± 0.8 and was lower than in patients with an intermediate or high probability of advanced liver fibrosis (-0.4 ± 0.9, *P* < 0.0001). Patients with a low probability of advanced liver fibrosis had a lower CHD risk at baseline, as estimated by the Framingham risk score (FRS) calculation, compared to patients with an intermediate or high probability of advanced liver fibrosis (14% *vs* 19%, *P* = 0.003).

Clinical outcomes of long-term follow-up

The mean follow-up of the total cohort was 11.9 ± 3.9 years for a total of 3594 person-years. Approximately 47% of patients with a low probability of advanced liver fibrosis at baseline progressed to an intermediate or high probability of advanced liver fibrosis at the end of follow-up, while 94% of patients with an intermediate

NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; NFS: NAFLD fibrosis score; LDL: Low-density lipoprotein.

or high probability of advanced liver fibrosis remained in the same group. At the end of the follow-up, patients with an intermediate or high probability of advanced liver fibrosis had a significantly higher BMI, more frequent diabetes, and more frequent histories of hypothyroidism, cholecystectomy and obstructive sleep apnea. Furthermore, the patients with an intermediate or high probability of advanced liver fibrosis were more likely to use metformin, glitazones and aspirin compared to those with a low probability of advanced liver fibrosis ($P < 0.05$).

A history of diabetes at baseline was found in 16%, while the proportion of patients with NAFLD who developed impaired fasting glycemia or diabetes during the follow-up was 89 patients (29%) with an average interval of 6.3 ± 4.2 year (range 0.2-17.2) from the diagnosis of NAFLD. Patients who developed impaired fasting glycemia or diabetes during the follow-up were more frequent male, had less hypertension, and had a lower NAFLD Fibrosis Score at baseline compared to those with diabetes at baseline ($P < 0.05$). The primary endpoints of both groups were not significantly different.

Patients with an intermediate or high probability of advanced liver fibrosis had a significantly higher glucose and a higher AST/ALT ratio at the end of follow-up compared to those with a low probability of advanced liver fibrosis. Hematocrit, platelet count, AST, ALT, albumin, cholesterol and low-density lipoprotein (LDL)-cholesterol level were significantly lower in patients with an intermediate or high probability of advanced liver fibrosis compared to those with a low probability of advanced liver fibrosis (Table 2). At the end of follow-up, 55 patients developed primary endpoints, including death or the presence of CHD or liver complications. Thirty of these patients had new-onset CHD, whereas 8 of 30 patients (27%) died from CHD-related complications during the follow-up period (Table 2). Patients with new CHD events ($n = 30$) were significantly older and had a higher systolic blood pressure (SBP), FRS at baseline, calculated % CHD risk at baseline, and NFS at the end of follow-up and exhibited a lower ALT than those patients without new CHD events ($n = 272$) ($P < 0.05$). In addition, the NFS at baseline was similar in patients with and without new CHD events (-1.2 ± 1.6 *vs* -1.8 ± 1.4, $P = 0.07$). Liver complications occurred in 6 patients, 5 of whom (83%) died during the follow-up. The liver complications included massive ascites requiring abdomi-

Table 3 Causes of mortality in 39 patients with nonalcoholic fatty liver disease

Causes of death	All causes mortality *n* (% of death)	All causes mortality (% of 302 patients)
Non-liver cancer	13 (33.3)	4.3%
Coronary heart disease	8 (20.5)	2.6%
Liver-related mortality (including hepatocellular carcinoma)	5 (12.8)	1.7%
Infection (including sepsis)	4 (10.3)	1.3%
Stroke	3 (7.7)	1.0%
Cardiac arrhythmia	2 (5.1)	0.7%
COPD and/or respiratory failure	2 (5.1)	0.7%
Other causes of death (GI bleeding, renal failure)	2 (5.1)	0.7%
Total	39 (100)	12.9%

COPD: Chronic obstructive lung disease; GI: Gastrointestinal.

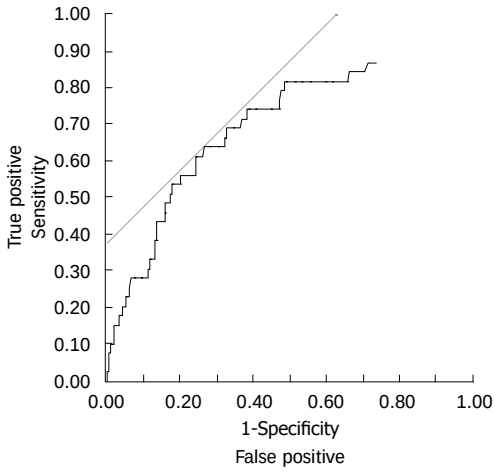

Figure 1 Presence of death estimated by the nonalcoholic fatty liver disease fibrosis score at baseline. Using the receiver operating characteristics curve, the nonalcoholic fatty liver disease fibrosis score at baseline of -0.9 was the best cutoff value for predicting death based on a sensitivity of 62%, specificity of 76%, positive predictive value of 28%, negative predictive value of 93% and area under the curve of 0.7.

nal paracentesis (n = 3), hepatopulmonary syndrome and hepatocellular carcinoma (n = 1 each).

A total of 39/302 (13%) patients died during the follow-up period. The leading causes of death were non-hepatic malignancy (n = 13/39; 33.3%), CHD (n = 8/39; 20.5%), and liver related mortality (n = 5/39; 12.8%). The other 13 patients (33.3%) died from various causes (Table 3). The primary types of cancers were gastric cancer (n = 2), colon cancer (n = 2), pancreatic cancer (n = 2), breast cancer (n = 2), leiomyosarcoma of uterus (n = 1), diffuse B cell lymphoma (n = 1), endometrial cancer (n = 1), lung cancer (n = 1) and unknown primary cancer with liver metastasis (n = 1). Additionally, our study showed a significant, graded relationship between the NAFLD fibrosis score, classified into 3 subgroups (low, intermediate and high probability of liver fibrosis), and the occurrence of primary endpoints, as shown in Table 4.

Predicting mortality

Patients who died (n = 39) were significantly older with more frequent diabetes and had a higher SBP, NFS at baseline, FRS, glucose, and a lower diastolic blood pressure, ALT and albumin (Table 5). Moreover, they had greater NFS changes per year than those who survived (n = 263, P <0.05). Three models of multivariate analysis were used to identify the best fit model for predictors of death and are illustrated in Table 6. In model 1, we added 9 variables, including gender, systolic blood pressure, diastolic blood pressure, NFS at baseline, use of metformin, use of simvastatin, use of aspirin, presence of new-onset CHD and new-onset liver complications, without interaction among these variables. Model 2 included 10 variables, gender, systolic blood pressure, diastolic blood pressure, NFS at baseline, NFS changes per year, use of metformin, use of simvastatin, use of aspirin, presence of new-onset of CHD and new-onset of liver complications without interaction among these variables. Finally, model 3 added the interaction between NFS at baseline and NAFLD NFS changes per year with the use of aspirin, metformin, and simvastatin into model 2. We did not add the FRS into these models due to the repetition of several variables in the NFS and the FRS. Model 3 was the best fit model, which found that a higher NFS at baseline and more frequent new-onset CHD were significantly predictive of death (OR = 2.6 and 9.2, respectively; P < 0.0001). The use of metformin or simvastatin for at least 3 mo during the follow-up were associated with fewer deaths in patients with NAFLD (OR = 0.2 and 0.03, respectively; P < 0.05).

Table 7 showed the results of the comparison of NAFLD patients with and without death after excluding those with established type 2 diabetes at baseline (n = 254). After excluding patients with established type 2 diabetes at baseline, we found that a higher NFS at baseline and higher alkaline phosphatase remained significantly predictive of death (OR = 1.9 and 1.006; P <0.0001 and 0.012, respectively) as shown in Table 8. Additionally, Table 9 showed that non-diabetic patients with intermediate or high probability of liver fibrosis had a significantly higher rate of primary end point and all-cause death than those patients with low probability of liver fibrosis.

Using the ROC curves to predict death, we found that a baseline NFS of -0.9 was the best cutoff value with a sensitivity of 62%, specificity of 76%, positive predictive value of 28%, negative predictive value of 93% and AUC of 0.7 (Figure 1).

The median rate of annual NFS change for all patients was 0.1 (IQR of 0.02, 0.13). The rate of annual NFS change in patients with an intermediate or high probability of advanced liver fibrosis was significantly lower than in patients with a low probability of advanced liver fibrosis (0.06 *vs* 0.09, P = 0.004). The annual NFS change in patients who died was significantly higher than those in patients who survived (0.14 *vs* 0.07, P = 0.03). At the end of the follow-up, we classified the patients into 3 subgroups according to the progression pattern of the

To avoid overestimation of the model, we excluded those variables used as a part of NAFLD fibrosis score calculation (age, history of diabetes, aspartate aminotransferase/alanine aminotransferase ratio, platelet count, albumin, body mass index and Framingham risk score). NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; FRS: Framingham risk score; CHD: Coronary heart disease; NFS: NAFLD fibrosis score.

liver fibrosis by comparing the NFS at baseline to that at the end of follow-up. Most patients were in the stable-fibrosis (60%) and progressive-fibrosis (37%) groups, whereas only 3% were in the regressive-fibrosis group. The annual NFS change in the progressive-fibrosis group and the stable-disease group was 0.20 ± 0.02 and 0.05 ± 0.08, respectively (*P* = not significant).

DISCUSSION

In the current study, we found that a higher NFS at baseline and the presence of new-onset CHD were significantly predictive of death. The use of noninvasive methods to predict poor clinical outcomes in NAFLD patients during follow-up is urgently needed. Studies of noninvasive markers used to identify steatohepatitis patients from NAFLD patients require validation before being widely used, as previously suggested[22]. Although liver biopsy is the currently recommended practice for identifying liver fibrosis, in NAFLD patients with risk factors that include older age, diabetes, severe obesity and metabolic syndrome, serial liver biopsies are invasive and are not applicable in clinical practice. Recently, Rafiq *et al*[22] showed that at least 3 risk factors, including type

Table 6 Multivariate logistic regression model showing OR (95%CI) for predictors for death in 302 patients with non-alcoholic fatty liver disease

Multivariate analysis	*P* value	OR	95%CI

Model 1 without interaction among 9 included variables: gender, systolic blood pressure, diastolic blood pressure, nonalcoholic fatty liver disease (NAFLD) fibrosis score at baseline, use of metformin, use of simvastatin, use of aspirin, presence of new-onset of coronary heart disease (CHD) and new onset of liver complications; Model 2 without interaction among 10 included variables: gender, systolic blood pressure, diastolic blood pressure, NAFLD fibrosis score (NFS) at baseline, NFS changes per year, use of metformin, use of simvastatin, use of aspirin, presence of new-onset coronary heart disease (CHD) and new onset of liver complications; Model 3 added variables of interaction between NFS at baseline and NFS changes per year, interaction among use of aspirin, metformin, aspirin and simvastatin into model 2.

2 diabetes, older age and low albumin level, were predictors of mortality and liver-related mortality. Most of these risk factors are components of the NFS[9]. Thus, a benefit of the current study is an extension of the clinical use of the NFS system for predicting death in patients with NAFLD.

Our results show that the annual NFS change in patients who died was two times higher than in survivors during the follow-up. Thus, it would be valuable to calculate NFS in newly diagnosed patients.

The annual rate of NFS change in the progressive-fibrosis group was approximately 4 times higher than that in the stable-disease group. Therefore, the median value of the annual rate of NFS change might be used as a surrogate marker for progression of liver fibrosis, but this measure requires further study to validate its benefit.

The long-term outcomes of patients with NAFLD are not uniform across the spectrum of the disease[3,22,23]. Poor outcomes are more frequent in patients with NASH, which was confirmed by our results, which showed patients with an intermediate or high probability of advanced liver fibrosis had an increased frequency of primary endpoints, all-cause deaths, and liver complications compared to those with a low probability of advanced liver fibrosis.

Several previous studies have demonstrated a higher mortality rate (30%-45%) than observed in the current study (13%). This difference may be at least partly explained by a difference in patient selection. For instance, the prevalence of diabetes or impaired glucose tolerance, a well-known risk factor for increased mortality, was three times higher in a Swedish study than in the current study (53% *vs* 16%)[3]. In addition, previous studies did not exclude patients with known CHD or known liver complications at baseline[3,22,23].

The use of metformin or simvastatin was found to be a protective factor against death in the present study. This finding is in line with a study by Ekstedt *et al*[24], who showed a significant reduction in liver steatosis in NAFLD patients on statins *vs* those not on statins. A recent study found diabetes mellitus to be one of the important predictors for developing moderate to severe liver fibrosis[25], and treatment with metformin improved liver histology and ALT levels in one-third of patients with NASH[26]. Two other studies suggested that metformin improved only the insulin sensitivity but did not improve liver histology in NASH patients[26,27]. Limited data exist concerning the efficacy of metformin in patients with NAFLD, and the result of the current study does not necessarily imply causality. Our results show that the use of simvastatin seems to improve the prognosis in patients with NAFLD. This improvement may relate to the effect on prevention of new-onset CHD, which accounted for 20% of deaths in our study. Recent data showed that the statins are safe and well-tolerated in patients with NAFLD[28-32]. Moreover, the use of statins was associated with a reduction of hepatic steatosis in NAFLD patients[24,32,33]. No study has assessed the efficacy of statins to reduce CHD mortality in NAFLD patients, although the benefits are well-recognized for both the primary and secondary prevention of CHD and the reduction of overall mortality in the general population[34,35]. Thus, the benefit of statins for CHD prevention in NAFLD patients with dyslipidemia and/or a high calculated risk of coronary heart disease by the FRS should be considered[36,37].

The main strengths of our study are the inclusion of NAFLD patients from the community along with the long-term follow-up. All patients had complete data for calculation of the NFS at the time of NAFLD diagnosis and at the end of the follow-up. The exclusion of known CHD or liver cirrhosis with complications at baseline is important to reduce the overestimation of the incidence of primary endpoints or mortality rate during the follow-up period.

Our study has several limitations. First, only 6.6% of the patients with a low probability of advanced liver fibrosis died, which was less than expected (10%) by a sample size calculation and may affect the power of the study. Second, most of our patients in Olmsted County are white, and recent data showed that non-Caucasian

NAFLD: Nonalcoholic fatty liver disease.

race was an important predictor of decreased survival[22]. With the relatively small sample size and the represented local population in the United States, our results are not necessarily applicable in other ethnic groups.

The current study is important because we extended the clinical use of the NFS system for predicting death or liver complications in NAFLD patients. A higher NFS at baseline and the presence of new-onset CHD can be used as prognostic predictors for mortality and liver complications among NAFLD patients. Further research is needed to validate the benefit of the NFS for predicting death or liver complications in NAFLD patients with other ethnic groups. The NFS is simpler and less invasive than liver biopsy for the initial evaluation of the degree of liver fibrosis in patients with NAFLD. The NFS should be calculated for all patients with NAFLD at initial consultation to estimate the probability of advanced liver fibrosis.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) is one of the most common causes of chronic liver disease in Western countries. During an average 7.6 years of follow-up, 13% of the patients died, mainly from malignancy, coronary heart disease (CHD) and liver-related mortality.

Research frontiers

Another study revealed that the survival of patients with nonalcoholic steatohepatitis was reduced and that these patients died significantly more often from CHD and liver-related causes. Patients with more advanced liver fibrosis tend to have more liver complications than those without liver fibrosis.

Innovations and breakthroughs

A study from Japan validated the NAFLD Fibrosis Score and found it to have an acceptable sensitivity, specificity, and positive and negative predictive values for advanced liver fibrosis of 100%, 83%, 63%, and 100%, respectively.

Peer review

In this manuscript, the authors intend to evaluate whether the NAFLD fibrosis score could act as a prognostic predictor for mortality and liver complications among NAFLD patients. It is suggested that the NAFLD fibrosis score is a simple, non-invasive method for predicting prognosis in patients with NAFLD. In general, this paper is significant and of clinical importance.

Table 9 The association between the primary end point and the grading of the nonalcoholic fatty liver disease fibrosis score, classified into 2 subgroups, after excluding those with established type 2 diabetes at baseline *n* (%)

Grading of the NAFLD fibrosis score (*n* = 254)	Low prob. of advanced liver fibrosis (*n* = 176)	Intermediate prob. or High prob. of advanced liver fibrosis (*n* = 78)	*P* value

Abstract

AIM: To investigate the effects of different concentrations of *Schistosoma japonicum* (*S. japonicum*) egg antigen on fibrogenesis and apoptosis in primary hepatic stellate cells (HSCs).

METHODS: A mouse model of schistosomiasis-associated liver fibrosis (SSLF) was established by infecting mice with schistosomal cercaria *via* the abdomen. HSCs were isolated from SSLF mice by discontinuous density gradient centrifugation, and their identity was confirmed by immunofluorescence double staining of α-smooth muscle actin (α-SMA) and desmin. The growth inhibitory effect and 50% inhibitory concentration (IC50) of *S. japonicum* egg antigen for primary HSCs (24 h) were determined using a cell counting kit-8 (CCK-8) assay. The expression levels of α-SMA, matrix metalloproteinase-9 (MMOL/LP-9) and tissue inhibitor of metalloproteinases-1 (TIMP-1) in HSCs in response to different concentrations of *S. japonicum* egg antigen were detected by Western blotting and real-time reverse transcription-polymerase chain reaction. The levels of phospho-P38 (P-P38), phospho-Jun N-terminal kinase (P-JNK) and phospho-Akt (P-AKT) in HSCs were detected by Western blotting.

RESULTS: An SSLF mouse model was established, and primary HSCs were successfully isolated and cultured. *S. japonicum* egg antigen inhibited HSC proliferation in a concentration-dependent manner. The IC50 of the *S. japonicum* egg antigen was 244.53 ± 35.26 μg/mL. *S. japonicum* egg antigen enhanced α-SMA expression at both the mRNA and protein levels and enhanced TIMP-1 expression at the mRNA level in HSCs ($P < 0.05$), whereas the expression of MMOL/LP-9 was attenuated at both the mRNA and protein levels in a concentration-dependent manner ($P < 0.05$). A high concentration of *S. japonicum* egg antigen enhanced P-P38, P-JNK and P-AKT activation ($P < 0.05$). The changes in α-SMA and MMOL/LP-9 expression induced by *S. japonicum* egg antigen were closely correlated with P-P38 and P-JNK activation ($P < 0.05$). The attenuation of MMOL/LP-9 was also correlated with P-AKT activation ($P < 0.05$), but the increase in α-SMA expression was not. TIMP-1 expression was not correlated with P-P38, P-JNK or P-AKT activation.

CONCLUSION: *S. japonicum* egg antigen promotes fibrogenesis, activates the P38/JNK mitogen-activated protein kinase and AKT/PI3K signaling pathways and inhibits proliferation in primary HSCs isolated from SSLF mice in a concentration-dependent manner.

Liu P, Wang M, Lu XD, Zhang SJ, Tang WX. *Schistosoma japonicum* egg antigen up-regulates fibrogenesis and inhibits proliferation in primary hepatic stellate cells in a concentration-dependent manner. *World J Gastroenterol* 2013; 19(8): 1230-1238 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1230.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1230

INTRODUCTION

Schistosomiasis is a water-borne parasitic disease that plagues many tropical and subtropical regions. At least 200 million people in 76 countries are currently afflicted by this disease, and a further 500-600 million people are at risk of infection[1]. *Schistosoma japonicum* (*S. japonicum*), the Asian schistosome, causes schistosomiasis in China, Japan, the Philippines and Indonesia. A nationwide schistosomiasis survey carried out in 2003 indicated that there were still more than 800 000 people infected with *S. japonicum* in China[2].

Despite recent progress in anti-schistosomal strategies, clinical management remains a challenge because schistosomiasis-associated liver fibrosis (SSLF) is a complex, multi-step and often fatal disease. Cercaria that are transmitted through the skin can lay a large number of eggs, which then pass through the sinusoidal endothelial vascular system, settle in the liver, release immol/Lunocompetent products, interact with various liver cells and finally lead to liver fibrosis[3]. This liver fibrosis could develop into an irreversible advanced stage upon repeated exposure to the causative agents (*i.e.*, *S. japonicum* eggs). Primary hepatic stellate cells (HSCs) are believed to be the crucial contributors to the fibrotic process by producing extracellular matrix and interrupting the balance of fiber generation *vs* degradation[4]. Some studies have investigated the mechanism underlying the pathogenesis of SSLF. *S. mansoni* eggs can stimulate hepatic endothelial cell proliferation[5] and migration, promote angiogenesis[6], induce fibroblast proliferation[7] and collagen synthesis[8] and down-regulate LX-2 activation and fibrogenesis[9]. However, little is known about the mechanisms that are active in HSCs during the development and progression of SSL[3,10].

In this study, primary HSCs isolated from SSLF mice were exposed to different concentrations of *S. japonicum* egg antigen and then analyzed to better understand the interaction between HSCs and SSLF.

MATERIALS AND METHODS

Animals

Healthy 4- to 6-wk-old male BALB/C mice were obtained from a schistosomiasis control station in Hubei province, China.

Reagents

S. japonicum egg antigen [0.01 g/mL in phosphate-buffered saline (PBS)] was obtained from the Hubei schistosomiasis control station and diluted to the working concentration in Dulbecco's modified Eagle's medium (DMEM) supplemented with 2% fetal bovine serum (FBS) before use.

Animal model development

The SSLF model was established by abdominal infection with schistosomal cercaria according to the method used in a previous study[11]. In brief, mice in the model group were percutaneously infected with *S. japonicum* by placing a glass slide carrying 20 ± 2 cercariae in non-chlorinated water on the abdomen of each mouse for 15 min. Mice in the control group were treated with non-chlorinated water containing no cercariae. All mice were raised for 6 wk under pathogen-free conditions with free access to food and water. All animal experiments were performed in accordance with the Guide for the Care and Use of Laboratory Animals of the Chinese Council on Animal Care. Liver samples were taken from 10 infected and 10 normal mice and fixed in 4% (v/v) paraformaldehyde (PFA) in PBS.

Masson staining

Masson staining was performed using standard methods to observe collagen fiber deposition. About 5 middle-power fields were randomly selected from each sample for analysis, and the ratio of the area occupied by collagen fibers to the total area was quantified using Image Pro Plus 6.0 software (Media Cybernetics Inc., United States).

Hepatic stellate cell isolation and culture

HSCs were prepared by the discontinuous density gradient centrifugation technique previously described by Schafer *et al*[12], with minor modifications. Briefly, the liver was perfused with Solution I [137 mmol/L NaCl, 5.4 mmol/L KCl, 0.6 mmol/L NaH_2PO_4•$2H_2O$, 0.8 mmol/L Na_2HPO_4•$12H_2O$, 10 mmol/L HEPES, 0.5 mmol/L EGTA, 4.2 mmol/L $NaHCO_3$, 5 mmol/L glucose, 100 U/mL penicillin and 100 U/mL streptomycin (Gibco, United States), pH = 7.4] and Solution II [137 mmol/L NaCl, 5.4 mmol/L KCl, 0.6 mmol/L NaH_2PO_4•$2H_2O$, 0.8 mmol/L Na_2HPO_4•$12H_2O$, 10 mmol/L HEPES, 3.8 mmol/L $CaCl_2$•$2H_2O$, 24.2 mmol/L $NaHCO_3$, 5 mmol/L glucose, 600 mg/L collagenase IV (Gibco, United States), 400 mg/L pronase (Sigma, United States), 20 mg/L DNAse (Gibco, United States), pH = 7.4] through the hepatic portal vein. The livers were removed and forced through a 200 gauge mesh. Parenchymal cells were separated by centrifugation at 20 *g* for 5 min. The supernatant was transferred to a 50 mL centrifuge tube and centrifuged at 500 *g* for 7 min. The pellet was resuspended in 15% OptiPrep (Sigma, United States), and 11% OptiPrep and 5 mL GBSS (120 mmol/L NaCl, 5 mmol/L KCl, 0.84 mmol/L Na_2HPO_4•$2H_2O$, 0.22 mmol/L KH_2PO_4, 1.9 mmol/L $MgCl_2$•$6H_2O$, 1.5 mmol/L $CaCl_2$•$2H_2O$, 27 mmol/L $NaHCO_3$, 5 mmol/L glucose, pH = 7.4) were

then layered on the top of the 15% OptiPrep, and the gradient was centrifuged at 1400 *g* for 17 min. The interface between the 11% OptiPrep and the GBSS was collected and washed twice with GBSS. The collected cells were cultured in DMEM containing 10% FBS (Gibco, United States). The cell viability, as measured by a Trypan Blue exclusion assay, was approximately 90%. Primary HSCs from passages 7-8 were used in this study.

Immunofluorescence staining

Immunofluorescence double staining of α-smooth muscle actin (α-SMA) and desmin was used to identify activated HSCs. Briefly, cell slides were fixed in 4% PFA and incubated with a blocking solution containing 0.1% Triton X-100 and 5% bovine serum albumin (BSA) in PBS, followed by incubation with anti-desmin (Abcam, United Kingdom) and anti-α-SMA (Boster, China) primary antibodies at 4 ℃ overnight. After three washes with PBS, the slides were incubated with secondary FITC-conjugated antibodies and Cy3-conjugated antibodies (Proteintech, United States) for 1 h at 37 ℃ and then with Hoechst 33258 for 5 min. The cells were observed and imaged using a TE-2000 Nikon Inverted fluorescence microscope, and the number of positive cells per 100 cells was analyzed.

Cell counting Kit-8

The cell growth inhibitory effect and 50% inhibitory concentration (IC50) of *S. japonicum* egg antigen for primary HSCs were determined using a cell counting kit-8 (CCK-8) assay. HSCs were treated as follows: cultured cells (1×10^4/well) in a 96-well plate were exposed to a range of concentrations of *S. japonicum* egg antigen (1, 5, 25, 125, 250, 625, 1250, 2500 and 3125 μg/mL) for 24 h, and 10 μL of water soluble tetrazolium-8 (WST-8) (Promoter, China) was then added to the medium containing the *S. japonicum* egg antigen. The cells were incubated then for 2 h. The absorbance of each well was read at 450 nm, and a blank well that contained only culture medium and was used for background correction. The percent inhibition was calculated according to the following formula: Inhibition (%) = [1 - (treated/control)] × 100[13,14]. The IC50 was determined using Statistical Product and Service Solutions (SPSS) 16.0 software (SPSS Inc., United States).

Real-time reverse transcription-polymerase chain reaction

Cultured cells were incubated with various concentrations of *S. japonicum* egg antigen (0, 5, 10, 15, 50, 250 μg/mL) for 24 h. Total RNA was isolated from HSCs using the TRIzol reagent (Invitrogen, United States) according to the protocol described by the manufacturer. RNA samples were quantified by measuring the absorbance at 260 nm and 280 nm using a spectrophotometer, and all samples had an *A*260/*A*280 ratio between 1.8 and 2.0, which indicated a high purity of the extracted RNA. The RNA concentrations were calculated based on the absorbance at 260 nm. Aliquots of total RNA (0.5 μg) from each sample were reverse transcribed into cDNA according to the instructions provided with the first-strand cDNA synthesis kit (TaKaRa, Japan). Equal amounts of the reverse transcription products were subjected to polymerase chain reaction amplification using SYBR Green as a fluorescent indicator on an AB iCycler system (AB, United States). The levels of α-SMA, matrix metalloproteinase-9 (MMOL/LP-9) and tissue inhibitor of metalloproteinases-1 (TIMP-1) mRNAs were normalized to the level of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA. The fold change in the expression of target genes between the experimental and control samples was calculated using the $2^{-\Delta\Delta CT}$ method, as previously described[15]. The primers used in this study were synthesized by Invitrogen Ltd. (Invitrogen, United States): α-SMA sense CGGGAGAAAATGACCCAGATT, α-SMA antisense GGACAGCACAGCCTGAATAGC, MMOL/LP-9 sense ACAGCCAACTATGACCAGGAT, MMOL/LP-9 antisense CAGGAAGACGAAGGGGAAGAC, TIMP-1 sense CTTGGTTCCCTGGCGTACTC, TIMP-1 antisense ACCTGATCCGTCCACAAACAG, GAPDH sense GGTTGTCTCCTGCGACTTCA and GAPDH antisense GGGTGGTCCAGGGTTTCTTA.

Western blotting

Western blot analysis was performed as described previously[16]. In brief, proteins from HSCs were extracted using RIPA lysis buffer (50 mmol/L Tris, 150 mmol/L NaCl, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, pH = 7.4) containing protease inhibitors. After the samples were boiled for 5 min at 95 ℃ in 5 × loading buffer, equal amounts (50 μg) of cell homogenates were separated by 12% SDS-PAGE. The proteins were then electrophoretically transferred at 250 mAH onto polyvinylidene fluoride membranes. The membranes were blocked with 5% nonfat dry milk or BSA in Tris-buffered saline-Tween 20 (TBST) and probed at 4 ℃ overnight with primary antibodies against α-SMA (1:200, Boster, China), MMOL/LP-9 (1: 200, Boster, China), TIMP-1and β-actin (1:500, Santa Cruz, United States), phospho-P38 (P-P38) and total P38 (T-P38) (1:1000, Cell Signaling Technology, United States), phospho-JNK (P-JNK) and total-JNK (T-JNK) (1:1000, Cell Signaling Technology, United States), phospho-AKT (P-AKT) (1: 1000, Cell Signaling Technology, United States) and total-AKT (T-AKT) (1:400, Santa Cruz, United States). The membranes were then washed and incubated for 1 h with horseradish peroxidase-conjugated secondary antibodies diluted 1:5000 or 1:2000. The membranes were washed, and all blots were visualized using an ECL detection system (Biouniquer, China). The bands were quantitated in grayscale using Image J software (NIH, United States).

Statistical analysis

The results of multiple observations are presented as the means ± SD of at least 3 independent experiments.

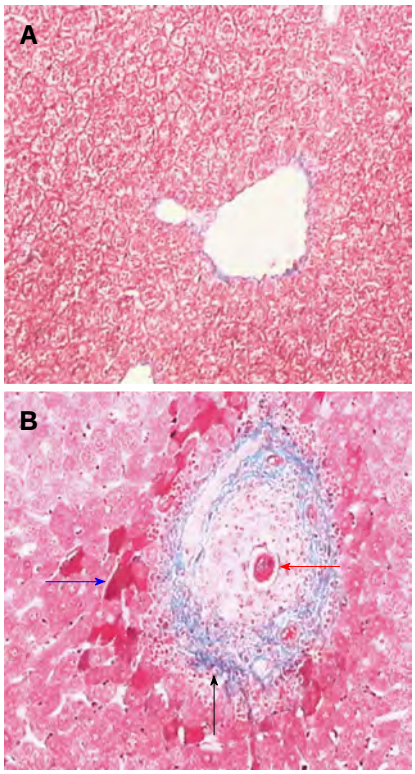

Figure 1 Masson staining of 6 wk post-infect mice livers (× 200). A: Normal mice; B: Infected mice, the red arrow indicated the eggs deposited in the vein, the blue represented acidophilic necrosis, and the black was the collagen fiber deposited around the vein.

Table 1 Ratio of collagen fiber deposited area to the totalin the normal and infected mice livers (mean ± SD)

Group	*n*	Ratio of deposited collagen fiber area against the total
Normal	10	5.18% ± 1.88%
Infected	10	14.53% ± 2.90%[a]

[a]$P < 0.05$ *vs* Normal.

Student's *t* test was used to evaluate the difference in the ratio of the collagen fiber-deposited area to the total area between infected and normal mouse livers. ANOVA was used to evaluate the differences between the *S. japonicum* egg antigen-treated group and the control group. Person linear correlation analysis was used to analyze the correlations between the α-SMA, MMOL/LP-9 and TIMP-1 expression levels and the P-P38, P-JNK and P-AKT levels. All *P* values were two sided, and $P < 0.05$ was considered statistically significant. Statistical analysis was performed using SPSS 16.0 software.

RESULTS

Establishment of the mouse model of SSLF

Masson staining showed that collagen fibers were deposited at the periphery of the eosinophilic granuloma and that eggs were deposited in the venae of mouse liver tissues at 6 wk post-infection; in contrast, there were no collagen fibers deposited in the normal mouse livers except in the vessels (Figure 1). In addition, the ratio of the collagen fiber-deposited area to the total area was significantly greater in the SSLF livers than in the normal livers (Table 1). The above results suggest that the SSLF mouse model was established successfully.

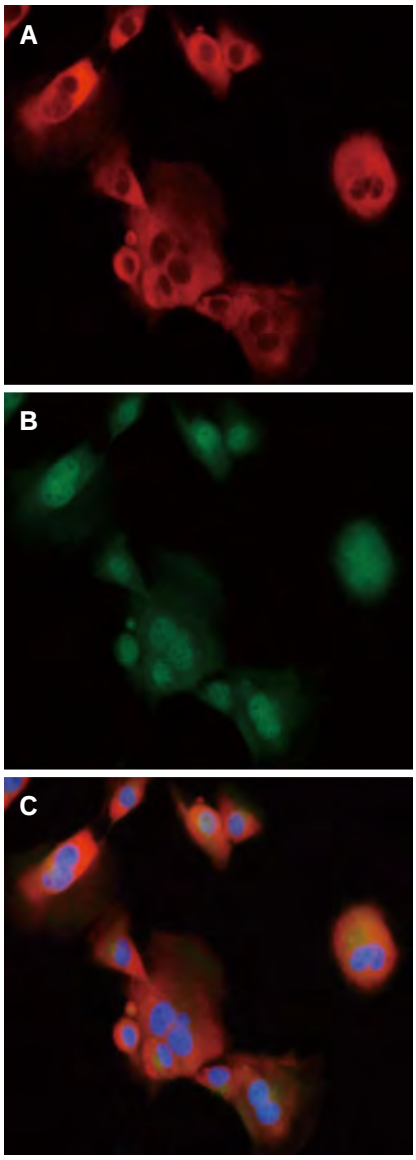

Figure 2 Immunofluorescence staining in primary primary hepatic stellate cells (× 400). A: α-Smooth muscle actin (red hue); B: Desmin (green hue); C: Overlay.

Identification of isolated HSCs

Primary HSCs isolated from SSLF mice displayed a quiescent phenotype. When cultured in plastic culture dishes, these cells began to exhibit an activated phenotype. The expression levels of α-SMA and desmin increased, and this feature was used to identify activated HSCs. Immunofluorescence double staining showed that α-SMA and desmin were expressed in the cytoplasm of HSCs (Figure 2). Approximately 95% of the cells expressed both α-SMA and desmin, suggesting that primary HSCs were

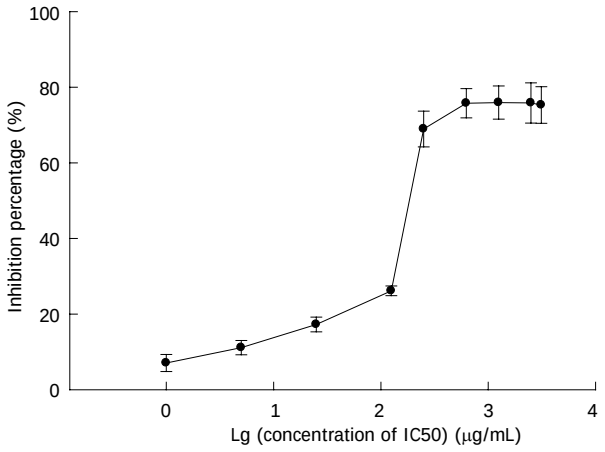

Figure 3 **Inhibitory proliferation of *Schistosoma japonicum* egg antigen in primary hepatic stellate cells.** The black dots were quantification of 3 independent experiments.

isolated successfully.

Inhibitory effect and IC50 of S. japonicum egg antigen for primary HSCs

Figure 3 shows that *S. japonicum* egg antigen inhibited the proliferation of primary HSC in a concentration-dependent manner. The percent inhibition values for *S. japonicum* egg antigen were 7.06% ± 2.26% for 1 μg/mL, 11.13% ± 1.90% for 5 μg/mL, 17.25% ± 1.95% for 25 μg/mL, 26.16% ± 1.28% for 125 μg/mL, 68.96% ± 4.73% for 250 μg/mL, 75.77% ± 3.87% for 625 μg/mL, 75.95% ± 4.40% for 1250 μg/mL, 75.84% ± 5.33% for 2500 μg/mL and 75.30% ± 4.84% for 3125 μg/mL. The IC50, defined as the concentration of a substance that reduces cell survival by 50%, is a useful parameter to quantify the effect of a substance on cell survival. In this study, the IC50 of *S. japonicum* egg antigen was calculated to be 244.53 ± 35.26 μg/mL.

Expression of α-SMA, MMP-9 and TIMP-1 in response to S. japonicum egg antigen in vitro

As shown in Figure 4, *S. japonicum* egg antigen at 50 or 250 μg/mL enhanced α-SMA expression in HSCs at both the mRNA and protein levels. At the mRNA level, the fold change in α-SMA expression was 1.97 ± 0.18 in response to 50 μg/mL and 2.18 ± 0.22 in response to 250 μg/mL relative to the control (1.00 ± 0.10, $P < 0.05$) (Figure 4C). At the protein level, the α-SMA/β-actin ratio was 0.94 ± 0.03 at 50 μg/mL and 1.06 ± 0.04 at 250 μg/mL, compared with 0.63 ± 0.05 for the control ($P < 0.05$, Figure 4A and B).

However, at the mRNA level, 3.45 ± 0.36-fold reduction in response to 50 μg/mL and 4.49 ± 0.28-fold reduction in response to 250 μg/mL in MMOL/LP-9 expression were observed after 24h with egg antigen treatment, compared with 1.05 ± 0.12 for the control ($P < 0.05$, Figure 4C). At the protein level, the MMOL/LP-9/β-actin ratios were 0.59 ± 0.03 at 50 μg/mL and 0.49 ± 0.10 at 250 μg/mL, compared with 0.98 ± 0.08 for the

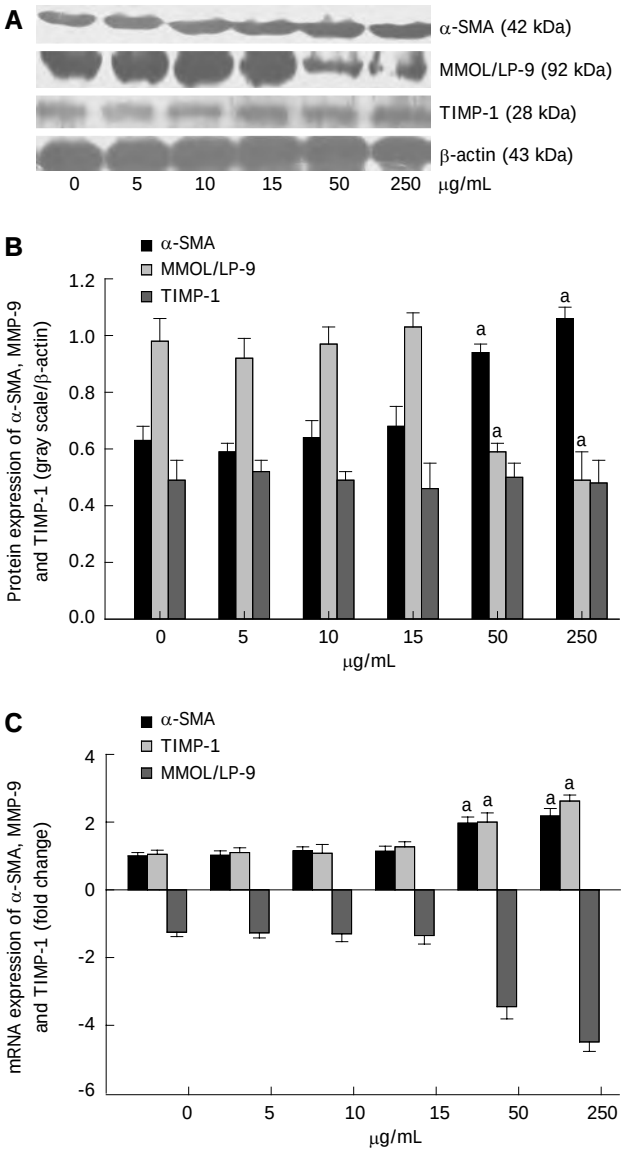

Figure 4 Western blotting (A, B) and real-time polymerase chain reaction (C) of α-smooth muscle actin, matrix metalloproteinase-9 and tissue inhibitor of metalloproteinases-1 induced by *Schistosoma japonicum* egg antigen in primary hepatic stellate cells. A: Western blotting of α-smooth muscle actin (α-SMA), matrix metalloproteinase-9 (MMOL/LP-9) and tissue inhibitor of metalloproteinases-1 (TIMP-1), and representatives of 3 independent experiments; B: The histograms reported as ratio of respective target gray scale to that of β-actin. C: The histograms represented the fold change of target genes normalized to glyceraldehyde-3-phosphate dehydrogenase levels and quantified of 3 independent experiments. [a]$P < 0.05$ *vs* 0 μg/mL.

control ($P < 0.05$, Figure 4A and B). In addition, *S. japonicum* egg antigen also enhanced TIMP-1 expression at the mRNA level. The fold change in TIMP-1 mRNA expression was 2.00 ± 0.27 in response to 50 μg/mL and 2.62 ± 0.18 in response to 250 μg/mL compared with 1.05 ± 0.13 for the control ($P < 0.05$, Figure 4C). However, as shown in Figure 4A and B, *S. japonicum* egg antigen had no effect on TIMP-1 expression at the protein level.

Collectively, the above observations indicate that *S. japonicum* egg antigen promoted fibrogenesis in HSCs and participated in the extracellular matrix remodeling observed in SSLF.

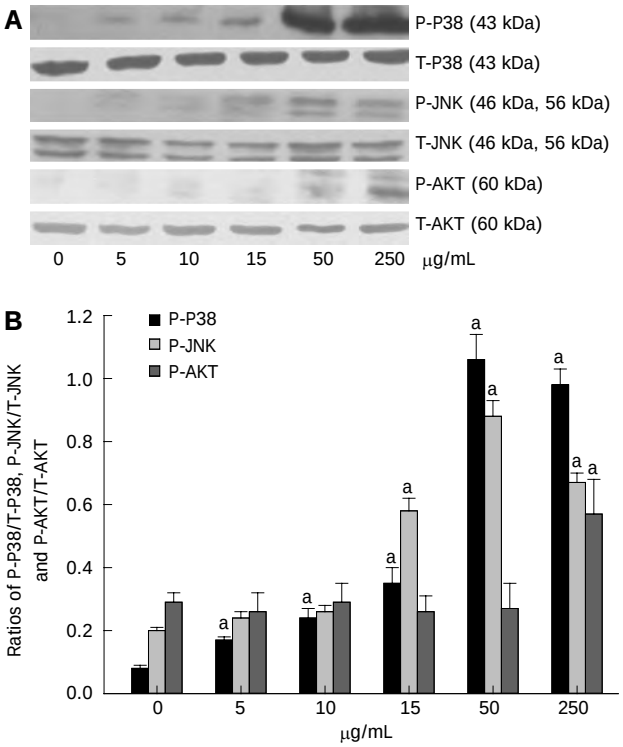

Figure 5 **Western blotting of phospho-P38, phospho-Jun N-terminal kinase and phospho-Akt activation induced by *Schistosoma japonicum* egg antigen in primary hepatic stellate cells.** A: Western blotting of phospho-P38 (P-P38), phospho-Jun N-terminal kinase (P-JNK) and phospho-Akt (P-AKT), and representatives of 3 independent experiments; B: The histograms respectively reported as ratio of P-P38/T-P38, P-JNK/T-JNK, and P-AKT/T-AKT. $^{a}P < 0.05$ *vs* 0 μg/mL.

P38/JNK MAPK and AKT signaling pathway activation by S. japonicum egg antigen in vitro

As shown in Figure 5, the P-P38, P-JNK and P-AKT activation levels were enhanced by stimulation with the *S. japonicum* egg antigen. The P-P38/T-P38 ratio was 1.03 ± 0.08 at 50 μg/mL and 1.05 ± 0.01 at 250 μg/mL *vs* 0.18 ± 0.02 for the control ($P < 0.05$). The P-JNK/T-JNK ratio was 0.58 ± 0.04 at 15 μg/mL, 0.88 ± 0.05 at 50 μg/mL and 0.67 ± 0.03 at 250 μg/mL *vs* 0.20 ± 0.01 for the control ($P < 0.05$). The P-AKT/T-AKT ratio was 0.57 ± 0.11 at 250 μg/mL *v* 0.29 ± 0.03 for the control ($P < 0.05$). The above results indicate that *S. japonicum* egg antigen activated the P38/JNK mitogen-activated protein kinase (MAPK) and AKT signaling pathways in a concentration-dependent manner.

Relationships among the levels of the α-SMA, MMP-9 and TIMP-1 and P-P38, P-JNK and P-AKT in HSCs

α-SMA protein expression was positively correlated with the P-P38 ($r = 0.669$, $P = 0.002$) and P-JNK levels ($r = 0.686$, $P = 0.002$). MMOL/LP-9 expression was negatively correlated with the P-P38 ($r = -0.976$, $P = 0.000$), P-JNK ($r = -0.86$, $P = 0.000$) and P-AKT levels ($r = -0.529$, $P = 0.024$). However, TIMP-1 expression was not correlated with the P-P38, P-JNK or P-AKT level. α-SMA expression was not correlated with the P-AKT level.

DISCUSSION

HSC activation is considered the key step in liver fibrogenesis, representing a transition from the quiescent state into a proliferative, fibrogenic and contractile state. HSCs reside in the space of disse and are recruited to areas of hepatic injury by chemokines, where they become activated[17]. During this process, HSCs are transformed from the quiescent to activated phenotype, a process that is accompanied by an increase in the expression levels of α-SMA and desmin[18,19], which are considered to be markers of HSC activation. The activated HSCs adopt a myofibroblast-like phenotype and secrete collagen-rich matrix into the extracellular space, leading to liver fibrosis[20]. HSCs have been implicated as the effector cells of hepatic fibrosis and cirrhosis associated with hepatitis B virus, hepatitis C virus, genetic hemochromatosis, biliary atresia, cystic fibrosis and alcoholic liver disease in humans[20-23]. HSCs also play a role in eosinophilic granulomatous inflammol/Lation and SSLF[24-26]. Bartley *et al*[25] showed that activated HSCs could be detected at the edges of eosinophilic granulomas in *S. japonicum*-infected mice livers at 6 wk post-infection, and the localization of these cells was coincident with areas of collagen deposition. In this study, collagen fiber deposition was observed at the periphery of the eosinophilic granuloma, consistent with the previous reports[25]. In addition, we also found that *S. japonicum* egg antigen inhibited HSC proliferation in a concentration-dependent manner.

Activated HSC-secreted MMOL/LPs (*e.g.*, MMOL/LP-9) and their inhibitors (*e.g.*, TIMP-1) remodel the tissue matrix[22], and an imbalance in MMOL/LP/TIMP expression has been associated with cumulative fibrosis[27]. The expression of α-SMA is increased in the livers of SSLF patients and infected mice and is closely correlated with the degree of liver fibrosis[25,27]. In our experiment, the *S. japonicum* egg antigen attenuated MMOL/LP-9 expression and enhanced α-SMA expression at both the mRNA and protein levels, and it also enhanced TIMP-1 expression at the mRNA level. However, the TIMP-1 protein level was not affected. The mRNA and protein expression levels are not always proportional due to the activities of various regulatory mechanisms, *e.g.*, post-transcriptional modulation by miRNAs. The above results imply that the *S. japonicum* egg antigen is involved in MMOL/LP-9-mediated matrix remodeling and thus collagen deposition, leading to liver fibrosis. The results of our study partially contradict to the previous report that *S. mansoni* eggs can down-regulate the activation of and fibrogenesis in the human hepatic stellate cell line LX-2[9]. One potential reason for this discrepancy is the different cell models and schistosomal egg antigens used in the two studies. *In vitro* exposure to schistosome eggs induces only limited activation of human dendritic cells (DCs) but strong activation of murine DCs[28]. Similarly, in this study, the same concentrations of egg antigen (5 μg/mL,

10 μg/mL, and 15 μg/mL) that attenuated α-SMA expression in human LX-2 cells had no effect on primary mouse HSCs. In addition, *S. japonicum* and *S. mansoni* eggs release different antigens[29], which may play a role in the discrepancy.

MAPKs are pivotal transmitters of extracellular signals such as hormones, cytokines, growth factors, and various environmental stress signals[30]. The MAPK family has three major subfamilies: ERK, P38, and JNK, and the P38 and JNK pathways are involved in HSC transformation[31] and in the regulation of the complex life cycle and host-parasite interactions of *S. japonicum*[32]. Many studies have shown that the regulation of MMOL/LP-9[33-36] and α-SMA[37-39] in various cell models is dependent on the activation of the P38 and (or) JNK signaling pathways. In addition, AKT/PI3K activation contributes to liver[40], hear[41] and pulmonar[42-44] fibrosis. To gain insight into the potential signaling mechanisms mediating the HSC responses induced by the *S. japonicum* egg antigen, we investigated the roles of the P38/JNK MAPK and AKT signaling pathways by assessing their phosphorylation status in primary HSCs after stimulation by the *S. japonicum* egg antigen. In this study, the P-P38 and P-JNK levels were significantly enhanced after the treatment. The increase in α-SMA expression that was stimulated by the *S. japonicum* egg antigen was positively correlated with the P-P38 and P-JNK levels but not the P-AKT level. Attenuated MMOL/LP-9 expression was negatively correlated with the P-P38, P-JNK and P-AKT levels. TIMP-1 expression was not correlated with the P-P38, P-JNK or P-AKT level. We also noted that only *S. japonicum* egg antigen concentrations of 250 μg/mL or greater were associated with AKT activation, suggesting that AKT signaling may have a less important role than P38/JNK MAPK signaling in the induction of fibrogenesis by the *S. japonicum* egg antigen.

In conclusion, the results of this study suggest that the *S. japonicum* egg antigen promotes fibrogenesis and inhibits the proliferation of primary HSCs in a concentration-dependent manner. These effects of the *S. japonicum* egg antigen may be attributed to the activation of the P38/JNK signaling pathways in HSCs. Thus, inhibitors of the P38/JNK signaling pathways may serve as potential therapeutic treatments for SSLF.

ACKNOWLEDGMENTS

The authors thank Doctor Ying Chang for her revision of the manuscript. The authors would also like to acknowledge Doctor Zhi-Jun Wang for providing technical assistance during preliminary experiments.

COMMENTS

Background

Under the action of stimulus, hepatic stellate cells (HSCs) are activated and secreted extracellular matrix (ECM) into extracellular space, which leads to liver fibrosis. HSCs have been attributed as the effector cells for schistosomiasis-associated liver fibrosis (SSLF). Continuous schistosome eggs deposition in liver tissue was the chief factors leading to SSLF. So the study on the interaction between schistosome eggs antigen and HSCs is very important.

Research frontiers

As the effector cells of liver fibrosis, HSC is usually used as the cell model to study the liver fibrosis *in vitro*. The research hotspot on SSLF is the effects induced by schistosome eggs in HSCs and the involved mechanisms, and finding out the targets of treatment on SSLF for future.

Innovations and breakthroughs

The authors isolated primary HSCs which maintained the original features of HSC genes, and tried to explore the involved signaling pathways. The results of this study showed that *Schistosoma japonicum* (*S. japonicum*) eggs promoted the fibrogenesis and inhibited the proliferation of primary HSCs *in vitro*, P38/JNK MAPK signaling pathways might play an important role in the fibrogenesis induced by *S. japonicum* eggs, however AKT/PI3K signaling pathway might be not involved.

Applications

The results of this study suggest that *S. japonicum* egg antigen induced-fibrogenesis is related with P38/JNK MAPK signaling pathway activation, and the inhibitors of the P38/JNK signaling pathways may serve as potential therapeutic treatments for SSLF.

Terminology

Schistosomiasis is a water-borne parasitic disease that plagues many tropical and subtropical regions in world. There are 6 types schistosome which can infect humans: *Schistosoma haematobium*, *Schistosoma mansoni*, *S. japonicum*, *Schistosoma mekongi*, *Schistosoma intercalatum*, *Schistosoma malayensis*. *S. japonicum*, the Asian schistosome, causes schistosomiasis in China, Japan, the Philippines and Indonesia. Cercariae of schistosome parasitize in oncomelania that live in water and infect humans through bare skins, develop into imaginess in human bodies, and produce a large number of eggs which can deposit in liver tissues. With the eggs continuous deposition, eosinophilic granuloma and liver fibrosis, which are the pathological characteristics of schistosomiasis, are finally induced.

Peer review

This is a good study in which authors describe the fibrogenesis and inhibitory proliferation effects induced by *S. japonicum* in primary HSCs, and analyzed the signaling pathways (*e.g.*, P38/JNK MAPK) which may be involved in the above effects. The results are interesting and suggest that the inhibitors of the P38/JNK signaling pathways may serve as potential therapeutic treatments for SSLF in future.

Abstract

AIM: To investigate the effect of high mobility group A2 (*HMGA2*) gene silencing on gastric cancer MKN-45 cells *in vitro*.

METHODS: HMGA2 short hairpin RNA (shRNA) expression plasmids were constructed, including a pair of random scrambled sequences. Human gastric cancer cell line MKN-45 cells were divided into three groups: blank control group (non-transfected cells), transfected group (cells transfected with HMGA2 shRNA recombinant plasmid) and scrambled sequence group (transfected with random scrambled plasmid). Cells were transfected with HMGA2 shRNA recombinant plasmids and scrambled plasmid *in vitro*, and the cells transfection efficiency was assayed by fluorescence microscopy. The HMGA2 messenger RNA (mRNA) expression was detected by reverse transcription polymerase chain reaction, gastric cancer cells apoptosis was detected by flow cytometry, cell proliferation was detected by methyl thiazol tetrazolium, and the protein expression of phosphatidylinositol 3-kinase (PI3K), protein kinase B (Akt), P27, caspase-9 and B-cell leukemia/lymphoma-2 (Bcl-2) were analyzed by Western blotting.

RESULTS: Compared with the blank control group and the scrambled sequence group, the levels of HMGA2 mRNA and protein expression in the transfected group were significantly reduced ($P < 0.05$). The relative HMGA2 mRNA expression levels of the blank control group, transfected group and scrambled sequence group were 0.674 ± 0.129, 0.374 ± 0.048 and 0.689 ± 0.124, respectively. The relative HMGA2 protein expression levels of the blank control group, transfected group and scrambled sequence group were 0.554 ± 0.082, 0.113 ± 0.032 and 0.484 ± 0.123, respectively. Moreover, transfection with the scrambled sequence had no effect on the expression of HMGA2. After being transfected with shRNA for 24, 48 and 72 h, the cell apoptotic rates of the transfected group were 21.65% ± 0.28%, 39.98% ± 1.82% and 24.51% ± 0.93%, respectively, which significantly higher than those of blank control group (4.72% ± 1.34%, 5.83% ± 0.13% and 5.22% ± 1.07%) and scrambled sequence group (4.28% ± 1.33%, 7.87% ± 1.43% and 6.71% ± 0.92%). After 24, 48 and 72 h, the cell proliferation inhibition rates in the transfected group were 31.57% ± 1.17%, 39.45% ± 2.07% and 37.56% ± 2.32%, respectively; the most obvious cell proliferation inhibition appeared at 48 h after transfection. Compared with the blank control group and scrambled sequence group, after transfection of shRNA for 72 h, the protein expression levels of PI3K (0.042 ± 0.005 *vs* 0.069 ± 0.003, 0.067 ± 0.05), Akt (0.248 ± 0.004 *vs* 0.489 ± 0.006, 0.496 ± 0.104) and Bcl-2 (0.295 ± 0.084 *vs* 0.592 ± 0.072, 0.594 ± 0.109) were significantly reduced. The protein expression levels of P27 (0.151 ± 0.010 *vs* 0.068

± 0.014, 0.060 ± 0.013) and caspase-9 (0.136 ± 0.042 *vs* 0.075 ± 0.010, 0.073 ± 0.072) were significantly upregulated.

CONCLUSION: *HMGA2* shRNA gene silencing induces apoptosis and suppresses proliferation of MKN-45 cells.

Wei CH, Wei LX, Lai MY, Chen JZ, Mo XJ. Effect of silencing of high mobility group A2 gene on gastric cancer MKN-45 cells. *World J Gastroenterol* 2013; 19(8): 1239-1246 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1239.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1239

INTRODUCTION

Gastric cancer is one of the most common malignancies, being the fourth most common cancer and the second leading cause of cancer related deaths (740 000 deaths in 2008), with nearly one million newly diagnosed cases each year[1]. Up to now, the exact molecular mechanisms involved in carcinogenesis and progression of gastric cancer have remained unclear. Therefore, investigating the cell proliferation and apoptosis involved in these processes is essential for gastric cancer research.

The high mobility group A2 (*HMGA2*) gene is a member of the high mobility group AT-hook (HMGA) gene family. HMGA2 plays a critical role in several cellular biological processes, including cell transformation, growth, differentiation, senescence and cycle control[2-4]. Normally, HMGA2 is abundantly expressed during embryogenesis, whereas its expression is low or absent in normal adult differentiated tissues[5,6]. Evidence shows that HMGA2 is overexpressed in breast cancer[7], pancreatic cancer[8,9], esophageal squamous cell carcinoma[10], non-small cell lung cancer[11], oral squamous cell cancer[12], bladder cancer[13], ovarian cancer[14,15] and colorectal cancer[16,17]. Its expression is correlated with malignant degree, pathological type and metastasis[18]. Thus, HMGA2 might play a central role in the disease progression of many types of tumors. Overexpression of HMGA2 has also been described in gastric cancer[19]. The study showed that the overexpression of HMGA2 in gastric cancer patients was significantly correlated with poor prognosis and low overall survival. However, the exact mechanism of HMGA2 in gastric cancer is not clear.

The phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) signaling pathway plays a central role in many human cancers. Akt regulates cell proliferation, differentiation and apoptosis *via* activation or inhibition of downstream target proteins, such as P27, caspase-9 and B-cell leukemia/lymphoma-2 (Bcl-2)[20,21].

The aims of the present study were to investigate the effect of HMGA2 expression on gastric cancer cell proliferation and apoptosis. Moreover, the expressions of PI3K, Akt, P27, caspase-9 and Bcl-2 were detected to exploit the possible mechanism.

MATERIALS AND METHODS

Construction of HMGA2- shRNA expression plasmid

The human *HMGA2* was treated as the target gene (Accession Number: NM-003484) and four pairs of short hairpin RNA (shRNA) oligonucleotides were designed and synthesized (Cyagen Biosciences Inc., United States). A pair of random scrambled sequences, which have no homologous relation with any human gene sequences and whose shRNAs would not interfere with human mRNA were also designed (Table 1). The complementary form was obtained by annealing, which was then cloned and inserted into vector pLLU2 to construct a recombinant plasmid. The plasmid was transformed into stb13 strain. Finally, the plasmid was identified by restriction enzyme digestion and sequenced (Cyagen Biosciences Inc., United States). According to the preliminary experimental results, the first pair shRNA oligonucleotides (Table 1) was the best interfering sequence, and the recombinant plasmid harboring it was used for subsequent experiments.

Cell culture and transfection

Gastric cancer MKN-45 cells (ATCC, United States) were cultured in Dulbecco's modified Eagle's medium (DMEM) (Solarbio Science and Technology Co., Ltd., Beijing, China) containing 10% placental bovine serum. After 24 h incubation at 37 ℃ with 5% CO_2, logarithmic growth phase cells in good condition were digest by 0.25% trypsin + ethylenediaminetetraacetic acid. After calculating the cell number, cells were seeded into 6-well plates at 1×10^5 cells per well. When the cells reached more than 80% confluence (usually the next day), plasmid and lipofectamine were added dropwise to form a mixture of 1:1 with mixing. After culturing in serum-free and antibiotic-free DMEM for 6 h, the culture medium was replaced by DMEM and the cultured was continued for 24 h. The cells were then transfected using a Lipofectamine™2000 Transfection Kit (Invitrogen, United States) according to the manufacturer's instructions. Cells were randomly counted in 10 microscope fields at 24, 48 and 72 h after transfection. The ratio of the number of cells with green fluorescent emission and the total cells number indicated the transfection efficiency. Non-transfected cells from the same batch were collected as the blank control group. The cells transfected with the random scrambled sequence plasmid served as the scrambled sequence group.

Reverse transcription polymerase chain reaction analysis

Total RNA was isolated using TRIzol (Sangon Biotech Co., Ltd., Shanghai, China). A Reverse Transcriptase Kit (Fermentas China Co., Ltd.) was used to create cDNA, according to the manufacturer's instructions: 1 μg RNA, Oligo dT_{18} as the primer, and 42 ℃ for 60 min followed by 70 ℃ for 5 min. chain reaction (RT-PCR) assays were carried out using on an ABI 2720 (Applied Biosystems, Foster City, CA, United States). The PCR primers (synthesized by Sangon Biotech Co., Ltd., Shanghai, China) used to detect HMGA2 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were as follows: HMGA2, upstream primer 5'-TACTCTGTCTCTGCCTGTGC-3', downstream primer 5'-GGAGTGAATTGTGTCCCTTGA-3' (product length 228 bp); GAPDH, upstream primer 5'-GAAGGTGAAGGTCGGAGTC-3', downstream primer 5'-TCACACCCATGACGAACAT -3' (product length 401 bp). The 25 μL PCR amplification reaction mixture contained: cDNA, 1.5 μL; Taq Mix, 12.5 μL; 10 μmoL/L; each primer, 1 μL; RNase-free Water, 9 μL. Amplification reaction program: initial denaturation at 95 ℃ for 5 min; 35 cycles of denaturation at 94 ℃ for 30 s, annealing at 58 ℃ for 35 s, extension at 72 ℃ for 30 s; and final extension at 72 ℃ for 7 min. The PCR products were analyzed on agarose gels; gel analysis software was used to analyze the bands. The gray value ratio of the objective band and the β-actin band indicated the relative expression levels of HMGA2 mRNA.

Western blotting analysis of the protein expression levels of HMGA2, PI3K, Akt, P27, caspase-9 and Bcl-2

Cells were lysed in RIPA cell lysis buffer (Sangon Biotech Co., Ltd., Shanghai, China). The ratio of lysate and loading buffer was 4:1, degeneration and proteins were extracted. About 80 μg of proteins were fractionated by electrophoresis on sodium dodecyl sulfate-polyacrylamide gels and electroblotted onto a polyvinylidene fluoride membrane. The membrane was blocked with 5% nonfat milk for 2 h at room temperature and incubated overnight with the primary antibody (Santa Cruz Biotechnology, inc., United States). The membrane was washed with Tris-Buffered-Saline with Tween (TBST) three times for 10 min each, and then incubated for 2 h at room temperature with the secondary antibody (Zhongshanjinqiao Biotechnology Co., Ltd., Beijing, China). The membranes were washed with TBST 3 times for 10 min each, before being developed and fixed. β-actin (Zhongshanjinqiao Biotechnology Co., Ltd., Beijing, China) was used as an internal control. Gel analysis software was used to scan and analyze the bands. The gray value ratio of objective band and internal loading control band was used to determine the objective proteins expression levels.

Flow cytometric analysis of cell apoptosis

Each group of cells was digested into a single cell suspension using 0.25% trypsin. One hundred μL of buffer from the Annexin v-FITC and PE Apoptosis Detection Kit (BD Co., United States), 5 μL ADD and 5 μL PE were added to the cells, which were incubated without shaking at room temperature for 15 min in the dark. About 400 μL of buffer was then added, then the apoptosis rate of each group of cells was assayed by flow cytometry.

In vitro cell proliferation assay

A suspension of each group of cells was obtained by 0.25% trypsin digestion. The cells were centrifuged (1000 *g*, 5 min), resuspended in 1 mL culture medium and counted. A cell suspension containing 2×10^4/200 μL cells was distributed into 96-well plates: six sets of parallel holes were used for each group. The cells were then incubated at 37 ℃ in 5% CO_2. One 96-well plate was removed daily and 20 μL per well of a fresh new methyl thiazol tetrazolium (MTT) solution (5 mg/mL) was added, and the plate incubated at 37 ℃ for 4 h. The supernatants were removed, and 150 μL of dimethyl sulfoxide was added to each well and the plates were oscillated for 10 min. The optical density value (*A* value) of the cells in each well was measured by an enzyme-labeling instrument at a wavelength of 570 nm, and a growth curve for the cells was drawn. The cell proliferation inhibition rate (CPIR) was calculated according to the formula: CPIR (%) = $(1 - A_{\text{experimental group}} / A_{\text{control group}}) \times 100\%$.

Statistical analysis

SPSS 13.0 software (Chicago, United States) was used to perform the statistical analysis. Data were expressed as mean ± SD. One-way analysis of variance was used to analyze the correlation of data among three or more groups, and an *SNK* test was used for pairwise comparison between groups. $P < 0.05$ was considered significant.

RESULTS

Fluorescence microscopy analysis of cell transfection

The result showed that the transfection efficiency of the

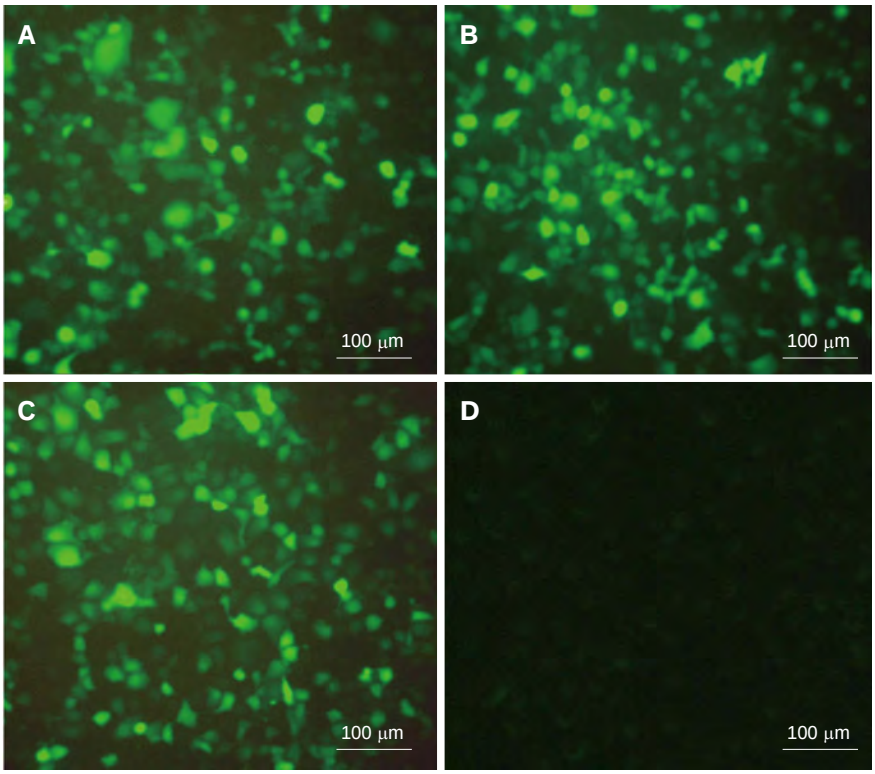

Figure 1 Cell transfection under the fluorescence microscope (magnification, ×400). A: Transfected group 24 h after transfection; B: Transfected group 48 h after transfection; C: Transfected group 72 h after transfection; D: Scrambled sequence group 48 h after transfection.

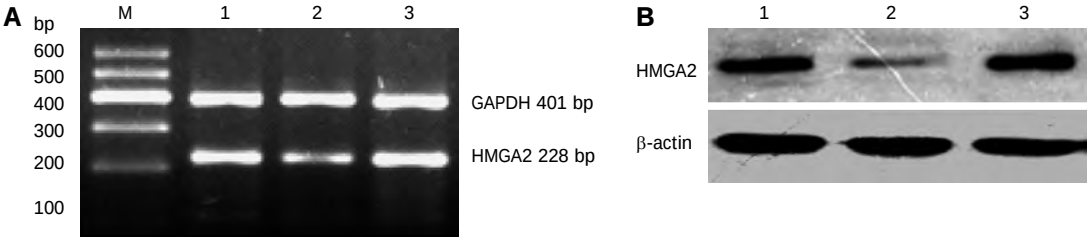

Figure 2 Expression of high mobility group A2 messenger RNA and high mobility group A2 protein. A: Expression of high mobility group A2 (*HMGA2*) messenger RNA (mRNA); B: Expression of HMGA2 protein. M: Marker; 1: Blank control group; 2: Transfected group; 3: Scrambled sequence group. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

transfected group cells was 60%-70% after transfection for 48 h and was significantly higher than that at 24 h. Compared with 48 h, there was no significant change at 72 h. The scrambled sequence group cells were not transfected at any time (Figure 1).

Expression of HMGA2 mRNA in each group of cells

Compared with the blank control group and the scrambled sequence group, the expression of HMGA2 mRNA in the transfected group was significantly reduced (0.374 ± 0.048 *vs* 0.674 ± 0.129 and 0.689 ± 0.124, $P < 0.05$); however, the difference between the blank control group and the scrambled sequence group was not statistically significant ($P > 0.05$) (Figure 2). The results showed that the RNA interference had a targeted inhibition affect on the *HMGA2* gene.

Expression of HMGA2 protein in each group of cells

Compared with the blank control group and scrambled sequence group, the HMGA2 the protein expression was significantly decreased, the difference was statistically significant (0.113 ± 0.032 *vs* 0.554 ± 0.082 and 0.484 ± 0.123, $P < 0.05$); however, the difference between the blank control group and the scrambled sequence group was not statistically significant ($P > 0.05$) (Figure 2). The results showed that transfection of HMGA2 shRNA expression vector had significantly inhibited the protein expression from the target gene.

Apoptosis analysis of gastric cancer cells

The cell apoptotic rate of the transfected group was significantly higher than that of the blank control group and scrambled sequence group; the difference was statistically significant ($P < 0.05$). The highest cell apoptotic rate appeared at 48 h after transfection. The difference between the blank control group and the scrambled sequence group was not statistically significant ($P > 0.05$) (Figure 3).

Cell proliferation assay

The MTT assay revealed that there were remarkable dif-

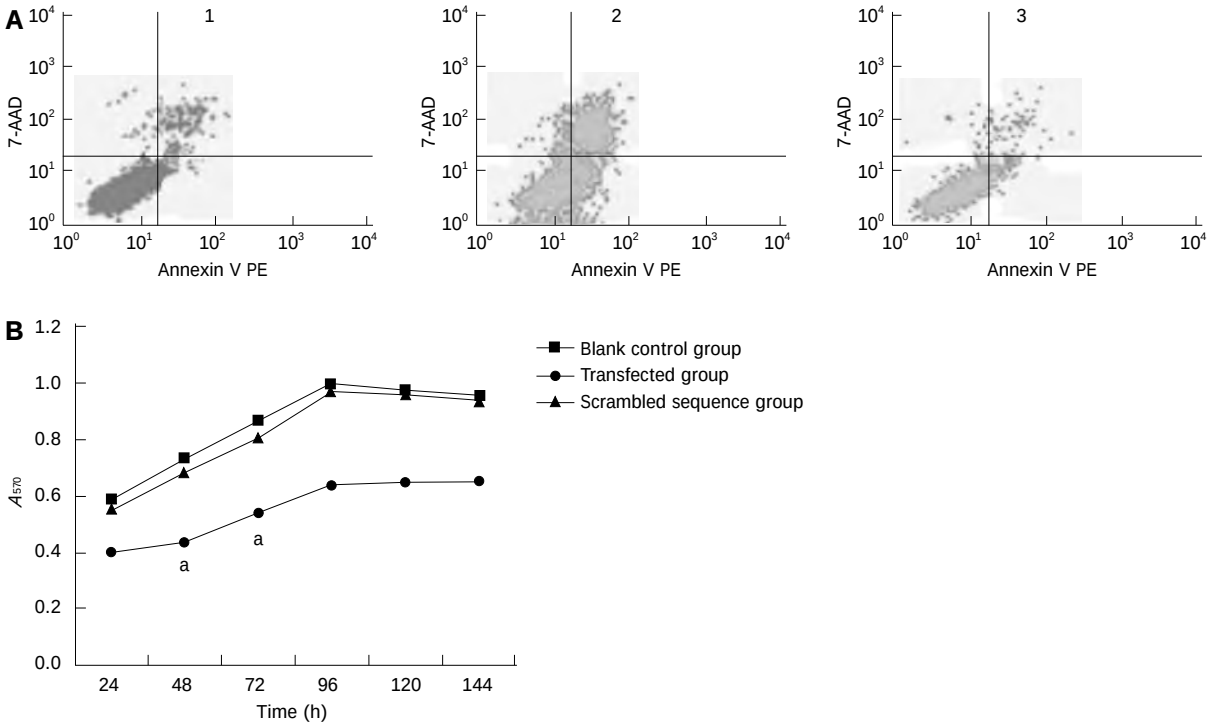

Figure 3 Apoptosis and cell proliferation analysis. A: Flow cytometry. The cell apoptotic rate of the transfected group was significantly higher than those of the blank control group and the scrambled sequence group; B: Cell proliferation analysis. $^{a}P < 0.05$ *vs* black control group. 1: Blank control group; 2: Transfected group; 3: Scrambled sequence group.

ferences in cell proliferation at 24, 48 and 72 h after transfection with shRNA. The most obvious cell proliferation inhibition appeared at 48 h after transfection in the transfected group ($P < 0.05$). There was no significant difference in the inhibition rate of the blank control group and the scrambled sequence group ($P > 0.05$) (Figure 3).

Expression of PI3K, Akt, P27, caspase-9 and Bcl-2 proteins

Compared with the blank control group and scrambled sequence group, after transfection of shRNA for 72 h, the protein expression levels of PI3K (0.042 ± 0.005 *vs* 0.069 ± 0.003 and 0.067 ± 0.05, $P < 0.05$), Akt (0.248 ± 0.004 *vs* 0.489 ± 0.006 and 0.496 ± 0.104, $P < 0.05$) and Bcl-2 (0.295 ± 0.084 *vs* 0.592 ± 0.072 and 0.594 ± 0.109, $P < 0.05$) were significantly reduced. Difference between the blank control group and the scrambled sequence group were statistically significant ($P > 0.05$) (Figure 4A and B). The protein expression levels of P27 (0.151 ± 0.010 *vs* 0.068 ± 0.014 and 0.060 ± 0.013, $P < 0.05$) and caspase-9 (0.136 ± 0.042 *vs* 0.075 ± 0.010 and 0.073 ± 0.072, $P < 0.05$) were significantly upregulated. The difference between the blank control group and the

scrambled sequence group was not statistically significant ($P > 0.05$) (Figure 4C and D).

DISCUSSION

Activation of oncogenes, inactivation of suppressor genes and abnormal expression of apoptosis-related genes are closely related to carcinogenesis and progression of gastric cancer. HMGA2 is a transcription factor that is involved in transcriptional regulation of various tumor-related genes[22]. Several studies[14,15,23] have showed that HMGA2 plays a critical role in the processes of many tumors, including enhancing cell growth and invasion. Moreover, the prognosis of patients with high HMGA2 expression is worse than those with low HMGA2 expression[24,25]. The clinical association of HMGA2 with gastric cancer has been reported[19]. The study showed that overexpression of HMGA2 appeared in human gastric cancer, and might be involved in cancer invasion and metastasis. However, the exact mechanism of HMGA2's involvement in gastric cancer is not clear, especially in relation to signaling pathways and the molecular mechanism.

In the present study, fluorescence microscopy revealed that the transfection efficiency of the transfected group cells can reach about 60%-70%, and that recombinant plasmid was effectively expressed in cells. HMGA2 shRNA transfection could effectively inhibit the expression of *HMGA2* gene. The inhibition was achieved without off-target effects, which was confirmed at the mRNA and protein levels by RT-PCR and Western blotting. According to the results of MTT and flow cytometry, cell proliferation was inhibited and apoptosis was increased after transfection. Therefore, we conclude that HMGA2 shRNA gene silencing can effectively induce proliferation inhibition and apoptosis of MKN-45 cells *in vitro* without off-target effects.

The PI3K/Akt signaling pathway plays important roles in cell survival and resistance to apoptosis[26]; it has been shown to be activated in many cancers and activated Akt acts to phosphorylate P27, caspase-9 and Bcl-2 to promote the resistance of cancer cells to apoptosis[20,21]. A study showed that activation of the PI3K/Akt signaling pathway is induced by overexpression of HMGA2[27]. In this study, western blotting showed that the expressions of PI3K and Akt protein were reduced in the transfected group. Thus, decreased expression of HMGA2 inhibits the activity of thePI3K/Akt signaling pathway.

P27 is a cyclin-dependent kinase (CDK) inhibitor that functions as a fail-safe mechanism in DNA repair and apoptosis[28]. A report showed that the *P27* gene reduced cell mitosis division and inhibited cell generation[29]. Overexpression of P27 inhibits CDK activation and entry into the S phase of the cell cycle[30]. The expression level of P27 was positively correlated with cell differentiation, and its loss of function may subsequently contribute to tumorigenesis[31]. Caspase-9, a member of the protease family, is intimately associated with the initiation of apoptosis, and is thought to be activated, while Akt is inhibited[32]. Activated caspase-9 is able to cleave caspase-3, leading to apoptosis[33]. Bcl-2 is a key anti-apoptotic protein involved in the regulation of apoptosis and is overexpressed in many tumors[34-36]. A previous study showed that Bcl-2 delays cell cycle entry by inhibiting Myc activity through the elevation of p27. Bcl-2 can be induced to express *via* the PI3K/Akt signaling pathway and inhibit cell apoptosis[21,37].

In our study, western blotting revealed that the protein expression levels of Bcl-2 were reduced, whereas the protein expression level of P27 and caspase-9 were upregulated. Thus, decreased expression of HMGA2 inhibits the activity of the PI3K/Akt signaling pathway, and than inhibits cells proliferation and increases apoptosis *via* upregulation of the protein expression of P27 and caspase-9, and decreased protein expression of Bcl-2.

In summary, our results demonstrated that HMGA2 shRNA gene silencing could induce apoptosis and suppress proliferation of MKN-45 cells *in vitro*. The PI3K/Akt signaling pathway, P27, caspase-9 and Bcl-2 may play important roles in this HMGA2-mediated effect. We suggest that HMGA2 shRNA gene silencing may be suitable for gastric cancer therapy by suppressing the proliferation and inducing apoptosis of gastric cancer cells.

COMMENTS

Background

The newly discovered oncogene, high mobility group A2 (*HMGA2*), is an endonuclear chromatin protein, which is highly expressed in many malignant tumors. The mechanism by which HMGA2 causes tumors remains unclear, particularly in gastric cancer.

Research frontiers

RNA interference can specifically mediate degradation of HMGA2 messenger RNA, block the expression of the gene, inhibit cell proliferation and increase apoptosis, which could be exploited for gastric cancer gene therapy.

Innovations and breakthroughs

This study demonstrated that RNA interference (RNAi) specifically downregulated the expression of HMGA2, inhibited cell proliferation and increased apoptosis. The mechanism appears to be that the decreased expression of HMGA2 inhibits the activity of the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (Akt) signaling pathway. Inhibition of cell proliferation and increased apoptosis is associated with upregulated protein expression of P27 and caspase-9, and decreasing expression of B-cell leukemia/lymphoma-2 (Bcl-2).

Applications

The aims of this study were to investigate the effect of HMGA2 expression on gastric cancer cell proliferation and apoptosis. RNAi was used regulate the expression of HMGA2. Moreover, the expression of PI3K, Akt, P27, caspase-9 and Bcl-2 were detected to investigate the possible mechanism. This will help enrich the theoretical research into the pathogenesis of gastric cancer, and provide an experimental basis for clinical diagnosis and gene therapy of gastric cancer.

Peer review

This is a well-written manuscript and the results are interesting. It has potential application in gastric cancer gene therapy.

Abstract

AIM: To identify key variables associated with colon cancer testing using the 2009 California Health Inventory Survey (CHIS).

METHODS: The CHIS has been conducted biennially since 2001 using a two-stage, geographically stratified random-digit-dial sample design to produce a representative sample of the entire State. For this study we used survey data from 2001-2009 inclusive. We restricted our analysis to White, Black, and Hispanic/Latinos aged 50-80 years. Weighted data was used to calculate the proportion of participants who underwent some form of colon cancer testing (colonoscopy, flexible sigmoidoscopy or fecal occult blood testing) within the previous 5 years stratified by race/ethnicity. For inferential analysis, boot-strapping with replacement was performed on the weighted sample to attain variance estimates at the 95%CI. For mean differences among categories we used *t*-tests and for comparisons of categorical data we used Pearson's χ^2. Binary logistic regression was used to identify independent variables associated with undergoing some form of testing. Trend analysis was performed to determine rates of testing over the study period stratified by race.

RESULTS: The CHIS database for 2009 had 30 857 unique respondents corresponding to a weighted sample size of 10.6 million Californians. Overall, 63.0% (63.0-63.1) underwent a colon cancer test within the previous 5 years; with 70.5% (70.5%-70.6%) of this subset having undergone colonoscopy. That is 44.5% (44.4%-44.5%) of all individuals 50-80 underwent colonoscopy. By multivariable regression, those tested were more likely to be male (OR = 1.06; 95%CI: 1.06-1.06), Black (OR = 1.30; 95%CI: 1.30-1.31), have a family member with colon cancer (OR = 1.71; 95%CI: 1.70-1.72), and have health insurance (OR = 2.71; 95%CI: 2.70-2.72). Progressive levels above the poverty line were also associated with receiving a test (100%-199%: 1.21; 1.20-1.21), (200%-299%:1.41; 1.40-1.42), (> 300:1.69; 1.68-1.70). The strongest variable was physician recommendation (OR = 3.90; 95%CI: 3.88-3.91). For the Hispanic/Latino group, additional variables associated with testing were success of physician-patient communication (OR = 2.44; 95%CI: 2.40-2.48) and naturalized citizenship status (OR = 1.91; 95%CI: 1.89-1.93). Trend analysis demonstrated increased colon cancer testing for all racial/ethnic subgroups from 2001-2009 although the rate remained considerably lower for the Hispanic/Latino subgroup.

CONCLUSION: Using CHIS we identified California citizens most likely to undergo colon cancer testing. The strongest variable associated with testing for all groups was physician recommendation.

INTRODUCTION

Colorectal cancer is the fourth leading cause of new cancer cases diagnosed in the United States and is the second leading cause of cancer death[1]. Population-based surveys such as the Behavior Risk Factor Surveillance System (BRFSS) and the National Health Interview Survey (NHIS) suggest that colon cancer screening tests are underutilized in the United States[2]. Based on Surveillance, Epidemiology and End Results (SEER) data, adults over the age of 50 demonstrate a low prevalence of colon cancer screening[2-5]. One study reported that only 59% of adults aged ⩾ 50 years were screened for colon cancer[6].

Colon cancer can be prevented in most cases by strict adherence to accepted colon cancer screening guidelines[7]. A position paper co-authored by several specialty societies listed flexible sigmoidoscopy, Computed tomography colonography, barium enema every 5 years, or colonoscopy every 10 years in average risk adults ⩾ 50 years of age as acceptable for the detection of adenomatous polyps and cancer[7-10]. Annual fecal occult blood testing (FOBT), preferably with immunochemical methodology, as an acceptable alternative method for cancer screening[7,8]. Cancer screening using stool DNA remains under investigation[8,10]. Despite a lack of evidence from randomized controlled trials, colonoscopy has been shown to be a more sensitive test for the detection of adenomas and colon cancer than flexible sigmoidoscopy +/- FOBT[11,12].

Factors identified as positive predictors of colon cancer screening participation have included older age, male gender, married status, negative smoking history, higher education, white non-Hispanic race, family history of colon cancer, regular medical care, physician recommendation, participation in other preventive health care services, and health insurance coverage[2,4,13-26].

The California Health Inventory Survey (CHIS) is the nation's largest state health survey. A random-dial telephone survey is conducted every two years on a wide range of health topics. CHIS data gives a detailed picture of the health care needs of California's large and diverse population. More than 50 000 Californians including adults, teenagers and children, are surveyed[27]. The specific aim of this study was to explore the CHIS database to identify demographic, socioeconomic, health and behavioral factors associated with participation in colon cancer testing. In addition, another aim was to perform a detailed analysis of the Latino population.

MATERIALS AND METHODS

CHIS is a collaborative project of the University of California at Los Angeles Center for Health Policy Research, the California Department of Health Services, and the Public Health Institute. (http://www.chis.ucla.edu/methodology.html). The survey has been conducted biennially since 2001 using a two-stage, geographically stratified random-digit-dial sample design to produce a representative sample of the State. At the first stage, telephone numbers are drawn within predefined geographic areas or "strata". Telephone numbers are screened to determine if they are households and thus eligible for the survey. At the second stage, one adult is randomly selected among all adults living in a household.

Questionnaires in CHIS include, among others, health status, health conditions, physical disability, mental health, health behaviors, women's health, cancer history and prevention, food environment, neighborhood and housing, access to and use of health care, health insurance, public program eligibility, interpersonal violence, employment, income and demographics including preferred spoken language, language of TV, radio, and newspaper. Participant citizenship, immigration status, country of birth and English language proficiency is also ascertained.

Data processing

For this study CHIS data from 2001-2009 was downloaded in SPSS v19 (IBM, Armonk, NY, United States) format. Each survey was individually weighted using the final sample weight (RAKEDW0). RAKEDW0 accounts for sample selection probabilities and statistical adjustments for possible under coverage and nonresponse biases. It is essential to weigh the data for valid variance estimation otherwise it will be underestimated.

Statistical analysis

We first analyzed the group aged 50-80 years from the most recent survey, 2009. Racial/ethnic analysis was limited to White, Black, and Hispanic/Latino groups as classified by the UCLA CHPR definition. For descriptive and inferential analyses, boot-strapping with replacement (iterations = 1000) was performed to attain variance estimates at the 95%CI[28,29]. This was performed using the bootstrapping module for SPSS. For mean differences among categories we used *t*-tests and for comparisons of categorical data we used Pearson's χ^2. We performed multivariable logistic regression using colon cancer testing (colonoscopy, flexible sigmoidoscopy or FOBT) as the dependent variable. Independent predictor variables entered into the model were those judged to be of clinical importance in univariate analysis. The output was expressed as odds ratios and their bootstrapped 95% confidence intervals. We subsequently stratified our sample and repeated the regression analysis for those in the Hispanic/Latino sub-group.

We used weighted CHIS data for 2001-2009 to calculate the proportion of participants who underwent some form of colon cancer testing within the previous 5 years stratified by race/ethnicity. The proportion was derived by dividing the number of individuals age 50-80 in each race who underwent testing in a given year by the total number of 50-80 year olds in that particular racial/ethnic

Table 1 Characteristics of California Health Inventory Survey participants ages 50-80 years (bootstrap 95%CI)

category for that year. A two-tailed *P* value < 0.05 was considered significant for hypothesis testing.

RESULTS

Patients

There were 47 614 individual participants in the 2009 CHIS survey. This corresponded to a full weighted sample size of 27.6 million individuals from the State of California. There were 30 857 unique respondents between the ages of 50-80 years corresponding to a weighted sample of 10.6 million citizens. Table 1 categorizes these participants as to whether they received at least one colon cancer test within the previous 5 years and further identifies those who received colonoscopy. Overall, 63.0% (63.0-63.1) underwent a colon cancer test; with 70.5%

(70.5-70.6) of this subset having undergone colonoscopy. That is 44.5% (44.4-44.5) of all individuals 50-80 underwent colonoscopy. The mean age of CHIS participants between the ages of 50-80 years was 63.33 (63.32-63.33). Those who underwent colonoscopy were approximately three years older. Whites comprised the largest racial group at 60.8% (60.8-60.9) followed by Hispanic/Latinos 14.8% (CI 14.8-14.9). Hispanic/Latinos were least likely to undergo a colon cancer test. There were minimal differences in body weight among the test categories; however current smokers were far less likely to undergo a colon cancer test. There appeared to be no association between alcohol use and testing status.

There was an association between educational attainment and colon cancer testing. Those who underwent a colonoscopy were nearly twice as likely [20.4% (20.4-20.5) *vs* 10.7% (10.7-10.8)] to have graduated high school. Marital status and household income also appeared to be associated with testing. Those tested were far more likely to be living above the poverty line threshold as defined by the United States Department of Labor. Among those who underwent a test, 4.6% (4.6-4.6) were uninsured. In contrast, among those who did not undergo a test, 17.8% (17.8-17.9) were uninsured. Factors associated with colonoscopy (Table 2).Respondents who underwent colonoscopy reported more frequent doctor visits in the year prior to the survey. They also reported receiving most of their medical care in a doctor's office setting compared to those who did not [78.1 (78.1-78.2) *vs* 65.1 (65.0-65.1)]. Those who underwent a colonoscopy had a higher prevalence of medical problems such as diabetes and were more likely to participate in health screening tests such as mammograms for females and prostate specific antigen (PSA) tests for males. The prevalence of having a family history of colorectal cancer (CRC) in a first degree relative, usually a parent, was two-fold higher in respondents who underwent colonoscopy [10.7 (10.7-10.7) *vs* 4.8 (4.8-4.8)]. Participants who underwent a colonoscopy were far more likely to receive a recommendation for this test from their physician. A substantial majority were performed for "routine screening". Characteristics of Hispanic/Latino CHIS Participants (Table 3).

The largest number of Hispanic/Latino CHIS participants were of Mexican origin. The prevalence of testing was higher for naturalized citizens compared to those born in the United States. Non-citizens were least likely to undergo testing. Those who did not undergo testing lived within the United States longer than those who were tested.

The ability to speak English and the language spoken at home was associated with testing status. The prevalence of testing in those who spoke "very good" or "good" English compared to their less proficient counterparts was [37.2% (37.0-37.3) *vs* 26.2% (26.1-26.4)]. Those tested were more likely to speak English in their home. In addition, the language of TV/radio/newspaper was also associated with testing. Among Hispanic/Latino respondents who underwent colon testing, rates were higher for those who listened and watched media in English. Testing rates were lowest for those who listened and watched only in Spanish. Respondents were considerably more likely to have undergone a colon test if their doctor conducted the interview in English [41.0% (40.8-41.1) *vs* 21.5% (21.4-21.6)]. Lastly, participants who did not have a test were twice as likely to have "Had hard time understanding their doctor at the last visit" [7.3 (7.2-7.4) *vs* 3.5 (3.5-3.6)]. Multivariable analysis (Table 4).

The output from the regression model demonstrated that Blacks had an odds ratio 30% higher than Whites for undergoing a colon cancer test. Male gender, family history of colon cancer, and progressive levels above the poverty line were also factors independently associated with testing. Having health insurance and a physicians' recommendation were the strongest predictors of testing. For the Hispanic/Latino group, additional independent factors associated with testing included citizenship sta-

tus and ability to understand their physician during their most recent office visit.

Colon Cancer Testing Trend Data (Figure 1). Figure 1 displays the proportion of CHIS participants age 50-80 who underwent colon cancer testing (colonoscopy, flexible sigmoidoscopy or FOBT) within the previous 5 years stratified by race/ethnicity. The proportion tested increased in all groups between 2001 and 2007 and then appeared to plateau. Overall, the prevalence of testing was nearly identical among Whites and Blacks. The proportion of Hispanic/Latinos who underwent a test rose from approximately 35% in 2001 to 50% in 2009.

DISCUSSION

According to the 2009 CHIS survey, approximately 63.0% of participants aged 50-80 had a colon cancer test such as FOBT, flexible sigmoidoscopy or colonoscopy within the previous 5 years. Of these, approximately 70% underwent colonoscopy as the colon cancer test. Regression analysis demonstrated that those who underwent at least one colon cancer test were more likely to be male, Black, have a family history of CRC, and have health insurance. Progressive levels above the poverty line were also associated with receiving a test. The strongest variable associated with undergoing a test was physician recommendation. For the Hispanic/Latino group, those at increased risk for no testing were those born in the United States and those who "Had hard time understanding their doctor at the last visit".

Trend analysis demonstrated that the proportion of Blacks in California undergoing a colon cancer test is in-

creasing in parallel with other racial/ethnic groups. This is encouraging as prior studies had identified white, non-Hispanic race as a predictor of colon cancer testing[29]. The increased participation by Blacks may be due to the more widespread use of colonoscopy as a colon cancer test. One survey revealed that this is the preferred colon cancer test by this group[13]. We were surprised to find no association between colon cancer testing and educational level. Prior studies suggested educational attainment was a positive predictor of colon cancer screening[27,30]. Similar to prior large population-based studies, our study also identified males, a family history of colon cancer, having health insurance, progressive levels above the poverty line, and having undergone screening with PSA or mammography as predictors of adherence to colon cancer testing[21]. Most importantly, our study confirms physician recommendation as the strongest variable associated with testing.

Several population-based studies looking at predictors of colorectal cancer screening participation have been performed[30]. BRFSS is a nationwide population-based telephone survey designed to measure preventive health practices, such as adherence to colon cancer testing and risk factors for adherence or non-adherence. A study of 52 754 respondents over age 50 in 1997 demonstrated low participation in colon cancer screening protocols with 19.8% for FOBT, 30.5% for sigmoidoscopy and 41.1% for either[21]. Respondents who underwent other preventive testing such as mammography or PAP smear demonstrated a higher adherence to screening[21]. Similarly, responses of 64 084 BRFSS participants over the age of 50 in 1999 demonstrated that colon cancer screening was reported by 43.4%, with 22.8% undergoing colonoscopy or sigmoidoscopy and 9.9% undergoing FOBT[30]. Negative predictors of screening included < college education and lack of health care coverage[30]. An examination of the 2002 BRFSS demonstrated a disparity in colon cancer testing between Hispanic and non-Hispanic Whites. Only, 41.9% of Hispanic respondents aged > 50 underwent colon cancer testing in the past year by either FOBT or colonoscopy/sigmoidoscopy compared to 55.2% of non-Hispanic whites[19].

The NHIS is an in-person survey conducted by the Centers for Disease Control and Prevention. The 2000 NHIS survey revealed that less than half of the United States population > 50 years underwent colon cancer screening at the recommended time intervals[23]. The strongest predictor of adherence was a physician visit within the previous year. A usual source of care, having undergone recent health preventive services such as a

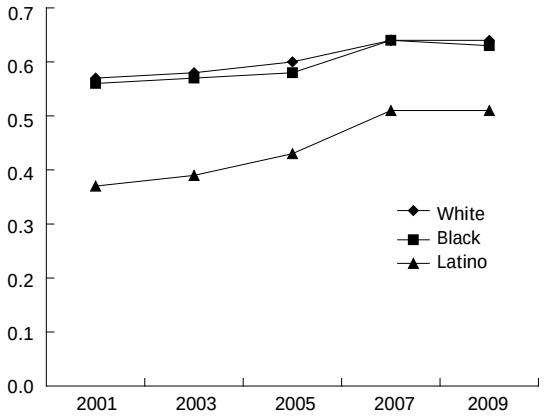

Figure 1 Proportion of individuals aged 50-80 undergoing a colon cancer test in the previous 5 years stratified by race/ethnicity.

mammogram or PAP smear, and physician recommendation were also important predictors[23].

An analysis of health behaviors of Medicare enrollees living in the United States was conducted using the SEER database[3]. A random sample of Medicare claims from 14 states for the period 1995 to 2003 were reviewed and demonstrated increased use of colonoscopy for colon cancer testing as well as a decline in the use of FOBT and sigmoidoscopy. The transition to use of colonoscopy was more rapid in Whites than non-Whites[3]. A similar study of Medicare claims in SEER regions from 1996-2005 showed a persistence of racial and ethnic disparities in the use of colonoscopy for screening as Whites were more likely to undergo this test as the physician preferred modality than Blacks or Hispanics[29]. Data collected in 2003 from 11 SEER regions demonstrated racial/ethnic disparities in colon cancer screening that varied significantly by geography[5]. A telephone survey of Medicare consumers living in three urban counties in North Carolina and 17 urban and rural counties in South Carolina was performed in 2001[17]. Overall, 56.8% of Whites adhered to Medicare-covered intervals for colon cancer testing compared to only 39.1% of Blacks[17]. Blacks preferred to undergo a colonoscopy rather than FOBT.

A major strength of our study is the sampling methodology incorporated into CHIS. Once weighted, the sample is representative of the entire population of the State of California including recent immigrants. Bootstrap methodology with resampling allows for accurate variance estimates. The repeated nature of the survey allows for the identification of trends in the use of health care services for the population. The incorporation of health behaviors, income, education, insurance coverage and other integral variables allows for adjusted estimates of healthcare utilization.

There are important weaknesses of our results. First, the indication for colon cancer testing is not available for every biennial survey. Other than 2009 (Table 2), we were not able to determine whether testing was performed for screening or was indicated for a sign/symptom of colonic disease. Therefore we were careful to use the terms "testing" and "screening" separately in our analysis and discussion. The dependent variable in this manuscript is clearly colon cancer testing. Erroneous conclusions about the presented trend data may be drawn if this is not kept in mind. For example, Blacks may be undergoing more colon tests over time because they are more willing to see their doctor for blood in their stools.

Another important weakness is that medical records are unavailable to confirm testing. Without records, we are left with the possibility of recall bias by the participants which could lead to misclassification. Examples include inability to remember that a doctor recommended a colon cancer test, or even that the participant had a test. Another shortcoming without records is that we are unable to separate whether patients underwent a sigmoidoscopy or FOBT as these results are reported in aggregate. Finally, without personal knowledge of the physician-patient interaction, we cannot further explain the variable "Had hard time understanding their doctor at the last visit". According to CHIS documentation for 2009, only 1.67% of those responding yes to this question answered that this was due to language differences. Other possibilities may include visual, auditory, or intellectual disabilities.

In conclusion, approximately 63% of California citizens between the ages of 50 and 80 have some form of colon cancer testing. Males, Blacks, insured, those with a family history of colorectal cancer, and those living above the poverty line were more likely to undergo a test. The strongest variable associated with testing was physician recommendation. For Hispanic/Latinos, those born in the United States and those with difficulty understanding their doctor are at increased risk for no testing. Our data is encouraging in that the level of participation in colon cancer testing appears to be increasing over the past decade for all studied racial/ethnic groups.

COMMENTS

Background

Colorectal cancer is the fourth leading cause of new cancer cases diagnosed in the United States and is the second leading cause of cancer death. Population-based surveys such as the Behavior Risk Factor Surveillance System (BRFSS) and the National Health Interview Survey (NHIS) suggest that colon cancer screening tests are underutilized in the United States. Colon cancer can be prevented in most cases by strict adherence to accepted colon cancer screening guidelines. Despite a lack of evidence from randomized controlled trials, colonoscopy has been shown to be a more sensitive test for the detection of adenomas and colon cancer than flexible sigmoidoscopy +/- fecal occult blood test (FOBT). The California Health Inventory Survey (CHIS) is the nation's largest state health survey. CHIS data gives a detailed picture of the health care needs of California' s large and diverse population. The specific aim of this study was to explore the CHIS database to identify demographic, socioeconomic, health and behavioral factors associated with participation in colon cancer testing. In addition, another aim was to perform a detailed analysis of the Latino population.

Research frontiers

Colorectal cancer is one of the leading causes of cancer diagnosed in the United States. Prior population-based studies reported positive and negative predictors of adherence to colon cancer testing with mixed results. This large population-based study seeks to clarify these predictors and to provide a detailed analysis of the Latino population.

Innovations and breakthroughs

A major strength of our study is the sampling methodology incorporated into

CHIS. Once weighted, the sample is representative of the entire population of the State of California including recent immigrants. Bootstrap methodology with resampling allows for accurate variance estimates. The repeated nature of the survey allows for the identification of trends in the use of health care services for the population. The incorporation of health behaviors, income, education, insurance coverage and other integral variables allows for adjusted estimates of healthcare utilization.

Applications

The study indicates approximately 63% of California citizens between the ages of 50 and 80 have some form of colon cancer testing. Males, Blacks, insured, those with a family history of colorectal cancer, and those living above the poverty line were more likely to undergo a test. The strongest variable associated with testing was physician recommendation. For Hispanic/Latinos, those born in the United States and those with difficulty understanding their doctor are at increased risk for no testing. Author's data is encouraging in that the level of participation in colon cancer testing appears to be increasing over the past decade for all studied racial/ethnic groups. Most importantly, the data can be used to remove barriers to colon cancer testing amongst the general population and minorities such as the Latino population.

Terminology

CHIS is the nation's largest state health survey. A random-dial telephone survey is conducted every two years on a wide range of health topics. CHIS data gives a detailed picture of the health care needs of California's large and diverse population. Colon cancer testing includes annual FOBT, flexible sigmoidoscopy +/- FOBT, and/or colonoscopy.

Peer review

This large population-based study provides insight into predictors of undergoing colon cancer testing. This data can be used to reduce the prevalence of colorectal cancer in the United States by removing barriers to colon cancer testing in the general population which includes minorities.

Abstract

AIM: To validate the utility of magnetic resonance imaging (MRI) for the clinical management of acute ischemic colitis (IC).

METHODS: This is a magnetic resonance (MR) prospective evaluation of 7 patients who were proved to have acute IC on the basis of clinical, endoscopic and computed tomography (CT) findings and who were imaged in our institution between February 2011 and July 2012. The mean age of the patients was 72.28 years. Abdominal CTs were obtained using a 64-detector row configuration for all patients with un-enhanced and contrast-enhanced scans, in the late arterial phase (start delay 45-50 s) and in the portal venous phase (start delay 70-80 s). The MR examinations were performed using a 1.5T superconducting magnet, using Fast Imaging Employing Steady State Acquisition and T2-weighted fast-recovery fast-spin echo sequences in axial and coronal plane. CT and MRI examinations were analysed for the presence of colonic abnormalities and associated findings.

RESULTS: Segmental involvement was seen in 6 patients (85.71%), with a mean length of involvement of 412 mm (range 145.5-1000 mm). Wall thickness varied between 6 mm and 17.5 mm (mean 10.52 mm) upon CT examinations and from 5 to 15 mm (mean 8.8 mm) upon MR examinations. The MRI appearance of the colonic wall varied over the time: Type Ⅰ appearance with a 3 layer sandwich sign was seen in 5 out of 12 examinations (41.66%), patients underwent MR within a mean of 36 h (ranging from 1 to 54 h) after the CT examination. Type Ⅱ and Ⅲ appearance with a 2 layer sign, was seen in 4 examinations (33.33%), patients underwent MR within a mean of 420.5 h (ranging from 121 to 720 h) after the CT examination. In the remaining three MRI examinations, performed within a mean of 410 h (ranging from 99.5 to 720 h) the colonic wall appeared normal.

CONCLUSION: MRI, only using precontrast images, may be used as a substitute for invasive procedures in diagnosis and follow-up of acute IC.

Mazzei MA, Guerrini S, Cioffi Squitieri N, Imbriaco G, Chieca R, Civitelli S, Savelli V, Mazzei FG, Volterrani L. Magnetic resonance imaging: Is there a role in clinical management for acute ischemic colitis? *World J Gastroenterol* 2013; 19(8): 1256-1263 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1256.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1256

INTRODUCTION

Ischemic colitis (IC) is a relatively common disease[1] and it is considered the most frequent form of intestinal ischemia and the second most frequent cause of lower gastrointestinal bleeding[2]. It represents the consequence of an acute or, more commonly, chronic decrease or blockage in the colonic blood supply, which may be either occlusive or non- occlusive in origin[3]. The original insult causing the ischemic event can rarely be established, but frequently occurs in elderly patients with diffuse disease in small segmental vessels and various co-morbidities. Today, with the introduction of new therapies, pharmacological causes could also be considered[4,5]. The anatomic damage results in ischemic necrosis of variable severity that can range from superficial mucosal involvement to full-thickness transmural necrosis[6]. The treatment depends on the acuteness and severity of the presentation[3]. Most cases of IC are transient and resolve spontaneously and such patients do not require specific therapy, instead very mild cases can be managed on an outpatient basis with a liquid diet, close observation and antibiotics[7]. IC rarely presents itself in a gangrenous form (acute fulminant IC).

The incidence of IC is underestimated because it often has a mild transient nature, clinical presentation can be nonspecific and highly variable, therefore, the diagnosis largely depends on clinical suspicion. In this context the role of imaging techniques remains controversial[8]. Standard radiology yields non-specific and late findings, while computed tomography (CT), the main technique for the noninvasive diagnosis of mesenteric ischemia, is well suited to confirm the clinical suspicion of IC, to suggest IC when it is unsuspected and to diagnose complications, however it requires the use of radiation and an iodinates contrast agent, limiting the possibility to use this technique in a short term follow-up[9-14]. Recently Iacobellis *et al*[15] has proposed magnetic resonance imaging (MRI) as a substitute for invasive procedures in diagnosing and grading acute IC, allowing for the early identification of pathological findings and by defining the evolution of ischemic lesions with 7T magnetic resonance imaging (7T-MRI) on an animal model with acute IC. The purpose of this study was to validate the utility of MRI in the clinical management of acute IC. In particular to show our experience in daily practice, focusing the attention both on the diagnosis and follow-up of this pathological condition.

MATERIALS AND METHODS

Patients population

All human procedures were approved by our Institutional Care Committee.

This is a magnetic resonance (MR) prospective evaluation of 11 patients who were proved to have acute intestinal ischemia on the basis of clinical, endoscopic and CT findings and who were imaged in our institution between February 2011 and July 2012. Among the initial 11 patients, 7 were included in the study because they were identified as having IC. Two patients with extensive small intestinal infarction because of the occlusion of superior mesenteric artery and 2 patients with the occlusion of superior mesenteric vein were not included.

Of the 7 patients, 2 were men and 5 women, with a mean age of 72.28 years (range, 54-97 years). Clinical charts, CT and MR examinations were reviewed. Imaging evaluation was requested because of the following clinical findings: sudden-onset of abdominal pain in all the patients (n = 7) (100%), bloody diarrhoea or bright red rectal blood in 4 patients (57.14%), nausea and vomiting in 1 patient (14.29%), elevated white blood cells (WBC) in 5 patients (71.42%), elevated Lactate dehydrogenase (LDH) levels in 6 patients (85.71%).

Five (71.42%) of these patients had arteriosclerotic cardiovascular disease on the basis of the findings from a clinical evaluation or cardiac work-up. Their mean age was 77 years. One patient (14.29%, 54 years old), during treatment of Lenalidomide for a relapsed multiple myeloma and one patient (14.29%, 80 years old) had hypotensive episodes associated with a recent exacerbation of chronic pancreatitis.

The diagnosis of IC was suspected on the basis of the clinical presentation and CT findings and was confirmed in all the patients: in 5 patients, an endoscopic procedure alone (sigmoidoscopy or colonoscopy) was performed, alternatively an endoscopic procedure and biopsy was performed on 1 patient; and 1 patient, underwent endoscopy and surgery with histological specimen evaluation.

Multidetector-row computed tomography imaging protocol

Abdominal CTs were obtained using a 64-detector row configuration for all patients (Discovery CT 750HD, General Electric Healthcare, Milwaukee, WI, United States). In all patients the examination was performed with a spiral technique in a cranio-caudal direction (from the base of the lungs to the pelvic brim) and supine position. All patients underwent un-enhanced and contrast-enhanced CT, in the late arterial phase (start delay 45-50 s) and in the portal venous phase (start delay 70-80 s) with an intravenous injection of 2 mL/kg of non-ionic contrast material (Iopamiro 370; Bracco Diagnostics, Milan, Italy), followed by 40 mL of saline solution using a peristaltic semiautomated power injector (4 mL/s flow

rate, SIAS 757, Bologna, Italy) with an 18-gauge needle in the antecubital vein. Oral medium contrast was not given to any of the patients; rectal air or rectal contrast material was not administered. The following technical parameters were used: effective slice thickness of 3.75 mm for plain acquisition, 1.25 mm in the late arterial phase and 2.5 mm in the portal venous phase; beam pitch of 0.938, reconstruction interval of 0.8 mm, tube voltage of 120-140 KVp and reference mAs of 250/700 mA. Automatic tube current modulation was used to minimise radiation exposure. Standard reconstruction algorithm was used. Patients were instructed not to breath during helical imaging to avoid motion artefacts.

MRI techniques

The MR examination was performed using a 1.5T superconducting magnet (SIGNA HD 1.5, General Electric Healthcare, Milwaukee, WI, United States), using the following sequences: Fast Imaging Employing Steady State Acquisition (FIESTA, TR/TE, 3.8/1.6; matrix size, 192 × 320; section thickness, 6 mm; intersection gap, 1 mm; field of view, 480 mm × 480 mm; NEX, 1; breath-hold) on coronal plane and T2-weighted fast-recovery fast-spin echo sequence (FRFSE: TR/TE, 6000/70, matrix size, 320 × 256; section thickness, 4mm; intersection gap, 0.4 mm; field of view, 480 mm × 480 mm; NEX, 4; respiratory triggering) in axial and coronal plane. An eight channel body phase-array surface coil was employed. Oral and intravenous medium contrast were not given to any of the patients.

Image analysis and comparison

CT scans and MR images were evaluated by two Radiologists (Mazzei MA and Mazzei FG) experienced in gastrointestinal imaging, reaching a consensus agreement. The following were assessed: the location and length of the colonic segment involved; the appearance and degree of wall thickening; the presence of a double-halo or target configuration (two or three concentric rings); pericolic streakiness, peritoneal fluid or blood, presence of intramural, mesenteric, or portal venous gas, and free intraperitoneal air or other relevant abdominal findings were also recorded.

The bowel wall was considered thickened if it measured more than 3 mm in diameter. Right side colonic involvement was defined as abnormalities affecting a segment or the entire ascending colon including the hepatic flexure. Left-side involvement was defined as abnormalities starting at or distal to the splenic flexure. Finally, the gross appearance of the affected colonic wall at CT was divided into three morphologic groups according to Balthazar *et al*[14]: (1) Type I CT (acute IC), wall thickening with heterogeneous enhancement and zones of low attenuation compatible with severe colonic edema; there was enhancement of the mucosa consistent with an acute process, a shaggy contour, a loss of colonic haustra, with varying degrees of pericolic streakiness; (2) Type II CT (subacute IC), the CT appearance showed concentric and symmetric mild mural thickening and homogeneous attenuation of the wall of the colon with a sharply defined contour and with or without minimal pericolic streakiness; and (3) Type III CT (gangrenous IC): there was circumferential intramural air consistent with pneumatosis coli.

A similar classification was realised by the analysis of MR images and a correlation between the gross appearance of the affected colonic wall on both CT and MRI and the time from the onset.

RESULTS

Patient demographic information (age and sex), pre-existing disease, number of CT and MR examinations during hospitalisation, diagnostic proof (S = surgery, B = biopsy and E = endoscopy) and status at the time of discharge (D = died; L = living) for the 7 patient are summarised in Table 1. The diagnostic CT examinations were performed within a mean of 45.5 h (range, 2-168 h) after the clinical onset of symptoms, while the first MR examinations were performed in 4 patients within 48 h (mean of 14.8 h; range, 1-40 h) after the date of the CT examination, in 5 patients between 48 h and 15 d (mean of 137.5 h, range 54-240 h), and in 3 patients after 15 d from the CT examinations (mean of 524 h, range 384-720 h). Three patients underwent only one MRI examination, 3 patients were studied twice and 1 patient was studied three times, for a total of 12 MRI examinations. The duration of the MRI follow-up of the 7 patients considered varied from 1 to 30 d from the date of the CT examination.

Among the 7 patients, 6 (85.71%) exhibited a segmental involvement of the colon and 1 patient (14.29%) had the entire colon involved. The length of involvement in the patients with a segmental distribution, obtained using 2D reformat reconstructions on CT images, ranged from 145.5 to 1000 mm, with a mean length of 412 mm. The thickness of the wall of the colon in the affected segments varied from 6 to 17.5 mm, with a mean bowel wall thickness of 10.52 mm on CT images, and from 5 to 15 mm, with a mean bowel wall thickness of 8.8 mm, on MR images. Two out of 6 patients (33.33%) with a segmental involvement of the colon exhibited a left-sided and splenic flexure colitis, 1 (16.66%) a left-sided colitis only, 1 (16.66%) a left-sided colitis and IC of the transverse colon and splenic flexure, 1 (16.66%) an IC of the transverse colon only, and 1 (16.66%) an IC of the sigmoid colon. In the 1 patient with ischemic pancolitis, the diagnosis was confirmed at colonoscopy and total colectomy.

The gross appearance of the affected colonic wall at CT, divided into three morphologic groups, according to Balthazar *et al*[14], showed that Type I CT was present in 5 out of 7 patients (71.4%) and Type II CT in 2 out of 7 patients (28.6%). The diagnostic CT examinations in 5 patients with Type I CT appearance was performed within a mean of 36 h (ranging from 2 and 48 h) after the clinical onset of symptoms, showing an acute form of

Table 1 Patients demographic characteristic

Patient	Sex	Age (yr)	Pre-existing disease	Number of CT/MR	Diagnostic proof	Status of discharge
1	F	54	Multiple myeloma relapsed treated with Lenalinomide	1/2	E	L

CT: Computed tomography; MR: Magnetic resonance; F: Female; M: Male; B: Biopsy; E: Endoscopy; D: Died; L: Living.

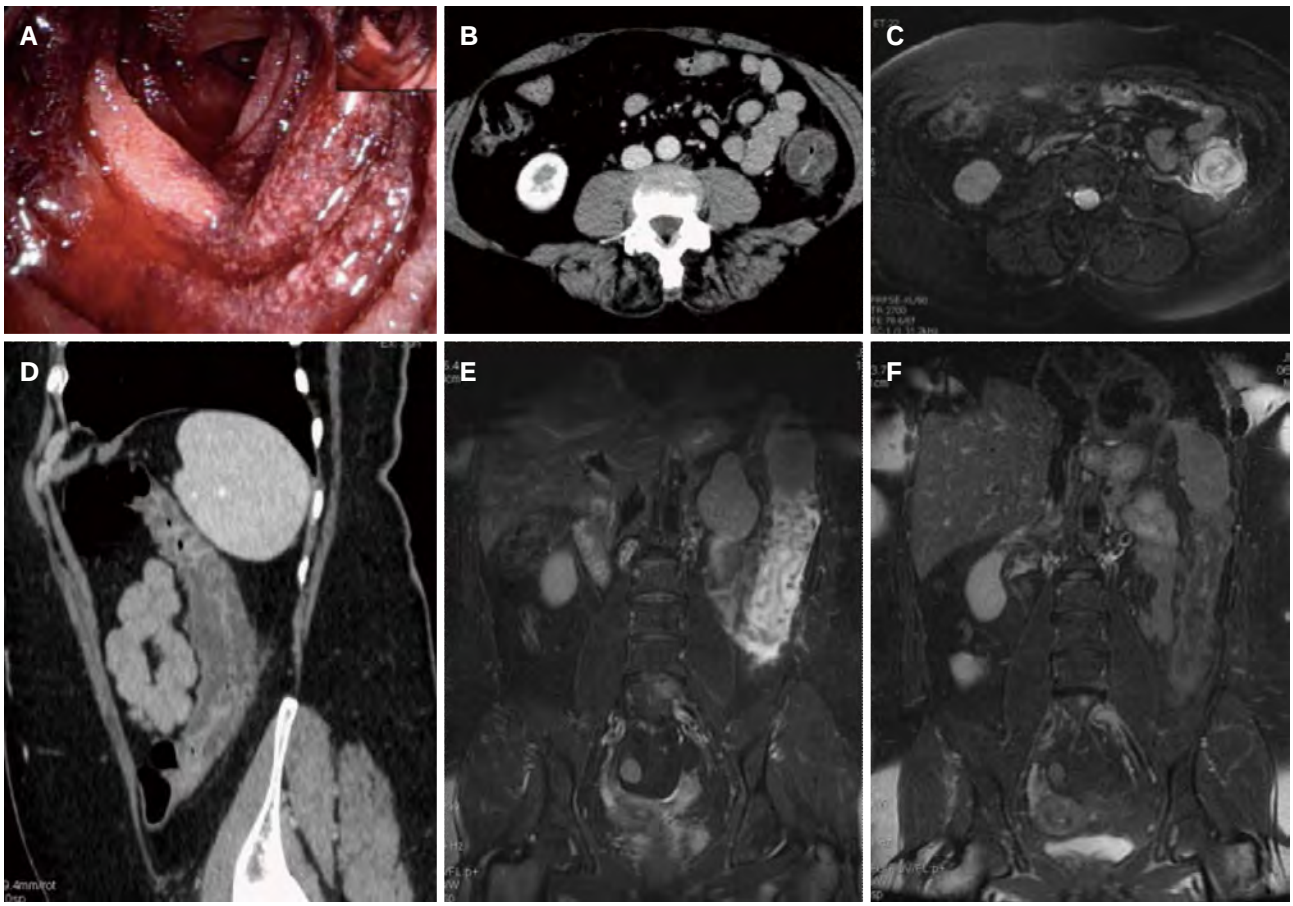

Figure 1 Magnetic resonance imaging follow-up of a patients with ischemic colitis resolved promptly. Ischemic colitis (IC) of left side colon in a 57 year old woman with a recent history of acute hypertensive crisis, who presented with left lower quadrant pain and massive rectal bleeding. A: Endoscopic procedure showed multiple necrotic area; B and C: Contrast-enhanced computed tomography (CT) and axial T2 fast-recovery fast-spin echo sequence (FRFSE) magnetic resonance imaging (MRI), after 32 h from CT, showed acute IC (Type Ⅰ CT and MRI) with wall thickening, three layer sandwich sign and a mild amount of free fluid in the paracolic gutter; D and E: 2D coronal reformat CT and coronal T2 FRFSE MRI, at the same time, showed the entire involved tract; F: Ischemia risolved without complications with conservative therapy as shown in the follow-up MRI.

IC.

As the morphologic CT groups, the gross appearance of the affected colonic wall upon MRI could be divided into 3 groups: (1) Type I MRI, in the first group, wall thickening with a 3 layer sandwich sign showing high signal intensity of the intermediate layer and the low signal intensity of the inner and outer layers, were present in 5 MR examinations (4 patients, 1 patient had 2 MR examinations with an interval of 48 h due to worsening of clinical symptoms). The MR examinations with Type I appearance were performed within a mean of 36 h (ranging from 1 to 54 h) after the CT examination and the same patients with Type I MRI showed the Type I appearance at CT, according to an acute form of IC (Figures 1 and 2); (2) Type Ⅱ MRI, in the second group, which consisted of 2 patients, there was a wall thickening with a 2 layer sign (high signal intensity of the inner layer and low signal intensity of the outer layer. The MR examinations with Type Ⅱ appearance were performed within a mean of 420.5 h (ranging from

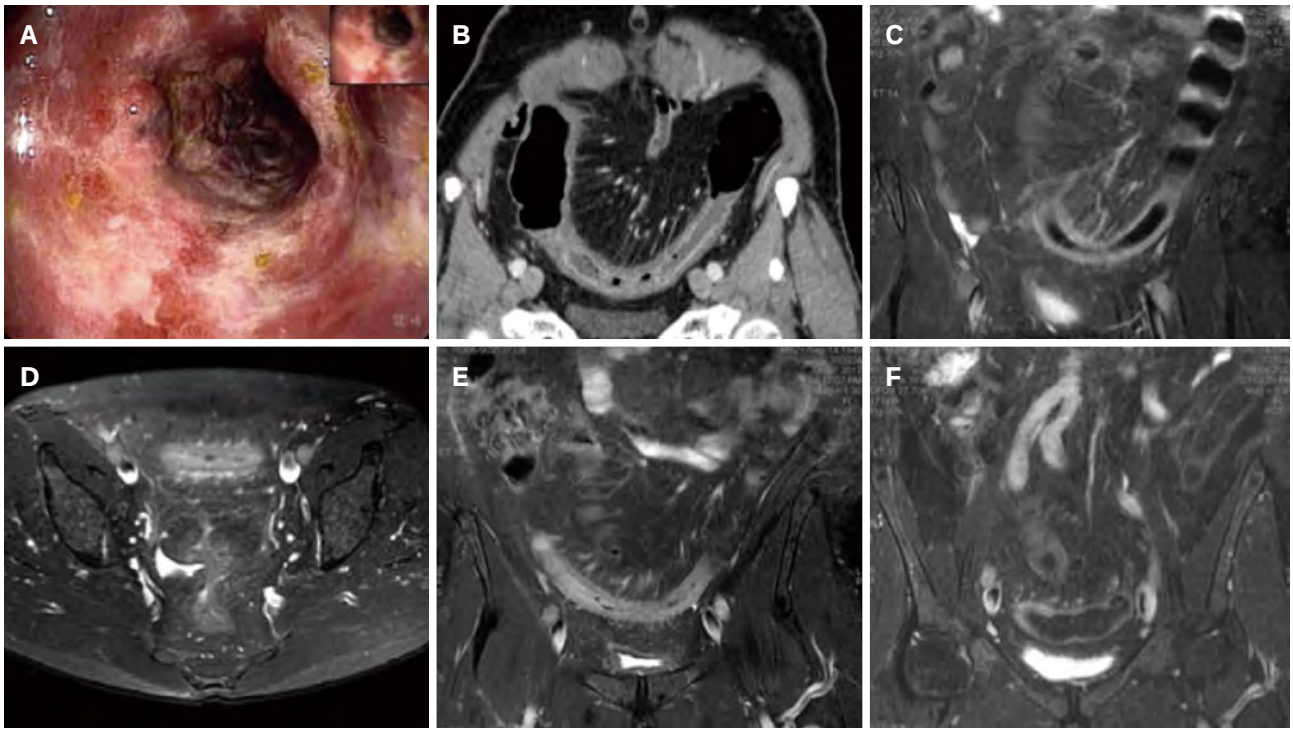

Figure 2 Magnetic resonance imaging follow-up of a patient with ischemic colitis and worsening of clinical symptoms. Ischemic colitis (IC) of sigmoid colon in a 62-year-old man with left lower quadrant pain and elevate lactate dehydrogenase levels, who presented with melena and a recent history of stenting procedures for ischemic cardiopathy. A: Endoscopic procedure showed multiple necrotic area; B: 2D (two dimensional) coronal reformat contrast-enhanced computed tomography (CT) showed acute IC (Type Ⅰ CT); C-E: The patient had 2 magnetic resonance examinations (C and D-E) with an interval of 48 h due to worsening of clinical symptoms, with an increase of the length and thickness of the involved tract (D-E); F: The ischemic process resolved without complication after parenteral nutrition, as showed in the follow-up magnetic resonance imaging, performed after 384 h from the date of CT examination.

121 to 720 h) after the CT examination, according to a subacute form of IC; and (3) Type Ⅲ MRI, in the third group, which consisted of 2 patients, the MR appearance showed a wall thickening with a inversed 2 layer sign (high signal intensity of the outer layer and low signal intensity of the inner layer). The MR examinations with Type Ⅲ appearance were performed within a mean of 420.5 h (ranging from 384 to 457 h) after the CT examination, according to a subacute form of IC.

In the remaining 3 MRI examinations, performed within a mean of 410 h (ranging from 99.5 to 720 h) the colonic wall appeared normal.

No patients had circumferential intramural air consistent with pneumatosis coli.

Mild to moderate amounts of free abdomen fluid were present in all patients (100%) on the CT examination, and in 4 out of 4 of the first MR examinations (performed within 48 h from the date of CT examination) and in 1 out of 5 in the second MRI examinations (performed between 48 h and 15 d from the date of CT examination).

The free fluid was mainly located in the paracolic gutters and in the Douglas. No high-attenuation fluid consistent with blood was present. No reduction in caliber of mesenteric vessels was found.

On the basis of the result of the initial CT examination, endoscopic findings and clinical evaluation, no surgery was performed on any of the patients. Surgery was performed 3 wk after the initial episode because of the development of a sealed-off perforation of the transverse colon in one of the patients.

The site of the affected tract and it's length (mm), gross appearance on CT (type according Balthazar *et al*[14], thickness of the affected wall and presence or absence of peritoneal fluid) and on MRI (type, thickness of the affected colonic wall and presence or absence of peritoneal fluid), in relation to the date of each examination were reported in Table 2.

DISCUSSION

The diagnosis of IC largely depends on clinical suspicion, especially since many other conditions (*e.g.*, infectious colitis, inflammatory bowel disease, diverticulitis, colon cancer) are presented with abdominal pain, diarrhoea and hematochezia[3]. Endoscopy has become the diagnostic test of choice in establishing the diagnosis of IC, although, it can be limited because it could be performed without bowel preparation to prevent hypoperfusion caused by dehydrating cathartics; in addition a minimal air insufflation should be used to prevent perforation[7,8].

From a radiological point of view, a CT examination is actually considered the main technique for the noninvasive diagnosis of mesenteric ischemia and also in cases of acute abdomen from different and various origins, because it can suggest IC when it is unsuspected, can diag-

Table 2 Gross appearance on computed tomography and magnetic resonance imaging

Patient	Involved tract/length (mm)	CT Ⅰ range 2-168 h[1]	MRI Ⅰ within 48 h[2]	MRI Ⅱ > 48 h < 15 d[2]	MRI Ⅲ > 15 d[2]
1	Left side colon and splenic flexure/314	Type Ⅰ/12 mm; free fluid	Type Ⅰ/10 mm; free fluid		Type Ⅲ/6 mm; no free fluid

nose complications and exclude other illnesses. However it requires the use of ionizing radiation and an iodinates contrast agent, limiting the possibility to use this technique in a short term follow-up[9-14].

Recently Iacobellis *et al*[15] has reported that MRI can play a relevant role in the diagnostic management of acute IC and may be substituted for other invasive endoscopic procedures in the diagnosis and grading of IC when an ischemic injury is suggested. Prior publications have described the feasibility of using MRI to evaluate a full range of colonic disease processes, including only one case of IC but without pathological confirmation and using precontrast and postcontrast imaging[16]. Our study is based on the assumption that a parallel between the experimental colonic ischemic damage in the animal model and humans is reasonable[15]. Then our aim has been to validate the utility of MRI in the clinical diagnosis and follow-up of IC, using combined Fast Imaging Employing Steady State Acquisition on a coronal plane and T2-weighted fast-recovery fast-spin echo sequences, both on an axial and coronal plane. About 71.4% of patients that underwent a CT examination within 48 h showed Type I of gross appearance of an involved colonic wall (wall thickening with heterogeneous enhancement and zones of low attenuation compatible with severe colonic edema and enhancement of the mucosa consistent with an acute process, a shaggy contour, a loss of colonic haustra, with varying degrees of pericolic streakiness). The same patients with Type I CT showed Type I appearance at MRI, according to an acute form of IC. The reason why the gross appearance of the involved colonic wall had a thickened and edematous appearance is related to the fact that usually IC is a form of non-occlusive ischemic disease and in most cases, however, there is no evidence of obstruction of a major artery or vein. Then a decrease in blood flow to 20% of the normal flow, associated with small-vessel disease (hypoxia), and reperfusion injury when the blood flow is reestablished are the responsible factors[17,18]. Consequently, any part of the colon can be involved, with no correlation established between the length and site of the involvement and distribution of the superior mesenteric or inferior mesenteric artery or vein[17,19,20]. Segments commonly affected by IC are the splenic flexure (Griffith point) because the marginal artery of Drummond (a system of arcades connecting the major arteries) is occasionally tenuous here and is absent in upto 5% of patients, and the anastomotic plexus between the inferior mesenteric artery distribution and the hypogastric vascular supply (point of Sudeck) at the rectosigmoid junction, because it is distal to the last collateral connection with proximal arteries[7,21]. In our case population a segmental distribution was apparent in 85.71% (6 patients).

The striking differences in the gross morphology of ischemic segment as detected at MRI is probably related to the timing of the examination and to the pathophysiology of the developing anoxic process. In the initial phases of anoxia, mucosal damage occurs first; with more severe and prolonged forms of anoxia, submucosa hemorrhage, edema, and pericolic congestive and edematous changes developing later due to the reperfusion event. Indeed, in the subacute phase (MRI examination performed between 3 and 30 d) the gross morphology has been changed (MRI Type Ⅱ or Ⅲ) with a reduction of the thickness of the involved wall (mean 7.2 mm, range 5-8 mm) and a double ring appearance (high signal intensity of the inner layer and low signal intensity of the outer layer for Ⅱ type MRI and high signal intensity of the outer layer and low signal intensity of the inner layer for Type Ⅲ MRI), probably for the reduction of edematous phenomena like the CT Type Ⅱ according to Balthazar.

Although up to 85% of cases of IC managed conservatively improve within 1 or 2 d and resolve completely within 1 or 2 wk, close to one-fifth of patients develop peritonitis or deteriorate clinically and require surgery. Surgical resection is required when an irreversible ischemic injury and chronic colitis develop as both can lead to bacteremia and sepsis, colonic stricture, persistent abdominal pain and bloody diarrhoea, and protein-loosing

enteropathy[8]. The advantage of the use of MRI for clinical management of IC, is the possibility to perform a short term follow-up without the employment of ionizing radiation or intravenous contrast material. As demonstrated in our study MRI could be used, instead of CT to suggest the diagnosis of the IC in the proper clinical setting, particular when a segmental distribution is evident, in the depiction of other abnormal conditions that may be seen in patients suspected of having IC, and in a short term follow-up, when a clinical worsening occurs, to adequately manage the patient.

Some limitations of the present study should be outlined. Firstly, our patient selection process does not allow for an evaluation of the sensitivity or specificity of MRI for the diagnosis or detection of IC. The other major limitation of both CT and MR imaging in the diagnosis of colonic ischemia is the lack of specificity. The gross morphologic features overlap with those of inflammatory colitis, although the segmental distribution is more often seen in ischemia[22]. In spite of the limited number of subjects who were examined, we are convinced that MRI can provide a valid imaging for the identification of pathological findings of acute IC. Moreover MRI in combination with clinical suspicion, endoscopic and histological findings, can play a key role in the diagnosis and management of IC. In particular MRI can discriminate patients with urgent operative intervention from patients in which a follow-up can be proposed as an alternative to surgery. All these allow for an earlier detection and effective follow-up of IC with a possible earlier adequate treatment.

ACKNOWLEDGMENTS

We thank Miss Julia Hassall for reviewing the manuscript and Miss Francesca Seri and Mr. Duccio Guerrieri for performing the majority of MR examinations.

COMMENTS

Background

The incidence of ischemic colitis (IC) is underestimated because it often has a mild transient nature, clinical presentation can be nonspecific and highly variable, therefore, the diagnosis largely depends on clinical suspicion. In this context the role of imaging techniques remains controversial. Standard radiology yields non-specific and late findings, while computed tomography (CT), the main technique for the noninvasive diagnosis of mesenteric ischemia, is well suited to confirm the clinical suspicion of IC, to suggest IC when it is unsuspected and to diagnose complications, however it requires the use of radiation and an iodinates contrast agent, limiting the possibility to use this technique in a short term follow-up.

Research frontiers

The role of magnetic resonance imaging (MRI) in the diagnostic management of acute IC is still controversial, and nothing is known about the *in vivo* magnetic resonance findings of IC or about the relationship between MR findings and the onset of clinical symptoms.

Innovations and breakthroughs

To be known, this is the first study using MRI for the evaluation of IC and for the comparison between MRI and CT findings in this pathological condition.

Applications

MRI in combination with clinical suspicion, endoscopic and histological findings, can play a key role in the diagnosis and management of IC. In particular MRI can discriminate patients with urgent operative intervention from patients in which a follow-up can be proposed as an alternative to surgery. In particular the advantage of the use of MRI for clinical management of IC, is the possibility to perform a short term follow-up without the employment of ionizing radiation or intravenous contrast material.

Terminology

Fast imaging employing steady state acquisition sequence (FIESTA): provides images of fluid filled structures with very short acquisition times. The FIESTA sequence uses the T2 steady state contrast mechanism to provide high signal noise ratio images with strong signal from fluid tissues while suppressing background tissue for contrast and anatomic detail of small structures; IC: inflammation of the colon due to colonic ischemia resulting from alterations in systemic circulation or local vasculature.

Peer review

This paper is well written, is original and has good information. It merits to be admitted to publish without susbtantial changes.

Abstract

AIM: To compare small bowel (SB) cleanliness and capsule endoscopy (CE) image quality following Ensure®, polyethylene glycol (PEG) and standard preparations.

METHODS: A preparation protocol for CE that is both efficacious and acceptable to patients remains elusive. Considering the physiological function of the SB as a site for the digestion and absorption of food and not as a stool reservoir, preparation consisting of a liquid, fiber-free formula ingested one day before a CE study might have an advantage over other kinds of preparations. We conducted a prospective, blind-to-preparation, two-center study that compared four types of preparations. The participants' demographic and clinical data were collected. Gastric and SB transit times were calculated. The presence of bile in the duodenum was scored by a single, blinded-to-preparation gastroenterologist expert in CE, as was cleanliness within the proximal, middle and distal part of the SB. A four-point scale was used (grade 1 = no bile or residue, grade 4 $\geqslant$ 90% of lumen full of bile or residual material).

RESULTS: The 198 consecutive patients who were referred to CE studies due to routine medical reasons were divided into four groups. They all observed a 12-h overnight fast before undergoing CE. Throughout the 24 h preceding the fast, control group 1 (n = 45 patients) ate light unrestricted meals, control group 2 (n = 81) also ate light meals but free of fruits and vegetables, the PEG group (n = 50) ate unrestricted light meals and ingested the PEG preparation, and the Ensure group (n = 22) ingested only the Ensure formula. Preparation with Ensure improved the visualization of duodenal mucosa (a score of 1.76) by decreasing the bile content compared to preparation with PEG (a score of 2.9) (P = 0.053). Overall, as expected, there was less residue and stool in the proximal part of the SB than in the middle and distal parts in all groups. The total score of cleanliness throughout the length of the SB showed some benefit for Ensure (a score of 1.8) over control group 2 (a score of 2) (P = 0.06). The cleanliness grading of the proximal and distal parts of the SB was similar in all four groups (P = 0.6 for both). The cleanliness in the middle part of the SB in the PEG (a score of 1.8) and Ensure groups (a score of 1.7) was equally better than that of control group 2 (a score of 2.1) (P = 0.057 and P = 0.07, respectively). All 50 PEG patients had diarrhea as an anticipated side effect, compared with only one patient in the Ensure group.

CONCLUSION: Preparation with Ensure, a liquid, fiber-free formula has advantages over standard and PEG preparations, with significantly fewer side effects than PEG.

INTRODUCTION

Capsule endoscopy (CE) has become a commonly applied technology for examining the small bowel (SB) mucosa[1-8]. A review of the literature revealed that there is no universally accepted protocol for bowel preparation before a CE study[9-23]. A proper preparation is one that decreases the presence of debris, food remnants, bile and stool content in the intestinal lumen and significantly increases diagnostic accuracy. Preparation by a 12-h fast and light meals one day before the procedure, as suggested by the manufacturer of the capsule, is inadequate. Investigators have prepared the bowels of their patients with different doses of purgatives [polyethylene glycol (PEG) or sodium phosphate solution] or prokinetics (erythromycin, metoclopramide, domperidone and tegaserod) and/or anti-bubble agents (simethicone)[9-23]. The main disadvantage of purgatives is that they are not well tolerated by patients. Moreover, the efficacy of both purgatives and prokinetics is controversial.

The physiologic function of the small intestine is very different from that of the colon. While the colon functions as a stool reservoir and is full of stool even during a fast, the small intestine is free of stool or any content after a 24- to 48-h fast. Since instructing patients to observe such prolonged fasting before undergoing CE is unreasonable, ingestion of a liquid, fiber-free formula instead of food during the 24 h preceding a CE examination would appear to be a more practical option for ensuring sufficient cleanliness of the small intestine as well as good patient compliance. This idea has not been investigated before.

The aim of this two-center prospective study was to compare the SB cleanliness and the quality of CE images of patients who were prepared by ingestion of Ensure (a fiber-free liquid formula) with those of patients who were assigned the PEG and two control groups.

MATERIALS AND METHODS

This prospective, blind-to-preparation investigation was conducted in two Israeli medical centers, the Tel-Aviv Sourasky Medical Center (TASMC) and the Hillel-Yaffe Medical Center (HYMC). The protocol of the study was approved by the local Helsinki committees of both centers. Consecutive patients who were referred to CE studies were asked to sign informed consent forms to participate in the study. The usual medical indications for CE referral were: (1) suspected Crohn's disease (CD); (2) gastrointestinal (GI) bleeding of unknown origin (normal gastroscopy and colonoscopy); (3) iron deficiency anemia of unknown origin (normal gastroscopy and colonoscopy, negative celiac serology); (4) suspected malabsorption disease; (5) unexplained abdominal pain; (6) unexplained chronic diarrhea; and (7) abnormal SB findings on abdominal computerized tomogram (CT).

The exclusion criteria were: age < 18 and > 70 year, pregnancy, previous surgery involving the GI tract, previous intestinal obstruction, and refusal to participate in the study. Because of its sucrose content, diabetes mellitus was an exclusion criterion for the Ensure group only. The relevant demographic and medical data were collected, including: age, gender, the indication for a CE study, chronic diseases, medications, previous surgeries, and previous GI endoscopic examinations.

Study group assignment

The patients were divided into four groups and they all observed a 12-h overnight fast before undergoing CE, whatever preparation protocol they followed.

The patients who were evaluated at HYMC were randomly divided into two groups. Those assigned to the PEG group were instructed to eat light meals and to ingest two liters of PEG one day before undergoing CE. Those assigned to the Ensure group were instructed to drink up to four cans of the Ensure Plus® formula ad libitum throughout 24 h, and to stop all other food/beverage intake except for water. Ensure Plus® (Abbott Laboratories) is a popular, fiber-free, polymeric-balanced formula with a caloric content of 355 kcal/can, 13 g protein, 50.1 g carbohydrates, 11.4 g fat, minerals, trace elements and vitamins.

The patients who underwent the CE study due to medical indications in TASMC during the same period of time comprised the two control groups: the control group 1 patients were instructed to eat light meals during the day before the CE, and the control group 2 patients followed a low-fiber diet (without fruits, vegetables and fiber supplements) for 2 d before CE and ate light meals one day before undergoing CE.

The CE procedure was standard in both centers. All patients ingested a PillCam™ SB 2 wireless video capsule (Given® Diagnostic Imaging System, Yokneam, Israel) with a small amount of water. An array of 8 sensors was attached to the abdominal wall, and a recorder with a battery was fastened around their waists with a belt. The patients were allowed to drink liquids two hours after ingesting the capsule and to eat a light meal four hours later. Eight hours after capsule ingestion, the recorder was disconnected and the sensors were removed. The recorded digital information was downloaded onto the computer and the images were analyzed using RAPID® software. The CE films were examined by gastroenterologists with CE expertise in both medical centers. Afterwards, a single independent expert who was unaware of the provenance of the films reviewed all films for the presence of bile and degree of cleanliness.

The following data were collected and analyzed from the CE studies: (1) Indications for the CE study grouped into 3 categories (suspected CD, obscure GI bleeding, others); (2) Gastric transit time as calculated from the

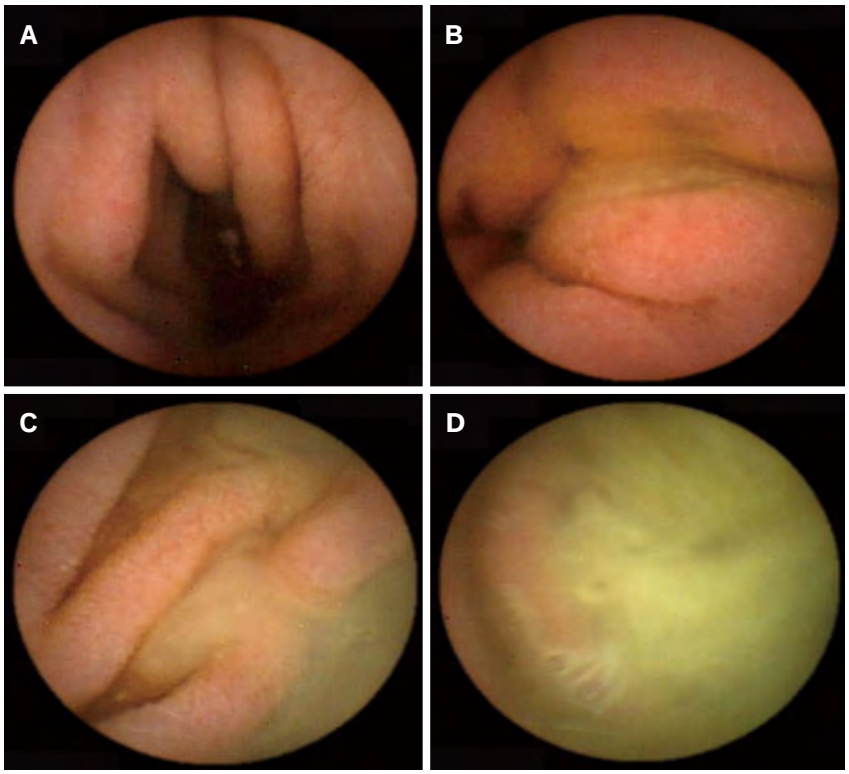

Figure 1 Grading of the presence of bile in the duodenum. A: Grade 1; B: Grade 2; C: Grade 3; D: Grade 4.

first view of the gastric mucosa to the first image of the duodenum, expressed in minutes; (3) SB transit time as calculated from the first view of the duodenum up to the first cecal image, expressed in minutes; (4) Final diagnosis grouped into six categories (established CD, angiodysplasia, polyps, nonspecific findings, normal examination, others); (5) Cecum arrival: a CE study was defined as having been completed if the capsule reached the cecum. An abdominal X ray was performed to exclude capsule retention in cases of non-arrival; (6) The bile presence score: the presence of bile in the duodenum lumen was evaluated using a scale of 1 to 4, with 1 representing none and 4 indicating more than 90% of the lumen being full of bile (Figure 1); (7) The cleanliness score: SB cleanliness was evaluated by a 4-point scale, with 1 indicating no residual material in the lumen and 4 indicating more than 90% of the lumen having residual material (Figure 2). The SB section of the CE study was divided into three parts: proximal, middle and distal. Each part received a separate cleanliness score; (8) Extra-SB findings, *i.e.*, the number of recorded findings in the esophagus, stomach and cecum; and (9) Follow-up, including the number of Ensure cans that were consumed, possible side effects of Ensure and PEG, level of satisfaction from preparation in PEG and Ensure groups, patient compliance with the preparation's protocol.

Statistical analysis

Descriptive statistics are given as mean and standard deviation for continuous variables and frequency distribution for categorical variables. Comparisons between patients with different protocols of preparation with regard to demographics (age, gender), clinical parameters (indications for CE study) and CE data (final diagnosis, gastric and SB transit times, cecal arrival rate, duodenal bile score and cleanliness score) were performed using the Chi-square, Fisher's Exact and unpaired *t*-tests. The non-parametric Mann-Whitney test was also applied if the continuous parameters did not follow a normal distribution. Pairwise comparisons were performed when the results of the overall tests were significant. The False Discovery Rate method for adjustment of significance level was used. Comparison of continuous variables between groups was performed by one-way analysis of variance (ANOVA) and the non-parametric ANOVA Kruskal-Wallis test.

Ryan-Einot-Gabriel-Welsch pair-wise comparisons between groups were employed when the ANOVA indicated significant results. Additionally, post-hoc tests using Mann-Whitney tests with Bonferroni adjustment were performed when Kruskal-Wallis test revealed significant relations between groups and other clinical parameters. The relationships between transit time and other continuous parameters were examined by the Spearman's correlation coefficients. All statistical analyses were performed using SAS for Windows 9.2. The statistical tests were defined as having a confidence interval of 95%. $P < 0.05$ was considered statistically significant.

RESULTS

A total of 139 patients were screened to participate in the PEG and Ensure groups. Sixty-seven of them were

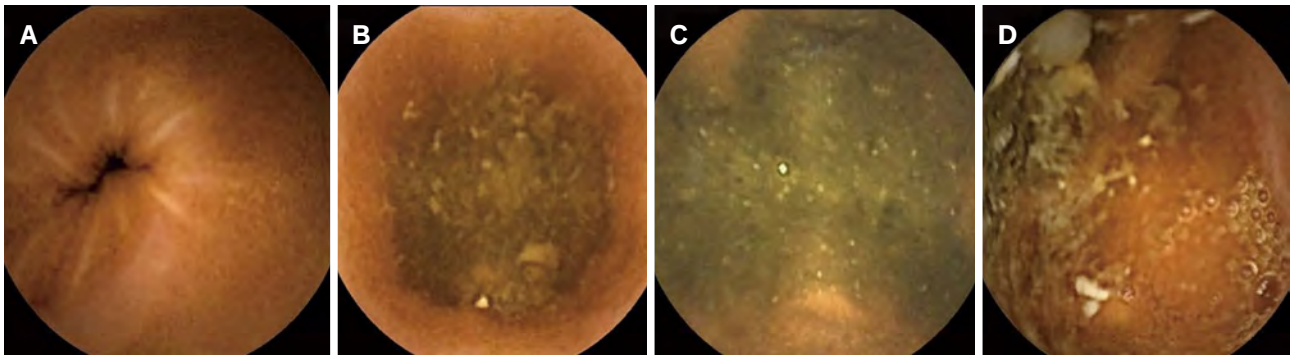

Figure 2 Grading of small bowel cleanliness. A: Grade 1; B: Grade 2; C: Grade 3; D: Grade 4.

[1]Incomplete cases = non-arrival to the cecum. CE: Capsule endoscopy; CD: Crohn's disease; PEG: Polyethylene glycol; GI: Gastrointestinal.

excluded from the study due to the following reasons: About 13 patients had diabetes mellitus, 18 patients were younger than 18 years, 11 patients had previous intestinal surgeries, 8 patients had an urgent CE study, and 17 patients refused to participate in the study. The remaining 72 patients were divided into either the PEG (n = 50) or Ensure (n = 22) groups. Control group 1 consisted of 45 patients and control group 2 consisted of 81 patients.

Table 1 presents the demographic data of these four groups of patients. The PEG and Ensure groups were younger than both control groups. About 24%-25% of all patients in the control groups were referred to the CE study in order to rule out CD, about 60%-65% to identify a reason for obscure GI bleeding and about 11%-14% for other indications. The percentage of cases with suspected CD was higher in the PEG and Ensure groups than in the control groups. The reason for these age and referral differences between the study and control groups was related to the refusal of more of the older patients to drink PEG or Ensure. The rate of cases with non-arrival of the capsule to the cecum was not significantly different between the groups (P = 0.14). Capsule retention was excluded in all cases of incomplete studies by abdominal X-ray. One control patient and two Ensure patients had an extremely prolonged gastric transit time (> 4 h) without any anatomic reason on gastroscopy. These three patients were considered as having gastroparesis and were not included in the evaluation of the rate of non-arrival to the cecum. These patients with a gastroparesis were 25, 33 and 56 years old with no previous intestinal surgery and no diabetes mellitus. They were referred to CE study to exclude CD and celiac disease and to identify a reason for iron deficiency anemia.

In order to provide a reliable analysis of image quality of CE studies, all cases of incomplete studies (non-arrival to cecum and gastroparesis) and those with incomplete data were excluded from the analyses in Table 2. All four resultant groups were very similar to the original groups with respect to age and indications for CE study. Overall, 107 of those 157 cases had a normal study or non-specific findings (68%). The rate of positive findings by CE was 32%. Twelve of 53 patients with suspected CD were diagnosed as having definite CD, with a yield of 23% (7.6% of all CE studies). There was an 18% rate of various extra-SB findings. Both gastric transit time and SB transit time for the four groups showed no statistical difference (P = 0.29 and P = 0.7, respectively), ranging between 29.1-40.1 min and 220.4-228 min for gastric and SB transit times, respectively.

The presence of duodenal bile was similar in both control groups (Table 3). Much more bile interfered with the visualization of duodenal mucosa in the PEG group (a score of 2.9) than in the Ensure group (a score of 1.76), and the difference almost reached a level of significance (P = 0.053). Overall, as expected, there was less residue and stool in the proximal part of the SB than in the middle and distal parts in all groups. The cleanliness grading of the proximal and distal parts of the SB was similar in

SB: Small bowel; PEG: Polyethylene glycol.

all four groups ($P = 0.6$ and $P = 0.6$, respectively). The scores of the middle part of the SB in the PEG and Ensure groups were lower than that of the control group 2 ($P = 0.057$ and $P = 0.07$, respectively). The total cleanliness score for the entire length of the SB showed some difference between that same control group and the Ensure group ($P = 0.06$), with a benefit for the latter.

Patient compliance among the PEG and Ensure groups was similar (1.25 and 1.2, respectively, $P = 0.7$), as was subjective feeling during the preparation for CE ($P = 0.163$). The patients succeeded in drinking an average of two cans of Ensure, ranging from 0.25 to 4 cans per day. All 50 PEG patients had diarrhea during the day they drank it, compared to only one of the 22 patients in the Ensure group.

DISCUSSION

Our prospective, blind-to-preparation, two-center study demonstrated that a preparation by a liquid, fiber-free formula (Ensure) before a CE study has several advantages over other types of preparation. First, it improved the visualization in the duodenum by slightly decreasing the amount of bile compared with the control groups and by decreasing the amount of bile to a level that almost reached statistical significance compared with the PEG group ($P = 0.053$). Secondly, the total score of cleanliness throughout the length of the SB showed some benefit for the Ensure preparation over one of the control groups ($P = 0.06$). Finally, the cleanliness in the middle part of the SB of the patients in both the PEG and Ensure groups was better than that of one of control groups ($P = 0.057$ and $P = 0.07$, respectively). However, all patients in the PEG group had diarrhea as a side effect, compared to only one patient in the Ensure group.

Many studies have dealt with the issue of preparation before a CE study by means of different kinds of

prokinetics and purgatives[9-23]. In contrast, our current study approached this problem by considering the physiological function of the SB as a place for the digestion and absorption of food and not as a reservoir for stools. As such, we expected that preparation with a liquid, fiber-free formula for one day before the CE study (followed by a 12-h overnight fast) should ensure SB cleanliness by keeping the amount of residue in the SB to a minimum. The results of our study bore out these expectations by demonstrating a positive impact of Ensure preparation on the bile score in the duodenum compared with the score for the PEG group and a total cleanliness score compared with one of the control groups. The Ensure preparation proved itself as good as PEG in terms of cleanliness in the middle part of the SB, with much less reported diarrhea. The statistical differences that showed strong trends but that rarely decreased below 0.05 to indicate significance could probably be related to the relatively small number of patients in the Ensure preparation group.

Our choice of Ensure Plus to serve as a very low-residue diet was arbitrary. We could have used any other commercially available free-fiber liquid formula and even a milkshake or soy-milkshake.

The efficacy of the PEG preparation is controversial. Some studies showed its benefit over a 12-h fast[17,18,20], while others reported no advantage[16,23]. It is obvious that preparation with 2 liters of PEG is as good as 4 liters[20]. More bile in the images of the PEG group led to poorer image quality in the duodenum than that of the Ensure group. The cleanliness in the middle part of the SB was similar to that of the Ensure group and better than that of the control groups, without there being any effect on the cleanliness of the proximal and distal parts. However, diarrhea as a common side effect was a significant disadvantage of PEG compared with Ensure and the control groups.

This study has a number of limitations. Although we succeeded in recruiting enough patients in the PEG and control groups for conducting capsule studies, the Ensure group was small. Therefore, some of our results could not reach a level of statistical significance. In addition, there were some basic differences between the groups: the PEG and ENSURE groups included younger populations with a higher percentage of CD patients. One important advantage of this study was the fact that all the scoring was done by a single blind-to-preparation expert in CE studies.

In summary, this prospective, two-center study raised, for the first time, the option of preparation for CE study with a liquid, fiber-free formula, and showed that it has some advantage over standard preparation or/and PEG, with significantly fewer side effects than PEG.

COMMENTS

Background

Capsule endoscopy (CE) has become a commonly used technology for examining the small bowel (SB) mucosa. A proper preparation decreases the amount of debris, food remnants, bile and stool present in the intestinal lumen and significantly increases diagnostic accuracy. However, there is no universally accepted protocol for SB preparation before a CE study. A standard preparation by 12-h fast and light meals one day before the procedure is inadequate. Preparations with purgatives are not well tolerated by patients, and their efficacy is controversial.

Research frontiers

Considering the physiological function of the SB as a site for the digestion and absorption of food and not as a stool reservoir, a preparation consisting of a liquid, fiber-free formula (like Ensure®) ingested one day before a CE study might have an advantage over other kinds of preparations. The aim of this two-center prospective, blind-to-preparation study was to compare the SB cleanliness and the quality of CE images of patients who were prepared by ingestion of Ensure® with those of patients who were assigned to the polyethylene glycol (PEG) group and two control groups that received standard preparation.

Innovations and breakthroughs

Preparation with Ensure® improved the visualization of duodenal mucosa by decreasing the bile content compared to preparation with PEG. The total score of cleanliness throughout the length of the SB showed some benefit for Ensure® over one of control groups. The cleanliness in the middle part of the SB in the PEG and Ensure® groups was equally better over of one of the control groups. As expected, all 50 PEG patients had diarrhea as a side effect, compared with only one patient in the Ensure group. This study presents for the first time a novel idea that preparation for undergoing CE of the SB should be completely different from the preparation for endoscopic examination of a colon and should be based on fasting and a liquid, fiber-free formula and not on purgatives.

Applications

This study results suggest that the preparation with Ensure®, a liquid, fiber-free formula has advantages over standard and PEG preparations, with significantly fewer side effects than PEG.

Terminology

Capsule endoscopy: CE is a technology that uses a swallowed wireless video capsule for photographing the inside of the esophagus, stomach, and small intestine. The images are transmitted it to a belt-holded recorder. It is a well-accepted tool which provides a direct and noninvasive approach to view the entire small bowel mucosa. This technology has enriched the knowledge on small bowel pathology and revolutionized the overall management of SB diseases.

Peer review

The manuscript is well-written and refers to an important issue in light of the increasing utility of the CE modality. The authors present a novel approach to a common "real life" issue and provide a new opportunity for an easy and convenient preparation.

Abstract

AIM: To evaluate effective alternative antibiotics in treatment of cefotaxime-resistant spontaneous bacterial peritonitis.

METHODS: One hundred cirrhotic patients with spontaneous bacterial peritonitis [ascitic fluid polymorphonuclear cell count (PMNLs) ⩾ 250 cells/mm^3 at admission] were empirically treated with cefotaxime sodium 2 g/12 h and volume expansion by intravenous human albumin. All patients were subjected to history taking, complete examination, laboratory tests (including a complete blood cell count, prothrombin time, biochemical tests of liver and kidney function, and fresh urine sediment), chest X-ray, a diagnostic abdominal paracentesis, and the sample subjected to total and differential cell count, chemical examination, aerobic and anaerobic cultures. Patients were divided after 2 d by a second ascitic PMNL count into group Ⅰ; patients sensitive to cefotaxime (n = 81), group Ⅱ (n = 19); cases resistant to cefotaxime (less than 25% decrease in ascitic PMNL count). Patients of group Ⅱ were randomly assigned into meropenem (n = 11) or levofloxacin (n = 8) subgroups. All patients performed an end of treatment ascitic PMNL count. Patients were considered improved when: PMNLs decreased to < 250 cells/mm^3, no growth in previously positive culture cases, and improved clinical manifestations with at least 5 d of antibiotic therapy.

RESULTS: Age, sex, and Child classes showed no significant difference between group Ⅰ and group Ⅱ. Fever and abdominal pain were the most frequent manifestations and were reported in 82.7% and 80.2% of patients in group Ⅰ and in 94.7% and 84.2% of patients in group Ⅱ, respectively. Patients in group Ⅱ had a more severe ascitic inflammatory response than group Ⅰ and this was demonstrated by more ascitic lactate dehydrogenase (LDH) [median: 540 IU/L (range: 150-1200 IU/L) *vs* median: 240 IU/L (range: 180-500 IU/L), P = 0.000] and PMNL [median: 15 000 cell/mm^3 (range: 957-23 822 cell/mm^3) *vs* 3400 cell/mm^3 (range: 695-26 400 cell/mm^3), P = 0.000] counts. Ascitic fluid culture was positive in 32% of cases. Cefotaxime failed in 19% of patients; of these patients, 11 (100%) responded to meropenem and 6 (75%) responded to levofloxacin. Two patients with failed levofloxacin therapy were treated according to the *in vitro* culture and sensitivity (one case was treated with vancomycin and one case was treated with ampicillin/sulbactam). In group Ⅱ the meropenem subgroup had higher LDH (range: 108-860 IU/L *vs* 120-491 IU/L, P = 0.042) and PMNL counts (range: 957-23 822 cell/mm^3 *vs* 957-15 222 cell/mm^3, P = 0.000) at initiation of the alternative antibiotic therapy; there was no significant difference in the studied parameters between patients responsive to meropenem and patients responsive to levofloxacin at the end of therapy (mean ± SD: 316.01 ± 104.03

PMNLs/mm^3 *vs* 265.63 ± 69.61 PMNLs/mm^3, *P* = 0.307). The isolated organisms found in group Ⅱ were; *enterococci*, *acinetobacter*, expanded-spectrum β-lactamase producing *Escherichia coli*, β-lactamase producing *Enterobacter* and *Staphylococcus aureus*.

CONCLUSION: Empirical treatment with cefotaxime is effective in 81% of cases; meropenem is effective in cefotaxime-resistant cases.

Effect of alternative antibiotics in treatment of cefotaxime resistant spontaneous bacterial peritonitis. *World J Gastroenterol* 2013; 19(8): 1271-1277 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1271.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1271

INTRODUCTION

Spontaneous bacterial peritonitis (SBP) is infection of ascitic fluid in cirrhotic patients. In 1985, results of a randomized trial demonstrated that cefotaxime, as a third-generation cephalosporin, achieved cure in SBP episodes for 85% of patients, compared to 56% of patients who received ampicillin plus tobramycin[1]. Since then, cefotaxime has become the empiric antibiotic of choice for the treatment of SBP. Mortality rates reduced from 90% when it was first described to around 20%-40%[2]. The widespread use of diagnostic paracentesis, as well as the prompt initiation of empiric antibiotic therapy, based on the results of ascitic polymorphonuclear (PMNL) cell count, has contributed in the improvement of survival in these patients[3]. Recent reports showed that resistance to third generation cephalosporins (including cefotaxime) is increasing[4,5] and this may increase the need to develop alternative antibiotics. The primary aim of this study was to evaluate effective alternative antibiotics in treatment of cefotaxime-resistant spontaneous bacterial peritonitis.

MATERIALS AND METHODS

Study design

This prospective study was conducted at the Tropical Medicine Department, Zagazig University Hospitals, Zagazig, Sharkia Governorate, Egypt during the period from October 2010 to October 2011. This study was approved by the Ethical committee of our institution. Written informed consents were obtained from all patients. For patients with any grade of hepatic encephalopathy, the written informed consents were obtained from the first degree relatives.

Patient management

All patients were inpatients and underwent diagnostic abdominal paracentesis with a differential leucocyte count, microbiological culture, and biochemical analysis at admission. Cefotaxime sodium 2 g/12 h (*iv*) was used as the initial empirical therapy because it is supported by the current guidelines as the first line of therapy for SBP[2]. It was subsequently maintained or replaced depending on the clinical course, a second abdominal paracentesis with PMNL count, and the *in vitro* susceptibility of the isolated microorganisms, up to a planned period of 5-7 d in a hospitalized basis.

After 48 h, a second abdominal paracentesis was done; cases with < 25% reduction in PMNL count were considered resistant to cefotaxime and were then randomly assigned to receive either meropenem 1 g/8 h (*iv*) or levofloxacin 1 g/12 h (*iv* drip). They were randomized by matching the sample (resistant group) and were classified into matched pairs; one from each pair was randomly enrolled into either the meropenem subgroup or the levofloxacin subgroup. One patient who was initially assigned to the levofloxacin subgroup was moved to the meropenem subgroup due to drug availability at the time of therapy. The final number was 11 patients in the meropenem subgroup and 8 in the levofloxacin subgroup.

The choice of these antibiotics was not only a matter of availability but also mainly due to previous reports of activity against bacterial species causing SBP[6,7] both *in vitro*[8] and *in vivo*[9] at national[10] and international[11] levels.

Five days after initiation of alternative antibiotic therapy an end of treatment diagnostic abdominal paracentesis was performed; cases with < 25% reduction in PMNL count from the second puncture counts were treated according to the results of *in vitro* culture and sensitivity that were available. All cases with initially positive ascitic fluid culture were re-cultured. Intravenous expansion was performed with human albumin 20 g *iv* infusion at the time of diagnosis and after 48 h.

All patients underwent a final diagnostic paracentesis with a differential leucocyte count at the end of therapy. The antibiotic dosage was adjusted to renal function throughout the treatment period. Diuretics were routinely discontinued at the time of diagnosis of SBP and therapeutic paracentesis was not allowed during the study.

Clinical and laboratory assessment

All patients were subjected to history taking, complete clinical examination, laboratory tests (including a complete blood cell count, prothrombin time, biochemical tests of liver and kidney function, and fresh urine sediment), chest x-ray film, a diagnostic abdominal paracentesis, and the sample was subjected to total and differential cell count, chemical examination, aerobic and anaerobic culture. These were performed in all the cirrhotic patients with ascites on the day of admission and

whenever they developed symptoms and signs suspicious for SBP (*i.e.*, fever, change in mental status, abdominal pain, development of renal failure, hypotension, *etc.*) during the hospitalization period.

The ascitic fluid samples were collected under aseptic conditions in tubes containing ethylenediamine tetraacetic acid anticoagulant and then tested to determine white blood cell and PMNL counts by automated cell blood counter; chemical analysis for glucose, lactate dehydrogenase (LDH) and total protein were also done. All the specimens were analyzed within one hour. Moreover, 10 mL of ascitic fluid was inoculated directly at the patient's bedside into aerobic and anaerobic blood culture bottles for bacteriological examination.

Microbiological analysis

Ascitic fluid cultures were performed at the time of the initial paracentesis in the blood culture bottles (Remaux, France) at the bedside. All were incubated aerobically and anaerobically at 37 ℃ for 2 d before a subculture was done. Cases were considered negative after 7 d. All initially positive cases were re-cultured and cases were considered resolved from infection when PMNLs count had dropped to < 250/mm^3 and all culture cases were negative.

Definitions

Cirrhosis: Cirrhosis diagnosed based on clinical, biochemical, histological and/or radiological findings and Child class was assessed for each patient.

SBP: SBP was defined as the presence of ⩾ 250 PMNLs/mm^3 in the ascitic fluid[2].

Resolution of SBP: Resolution of SBP was defined as reduction of the elevated ascitic fluid PMNL count to < 250/mm^3, negative culture in previously positive cases with resolution of the clinical manifestations and normalization of the impaired renal function.

Resistance: Resistance to empiric therapy was considered when < 25% reduction in PMNL count from the base line was achieved after 48 h[2].

Exclusion criteria: (1) Non-cirrhotic ascites (including malignant ascites); (2) Cases with secondary bacterial peritonitis; and (3) Bacterascites (*i.e.*, positive ascitic fluid culture with < 250 neutrophils/mm^3).

Statistical analysis

Data were checked, entered and analyzed using SPSS Version 15. Data were expressed as mean ± SD for quantitative variables, number and percentage for qualitative ones. χ^2 or Fisher exact, *t* test and paired *t* test were used when appropriate. $P < 0.05$ was considered significant.

RESULTS

General characteristics and clinical presentation

Baseline characteristics of patients are presented in Table 1. Age and gender were comparable in group Ⅰ and group Ⅱ. In group Ⅰ, the numbers in Child class B and C were 21% and 79% while in group Ⅱ they were 5.3% and 94.7%, respectively. This means that most cefotaxime resistance cases were associated with advanced liver disease.

Fever and abdominal pain were the most frequent manifestations and were reported in 82.7% and 94.7% of patients in group Ⅰ and in 80.2% and 84.2% of patients in group Ⅱ, respectively. Asymptomatic patients were found in 18.5% of the cefotaxime sensitive group, but all patients of the resistant group presented with symptoms and signs. Regarding the laboratory parameters (Table 2), patients in group Ⅱ had a greater peripheral blood leucocyte response than group Ⅰ.

Microorganisms

Ascitic fluid culture was positive in only 32% of cases. There were 26 ascitic fluid culture positive cases within group Ⅰ (out of 81); the isolated organisms were *Escherichia coli* (*E. coli*) in 13 (50%), *Klebsiella* in 7 (27%), *Enterobacter*, and *Strep. viridans* each in 2 (8%), *Pneumococci* and *S. aureus* each in 1 (4%) (Figure 1A). There were 6 ascitic fluid culture positive cases within group Ⅱ (out of 19); the isolated organisms were *E. coli* in 2 (33%), *Enterobac-*

PMNLs (/mm^3)	3400 (695-264 00)	15 000 (957-23 822)	3.852	0.000

Data are presented by mean ± SD or median (range). INR: International normalized ratio; WBC: White blood cell; LDH: Lactate dehydrogenase; PMNLs: Polymorph nuclear leucocytes.

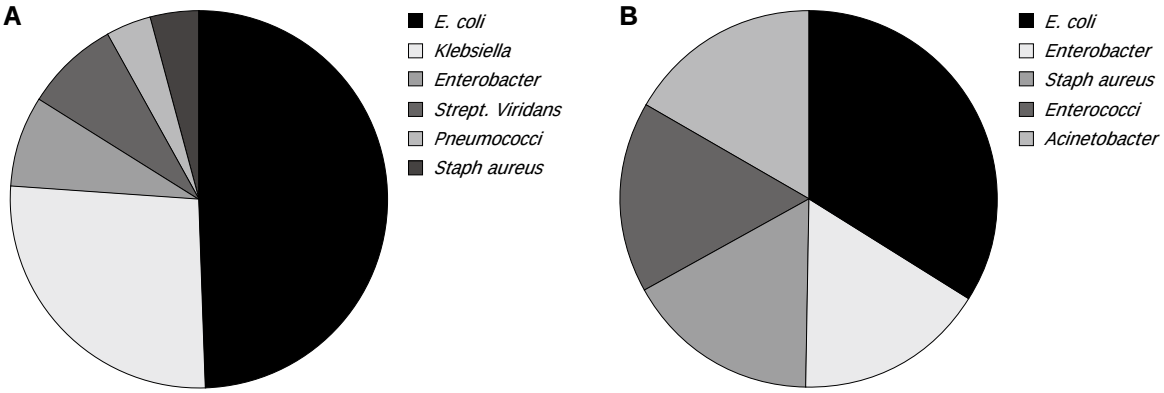

Figure 1 Isolated organisms in groups. A: Group Ⅰ; B: Group Ⅱ. *E. coli*: *Escherichia coli*.

ter, *S. aureus*, *Enterococci* and *Acinetobacter* each in one (16%) (Figure 1B).

Ascitic fluid analysis

Data for all patients are presented in Tables 2 and 3. Patients in group Ⅱ had a more severe ascitic inflammatory response than group Ⅰ and this was demonstrated by the more ascitic LDH and PMNL counts. In group Ⅰ, apart from the significant reduction in PMNL count, none of the biochemical parameters showed significant changes at the end of therapy. In group Ⅱ the meropenem subgroup had higher LDH and PMNL count at initiation of the alternative antibiotic therapy; there was no significant difference in the studied parameters between patients responsive to meropenem and levofloxacin at the end of therapy.

Treatment outcomes

Cases were treated for a median of 5-12 d. Cases in group Ⅰ (n = 81) were treated by cefotaxime for 5-7 d, while patients in group Ⅱ were treated as follows: the meropenem subgroup was treated for 5 d, the levofloxacin subgroup was treated for 5 d, 2 cases who were resistant to levofloxacin were treated with vancomycin in one case and ampicillin/sulbactam in one case, according to the *in vitro* culture and sensitivity results, for further 5 d and were recultured and examined by an end of treatment ascitic PMNL count before being considered cured.

The clinical and laboratory parameters of group Ⅱ patients showed no major improvement with the initial empirical therapy; whereas noticeable improvements in many of the parameters were achieved when the alternative antibiotic therapy was given. This was obvious in hepatic encephalopathy (HE) which was encountered in 30.9% of patients in group Ⅰ and 63.2% of patients in group Ⅱ (grade Ⅱ-Ⅲ HE), where an improvement of consciousness level was achieved after antibiotic treatment of SBP. All patients of group Ⅱ, in spite of starting treatment of HE, showed no major improvement with cefotaxime, but improvement of consciousness level occurred after the resolution of SBP by the alternative antibiotic therapy.

Table 3 Ascitic fluid parameters in group Ⅱ at the beginning and end of alternative therapy

Variable	Meropenem subgroup (n = 11)	Levofloxacin subgroup (n = 8)	t	P value
At initiation of alternative therapy				
Glucose (mg/dL)	100.45 ± 80.33	113.50 ± 9.58	0.390	0.702
Protein (mg/dL)	1850.00 ± 529.26	1360.83 ± 572.08	1.771	0.097
LDH (IU/L)	450 (108-1200)	237 (120-831)	2.223	0.042
PMNLs/mm^3	18 061 (957-23822)	3540 (957-15222)	3.622	0.000
At end of therapy				
Glucose (mg/dL)	102.81 ± 39.35	124.00 ± 29.17	1.150	0.268
Protein (mg/dL)	1660.00 ± 418.85	1163.33 ± 516.78	2.156	0.052
PMNLs/mm^3	316.01 ± 104.03	265.63 ± 69.61	1.056	0.307

Data are presented by mean ± SD or median (range). LDH: Lactate dehydrogenase; PMNLs: Polymorph nuclear leucocytes.

DISCUSSION

Cefotaxime as a standard treatment of SBP has been tried for many years with many reports of evolving resistance to cefotaxime and other third-generation cephalosporins in SBP[2,5]. Resistance to cefotaxime in this work is 19%, close to 21.5% recently reported by Ariza *et al*[5].

In this study cefotaxime resistance is not related to age or sex of patients, and the male predominance in our study is directly related to the higher rates of cirrhosis and risk of exposure and is in agreement with previous studies from other parts of the world[12,13].

Clinical manifestations of SBP are nonspecific; the most frequently encountered symptoms and signs are fever (69%) and abdominal pain (59%),[14]. This was the position in our study where fever and abdominal pain were the most frequent clinical manifestations.

However approximately 10% of patients with SBP are asymptomatic[14]; in our study asymptomatic patients made up 18.5% of the cefotaxime sensitive group, but all patients in the resistant group had clinical manifestations. This notion, together with the low yield of ascitic fluid culture, raised the value of PMNL count ⩾ 250 cell/mm^3 as the most important parameter for the diagnosis of SBP.

It is well known that infection in cirrhotic patients, especially SBP, precipitates HE and has been related to variceal bleeding both in terms of pathogenesis of portal pressure increase and severity of bleeding episodes[15] hence the related mortality was reduced by prompt antibiotic therapy[16] and this is confirmed by our study.

SBP occurs due to bacterial translocation, mainly in patients with advanced cirrhosis and severe liver functional damage[13,14,17]; this is confirmed in this study as SBP developed only in patients with Child classes B and C.

In this study, resistance to cefotaxime is associated with more advanced liver disease, because 94.7% and 5.3% of cases were Child C and B respectively. This notion needs further evaluation.

The low proportion of positive ascitic fluid cultures is probably due to the relatively low concentration of bacteria in the ascitic fluid as compared with the infections in other organic fluids (*e.g.*, urine)[18]. For the same reason, a therapy based on the isolation of the responsible bacteria is seldom achievable and antibiotic treatment cannot be delayed to the moment when microbiological results are available[19]. That is why cefotaxime as an empirical therapy should be begun without delay.

In the cefotaxime sensitive group gram negative bacteria were the most frequent (22/26; 85%) and *E. coli* was the most predominant; however Gram positive bacteria were isolated in 4 patients. In the resistant group, bacteria were isolated in 6 patients; these results are closely similar to Taşkiran *et al*[20] study which revealed positive ascitic fluid culture in 29.4% of cases with predominantly Gram negative bacteria. Angeloni *et al*[12] revealed positive cultures in 30% of episodes with predominantly Gram negative bacteria; in these episodes the percentage of treatment failure of the initial therapy with cefotaxime was 32% and this result is similar to our findings.

In our patients, cefotaxime failed because the isolated organisms were intrinsically resistant to cefotaxime as *Enterococci* (one patient) and *Acinetobacter* spp (one patient) or were capable of degrading the expanded-spectrum cephalosporins as expanded-spectrum β-lactamase producing (ESBL) *E. coli* (two patients) or β-lactamase producing *Enterobacter* species (one patient) or bacteria with inherent insufficient susceptibility to cefotaxime, such as *S. aureus* (one patient). Our study supports previous reports[21] about the introduction of new organisms in the development of SBP.

The efficacy of empiric antibiotic treatment can rarely be based on the amelioration of symptoms or on microbiological results. Therefore, a reduction of PMNL count below 250 cell/mm^3 or a 25% reduction of the initial value has been suggested as the main criterion for establishing the efficacy of antibiotics and the need for switching therapy. Our study confirms the validity of such an approach. Based on PMNL count, we identified the failure of the initial therapy on time.

Meropenem use was successful in 100% of resistant cases. Levofloxacin was successful in 75% of resistant cases, a result lower than reported for *in vivo*[9,22] and *in vitro* isolates where all aerobic isolates of SBP were sensitive to levofloxacin[23]. Other studies recommended meropenem use, not only in severe cases but also when ESBL producing *E. coli* is seen in the cultures and points to a relation between quinolone resistance and ESBL production[7,24]. Types of the isolated bacteria in group Ⅱ of our study explain the efficacy of meropenem over levofloxacin.

Albumin use was suggested in SBP management[25], although it was not included in the treatment protocols. However the guidelines for the prevention and treatment of hepato-renal syndrome[26] suggested that albumin administration may reduce the incidence of renal failure and mortality in patients with SBP; consequently, all

our patients received albumin. Some patients recorded a temporary increase in serum creatinine. All these patients showed improvement of kidney function with the use of proper antibiotics and resolution of SBP.

In conclusion, our study suggests that use of cefotaxime as the first line of treatment is considered valid, since a switch to another antibiotic was necessary only in 19% of our cases and we suggest meropenem as an effective alternative in resistant cases. This study also confirmed the value of a second abdominal paracentesis 48 h after initiation of empiric therapy to detect resistant cases early.

COMMENTS

Background

Spontaneous bacterial peritonitis is infection of ascitic fluid in cirrhotic patients with high mortality rates. Cefotaxime has become the empiric antibiotic of choice for the treatment since 1985. Mortality rates reduced from 90% when cefotaxime was first described to around 20%-40%. Recent reports showed that resistance to third generation cephalosporins (including cefotaxime) is increasing and this may increase the need to develop alternative antibiotics.

Research frontiers

Eradication of ascitic fluid infection is the goal of antibiotic therapy. This study confirmed the validity of cefotaxime as an empiric first line therapy for spontaneous bacterial peritonitis and identified meropenem as an effective alternative in cases of cefotaxime resistance.

Innovations and breakthroughs

Cefotaxime as the empiric first line therapy for spontaneous bacterial peritonitis is effective in 81% of cases. Meropenem is effective in 100% of cefotaxime-resistant cases, while levofloxacin is effective in 75% of cefotaxime-resistant cases.

Applications

This article emphasises the value of meropenem and levofloxacin as effective alternatives to cefotaxime in resistant cases.

Terminology

Spontaneous bacterial peritonitis is infection of ascitic fluid in patients with cirrhosis; Cefotaxime (a third generation cephalosporin) is utilized primarily for its activity against Gram-negative aerobic organisms. The drug exhibits moderate activity against Gram-positive bacteria. Meropenem is an ultra-broad spectrum injectable antibiotic used to treat a variety of infections. It is a beta lactam antibiotic and belongs to the subgroup of carbapenems; Levofloxacin is a synthetic chemotheraputic antibiotic which belongs to fluoroquinolone drug class and is used to treat severe or life-threatening bacterial infections or bacterial infections that have failed to respond to other antibiotic classes.

Peer review

The clinical study focused on the effect of cefotaxime as the empiric first line therapy for spontaneous bacterial peritonitis and effectiveness of meropenem and levofloxacin as alternatives in case of cefotaxime resistance. This will be useful for future planning of therapy and clinical application.

Abstract

AIM: To determine whether fluid injection during radiofrequency ablation (RFA) can increase the coagulation area.

METHODS: Bovine liver (1-2 kg) was placed on an aluminum tray with a return electrode affixed to the base, and the liver was punctured by an expandable electrode. During RFA, 5% glucose; 50% glucose; or saline fluid was infused continuously at a rate of 1.0 mL/min through the infusion line connected to the infusion port. The area and volume of the thermocoagulated region of bovine liver were determined after RFA. The Joule heat generated was determined from the temporal change in output during the RFA experiment.

RESULTS: No liquid infusion was 17.3 ± 1.6 mL, similar to the volume of a 3-cm diameter sphere (14.1 mL). Mean thermocoagulated volume was significantly larger with continuous infusion of saline (29.3 ± 3.3 mL) than with 5% glucose (21.4 ± 2.2 mL), 50% glucose (16.5 ± 0.9 mL) or no liquid infusion (17.3 ± 1.6 mL). The ablated volume for RFA with saline was approximately 1.7-times greater than for RFA with no liquid infusion, representing a significant difference between these two conditions. Total Joule heat generated during RFA was highest with saline, and lowest with 50% glucose.

CONCLUSION: RFA with continuous saline infusion achieves a large ablation zone, and may help inhibit local recurrence by obtaining sufficient ablation margins. RFA during continuous saline infusion can extend ablation margins, and may be prevent local recurrence.

INTRODUCTION

Radiofrequency ablation (RFA) is a technique by which deposition of electromagnetic energy is used to thermally ablate hepatic tumor tissue[1] and is now the standard method for local treatment of hepatic malignancy[2-9].

Several types of device are currently used for such therapy, such as the Cool-tip system (single electrode) made by Covidien, and the RFA systems made by Boston Scientific and AngioDynamics (the Starburst XL electrode)[10]. The former uses a single-electrode puncture needle, whereas the latter both employ a needle elec-

trode with an expandable array of fine needles extending from the tip. The expandable array of the StarBurst XL electrode is also fitted with an infusion port. To date, various techniques have been devised to secure adequate ablation margins[11]. We investigated whether ablation margins could be extended by fluid infusion from the infusion port of an expandable electrode.

We conducted an *ex vivo* experiment on bovine liver to investigate whether ablation margins could be extended by fluid infusion from a StarBurst XL electrode in order to avoid the influence of the cooling effect *in vivo* experiment.

MATERIALS AND METHODS

RFA setting and ablation protocol

A StarBurst XL electrode (AngioDynamics; Queensbury, NY) and RITA1500X generator (AngioDynamics) were used to provide RFA. One to two kilograms of bovine liver form an abattoir was used which had been exposed to room temperature for several hours until the baseline mean liver temperature ranged between 15 ℃ and 21 ℃, placed on an aluminum tray with a return electrode affixed to the base and the liver was punctured by the StarBurst XL electrode, with a maximum array expansion of 5 cm in diameter, under ultrasonographic guidance by convex probe using a Logiq 7 ultrasound device (GE Healthcare, Tokyo, Japan). Stepped ablation was performed, with the electrode first expanded to 2 cm after reaching the set temperature of 105 ℃, then expanded by 3 cm after reaching the set temperature of 105 ℃, with single ablation maintained at each diameter for 7 min. An infusion line was connected to the infusion port on the electrode, and the other end of the infusion line was connected to a syringe pump. Continuous liquid infusion was initiated at the same time as radiofrequency output. Three infusion liquids were used with the continuous infusion rate was set at 1.0 mL/min: 5% glucose; 50% glucose; and saline[12].

After stopping radiofrequency output, specimens were sectioned along the longitudinal and transverse axes of each lesion. Measurement of the coagulation diameter perpendicular to the electrode axis was based on consensus of two observers (Ishikawa T, Kubota T). Macroscopic changes in specimens have been demonstrated to correlate well with coagulation necrosis at histological examination[13]. Furthermore, the central white area of the RF-induced ablation zone was found to correspond to the necrotic zone[14].

The liver blocks containing lesions were dissected along the axis along which the electrode was inserted, and the central white area of the RF-induced ablation zone was found to correspond to the necrotic zone[15]. For macroscopic examination, two observers used calipers to measure, in the central white area of coagulation necrosis in each pathologic specimen, the overlapping width, the longest diameter of each ablation sphere along the electrode, and the shortest diameter at the midpoint between the two electrodes[16].

The region of discoloration indicating ablation of the bovine liver was measured, and the volume of ablation was calculated using the formula for calculating the volume of an ellipsoid ($V = 4/3abc\pi$).

An intergroup comparison of calculated thermocoagulated volumes was performed using Student's *t*-test with Bonferroni correction.

In addition, the generated Joule heat was calculated from the data for output changes over time during the RFA experiment.

Statistical analysis

In the intergroup comparison of calculated thermocoagulated volumes, an unpaired Student's *t*-test was used and *P* values were calculated with a correction of the α significance level by Bonferroni's method based on the number of test repetitions. For all statistical analyses, values of $P < 0.05$ were considered statistically significant.

RESULTS

Figure 1 shows cross-sectional photographs of ablated regions of liver and graphs of changes over time in temperature, output and impedance during RFA for each continuous infusion condition. Changes in impedance over time after array expansion to 3 cm tended to gradually increase in RFA without infusion and with glucose, but the steady state of impedance was seen when RFA was used with saline (Figure 1). The ablation zone also widened and presented a circular shape when saline was used.

Experimental result shows mean ± SD values for dimensions of ablation, calculated volume, mean output during RFA, and calculated Joule heat. Mean thermocoagulated volume was significantly larger with continuous infusion of saline (29.3 ± 3.3 mL) than with 5% glucose (21.4 ± 2.2 mL), 50% glucose (16.5 ± 0.9 mL) or no liquid infusion (17.3 ± 1.6 mL) ($P < 0.01$). The ablated volume for RFA with saline was approximately 1.7-times greater than for RFA with no liquid infusion, representing a significant difference between these two conditions.

An increasing trend in ablation volume was also seen in RFA with 5% glucose, although not to the same extent as with saline. In RFA with 50% glucose, the ablated volume was very similar to RFA with no liquid infusion, and differed significantly from RFA with saline.

Mean radiofrequency output tended to be higher in RFA with saline than with no liquid infusion, but tended to be low in RFA with glucose. The mean total Joule heat generated during RFA was highest with saline, and low with glucose.

DISCUSSION

RFA is a therapeutic technique that utilizes the principle of conductive heating, in which heat is generated by friction from moving electrons when current, is passed through a conductor[17]. Specifically, by passing electricity

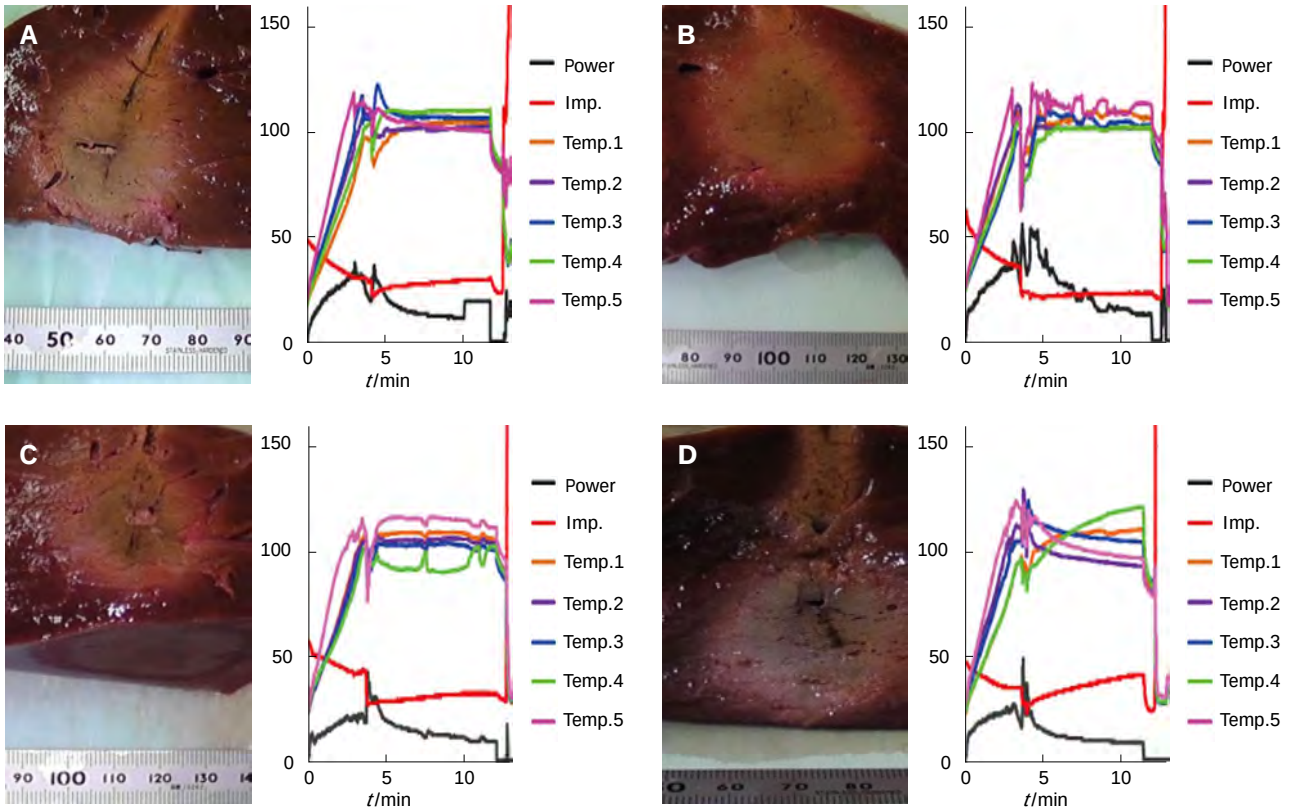

Figure 1 Transection of liver specimen with radiofrequency ablation lesion (on the left side) and graphic depiction of changes occurring in temperature (middle) with tissue impedance (red line) and power (black line) during radiofrequency ablation (on the right side) in the four groups. A: No continuous liquid infusion; B: Saline; C: 5% glucose; D: 50% glucose.

through a needle electrode inserted into the human body, coagulation and necrosis of a malignant neoplasm or other lesion tissue is induced[18,19]. The basic principle of RFA as treatment for hepatic malignancy is the generation of Joule heat by high-frequency current in living tissue between the needle electrode and a return electrode. Although the heat generated by this high-frequency current arises in all the conducting tissue pathways, high temperatures only develop in tissues near the electrode, where the current density is high. Barely any heat arises in tissues further from the electrode because of the fall in current density and the cooling (or radiator) effect of blood flow.

Although this principle brings about ablation in tissue near the electrode, the vapor microbubbles generated in the ablation region are removed by blood flow, lowering the electrical conductivity of tissue and consequently sometimes preventing adequate ablation of the target zone[2]. Efficient generation of conductive heating is therefore necessary to achieve adequate ablation margins[20]. Temperature-controlled systems for facilitating adequate ablation of the target zone by preventing excessive heating of tissue have been commercialized, but our experiments aimed to test the effect of RFA used in combination with continuous infusion of a liquid to the target tissue. Specifically, we conducted *ex vivo* experiments on bovine liver to investigate whether infusion of a liquid from the infusion port of a StarBurst XL electrode could enhance the efficiency of conductive heating.

The mean ablated volume when RFA was performed by StarBurst XL electrode with no liquid infusion was 17.3 ± 1.6 mL, similar to the volume of a 3-cm diameter sphere (14.1 mL). On the other hand, when RFA was used with a continuous infusion of liquid, the mean ablation volume was 29.3 ± 3.3 mL with saline, 21.4 ± 2.2 mL with 5% glucose, and 16.5 ± 0.9 mL with 50% glucose ($P < 0.01$). This shows that the ablated region expanded significantly when saline was used. In RFA with continuous liquid infusion, the ablated volume was significantly higher than in RFA without liquid infusion, and when saline in particular was used, the mean point estimate volume increased approximately 1.7-fold. In order to maintain the steady state of impedence for RFA during saline continuous injection, current density between electrodes should therefore be decreased to within the range within which current causes an increase in tissue temperatures, without boiling. We speculate that changing the electrical conductance of the tissue by infusing saline could be a good solution. Furthermore, we propose the following three reasons for these results.

First, in RFA without liquid infusion, water in tissues near the electrode forms microbubbles, some of which move to the area around the tissue. The moisture percentage near the electrode thus decreases and electrical conductivity of the tissue falls. This is supported by the finding that impedance gradually increased during RF

output. In contrast, when RFA is used with continuous liquid infusion, the moisture percentage in tissue near the electrode remains stable or is increased, maintaining or increasing electrical conductivity and leading to expansion of the ablated region. Furthermore, saline was likely more effective in extending the ablated region than glucose when used with RFA because saline is a conductive solution.

Second, ablation of tissue near the electrode results from the thermal conversion effect of Joule heat due to a high current density. The thermal conversion effect of Joule heat alone is insufficient to induce ablation of the surrounding tissue, and we speculate that such ablation is the result of synergistic effects involving, for example, heat conduction from tissue near the electrode to surrounding tissue, or transfer of heated water or high-temperature microbubbles generated near the electrode to the surrounding tissue. Infusion of liquid would promote this transfer of heated water or high-temperature microbubbles to the surrounding tissue, with the ultimate effect of extending the ablated region.

Third, the type of infusion liquid was relevant, with a significant difference in ablated volume seen between the saline and 50% glucose solutions. This is probably because although a highly concentrated glucose solution would be expected to extend the ablation region through the effects described in the two points above, the non-ionic nature of the solution may lower the electrical conductivity of the target tissue. Considering that ablated volumes were similar in RFA with 50% glucose infusion and without any liquid infusion, the negative effects of this highly concentrated but non-ionic solution cancelled out the effects described in the first two points above, resulting in no marked extension of the ablated region.

Shorter treatment time (RFA time) may be another effect of RFA with continuous liquid infusion. This could be due to an increase in thermocoagulation efficiency at the target tissue arising from the transfer of high-temperature microbubbles or heated water to the surrounding tissue, as suggested in the second point above.

Furthermore, RFA with continuous liquid infusion tended to produce a larger thermocoagulated region with a lower total Joule heat compared to RFA without liquid infusion. Saline infusion in particular demonstrated high ablation efficiency at the target tissue, and could therefore prove highly useful[21].

This high ratio reveals the strong ablative action on the target tissue, and suggests that RFA with continuous saline infusion can achieve efficient ablation of tissue near the electrode. While this *ex-vivo* procedure cannot be directly adopted for use in clinical settings, RFA during continuous saline infusion can achieve a large thermocoagulation region in a short time and may be able to inhibit local recurrence by securing ablation margins.

There are several limitations to this study. The most important limitation was the absence of blood flow. *In vivo*, the volume of coagulation will be smaller and the amount of applied energy will be higher due to the removal of heat by the presence of blood flow[22]. This *ex-vivo* procedure cannot be directly adopted for use in a clinical setting. Using the same RF device, the size of the ablation zone *in vivo* was smaller than when *ex vivo*[23]. However, RFA during saline injection has potentially broad clinical merit and can assist in the planning of a methodological strategy. The relationship between parameters was calculated for a particular RF system, therefore, a different multipolar RF system would change the mathematical modeling. Moreover, the physiologic variability of thermal and electrical tissue properties is supposed to lead to a variable efficiency of applied energy under *in vivo* conditions. Consequently, the accuracy of mathematical modeling derived from *ex vivo* data will be restricted in the clinical application of multipolar RF ablation. Therefore, mathematical modeling has to be adjusted for *in vivo* conditions and due to the physiologic variability[24] of parameters the accuracy of predicted volumes is supposed to be reduced.

Finally, the findings of this study reflect certain model-specific characteristics, such as its hypovascularity, outcomes in other more clinically relevant tumor model may differ. Therefore, extrapolation to other types of tumors should be performed with caution.

In conclusion, we confirmed the effect of continuous liquid infusion in expanding the RFA thermocoagulated region in *ex vivo* experiments using a Starburst XL electrode system. Our results indicate that RFA with continuous saline infusion can significantly expand the volume of thermocoagulation in temperature-controlled RFA systems. RFA with continuous saline infusion can achieve a large thermocoagulation region in a short time and may be able to inhibit local recurrence by securing ablation margins[25,26].

COMMENTS

Background

Radiofrequency ablation (RFA) is now the standard method for local treatment of hepatic malignancy. To date, various techniques have been devised to secure adequate ablation margins. This study was investigated whether ablation margins could be extended by fluid infusion from the infusion port of an expandable electrode.

Research frontiers

In this study, authors confirmed that ablation margins by RFA could be extended by saline infusion from the infusion port of an expandable electrode.

Innovations and breakthroughs

While this *ex-vivo* procedure cannot be directly adopted for use in clinical settings, RFA during continuous saline infusion can achieve a large thermocoagulation region in a short time and may be able to inhibit local recurrence by securing ablation margins.

Applications

In this study, RFA with continuous saline infusion can achieve a large thermocoagulation region in a short time and may be able to inhibit local recurrence by securing ablation margins.

Peer review

This is a very novel study that Starburst RFA device and infusion saline and dextrose to study differences in burn volume with RFA. The results are interesting and suggest that RFA during continuous saline infusion can extend ablation margins.

Abstract

AIM: To characterise the *cag* pathogenicity island in *Helicobacter pylori* (*H. pylori*) isolates by analysing the strains' *vacA* alleles and metronidazole susceptibilities in light of patient ethnicity and clinical outcome.

METHODS: Ninety-five *H. pylori* clinical isolates obtained from patients with dyspepsia living in Malaysia were analysed in this study. Six genes in the *cag*PAI region (*cagE*, *cagM*, *cagT*, *cag13*, *cag10* and *cag67*) and *vacA* alleles of the *H. pylori* isolates were identified by polymerase chain reaction. The isolates' metronidazole susceptibility was also determined using the *E*-test method, and the resistant gene was characterised by sequencing.

RESULTS: More than 90% of the tested isolates had at least one gene in the *cag*PAI region, and *cag67* was predominantly detected in the strains isolated from the Chinese patients, compared with the Malay and Indian patients ($P < 0.0001$). The majority of the isolates (88%) exhibited partial deletion (rearrangement) in the *cag*PAI region, with nineteen different patterns observed. Strains with intact or deleted *cag*PAI regions were detected in 3.2% and 8.4% of isolates, respectively. The prevalence of *vacA* s1m1 was significantly higher in the Malay and Indian isolates, whereas the isolates from the Chinese patients were predominantly genotyped as *vacA* s1m2 ($P = 0.018$). Additionally, the isolates from the Chinese patients were more sensitive to metronidazole than the isolates from the Malay and Indian patients ($P = 0.047$). Although we attempted to relate the *cag*PAI genotypes, *vacA* alleles and metronidazole susceptibilities to disease outcome, no association was observed. The *vacA* alleles were distributed evenly among the strains with intact, partially deleted or deleted *cag*PAI regions. Interestingly, the strains exhibiting an intact *cag*PAI region were sensitive to metronidazole, whereas the strains with a deleted *cag*PAI were more resistant.

CONCLUSION: Successful colonisation by different *H. pylori* genotypes is dependent on the host's genetic makeup and may play an important role in the clinical outcome.

INTRODUCTION

Helicobacter pylori (*H. pylori*) demonstrates great genetic diversity, as evidenced by the apparently unlimited number of unique strains differing in genome size, gene order, gene content and allelic profile[1]. The high levels of genetic diversity in clinical isolates and the presence of certain virulence genotypes may confer a selective advantage to certain strains in different hosts. Therefore, the virulence genotype of *H. pylori* is a potentially useful predictor of the clinical outcome of gastric mucosal colonisation.

H. pylori possess a number of virulence determinants that modulate the organism's interaction with a host[2,3]. These virulence factors include the secreted, vacuolating cytotoxin VacA and the gene products of the pathogenicity island (*cag*PAI). The presence of these genetic loci correlates with the more severe *H. pylori*-associated pathologies, peptic ulcers and gastric cancer. Screening for the *cag*PAI genes is frequently performed due to the genes' involvement in virulence characteristics. An infection with *cag*PAI-positive *H. pylori* strains significantly increases the risk of developing severe gastric mucosal inflammation, duodenal ulceration and gastric cancer[4-6]. It has been observed that only one-half to two-thirds of isolates from Western patients express the *cag*PAI region, whereas almost all of the East Asian strains express this region. As there is limited information on the structure of the *cag*PAI in Malaysian patients, the role of *cag*PAI rearrangement in *H. pylori* isolates from various ethnic populations within this country should be investigated.

The *vacA* gene is another *H. pylori* virulence factor that exhibits great polymorphism and diverse allelic combination. The variable structure, resulting in different allelic arrangements in the gene, is related to differences in cytotoxin production and to the distinct clinical outcomes of *H. pylori* infection[7-9]. For example, a recent study performed at our institute has demonstrated a correlation between the presence of genetic polymorphisms in the *vacA* gene and the severity of gastritis[10].

H. pylori infection can be effectively cured by antibiotics. More specifically, metronidazole is commonly used in conjunction with either amoxicillin or clarithromycin and a proton-pump inhibitor to eradicate *H. pylori* infection[11,12]. Metronidazole is also used in the treatment of other diseases, such as gynaecological infections, and has contributed to the increased antibiotic resistance of *H. pylori*[13]. In Malaysia, the prevalence of metronidazole-resistant strains is 37%, which may be one of the factors contributing to the failed eradication of *H. pylori* infection in the country[14].

The population of Malaysia consists of three major ethnic groups (Malay, Chinese and Indian) that are historically associated with differences in *H. pylori* infection[15-17]. *H. pylori*-associated gastroduodenal diseases typically do not reflect the prevalence of *H. pylori* infection[15]. Furthermore, geographical and population differences in *H. pylori* virulence factors and disease severity underscore the importance of investigating the relationship between the genotypes of the causative strains and the clinical outcome. Therefore, to further understand the dynamics of the genetic traits of the *H. pylori cag*PAI regions, *vacA* alleles and metronidazole susceptibilities in Malaysia's multi-ethnic population, we investigated the possible association between these *H. pylori* virulence factors and infection in patients of different ethnicities and clinical outcomes.

MATERIALS AND METHODS

Patients

Patients with dyspepsia who had undergone an upper gastrointestinal scope (OGDS) at Universiti Kebangsaan Malaysia Medical Centre (Kuala Lumpur, Malaysia) between May 2004 and December 2007 were recruited. Any patients who had received antibiotics 4 wk prior to OGDS were excluded. Written informed consent was obtained from each patient, and the protocol was approved by the Research Ethics Committee (protocol number FF-075-2003) of the University.

H. pylori culture

Biopsies were subcultured for *H. pylori* on Columbia agar base (Oxoid, Basingstoke, England) containing Dent's supplement (Oxoid, Basingstoke, England) and 7% defibrinated sheep blood. The plates were incubated at 37 ℃ for 5 d under microaerophilic conditions.

DNA extraction

H. pylori genomic DNA was prepared using a High Pure polymerase chain reaction (PCR) Template Preparation Kit (Roche, Mannheim, Germany) according to the manufacturer's instructions.

Detection of metronidazole susceptibility and resistance genotype

Metronidazole susceptibility was determined using the E-test method (AB Biodisk, Solna, Sweden). First, an *H. pylori* culture suspension with a McFarland turbidity of 3.0 was used to inoculate Columbia agar supplemented with 10% defibrinated sheep blood. The plates were then incubated at 35 ± 2 ℃ for 3-5 d under microaerophilic conditions. The isolates were classified as resistant to metronidazole when the MIC value was > 8 μg/mL[18]. The *rdxA* genes were amplified by PCR using specific primers, as previously described[19], and then subjected to sequencing.

Detection of cagPAI genes

Two loci were selected in the *cag* I region (*cagE* and

cagM), and four loci were chosen from the *cag* Ⅱ region (*cagT*, *cag13*, *cag10* and *cag67*). Additionally, the insertion sequence IS605 was selected. The presence of these selected genes was determined by PCR using specific primers, as previously described[20]. PCR was conducted in 25 μL volumes containing 1 × PCR buffer, 0.2 mmol/L dNTP mix, 10 pmol of each primer, 1 U Taq polymerase (BioTherm, GeneCraft, Germany) and 1 μL of the DNA sample. The PCR amplification conditions consisted of 35 cycles at 94 ℃ for 1 min, 50-55 ℃ for 30 s, 72 ℃ for 1 min, and one cycle for the final extension at 72 ℃ for 10 min. The amplified product was electrophoresed on a 1% agarose gel.

Detection of vacA alleles

The *vacA* genotyping was performed by multiplex PCR using specific primers, as previously described[10,21]. PCR was conducted in 25-μL volumes containing 1 × PCR buffer, 0.2 mmol/L dNTP mix, 6 pmol of each primer, 0.75 U Taq polymerase (BioTherm, GeneCraft, Germany) and 1 μL of the DNA sample. The PCR amplification conditions consisted of an initial denaturation step at 94 ℃ for 4 min, followed by 30 cycles of denaturation at 94 ℃ for 30 s, primer annealing at 55 ℃ for 30 s, extension at 72 ℃ for 30 s, and one cycle for the final extension at 72 ℃ for 7 min. The amplified products were electrophoresed on a 1.5% agarose gel.

Statistical analysis

A statistical analysis was performed using the χ^2 test. A value of $P < 0.05$ was considered statistically significant.

RESULTS

H. pylori clinical isolates

A total of 95 clinical *H. pylori* isolates were obtained from 40 male and 55 female patients with a mean age of 55.47 ± 16.87 years (age range of 17-89 years) and from three different ethnic groups (12 Malays, 59 Chinese and 24 Indians). The endoscopic findings were as follows: nonulcer dyspepsia (n = 76), gastric ulcer (n = 9), duodenal ulcer (n = 6) and both gastric and duodenal ulcers (n = 2). The OGDS findings were not available for two of the patients. Nonulcer dyspepsia was further classified as endoscopically normal stomach (n = 12), antrum-predominant gastritis (n = 43), corpus-predominant gastritis (n = 2) and pangastritis (n = 19). No significant association was found between patient ethnicity (Chinese versus non-Chinese) and the endoscopic findings (nonulcer dyspepsia versus peptic ulcer).

cagPAI genotype

Of the 95 *H. pylori* isolates, 87 (91.6%) were *cag*PAI-positive, and the remaining 8 (8.4%) lacked all selected *cag*PAI genes. For the *cag*PAI-positive strains, intact *cag*PAI genes were detected only in 3 isolates, whereas other isolates exhibited partially deleted (rearranged) *cag*PAI genes. Additionally, the *IS605* gene was detected in 4 (4.2%) isolates. Further analyses indicated that the positivity of the *H. pylori* isolates was 61.1% (58/95), 53.7% (51/95), 4.2% (4/95), 82.1% (78/95), 76.8% (73/95) and 65.3% (62/95) for *cag67*, *cag10*, *cag13*, *cagT*, *cagM* and *cagE*, respectively.

Table 1 Distribution of *Helicobacter pylori cag*PAI genes isolated from patients of different ethnicities *n* (%)

*cag*PAI genes	Ethnic groups			*P* value
	Malay	Chinese	Indian	
cag Ⅰ region				
cagE	7 (58.3)	41 (69.5)	14 (58.3)	0.541
cagM	9 (75.0)	45 (76.3)	19 (79.2)	0.948
cag Ⅱ region				
cagT	11 (91.7)	49 (83.1)	18 (75.0)	
cag13	0	4 (6.8)	0	
cag10	6 (50.0)	29 (49.2)	16 (66.7)	0.336
cag67	6 (50.0)	47 (79.7)	5 (20.8)	< 0.0001

As shown in Table 1, the presence of *cagE* and *cagM* in the *cag*I region was distributed evenly among the isolates from patients of different ethnicities, with no significant differences between the ethnicities. The *cagT* gene was frequently detected in isolates from the Malay patients, whereas *cag13* was only detected in the isolates from the Chinese patients. The presence of *cag67* was significantly higher in the isolates from the Chinese patients than in the isolates from the Malay patients and was lowest in the isolates from the Indian patients. The *cag*PAI genes were detected in greater than 50% of the isolates from the nonulcer and ulcer patients, except for *cag13*, which was only detected in the patients with a normal stomach or gastritis. Thus, different *cag*PAI genes were present in the majority of the isolates examined, irrespective of disease state.

Of the 95 clinical isolates, only 3 (3.2%) contained an intact *cag*PAI, whereas 84 (88.4%) exhibited partial deletions within the *cag*PAI region, and 8 (8.4%) lacked the entire selected gene in the *cag*PAI. As shown in Table 2, thirteen isolates appeared to have a diverged *cag*PAI, in which the two selected genes for the *cag* Ⅰ region had been deleted, although the genes in the *cag* Ⅱ region were conserved, with at least one gene present. In contrast, ten strains had only one gene in either the *cag* Ⅰ or the *cag* Ⅱ region. The single gene detected was *cagM*, *cagT* and *cag67* in 3, 6 and 1 isolate, respectively. The most commonly partially deleted *cag*PAI genotypes were detected in 26 (27.4%), 16 (16.8%) and 13 (13.7%) isolates, with *cag*PAI regions of types C, I and N, respectively. These isolates exhibited at least four genes in the *cag*PAI region, and the genes in the *cag*I region were conserved in these isolates. Additionally, the *IS605* gene was detected in the isolates from the Chinese (n = 2) and Indian (n = 2) patients. Three of these isolates contained all of the selected genes for *cag*PAI, except *cag13*, and one isolate lacked the *cag13* and *cag10* genes.

As shown in Table 3, three isolates with an intact *cag*-

PAI were obtained from the Chinese patients. Nineteen of the 59 (32.2%) isolates from the Chinese patients possessed partially deleted *cag*PAI regions of type C, compared with 25% and 16.7% of the isolates from the Malay and Indian patients, respectively. Interestingly, the isolates from the Indian patients showed a high proportion of partially deleted *cag*PAI regions of type N (37.5%) and deleted *cag*PAI regions (16.7%). An analysis of the disease state, with reference to strain genotype, revealed a relationship between the *cag*PAI genotype and disease severity. The isolates from those patients with peptic-ulcer disease (PUD) primarily exhibited *cag*PAI regions of type C, which contained more genes in the rearranged *cag*PAI genotypes. In contrast, a larger number of isolates from the patients with pangastritis or antrum-predominant gastritis possessed *cag*PAI regions of type I or N, respectively, compared with the isolates from the patients with peptic ulcers.

vacA genotype

The *vacA* s1m1, s1m2 and s2m2 genotypes were identified in 51.6% (49/95), 42.1% (40/95) and 4.2% (4/94) of the isolates, respectively. Additionally, two (2.1%) isolates possessed the *vacA* s1m1m2 genotype. The *vacA* s1m1 genotype was further classified as *vacA* s1am1 (63.3%, 31/49), s1cm1 (22.4%, 11/49) or s1as1cm1 (14.3%, 7/49), and the *vacA* s1m2 genotype was further classified as *vacA* s1am2 (65%, 26/40), s1cm2 (22.5%, 9/40) or s1as1cm2 (12.5%, 5/40). An analysis of the distribution of the *vacA* alleles with respect to patient ethnicity and disease state is shown in Table 4. We found a significant distribution of different *vacA* alleles according to patient ethnicity. The *vacA* s1m1 genotype was significantly more prevalent in the isolates from the Malay and Indian patients, whereas the *vacA* s1m2 genotype was predominantly detected in the isolates from the Chinese patients ($P = 0.018$). The *vacA* s2m2 genotype was only isolated from the Malay and Indian patients, and a mixed genotype of the m region was identified in the isolates from the Chinese patients. Further analyses of the *vacA* subgenotypes with respect to patient ethnicity revealed that the highest proportion of isolates harbouring the *vacA* s1am1 subgenotype were from Indian patients (93.8%, 15/16). The prevalence of the *vacA* s1cm1 genotype was similar in proportion in the isolates from the Malay (37.5%, 3/8) and Chinese (32%, 8/25) patients, although this subgenotype was not detected in the isolates from the Indian patients. In contrast, the *vacA* s1am2 subgenotype was detected in all of the ethnic groups, whereas the *vacA* s1cm2 subgenotype was only identified in the isolates from the Chinese patients. No significant difference was observed in the distribution of the *vacA* s1m1 and s1m2 strains with respect to the disease state ($P = 0.686$).

Metronidazole susceptibility

In this study, metronidazole resistance was observed in 45.3% (43/95) of the isolates. The resistant strains exhibited MIC values ranging from 8 to > 256 mg/L, with an MIC value > 256 mg/L for the majority of the strains (62.8%, 27/43). As shown in Table 4, a strong association was observed between metronidazole susceptibility and patient ethnicity. The Chinese patients were more prone to infection with metronidazole-sensitive *H. pylori* strains, whereas the Malay and Indian patients were more likely to be infected with the antibiotic-resistant strains. The strains isolated from the patients with PUD were more sensitive to metronidazole than the strains from the patients with pangastritis, although this difference was not statistically significant. DNA sequence analyses of the *rdxA* gene revealed the presence of missense, frameshift and nonsense mutations in 30, 3 and 4 isolates, respectively. All of the tested metronidazole-sensitive strains harboured only missense mutations, whereas all three types of mutations were identified in the antibiotic-resistant strains.

Distribution of H. pylori cagPAI genotypes, vacA alleles and metronidazole susceptibilities

As shown in Table 5, the isolates with intact *cag*PAI regions carrying the *vacA* s1m2 allele were sensitive to metronidazole. Of the isolates with a rearranged *cag*PAI region, the type C strains predominantly harboured the *vacA* s1m2 allele, whereas a high proportion of the types I and N *cag*PAI strains harboured the *vacA* s1m1 allele. However, these strains were found to be more sensitive to metronidazole. In contrast, the isolates exhibiting a deleted *cag*PAI region predominantly carried the *vacA* s1m2 allele and were more resistant to metronidazole.

DISCUSSION

The *cag*PAI and *vacA* genotypes are widely used to characterise the virulence of *H. pylori* and the relationship of such virulence to disease severity, although direct associations with peptic ulcers and gastric cancer have not been established[22,23]. Rather, the development of severe histological changes in the gastric mucosa may depend on the synergistic effect of bacterial and host factors[24].

The genotypic characteristics of the *H. pylori cag*PAI genes show great variability worldwide. The rearrangement of the *cag*PAI varies between different populations and geographical regions, with variations of 50%-65% in areas of the Indian subcontinent[25,26], 32% in France[27], 9% in Sweden[28] and the United States[29] and 1% in Japan[30]. In the present study, more than 90% of the clinical isolates were positive for at least one of the selected *cag*PAI genes. The *cag*PAI genes tested in this study did not include the *cagA* gene, as we previously demonstrated[31] that the majority of the *H. pylori* strains circulating in our study population were *cagA*-positive. In the six genetic loci studied, the most frequently deleted gene was *cag13*, and the least frequently deleted gene was *cagT*. The IS605 insertion sequence was present in less than 5% of the *H. pylori* isolates examined, and the majority of the isolates harboured a rearranged *cag*PAI gene. Analyses of the individual *cag*PAI genes showed that *cag67* was more conserved in the isolates from the Chinese patients, whereas the rearrangement of *cagE* occurred at a higher frequency in the isolates from the Malay and Indian patients, although this difference was not significant.

We also observed that the majority of the *H. pylori* clinical isolates expressed partially deleted *cag*PAI regions and that only few isolates exhibited either intact or deleted *cag*PAI regions. Previous studies have reported the occurrence of different proportions of intact *cag*PAI in their isolates. Ali *et al*[32] found that 37.4% of isolates exhibited intact *cag*PAI regions, whereas other researchers[30,33] reported that more than 96% of isolates contained intact *cag*PAI. In the present study, the isolates expressing intermediate genotypes (deletions within the *cag*PAI region) were more commonly encountered than those isolates with intact or deleted *cag*PAI regions. Moreover, a large proportion of the isolates exhibiting *cag*PAI rearrangement lacked an IS605 sequence, suggesting that this insertion sequence did not play a role in *cag*PAI disruption in the clinical isolates.

Additionally, we found that no single gene in the *cag*PAI region can be used as a genetic marker for an intact *cag*PAI because a large proportion of the clinical isolates exhibited gene rearrangement in the *cag*PAI region. Due

Table 5 Distribution of *Helicobacter pylori cag*PAI genotypes, *vacA* alleles and metronidazole susceptibilities *n* (%)

*cag*PAI status	*vacA*		Metronidazole susceptibility		*vacA*/metronidazole susceptibility

[1]One strain with the *vacA* s1m1m2 genotype was not included; [2]Two strains with the *vacA* s2m2 genotype were not included.

to the region's large size (approximately 40 kbp), the absence of these genes in certain clinical isolates did not necessarily indicate the complete absence of the *cag*PAI, as indicated in 9 isolates positive for a single gene. Regarding *cag*PAI rearrangement, 19 different genotypes (types B to T) have been identified. The three most common *cag*PAI genotypes identified in the clinical strains revealed that the genes at the left end of the *cag*PAI region were more unstable and prone to rearrangement than the genes in the middle and at the right end of the *cag*PAI region. This finding was supported by analyses of the individual genes, which demonstrated more gene rearrangement at the left end of the *cag*PAI region (*cag13*, *cag10* and *cag67*). Therefore, the genes in the middle and at the right end of the *cag*PAI region may play an important role in the pathogenesis of *H. pylori* infection in the study population.

In the current study, specific *cag*PAI genotypes were isolated from patients of different ethnicities. All of the isolates with intact *cag*PAI regions and less *cag*PAI rearrangement were from the Chinese patients, whereas the Indian patients were infected with strains exhibiting more rearranged or deleted *cag*PAI regions, and the Malay patients tended to be infected with various *cag*PAI genotypes. Thus, the presence of different *cag*PAI genotypes in different ethnicities may be related to the genetic characteristics of both the colonising *H. pylori* strain and the host. Although the relationship between the *cag*PAI genotype and disease state was unclear, we observed that certain types of infecting strains exhibited different *cag*PAI rearrangements in nonulcer and ulcer patients.

A significant difference was observed in the prevalence of *vacA* genotypes among patients of distinct ethnicities. As the Chinese patients were more likely to be infected with the *vacA* s1m2 strains, these strains may be regarded as more pathogenic, consistent with previous reports showing a higher frequency of peptic ulcers and gastric cancer in the Chinese patients in a similar study population[15,34]. In our study population, the smaller proportion of patients with PUD than NUD may have contributed to the lack of a significant association between the endoscopic findings and patient ethnicity, as analysis was conducted on the samples with positive cultures. Additionally, we demonstrated that the *vacA* s1m2 genotype was significantly associated with enhanced gastric inflammation[10]. In contrast, the *vacA* s2m2 strains were isolated only from the Malay and Indian patients, suggesting that these strains are less virulent. Consistent with this finding, Chinese ethnicity has been associated with infection by strains lacking the *vacA* s2m2 allele[35,36]. As Miernyk *et al*[37] recently reported a high proportion of *vacA* s2m2 strains isolated from Alaskan natives, it would be interesting to examine whether the disease outcome in Alaskan natives is similar to the outcome in the Malay and Indian patients in our study population. The current study also revealed the proportions of different *vacA* subgenotypes in each ethnic population. More specifically, the *vacA* s1cm1 genotype was not detected in the isolates from the Indian patients, whereas the *vacA* s1cm2 genotype was only detected in the isolates from the Chinese patients.

A previous report demonstrated a higher prevalence of resistance to metronidazole than to other antibiotics in *H. pylori* isolates from Malaysia[14]. In the current study, we attempted to further relate the metronidazole susceptibility of *H. pylori* to patient ethnicity and to correlate this susceptibility with the *cag*PAI and *vacA* genotypes. We noted a significant association between the metronidazole-sensitive *H. pylori* strains and Chinese ethnicity, whereas the Malay and Indian patients were more likely to be infected with the metronidazole-resistant strains. This finding may reflect differences in metronidazole use between different ethnic populations. The pattern of metronidazole susceptibility in different ethnicities paralleled the specific genotypes of the infecting strains. For example, the strains of the specific *cag*PAI genotype and *vacA* allele isolated from the Chinese patients were more sensitive to metronidazole.

The presence of frameshift and nonsense mutations in the antibiotic-resistant *H. pylori* strains suggested that these mutations confer resistance to metronidazole. However, more than half of the resistant strains exhibited missense mutations that were also detected in the antibiotic-sensitive strains. This finding implied that *rdxA* is not the only gene involved in the metronidazole-resistant phenotype and thus is not a reliable epidemiological marker. Rather, other genes or mechanisms may be implicated in the generation of resistance[38-40].

We observed no association between the specific *H. pylori* genotypes and the strains' antibiotic susceptibilities

in severe disease. These results may be complicated by the fact that most of the patients in our study population had gastritis. Although the *cag*PAI and *vacA* alleles are important virulence factors in infection, the development of disease is likely to involve a highly complex interplay of many bacterial and/or host factors.

The distribution of the *vacA* s1m2 genotype was broad, as this genotype was detected in the majority of the strains with intact *cag*PAI regions or *cag*PAI rearrangement of type C (positive for more *cag*PAI genes than other types) and the metronidazole-resistant strains. This finding may indicate that the *vacA* s1m2 strains have variable pathogenic properties when combined with other genotypic characteristics. The isolates with the deleted *cag*PAI regions were also primarily linked to metronidazole resistance. As these isolates may induce less inflammation in the host gastric epithelia, their genotypic characteristics may reduce antibiotic delivery and thus hinder the eradication of *H. pylori*. In contrast, the *vacA* s1m2 genotype could not contribute to metronidazole resistance, as this genotype was distributed evenly between the antibiotic-sensitive and -resistant strains[41,42].

In conclusion, we report a large proportion of *H. pylori* isolates harbouring *cag*PAI rearrangement and demonstrate that metronidazole susceptibility varies with patient ethnicity. The distinct distribution of the *H. pylori* *cag*PAI genotypes, *vacA* alleles and metronidazole susceptibilities in the different ethnicities of Malaysia may contribute to varying risk of gastroduodenal diseases. These distinct, patient ethnicity-associated *H. pylori* genotypes may have important clinical and epidemiological implications. Finally, the present study of *H. pylori*-specific genotypes from different host genetic backgrounds enhances our understanding of bacterium-host interactions and bacterial ecology in various niches. Further information on the characteristics of *H. pylori* will allow a more precise identification of virulent strains and a better definition of risk factors in susceptible hosts.

We thank Universiti Kebangsaan Malaysia for providing both the permission and the facilities to conduct and publish this research. We are also grateful to all of the staff of the Endoscopy and Histopathology Units at UKMMC for their technical help.

COMMENTS

Background

The prevalence of *Helicobacter pylori* (*H. pylori*) infection in Malaysia consistently revealed ethnic differences, with Indians exhibiting higher infection rates than the Chinese and Malays. In contrast, peptic-ulcer disease and gastric carcinoma are known to be more prevalent in the Chinese and lowest in the Indians. The great genetic diversity of *H. pylori* may play an important role in the consequences of infection in different hosts. The *cag*PAI and *vacA* genes are well-established *H. pylori* virulence factors that interact with the host cells and disrupt downstream signalling pathways. The *cag*PAI structures, *vacA* alleles and metronidazole susceptibilities of different strains in hosts of varying genetic makeup may enhance the knowledge of bacterium-host interactions in *H. pylori* infections in multiethnic populations.

Research frontiers

The specific genotypes stemming from the *cag*PAI and *vacA* alleles were identified in *H. pylori* strains isolated from different ethnic groups. The strains isolated from the Chinese and peptic-ulcer disease (PUD) patients were more sensitive to antibiotics, indicating a selective advantage that occurred during early infection and persisted in chronic infection. In the present study, however, no association between the specific *H. pylori* genotypes and PUD could be determined due to the small number of PUD cases. Consistent with this observation, previous epidemiological studies have reported that less than 20% of patients infected with *H. pylori* are diagnosed as PUD.

Innovations and breakthroughs

Past reports have highlighted the importance of *H. pylori* genetic diversity in chronic infection. The current study emphasises and adds to findings from the same institution, demonstrating that the genetic background of the *H. pylori* strains may play an important role in the risk of gastroduodenal disease in different ethnic groups.

Applications

The results of this study provide insight into the effects of the genomic diversity of *H. pylori* on hosts of different genetic backgrounds. Therefore, these findings can be used in the development of advanced screening tools for diagnosing and determining the prognosis of *H. pylori* infection.

Terminology

The term *cag*PAI is defined as the *cag* pathogenicity island, a common gene sequence believed to be responsible for pathogenesis. This sequence contains approximately 40 kbp of nucleotides encoding over 40 genes. The pathogenicity island is typically absent from the *H. pylori* strains isolated from human carriers of *H. pylori* who remain asymptomatic.

Peer review

The authors investigated the diversity of the *H. pylori* virulence factors (the *cag*PAI and *vacA* alleles) and metronidazole susceptibilities of strains isolated from patients of different ethnicities. The association between specific *H. pylori* genotypes and patient ethnicity provides insight into the pathogenesis of *H. pylori* infection in different hosts and possibly the different risk factors in *H. pylori* infection.

Abstract

AIM: To determine an optimal cutoff value for abnormal splenic artery diameter/proper hepatic artery diameter (S/P) ratio in cirrhosis-induced portal hypertension.

METHODS: Patients with cirrhosis and portal hypertension (n = 770) and healthy volunteers (n = 31) underwent volumetric computed tomography three-dimensional vascular reconstruction to measure the internal diameters of the splenic artery and proper hepatic artery to calculate the S/P ratio. The cutoff value for abnormal S/P ratio was determined using receiver operating characteristic curve analysis, and the prevalence of abnormal S/P ratio and associations between abnormal S/P ratio and major complications of portal hypertension were studied using logistic regression.

RESULTS: The receiver operating characteristic analysis showed that the cutoff points for abnormal splenic artery internal diameter and S/P ratio were > 5.19 mm and > 1.40, respectively. The sensitivity, specificity, positive predictive value, and negative predictive value were 74.2%, 45.2%, 97.1%, and 6.6%, respectively. The prevalence of an abnormal S/P ratio in the patients with cirrhosis and portal hypertension was 83.4%. Patients with a higher S/P ratio had a lower risk of developing ascites [odds ratio (OR) = 0.708, 95%CI: 0.508-0.986, P = 0.041] and a higher risk of developing esophageal and gastric varices (OR = 1.483, 95%CI: 1.010-2.175, P = 0.044) and forming collateral circulation (OR = 1.518, 95%CI: 1.033-2.230, P = 0.034). After splenectomy, the portal venous pressure and maximum and mean portal venous flow velocities were reduced, while the flow rate and maximum and minimum flow velocities of the hepatic artery were increased (P < 0.05).

CONCLUSION: The prevalence of an abnormal S/P ratio is high in patients with cirrhosis and portal hypertension, and it can be used as an important marker of splanchnic hemodynamic disturbances.

Zeng DB, Dai CZ, Lu SC, He N, Wang W, Li HJ. Abnormal splenic artery diameter/hepatic artery diameter ratio in cirrhosis-induced portal hypertension. *World J Gastroenterol* 2013; 19(8): 1292-1298 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1292.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1292

INTRODUCTION

Splanchnic and systemic hemodynamic disorders are

common in patients with cirrhosis[1,2]. The systemic hyperdynamic circulation manifests as increased cardiac output and heart rate, and decreased arterial blood pressure and systemic vascular resistance[3,4]. The splanchnic hemodynamic disorder mainly manifests as increased vascular resistance and comparative visceral ischemia, which are associated with hepatic encephalopathy, hepatorenal syndrome, and portal hypertension[5]. Currently, portal hypertension has been found to be attributed to abnormally high portal venous inflow and high resistance in the portal system[6].

The splanchnic hemodynamic disorder in portal hypertension has been studied in a few studies, and some results support the significance of splenic and hepatic artery changes in portal hypertension. As early as in 1970, Yamauchi *et al*[7] observed an increase in the radius of the splenic artery in patients with portal hypertension, and such increase was not present in splenomegaly without portal hypertension. They found an association between the radius of the splenic artery and portal pressure and the degree of reduction in the portal pressure after splenectomy in patients with portal hypertension, and the dilatation of the splenic artery was accompanied by an increase in the diameter of the proper hepatic artery in those patients[7]. Subsequent studies confirmed the increases in the diameters of the splenic and hepatic arteries in patients with liver cirrhosis as compared with healthy controls[8,9], and further found that changes in the splenic artery occur prior to the onset of clinically evident portal hypertension[8].

Splenic and hepatic arterial blood flow distribution abnormalities are also very common in patients who have received liver transplantation. A study by Quintini *et al*[10] confirmed that hepatic artery hypoperfusion in liver transplant recipients can be induced by increased portal venous blood flow because over-perfusion of the portal vein cleared adenosine at the terminal end of the hepatic artery, resulting in hepatic artery contraction, *i.e.*, "hepatic arterial buffer response". Persistence of this response may cause further deterioration of splenic and hepatic arterial blood flow abnormalities, and result in a series of related complications known as splenic artery steal syndrome (SASS) or splenic artery syndrome that includes liver dysfunction, ischemic bile duct injury, and graft dysfunction or loss. Kirbas *et al*[11] performed multi-detector computed tomography (CT) in post-liver transplanted patients, and the authors proposed that a splenic artery diameter > 4 mm or a splenic artery diameter/hepatic artery diameter ratio > 1.5 indicates presence of SASS, thus establishing the importance of splenic artery diameter and the splenic artery diameter/hepatic artery diameter ratio in the clinical diagnosis of splenic and hepatic arterial blood flow distribution abnormalities.

Small-for-size syndrome (SFSS) is a common clinical complication that occurs after segmental liver transplantation[12,13]. Although the pathogenesis of the SFSS is still controversial, it is assumed that portal hypoperfusion with high intravascular shear stress is a causative factor[14-16]. In 2003, a group of researchers reported that portal flow should be modulated perioperatively in adult living-donor liver transplantation if a suboptimal graft-to-recipient body weight ratio is accompanied by high recipient portal inflow[17]. The authors found that splenic artery ligation could decrease recipient portal inflow, increase recipient hepatic arterial flow, and resolve refractory ascites, and neither SFSS nor vascular complications occurred in recipients undergoing splenic artery ligation[17]. Gruttadauria *et al*[18] obtained similar findings when they applied splenic artery embolization (SAE) for the treatment of SFSS after living-related donor liver transplantation. Their results showed that clinical conditions in patients with SFSS rapidly improved after SAE, and they thought that early SAE can protect the segmental graft against the harmful effects of the portal overflow[18]. Other animal and clinical studies of patients with liver cirrhosis and idiopathic portal hypertension showed that splenectomy can reduce portal venous blood flow and portal venous pressure, and increase hepatic arterial blood flow[19,20].

In this study, we examined whether splenic artery diameter and the splenic artery internal diameter/proper hepatic artery internal diameter (S/P) ratio are of clinical significance in patients with cirrhosis and portal hypertension. We determined the optimal cutoff values for abnormal splenic artery diameter and S/P ratio, observed the prevalence of an abnormal S/P ratio, and studied the associations between the S/P ratio and major complications of portal hypertension in patients with cirrhosis. The preoperative and postoperative portal vein hemodynamic indexes were further compared in patients undergoing splenectomy to explore the significance of splenectomy in the treatment of portal hypertension and its complications.

MATERIALS AND METHODS

Participants

A total of 1000 patients with liver cirrhosis and portal hypertension who sought medical treatment at our hospital from January 2011 to May 2011 were recruited. All patients had a pathological diagnosis of liver cirrhosis. Clinical diagnosis of portal hypertension was made in the setting of end-stage liver disease, and in the presence of ascites and/or varices. Of the 1000 patients, 230 were excluded: 109 with hepatic artery variations, 66 with post-splenectomy, 51 with partial splenic artery embolization, and 4 with transjugular intrahepatic portosystemic stent shunting. Thus, a total of 770 patients with liver cirrhosis and portal hypertension were enrolled (554 males and 216 females), of whom 558 had biochemical examination results. Thirty-one healthy volunteers who participated in the donor screening for the living-related liver transplantation were also enrolled. This study was approved by the Institutional Review Boards of our hospital, and all the participants provided written informed consent.

Laboratory tests

All the patients received routine blood, coagulation, and liver function tests in a fasting state. The routine blood

tests were performed with an SYSMES-2100 automatic blood cell analyzer and reagents (SYSMES Co., Japan). Coagulation tests were performed with a CA-7000 automatic coagulation instrument and ancillary reagents (SYSMES Co., Japan). Liver function tests were performed with an AU5400 automatic biochemical analyzer and related reagents (Mishima Olympus Co., Japan).

Measurement of splenic and proper hepatic artery internal diameter

All the patients underwent abdominal enhanced computed tomography (CT) scanning with a General Electric (GE) Lightspeed VCT 64-slice scanner (GE, Milwaukee, WIS, United States). For scanning, the collimator width was 0.625 mm, the tube current was 380 mA, the tube voltage was 120 kV, the slice thickness was 5 mm, the slice interval was 5 mm, and the reconstruction slice thickness was 0.625 mm. A high-pressure syringe was used to inject 100 mL contrast agent iopromide (370 mg/mL) via the antecubital vein at a flow rate of 2.5-3.5 mL/s, and the scan phases were the arterial phase (20-25 s), venous phase (65-70 s), and delayed phase (180 s). The data were input into a GE ADW 4.3 image workstation, and multiplanar reconstruction, maximum intensity projection, and volume rendering post-processing were performed. The splenic and proper hepatic artery internal diameters were measured in the arterial phase. The internal diameter of the proper hepatic artery was measured within 1 cm from its origin. The internal diameter of the splenic artery was measured at 3 locations: within 1 cm from its origin, at the upper edge of the pancreas, and within 1 cm from the point where the splenic artery branches originate. The mean value was calculated and recorded as the internal diameter of the splenic artery. The S/P ratio was then calculated.

Measurement of hemodynamic indexes of portal vein and hepatic artery before and after splenectomy

The free portal venous pressure was measured by catheterization via the right gastroepiploic vein before and after splenectomy. Doppler ultrasound (Esaote, Italy) was used to measure the hemodynamic indexes of the portal vein and hepatic artery within 1 wk prior to splenectomy and within 2 wk after splenectomy. Indexes measured were the portal venous flow rate and the maximum and mean portal venous flow velocities, the flow rate and maximum and minimum flow velocities of the hepatic artery, and the resistance index (RI) of the hepatic artery.

Statistical analysis

Demographic characteristics were presented as number (%) for sex, causes of cirrhosis, and level of liver function, mean ± SD for age, and median [interquartile range (IQR): Q1-Q3] for the internal diameters of the splenic artery and proper hepatic artery and the S/P ratio because data were not normally distributed. Data of patients with cirrhosis and healthy controls were compared using Pearson χ^2 test for sex, two-sample *t* test for age, and Mann-Whitney *U* test for splenic artery diameter, proper hepatic artery diameter, and the S/P ratio, respectively. Receiver operating characteristic (ROC) curve analysis through binary logistic regression was carried out to identify the optimal cutoff values of abnormal internal diameter of the splenic artery and S/P ratio. The prevalence of an abnormal S/P ratio in patients with cirrhosis and portal hypertension was calculated based on the identified cutoff value. Associations between the S/P ratio and complications of cirrhosis and portal hypertension were analyzed using univariate logistic regression. The preoperative and postoperative portal vein hemodynamic indexes and routine blood test data of patients undergoing splenectomy were presented as mean ± SD or median (IQR: Q1-Q3) if data were not normally distributed. The preoperative and postoperative data were compared using paired *t* test or Wilcoxon sign-rank test if data were not normally distributed. All statistical assessments were two-tailed and the significance level α was set at 0.05. All statistical analyses were performed using SPSS 17.0 statistics software (SPSS Inc, Chicago, IL, United States).

RESULTS

Demographic characteristics of participants

A total of 770 patients with cirrhosis and portal hypertension (554 males and 216 females) and 31 healthy controls (16 males and 15 females) were enrolled. Their demographic characteristics are summarized in Table 1. The mean age of patients with cirrhosis and portal hypertension was 53.3 ± 11.3 years, and the mean age of healthy controls was 46.0 ± 12.0 years. Among the patients with cirrhosis and portal hypertension, 622 had cirrhosis due to hepatitis B, 61 had alcoholic cirrhosis, 39 had cirrhosis due to hepatitis C, 24 had autoimmune liver disease, 7 had drug-induced liver damage, 4 had Budd-Chiari syndrome, 4 had cirrhosis caused by hepatitis B and C, 3 had alcoholic cirrhosis with hepatitis B virus infection, 2 had idiopathic portal hypertension, 1 had hepatolenticular degeneration, 1 had cryptogenic cirrhosis, 1 had nonalcoholic fatty liver cirrhosis, and 1 had cirrhosis due to unknown cause.

Internal diameter of splenic artery and S/P ratio

Patients with cirrhosis and portal hypertension had a higher internal diameter of the splenic artery and S/P ratio than healthy controls (both, $P < 0.05$). The median internal diameter of the splenic artery was 5.35 mm (IQR: 4.67-6.18 mm) in patients with cirrhosis and portal hypertension and 4.60 mm (IQR: 4.32-5.32 mm) in healthy controls. The median S/P ratio was 1.48 (IQR: 1.19-1.82) in patients with cirrhosis and portal hypertension and 1.36 (1.13-1.48) in healthy controls (Table 1). The internal diameter of the proper hepatic artery was not significantly different between patients with cirrhosis and portal hypertension and healthy controls.

ROC curve analysis showed that the optimal cutoff values of abnormal internal diameter of the splenic artery and S/P ratio were > 5.19 mm and > 1.40, respectively (Figure 1). The sensitivity, specificity, positive pre-

[1]Indicates significant difference between patients with cirrhosis and portal hypertension and healthy controls. Data were presented as number (%) for sex, cause of cirrhosis, and level of liver function; mean ± SD for age; and median (interquartile range: Q1-Q3) for the internal diameters of the splenic artery and proper hepatic artery and the splenic artery internal diameter/proper hepatic artery internal diameter (S/P) ratio because data were not normally distributed. Data of patients with cirrhosis and healthy controls were compared using Pearson χ^2 for sex, two-sample *t* test for age, and Mann-Whitney *U* test for S/P ratio, respectively. NA: Not assessed.

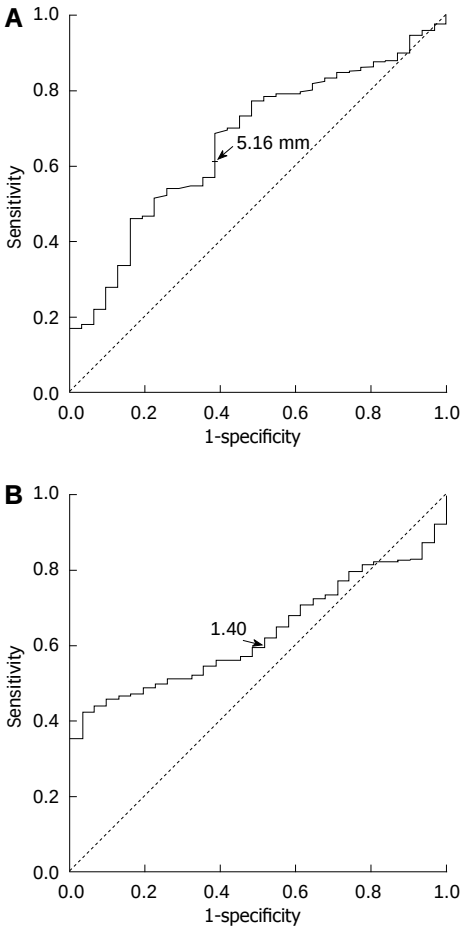

Figure 1 Receiver operating characteristic curve analysis for identifying the optimal cutoff values. A: Abnormal internal diameter of the splenic artery; B: Abnormal splenic artery internal diameter/proper hepatic artery internal diameter (S/P) ratio for patients with cirrhosis and portal hypertension. Binary logistic regression showed that the areas under the receiver operating characteristic curve were 0.667 (95%CI: 0.581-0.753) and 0.633 (95%CI: 0.572-0.694) for the internal diameter of the splenic artery and S/P ratio, respectively (both, $P < 0.05$). The optimal cutoff values were identified to be > 5.19 mm for abnormal internal diameter of the splenic artery and > 1.40 for abnormal S/P ratio.

dictive value, and negative predictive value were 74.2%, 45.2%, 97.1%, and 6.6%, respectively. Using the cutoff value of 1.40, 640 patients (83.4%) with cirrhosis and portal hypertension had an abnormal S/P ratio, and 28 healthy controls (90.3%) had a normal S/P ratio.

Associations between S/P ratio and complications in patients with cirrhosis and portal hypertension

Results of univariate logistic regression are presented in Table 2. The results showed that patients with a higher S/P ratio had a lower risk of developing ascites [odds ratio (OR) = 0.708, 95%CI: 0.508-0.986, $P = 0.041$]. However, patients with a higher S/P ratio had a higher risk of developing esophageal and gastric varices (OR = 1.483, 95%CI: 1.010-2.175, $P = 0.044$) and forming collateral circulation (OR = 1.518, 95%CI: 1.033-2.230, $P = 0.034$).

Portal vein hemodynamic indexes and routine blood test results in patients with cirrhosis and portal hypertension before and after splenectomy

A total of 17 patients with cirrhosis and portal hypertension underwent splenectomy. Table 3 presents the comparison of the preoperative and postoperative portal vein hemodynamic indexes in these patients. After splenectomy, the portal venous pressure and maximum and mean portal venous flow velocities were significantly reduced compared with the preoperative values (all, $P < 0.05$). The postoperative flow rate, maximum flow velocity, and minimum flow velocity of the hepatic artery were significantly higher than the preoperative values (all, $P < 0.05$). The RI of the hepatic artery was significantly reduced after splenectomy ($P < 0.001$).

Table 4 presents the comparison of the results of the preoperative and postoperative routine blood tests in patients with cirrhosis and portal hypertension who underwent splenectomy. After splenectomy, total bilirubin, direct bilirubin, white blood cell (WBC) count, and platelet count were significantly increased (all, $P < 0.05$), and creatinine levels were significantly decreased ($P < 0.05$).

DISCUSSION

The results of this study showed that patients with cirrhosis and portal hypertension had a significantly greater internal diameter of the splenic artery and higher S/P ratio than healthy controls, but not a significantly differ-

ent internal diameter of the proper hepatic artery. The finding of an increased diameter of the splenic artery in patients with cirrhosis and portal hypertension is consistent with the findings of prior studies[7-9]. The results indicate that excessive perfusion of the splenic artery increases the return blood flow in the splenic vein, thereby

increasing the blood flow in the portal venous system resulting in portal hypertension. However, an increase in the diameter of the hepatic artery was observed in patients with portal hypertension in some early studies[7-9], a finding not observed in our study. A possible reason for this discrepancy is that different imaging methods were used to measure the arterial internal diameter and current enhanced CT scanning is more accurate than the imaging methods used in earlier studies.

The optimal cutoff values for the abnormal internal diameter of the splenic artery and S/P ratio were identified to be > 5.19 mm and > 1.40, respectively, by the ROC curve analysis. When the abnormal S/P ratio > 1.40 was used, 83.4% of patients with cirrhosis and portal hypertension had an abnormal S/P ratio. The prevalence of an abnormal S/P ratio is very high in patients with cirrhosis and portal hypertension, indicating that an abnormal S/P ratio can be used as a marker of splanchnic hemodynamic disturbances in these patients. Machálek *et al*[21] summarized measurements of the splenic artery internal diameter of 30 normal spleens, and found that splenic artery thickening was indicated by an internal diameter of the splenic artery greater than 5.6 ± 1.3 mm. In our study, we found that an internal diameter of the splenic artery greater than 5.19 mm is the best cutoff value to predict cirrhosis and portal hypertension, which is consistent with the finding of Machálek *et al*[21]. Kirbas *et al*[11] proposed that a splenic artery diameter > 4 mm or a splenic artery diameter/hepatic artery diameter ratio > 1.5 indicates presence of SASS after liver transplantation, which is similar to the S/P ratio cutoff point of 1.40 for patients with cirrhosis and portal hypertension determined in our study. However, Kirbas *et al*[11] reported a much lower abnormal value for the internal diameter of the splenic artery than the value reported by Machálek *et al*[21] and our study, which may be due to the a different measurement method used by them.

Our results indicated associations between the S/P ratio and major complications in patients with portal hypertension. Patients with a higher S/P ratio had a lower risk of developing ascites (OR = 0.708, 95%CI: 0.508-0.986, $P = 0.041$) and a higher risk of developing *esophageal* and *gastric* varices (OR = 1.483, 95%CI: 1.010-2.175, $P = 0.044$) and forming collateral circulation (OR = 1.518, 95%CI: 1.033-2.230, $P = 0.034$). The results indicate that the S/P ratio has a great clinical significance for predicting major complications of portal hypertension in patients with cirrhosis.

Studies have also shown that splenectomy can reduce portal venous blood flow and portal venous pressure, increase hepatic arterial blood flow, and improve liver function, thereby decreasing major complications of portal hypertension[22,23]. Our study showed that splenectomy significantly reduced portal venous pressure and *maximum* and mean portal venous flow velocities, and increased the flow rate, maximum flow velocity, and minimum flow velocity of the hepatic artery. The study of SASS after liver transplantation by Mogl *et al*[24] found a significant elevation of the RI of the hepatic artery (0.79 ± 0.14) in patients with SASS, which was significantly reduced (0.65 ± 0.09) after splenic artery embolization. In our study, the preoperative and postoperative RIs of the hepatic artery were 0.74 ± 0.05 and 0.64 ± 0.07, respectively, which is consistent with the findings of Mogl *et al*[24], Our results also showed that postoperative WBC count and platelet levels were significantly increased compared with the preoperative values, indicating that these indexes can be restored to normal values. These results indicate that the major complications of cirrhosis and portal hypertension and splanchnic hemodynamic disturbances can be improved by splenectomy.

The hepatic-venous pressure gradient (HVPG) is the gold standard for the evaluation of the presence and severity of portal hypertension[25]. A limitation of this study is that portal hypertension was diagnosed using clinical criteria, but not based on HVPG results. In addition, the mean age of our healthy controls was younger than that of patients with cirrhosis and portal hypertension. However, the diameter of the splenic artery was not significantly affected by age or gender in adults.

In conclusion, the prevalence of an abnormal S/P ratio is high in patients with cirrhosis and portal hypertension, and it can be used as an important marker of splanchnic hemodynamic disturbances in these patients. The S/P ratio is closely related to major complications of portal hypertension including ascites, esophageal and gastric varices, and collateral circulation formation. Splenectomy is effective for decreasing portal venous pressure and delaying the progress of liver cirrhosis and portal hypertension.

We would like to thank Dr. Mao J for her help in writing and editing this paper.

COMMENTS

Background

The splanchnic hemodynamic disorder in portal hypertension has been studied, and the significance of splenic and hepatic artery changes in portal hypertension has been noted. In patients who have received liver transplantation, the importance of the splenic artery diameter and the splenic artery diameter/hepatic artery diameter ratio in the clinical diagnosis of splenic and hepatic arterial blood flow distribution abnormalities has been established.

Research frontiers

Splenic and hepatic arterial blood flow abnormalities are common in patients with cirrhosis and portal hypertension, but the clinical significance of the splenic artery diameter and splenic artery internal diameter/proper hepatic artery internal diameter (S/P) ratio in those patients has not been clearly elucidated.

Innovations and breakthroughs

For the first time, the authors determined the optimal cutoff values of abnormal internal diameter of the splenic artery and S/P ratio in patients with cirrhosis and portal hypertension, which were > 5.19 mm and > 1.40, respectively. A high prevalence of an abnormal S/P ratio and close associations between the S/P ratio and the major complications of portal hypertension including ascites, *esophageal* and *gastric* varices, and collateral circulation formation were found in patients with cirrhosis and portal hypertension.

Applications

The study results suggest that an abnormal internal diameter of the splenic artery and S/P ratio are of clinical significance in patients with cirrhosis and

portal hypertension, and an abnormal S/P can be used as an important marker of splanchnic hemodynamic disturbances in these patients.

Terminology

In this study, the splenic and proper hepatic artery internal diameters refer to the values measured in the arterial phase of abdominal enhanced computed tomographic (CT) scanning. The internal diameter of the proper hepatic artery was measured within 1 cm from its origin. The internal diameter of the splenic artery was measured at 3 places: within 1 cm from its origin, at the upper edge of the pancreas, and within 1 cm from the point that the splenic artery branches originate. The mean value was calculated and recorded as the internal diameter of the splenic artery. The S/P ratio was then calculated.

Peer review

It is a nice study which sought and found correlations between splenic artery internal diameter/proper hepatic artery internal diameter ratio, calculated by a non-invasive tool (3D CT scan) and clinical complications of portal hypertension. The study is original and the manuscript is well written.

Abstract

AIM: To investigate the feasibility and long-term functional outcome of ileal pouch-anal anastomosis with modified double-stapled mucosectomy.

METHODS: From January 2002 to March 2011, fourty-five patients underwent ileal pouch anal anastomosis with modified double-stapled mucosectomy technique and the clinical data obtained for these patients were reviewed.

RESULTS: Patients with ulcerative colitis (n = 29) and familial adenomatous polyposis (n = 16) underwent ileal pouch-anal anastomosis with modified double-stapled mucosectomy. Twenty-eight patients underwent one-stage restorative proctocolectomy, ileal pouch anal anastomosis, protective ileostomy and the ileostomy was closed 4-12 mo postoperatively. Two-stage procedures were performed in seventeen urgent patients, proctectomy and ileal pouch anal anastomosis were completed after previous colectomy with ileostomy. Morbidity within the first 30 d of surgery occurred in 10 (22.2%) patients, all of them could be treated conservatively. During the median follow-up of 65 mo, mild to moderate anastomotic narrowing was occurred in 4 patients, one patient developed persistent anastomotic stricture and need surgical intervention. Thirty-five percent of patients developed at least 1 episode of pouchitis. There was no incontinence in our patients, the median functional Oresland score was 6, 3 and 2 after 1 year, 2.5 years and 5 years respectively. Nearly half patients (44.4%) reported "moderate functioning", 37.7% reported "good functioning", whereas in 17.7% of patients "poor functioning" was observed after 1 year. Five years later, 79.2% of patients with good function, 16.7% with moderate function, only 4.2% of patients with poor function.

CONCLUSION: The results of ileal pouch anal anastomosis with modified double-stapled mucosectomy technique are promising, with a low complication rate and good long-term functional results.

INTRODUCTION

Ileal pouch anal anastomosis (IPAA) is the operative approach for patients requiring restorative proctocolectomy (RPC) due to familial adenomatous polyposis (FAP) and ulcerative colitis (UC). There are two types of IPAA have been performed: a handsewn technique with mucosectomy[1] and a stapling technique with the retention of the mucosa of the rectal stump[2]. Both approaches have advantages and disadvantages. For handsewn technique with mucosectomy, all colorectal mucosa is removed which is thought freeing the patients from the risk of further inflammatory disease, dysplasia or cancer in UC and reducing the risk of polyposis or cancer in FAP, but the manipulation of the anal canal and the excision of the anal transition zone (ATZ) is associated with significant impairment in anal sensation, therefore results in the risk of postoperative problems with continence[3]. For stapling technique with the retention of mucosa which is favoured as it is simpler and provides better functional results, the retention of the potentially diseased rectal mucosa exposes patients not only to disease recurrence but also to malignant degeneration[4,5].

We modify double-stapled techniques by sparing 5 cm short rectal muscular cuff and retaining the mucosa only in ATZ. The aim of this study is to evaluate whether ileal pouch-anal anastomosis with modified double-stapled mucosectomy is a safe and feasible procedure and its long-term functional outcomes.

MATERIALS AND METHODS

Between January 2002 and March 2011, 16 FAP patients and 29 UC patients received IPAA in our hospital. There were 22 males and 23 females with a mean age of 42.4 years (range: 17-67 years). The study is approved by the institutional ethics committee. The main symptoms included diarrhea, mucus or blood in the stool, abdominal pain, and weight loss. Colonoscopic examinations were performed in all patients, and biopsy results were consistent with adenomatous polyposis and ulcerative colitis. Malignant adenomatous polyps were found in three patients diagnosed with FAP.

Surgical procedure and technique

All patients underwent 2-stage procedures. For patients underwent elective surgery, we performed restorative proctocolectomy, ileal J-pouch anal anastomosis and protective ileostomy. Ileostomy was closed 4-12 mo postoperatively.

For patients underwent urgent surgery, we performed colectomy and ileostomy in first stage. Six month later, the proctectomy and ileal J-pouch anal anastomosis were completed. No protective stoma was made.

The operative technique was performed as previously described[6] and is modified. After completing mobilization of the colon, the rectum and the ileocecal region, the end of the ileum (5 cm from the ileocecal region for patient with FAP and more than 15 cm for patient with UC) was cut and closed, a J-shaped pouch with a length of 15 cm was made using a linear stapler (Ethicon, PROXIMATE® Linear Cutter 100). Then, the rectum was resected at the level above the seminal vesicle and the specimen was removed (Figure 1). The mesoileum was trimmed to mobilize the pouch and eliminate any tension on it. A 2 cm incision at the end of pouch was made, the anvil was inserted into it after creating a purse-string suture. The anus was effaced using Lone-Star Retractor, 1:100 000 adrenaline normal saline is injected under the rectal mucosa to separate it from the muscular

Length of postoperative hospitalization, d [median (range)]	12 (9-35)
Interval to closure of the ileostomy, mo [median (range)]	5 (4-12)

UC: Ulcerative colitis; FAP: Familial adenomatous polyposis.

layer. The mucosal and submucosal tube was incised by needle diathermy from 2 cm above the dentate line to the apex of rectal cuff (Figure 2A). We performed transanal purse-string suturing of the rectum 2 cm above the dentate line using 2-0 monofilaments, the J-pouch was pulled down into the muscular cuff. Then, a circular stapler was inserted transanally, and the purse-string sutures were tightened to secure the stapler in place, the anvil was attached in position and the end-to-end anastomosis was created (Figure 2B).

The postoperative anal function was assessed by Kirwan classification[7] and Pouch-specific function score (Oresland score[8], range, 0-15, with a score of 15 denoting the poorest function). The Kirwan classification was graded as full continence, incontinence of gas, occasional minor soiling, frequent major soiling and incontinence. The Oresland score included items on number of daytime and nighttime bowel movements, seepage, pad usage, urgency, diet, medication, and social handicap. Individual items were summed to form an overall pouch-specific functional score (0 being the best score, 15 the worst) which was classified as indicating good functioning (score 0-4), moderate functioning (score 5-7) and poor functioning (score 8-15)[9].

Pouchitis was diagnosed by symptoms of bloody diarrhea, urgent need to pass stool, incontinence, and pain or discomfort while passing stool[10].

Data collected included patient demographics, operative time, operative blood loss, complications, mortality, re-operation rate, length of hospital stay, readmission rates and reasons for readmission, pouchogram details, time to ileostomy closure, follow-up and long-term functional outcome.

RESULTS

The study cohort included 29 UC patients and 16 FAP patients who were treated by ileal pouch anal anastomosis with modified double-stapled mucosectomy. Twenty-eight patients underwent a RPC + IPAA and protective ileostomy in one stage, the ileostomy was closed 4-12 mo postoperatively. Seventeen patients underwent restorative proctectomy and IPAA after previous colectomy with ileostomy, all of whom were UC patients.

Demographic and operative data for the patients are presented in Table 1. The median operative time was 225 min, and in 15 patients, the operative time was more than 4 h. The median estimated blood loss was 550 mL, with a maximum estimated blood loss of 1200 mL, 36 patients requires transfusion and the median volume of blood transfusion was 600 mL. The median postoperative hospitalization was 12 d. The median interval to closure of the ileostomy was 5 mo.

There were no instances of operation-related mortality. Morbidity within the first 30 d of surgery occurred in 10 (22.2%) patients. Three patients developed an intestinal obstruction and could be treated conservatively, but one of the patient had a repeated attack of incomplete intestinal obstruction postoperatively. Two patients developed pelvic abscess and requires percutaneous puncture drainage guided by computed tomography. Six infectious complications occurred in five patients, four wound infection, one urinary tract infection and one pulmonary infection, and all could be treated with prolonged antibiotics or dressing change.

The patients were followed-up for a median period of 65 mo (range, 12-110 mo). After the closure of stoma, mild to moderate anastomotic narrowing was seen in 4 patients (8.8%), the majority being easily managed with digital dilation in the outpatient department. one patient developed persistent anastomotic stricture and require transanal endoscopic microsurgery dilatation. Sixteen patients developed at least 1 episode of pouchitis and the cumulative risk of pouchitis was 35.6%. Two patients with malignant adenomatous polyps died 2 years and 2.5 years after surgery and only 2 patients diagnosed dysplasia by biopsy in the remaining patients.

The median 24 h bowel movements was 7 evacuations per day, 4 evacuations per day and 4 evacuations per day at 1 year, 2.5 years and 5 years after closure of stoma, more than half of the patients reported more than five stools throughout the day 1 year after closure of stoma, but stool frequency decreased gradually, stabilizing at less than five evacuations per day at 2.5 years, and it was five or less in 70% of patients after 5 years. The proportion of patients that had stools every night decreased from 62.2% to 22.8% from 1 to 2.5 years, but this parameter did not improve further after 2.5 years. Urgency of defecation remained unchanged after 2.5 years although there was a tendency towards more patients being able to defer defecation for a longer time. There was no incontinence in our patients. Moreover, impaired continence, a frequent problem initially, also diminished with time, occurring in 33.3% of patients at 1 year. At 2.5 years, however, soiling or seepage occurred in only 5.7% patients during daytime and 20% patients at night, suggesting that improvement of continence can

Functional Oresland score [median (range)]	15	6 (1-12)	3 (0-11)	2 (0-9)	

[1]Urgency of defecation is inability to defer evacuation for more than 30 min; [2]Social handicap is not able to resume full time occupation or to participate in social life; [3]χ^2 test of 45 patients.

be expected to occur even beyond one year. More than half patients mentioned dietary restrictions and 44% patients needed regular medication for stool regulation after 1 year, the rate decreased to 22.8% and 17.1% after 2.5 years and was 8.3% and 4.2% after 5 years. Less than 10% patients felt affected in their everyday life through the functional impairments after 5 years. The difference in 24-h stool frequency, night time defecation, Soiling or seepage at night, dietary restrictions and regular medication for stool regulation has statistical significance. Overall, the median functional Oresland score was 6, 3 and 2 after 1 year, 2.5 years and 5 years respectively. Nearly half patients (44.4%) reported "moderate functioning" (as described in Method), 37.7% reported "good functioning", whereas in 17.7% of patients "poor functioning" was observed after 1 year. Five years later, 79.2% of patients with good function, 4 patients (16.7%) with moderate function, only 4.2% of patients with poor function (Tables 2 and 3). Despite defects in function, patients' satisfaction was generally excellent. So far only one patients have preferred conversion to an ileostomy once more.

DISCUSSION

Restorative proctocolectomy, mucosectomy with ileal pouch-anal anastomosis has become widely accepted and is now considered the standard procedure for patients with ulcerative colitis as well as familial adenomatous polyposis since 1980s[11].

Since both UC and FAP are mucosal diseases, mucosectomy has the advantage of removing the diseased colorectal mucosa, particularly if taken down to the dentate line[12]. In both these conditions an ideal operation would remove all colonic and rectal mucosa thus exempting the patients from the risk of further inflammatory disease, dysplasia or cancer in UC and reducing the risk of polyposis or cancer in FAP. However, it has suggested that mucosectomy with a handsewn anastomosis results in poorer function, more than 50% of patients complained of seepage at night[13] and incontinence were inevitable in some of patients. Moreover, Bullard[14] looked at a 12 years long-term functional outcome using a questionnaire for 235 patients and found that most patients had stable pouch function over time, but a proportion(in 18% patients) suffered measurable deterioration particularly 12 or more years after surgery and improved function was found only in 1% patients. Without prophylactic surgical intervention, malignant transformation into carcinoma occurs in majority FAP patients in the fourth decade of life[15]. Therefore, most patients undergoing pouch surgery are younger and have a long life expectancy. Thus, long-term morbidity and functional outcome is important for their quality of life after surgery.

In order to improve the anal function and prevent incontinence, stapled anastomosis without mucosectomy which confers functional benefit compared with handsewn anastomosis and mucosectomy is performed by many surgeons, but the retained rectal mucosa is

Table 3 Kirwan classification after surgery *n* (%)

Kirwan classification	1 yr (*n* = 45)	2.5 yr (*n* = 35)	5 yr (*n* = 24)	*P* value[1]
Stage I (full continence)	30 (66.7)	28 (80)	19 (79.1)	0.785
Stage II (incontinence of gas)	5 (11.1)	3 (8.6)	2 (8.3)

thought a disease-bearing tissue, if left untreated, may present a significant future risks for disease recurrence or malignant transformation[16] and lifelong surveillance is required for these patients[17].

The idea of the modified double-stapled mucosectomy technique was born as a result of the aforementioned disadvantages associated with the previous techniques. The characteristics of our technique is that we retain 5 cm short rectal muscular cuff, remove great part of rectal mucosa excluding the mucosa in ATZ which is usually commenced just above the dentate line and situated a median of 1.05 cm above the lower border of the internal sphincter[18]. Because of the preservation of mucosa in ATZ which is important for anal sensation[19,20], functional results are significantly improved in our series. There was no incontinence in our patients, soiling or seepage occurred in only 5.7% patients during daytime and 20% patients at night after 2.5 years. After 5 years, 24-h stool frequency was five or less in 70% of patients and only 4.2% patients needed regular medication for stool regulation. Most patients can restore normal life and patients' satisfaction was generally excellent. So far only one patients have preferred conversion to an ileostomy once more. Furthermore, retention of 5 cm short rectal muscular cuff has the advantage of making the ileal pouch fully dilate to replace the function of rectum.

The main debate of our technique is regarding the risk of dysplasia and ongoing inflammation in the retained rectum because this method leaves behind intact mucosa of the ATZ. Although residual mucosa can remain inflamed in patients and may become dysplastic, anal transitional zone dysplasia after ileal pouch-anal anastomosis is infrequent, Remzi reported the incidence of dysplasia after stapled RPC was 3%-4.5%[21] and it had not been substantiated that preservation of ATZ lead to the development of cancer in the ATZ. We think it is a inspiring result and take the following measures to minimize the risk. Firstly, cancer risk may be reduced by ensuring that a minimal length of rectal mucosa to be retained. In carrying out our modified double-stapled IPAA, the anastomosis should be performed at a lower level just above the ATZ. Secondly, we recommended that long-term monitoring is necessary and it is easy to find lesions by digital rectal examination when the level of the anastomosis is lower. In such cases, trananal biopsy is convenient. In our study, only 2 patients (4.4%) diagnosed dysplasia by biopsy during the median follow-up period of 65 mo and no patient finds development of adenocarcinoma in the ATZ.

Our study showed a better outcome regarding pelvic-related postoperative complications, only two of the patients (4.4%) developed a peripouch-localized abscess without systemic signs of infection and could be treated by percutaneous puncture drainage which are better than previously reported rates of pelvis sepsis following pouch surgery[22,23]. Thus, we speculate that the retention of rectal muscular cuff has no relation with the pelvic-related infectious complications and retention of short rectal muscular cuff (only 5 cm) can reduce the operative time and the possibility of bleeding. Furthermore, we don't suture the J-pouch with the rectal cuff and the tissue space was blocked out by fibrin glue which can protect against pelvic sepsis, if there is anastomotic leakage, symptoms will be minimized.

On the other hand, the choice of IPAA technique should be based on the situation of patients to make a comprehensive consideration for both oncologic and functional outcome. When the patients at high risk of cuff dysplasia or inflammation, we think it is better to perform a handsewn technique with mucosectomy rather than attempting stapling technique with the retention of partial mucosa of the rectal stump in order to avoid carcinoma formation after IPAA.

Several limitations of our study should be noted. The design was retrospective and our modified technique was not compared with the handsewn technique or the standard stapling technique of the same surgeon. Another study limitation is the small number of patients. Despite being a modified technique of IPAA, small patient numbers precluded robust analysis of the association between clinical and postoperative outcome.

In conclusion, ileal pouch-anal anastomosis with modified double-stapled mucosectomy seems to be a technically feasible and clinically acceptable alternative procedure for the removal of potentially diseased rectal mucosa retained only in ATZ to achieve an improved anal function after surgery.

COMMENTS

Background

Ileal pouch anal anastomosis (IPAA) is the operative approach for patients requiring restorative proctocolectomy due to familial adenomatous polyposis and ulcerative colitis. But the conventional handsewn technique or stapling

technique have their disadvantages such as poor postoperative anal function or disease recurrence. Modify double-stapled techniques by sparing 5 cm short rectal muscular cuff and retaining the mucosa only in anal transition zone is designed to ameliorate aforementioned disadvantages and improve the clinical effects.

Research frontiers

Handsewn technique with mucosectomy and stapling technique with the retention of the mucosa of the rectal stump are the routine methods of IPAA. In the area of improving anal function and reducing the risk of disease recurrence, the research hotspot is to deeply understand the anatomy of anus and modify the surgical technique.

Innovations and breakthroughs

In the previous reports of IPAA, the most applicable methods are handsewn technique with mucosectomy and stapling technique with the retention of the mucosa of the rectal stump. The authors modify double-stapled techniques by sparing 5 cm short rectal muscular cuff and retaining the mucosa only in anal transition zone. This is the first study to report the long-term functional outcomes with this technique in China. Furthermore, the results of the modified technique are promising, with a low complication rate and good long-term anal function.

Applications

The study results suggest that ileal pouch anal anastomosis with modified double-stapled mucosectomy is a feasible surgical technique for patients with familial adenomatous polyposis and ulcerative colitis.

Terminology

Ileal pouch-anal anastomosis: IPAA is constructed for people who have had their large intestine surgically removed due to disease or injury. It is formed by folding loops of small intestine (the ileum) back on themselves and stitching or stapling them together. The internal walls are then removed thus forming a reservoir. The reservoir is then stitched or stapled with the anal mucosa. Familial adenomatous polyposis: Familial adenomatous polyposis is an inherited condition in which numerous polyps form mainly in the epithelium of the large intestine. While these polyps start out benign, malignant transformation into colon cancer occurs when not treated; Ulcerative colitis: Ulcerative colitis is a form of inflammatory bowel disease, a disease of the colon, that includes characteristic ulcers, or open sores. The main symptom of active disease is usually constant diarrhea mixed with blood, of gradual onset; Anal transition zone: Anal transition zone is usually commenced just above the dentate line and situated a median of 1.05 cm above the lower border of the internal sphincter. It is important for anal sensation.

Peer review

Interesting paper, some fine tuning is needed but certainly adds to the knowledge.

Abstract

AIM: To determine the effect and molecular mechanism of ezrin-radixin-moesin-binding phosphoprotein-50 (EBP50) in hepatocellular carcinoma (HCC).

METHODS: Three human HCC cell lines, *i.e.*, SMMC7721, HepG2 and Hep3B, were used. We transfected the Pbk-CMV-HA-EBP50 plasmid into SMMC7721 cells with Lipofectamine 2000 to overexpress EBP50. Western blotting were performed to determine the effects of the plasmid on EBP50 expression and to detect the expression of β-catenin and E-cadherin before and after the transfection of the plasmid into SMMC7721 cells. *In vitro* cell proliferation was assessed with a Cell Counting Kit-8 (CCK-8) assay. Cell cycle distribution was assessed with flow cytometry. Invasion and migration ability of before and after the transfection were determined with a transwell assay. Cell apoptosis was demonstrated with Annexin V-FITC. The effect of EBP50 overexpressing on tumor growth *in vivo* was performed with a xenograft tumor model in nude mice.

RESULTS: The transfection efficiency was confirmed with Western blotting (1.36 ± 0.07 *vs* 0.81 ± 0.09, $P < 0.01$). The CCK8 assay demonstrated that the growth of cells overexpressing EBP50 was significantly lower than control cells ($P < 0.01$). Cell cycle distribution showed there was a G0/G1 cell cycle arrest in cells overexpressing EBP50 (61.3% ± 3.1% *vs* 54.0% ± 2.4%, $P < 0.05$). The transwell assay showed that cell invasion and migration were significantly inhibited in cells overexpressing EBP50 compared with control cells (5.8 ± 0.8 *vs* 21.6 ± 1.3, $P < 0.01$). Annexin V-FITC revealed that apoptosis was significantly increased in cells overexpressing EBP50 compared with control cells (14.8% ± 2.7% *vs* 3.4% ± 1.3%, $P < 0.05$). The expression of β-catenin was downregulated and E-cadherin was upregulated in cells overexpressing EBP50 compared with control cells (0.28 ± 0.07 *vs* 0.56 ± 0.12, $P < 0.05$; 0.55 ± 0.08 *vs* 0.39 ± 0.07, $P < 0.05$). *In vivo* tumor growth assay confirmed that up-regulation of EBP50 could obviously slow the growth of HCC derived from SMMC7721 cells (28.9 ± 7.2 *vs* 70.1 ± 7.2, $P < 0.01$).

CONCLUSION: The overexpression of EBP50 could inhibit the growth of SMMC7721 cells and promote apoptosis by modulating β-catenin, E-cadherin. EBP50 may serve asa potential therapeutic target in HCC.

cancer. *World J Gastroenterol* 2013; 19(8): 1306-1313 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1306.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1306

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third most common cause of mortality due to cancer in the world[1]. The low rate of early diagnosis renders the tumors unresectable and results in metastasis to the lymph nodes or distant organs. In addition, HCC cells are relatively resistant to chemotherapy; thus, the overall survival rate is poor. Recently, targeted molecular therapy has been shown to be effective in treating HCC, which encouraged us to study the cellular and molecular mechanisms of HCC and identify more effective treatments.

The etiology of hepatocarcinogenesis is still not fully understood, the activation of oncogenes, dysfunction of tumor suppressor genes, and aberrant activation of signal transduction pathways have been described. β-catenin is a key effector molecule in the Wnt signaling pathway and also plays an important role in cell-cell adhesion[2,3]. E-cadherin is a member of the cadherin family and is a classical type I cadherin. Both β-catenin and E-cadherin are membrane-associated proteins that are essential for regulating and providing cellular adhesion. Membrane-associated adhesion proteins regulate cell motility, including metastasis and invasion, and they link the extracellular matrix and actin cytoskeleton, which is critical in many biological signal transduction pathways. β-catenin and E-cadherin dysfunction has been described in several tumors, such as breast[4], prostate[5], gastric[6], colorectal[7], lung[8], oral[9] and hepatocellular carcinoma[10].

Ezrin-radixin-moesin-binding phosphoprotein-50 (EBP50, also known as NHERF1) is a 55-kDa phosphoprotein, and it belongs to the family of PDZ scaffolding proteins. Previous studies suggest that EBP50 is a potential tumor suppressor in several types of tumors[11-15]. Our previous studies also showed that EBP50 can inhibit the growth of gastric and pancreatic cancer cells[16,17]. EBP50 is mainly localized at the apical plasma membrane in human epithelial tissues[18]. The loss of normal apical membrane expression and/or distribution to the cytoplasm and nuclear overexpression was found in several human cancers[12-15,18]. Shibata *et al*[19] found that 45% of HCC cases expressed high levels of EBP50 mRNA, and 55% of HCC cases showed no difference. The cytoplasmic and nuclear accumulation of the EBP50 protein was present in 55% of HCC tissues compared with the surrounding noncancerous liver tissue, and EBP50 interacts with β-catenin to participate in hepatocarcinogenesis. The role of EBP50 as an oncogene or a tumor suppressor in HCC remains unclear.

In this study, we examined the effects of EBP50 upregulation on cell growth, migration, invasion, and apoptosis in the HCC cell line SMMC7721 and determined the expression of β-catenin and E-cadherin to elucidate the role of EBP50 in HCC.

MATERIALS AND METHODS

Cell lines and plasmids

The human HCC cell lines Hep3B, SMMC7721, HepG2 were obtained from the Cell Bank of Shanghai Institute for Biological Sciences (Shanghai, China). Of the three cells lines, the SMMC7721 cell line has relatively low EBP50 protein expression levels. These cells were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum at 37 ℃ in a humidified atmosphere of 5% CO_2. The pBK-CMV-HA-EBP50 plasmid was kindly provided by Dr. Randy Hall from Emory University (Atlanta, GA, United States).

Stable transfection

The pBK-CMV-HA-EBP50 plasmid or the pBK-CMV-HA vector was transfected into SMMC7721 cells with Lipofectamine^{TM} 2000 (Invitrogen, CA, United States) according to the manufacturer's protocol. G418 (350 μg/mL) was used to select stably transfected cells. Single-cell clones were isolated for clonal expansion. The transfection efficiency was determined with Western blotting. Subsequently, stably transfected cell clones were cultured and amplified in culture medium supplemented with 350 μg/mL G418.

Cell proliferation assay

The cell-counting kit-8 (CCK-8, Dojindo, Japan) colorimetric assay was used to measure cell proliferation and viability with triplicate experiments for each set of conditions. We seeded 5×10^3 cells per well in a 96-well plate. Cell viability was assessed using the Cell Counting Kit after culture for 24 h. The absorbance at 450 nm wasmeasured with a plate reader.

Western blotting

Western blotting was performed as described previously[20]. The specific antibodies were rabbit anti-EBP50 antibody (1:1000, Abcam; Pierce, GA, United States), rabbit anti-β-catenin antibody (1:1000, Abcam), mouse anti-E-cadherin antibody (1:1000, Abcam), and mouse anti-β-actin antibody (1:1000, Abcam).

Transwell assay

Invasion through a Matrigel-coated filter was measured in transwell chambers (Corning, New York, NY, United States) as described previously[14]. Cells (1×10^4) were trypsinized and suspended in the upper chambers. After incubation for 24 h, the transwell chambers were fixed with 4% paraformaldehyde and stained with Giemsa (Sigma). Cells in five randomly selected fields were photographed, and the number of trans-membrane cells wascounted.

Cell cycle assay

Cells were trypsinized and fixed in 70% ethanol on

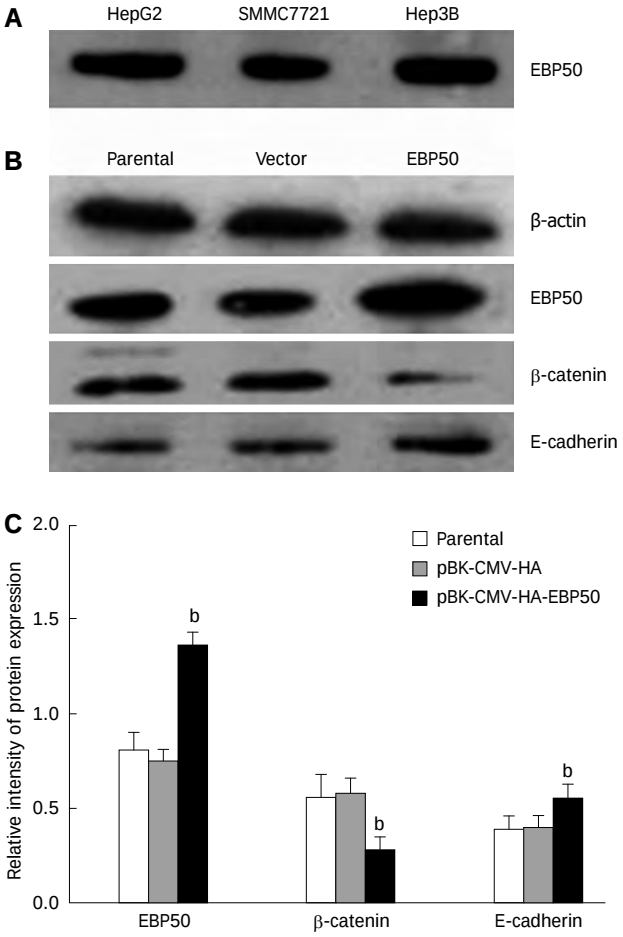

Figure 1 Ezrin-radixin-moesin-binding phosphoprotein-50, β-catenin, and E-cadherinprotein levels were detected with Western blotting. A: The expression of ezrin-radixin-moesin-binding phosphoprotein-50 (EBP50) protein in Hep3B, SMMC7721, HepG2; B: Western blotting analysis of EBP50, β-catenin, and E-cadherinprotein protein before and after transfection; C: Analysis of the expression of proteins. $^{b}P < 0.01$ *vs* parental or pBK-CMV-HA.

ice and then stained with 50 μg/mL propidium iodide (Sigma) and 0.1 μg/mL RNase A (Sigma). The cells were then analyzed with flow cytometry using a FACStar Plus, and Cell Quest software was used to calculate the percentage of the cell population in each phase.

Cellular apoptosis assay

Apoptosis was assessed with the Annexin V-FITC kit according to the manufacturer's protocol. A total of 1×10^6 cells/mL were washed twice with cold PBS and resuspended in binding buffer. A total of 5 mL of Annexin V-FITC and 10 mL of propidium iodide (PI) were added (BioVision, Mountain New, CA, United States), and the cells were incubated for 10 min at room temperature in the dark. At the end of the incubation, 200 μL of binding buffer was added, and the cells were immediately analyzed with flow cytometry. Cell Quest software was used to analyze flow cytometry data.

Ex vivo tumor growth assay

Male nude mice (4-6 wk old, $n = 6$) were (Beijing HFK Biosciencs Co., Ltd) used in the experiments. After alcohol preparation of the skin, 1×10^6 SMMC cells (pBK-CMV-HA-EBP50, pBK-CMV-HA vector and control cells), suspended in 100 μL PBS, were subcutaneously inoculated into the dorsal area of the nude mice. Six weeks after injection, At the end of the experiment, tumors were harvested and weighed. All experiments were performed according to the recommendations of the Institutional Animal Care and Use Committee, and the study protocol was approved by the Ethics Committee for Animal Research of Wuhan University, China.

Statistical analysis

The results were analyzed using SPSS 13.0 statistical software. All of the data are presented as the means ± SD. Statistically significant differences between groups in each assay were compared with a one-way analysis of variance (ANOVA), and $P < 0.05$ was considered to be statistically significant.

RESULTS

EBP50 expression in HCC cells

We used Western blotting to evaluate the expression of EBP50 in human HCC cell lines, with SMMC7721 expressing the lowest of the three cell lines (Figure 1). To investigate the role of EBP50 in HCC, we overexpressed EBP50 in SMMC7721 cells, which expressed relatively low levels of endogenous EBP50. SMMC7721 cells were transfected with pBK-CMV-HA-EBP50 or the pBK-CMV-HA vector to establish vector control cells. To evaluate the transfection efficiency, we determined the protein expression of EBP50 with Western blotting (Figure 1). The data showed that after transfection for 48 h, the protein levels of EBP50 were upregulated in pBK-CMV-HA-EBP50-transfected cells compared with pBK-CMV-HA vector-transfected cells and parental cells (1.36 ± 0.07 *vs* 0.81 ± 0.09 or 0.75 ± 0.06, $P < 0.01$).

Expression of β-catenin and E-cadherin in HCC cells

To investigate the biological effect of EBP50 in HCC and the potential signaling pathway through which it acts, we analyzed the expression of β-catenin and E-cadherin in pBK-CMV-HA-EBP50-and pBK-CMV-HA-transfected cells and untransfected cells. The protein levels of β-catenin was downregulated (0.28 ± 0.07 *vs* 0.56 ± 0.12 or 0.58 ± 0.08, $P < 0.05$) and E-cadherin (0.55 ± 0.08 *vs* 0.39 ± 0.07 or 0.40 ± 0.06, $P < 0.05$) was upregulated in pBK-CMV-HA-EBP50-transfected cells (Figure 1). The expression level was the same as previously reported by Hayashi *et al*[12].

Overexpression of EBP50 suppresses cancer cell growth

To assess the potential effects of EBP50 overexpression on cell proliferation and survival, we measured the number of viable cells at different times in vitro with CCK-8 assays. The pBK-CMV-HA vector had no effect on the proliferative ability of SMMC7721 cells, whereas pBK-

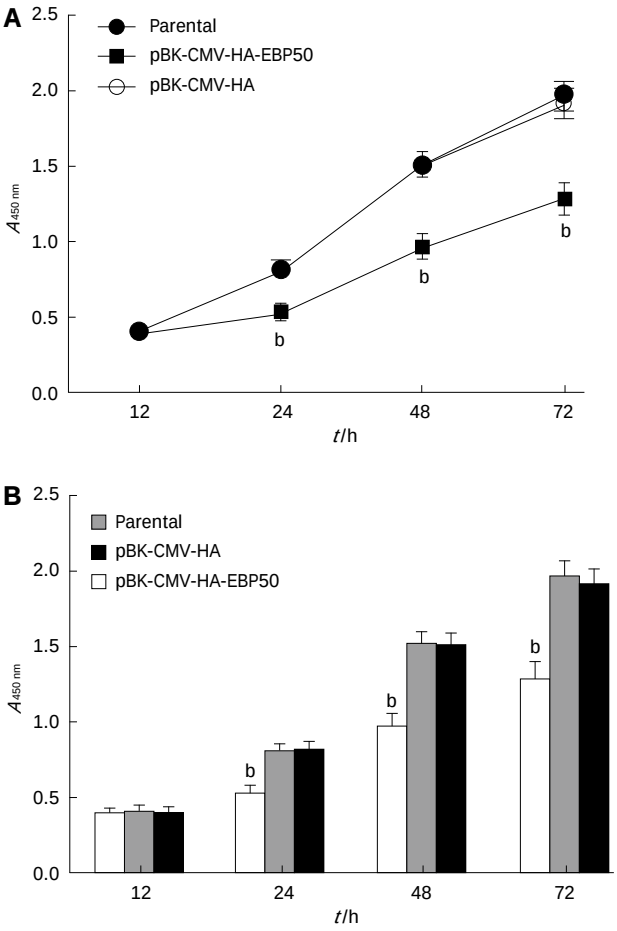

Figure 2 Growth rate comparison of parental, pBK-CMV-HA-EBP50, pBK-CMV-HA cells with a Cell Counting Kit-8 assay. A: Growth rate comparison of parental, pBK-CMV-HA-EBP50, pBK-CMV-HA cells; B: Analysis of the growth rate. $^{b}P < 0.01$ *vs* parental or pBK-CMV-HA.

CMV-HA-EBP50-transfected cells showed a dramatic reduction in proliferation ($P < 0.01$, Figure 2).

The cell cycle distribution was measured to determine whether the growth-inhibitory activity of EBP50 on SMMC7721 cell proliferation was due to cell cycle alterations. Compared with the control cells, the percentage of pBK-CMV-HA-EBP50 cells in G0/G1 phase was increased to 61.3% ± 3.1% from 54.0% ± 2.4% in parental cells and 54.5% ± 1.9% in mock cells ($P < 0.05$, Figure 3).

Overexpression of EBP50 suppresses cancer cell migration and invasion

We explored whether the over-expression of EBP50 resulted in decreased invasion and migration in cancer cells with a transwell assay. As shown in Figure 4A-D, the number of migrated pBK-CMV-HA-EBP50 cells (5.8 ± 0.8 cells/HP) was lower than the pBK-CMV-HA vector cells (20.4 ± 1.1 cells/HP) and parental cells (21.6 ± 1.3 cells/HP) ($P < 0.01$), which indicates that EBP50 could significantly suppress the invasive ability of SMMC7721 cells. No significant difference was found between SMMC7721 parental cells and the pBK-CMV-HA vector cells. The result showed that upregulating EBP50 expression in SMMC7721 cells inhibited tumor cell invasion and migration.

Overexpression of EBP50 promotes cell apoptosis

Apoptosis was investigated with an annexin V/propidium iodide assay. The pBK-CMV-HA-EBP50 cells showed an approximately fourfold increase in apoptosis ($P < 0.05$) compared with the parental group and the pBK-CMV-HA vector group (Figure 4E), suggesting that the pBK-CMV-HA-EBP50 plasmid enhances SMMC7721 apoptosis.

Overexpression of EBP50 decreased the growth of the tumor ex vivo

The cell growth response as result of NHERF1 overexpression was also examined in the nude mice model. We compared the growth of SMMC7721 cells infected with pBK-CMV-HA-EBP50, pBK-CMV-HA vector and control cells *ex vivo*. At 6 wk after inoculation, obvious tumors were formed in the two control groups of mice inoculated with SMMC7721 cells or the pBK-CMV-HA vector, while tumor growth was obviously suppressed in mice inoculated with pBK-CMV-HA-EBP50 cells. As shown in Figure 5, tumors formed from pBK-CMV-HA-EBP50 (28.9 ± 7.2 mg) were significantly smaller than those from pBK-CMV-HA and control cells (68.9 ± 7.9 mg, 70.1 ± 7.2 mg, $n = 6$) ($P < 0.01$), suggesting that expression of EBP50 suppressed tumor growth *ex vivo*.

DISCUSSION

In the present study, to determine the role of EBP50 in HCC as an oncogene or a tumor suppressor, we used the pBK-CMV-HA-EBP50 plasmid to increase the expression of EBP50 in SMMC7721 cells. Western blotting analysis proved that EBP50 protein levels were significantly upregulated in pBK-CMV-HA-EBP50-transfected SMMC7721 cells. The proliferation rate of cells over-expressing EBP50 was lower than the pBK-CMV-HA vector and parental SMMC7721 cells (Figure 2). In a transwell assay, the number of migrated cells over-expressing EBP50 was significantly lower than control cells, indicating that the over-expression of EBP50 can inhibit the anchorage-independent growth of HCC cells (Figure 4). Cellular apoptosis analysis showed that EBP50 overexpression could increase apoptosis and induce G0/G1 cell cycle arrest in HCC cells (Figures 3 and 4). *Ex vivo* tumor growth assay confirmed that cells overexpressing EBP50 could obviously slow the growth of HCC cells (Figure 5). Zheng *et al*[11] reported that EBP50 overexpression could inhibit breast cancer cell proliferation and promote cell apoptosis through decreasing ERK activation. The current study also suggests EBP50 as a potential tumor suppressor in HCC.

The molecular mechanisms through which EBP50 exerts its tumor suppressor functions are diverse. EBP50 contains two PDZ domains and an ERM domain. PDZ domains have been implicated in protein-protein interac-

tions, and the ERM domain binds to ezrin through its ERM-binding region[21]. In normal cells, EBP50 interact with cyclin dependent kinase and PP2A through its reversible phosphorylation of the protein to regulate cell division[22]. EBP50 interacts with many tumor-related proteins through these domains, including PTEN, PDGFR, EGFR, podocalyxin,and GPCRs, to participate in tumorigenesis[23-29]. EBP50 forms a complex with beta-catenin to promote Wnt signaling and may participate in the development of HCC[19].

Both β-catenin and E-cadherin play an essential role in cell-cell junctions in Wnt signal pathway. β-catenin binds directly to the cytoplasmic tail of E-cadherin to form a bridge between E-cadherin and the actin cyto-

skeleton and stabilizes adherens junctions[30]. The plasma membrane localization of β-catenin allows it to function as a tumor suppressor by interacting with E-cadherin, and the phosphorylation of β-catenin results in its accumulation in the cytoplasm and translocation to the nucleus, which allows it to act as an oncogenic protein by increasing the transcription of genes involved in growth control[31]. The loss of membranous E-cadherin expression was found in highly aggressive tumors including HCC and contributed to their high metastatic potential[32-34]. Aberrant activation of Wnt/β-catenin signaling has been reported in a wide range of HCC[35].

In our study, EBP50 upregulation resulted in an increase in E-cadherin levels and a decrease in β-catenin levels. EBP50 is required to maintain a fraction of the cortical β-catenin protein at the membrane; EBP50 binds to the C-terminal PDZ motif of β-catenin through its PDZ2 domain, and this association is required for β-catenin localization at cell-cell junctions[36]. In EBP50-depleted cells, there was a shift of β-catenin to the nucleus and an increased invasiveness of cells[12]. In EBP50-deficient MEFs, disorganization of E-cadherin-mediated adherens junctions and an increase in β-catenin transcriptional activity was observed[26], suggesting that the depletion of EBP50 decreased the interaction between β-catenin and E-cadherin. Because of the contributing role of β-catenin and E-cadherin in HCC hyperplasia and tumorigenesis[10,19], it is conceivable that the regulation of β-catenin/E-cadherin as a result of EBP50 overexpression contributes to HCC initiation or progression.

Our results suggest a tumor-suppressing role of EBP50 and establish that it may be a promising target for therapeutic intervention in HCC. Additionally, the interactions of EBP50 with β-catenin/E-cadherin enhance the tumor suppressor properties of EBP50 in HCC.

ACKNOWLEDGMENTS

The Pbk-CMV-HA-EBP50 plasmid was kindly provided by Dr. Randy Hall from Emory University.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the fifth most common cancer globally and relatively resistant to chemotherapy, it encouraged us to study the cellular and molecular mechanisms of HCC targeted molecular therapy. ezrin-radixin-moesin-binding phosphoprotein-50 (EBP50) is a PDZ scaffolding protein, previous studies suggest that EBP50 is a potential tumor suppressor in colorectal, prostatic, biliary, breast, gastric and pancreatic cancer, and it has an abnormal expression in HCC. But EBP50 is an oncogene or a tumor suppressor in HCC remains unclear. The authors aimed to examine the role of EBP50 and whether it interact with the β-catenin/E-cadherin pathway in HCC.

Research frontiers

Targeted molecular therapy is a new effective treatment for cancer including HCC. EBP50 is a potential tumor suppressor in several cancers, but the role of EBP50 is an oncogene or a tumor suppressor remains controversial and its exact role in HCC remains unknown.

Innovations and breakthroughs

Authors used a pBK-CMV-HA-EBP50 plasmid to overexpress EBP50 in SMMC7721 cells. The results showed that overexpression of EBP50 could inhibit the growth, migration, invasion of SMMC7721 cells and promote cell apoptosis, and modulate the expression of beta-catenin, E-cadherin. EBP50 may serve as a potential therapeutic target in HCC. It suggested that EBP50 is a tumor suppressor and interact with β-catenin/E-cadherin in HCC.

Applications

The results showed that EBP50 is a tumor suppressor and interact with β-catenin/E-cadherin in HCC. It may contribute to the future research of HCC and be a promising target for therapeutic intervention in HCC.

Terminology

Ezrin-radixin-moesin-binding phosphoprotein-50: EBP50 (also known as NHERF1) is a 55-kDa phosphoprotein; β-catenin: A adhesion protein, a key mediator in the canonical Wnt signal pathway; E-cadherin: A member of the cadherin family and is a classical type I cadherin.

Peer review

The function of EBP50 as a tumor suppressor has been studied in other cancers, but not in HCC. The expression in HCC was not significantly different between patient cases reported by Shibata *et al*. Thus they examined the effects of EBP50 up-regulation on cell growth, migration, invasion, and apoptosis in the HCC cell line SMMC7721 and determined the conclusion. This conclusion is meaningful in the sense characterized the function of EBP in HCC cells.

Abstract

Gastritis cystica profunda (GCP) is a rare condition caused by ectopic entrapment of gastric glands, probably secondary to the disruption of muscularis mucosae. GCP is often associated with gastric adenocarcinoma, and loss of the KCNE2 subunit from potassium channel complexes is considered a common primary target molecule leads to both GCP and malignancy. In this study, we, for the first time, analyzed the expression of KCNE2 in surgically excised tissue from human gastric cancer associated with GCP and confirmed that reduced KCNE2 expression correlates with disease formation.

Gastric adenocarcinoma arising in gastritis cystica profunda presenting with selective loss of KCNE2 expression. *World J Gastroenterol* 2013; 19(8): 1314-1317 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i8/1314.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i8.1314

INTRODUCTION

Gastritis cystica profunda (GCP) is a rare condition with nonspecific symptoms and radiographic images, making its diagnosis difficult without definitive surgical resection[1]. Clinically, GCP can be misdiagnosed as gastric lymphoma, stromal tumors, gastric cancer, or Menetrier disease. Histopathologically, GCP shows disruption of the integrity of muscularis mucosa that leads to cystically dilated submucosal glands with superficial inflammation in the lamina propria[1,2]. Since the majority of GCP cases are seen secondary to prolonged chronic inflammation, ischemia, gastric surgery and suturing material, an injury of the muscularis mucosae is assumed to trigger the ectopic entrapment of gastric glands in the submucosa, the muscularis mucosae or serosa and to lead to GCP[1,2]. Moreover, GCP is often associated with gastric adenocarcinoma indicates that it can lead to a secondary malignancy[2]. Indeed, experiments have shown that animals predisposed to Helicobacter infection develop not only secondary GCP but also subsequent gastric carcinoma[3]. This close association between GCP and malignancy has been interpreted as concurrent sharing of causative factors common to both disease conditions[1,3]. Recently, with the use of the KCNE2 (also known as MiRP1) deficient mouse model, loss of the KCNE2 subunit from potassium channel complexes is considered a common primary target molecule that gives rise to both GCP and malignancy[4].

Here, the expression of KCNE2 in surgically excised tissue from human gastric cancer associated with GCP is, for the first time, analyzed to confirm that its reduced level correlates with disease formation.

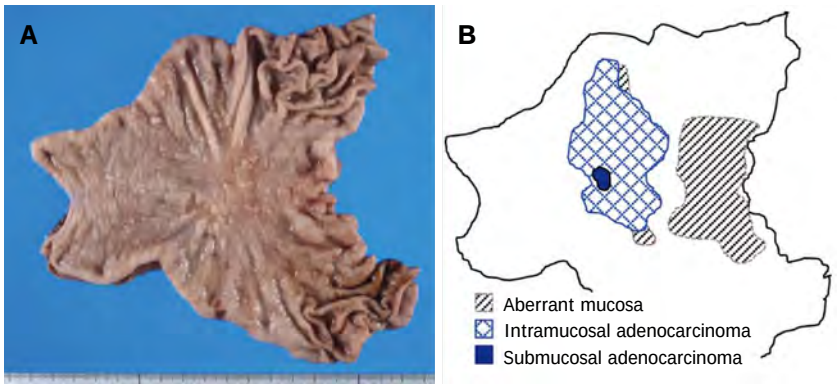

Figure 1 Macroscopic finding and distribution of ectopic cystic lesion and cancer in surgically excised stomach. Surgically excised stomach (A) and schematic distribution of the lesions (B). Ectopic cystic mucosa is located mainly on the oral side and partly in the body part overlapped with a cancer lesion (shaded area). A well- to moderately-differentiated tubular adenocarcinoma in the intramucosal layer (checked area) and part of a poorly-differentiated component infiltrating the submucosal layer (blue area) are located mainly in the body part of the stomach.

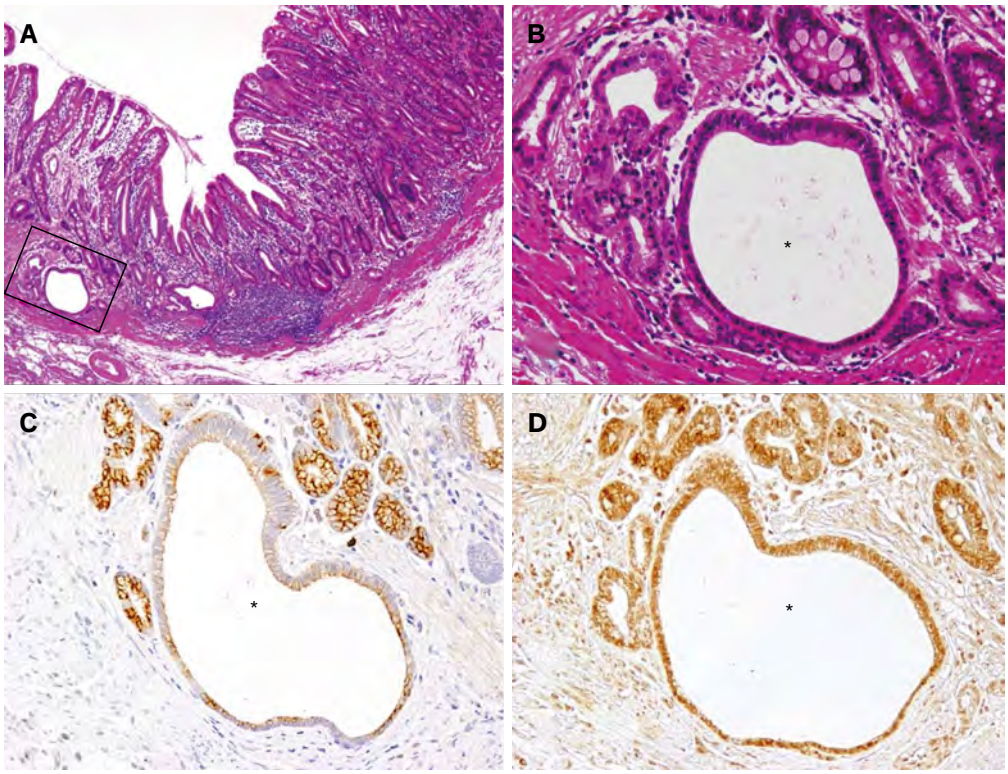

Figure 2 Expression of KCNE2 and estrogen receptor in non-neoplastic cystic lesion by immunohistochemistry. A: Low power magnification of a transitional area from the non-neoplastic mucosal layer with intramucosal cystic lesions (left) to the intramucosal adenocarcinoma (right, HE, × 40); B: High power magnification (A, squared area) around the intramucosal cystic lesion (asterisk, HE, × 200); C: KCNE2 immunostaining of a serial section of (B) shows that KCNE2 is almost negative in the dilated cystic gland (asterisk), while the surrounding non-cystic glands are positive (× 200); D: Estrogen receptor immunostaining of serial sections of (B) and (C) show that ER is equally expressed in both cystic (asterisk) and non-cystic glands (× 200).

CASE REPORT

A 63-year-old man was admitted to the hospital with the chief complain of abdominal pain. The patient's past medical and family history was unremarkable. An endoscopic and other examinations revealed the presence of multiple erosive lesions, and a biopsy demonstrated only severe superficial gastritis with erosion. Under the diagnosis of benign erosive gastritis, the patient was treated with medication and followed up monthly. After one year, however, a follow-up endoscopic examination revealed an irregularly-shaped ulcerating lesion, and the pathological diagnosis of adenocarcinoma was made through biopsy analysis. The patient underwent distal partial gastrectomy, and pathological examination of the excised stomach (Figure 1A) revealed the presence of ectopic cystic mucosa with intestinal metaplasia, especially in the oral side (Figure 1B, dotted area, Figure 2B: HE, × 200). Overlaying the ectopic cystic mucosa, a well- to moderately-differentiated tubular adenocarcinoma was

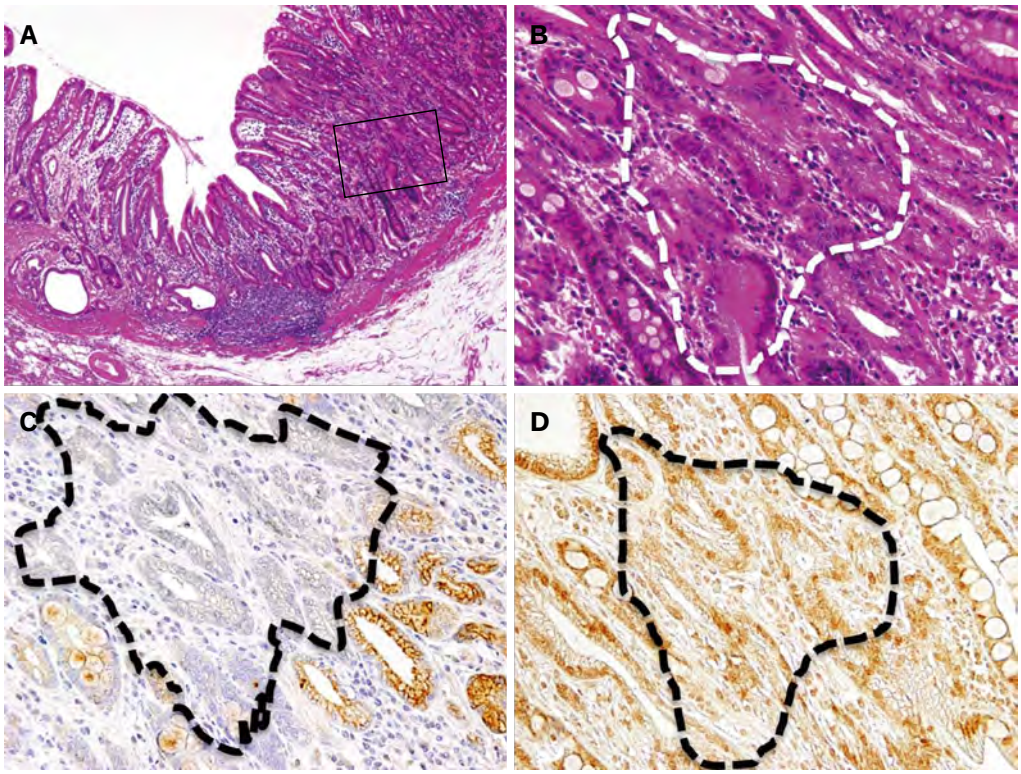

Figure 3 Expression of KCNE2 and estrogen receptor in adenocarcinoma area. A: Low power magnification of a transitional area from the non-neoplastic mucosal layer with intramucosal cystic lesions (left) to the intramucosal adenocarcinoma (right, HE, × 40); B: High power magnification (A, squared area) around the intramucosal adenocarcinoma (circled by white-hatched line, HE, × 200); C: KCNE2 immunostaining of a serial section of (B) shows that KCNE2 expression is almost negative in adenocarcinoma (circled by black-hatched line), while the surrounding non-neoplastic glands are positive (× 200); D: Estrogen receptor immunostaining of serial sections of (B) and (C) show that estrogen receptor is equally expressed in both cancerous (circled by black-hatched line) and non-neoplastic glands (× 200).

observed in the superficial proper mucosal layer (M), with part of a poorly-differentiated component infiltrating the submucosal layer (SM) in the body of the stomach (Figure 1B, hatched area, Figure 3B: HE, × 200). The pathological diagnosis of gastric adenocarcinoma arising in gastritis cystica profunda was made.

Immunohistochemistry

Since targeted deletion of *KCNE2* in mice causes gastric lesions resembling gastritis cystica profunda and gastric neoplasia[4], we examined the expression of KCNE2 in the current case immunohistochemically. Also, since signaling through the estrogen receptor (ER) modulates KCNE2 expression[5], we additionally examined the expression of ER. To determine the localization of KCNE2 and ER, rabbit polyclonal anti-KCNE2 antibody (ABCAM, Cambridge, United Kingdom) and rabbit monoclonal anti-ER (EST) antibody (EPIOTOMICS, United States) were used as primary antibodies. Tissue sections were deparaffinized in xylene for 20 min (solvent refreshed at 10 and 5 min) and immersed in absolute ethanol for 10 min (solvent refreshed at 5 min), then rehydrated in 90% and 70% ethanol (5 min each), and finally placed in distilled water for 15 min (solvent refreshed every 5 min). The samples were inactivated in 1 mmol/L EDTA (pH 8.0) plus distilled water in a microwave for 15 min (high heat for 5 min and low heat for 10 min), and then cooled to approximately 25 ℃ over 1 h. After being undergoing liquid block treatment, the samples were immersed in PBS for 15 min (solvent refreshed every 5 min). After adding blocking buffer to the moisture chamber and incubating the samples with primary antibodies at room temperature for 1 h, they were washed 3 times for 5 min each in PBS, incubated in the moisture chamber at room temperature for 30 min with the secondary antibody diluted at 1:200 with PBS, immersed in PBS for 15 min (solvent refreshed every 5 min), then incubated with DAB for 15 min and washed in PBS.

Immunohistochemical analyses revealed that KCNE2 was universally and strongly expressed on the surface of the cells at the bottom of the cryptic glands, while its expression was diminished in the cystic or dilated lesions (Figure 2C). ER expression was observed in both non-cystic and cystic glands (Figure 2D). In adenocarcinoma, KCNE2 expression was significantly reduced compared with the surrounding non-cancerous gastric mucosa with intestinal metaplasia (Figure 3C), while ER expression was observed in both cancerous and non-cancerous glands (Figure 3D).

DISCUSSION

In this study the expression status of KCNE2 in surgically excised gastric adenocarcinoma coexisting with GCP was examined in light of that the KCNE2-deficient mouse model develops both GCP and gastric cancer.

Since KCNE2 expression is modulated by ER, and since ER expression status per se is related to carcinogenesis and progression stages of gastric cancer[6], we additionally examined the immunohistochemical expression of ER in in the excised tissue.

KCNE2 has originally been identified as a potassium channel protein, and in the stomach, it is expressed mainly in the cytoplasm of parietal cells[5,7,8]. Reduction of KCNE2 in experimental animal models results in profoundly reduced proton secretion, abnormal parietal cell morphology, achlorhydria, hypergastrinemia[5,8], and striking gastric glandular hyperplasia arising from an increase in the number of non-acid-secretory cells[4]. Functionally, KCNE2 also exerts anti-proliferative effects on gastric cancer cells by down-regulating Cyclin D1 and restricting cell growth[5,8]. Indeed, reflecting anti-proliferative or tumor-suppressor functions of KCNE2, long-term observation of *KCNE2* -/- mice has revealed that reduced KCNE2 expression causes diffuse hyperplasia in gastric mucosa, resulting in a pathologic condition similar to gastric cancer associated with GCP[4].

We examined here, for the first time, the expression of KCNE2 in surgically excised stomach tissue demonstrating both GCP and adenocarcinoma. While KCNE2 expression in both GCP and adenocarcinoma areas was diminished, that in surrounding non-neoplastic and non-cystic cells was clearly maintained, as determined by immunohistochemical analysis. These data, albeit from a single case study, suggest that selective loss of KCNE2 expression is related to the development and clinical manifestation of GCP with subsequent occurrence of cancer. Furthermore, because selective loss of KCNE2 expression is seen at the level of a single cystic gland and cancer cell nest unit, silencing KCNE2 expression may occur at the level of a single tissue progenitor cell. Although the precise molecular mechanism of such selective loss of KCNE2 expression is largely unknown, it is at least not by the loss of estrogen receptor signaling. We believe that these new data are important because they confirm previous experimental information, and should be assessed in other similar cases. Further genetical and epigenetics studies based on a cumulative case study are needed to elucidate the role of KCNE2 expression in the development of GCP.

Abstract

Hepatitis B virus (HBV) reactivation is a well-recognized complication in patients with chronic HBV infection receiving cytotoxic or immunosuppressive chemotherapy. Imatinib mesylate and nilotinib are selective Bcr/Abl tyrosine kinase inhibitors, which are now widely used in the treatment of patients with chronic myeloid leukemia. Although HBV reactivation induced by imatinib mesylate has been reported, nilotinib-related HBV reactivation has not been reported in the English literature. We report here 2 cases of HBV reactivation in chronic myeloid leukemia patients receiving imatinib mesylate and a novel case of nilotinib related HBV reactivation.

INTRODUCTION

Hepatitis B virus (HBV) reactivation is a well-recognized complication in patients with chronic HBV infection receiving cytotoxic or immunosuppressive chemotherapy for hematologic malignancies[1-4]. Imatinib mesylate (IM) (Glivec; Novartis, Basel, Switzerland), a selective Bcr/Abl tyrosine kinase inhibitor (TKI), is now widely used in the treatment of chronic myeloid leukemia (CML) and gastrointestinal stromal tumors[5,6]. Nilotinib (Tasigna; Novartis, Basel, Switzerland), a second generation TKI, was approved in 2007 for CML patients with resistance or intolerance to IM[5]. Although HBV reactivation induced by IM has been reported[7-12], nilotinib-related HBV reactivation has not been documented in current literature. We report here 2 cases of HBV reactivation in CML patients receiving IM and a novel case of nilotinib related Hepatitis B virus reactivation. Possible mechanism of TKI related HBV reactivation is discussed in this manuscript.

CASE REPORT

Case 1

A 43-year-old man was a HBV carrier who received regular follow-ups at our institution. On December 2011, he was diagnosed with CML, which was confirmed by the presence of Philadelphia chromosome (Ph+) in cytogenetic study. He started to receive IM 400 mg once daily. The pretreatment liver panel were alanine transaminase (ALT) = 40 U/L (normal 11-40 U/L), total bilirubin = 0.8 mg/dL (normal 0.3-1.2 mg/dL), albumin = 3.5 g/dL (normal 3.5-5.5 g/dL) and prothrombin time = 11 s (normal 10-12 s). Major molecular response (MMR, < 0.1% Bcr-Abl/Abl ratio according to the international scale (IS)

was achieved after 3.5 mo of IM treatment. His liver tests were within normal limits until 6 mo after IM treatment, when he started to feel easy fatigue. The patient denied usage of other medications such as acetaminophen or herbs. Laboratory investigation revealed an increased aspartate aminotransferase (AST) level of 273 U/L and an increased ALT level of 1086 U/L (Figure 1A). Hepatitis B surface antigen (HBsAg) and hepatitis B e-antigen (HBeAg) were positive. HBV DNA was positive at a concentration of 229 254 031 IU/mL. Results for hepatitis A immunoglobulin M (IgM) antibody, hepatitis C antibody, cytomegalovirus (CMV), Epstein Barr virus (EBV) and herpes simples 1/2 (HSV) were negative. Antinuclear antibodies (ANA) and immunoglobulins were within normal limits. Other biochemical studies such as bilirubin, alkaline phosphatase, and albumin were normal. Liver ultrasonography showed coarse liver parenchyma and normal biliary tract. Because HBV reactivation was considered, he started to receive entecavir 0.5 mg once daily. IM was not discontinued. After 1-mo treatment with entecavir, his ALT level fell to 117 IU/L and HBV DNA level was 11 IU/mL, as demonstrated in Figure 1A. Clinical symptoms resolved 6 wk later with entecavir. Complete molecular response (CMR, < 0.0001% Bcr-Abl/Abl ratio according to the IS) was achieved 9 mo after IM treatment. The clinical course of this patient is summarized in Figure 1A.

Case 2

A 67-year-old man with history of diabetes mellitus and HBV carrier received regular follow-ups at our hospital. He was diagnosed with CML with initial presentation of leukocytosis and thrombocytosis. He started to receive IM 400 mg once daily after bone marrow biopsy and cytogenetic study. The pretreatment liver panel were ALT = 26 U/L, total bilirubin = 1.1 mg/dL, albumin = 4.8 g/dL and prothrombin time = 12.6 s. Complete cytogenetic response (CCyR, < 1% Bcr-Abl/Abl ratio according to the IS) was achieved 7 mo after IM treatment. However, jaundice and anorexia developed 53 mo after IM treatment. Laboratory studies revealed an increased AST level of 110 U/L and an increased ALT level of 374 U/L (Figure 1B). Total bilirubin level was 2.74 mg/dL. HBsAg and HBeAg were positive. HBV DNA was positive at a concentration of 12 165 714 IU/mL. Results for hepatitis A IgM antibody, hepatitis C antibody, HSV, EBV, CMV, ANA were within normal limits. Liver ultrasonography showed no biliary tract dilatation. Entecavir 0.5 mg once daily was prescribed under the consideration of HBV reactivation. IM was not discontinued. After 1-mo treatment with entecavir, his ALT level fell to 41 IU/L, as demonstrated in Figure 1B. HBV DNA level was 10 IU/mL 12 mo after entecavir administration. Status of CMR was achieved on April, 2011. The clinical course of this patient is summarized in Figure 1B.

Case 3

A 50-year-old woman was referred to our institution

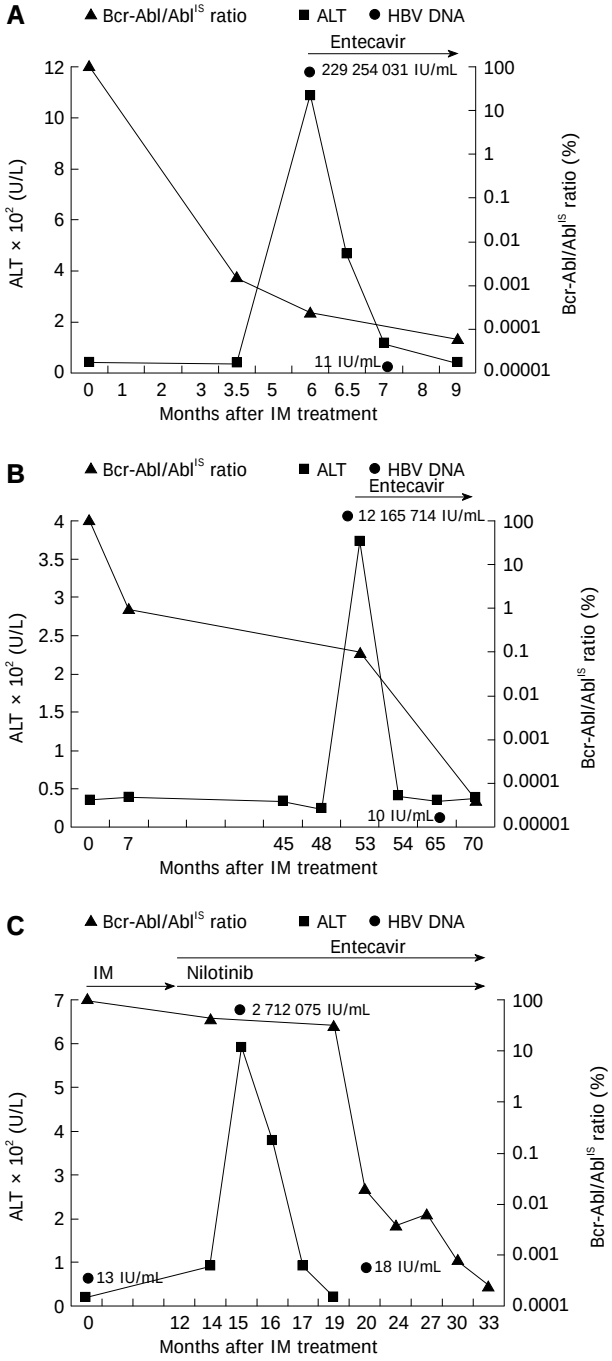

Figure 1 Clinical course of cases. A: Case 1, showing alanine transaminase (ALT) and Bcr-Abl/Abl^{IS} ratio over time; B: Case 2, showing ALT and Bcr-Abl/Abl^{IS} ratio over time; C: Case 3, showing ALT and Bcr-Abl/Abl^{IS} ratio over time. IM: Imatinib mesylate; IS: International scale.

on November 2009 for evaluation of leukocytosis, anemia, and thrombocytopenia. She was a HBV carrier. A diagnosis of CML was made based on the findings of proliferation of myeloid lineage cells and presence of Ph+ in bone marrow biopsy. IM 400 mg daily was used after diagnosis of CML. The pretreatment liver panel were ALT = 23 U/L, total bilirubin = 0.4 mg/dL, albumin = 4.1 g/dL and prothrombin time = 11 s. Because Bcr-Abl/Abl ratio was not significantly reduced 12 mo later with IM, treatment regimen was shifted to nilotinib

400 mg twice daily. However, 3 mo after treatment with nilotinib, the patient experienced tea-colored urine and easy fatigue. The patient denied usage of acetaminophen or herbs. Laboratory studies revealed an increased AST level of 346 U/L and an increased ALT level of 592 U/L (Figure 1C). Total-bilirubin level was 2.54 mg/dL. Coagulation profiles were normal. HBsAg was positive, whereas HBeAg was negative. Results for hepatitis A, hepatitis C, HSV, EBV, and CMV were negative. HBV DNA was positive at a concentration of 27 120 705 IU/mL. Liver ultrasonography showed normal results. Because HBV reactivation was considered, entecavir 0.5 mg once daily was prescribed. Nilotinib was not discontinued. After 2-mo treatment with entecavir, ALT level fell to 92 IU/L, as demonstrated in Figure 1C. HBV DNA was at a lower level of 18 IU/mL 6 mo after treatment with entecavir. Status of MMR was achieved 6 mo after entecavir treatment. The clinical course of this patient is summarized in Figure 1C.

DISCUSSION

HBV reactivation is characterized by an abrupt rise of HBV DNA in patients with previously inactive or resolved HBV infection during or closely after chemotherapy. The current generally accepted definition of HBV reactivation following chemotherapy is the development of hepatitis with a serum ALT greater than three times the upper limit of normal or an absolute increase of 100 IU/L, associated with a demonstrable increase in HBV DNA by at least a 10-fold[1,2]. HBV reactivation not only occurred in HBsAg-positive patients but also in HBsAg-negative patients with anti-hepatitis B core antibody positivity and/or anti-hepatitis B surface antibody positivity[1-4]. In a prospective study of 626 cancer patients undergoing chemotherapy, HBV reactivation occurred in nearly 20% of them[1]. The risk factors of HBV reactivation included male gender, younger age, HBeAg seropositivity, high pre-chemotherapy HBV DNA above 3×10^5 copies/mL, use of corticosteroids and anthracyclines, and duration of chemotherapy[1,4,13]. The pathogenesis of chemotherapy-induced HBV reactivation is not clear but may involve a 2-stage process, an initial immunosuppressive stage and an immune-restoration stage[3,4]. The initial immunosuppressive stage is characterized by marked increase in serum levels of HBV DNA and HBeAg. This stage is probably related to the suppression of immune mechanism that serves to control HBV replication. The immune-restoration stage occurs after subsequent withdrawl of immunosuppressive drugs, resulting in rapid destruction of infected hepatocyte.

IM, a rationally designed TKI that blocks the ATP-binding site of Bcr/Abl, is currently recommended as the first line therapy for CML[5,6]. However, resistance to IM may occur. Nilotinib was designed to overcome IM resistance with a better efficacy and mild adverse effects[5]. Hepatotoxicity has been reported in 1%-4% of CML patients treated with IM; however, liver dysfunction may resolve with either dose reduction or discontinuation of IM[14]. In the present study, the TKIs were not discontinued after hepatic flare. Hepatic dysfunction improved in three cases after receiving entecavir, thus excluding the possibility of considering IM or nilotinib related hepatotoxicity as the cause of hepatic flare in our study. In the third case of our study, the diagnosis of HBV reactivation was established by low pretreatment HBV load and high level at the time of hepatic flare. Although the HBV load was not examined before IM treatment in the first and second cases, HBsAg and HBeAg were positive before treatment and high level of HBV load was detected at the time of hepatic flare. It is reasonable to consider HBV reactivation as the cause of hepatic flare in these two cases of our study[15-18].

The mechanism of TKI-induced HBV reactivation remains unclear due to limited case reports. *In vitro* studies have shown that IM can inhibit T-cell activation[19] and proliferation[20]. Nilotinib inhibited the Src-family kinase LCK and T-cell function and hampered the proliferation and function of CD8+ T lymphocytes[21,22]. It is worth noting that HBV reactivation occurred after achieving MMR in the first case (Figure 1A) and after CCyR in the second case (Figure 1B), a similar condition as that in the report of Ikeda *et al*[7]. In the study of Mohamad *et al*[23], CML patients who were in complete molecular or cytogentic response after IM treatment restored function of plasmacytoid dendritic cells, which are crucial effectors in innate immunity. Therefore, the finding of hepatic flare after complete molecular or cytogenetic responses in the first two cases may provide evidence to support the hypothesis of immune-restoration stage of HBV reactivation. Furthermore, in the third case of our study, the hepatic flare occurred 5 mo before achieving CCyR (Figure 1C). This finding suggests that nilotinib treatment might provoke a different pathway other than that of IM to achieve immune restoration. Further studies may be needed to explain this observation. An important issue that should be addressed is the preemptive therapy with nucleoside/nucleotide analogues (NAs) in patients undergoing TKI therapy. Although preemptive treatment with NAs before immunosuppressive chemotherapy is recommended in European Association for the Study of the Liver Clinical Practice guidelines[24], there is no recommendation on whether NAs should be given in patients undergoing TKI therapy due to lack of prospective studies.

In conclusion, this case report highlights the importance that HBV reactivation may occur in hematologic patients undergoing TKI therapy. Once HBV reactivation is suspected during TKI treatment, early detection of HBV load and utilization of antiviral agent are suggested to achieve better clinical outcome.

Abstract

Multiple endocrine neoplasia type 1 (MEN1) is a rare hereditary syndrome known to predispose subjects to endocrine neoplasms in a variety of tissues such as the parathyroid glands, pituitary gland, pancreas and gastrointestinal tract. We herein report a patient with a past history of pituitary adenoma, presenting with symptoms of chronic diarrhea for nearly one year and a sudden upper gastrointestinal hemorrhage as well as perforation without signs. Nodules in the duodenum and in the uncinate process and tail of pancreas and enlargement of the parathyroid glands were detected on preoperative imaging. Gastroscopy revealed significant ulceration and esophageal reflux diseases. The patient underwent subtotal parathyroidectomy and autotransplantation, pylorus-preserving pancreaticoduodenectomy and pancreatic tail resection and recovered well. The results observed in our patient suggest that perforation and bleeding of intestine might be symptoms of Zollinger-Ellison Syndrome in patients with MEN1.

INTRODUCTION

Multiple endocrine neoplasia type 1 (MEN1) syndrome is transmitted as an autosomal dominant mutation of a suppressor gene located on chromosome 11q13 and it is a rare congenital disease. The classical clinical manifestation of MEN1 is composed of parathyroid hyperplasia, pancreatic endocrine tumor and pituitary adenoma[1]. The definition of MEN1 is the coincidence of at least two of the above mentioned tumors[1].

We herein report a case of MEN1 with sudden upper gastrointestinal hemorrhage and perforation 14 years after surgery for pituitary adenoma.

CASE REPORT

A 42-year-old man was hospitalized with symptoms of nausea, vomiting and diarrhea for more than one year. The patient, presenting with decreased vision, diminished interest in sex, fatigue, weakness and polyuria, was diagnosed with pituitary adenoma in 1998. His blood prolactin level was high (more than 200 ng/mL, reference range, 2-23 ng/mL). The patient underwent removal of the tumor *via* the trans-sphenoidal approach in February 1998. Histological examination of the surgical specimen

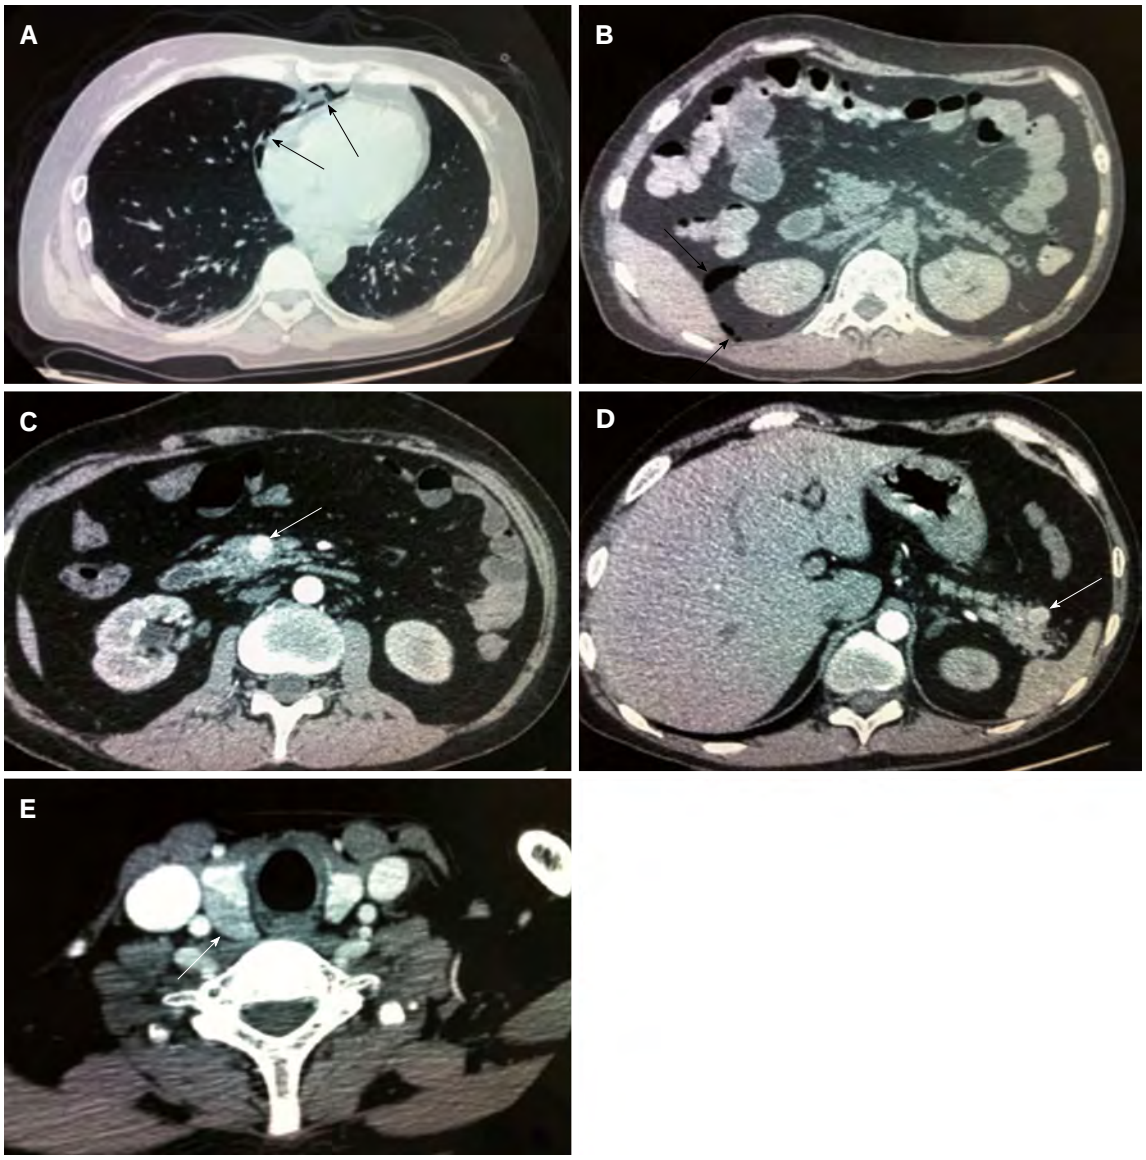

Figure 1 Computed tomography scan of the case. A: Chest Computed tomography (CT) shows a mediastinal emphysema (arrows); B: Epigastric CT shows accumulation of gas and fluid (arrows) in the anterior pararenal space just adjacent to the thickened wall of the horizontal part of the duodenum as well as accumulation of gas in the right perirenal space; C, D: A small intestine CT shows bowel wall thickening and strong enhancement of the horizontal part of the duodenum and a nodular mass (arrows) with a rich blood supply in the uncinate process (C) and tail (D) of the pancreas; E: Thyroid gland CT shows mild nodular goiter with nodules (arrow) posterior and lateral to the thyroid gland.

showed a chromophore cell adenoma. The patient's family history was notable for his brother also having a pituitary adenoma. In 2009, the patient underwent surgical procedures to remove a kidney stone. Recently, the patient had diarrhea, nausea and vomiting lasting for more than one year while gastroscopy and colonoscopy were performed prior to admission. Gastroscopy showed reflux esophagitis, esophageal protrusive lesion, gastric polyp and duodenal ulcer. Colonoscopy was normal. The patient was admitted on March 18, 2012. Physical examination revealed hypopigmentation of skin, sparse hair with normal blood pressure, body temperature, breath sounds and heart rhythms. The abdomen was prominently tender with normal bowel sounds and there was no shifting dullness found on the mass. Rectal examination was normal. Laboratory tests showed the following data: leukocytosis (22.40×10^9), mildly low hemoglobin level (115 g/L), elevated serum calcium (3.05 mmol/L, reference range, 2.1-2.55 mmol/L), low phosphorus level (0.57 μmol/L, reference range, 0.81-1.45 μmol/L), extremely high level of parathyroid hormone (PTH) (627 pg/mL, reference range, 15-65 pg/mL). Serum magnesium, calcitonin, electrolytes, glucose, liver and renal function were normal. Computed tomography (CT) scan of the chest revealed mediastinal emphysema with hypostasis in the inferior lobe of the lung (Figure 1A). Epigastric CT scan showed accumulation of gas and fluid in the anterior pararenal space just adjacent to the thickened wall of horizontal duodenum as well as accumulation of gas in the right perirenal space, which implied the possibility of duodenal perforation. CT imaging also found renal and hepatic cysts (Figure 1B). The patient complained of melena

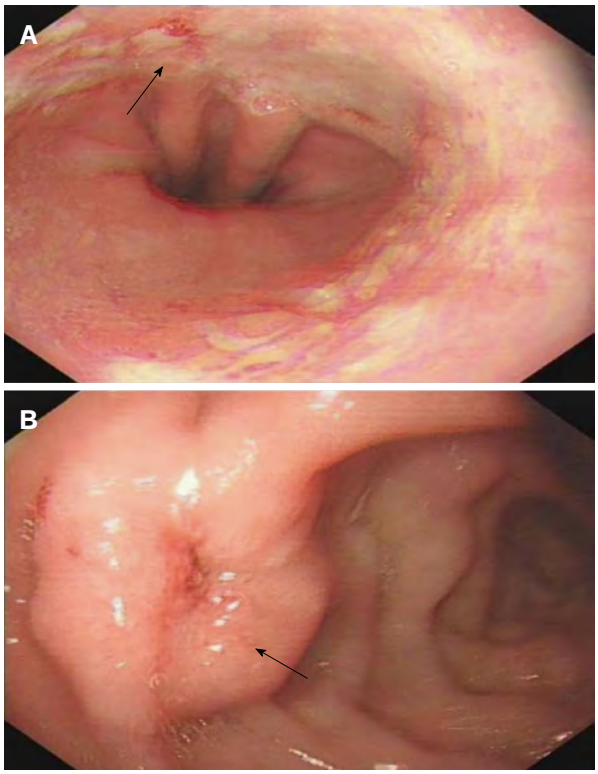

Figure 2 Gastroscopy reveals reflux esophagitis LA grade C and multiple deep ulcers in the descending part of duodenum, arrows indicate the erosion and ulcer respectively.

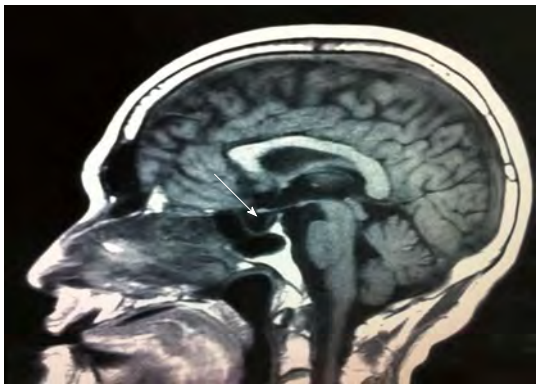

Figure 3 Pituitary Magnetic resonance imaging shows no space-occupying lesion in the sellar region (arrow).

two days after admission and the complete blood count showed medium anemia (hemoglobin 86 g/L) and positive stool occult blood (OB). Emergency gastroscopy was performed and revealed chronic superficial gastritis with erosion, reflux esophagitis LA grade C and multiple deep ulcers in the descending part of the duodenum (Figure 2). Pathological analysis showed chronic inflammation of duodenal mucosa. CT scan of the small intestine showed bowel wall thickening and strong enhancement of the horizontal part of the duodenum. A nodular mass with rich blood supply in the uncinate process and tail of pancreas led to a diagnosis highly suspicious for Zollinger-Ellison syndrome (ZES), and an adenoma on the left

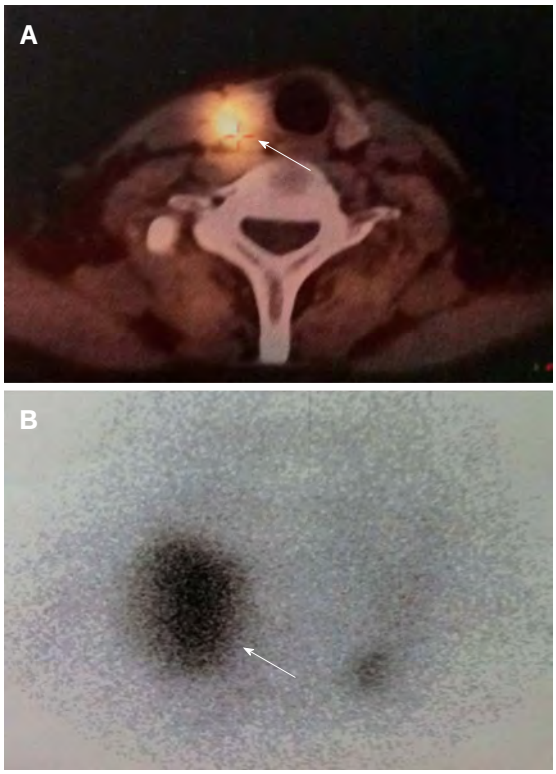

Figure 4 Radio-isotope scan reveals soft tissue masses (arrows) posterior to the thyroid gland which displayed abnormal uptake of 99mTc-MIBI.

adrenal gland and multiple liver cysts were also found in this CT image (Figure 1C-D). Magnetic resonance imaging (MRI) of the pituitary showed no space-occupying lesion in the sellar region (Figure 3). PTH was re-examined and the result was 401 pg/mL, which was still significantly higher than the normal value. Laboratory tests also revealed elevated serum gastrin (342.27 pg/mL, reference range, 0-108 pg/mL), elevated prolactin (127.50 ng/mL, reference range, 4.97-23.3 ng/mL) and low testosterone level (0.19 ng/mL, reference range, 2.8-8 ng/mL). Serum progesterone, follicle-stimulating hormone (FSH), luteotropic hormone, estradiol, cortisol, adrenocorticotropic hormone (ACTH), aldosterone and thyroid hormones were normal. CT scan of the thyroid gland showed a mild nodular goiter with nodules posterior and lateral to the thyroid gland, which might originate from an enlargement of the parathyroid glands (Figure 1E). A radioisotope scan revealed soft tissue masses posterior to the thyroid gland and abnormal uptake of 99mTc-MIBI, considered to be parathyroid adenoma or hyperplasia (Figure 4). The patient was diagnosed with MEN1 presenting as hyperparathyroidism, gastrinoma and prolactinoma. He underwent subtotal parathyroidectomy and autotransplantation on April 9, 2012. The pathology of all parathyroid glands was consistent with chief cell hyperplasia with immunohistochemical expression of CK19, CK8, CgA, Syn and NSE and negative expression of TTF-1, TG and Ki67 (Figure 5A). After operation, the levels of serum calcium and PTH fell to normal. The patient had no evidence of metastatic disease on preoperative studies. With the

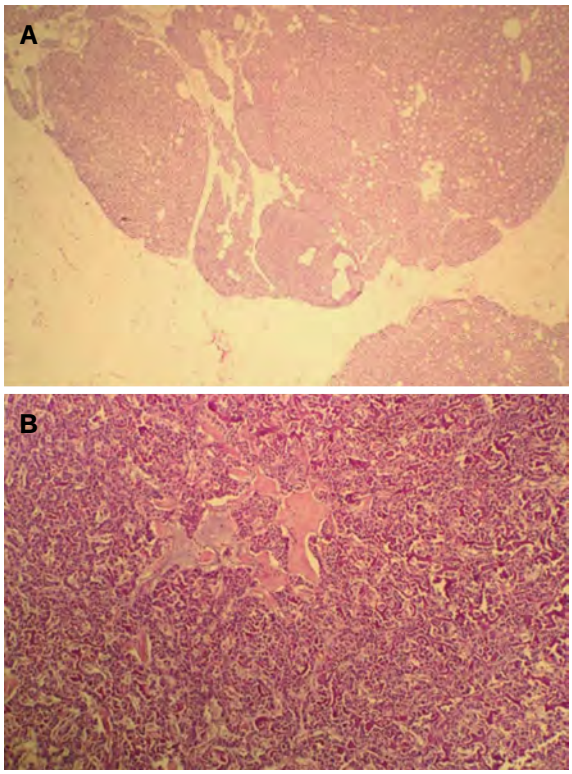

Figure 5 Histological and Pathological analysis of the case (hematoxylin and eosin staining, × 100). A: Histological analysis shows chief cell hyperplasia of parathyroid gland; B: Pathological analysis shows that tumor cells had acidophilic cytoplasm and round nucleoli which were uniform in size and shape, arranged in tubular, organoid and gyriform patterns.

pancreatic endocrine tumors being well-located in the CT image, pylorus-preserving pancreaticoduodenectomy and pancreatic tail resection were performed on April 24, 2012 for removing gastrinoma and cure of ZES. Pathological analysis showed that tumor cells had an acidophilic cytoplasm and round nucleoli which were uniform in size and shape, arranging in tubular, organoid and gyriform patterns (Figure 5B). The pathological diagnosis was a well-differentiated neuroendocrine tumor, infiltrating the muscular layer of the duodenal bowel wall, with no blood vessels and nerves involved and a well-differentiated neuroendocrine tumor also formed in the tail of pancreas, with immunohistochemical expression of NSE, Syn, CK8, CgA and α-AT, weakly positive expression of CK, CD56, Vim, CK19 and Ki67, and negative expression of 5-HT, insulin and ACTH. Pathologic examination of three lymph nodes near the duodenum and the head of pancreas showed chronic lymphadenitis. The postoperative level of serum gastrin was 39.34 pg/mL, and was returning to normal. The patient was discharged two weeks after the successful surgical resection of the tumor and is currently doing well but requires careful follow-up.

DISCUSSION

MEN1 can cause combinations of more than 20 different endocrine and nonendocrine tumors. Pituitary adenomas affect approximately 30% of patients and usually they are prolactin-secreting micro-adenomas or "nonfunctional" tumors[2]. Fasting prolactin concentration exceeding the upper limit of normal by 20-fold allows the diagnosis of prolactinoma[3]. In our case, the high prolactin level and CT imaging led to a diagnosis of pituitary adenoma which was further confirmed by histological analysis after operation. The patient had no other symptoms and was then considered to be cured. After a period of time, he suffered from chronic diarrhea lasting for nearly one year. There was little information regarding the cause of diarrhea until CT scan showed mediastinal emphysema and accumulation of gas and fluid in the anterior pararenal and right perirenal space which strongly implied the possibility of intestinal perforation. The patient had no positive abdominal physical signs that caused our bewilderment. While we were looking for the possible site of bowel perforation, the patient complained of melena unexpectedly and stool OB was positive, which led to the diagnosis of acute upper gastrointestinal bleeding. Emergency gastroscopy was performed and revealed multiple deep ulcers in the descending part of the duodenum, leading to the suspicion of gastrinoma, which was further confirmed by the elevated serum gastrin level and contrast-enhanced CT; and treatment with high-dose proton pump inhibitors was given. It is now evident that many affected patients have adrenal lesions. A non-functional adrenal cortical tumor was described in up to 40% of MEN1 cases and diagnosed by radiological imaging[4]. Our patient had an adenoma of the left adrenal gland but with normal testosterone, progesterone, FSH, ACTH, LH and aldosterone levels.

The patient had a significantly high serum calcium and PTH level which led to the diagnosis of hyperparathyroidism. Imaging showed parathyroid adenoma or hyperplasia. Hypercalcemia reminded us that the patient underwent a surgical procedure to remove a kidney stone three years ago. The patient stayed asymptomatic then and no further testing was performed, which suggested that clinical manifestation of MEN-1 is mostly mild for a long period of time and a lack of regular screening might result in numerous complications[5].

The fraction of MEN-1 in patients with primary hyperparathyroidism (HPT) is estimated at 1%-5%[6]. As is known, calcium is a secretagogue for gastrin, so HPT may exacerbate gastric acid secretion in concomitant ZES[7]. In practical terms, when serum calcium approaches or exceeds 2.75 mmol/L, surgery is recommended. The most common options for initial surgical management are either total parathyroidectomy and cervical thymectomy with heterotopic parathyroid autotransplantation or subtotal parathyroidectomy and cervical thymectomy. Subtotal parathyroidectomy is preferred because of the advantage of a lower risk of permanent hypoparathyroidism and an acceptable risk of recurrent HPT. In our patient, subtotal parathyroidectomy and autotransplantation were performed and the level of serum calcium decreased immediately. No hypoparathyroidism was detected post-operatively.

In MEN1, pancreatic neuroendocrine tumors occur

in 40%-80% of patients and are mostly non-functioning tumors or gastrinomas. The treatment of pancreaticoduodenal disease is quite controversial because of the inability to achieve biochemical cure consistently. In one retrospective analysis, surgical treatment for MEN-1-associated pancreatic tumors < 2 cm showed no advantage over conservative treatment[8]. However, analysis of another cohort of patients revealed that early detection and surgery are beneficial for MEN-1-associated pancreatic tumors[9]. Gastrinomas are the most common functional gastrointestinal neuroendocrine tumors, presenting in up to 54% of MEN1 patients. The diagnosis of ZES depends on proving elevated gastrin levels in the presence of high gastric acidity. Approximately one-third of patients with ZES can be diagnosed by a serum gastrin > 1000 pg/mL with a gastric pH < 3.0. The other two-thirds of patients require provocative tests. Our patient had a moderate increase in serum gastrin but serum gastrin remained < 1000 pg/mL and might require provocative tests to confirm the diagnosis. As the secretin supply was limited, nodules of our patient detected on preoperative imaging that caused significant ulceration and perforation, esophageal reflux symptoms and chronic diarrhea made the diagnosis valid. Prior to surgery, all MEN1 patients should be evaluated for coexisting neuroendocrine and other tumors as well as for the presence of metastases. Preoperative imaging is selected to define the extent of resection, and to identify tumors that would be outside the scope of resection. In our case, contrast-enhanced CT scan of the small intestine showed bowel wall thickening and strong enhancement of the horizontal part of the duodenum, a nodular mass with a rich blood supply in the uncinate process and tail of pancreas, but with no regional lymph nodes and hepatic metastases found. The lesions were well-located in CT imaging, hence no further imaging techniques, such as endoscopic ultrasound or somatostatin receptor scintigraphy, were necessary. The goals of surgical resection of pancreatic endocrine tumors are complete removal of the gross tumor burden, and preservation of pancreatic function. This often results in the subtotal resection of the distal pancreas, and enucleation of tumors in the head of the pancreas and duodenum. In all patients with gastrinoma, the duodenum should be opened and submucosal tumors resected. Total pancreatectomy is rarely indicated. According to all the information collected pre-operatively, our patient received pylorus-preserving pancreaticoduodenectomy and pancreatic tail resection. Postoperative complications were carefully monitored and an optimistic outcome was acquired. The level of serum gastrin returned to normal soon after surgery and the patient recovered well. We hope the patient is completely cured with no requirement for medication, but continued surveillance of all MEN1 patients is necessary and this patient is now under our careful follow-up.

Abstract

A 57-year-old man presented with intermittent dull abdominal pain after a period of 1 year. Abdominal computed tomography (CT) was performed. Except for the endoscopy, the work-up for possible medical causes remained inconclusive. An open-abdomen, partial surgical excision of the stomach was performed after the unsuccessful endoscopic resection. The pathology report revealed a glomus tumor of the stomach. Importantly, glomus tumors of the stomach are rare and are almost always benign. Therefore, the most important current role of imaging associated with the diagnostic approach and therapeutic plan for a glomus tumor is to differentiate it from other gastric submucosal tumors (SMTs). We report this case with representative radiologic findings, including CT and endoscopic ultrasound (EUS) reports, and also correlate them with clinical and pathologic presentations that can help in the early detection and differentiation of gastric SMTs from other SMTs. As such, the purpose of this report is to provide a better understanding of relevant CT and EUS features. Alternative treatments should be considered carefully according to the imaging results.

INTRODUCTION

Glomus tumors of the stomach are rare; predominantly benign; and commonly described as solitary, well-defined gastric submucosal tumors (SMTs) in the antrum with non-specific clinical manifestations[1-4]. Gastrointestinal stromal tumors (GISTs), undoubtedly the most common malignant SMTs of the stomach, have the capacity to become malignant and later metastasize. Therefore, the most important and plausible current role of imaging in the diagnostic approach and therapeutic plan for a glomus tumor is to differentiate it from other SMTs[1,4]. We report this case with representative radiologic findings, including computed tomography (CT) and endoscopic ultrasound (EUS) reports, and also correlate them with clinical pathologic presentations that can help in the early detection and differentiation of GISTs from other SMTs. The diagnosis was surgically confirmed. Contrast-enhanced CT showed peripheral nodular or homogeneous strong enhancement in the arterial phase and prolonged enhancement in the delayed phase[1-6].

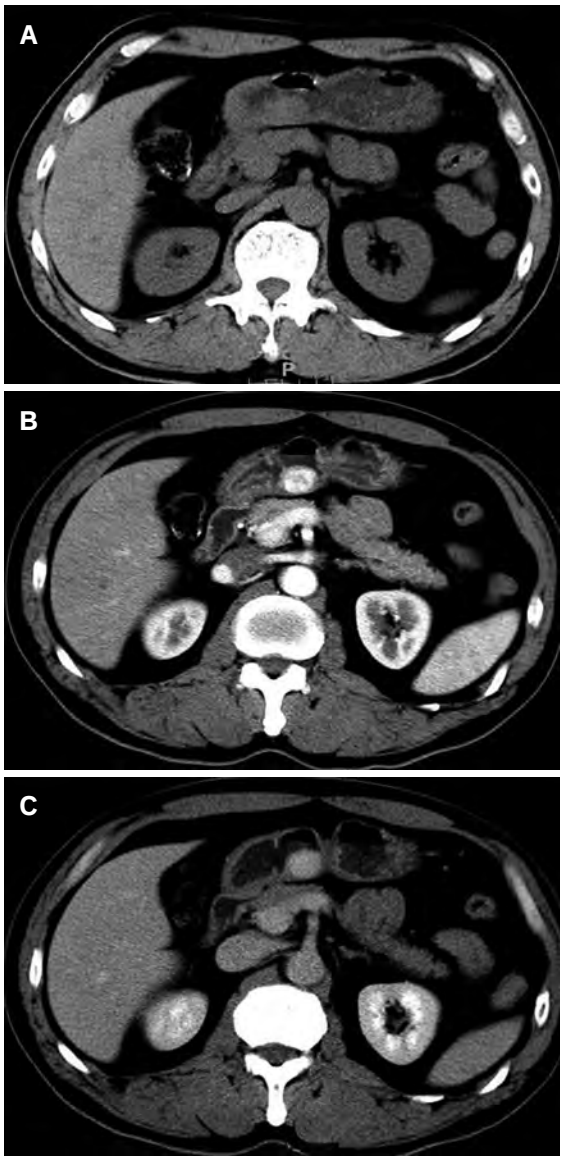

Figure 1 A 57-year-old man presented with intermittent dull abdominal pain after a duration of 1 year with a glomus tumor in the lesser curvature. A: A plain computed tomography (CT) scan of the tumor revealing a clear regular contour and an isodensity mass; B: The mass shows dense homogeneous enhancement with an intact overlying mucosa on early-phase contrast-enhanced CT; C: The mass shows continuous homogeneous enhancement on delay-phase contrast-enhanced CT.

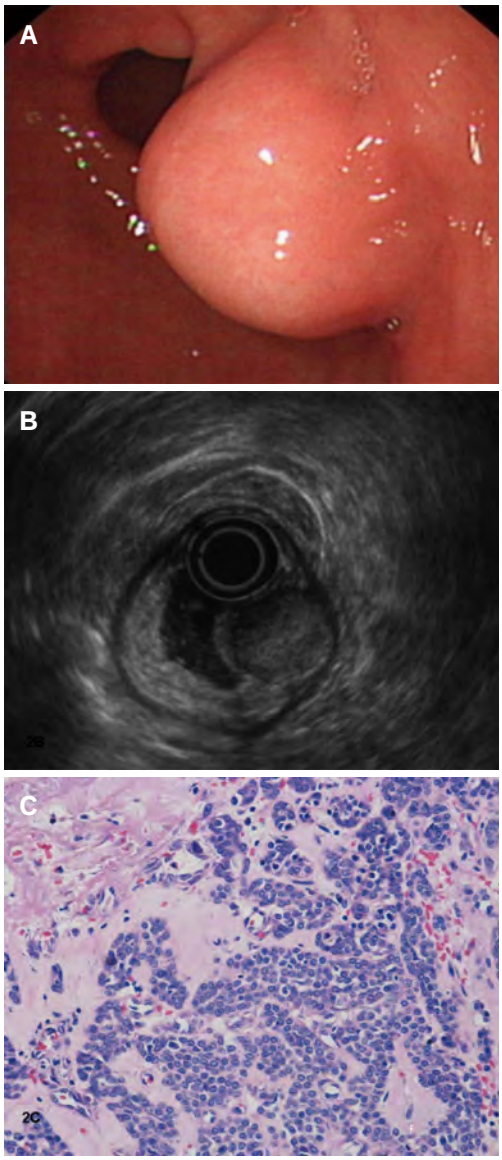

Figure 2 Gastroscopy shows a submucosa eminent lesion in the stomach wall. A: Endoscopic ultrasonic shows a solid mass originating from the superficial layer of the muscular propria. It is 20 mm × 16 mm in size, and a marginal halo can be observed; B: The mass appears as a round, hypoechoic lesion with homogenous echogenicity. After a failed endoscopic submucosal dissection with ligation for the treatment of the small tumor, a subtotal gastrectomy was performed; C: Microscopic examination shows numerous dilated, thin-walled vascular spaces surrounded by uniform glomus cells (hematoxylin and eosin stain, × 50).

CASE REPORT

One year ago, a 57-year-old man presented to the local primary hospital with intermittent dull abdominal pain, especially when hungry. At that time, an upper gastrointestinal endoscope revealed mild diffuse gastritis. The patient underwent conservative medical management for 8 mo, during which the abdominal pain disappeared. Over a recent 3-wk period, however, the pain reappeared at levels higher than observed previously. The patient was transferred to our hospital and subjected to further investigation. A plain CT scan of the tumor revealed a clear regular contour and an isodensity mass (Figure 1A). The mass showed dense homogeneous enhancement, suggesting a lesion with an abundant blood supply and an intact overlying mucosa on an early- (Figure 1B) and delayed-phase (Figure 1C) contrast-enhanced CT. The endoscope examination showed a submucosal gastric mass that was approximately 2.0 cm and was identified at the lesser curvature of the antrum (Figure 2A). A solid mass originated from the superficial layer of the muscular propria, measuring 20 mm × 16 mm, with a marginal halo. The mass appeared to be a round, hypoechoic lesion with homogenous echogenicity (Figure 2B).

Endoscopic submucosal dissection (ESD) was initially planned, although it was unsuccessful due to significant bleeding. As such, the patient was treated via open-abdomen partial surgical excision of the stomach. After 7 mo, an abdominal CT follow-up showed no sign of tumor recurrence.

Pathologic findings indicated that this was a glomus tumor, which is characterized by many vessels that are lined with endothelial cells and surrounded by a solid proliferation of round or cuboidal cells with a round nucleus and eosinophilic cytoplasm (Figure 2C). Immunohistochemical studies revealed that the tumor cells were positive for smooth muscle actin (40%) and muscle-specific actin (100%++) but negative for desmin and CD34/CD31.

DISCUSSION

Gastric tumors are either epithelial or mesenchymal in origin. Radiologic findings enable a straightforward differentiation between mucosal or submucosal tumors. However, the identification of benign or malignant tumors depends on their biological behavior. Approximately 85% to 90% of all gastric tumors are benign, and 50% of these are mesenchymal in origin. This subgroup of gastric tumors can be further divided into two groups. The first group arises from the somatic tissue, which includes smooth muscle tumors, neural tumors, lipocystic tumors, and tumors originating from vascular or perivascular tissues (*e.g.*, glomus tumors). In contrast, more than 95% of all malignant tumors of the stomach are adenocarcinomas. The remaining malignant tumor types include lymphomas, sarcomas (*e.g.*, malignant gastrointestinal stromal tumors), and carcinoid tumors, among others. The second group is larger and includes GISTs[1]. Glomus tumors in the stomach are rare and are almost always benign; therefore, the most important role of imaging in diagnostic and therapeutic approaches is the differentiation of GISTs from other gastric submucosal tumors.

In 1935, Masson published a monograph entitled "Les glomus cutanes del'Homme." The classic location of a glomus tumor is the subungual region of a digit, although it may occur anywhere in the body, including the skin, soft tissues, nerves, stomach, nasal cavity, trachea, and liver. Glomus tumors of the stomach typically appear as a submucosal nodule or mass on the antrum[2]. Although a glomus tumor of the stomach is a pathologic diagnosis, it should be included as a differential diagnosis if a solitary, hypervascular submucosal tumor is present in the stomach. Other mesenchymal tumors, such as carcinoid tumors, GISTs, neurilemmomas, and hemangiomas, may show a similar pattern. The overlap of radiologic findings in many gastric tumors makes their differentiation difficult. However, some unusual gastric tumors have characteristic radiologic features that may suggest a specific diagnosis. The incidence of gastric carcinoid tumors is increasing, and multiple tumors may occur from the fundus to the antrum. The imaging features of GISTs are variable, ranging from a small nodule with signal changes similar to the gastric muscle to a large mass with a cystic change, an intratumoral hemorrhage, necrosis, or ulceration with air-fluid levels. Hemangiomas are characterized by color changes in the vessels that appear blue or red in an endoscopy and may contain phleboliths that can be detected by CT. Neurilemmomas have a moderately or markedly higher hyperintensity with T2-weighted imaging. In combination with tumor size, location, enhanced pattern, and the intrinsic soft-tissue content, the high resolution provided by an magnetic resonance imaging may constitute one the noninvasive diagnostic or therapeutic options for gastric glomus tumors, in addition to surgery, endoscopic mucosal resectioning, and fine-needle aspiration biopsy[1,3,4].

Our report describes a method of discerning between gastric glomus tumors and other SMTs *via* CT and EUS imaging findings. Endoscopic submucosal enucleation is a feasible and safe procedure for the treatment of this lesion. However, further investigation and comparative studies are required to confirm the safety and efficacy of this method. Radiologically, glomus tumors appear as smooth submucosal masses with or without ulceration and may contain tiny flecks of calcification. Imaging results may suggest suspicious malignant findings, such as a large lesion measuring more than 3-5 cm, a lesion with irregular margins, a cystic space, a heterogeneous echo, or an interval change on follow-up. However, in the absence of such findings, close surveillance is recommended along with an operation and postoperative follow-ups at undefined time intervals[4-6].

In conclusion, CT and EUS findings that correlate with clinical presentations can contribute to the early detection and identification of gastric glomus tumors, particularly in terms of assessing the tumor blood supply. Endoscopists prefer ESD to open surgery, although the former necessitates caution due to complications that may occur due to significant bleeding.

Abstract

Phlegmonous gastritis is an unusual infection of the gastric wall, which is extremely rare and associated with a poor prognosis. Here, we report the case of a 65-year-old male patient with a history of splenectomy, who had phlegmonous gastritis after esophagectomy. Computed tomography revealed a remarkably distended thoracic stomach, and the gastric wall was locally thickened. Gastric mucosa was red and white in color and significantly edematous on gastroscopy. He was successfully treated with a combination of antibiotics and povidone-iodide intraluminal lavage. In addition to this case, the clinical presentations, imaging examinations as well as treatments of phlegmonous gastritis are discussed.

INTRODUCTION

Phlegmonous gastritis (PG) is an unusual infection of the gastric wall caused by suppurative bacteria. Mortality due to PG approached 92% before the advent of antibiotics and was as high as 64% even after antibiotics became available[1]. Clinical presentations of PG are generally nonspecific and include epigastric pain, vomiting and infection. Therefore, it is extremely difficult to make a correct diagnosis at the early onset, and many patients undergo gastrectomy due to the severity of the disease in the acute phase. Herein, we report a rare PG after esophagectomy which was successfully treated with conservative treatment.

CASE REPORT

A 65-year-old male patient was admitted with the complaint of epigastric discomfort for 1 wk. He had a history of splenectomy 18 mo previously due to a splenic rupture after a traffic accident. Esophageal erosions located 34 cm below the incisor teeth were revealed by preoperative gastroscopy. Pathological examination of the esophageal lesion indicated adenocarcinoma. Therefore, an exploratory thoracotomy was performed. During surgery, a 3 cm solid mass without well-defined borders was found in the lower esophagus. An esophagus resection followed by supra-arch esophagogastric anastomosis was performed.

However, on the first postoperative night, the patient became febrile with a fever of 39 ℃. The next morning, the high temperature continued and the patient suddenly developed dyspnea with SaO_2 continuously below 90% after oxygen *via* a face mask (5 L/min). Physical examination revealed weakened breath sounds in the left lower lobe and laboratory examinations showed decreased PO_2 (63.8 mmHg) and elevated leukocytes (21.3×10^4) and neutrophils (90.4%). Chest X-ray showed a large consolidation shadow of the left lung, and both costophrenic

Figure 1 Postoperative chest X-ray. A large consolidation shadow of the left lung, low density radiolucent areas on the left upper lobe and high density fragment images on the right lung are shown. Both costophrenic angles were obscure.

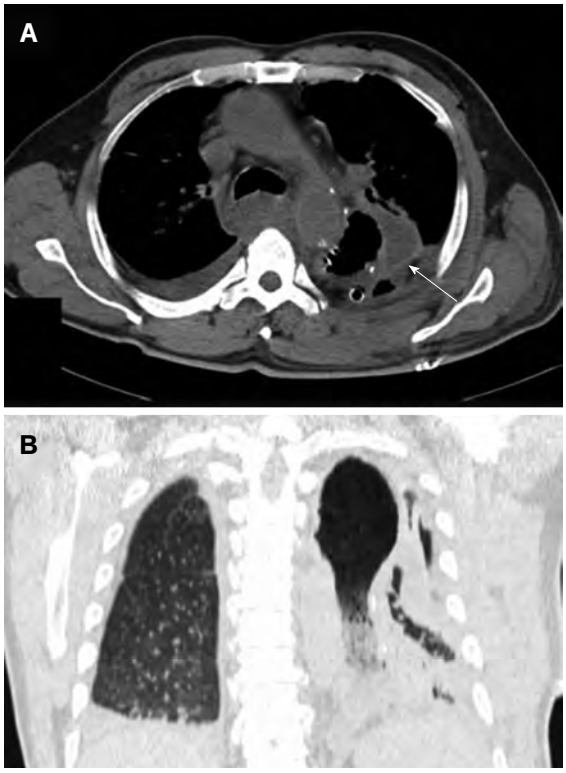

Figure 2 Computed tomography scan. A: Axial computed tomography (CT) imaging of the chest: The CT scan showed a remarkably distended thoracic stomach and a locally thickened gastric wall (arrow); B: Coronal CT scan of the chest: Imaging revealed a thoracic stomach with a large consolidation shadow and in air bronchograms of the left lung, pleural and pericardial effusions were also suggested.

angles were obscure (Figure 1). Therefore, tracheal intubation was performed based on the intended diagnosis of respiratory failure.

Over the next 5 d, the patient's body temperature remained at 39 ℃. Chest computed tomography (CT) revealed a remarkably distended thoracic stomach, and the gastric wall was locally thickened, pleural and pericardial effusions were also suggested (Figure 2). Gastrointestinal endoscopy revealed congestion and edema of the gastro-

Figure 3 Endoscopic examination of the postoperative stomach. The gastric mucosa was red and white in color, significantly edematous, and scattered erosions covered by purulent exudate were observed. No anastomotic leak was noted.

esophageal anastomosis, the gastric mucosa was red and white in color and significantly edematous, a large number of scattered erosions covered by a layer of purulent exudates were also observed (Figure 3). Thus, the diagnosis of PG, which was suspected on CT, was confirmed. The sputum culture revealed *Staphylococcus aureus*, whereas the bacterial culture was negative for the gastric aspirate.

Following the results of the sputum culture, the patient was treated with a combination of teicoplanin and linezolid (Zyvox), as well as intraluminal lavage with 2.5% povidone-iodine. After 3 d, his temperature decreased, PO_2, and PCO_2 levels returned to normal, and the patient was successfully extubated. Antibiotics were continued for two weeks and no evidence of gastric mucosa inflammation was detected by gastroscopy. The patient was discharged on the 30th day after surgery.

DISCUSSION

PG is a rare condition caused by various organisms, affects both sexes and occurs mainly in individuals aged 30-70 years[2]. The etiology of PG is still unknown, alcohol consumption, chronic gastritis, mucosal injury, drugs, immunosuppression and malignancy have been suggested to cause PG[3]. In the current case, PG occurred after esophagectomy, which has been rarely reported in the published literature. It was noted that this patient had a history of splenectomy 18 mo before esophagectomy, although there is no known relationship between PG and splenectomy, decreased immunity due to splenectomy combined with the post-surgical stress response may have facilitated the entry of bacteria into the gastric submucosa and the induction of PG.

The typical clinical presentation of PG is the acute onset of a triad of symptoms consisting of: epigastric pain, vomiting and fever. Other symptoms such as nausea, chills, hematemesis have also been reported[1,4]. The pain is sometimes relieved by sitting in an upright position (Deininger's sign), and purulent emesis is said to be pathognomonic for PG regardless of its rarity[5]. High leukocytosis, accelerated erythrocyte sedimentation rate,

and dysproteinemia are usually seen in peripheral blood analysis.

Imaging examinations are helpful in PG diagnosis. On CT scanning, marked gastric wall thickening and intramural hypodense areas can be seen[6]; while endosonography (EUS) can reveal thickened gastric wall and anechoic areas[4]. On endoscopy, PG gastric mucosa is usually edematous and appears purple in color with dirty necrotic materials covering the surface[7], which indicate serosa penetration or peri-serosa effusion which is rarely seen and is mostly restricted to the gastric wall. In the present case, the patient had severe left lower lobe pneumonia with pleural and pericardial effusions, which suggested bacterial colonization of the gastric mucosa through sputum swallowing due to pulmonary infection.

The culture of gastric pus or a sample taken during the endoscopic procedure may help to identify the bacteria involved and provides a reference for antibiotic selection. Nevertheless, many cases of PG fail to document the presence of bacteria in the gastric wall, but the correct diagnosis can be made without histological documentation or bacterial culture from the gastric aspirate[6], suggesting that a positive culture of gastric secretions is not necessary for the diagnosis of PG. Our patient showed many of the manifestations mentioned above, although no organism was isolated from gastric contents. Laboratory findings of *Staphylococcus aureus* in sputum, CT imaging and endoscopic findings of pus justified the diagnosis of PG.

The standard of treatment for PG is still not well established. Treatment mainly involves conservative management with antibiotics and surgical gastrectomy. As in our case, which was diagnosed in the early phase, PG can be treated with the correct antibiotics and supportive treatment. Otherwise, gastrectomy should be considered. Surgery can be partial or total dissection depending on the extent of inflammation. However, a review by Kim *et al*[4] revealed that surgical interventions are superior to antibiotic therapies with mortality of 20% and 50%, respectively. Other treatments such as endoscopic mucosal resection and simple aspiration under endoscopic ultrasonography have also been reported[7].

In conclusion, PG is a rare and fatal condition that needs early diagnosis and appropriate management. Endoscopy, CT, EUS, and pathogen culture can be helpful in the diagnosis. In this article, we present an unusual case of PG after esophagectomy, through early diagnosis and effective antibiotic treatment, the patient recovered successfully. Surgeons should be aware of the possibility of PG when dealing with complex acute abdominal diseases.
