Contents

Weekly Volume 19 Number 1 January 7, 2013

EDITORIAL

1 Precut sphincterotomy: A reliable salvage for difficult biliary cannulation
Saritas U, Ustundag Y, Harmandar F

FIELD OF VISION

8 Tumor-infiltrating B cells come into vogue
Linnebacher M

12 Is endoscopic therapy the treatment of choice in all patients with chronic pancreatitis?
Jabłońska B

TOPIC HIGHLIGHT

17 Clinical significance of cytomegalovirus infection in patients with inflammatory bowel disease
Garrido E, Carrera E, Manzano R, Lopez-Sanroman A

REVIEW

26 Current pathogenetic aspects of hepatic encephalopathy and noncirrhotic hyperammonemic encephalopathy
Cichoż-Lach H, Michalak A

35 Retroperitoneal fibrosis associated with immunoglobulin G4-related disease
Fujimori N, Ito T, Igarashi H, Oono T, Nakamura T, Niina Y, Hijioka M, Lee L, Uchida M, Takayanagi R

42 Nestin: A novel angiogenesis marker and possible target for tumor angiogenesis
Matsuda Y, Hagio M, Ishiwata T

BRIEF ARTICLE

49 Performance of liver stiffness measurements by transient elastography in chronic hepatitis
Ferraioli G, Tinelli C, Dal Bello B, Zicchetti M, Lissandrin R, Filice G, Filice C, Above E, Barbarini G, Brunetti E, Calderon W, Di Gregorio M, Gulminetti R, Lanzarini P, Ludovisi S, Maiocchi L, Malfitano A, Michelone G, Minoli L, Mondelli M, Novati S, Patruno SFA, Perretti A, Poma G, Sacchi P, Zanaboni D, Zaramella M

57 Comparison of fatty liver index with noninvasive methods for steatosis detection and quantification
Zelber-Sagi S, Webb M, Assy N, Blendis L, Yeshua H, Leshno M, Ratziu V, Halpern Z, Oren R, Santo E

65 Prolonged QT dispersion in inflammatory bowel disease
Yorulmaz E, Sezgin A, Yorulmaz H, Adali G, Ciftci H

72 Improvement of prognosis for unresectable biliary tract cancer
Sasaki T, Isayama H, Nakai Y, Takahara N, Sasahira N, Kogure H, Mizuno S, Yagioka H, Ito Y, Yamamoto N, Hirano K, Toda N, Tada M, Omata M, Koike K

78 Alcohol, postprandial plasma glucose, and prognosis of hepatocellular carcinoma
Abe H, Aida Y, Ishiguro H, Yoshizawa K, Miyazaki T, Itagaki M, Sutoh S, Aizawa Y

86 Short and long-term outcomes of endoscopic balloon dilatation for Crohn's disease strictures
Endo K, Takahashi S, Shiga H, Kakuta Y, Kinouchi Y, Shimosegawa T

92 Index of convexity: A novel liver function index using Tc-GSA scintigraphy
Miki K, Matsui Y, Teruya M, Kaminishi M, Kokudo N

97 *Helicobacter pylori* seropositivity in diabetic patients is associated with microalbuminuria
Chung GE, Heo NJ, Park MJ, Chung SJ, Kang HY, Kang SJ

103 A pilot study of single-use endoscopy in screening acute gastrointestinal bleeding
Cho JH, Kim HM, Lee S, Kim YJ, Han KJ, Cho HG, Song SY

108 Double guidewire technique *vs* transpancreatic precut sphincterotomy in difficult biliary cannulation
Yoo YW, Cha SW, Lee WC, Kim SH, Kim A, Cho YD

CASE REPORT

115 Vanishing bile duct syndrome in human immunodeficiency virus infected adults: A report of two cases
Oppenheimer AP, Koh C, McLaughlin M, Williamson JC, Norton TD, Laudadio J, Heller T, Kleiner DE, High KP, Morse CG

122 Atresia of the appendix vermiformis: A rare case of developmental abnormality
Yaylak F, Algin MC, Gungor Y, Korkmaz M

125 Russell body duodenitis in a patient with retroperitoneal metastasis of ureteral cancer
Takahashi Y, Shimizu S, Uraushihara K, Fukusato T

129 Small hepatocellular carcinoma with ring calcification: A case report and literature review
Murakami T, Morioka D, Takakura H, Miura Y, Togo S

133 Biliary phytobezoar resulting in intestinal obstruction
KimY, Park BJ, Kim MJ, Sung DJ, Kim DS, Yu YD, Lee JH

137 Endoscopic resection of co-existing severe dysplasia and a small esophageal leiomyoma
Ahn SY, Jeon SW

LETTERS TO THE EDITOR

141 Somatic second-hit mutations leads to polycystic liver diseases
Banales JM, Munoz-Garrido P, Bujanda L

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

Abstract

Even experienced endoscopists have 90% success in achieving deep biliary cannulation with standard methods. Biliary cannulation may become difficult in 10%-15% of patients with biliary obstruction and precut (access) sphincterotomy is frequently chosen as a rescue treatment in these cases. Generally, precut sphincterotomy ensures a rate of 90%-100% successful deep biliary cannulation. The precut technique has been performed as either a fistulotomy with a needle knife sphincterotome or as a transpapillary septotomy with a standard sphincterotome. Both methods have similar efficacy and complication rates when administered to the proper patient. Although precut sphincterotomy ensures over 90% success of biliary cannulation, it has been characterized as an independent risk factor for pancreatitis. The complications of the precut technique are not limited to pancreatitis. Two more important ones, bleeding and perforation, are also reported in some publications as being observed more commonly than during standard sphincterotomy. It is also reported that precut sphincterotomy increases morbidity when performed in patients without dilatation of their biliary tract. Nevertheless, precut sphincterotomy is a good alternative as a rescue method in the setting of a failed standard cannulation method. This paper discusses the technical details, timing, efficacy and potential complications of precut sphincterotomy.

INTRODUCTION

With the development of increasingly sophisticated imaging methods, endoscopic retrograde cholangiopancreatography (ERCP) is currently used more for the treatment than the diagnosis of biliary tract disease. The first choice of treatment for biliary calculus, postoperative bile leak and benign or malignant biliary stenosis is endoscopic, i.e., therapeutic ERCP. A preliminary condition to successful therapeutic ERCP is selective biliary cannulation. Deep biliary cannulation performed by an experienced endoscopist using standard cannulation techniques is successful in approximately 90% of cases[1]. Biliary cannulation may become particularly difficult in the 10%-15% of patients with an anatomical problem or a disease such as fibrosis, tumor of the sphincter of Oddi, periampullary diverticuli, calculus impaction in the sphincter, or status post Billroth I - Ⅱ. Such situations are also risk factors for complications of ERCP[2,3]. In a retrospective review of 502 patients, Fukatsu *et al*[4] were not successful in cannulating the biliary tract within the first 20 min using standard methods in 80 of these patients (16%) for one of the following reasons: female sex, post-hepatectomy

hypertrophy of the left lobe, status post Billroth I gastric resection with reconstruction, and malignant stenosis. In such patients, deep biliary cannulation fails often enough, notwithstanding the use of various instruments such as a tapered or standard-tip catheter, a sphincterotome, a guide wire, a metal-tip catheter, *etc.* Alternatively, the pancreatic duct ends up being cannulated. Every new attempt to cannulate through the papilla, or repeated cannulation of the pancreatic duct, inevitably increases the risk of post-ERCP pancreatitis (PEP)[5]. Published reports indicate that ten or more transpapillary cannulation attempts or more than five cannulations of the pancreatic duct are independent risk factors for PEP[2,3,5].

The most popular method to address a difficult cannulation is needle-knife (NK) precut sphincterotomy, which has been in use since the 1980s. The term precut was first used by Siegel[6] and later popularized by Huibregtse *et al*[7]. A more recent technique for difficult cases is transpancreatic precut sphincterotomy (TPS), which was described after 1990[8]. Although precut (access) sphincterotomy ensures over 90% success of biliary cannulation[9], it has been characterized as an independent risk factor for PEP[10,11]. Patients in whom the precut technique is applied are, however, already at a high risk for PEP; they have, as a rule, already undergone mechanical trauma due to previous attempts at transpapillary cannulation. Both situations are well known as PEP risk factors. Therefore, a timely use of the precut technique could reduce the risk of PEP. The complications of the precut technique are not limited to PEP. Two more important ones, bleeding and perforation, are reported in some publications as being observed more frequently than during standard sphincterotomy. It is also indicated that precut sphincterotomy increases morbidity when performed in patients who have no dilatation of their biliary tract. This paper discusses the technical details, timing, efficacy and complications of precut sphincterotomy.

TECHNICAL DETAILS

Precut sphincterotomy is an endoscopic technique used for deep biliary cannulation, and also for reaching the pancreatic duct in rare cases. It consists of an incision in the papilla in the absence of free biliary cannulation or a guide wire. The incision is performed most frequently with a needle-tip sphincterotome, and the technique is referred to as "NK precutting". Depending on the point of origin of the incision, the technique is designated as "standard" or "modified".

Standard technique

The incision starts at the orifice and proceeds upwards, in the direction of 11 h on a clock dial, until it is past the papillary protuberance. The length of the cut is determined by the intraduodenal part of the common bile duct: it stops at the upper limit of the duodenal bulge of the common bile duct.

Modified technique

The incision starts where the lower two thirds of the papillary protuberance meet the upper third, and it proceeds downwards on the left of the median line of the papilla and stops before reaching the papillary orifice. The incision depth is obtained with 2-3 pushes on the NK in a straight plane, while exerting sufficient pressure from the surface of the ampulla towards the catheter.

Transpancreatic precut sphincterotomy or transpancreatic papillary septotomy

This technique provides bile duct cannulation by entering the common duct or pancreatic duct through the papillary orifice and then cutting the septum that separates the pancreatic duct from the bile duct. Transpancreatic papillary septotomy can be either wire-guided after introducing a guide wire in the pancreatic duct, or it can be performed without a guide. The wire-guided method consists of introducing a soft guide in the pancreatic duct, then directing a papillotome, usually of the standard type, towards the bile duct to perform the cut. The catheter is introduced into the bile duct after its ostium has become visible. The unguided technique first introduces the sphincterotome into the common duct; the septum between the pancreatic and the bile ducts is incised, and the biliary and pancreatic orifices are made visible separately. The pancreatic orifice is generally lower than the central position, to the right of the papillary median line, and the bile duct orifice is to its left in the middle. The latter presents a velvety appearance with an off-yellow color. After visualizing the biliary orifice, deep biliary cannulation is performed, and the sphincterotomy operation is completed.

Different sphincterotomes have been developed for precutting and NK[12] (Table 1). The catheters may possess a single, double or triple lumen Iso-Tome. An isolated-tip papillotome to prevent energy leakage from the needle point has also been developed, as well as a coated-tip NK aimed toward preventing perforation. The Erlangen-type papillotome is one of these. It is similar to the standard traction-type sphincterotome, with a 5 mm monofilament cutting wire and a catheter tip measuring less than 1 mm. Other modifications of the short-tip or noseless sphincterotome are also used for precutting. They are available with insulated or non-insulated cutting wires. Yet another type of device used to perform a papillotomy to permit access is that of a catheter equipped with a small scissor at the tip[13]. The lower blade of the scissor is introduced into the papillary orifice, and the scissor blades close to obtain a cut.

How effective is a precut sphincterotomy in achieving deep biliary cannulation? Does it increase post-ERCP complications?

Standard cannulation techniques achieve deep biliary cannulation in approximately 90% of cases, while 10%-15% of cases present difficulties. Patients experiencing such difficulties generally have a disease such as

a stenosis or a tumor of the sphincter of Oddi, periampullar diverticula, status post-Billroth Ⅱ, *etc.*, or an anatomic abnormality. Cannulation difficulties lead to multiple attempts. The resulting trauma and edema create a favorable ground for PEP. Precut papillotomy is an invasive procedure to help achieve deep biliary cannulation. Studies and discussion of precut papillotomy have been ongoing since the early 1980s, when this technique was first used. Rabenstein *et al*[14] reviewed the patients on whom they had performed precut papillotomy and ERCP, dividing them in two groups based on the year of the operation, 1981-1987 and 1988-1993. In both periods, approximately one-third of the patients needed a precut papillotomy to achieve deep biliary cannulation, and precutting was successful in 85% of these cases. The complication rates of primary endoscopic sphincterotomy (6.8%) and precutting (7.3%) were similar. Foutch *et al*[15] succeeded in the deep cannulation of 414 of 456 patients (91%); endoscopic sphincterotomy was successful in 395 patients (87%), and 40 patients (9.7%) experienced complications, 21 (5.1%) of which were serious. Precutting, which was used in 52 patients because of insufficient deep cannulation or endoscopic sphincterotomy (EST), was successful in 47 patients (90%), 3 (5.8%) of whom experienced complications, and these complications were serious in 2 (3.8%). No mortality related to EST or precutting was observed. Binmoeller *et al*[16] used precutting with an Erlangen-type instrument in 123 (38%) of 327 patients. Selective biliary cannulation was successful in all patients. Hyperamylasemia, observed in half of the patients who underwent precutting, was present in 27% of the standard sphincterotomy group ($P < 0.001$), while clinical PEP and the bleeding frequency were similar in both groups (2.7% *vs* 2.4% and 1.6% *vs* 3.9%, respectively). Palm *et al*[17] compared their results in 121 patients on whom they had performed precutting with the same type of papillotome with the result of procedures performed in 481 other patients who had received standard sphincterotomy (a precut ratio of 25%). As in the earlier cited study, hyperamylasemia was more frequent in the patients who underwent precutting than in those with EST (31.3% *vs* 13.3%), while the rates of other complications were similar (7.18% *vs* 8.3%). Precutting resulted in a success rate of 98.2% for deep biliary cannulation. In a study comparing primary and secondary precutting, de Weerth *et al*[18] reported a 100% success rate of biliary cannulation with a cannulation time of 6.9 ± 1.8 min in the primary precutting. In 146 patients with secondary precutting who had previously undergone attempts at standard cannulation and sphincterotomy, 104 had a successful cannulation within 8.3 ± 2.1 min ($P < 0.001$), and 42 had to repeat the secondary precutting. PEP was observed with the same frequency in both groups (2.1% *vs* 2.9%), and 1 patient in the secondary precut group experienced light bleeding. The authors conclude that primary precutting is safer, more efficient and faster. Kasmin *et al*[19] achieved a successful biliary cannulation at the first attempt in 50 (67%) of 72 difficult patients, and 17 others were successful at the second attempt, for a total of 67 (93%) successful procedures with NK sphincterotomy. Complications were observed in eight (11%) patients, including guide wire-related perforation, bleeding from precutting and pancreatitis. A narrow common bile duct diameter was determined to be an independent risk factor for complications in patients undergoing precutting. In a study of the correlation of NK precut and PEP, Testoni *et al*[10] performed NK precutting in 12.8% of their 732 patients with naive papilla, with an 85% success rate. The PEP frequency was 14.9% in the precut group *vs* 6.1% in the non-precut group. Female sex, stenosis of the sphincter of Oddi, partial pancreatic drainage and more than 15 previous cannulation attempts were independent risk factors for PEP, while NK precutting was not. A stent was implanted in the pancreatic duct in 22 patients, and five of these experienced pancreatitis. The authors indicate that the pancreatic stent provides no protection from PEP to patients at risk. Perforation, bleeding or

severe pancreatitis were not observed. As for Cennamo *et al*[20], they applied criteria somewhat differently from the previous studies, performing precutting if the standard attempt failed within 5 min or after three repeated cannulations of the pancreatic duct; they compared this group of patients to those who had undergone late precutting after failed cannulation within 20 min. In the early precut group, cannulation was successful in 32 (92%) of 36 patients at the first attempt and 100% at the second. In 78 of the 110 late precut patients, biliary cannulation was achieved within an average of 7.6 min by standard methods, while precutting was performed in the first 20 min in the remaining patients. Deep biliary cannulation was successful at the first attempt in 26 (81%) of these patients and at the second in the remaining four. The complication rate was 8% in the early precut group and 6% in the late precut ($P = 0.7$). Patients with periampullary diverticuli, gastric surgery and papillary neoplasia were excluded from this study. Oddi's sphincter stenosis was not an exclusion criterion, but it was not found in any of the patients during the procedure. The authors concluded that there was no difference between the early and late precut patient groups with regard to biliary cannulation success rates and complication rates. Considering, however, the early decision regarding the failure of standard cannulation in the early precut group, it can be speculated that biliary cannulation could still have been achieved by standard methods with a longer trial in some of these patients. Another question is the exclusion of patients with important PEP risk factors and the absence of cases of stenosis of the sphincter of Oddi, which both may have contributed to the absence of a difference in terms of complications. Additionally, an apparent difference in the first-pass success rates in favor of the early precut patients, 92% *vs* 81%, was not discussed in the conclusion. A review of these studies (Table 2) shows that precutting is successful in achieving deep biliary cannulation in more than 95% of the cases, without causing a substantial increase in the complication rate.

The timing of the precutting intervention is important for reducing the complications. The number of transpapillary cannulation attempts and that of pancreatic duct cannulations are two of the most important factors contributing to PEP. Published reports indicate that ten or more transpapillary cannulation attempts or more than five cannulations of the pancreatic duct are independent risk factors for PEP. Precutting before reaching such a number of attempts would not constitute an additional PEP risk factor. In a meta-analysis by Cennamo *et al*[21] of six controlled, randomized studies, pancreatitis was found in 2.5% of patients undergoing early precutting *vs* 5.3% in those in whom the unsuccessful attempts continued (odds ratio 0.47, 95% confidence interval: 0.24-0.91); early precutting was shown to lower the risk of PEP. In another study, Tang *et al*[22] found fewer cases of PEP in patients subject to precutting before reaching 10 unsuccessful cannulation attempts through the papilla as opposed to those with 10 or more attempts. When comparing the patients who underwent early precutting with those in whom the endoscopists persisted with difficult cannulation, the success rates were, respectively, 75% and 73%, and the complication rates were 4% and 9%; the differences were not significant. Kaffes *et al*[23] performed early NK precut sphincterotomy in 70 (20%) patients out of a population of 346 undergoing therapeutic ERCP. The operation was performed in patients in whom selective biliary cannulation was not successful within the first ten min or those with more than five cannulations of the pancreatic duct. Successful biliary cannulation was achieved at the first attempt in 58 (83%) patients, and at the second attempt 24-48 h later, it was successful in 7 more patients. Precutting was unsuccessful in 5 patients. Thus the total success rate for biliary cannulation was 95%; six patients had light bleeding, and one had light pancreatitis. It was concluded that early precutting does not add to the PEP risk. Bruins Slot *et al*[24], reporting a success rate of 99% for precut sphincterotomy in achieving biliary cannulation with a complication rate of 12%, interestingly found a 0.1% PEP rate but observed relatively frequent perforation (3%) compared to other reports, where perforation is rare, and bleeding was reported in 5.5% of patients. The bleeding reported with the NK precutting procedure is characterized as mild, but it is generally more frequent than with standard sphincterotomy. As a result of all these reviewed studies, it may be said that, in addition to not representing a risk factor for developing PEP, early precut sphincterotomy does not cause complications in addition to those of the ERCP or standard sphincterotomy methods, and it is safe.

Should a transpancreatic septotomy and NK precut method be used, and what are their respective advantages and complications? To answer these questions, the results of several studies should be considered. In a paper by Goff[25], who also first described TPS, on the long-term comparative results of this technique *vs* those obtained with standard sphincterotomy, 51 (25%) patients of a total of 200 were subjected to precutting. Of these, 49 (94%) had a successful biliary cannulation at the first attempt; the complication rate was 2.1% for standard and 1.96% for precut sphincterotomy. Catalano *et al*[26] performed TPS in 29 patients and NK precutting in 34. The cannulation success rate was 100% in the former and 77% in

the latter group (P = 0.1). Complications were observed in one TPS patient (3,5%) and in six (17.7%) who had NK. Wang *et al*[27] applied TPS in 140 patients and NK in 76, with similar rates of biliary cannulation success, PEP, and other complications (90% *vs* 90.8%, 11.4% *vs* 11.8% and 14.9% *vs* 18.4%, respectively). Akashi *et al*[28] performed TPS without using a guide wire in 172 patients, with 163 (95%) successful biliary cannulations and a 10% complication rate. They note in their conclusions that the general complication rate of ERCP was low at 0.8%, and that of TPS was relatively elevated (P < 0.001). Kahaleh *et al*[29] obtained a deep biliary cannulation success rate of 85% without guide wire in 116 patients; three patients (2.6%) experienced bleeding, 9 (8%) had pancreatitis, and 2 (1.7%) had a perforation. The authors reported that these frequencies were no different than those of the standard sphincterotomy patients. Halttunen *et al*[30] used precutting in 588 (9%) of 6209 ERCP patients due to cannulation difficulties and compared TPS to NK. Precutting was successful in 529 of the 588 patients. Of these, 351 had TPS and 178 had NK. The success rate for biliary cannulation was 97.3% in the TPS group and 71.3% with NK (P < 0.001); the frequency of PEP was 8.8% in the TPS group and 5.1% in the NK patients (P = 0.16). The authors characterized TPS as a substantially efficient and safe technique (Table 3). Weber *et al*[31] inserted a soft guide wire in the pancreatic duct to perform TPS in 108 patients; 94 (87%) of these were successfully cannulated at the first attempt, and nine others were successful at a second session 1-4 d later, for a total success of 103 (95.4%) patients. PEP was observed in six (5.6%) cases, four of which were mild, and bleeding was similarly observed in six (5.6%) patients, four of whom required transfusion. There was no perforation and no mortality. The bleeding frequency was higher than usual in the last study; this may be related to the reported use of a pure cutting current. As summarized above, the results of TPS with or without the placement of a guide in the pancreatic duct seemed to be similar to each other with regard to the rates of biliary cannulation success and complications. Although there is thus no definite evidence as to the superiority of either method, the macroscopic appearance of the papilla and the presence or absence of bile duct dilatation may be decisive. Patients in whom there is no stenosis of the sphincter of Oddi and the bile duct, and thus no bulging in the duodenum of the duodenal portion of the bile duct, are not good candidates for fistulotomy or the modified technique of NK precut. The perforation risk due to precutting was elevated in such patients; TPS is more adapted to these cases. Patients with a stenosis of the sphincter of Oddi are at high risk for PEP, and biliary cannulation by TPS following the placement of a stent in the pancreatic duct is the procedure of choice. As for patients with an impacted calculus in the orifice, or those with a papillary orifice displaced downwards due to a tumor of the sphincter of Oddi, fistulotomy or NK precut by the modified technique are appropriate.

Stent placement in the pancreatic duct has also been attempted to prevent PEP. Goldberg *et al*[32] were successful in the deep cannulation of 38 (97.4%) out of 39 patients who presented cannulation difficulties, using TPS after having implanted a stent in the pancreatic duct. Two (5.1%) of these patients had mild pancreatitis. Performing TPS after pancreatic duct stent implantation seemed to be as successful in cannulation as other methods, while the lower pancreatitis frequency was doubtful. This was a retrospective study with few patients. Madácsy *et al*[33] implanted a pancreatic duct stent in 22 patients with a dysfunction of the sphincter of Oddi if cannulation had failed within the first ten min or if the pancreatic duct had been entered five times before performing NK precutting. Biliary cannulation was successful in 20 patients, and none developed PEP, which was present in 14 of the 35 control group patients. A reduction of the risk of PEP due to the use of a pancreatic stent in patients at high risk is a possibility; prospective studies with more patients are needed to resolve this issue. The stent mostly falls off spontaneously within 3-5 d from the time of implantation because its distal notch is generally left outside the duct. If the stent is still in place on the follow-up abdominal x-ray at one week, it must be pulled out by esophagogastroduodenoscopy.

In a study comparing the standard technique to the modified technique for NK[22], three patients in each group had bleeding, and one in the modified technique group had pancreatitis. No difference was detected among the two techniques regarding their complications. It is assumed that the pancreatic duct orifice is protected by the incision in the modified technique, which starts at the summit of the papillary protuberance and ends before reaching the orifice, and PEP will not develop after its use. The only patient who experienced pancreatitis in the cited study was, however, in the group that received the modified technique. It may be that edema due to temperature elevation in the tissues obstructs the pancreatic duct orifice. The emptying of the pancreatic duct is easier with the standard technique or TPS due to the incision of the common duct or even the pancreatic duct starting from the papillary orifice.

Articles on precut sphincterotomy generally start with the following disclaimer: "this method is efficient

and safe if performed by experienced endoscopists". Sphincterotomy and precutting are the most critical therapeutic operations during ERCP, and they necessitate a certain amount of experience. A study regarding this by Rabenstein *et al*[34] showed a complication frequency of 5.6% with endoscopists who treated 40 or more cases per year *vs* 9.3% for those with fewer cases ($P < 0.05$). In their study addressing the endoscopist's experience in precut fistulotomy, Lee *et al*[35] used this technique in 23% of cases, achieving 88.7% biliary cannulation success in the first session and 93.7% by the second session. PEP developed in 5.7% of cases. More than 15 cannulation attempts before fistulotomy was defined as being a PEP risk factor. The study determined that the operation duration decreased in an inverse relationship to the number of interventions practiced by the endoscopist, thus reducing the operative complications. Sufficient experience is of crucial importance not only for precutting but also for ERCP, especially for procedures of therapeutic nature. Experience is acquired by treating a large number of cases, following what is being performed, and continuously updating knowledge. The endoscopist will be entirely familiar with papillary anatomy after having observed many cases. The person performing the endoscopy must know what will be observed, what is being sought and what will be found in every millimeter that is being cut.

Is precutting the ultimate solution to difficult biliary cannulation? There is no doubt that it is not. A new technique is that of endoscopic ultrasound (EUS) rendezvous for common bile duct cannulation. Dhir *et al*[36] have compared precutting to the rendezvous technique with EUS in a non-randomized, retrospective study. Successful common bile duct cannulation was achieved in 90% of patients with precutting and 98% with EUS ($P = 0.03$); the complication rates were 6.9% and 3.4%, respectively ($P = 0.27$). The authors reported that the EUS rendezvous technique is more successful than precutting for difficult biliary cannulation. It would be wrong, however, to accept these results from a retrospective, non-randomized study as unbiased; additionally, conventional cannulation was considered to have failed after five attempts and EUS was initiated, where one may speculate that extending this limit to ten or another number could have allowed it to succeed. Without a doubt, the EUS rendezvous technique represents an important step to be used as a salvage procedure when precutting is insufficient.

CONCLUSION

Precutting is necessary in roughly 10% of patients with biliary obstruction. Precut sphincterotomy ensures a rate of 90%-100% successful deep biliary cannulation in patients in whom such cannulation is difficult. The frequency of side effects, varying between 5% and 10%, is not different from that of a standard sphincterotomy. Even with these efficacy and safety ratios, the method should remain reserved for patients who need a therapeutic intervention.

Abstract

Lymphocyte infiltration into solid tumors has been recognized as a main determinator of positive prognosis. For the most part this is attributed to cytotoxic T cells capable of directly destroying malignant cells. However, when considering the complex composition of the human immune system, recent findings of Nielsen *et al* on a potentially central role of tumor-infiltrating B cells is not really surprising. In this commentary article, I want to highlight the enormous potential impact of this observation for basic and translational research, prognostic procedures and ultimately for the development of future therapeutic concepts.

INVITED COMMENTARY ON HOT ARTICLES

Most previous studies on the infiltration of lymphocytes into human malignant tumors focused on $CD8^+$ T cells, the cell type with best antitumoral potential. And for many tumors, the degrees as well as the composition of tumor-infiltrating lymphocytes (TIL) have strong positive prognostic relevance[1]. However, recent findings established tumor-infiltrating B cells as next-best predictor of a positive patient outcome[2-4]. In their very recent publication, Nielsen *et al*[5] analyzed $CD20^+$ lymphocytes infiltrating into ovarian cancer. It is one of the very few detailed and comprehensive analysis of tumor-infiltrating B cells and moreover, it raises the question of functionality. The authors end up not only with confirmation of a strong association of $CD20^+$ TILs' presence and prolonged survival but with several findings shedding light into the true function of B cells in the immune systems' fight against cancer.

Major findings

First, they confirm earlier work demonstrating antigen-maturation and an activated phenotype of $CD20^+$ TIL [immunoglobulin (Ig)D^-, IgM^-, IgG^+][6-8]. Sequencing of the immunoglobulin genes consequently reveals high levels of somatic hypermutation in TIL B cells. This has also frequently been described for mammary carcinoma[6,7,9-12]. Thus the authors conclude that $CD20^+$ TILs have undergone activation, Ig class switching, somatic hypermutation, and clonal expansion; all of which are hallmarks of antigen exposure.

Furthermore, detailed analysis of the B cells' phenotype shows that naïve B cells were absent and only marginal amounts of germinal center B cells and plasmablasts ($CD38^+$ but $CD138^-$) were present. The vast majority of $CD20^+$ TILs were memory B cells (IgD^-, $CD38^{-/low}$) of an atypical type since they did not express the canonical memory marker CD27. The authors explain this finding

with either recent activation of B cells, since exposure of B cells to $CD70^+$ T cells leads to rapid CD27 down-regulation. Alternatively, the lack of CD27 expression on $CD20^+$ TIL may allow foregoing helper T cell-induced antibody production by ligation of CD27 with CD70. They conclude that $CD20^+$ TILs may thus directly contribute to cellular immunity. Other markers were expressed as expected from B cells: human leukocyte antigen (HLA)-ABC, HLA-DR, CD40 as well as moderate CD80 and CD86. This finding was interpreted as prerequisite for and hint towards functional antigen-presentation of the $CD20^+$ TIL to T cells in the tumor environment.

Finally, Nielsen *et al* observed an activated effector phenotype ($HLA\text{-}DR^+$, $CD45RO^+$, $CD45RA^-$, $CD62L^-$) of tumor-infiltrating $CD4^+$ and $CD8^+$ T cells. This finding is again consistent with the literature[13]. Moreover, they describe frequent co-localization of $CD8^+$ and $CD20^+$ lymphocytes both in the tumor stroma and epithelium. Clinical relevance comes from the fact that patients' survival is best when both $CD8^+$ and $CD20^+$ lymphocytes are present. The authors conclude that $CD20^+$ TIL most likely have a function as professional antigen presenting cells (APC) to support the T cells in the immune systems' fight against cancer. The latter is of extreme interest in the context of the development of novel immunotherapies. Even though dendritic cells (DCs) are established as the most potent and thus possibly also most important professional antigen presenting cell type, antigen-specific B cells may be similar if not more important in the body's fight against cancer cells. This assumption may seem a bit provocative, but Nielsen *et al*[5] hint towards the unique potential of B cells to concentrate the level of an antigen presented to T cells by membrane-IgG-guided antigen capture. Since the levels of tumor-released antigens are virtually highest in the tumor bed, it seems only logical for the $CD20^+$ antitumoral B cell to "work there".

Impact on future basic and translational research

The authors arrive at the conclusion that it will be necessary to identify the cognate antigens of $CD20^+$ TILs and to assess recognition by $CD4^+$ and $CD8^+$ TILs in order to definitively show that $CD20^+$ TILs serve as APC in the tumor environment. It will be a demanding task demonstrating simultaneous recognition of a given tumor antigen at the tumor site by all the cellular players involved: $CD4^+$, $CD8^+$ and $CD20^+$ TILs. Technically, this can be solved either by recombinant molecular biological tools, i.e., presence of T and B cell receptors. However, this approach is complicated by the fact that the exact receptor rearrangements should be known in advance. Alternatively, functional cellular tests using $CD20^+$ TIL B cells as APC to stimulate $CD4^+$ as well as $CD8^+$ TILs may also lead to the identification of antigens relevant for the immunological control of a given tumor. In our recent study on tumor-infiltrating B cells of colorectal cancer[14], we presented a simple method to immortalize and clone tumor-infiltrating B cells. The potential of these clones to functionally influence tumor growth either directly or in mutual interaction with T lymphocytes will be an interesting field of research[15]. Beside antigen identification, *in vitro* analysis using cell-cell interaction assays and even functional *in vivo* tests will be possible when using matched tumor cell lines or established tissue lines of primary tumor pieces engrafted in immunodeficient animals[16].

Another interesting aspect lies in the mere frequency of $CD20^+$ TILs in comparison to DCs; the latter are much less prominent in ovarian cancer. Many of the studies on DCs infiltrating tumor tissues used CD83 as a typical DC marker[17]. We frequently observed CD83-expression on the above mentioned *ex vivo* cloned and immortalized B cells[14]. Simultaneously, many of these clones totally or at least partially failed to express the classical B cell markers CD19 and CD20[14]. Although the marker expression may be influenced by the *in vitro* culture, one may still speculate on tumor-infiltrating B cells falsely counted as DCs - at least when CD83 was used as DC marker. Multi-color stainings on cryosections will help to clarify this question. Similarly, Nielsen *et al* shed light into another open question: which functional subtypes of B cells infiltrate tumor tissues? To definitely answer this, our above mentioned *ex vivo* cloning strategy will, together with classical analyses of different surface markers by immunohistochemical staining, possibly be very helpful.

Impact on future diagnostic procedures and prognosis

The contribution of B cells present in tumor tissues on the outcome of the disease is still largely cryptic. The data of Nielsen *et al*[5] clearly support a positive prognostic value of $CD20^+$ TIL in ovarian cancer. Together with recent similar findings of other groups on head and neck cancer[18], cutaneous melanoma[19] and breast cancer[20], it is likely that the presence of $CD20^+$ TIL may be a good prognosticator in general. Moreover, all the above mentioned analyses clearly focus on the B cell marker CD20 and broader analyses using B cell subset markers are definitely warranted in order to allow for diagnostic values of B cell subtypes infiltrating different cancers.

Contrary to these findings, it has been shown that B cells' presence in tumor draining lymph nodes is associated with lymphangiogenesis in a mouse model, which subsequently increases metastasis[21]. In human cancer, a metastasis-promoting role is discussed for B1 lymphocytes in melanoma[22] and B cell-secreted lymphotoxin can promote castration-resistant prostate cancer[23]. Taken together, these findings clearly imply that B lymphocytes' subtypes and most likely additional tissue context parameters will be predictive for either antitumoral or tumor-promoting activity of tumor-infiltrating B cells.

Impact on future therapeutic concepts

In my opinion, the most interesting argument brought forward by Nielsen *et al*[5] is the following: during pro-

longed immune responses as observed in autoimmunity, allograft rejection as well as chronic infection, B cells and T cells form so-called tertiary lymphoid structures. Thus, both cell types maintain a strong immune response in cooperative interactions at the affected site. The authors suggest that future antitumoral immunotherapies should be designed as to mimic these chronic immune reactions: T-cell responses are sustained over many months or years by direct interactions with co-localized B cells. Thus, it may be possible to generate more potent, sustained T-cell responses in the tumor environment by promoting the infiltration of tumor-reactive B cells. This line of argumentation is well taken, since in some colorectal cancers tumor-infiltrating B cells typically reside in tertiary lymphoid structures together with other tumor-infiltrating leukocyte populations thus permitting anti-tumor effects. This so-called "Crohn's like" reaction has repeatedly been associated with very good prognosis for colorectal cancer[24] and is especially associated with the molecular subtype with best prognostic behaviour; i.e., microsatellite-instability[25].

Another very promising strategy may base on the above mentioned unique potential of B cells to specifically concentrate antigens *via* their membrane-bound Ig molecules. I would like to speculate that tumor-antigen-specific B cells will have an enormous T cell stimulatory potential. Thus, cellular therapies can be envisioned basing on isolation and expansion of tumor-infiltrating and antigen-specific B cells.

In summary, improved understanding of the functional phenotype of tumor-infiltrating B cells ($CD20^{+}$ but possibly also $CD20^{neg}$ B cells), their target antigens, and their mechanism of recruitment to target tissues may not only help to understand the role of B cells in the natural curse of tumor diseases but also will have potentially strong impact on patients' diagnosis and last but not least will facilitate the design of more effective immunotherapies for the treatment of cancer.

Abstract

Chronic pancreatitis (CP) is a progressive inflammatory disease of the pancreas characterized by destruction of the pancreatic parenchyma with subsequent fibrosis that leads to pancreatic exocrine and endocrine insufficiency. Abdominal pain and local complications (bile duct or duodenal stenosis and pancreatic tumor) secondary to CP are indications for therapy. At the beginning, medical therapy is used. More invasive treatment is recommended for patients with pancreatic duct stones (PDS) and pancreatic obstruction in whom standard medical therapy is not sufficient. Recently, Clarke *et al* assessed the long-term effectiveness of endoscopic therapy (ET) in CP patients. The authors compared ET with medical treatment. They reported that ET was clinically successful in 50% of patients with symptomatic CP. In this commentary, current CP treatment, including indications for ET and surgery in CP patients, is discussed. Recommendations for endoscopic treatment of CP according to the European Society of Gastrointestinal Endoscopy Clinical Guidelines are reviewed. Different surgical methods used in the treatment of CP patients are also discussed. ET is the most useful in patients with large PDS, pancreatic duct obstruction and dilation. It should be the first-line option because it is less invasive than surgery. Surgery should be the first-line option in patients in whom ET has failed or in those with a pancreatic mass with suspicion of malignancy. ET is a very effective and less invasive procedure, but it cannot be recommended as the treatment of choice in all CP patients.

INVITED COMMENTARY ON HOT ARTICLES

I have read with great interest the recent article by Clarke *et al*[1] describing the endoscopic treatment in patients with chronic pancreatitis (CP). I would strongly recommend this article to the readers of *World Journal of Gastroenterology*. CP is a progressive inflammatory disease of the pancreas characterized by destruction of the pancreatic parenchyma with subsequent fibrosis that leads to pancreatic exocrine and endocrine insufficiency[2,3].

We can distinguish two stages in the natural CP course. At the beginning, recurrent acute pancreatitis is observed in patients. In the later stage, pancreatic exocrine and endocrine insufficiency manifested by maldigestion and malabsorption, loss of weight, steatorrhea and diabetes are reported[4].

Abdominal pain is the most common clinical symptom requiring therapy in patients with CP. It is caused by obstruction of the pancreatic duct either by stones

or stricture with increasing intraductal pressure and parenchymal ischemia[5]. Therefore, the main aim of CP treatment is to decompress the main pancreatic duct by pancreatic stone removal and pancreatic duct dilation. Different conservative and invasive methods are used in the treatment of CP. At the beginning, medical therapy with analgesics, oral pancreatic enzyme supplements, insulin and a low fat diet is used[6]. More invasive treatment is recommended for patients with pancreatic duct stones (PDS) and pancreatic obstruction in whom standard medical therapy is not sufficient. Local complications such as bile duct stenosis and pancreatic tumor are also indications for invasive treatment. Currently, two main invasive (endoscopic and surgical) methods are used in CP treatment. It should be emphasized that surgery is an older treatment method than endoscopic therapy (ET). The first case of surgical removal of PDS was reported in 1883[7]. ET as a less invasive treatment has become popular recently. Currently, both treatment methods are used in CP patients[8-26].

In their study, Clarke *et al*[1] analyzed the use and long-term effectiveness of ET in CP patients. The authors compared ET with medical treatment. They reported that ET was clinically successful in 50% of patients with symptomatic CP. When ET was not successful, surgery had successful outcomes in 50% of patients. Medical therapy was successful only in 31% of symptomatic patients. Based on their study, the authors concluded that ET was an effective treatment method in CP patients. This is a significant study and I agree with the authors' opinion. However, I would like to precisely define the use of endoscopic methods in CP patients. It is important to know which patients are good candidates for ET. Can we recommend this treatment method for all CP patients? In order to answer this question I would like to cite the most recent (2012) recommendations of the European Society of Gastrointestinal Endoscopy (ESGE) regarding therapeutic intervention in CP patients[8].

The ESGE recommends extracorporeal shock wave lithotripsy (ESWL) and endoscopic retrograde cholangiopancreatography (ERCP) as the first-line treatment method. Surgery should be considered in patients with a predicted poor outcome following ET. In patients with stones $\geqslant$ 5 mm obstructing the main pancreatic duct, the ESGE recommends ESWL as a first step, combined or not with endoscopic extraction of stone fragments depending on the expertise of the center. In CP patients with a main pancreatic duct stricture, the ESGE recommends placement of a single 10-Fr plastic stent, with stent exchange planned within 1 year. If ductal strictures persist after 12 mo of single plastic stenting, the ESGE recommends that endoscopic placement of multiple pancreatic stents or surgery should be discussed by a multidisciplinary team. The ESGE recommends ET as the first-line interventional option in pancreatic pseudocysts in CP patients. In CP-related biliary strictures, endoscopy and surgery should be considered depending on local expertise, patient co-morbidities, and expected patient compliance with repeat endoscopic procedures [8].

Some authors[9] recommend surgery as an initial treatment in CP patients with pancreatic and bile duct strictures with upstream dilation, and ET as a second-line option in high-risk surgical candidates.

Clarke *et al*[1] analyzed a cohort of 146 patients with CP, including 71 (49%) patients receiving ET. The authors analyzed patients following pancreatic and biliary sphincterotomy, pancreatic duct dilation, stone extraction, ESWL pancreatic and bile duct stenting, and transgastric pseudocyst drainage. The pancreatic duct stenting was the most frequent endoscopic procedure. The interesting aspect of this study is the analysis of 8 (11%) so-called bridge patients, in whom ET as the first step was followed by surgery. Another interesting aspect is comparison of the endoscopic with medical treatment.

There are a number of publications comparing endoscopy with surgery in CP patients in the literature. ET is less invasive than surgery. However, according to most authors, surgery is more effective compared to endoscopy[24,25]. Hirota *et al*[26] compared costs of these two treatment methods. Duration and frequency of hospitalizations, and medical costs were similar between the short-period endoscopic treatment group and surgery group. On the other hand, patients in the long-period endoscopic treatment group required significantly longer and more frequent hospitalizations, and had higher medical costs than both the short-period endoscopic treatment group and the surgery group. According to the authors' analysis, patients who underwent serial endoscopic stenting for more than 1 year showed no benefit compared with surgical treatment in terms of the frequency of hospital stays and medical costs.

In addition, I would like to describe the role of surgery in CP patients. I agree with Clarke *et al*[1] that ET is effective in CP patients, but I would not recommend this treatment method in all patients. In my opinion, patients with multiple strictures and dilation within the pancreatic duct can have more benefits following surgery. It is my belief that patients with a pancreatic mass with suspicion of malignancy and duodenal stricture secondary to CP should also undergo surgery. In the most frequently encountered situation, PDS are treated endoscopically, but in some cases surgery is necessary. In the study of Liu *et al*[5], indications for ET were $\leqslant$ 3 stones, stones confined to the pancreatic head and body, absence of restricted pancreatic duct, PDS diameter $\leqslant$ 10 mm, and noncompacted stone(s). Surgery was indicated for patients who needed treatment but did not meet the above-mentioned indications, or for whom conservative therapy had failed.

We can distinguish the following types of surgical procedures in CP patients: drainage operations (Puestow, Partington-Rochelle, Duval procedures), resectional operations (partial and subtotal or total pancreatectomies), resections with extended drainage (Beger, Frey procedures) and neurolysis (celiac plexus block). The most frequently performed surgical procedures are presented in Figure 1. Total pancreatectomy with islet autotransplan-

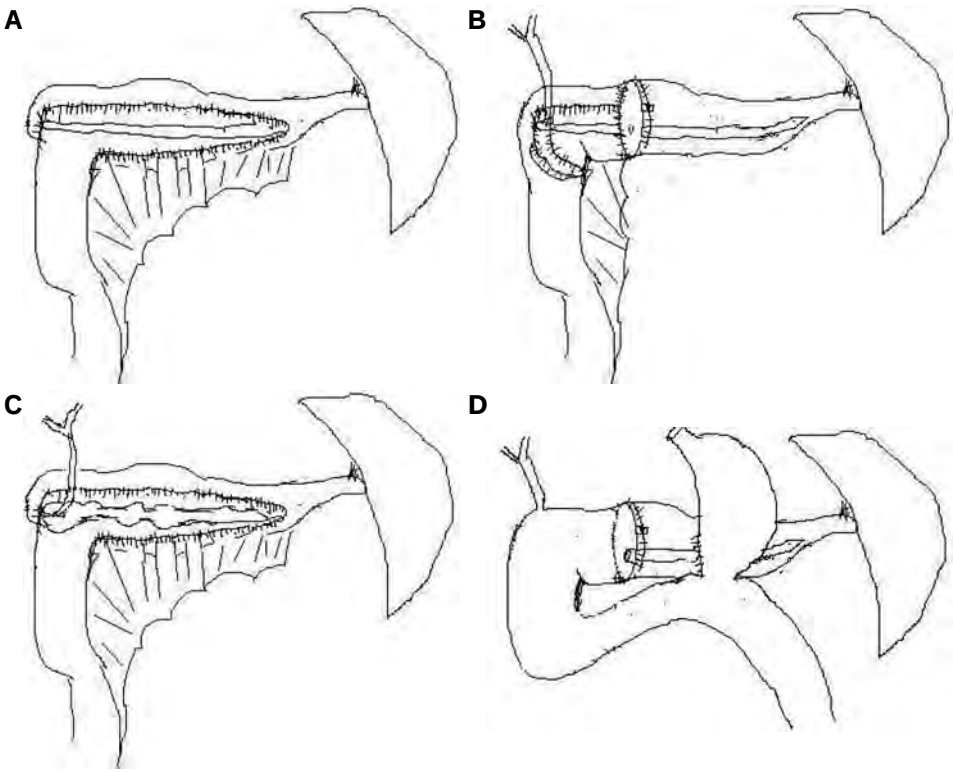

Figure 1 The most frequently performed surgical procedures. A: Partington-Rochelle procedure involving lateral (longitudinal) pancreaticojejunostomy (anastomosis between the longitudinally incised main pancreatic duct and Roux-Y jejunal loop); B: Beger procedure involving resection of the pancreatic head preserving the duodenum. The pancreas is transected at a border between the pancreatic head and body, leaving a thin pancreatic disc between the common bile duct and duodenum. The pancreatic body is drained by end-to-end pancreaticojejunostomy and pancreatic head disc is drained by side-to-side pancreaticojejunostomy using a Roux-Y jejunal loop; C: Frey procedure involving coring out of the pancreatic head overlying the main and accessory pancreatic ducts and uncinate process, keeping at least 5 mm pancreatic tissue posteriorly and medially along with opening the main duct in body and tail. The cored head and opened main duct are drained by lateral pancreaticojejunostomy using a Roux-Y jejunal loop; D: Whipple procedure involving pancreaticoduodenectomy with reconstruction by pancreaticojejunostomy, hepaticojejunostomy and gastrojejunostomy.

tation is an alternative surgical option for CP patients. It is important that this procedure can relieve pain and preserve β-cells in patients when other therapies fail[19,20]. Sutherland *et al*[20] from the University of Minnessota reported a > 30-year single-center series with good treatment results.

The Frey procedure is a safe and effective procedure with low morbidity and mortality rates in CP patients. It allows effective pain relief in about 90% of patients[27]. It is alternative and effective surgery for CP patients with a pancreatic inflammatory mass within the pancreatic head without malignancy[28].

According to Palanivelu *et al*[23], the Partington procedure is still the procedure of choice for patients with a dilated main pancreatic duct but without an inflammatory pancreatic head mass because it is simple and associated with a low postoperative morbidity and mortality, preserving pancreatic exocrine and endocrine function. Frey and Beger operations as duodenum-preserving pancreatic head resections (DPPHRs) with extended pancreatic duct drainage are recommended for patients with an inflammatory pancreatic head mass[29]. Furthermore, long-term results of two (Beger and Frey) DPPHRs in CP were compared by Keck *et al*[30]. This study revealed a better pain relief following the Frey procedure compared to the Beger operation.

There are some studies comparing DPPHRs and pancreaticoduodenectomy (PD) in treatment of CP patients. According to Zheng *et al*[18], both procedures are effective in relieving pain, but DPPHR is associated with less postoperative morbidity, including pancreatic exocrine and endocrine insufficiency, and better quality of life in patients following operation. Möbius *et al*[31] demonstrated a better quality of life and comparable pain relief and exocrine and endocrine pancreatic function in patients following DPPHR (Beger procedure) compared to patients following PD (Whipple procedure). Also, Witzigmann *et al*[32] revealed a better quality of life in CP patients following DPPHR compared to that experienced by patients following PD.

According to another recent study by Keck *et al*[33], both DPPHR and PD allow the achievement of effective pain relief and good quality of life without differences in endocrine or exocrine function in CP patients. According to Hildebrand *et al*[34], the Frey procedure is an advantageous alternative to the Whipple operation in CP patients. It is comparable to PD in pain relief and is less invasive (with lower morbidity and mortality rates, and a lower rate of newly occurring diabetes mellitus) than PD.

Similarly, McClaine *et al*[35] reported that DPPHR was equally as effective as PD in relieving pain and improving quality of life in CP patients; DPPHR was associated with a shorter hospital stay and less blood loss.

The choice of optimal surgery depends on size, number and location of PDS or presence of other complications (pancreatic mass, duodenal or biliary stenosis). In patients with pancreatic ductal stones, the PDS type should firstly be identified. Depending on location, four types of PDS have been established: type I in the head of the pancreas, type II in the body, type III in the tail, and type IV in the whole pancreas. Drainage by pancreatic ductotomy is generally recommended for patients with a dilated pancreatic duct (≥ 6 mm). The Beger procedure and PD are suitable for type I PDS; however, distal pancreatectomy is useful for type III PDS. For patients with type II PDS, the Partington-Rochelle procedure or segmental resection of the pancreas is recommended. For patients with type IV PDS, an alternative to drainage is a Child procedure (subtotal pancreatectomy)[4,5].

In conclusion, all methods including medical, endoscopic and surgical treatment are used in CP patients. Medical therapy is suitable in patients without complications at the outset of CP. ET is the most useful in patients with large PDS, pancreatic duct obstruction and dilation. It should be the first-line option because it is less invasive than surgery. The method of ET (pancreatic sphincterotomy or ESWL followed by pancreatic duct stenting) depends on the stone location and the pancreatic duct diameter. Surgery should be the first-line option in patients in whom ET failed or those with pancreatic mass with suspicion of malignancy. Therefore, although ET is a very effective and less invasive procedure, it cannot be recommended as the treatment of choice in all CP patients. In my opinion, surgical treatment without endoscopic treatment should be recommended for patients with duodenal stricture and pancreatic mass with suspicion of malignancy. In these patients, endoscopy should be used only in the diagnosis.

Abstract

Cytomegalovirus (CMV) infection is common in humans. The virus then enters a "latency phase" and can reactivate to different stimuli such as immunosuppression. The clinical significance of CMV infection in inflammatory bowel disease is different in Crohn's disease (CD) and ulcerative colitis (UC). CMV does not interfere in the clinical course of CD. However, CMV reactivation is frequent in severe or steroid-resistant UC. It is not known whether the virus exacerbates the disease or simply appears as a bystander of a severe disease. Different methods are used to diagnose CMV colitis. Diagnosis is classically based on histopathological identification of viral-infected cells or CMV antigens in biopsied tissues using haematoxylin-eosin or immunohistochemistry, other tests on blood or tissue samples are currently being investigated. Polymerase chain reaction performed in colonic mucosa has a high sensitivity and a positive result could be associated with a worse prognosis disease; further studies are needed to determine the most appropriate strategy with positive CMV-DNA in colonic mucosa. Specific endoscopic features have not been described in active UC and CMV infection. CMV colitis is usually treated with ganciclovir for several weeks, there are different opinions about whether or not to stop immunosuppressive therapy. Other antiviral drugs may be used. Multicenter controlled studies would needed to determine which subgroup of UC patients would benefit from early antiviral treatment.

Clinical significance of cytomegalovirus infection in patients with inflammatory bowel disease. *World J Gastroenterol* 2013; 19(1): 17-25 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/17.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.17

NATURAL HISTORY OF CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is a member of the *Herpesviridae* family which contains a double-stranded DNA. It often causes primary infection in humans, and later persists lifelong in a latent stage. In different situations of immunosuppression [birth, human immunodeficiency virus (HIV) infection, use of immunosuppressant therapy or chemotherapy] the virus can reactivate[1,2] and cause disease, but this may also occur in immunocompetent hosts.

In CMV infection, CMV antigens or antibodies can be detected in blood, whereas CMV disease symptoms

generally appear in a target organ[3]. The prevalence of CMV infection is high, ranging from 30%-100%[4-7], depending on age and race of population tested[8-10].

Primary CMV infection in immunocompetent individuals is usually asymptomatic, and rarely manifests itself as a mononucleosis-type disease similar to that caused by Epstein-Barr virus, consisting of fever, fatigue and cervical lymphadenopathy. Subsequently, the virus enters a latency phase in endothelial cells, macrophages or granulocyte stem cells[11-13]. Virus can reactivate in the healthy adult, this new activation being typically asymptomatic; however, this delicate balance can be disrupted in patients whose immune response is compromised, which may lead to development of symptoms in different organs, such as CMV colitis[13]. The use of highly active antiretroviral therapy in patients with HIV has decreased significantly CMV disease in these patients[14]; on the other hand, induced immunodeficiency in situations such as solid organ transplant or inflammatory bowel disease (IBD) sometimes allows CMV disease to develop, with significant morbidity and even mortality[15].

Antibody response to CMV infection reflects this relapsing-remitting pattern. In primary infection, an early increase of specific IgM antibodies occurs, which can be detected in the first week of infection[16], showing a sensitivity of 100% and a specificity of 99%[17]. Over the next 3-6 mo immunoglobulin M (IgM) antibodies fall to undetectable levels, although some may persist for up to 12-24 mo. Persistence of IgM antibodies could be related to concomitant immunosuppression[18]. Reactivation can cause again a rising IgM titers[17,19]. Immunoglobulin G (IgG) antibody production occurs within a few weeks of IgM increase[16]. When patients develop specific CMV IgG antibodies, they are considered "seropositives". In the reactivation of CMV, IgG antibody levels do not change, so that this situation can only be differentiated by the detection of an increase in IgM antibody titers that does not always occur. Thus, serology has a limited value in the diagnosis of reactivation[10]. Seronegative patients are not at risk for CMV disease, unless primoinfection occurs.

Gastrointestinal tract is a common site of CMV disease, with preference the esophagus and the colonic mucosa (especially at the right colon). The pouch mucosa behaves in a similar way to colon mucosa[20-22]. Clinical presentation of CMV colitis begins with watery diarrhoea that may be progress to rectal bleeding, abdominal pain, fatigue and fever. Other presentations such as fever of unknown origin, megacolon or digestive hemorrhage, are also possible.

It is unknown whether the virus remains in colon after a primary infection or if it disappears spontaneously[23]. A recent study[24] demonstrated persistence of colonic CMV [using polymerase chain reaction (PCR) method], following an acute ulcerative colitis (UC) flare-up despite remission of symptoms. The virus may disappear or not from the colon after an acute UC flare-up, but if it persists is detected only by PCR DNA, without displaying inflammatory changes in colonic mucosa or CMV antigens in infected colonic cells.

There have been reports of CMV colitis in immunocompetent hosts[25,26], especially in elderly patients with comorbidities in whom the disease followed a severe course with high mortality rate. Also, rare cases of CMV colitis preceding IBD have been reported[27].

RELATIONSHIP BETWEEN CMV AND IBD

The association between CMV and IBD was described long ago. The first case report dates from 1961, when Powell *et al*[28] described a patient with UC and cytomegalic inclusion disease. Since then, questions remain about the role of CMV in these patients: does CMV reactivation exacerbate the disease in patients with established IBD or is reactivation a consequence of IBD activity and its treatment with CMV acting as an innocent bystander[29-31]? Interpretation of existing results is limited because most studies are small and retrospective, different diagnostic methods of CMV detection are available and even different classifications are used for the severity of concomitant IBD[3].

CMV colitis occurs in "seropositive" patients with IBD. CMV does not appear to interfere with the clinical evolution of Crohn's disease (CD), and its involvement in UC is debated, especially in severe flare-ups.

DIAGNOSTIC TECHNIQUES

Diagnostic techniques for CMV infection

Serology: Serology is useful to determine previous viral exposure and identify patients at risk, as only seropositive patients (positive IgG antibodies in blood) may develop CMV disease[30,31].

Antigenemia assay: It detects viral protein pp65 produced in peripheral blood polymorphonuclear leukocytes. It is a simple and rapid technique, with a sensitivity of 60%-100% and a specificity of 83%-100%[32,33]. However, it does not differentiate between latent infection and active disease[23], no association exists with virus reactivation in the intestinal mucosa[31,34], and false negatives can occur in neutropenic patients[35].

PCR DNA amplification assay in blood: This test is supplanting antigenemia. Sensitivity ranges 65%-100% and specificity ranges 40%-92%[32,36,37]. This diagnostic method cannot differentiate between latency and activity states, so it is necessary to determine a cut-off above which active infection is diagnosed in patients with IBD[30,35], as well as in solid organ transplantation, where a viremia > 1000 copies/100 000 leukocytes indicates symptomatic CMV infection[38]. This method can be used both to detect disease and to monitor treatment response; a slow or absent decline in DNA levels after treatment could be an early indicator of drug resistance[39], and positive result after therapy indicates continuing treatment[40]. Most studies in patients with IBD have reported a correlation between

identification of CMV by PCR in blood and detection colonic CMV by haematoxylin and eosin (HE) or immunohistochemistry (IHC)[34,41-43].

PCR assay in stool: A qualitative and quantitative PCR assay for CMV DNA has been performed on human faecal specimens from immunocompromised patients[44,45].

Diagnostic techniques for CMV colitis

Histological diagnosis is considered the "gold standard" for diagnosing CMV disease in the gastrointestinal tract[46-51]. Several methods are available.

Histology by HE: Typically reveals cytomegalic cells that are 2 or 4 fold larger than normal cells, containing basophilic intranuclear inclusions in eccentric location surrounded by a clear halo, giving it an "owl's eye" appearence. Cells show a thickened nuclear membrane and smaller granular intracytoplasmic inclusions. Colonic biopsies should be taken from inflamed mucosa near or within the ulcer. This method has very high specificity (92%-100%), but its main problem is a poor sensitivity (10%-87%), making the diagnosis requires many samples and a trained pathologist[46,47]. Anecdotally cytomegalic cells have been described in colon biopsies from normal mucosa in healthy individuals[48,49].

IHC in colon biopsies: It involves the identification of CMV antigens in infected cells. It has a higher sensitivity than HE (78%-93%)[50,51]. Other techniques, however, do not rely on histology.

PCR DNA amplification assay in colon mucosa: PCR DNA amplification assay in colon mucosa has the greatest accuracy for virus detection[29,52,53] and may be used as a qualitative or quantitative method. PCR DNA levels in the colon are not related to viremia levels measured in blood[31,43,54,55]. Some studies detected prevalences greater than 30% in IBD patients[56], although the significance of a positive result in absence of histological signs of CMV infection is unclear. Very few studies have shown a correlation between histology (HE/IHC) and PCR results[31,43]. This suggests that detection of low DNA levels could determine latent infection and requires a cut-off level of viremia to distinguish infection from disease[30]. In other words, a positive result in colon does not necessarily reflect the involvement of CMV in UC flare-ups. A recent study from France suggests a cut-off of > 250 copies/mg for CMV disease[54] with a sensitivity of 100% and a specificity of 66%. To avoid false positives, and awaiting further studies, this determination should be performed only in patients with active UC refractory to conventional treatment.

Viral culture: Viral culture was previously regarded as the gold standard in CMV detection. Culture has a sensitivity of 45%-78% and a very high specificity (89%-100%). The virus is placed in a fibroblast tissue culture and diagnosis is made once the virus causes cytopathic changes in fibroblasts. The problem is that the result takes days to weeks[10], so this method is not used in clinical practice[57].

Typical endoscopic findings of CMV colitis: Typical endoscopic findings of CMV colitis are microerosions, deep ulcers and pseudotumoral lesions[58]. Most studies in patients with IBD, specifically in active UC, have not found specific endoscopic features[43,54,59,60]. Anecdotal studies describe some characteristic endoscopic (large, irregular, punched-out or longitudinal ulcers) with virus[61]. Discrepancy can be explained by the different criteria used to define CMV infection or disease.

In conclusion, different methods of detection of CMV have different sensitivities and specificities. In the setting of a severe UC flare-up refractory to conventional treatment, colonic IHC or PCR in blood should be performed, PCR presents a good correlation with the results of HE and IHC[30]. Serology and antigenemia only are useful as negative predictors for CMV infection, since they do not correlate with actual CMV colitis. The role of PCR positivity in colon remains to be determined, it is not known how to interpret its positivity in the absence of histological changes. However, recent studies imply positivity of this method in the disease prognosis[54]. Current European guidelines[62] recommend the use of tissue PCR or IHC to detect CMV in patients with UC resistant to immunomodulators, whereas older American guidelines[63] recommend performing sigmoidoscopic biopsy and viral culture in refractory cases of UC.

CMV PREVALENCE IN IBD

Overall prevalence of CMV is unknown in IBD patients. Most of studies have been carried out using a selected patient group and using different diagnostic methods, so that the available data include a wide range of prevalences.

CMV prevalence in CD

Seropositivity in CD patients is as high as in other populations (70%)[64,65], however CMV disease is rare in CD, making the virus an unlikely etiological factor in the novo development of IBD[27,64,66,67].

In most surveys, IHC did not detect CMV in CD patients, and PCR in tissue or stool samples found a very small frequency (< 5% of patients)[27,66-69], except in one study that used a highly sensitive PCR (detection < 10 copies of DNA) which detected CMV in 66% of individuals with CD and in 29% of controls, showing no association between CMV DNA and disease activity, suggesting the authors that small quantities of viral DNA are not clinically relevant[29].

Recently some theories have been published that explain these findings based on small studies[70], so results should be interpreted with caution. Tumor necrosis factor-α (TNFα) would be significantly associated with CMV infection or reactivation in IBD. However interferon-γ (IFNγ), which is produced from CD4 + T

cells[71], could suppress CMV reactivation. CD is considered a Th1-type inflammatory process with high expression of IFNγ, which does no help the virus reactivation and may explain the different prevalence of CMV disease in UC and CD[70].

CMV prevalence in UC

Prevalence of CMV infection is about 70%[31], a similar percentage to that of the general population.

Patients with inactive or mild-moderate UC did not show an increased risk of CMV colitis, using HE and IHC[27,31,41] or IHC in colectomy patients undergoing surgery for dysplasia or cancer[72].

The most extensive literature is on severe and/or steroid-refractory colitis. These two terms are used interchangeably in studies and are not defined clearly, so the results are difficult to interpret[30].

Severe colitis: The combination of serological tests and rectal biopsies found a CMV disease prevalence of around 20%[42,73]. Risk factors that have been identified are female gender, older age, pancolonic disease with active inflammation at histology and azathioprine therapy[60,72,73]. According only to antigenemia, prevalence increased to 34%[60], while using HE or IHC in colonic mucosa prevalence decreased to 3%[74].

Severe steroid-resistant colitis: In retrospective studies the prevalence according to HE was 0.5%[75]. The prevalence of CMV increased by combining HE and IHC with antigenemia (20%-40%)[31,41,72,76,77]. The prevalence using blood PCR was 60%[43], whereas PCR results in colon were lower (38%)[78]. There is a poor correlation between peripheral and colonic viral load, this can be explained by theory proposed by Criscuoli *et al*[24,42] about a specific genotype, which possibly has a particular colonic tropism and pathogenic character, whilst other genotypes are not pathogenic.

Urgent colectomy for colitis: A higher prevalence of CMV is expected in these patients because the greater severity of their disease, but the prevalence using HE or IHC ranged between 11.5% and 27%[77,79-82], which is similar to the previous groups.

Experimental studies have identified three factors that influence the reactivation of CMV infection in active colitis: (1) increased cell proliferation in inflamed tissue with ulcers that attract CMV; (2) inherent impaired natural killer cell activity presented by patients with IBD[83,84]; and (3) use of immunosuppressive drugs[31,42,69]. The third factor is controversial[73-75,80,85], since use of steroids may be either a risk factor or a surrogate marker of severity disease[41]. *In vitro* data suggest that steroids and cyclosporine could support the replication of CMV[76,86,87]. Infliximab treatment has not been associated with increased risk of CMV reactivation in IBD patients[66]. Moreover, TNFα has been identified as an activator of CMV, and thus infliximab (IFX) could promote viral latency, by lowering the levels of this cytokine[88,89]. This suggests that IFX could be used in patients with severe UC flare and CMV reactivation. However, some cases of tacrolimus-refractory UC that were treated with IFX did not have a favourable outcome[90].

CMV reaches the mucosa by way of monocytes and then colonize the colonic cells, acquiring particular affinity for the inflammatory sites, probably due to the presence of pro-inflammatory cytokines such as IFNγ and TNFα produced by macrophages and T-cells in active UC[91-94]. CMV avoids immune recognition of macrophages and uses immune specific functions to reactivate and spread[95]. Recent studies suggested CMV can appear only in inflamed tissue and is not found in healthy tissue[54].

Hommes *et al*[94] proposed the following sequence to explain the pathophysiology of CMV disease in patients with active UC: (1) initiation phase, mucosal inflammatory response induces expression of cytokines and chemokines which activates latently infected cells and the migration of monocytes and dendritic cells into the inflamed mucosa; (2) reactivation phase, in which infected monocytes differentiate into tissue macrophages and dendritic cells; and (3) consolidation phase, during which the virus causes an active replication predominantly in endothelial cells that likely exacerbates inflammation. The virus in the first and second phase has not led to histological damage and can only be detected by PCR-DNA. It would be appropriate to detect CMV in these phases, so the optimal treatment would be administered at an early stage before complicating the disease. They do not consider CMV as an innocent bystander but rather involved in resistance to immunosuppressive treatment.

In the same line, other authors suggest that the positivity of CMV DNA in the colonic mucosa in patients with refractory UC indicates uncontrolled intestinal inflammation, suggesting a change in immunosuppressive therapy[96].

Coincidental detection of primary CMV infection at the first appearance of IBD has been reported before[66,97], primary CMV infection in IBD patients without immunosupression[98,99], and even disseminated CMV infection in CD[100].

PROGNOSIS OF CMV COLITIS IN IBD

As discussed above, it is unclear whether CMV superinfection leads to a more aggressive course of pre-existing inflammatory disease[29,30].

Referring only to UC, case-reports and retrospective series[29,42,55,68,69] suggested that CMV may trigger a steroid-refractory flare-up and worsen disease prognosis[76,77,80,85,101], associated increased risk of toxic megacolon[81] and surgical intervention[31,77,82,102,103]. This hypothesis is supported by two prospective studies[41,54]. The second, a recent French study, relates positivity of CMV (PCR in colon > 250 copies/mg) to treatment resistance (steroids and other three line of treatment), demonstrating that early initiation of antiviral therapy in these cases delays treatment resistance

and improves prognosis[54].

However, other studies[3,27,34,43,72] that analyzed prognosis in patients with severe UC refractory to conventional treatments did not find increased disease severity nor increased rate of colectomy in CMV positive patients.

These conclusions are limited by differences in quality of existing studies.

TREATMENT OF CMV COLITIS IN IBD

It is difficult to draw conclusions about the role of antiviral therapy based on the available evidence[23], which is of varying quality.

Most authors recommend the use of antivirals[30,31,41,43,75] in steroid-refractory UC flare-up and CMV positive patients. Treatment can significantly decrease the mortality rate and need for surgery. However, some studies show that treatment of CMV does not alter disease course[80], and has even been shown the transience of positivity of serological tests (antigenemia, PCR) in patients with severe UC, but which as discussed earlier has little correlation with PCR determination in colon[34,94].

As CMV reactivation impact in clinical outcome is not yet elucidated, a rational approach would be to determine the CMV serology (IgG) when prescribing steroids in UC[31]. If steroid-refractoriness develops, rectal biopsies should be conducted only in seropositive patients, who are the ones who are at risk of developing CMV disease[31]. A detection of CMV (HE, IHC or PCR) in the inflamed mucosa should imply that standard therapies alone will not control intestinal inflammation, and make mandatory to consider alternative therapies[43], including CMV treatment[30]. If detection methods are not readily available, empiric therapy of IgG positive individuals with steroid-refractory disease is probably justified.

An original study recommended only antiviral treatment in severe UC with large ulcers (> 5 mm) and positive PCR in colon, all patients with positive PCR and no large ulcers in endoscopy responded to conventional therapy[104].

CMV colitis is typically treated with ganciclovir, although other antivirals have been used as foscarnet, valganciclovir and cidofovir[105-107]. Ganciclovir has a poor oral bioavailability so initially it has to be administered intravenously[105,106]. The recommended dosage is 5 mg/kg twice daily for at least 3 wk[107]. After some days of initial treatment the patient can switched to oral ganciclovir (1 g three times daily), although its value is uncertain. Treatment benefits must outweigh the risks associated with the medications used, as this drug can trigger significant adverse effects such as bone marrow suppression, particularly neutropenia[105]. Other side effects include headaches, somnolence, psychosis, elevated transaminases, fever and rash[105]. Foscarnet can be used when ganciclovir is contraindicated (90 mg/kg intravenously twice daily for 3-6 wk)[107]. Its main adverse effect is nephrotoxicity.

Response rate to antiviral therapy is 72% (range 50% to 83%)[31,41,43,75], but these data should be interpreted with caution because "response" was not uniformly defined in these studies and patients were treated concomitantly with immunosuppressants[30], although some authors decreased the dose of immunosuppressive drug[75]. Other authors consider to increase immunosuppressive therapies (other than corticosteroids) if CMV-DNA in colonic mucosa is detected, because a positive finding of CMV-DNA in inflamed colonic mucosa of patients with refractory UC suggests uncontrolled intestinal inflammation[96]. Antiviral treatment should be considerate in disseminated disease[108] which has very poor prognosis.

ECCO guides[62] and American College of Gastroenterology[63] recommend treatment when CMV is detected in colon tissue. Immunosuppressive therapy is stopped only in case of severe systemic CMV reactivation[62].

A multicenter randomized controlled trial with a large number of patients, using homogeneous diagnostic methods, including endoscopic evaluation, would be required to determine in which subgroup of patients early antiviral treatment would be useful[23,96].

Abstract

Hepatic encephalopathy is a medical phenomenon that is described as a neuropsychiatric manifestation of chronic or acute liver disease that is characterized by psychomotor, intellectual and cognitive abnormalities with emotional/affective and behavioral disturbances. This article focuses on the underlying mechanisms of the condition and the differences between hepatic encephalopathy and noncirrhotic hyperammonemic encephalopathy. Hepatic encephalopathy is a serious condition that can cause neurological death with brain edema and intracranial hypertension. It is assumed that approximately 60%-80% of patients with liver cirrhosis develop hepatic encephalopathy. This review explores the complex mechanisms that lead to hepatic encephalopathy. However, noncirrhotic hyperammonemic encephalopathy is not associated with hepatic diseases and has a completely different etiology. Noncirrhotic hyperammonemic encephalopathy is a severe occurrence that is connected with multiple pathogeneses.

HEPATIC ENCEPHALOPATHY

Introduction and division

Hepatic encephalopathy (HE) continues to be a major clinical problem. In subjects suffering from acute/chronic liver failure, HE can lead to coma and death. This medical state causes a broad range of neuropsychiatric disturbances with variable intensities, including poor concentration, psychomotor retardation, decreased reaction time, short-term memory impairment and sensory dysfunction[1,2]. According to the newest data, HE occurs as one of four types. Therefore, this encephalopathy syndrome might be classified into four groups: A, B, C and D[3-5]. Type A HE is inseparably associated with acute liver failure resulting from severe inflammatory and/or necrotic rapid onset liver disease (e.g., paracetamol overdose, excessive alcohol intake or acute fatty liver caused by pregnancy or Reye's syndrome). Type B HE is associated with portosystemic bypass in the absence of parenchymal liver disorders and is mainly connected with congenital abnormalities. Type C HE accompanies chronic liver failure (cirrhosis) and portal hypertension with portosystemic shunts. Type C has three subcategories: episodic (precipitated, spontaneous, or recurrent), persistent (mild, severe, or treatment-dependent) and minimal. In 2009, the International Society for the Study of Hepatic Encephalopathy and Nitrogen Metabolism completed these classifications and added the experimental models

associated with each type[6]. Finally, type D is associated with disorders of the urea cycle. Typically, these syndromes are rare hereditary disorders of urea biosynthesis caused by genetic defects in the urea cycle and have been described for each of the six enzymes that participate in urea formation. They occur mainly in neonates and more rarely in adults[7-16]. Alcohol, viral infections, drugs or toxins and biliary obstruction are several reasons for the development of cirrhosis. Portal hypertension resulting from cirrhosis stimulates the opening of embryonic venous channels. Portal-systemic shunts then allow intestinal toxins (ammonia, manganese and cytokines) to bypass the liver in the systemic circulation. A classification based on HE severity enables the division of HE into two types: (1) minimal hepatic encephalopathy (MHE); and (2) overt hepatic encephalopathy (OHE). MHE affects patients who have normal mental and neurological status; however, abnormalities appear in specific psychometric tests[17-20]. OHE is characterized by neurological and neuropsychiatric disruptions, which can be detected by bedside clinical tests[21].

Pathogenesis

Although the etiology of HE has not been conclusively established, it is widely agreed to be the result of numerous pathological processes. Research on the pathogenesis of HE is still being conducted, and several theories have been reported (Figure 1).

The ammonia hypothesis

The neurotoxicity of ammonia is well recognized and was first thought to play a significant role in the development of HE in the 1890s. In one study, creating a surgical shunt from the portal vein to the vena cava of dogs mitigated their aggression and irritability during the experiment[22]. Similar investigations led to the description of HE. In HE, complications from the hepatic detoxification of ammonia expose the brain to high ammonia concentrations. Consequently, these complications lead to neurotoxicity, which results in neuropsychiatric syndromes and abnormal cerebral blood flow[23,24]. The human body has several sources of ammonia. Primarily, ammonia is created in the colon as a byproduct of proteins and urea, which are metabolized by bacteria. Moreover, ammonia is produced in the small intestine as the result of the bacterial degradation of glutamine (an amino acid)[6,25]. Muscles and kidneys can also produce ammonia. However, ammonia appears to play a negligible role in organs that are beyond the gastrointestinal tract. In HE, the muscles and the kidneys are involved in the metabolism of ammonia to a greater extent than normal. In chronic liver failure, the skeletal muscle tissue (because of its large size) becomes a key organ that detoxifies ammonia in organisms. Liver disease often results in a condition requiring a hypoproteic diet. However, in the context of the role of muscles in hyperammonemia, this diet is not recommended for HE; a hypoproteic diet might decrease both muscle mass and ammonia detoxification. This proceeding is supported by the latest research proving that diet supplementation with branched-chain amino acids reduces MHE and improves muscle mass[26,27]. The kidneys also interact with the liver to metabolize ammonia. Under normal circumstances, 30% of produced ammonia is excreted in the urine. In liver disease, 70% of the synthesized ammonia is eliminated by this means. As a result, renal disturbanc-

es may intensify cognitive impairment during HE. Note that a healthy liver (periportal hepatocytes) protects the brain from ammonia by converting it into urea, which is excreted through the kidneys and into the colon. Ammonia is also detoxified by the formation of glutamine from glutamate, which occurs in the liver (the hepatocytes near the central vein) and the brain[28-30]. Therefore, HE, hepatocellular failure and portosystemic shunting disable the ability of the liver to neutralize ammonia, and the arterial levels of this compound become elevated. Because of the role it plays, ammonia is sometimes described as a key toxin in the etiology of HE. First, ammonia can induce astrocyte swelling as the result of osmotic imbalance. This phenomenon is thought to play a major role in the pathogenesis of HE. Astrocytes are the only brain cells that are able to metabolize ammonia. This metabolism occurs because of the presence of glutamine synthetase (a special enzyme) in the astrocytes, which transforms glutamate and ammonia into glutamine. Therefore, the intracellular level of glutamine rapidly increases in conjunction with the concentration of ammonia in liver disease. Glutamine is an osmocyte and causes the movement of water into the astrocytes. As the result, the astrocytes swell, and this process leads to cerebral edema and intracranial hypertension. In support of this theory, the administration of methionine sulfoximine (a glutamine synthetase inhibitor) prevents astrocytes from swelling in animal models[31-33]. Astrocytes that are exposed to ammonia for prolonged periods can undergo a morphologic transformation into Alzheimer's type Ⅱ astrocytes, which are defined by large nuclei, prominent nucleoli and marginated chromatin[34]. Hyperammonemia among neural cells also produces reactive oxygen species (ROS). These oxygen species are able to trigger astrocyte swelling and modulate Zn^{2+} mobilization, which results in the stimulation of the peripheral benzodiazepine receptor. Furthermore, ammonia increases the resting membrane potential in the brain, inactivates the neuronal chloride extrusion pumps, suppresses inhibitory postsynaptic potential formation and causes neuron depolarization[35]. This neuroinhibitory state is characteristic of HE. The molecular effects of ammonia reflect the behavioral changes in patients with hyperammonemia.

Bacterial products and bacterial infections in HE

Ammonia is an important factor in the pathogenesis of HE. However, approximately 10% of patients with significant encephalopathy have normal serum ammonia levels; this statistic supports the argument against the prevalence of the ammonia hypothesis. Furthermore, many cirrhosis patients have elevated ammonia levels and no evidence of encephalopathy. In addition to ammonia, other bacteria-produced substances may cause neurotoxicity in HE. Mercaptans exert their neurotoxic influence on human organisms as the result of the bacterial metabolism of amino acids. The phenols synthesized by bacteria from aromatic amino acids are also dangerous. Elevated levels of both mercaptans and phenols have been found in patients with chronic liver disease. These endogenous toxic substances, which are produced in the intestines, are absorbed into the portal venous flow. The toxins escape from liver catabolism because of the impaired liver function and the presence of portosystemic shunts. Finally, the toxins reach the brain through the blood-brain barrier (BBB) and cause cerebral function disorders[29]. Coexisting gastrointestinal bleeding enhances the flow of toxins into the systemic bloodstream. Bacterial flora might also be the source of benzodiazepine-like compounds, which are produced during the metabolism of amino acids. These compounds can impair the function of the astrocytes and disrupt gamma-aminobutyric acid (GABA)ergic neurotransmission. Similarly to bacterial flora, bacterial pathogens are also involved in the etiology of HE. Recent investigations underline the potential importance of acute infections caused by bacterial pathogens and the resulting inflammation in the neuropsychiatric symptoms of HE[36]. Moreover, the inflammatory response might modulate the reaction to hyperammonemia. In such a situation, cytokine-induced changes in ammonia diffusion can occur in the brain, and the expression of benzodiazepine receptors might increase.

The GABAergic neurotransmission theory

GABA is a principle inhibitory neurotransmitter. GABA-mediated transmission is based on the $GABA_A$/benzodiazepine receptor/chloride ionophore complex. This binding opens the ion channel and increases the amount of chloride in the neuron. Increased GABA-mediated neurotransmission contributes to motor function impairment and decreased consciousness, which are the main manifestations of HE[37,38]. Mechanisms leading to the increased GABAergic transmission in liver failure are not well known. Nevertheless, there is evidence suggesting that the amount of natural benzodiazepine receptor agonists in the liver increases with impaired function. Two observations confirm this theory. First, increased levels of these agonists have been found in the brain and body fluids of HE patients[3,21]. Furthermore, treatment based on flumazenil, a benzodiazepine receptor antagonist, ameliorates HE. The role of neurosteroids (e.g., tetrahydro-progesterone and tetrahydrodeoxycorticosterone) in the problem of GABAergic transmission should be noted[39]. Neurosteroids are potent agonists of the $GABA_A$ receptor, acting through a unique binding site to enhance GABAergic neurotransmission. Animal research revealed the ability of pregnenolone (an endogenous neurosteroid "antagonist") to decrease mortality in hyperammonemic models. The results demonstrate the important role of GABAergic enhancers in the pathology of HE. The enhancers are normally synthesized in astrocytes and appear in elevated concentrations in hyperammonemic mice or mice with acute liver failure. The elevated concentrations are caused by the glial cell

activity in ammonia-induced disorders. The specific path leading to neurosteroid synthesis is not yet clear; however, this phenomenon appears to be connected with ammonia-induced increases in the density of peripheral-type benzodiazepine receptors[40-42]. GABAergic neurotransmission might be enhanced by the increased access of GABA in the synaptic clefts. This phenomenon is caused by the loss of presynaptic feedback inhibition from the GABA release, which is the result of decreased $GABA_B$ receptor values. Finally, recent research suggests that ammonia itself might directly increase GABAergic transmission[43].

The idea of neuroinflammation

Ammonia dysmetabolism does not exist as the sole factor of the neurological changes observed in patients with HE. It is well known that sepsis is precipitating state that plays significant role in the decompensation of liver diseases[44-46]. The peripheral immune system communicates with the brain in response to infection and inflammation. This response results in neutrophil adhesion, migration across the BBB and release of chemokines, proinflammatory cytokines, proteases and ROS as well as inflammatory gene transcription[47]. Simultaneously, astrocytes and microglial cells release cytokines in response to injury or inflammation. Researchers have proven that the increased blood level of tumor necrosis factor (TNF), which occurs during inflammation, stimulates the glial cells to excrete the cytokines [interleukin (IL)-1, IL-6] and influences the permeability of the BBB[21,22,48-50]. In conclusion, the diffusion of ammonia into the astrocytes increases *in vitro*. Moreover, a recent study has revealed that TNF or IL-1 receptor gene deletion retards the process of encephalopathy and decreases the intensity of brain edema in mice with acute liver failure. In addition, treatment based on a TNF receptor antagonist (etanercept) similarly reduces the severity of encephalopathy and prevents brain edema[49]. The concept of neuroinflammation (microglial activation) is defined as a wide variety of neurological disorders including multiple sclerosis, Alzheimer's disease, stroke and acquired immune deficiency syndrome dementia complex. Microglial activation is followed by highly increased levels of proinflammatory cytokines (TNF, IL-1 and IL-6) in the brain[51,52]. This discovery revealed a new aspect of HE, provided a new look at the pathophysiology of HE and opened a new gate into the pharmacotherapy of HE. This neuroinflammatory concept is also supported by the therapeutic effect of mild hypothermia and indomethacin, which reduces the activation of microglial cells and simultaneously prevents the central proinflammatory process in mild HE[27,51,53,54]. Moreover, mild hypothermia remarkably decreases brain edema and the duration of HE. Intracranial pressure (ICP) may be reduced by hypothermia even in patients who are unresponsive to mannitol. The additional benefits of indomethacin depend on how it affects cognitive function *via* modulation of the glutamate-nitric oxide cyclic GMP pathway. Indomethacin might reduce ICP and cerebral edema independently of changing the cerebral blood flow (excepting the brain function modulation). Numerous studies have revealed the beneficial role of anti-inflammatory agents in the course of HE. Ibuprofen reportedly reduces locomotor disorders and increases the learning abilities of rats with portacaval shunts. Ibuprofen also normalizes blood and brain ammonia levels[46,55]. Consequently, anti-inflammatory therapy inhibits microglial activation during HE. The findings in different experimental models provide new therapeutic targets for HE and require further study.

Oxidative and nitrosative stress

The metabolism of astrocytes changes after exposure to ammonia, hyponatremia, benzodiazepines or inflammatory cytokines; under such circumstances, the production of reactive nitrogen species and ROS increases in the astrocytes. N-methyl-D-aspartate (NMDA) receptors play an important role in the production of free radicals. The stimulation of ammonia-induced NMDA receptors reduces antioxidant enzyme activity and increases the production of superoxide anions[56,57]. The presence of ammonia inside the astrocyte mitochondria (with the coexistence of calcium) initiates the process. Moreover, the ROS source (neutrophil metabolism) constitutes a systemic/local inflammatory state as well. Glutamine exposure is known to increase the oxidative stress among astrocytes (the "Trojan horse hypothesis")[32,58]. The other area of research interest involves RNA oxidation and the resulting impairment in protein synthesis. Molecular disorders lead to cognitive abnormalities in HE. ROS are involved in the nitration of tyrosine (the component of intracellular proteins). Nitrated tyrosine tends to selectively reduce the permeability of the BBB, which promotes astrocyte swelling and cerebral edema[59-61].

The 'two-hit hypothesis' is another pathological path leading to ROS output, and it is connected inseparably to the activity of ammonia. Liver disease followed by hyperammonemia constitutes a starting point (an 'initial hit') in this theory. Astrocyte swelling and oxidative stress appear next. Finally, there is a 'second hit', such as an ammonia load caused by an upper gastrointestinal bleed, dehydration, hyponatremia or infection. Astrocyte damage occurs, and the level of ROS increases further. This close connection between astrocyte swelling and oxidative stress generates an auto-amplifying signaling loop that results in the deterioration of neurocognitive abilities[22].

Changes in the blood-brain barrier

The BBB constitutes a highly specialized mechanism of brain microvasculature, and it is indispensable for the proper function of the central nervous system (CNS)[26]. The BBB consists of pericytes, capillary basement membranes, endothelial capillary cells and astrocytes, which encase the vessels[62]. There is evidence of BBB dysfunc-

tion in the pathogenesis of many CNS disorders (e.g., Alzheimer's disease and multiple sclerosis). The pathological appearance of HE is closely related to BBB changes. Swollen astrocytes constitute a well-known phenomenon in the course of HE[22,63]. The phenomenon is primarily caused by cellular and vasogenic edema and aquaporins (AQP). In CNS structures, elevated values of AQP 1, 4 and 9 are characteristic of brain edema[26]. The increased expression of these water channels serves an important role in the movement of water through the BBB and its pathological result. Moreover, AQPs have been reported to participate in apoptosis in the CNS[64,65]. Astrocyte disorders in HE result in changes to the BBB, reflected by the loss of ion homeostasis and the accumulation of intracellular water. Nevertheless, increased BBB ammonia permeability during hyperammonemia or HE is still a matter of controversy among scientists[66]. There are investigations that support and refute this theory. Several positron emission tomography studies have revealed elevated brain ammonia concentrations in HE. In addition, transmission electron microscopy demonstrated a disruption in the junction of BBB capillaries in the hippocampal area in a MHE model[26,35]. According to the presented data, the structure of the BBB and its connection to systemic hyperammonemia in HE require further exploration. The large number of studies conducted in this area indicates that it might be essential for the pathological appearance of HE.

Death of CNS cells

Brains exposed to high ammonia concentrations undergo several serious changes, including metabolic and neurophysiological disorders with pathological synaptic inhibition and excitation. As a result, alterations in cerebral energy metabolism appear and neurotransmitter-related processes begin to falter[59]. The mechanisms leading to cell death in the CNS are associated with changes in the neuronal mitochondria[67,68]. First, a reduction in the ATP concentration occurs in the course of HE. The two basic paths responsible for this modified energy metabolism are the NMDA receptors and the inhibition of the tricarboxylic acid cycle. The NMDA receptors are able to mediate mitochondrial swelling, neurotoxicity and neuron death during acute liver failure[57,69]. Furthermore, it is suggested that calcium plays a key role in the pathology of cell death in the CNS[22,26,70]. In HE, the mitochondrial calcium content becomes elevated because of acute ammonia intoxication. Calcium is able to enter the mitochondria *via* NMDA receptors[71,72]. This mechanism results in the release of glutamate and ROS and induces an apoptotic cascade among the neurons. Peripheral benzodiazepine receptors located in the mitochondrial membrane cells also cause the programmed death of neurons in association with calcium[21,40-42,73]. In conclusion, the loss of neuronal cells depends on the neurotoxicity of ammonia and mitochondrial dysfunction. The above-mentioned pathological mechanisms are reflected in the cerebral atrophy and mental retardation observed in patients suffering from HE[26].

Other pathogenic elements in HE

It is clear that the etiology of HE is complex and multifactorial. In addition, theories different from those presented above have been postulated to explain the pathogenesis of HE. The opioid, serotonergic and dopaminergic systems are likely involved. Furthermore, 'false' neurotransmitters (e.g., phenylethanolamine and octopamine) produced from aromatic amino acids are elevated in individuals with HE. These substances compete with real neurotransmitters and impair neurological functions[43]. The genetic background of HE is underlined. Genetic analyses showed that particular haplotypes in glutaminase (an enzyme that converts glutamine into glutamate) in patients suffering from cirrhosis affect the risk of HE. A characteristic section in the promoter region of the gene sequence for glutaminase has been detected that contains repeated base pairs. Studies have shown higher luciferase activity in the cells transfected with this doubled region. This research indicates that those repeated elements increase glutaminase transcriptional activity. As the result, genetic disorders appear to be responsible for the development of HE in patients with cirrhosis[74].

In addition to ammonia, manganese participates in the development of HE[75,76]. Manganese is an essential metal that is involved in the metabolism of carbohydrates, lipids and proteins. Manganese is an important cofactor of numerous enzymes. It is a neurotoxin that may be transported into the brain across the BBB and the brain-cerebrospinal fluid barriers. In such circumstances, it is preferentially accumulated in the basal ganglia. Manganese enhances neurosteroid synthesis *via* the activation of translocator proteins on astrocyte membranes[3]. Manganese affects the operations of certain proteins that interact with dopamine (a neurotransmitter), NMDA toxicity or oxidative and nitrosative stress. Three mechanisms of manganese neurotoxicity have been described[26,77,78]. The first is mitochondrial dysfunction and the disruption of energy metabolism; the second is connected with the inflammatory activation of the glial cells; and the third mechanism constitutes the disruption of synaptic transmission and neuroglial communication. This mechanism induces the phosphorylation of c-Jun and SEK1/MKK4 and the tyrosine phosphorylation of several proteins[79]. Manganese produces active oxygen species (superoxide hydrogen peroxide and hydroxyl radical) and toxic catecholamines (6-hydroxydopamine). Moreover, manganese is the first metal reported to induce apoptosis in the CNS[26]. Furthermore, manganese deposition has been detected by magnetic resonance imaging in the caudate nucleus and in the globus pallidus of cirrhotic patients. This detection might explain the presence of Parkinson symptoms (such as tremors) observed in certain patients with HE. Researchers have indicated that manganese enhances

neurosteroid synthesis and promotes the formation of Alzheimer's type II astrocytes[21].

The study conducted by Guevara *et al*[80] revealed that hyponatremia (serum sodium < 130 mEq/L) is an independent and serious predictor of overt HE. This hypothesis may open new strategies for HE treatment. The reduction of hyponatremia might be a novel therapeutic approach in preventing HE in liver cirrhosis[52].

Neuroendocrine correlations in the course of HE are not well recognized. Nevertheless, studies conducted on rats demonstrated decreased levels of prolactin in models suffering from HE. This disorder might be caused by a hyperammonemic state. Endocrinal curiosity reveals the necessity of further research in this area[26].

NONCIRRHOTIC HYPERAMMONEMIC ENCEPAHALOPATHY

Research shows that approximately 90% of adult hyperammonemia cases are caused by severe liver disease. A small number of cases have other causes and can be divided into two groups: (1) cases that are connected with increased ammonia production; and (2) cases that are caused by decreased ammonia elimination[81].

Increased ammonia production

Hyperammonemic encephalopathy may develop in patients with progressive multiple myeloma[82]. Several studies have demonstrated that malignant cells are able to produce excess ammonia as the result of increased amino acid metabolism. During intensive chemotherapy, leukemia patients tend to struggle with hyperammonemia[83]. Idiopathic hyperammonemia is also described among bone marrow recipients. The other reason for noncirrhotic hyperammonemic encephalopathy might be the presence of infections caused by urea-producing bacteria (*Proteus mirabilis*, *Escherichia coli*, *Klebsiella* and *Providencia rettgeri*). In extreme cases, the protein load and increased metabolism might cause the elevated ammonia level. Therefore, seizures, severe exercise, starvation, total parenteral nutrition or gastrointestinal bleeding can (rarely) result in encephalopathy.

Decreased ammonia elimination

Metabolic disorders and problems with ammonia elimination might be the source of encephalopathy. Such disorders include organic acidurias, urea-cycle disorders, dibasic aminoaciduria, impaired fatty acid oxidation and mistakes in pyruvate metabolism[7,11,12]. Noncirrhotic congenital portosystemic shunts can also cause an elevated ammonia level in the blood stream, and the intake of certain drugs (e.g., valproic acid, glycine, ribavirin and carbamazepine) may induce noncirrhotic hyperammonemic encephalopathy[84-87].

CONCLUSION

Encephalopathy can be caused by various factors. The most common causes are connected to liver disorders. The etiology is particularly complex, and researchers continue to explore the HE phenomenon. Nevertheless, hyperammonemia, inflammatory conception, oxidative stress and disrupted GABA-transmission appear to participate in the pathogenesis of HE. The pathophysiological mechanisms of noncirrhotic hyperammonemia encephalopathy are also multifactorial and include genetic disorders and side effects of drugs. Despite the rarity of this diagnosis, HE is a phenomenon worth examining because of its multifactorial character.

Abstract

Retroperitoneal fibrosis is a rare disease characterized by the development of inflammation and fibrosis in the soft tissues of the retroperitoneum and other abdominal organs. Retroperitoneal fibrosis can be of 2 types: idiopathic and secondary. The recently advocated concept and diagnostic criteria of immunoglobulin G4 (IgG4)-related disease, derived from research on autoimmune pancreatitis (AIP), has led to widespread recognition of retroperitoneal fibrosis as a condition caused by IgG4-related disease. We now know that previously diagnosed idiopathic retroperitoneal fibrosis includes IgG4-related disease; however, the actual prevalence is unclear. Conversely, some reports on AIP suggest that retroperitoneal fibrosis is concurrently found in about 10% of IgG4-related disease. Because retroperitoneal fibrosis has no specific symptoms, diagnosis is primarily based on diagnostic imaging (computed tomography and magnetic resonance imaging), which is also useful in evaluating the effect of therapy. Idiopathic retroperitoneal fibrosis can occur at different times with other lesions of IgG4-related disease including AIP. Thus, the IgG4 assay is recommended to diagnose idiopathic retroperitoneal fibrosis. High serum IgG4 levels should be treated and monitored as a symptom of IgG4-related disease. The first line of treatment for retroperitoneal fibrosis is steroid therapy regardless of its cause. For patients with concurrent AIP, i.e., IgG4-related retroperitoneal fibrosis, the starting dose of steroid is usually 30-40 mg/d. The response to steroid therapy is generally favorable. In most cases, the pancreatic lesion and retroperitoneal fibrosis improve after the initial treatment. However, the epidemiology, treatment for recurring retroperitoneal fibrosis, and long-term prognosis are still largely unknown. Further analysis of such cases and research are necessary.

INTRODUCTION

Retroperitoneal fibrosis is a rare disease characterized by

development of inflammation and fibrosis in the soft tissue of the retroperitoneum and other abdominal organs. The fibro-inflammatory tissue is most frequently found peripheral to the abdominal aorta, and the next most frequent location is peripheral to the iliac arteries, urinary duct, and renal arteries. In some cases, fibro-inflammatory tissue is most frequently found surrounding the pancreas. In a recently advocated concept, retroperitoneal fibrosis is regarded as part of chronic periaortitis[1]. Retroperitoneal fibrosis is generally divided into 2 types: idiopathic retroperitoneal fibrosis for which no clear cause is found, and secondary retroperitoneal fibrosis which occurs secondary to, for example, drug therapy and malignant tumors[1]. Idiopathic retroperitoneal fibrosis was first reported as retroperitoneal fibrosis causing ureteral obstruction by Albarran, a French urologist, in 1905. In 1948, 2 similar cases were reported by Ormond. Since then, idiopathic retroperitoneal fibrosis is also known as Ormond's disease[1,2]. About 30% of retroperitoneal fibrosis occurs secondary to drug therapy and malignant tumors[1,3].

The recently advocated concept of immunoglobulin G4 (IgG4)-related disease has led to widespread recognition of retroperitoneal fibrosis as one of the conditions caused by IgG4-related disease. The aforementioned concept of IgG4-related disease was derived from clinical experience and research on autoimmune pancreatitis (AIP). AIP was first reported as pancreatitis caused by autoimmunity in Japan[4,5]; subsequently, AIP was found to be often associated with increased serum IgG4 levels[6]. Hamano *et al*[7] reported in 2002 that abundant infiltration of IgG4-positive plasma cells was found in both pancreatic and retroperitoneal lesions from patients with AIP having concurrent retroperitoneal fibrosis. AIP is concurrently found not only with retroperitoneal fibrosis, but also with sclerosing cholangitis, sclerosing sialadenitis, and other various extrapancreatic lesions. Histopathologically, these lesions are characterized by the infiltration of IgG4-positive plasma cells as seen in pancreatic lesions. Based on these observations, the concept of IgG4-related sclerosing disease was proposed by Kamisawa *et al*[8,9]. Since the same disease condition can be found all over the body, the concept and diagnostic criteria for IgG4-related disease have been published not only in association with AIP, but also with rheumatological and nephrological diseases, and have attracted considerable attention in recent times[10,11]. In a consensus meeting, Japanese investigators recommended the adoption of the term "IgG4-related disease" from among many suggested names, and proposed comprehensive diagnostic criteria for this condition[12,13]. The concept of IgG4-related disease has been more or less established, and AIP is now regarded as a pancreatic lesion of IgG4-related disease. The number of reports on retroperitoneal fibrosis as an extrapancreatic lesion of AIP has increased, and retroperitoneal fibrosis is now regarded as a typical lesion of IgG4-related disease[12].

Because retroperitoneal fibrosis is essentially a rare disease, and the concept of IgG4-related disease is relatively new, not many studies have been published on IgG4-related retroperitoneal fibrosis. Moreover, the percentage of retroperitoneal fibrosis that is IgG4-related and the clinical differences, if any, between IgG4- and non-IgG4-related retroperitoneal fibrosis are unknown. In this report, based on our observation of patients with AIP, we describe the relationship between retroperitoneal fibrosis and IgG4-related disease, their clinical features, and the effect of therapies.

EPIDEMIOLOGY

Idiopathic retroperitoneal fibrosis is a rare disease, and epidemiological data are seldom found. However, epidemiological data from Finland indicate that idiopathic retroperitoneal fibrosis affects 0.1 in every 100 000 people, and the prevalence is 1.38 in every 100 000 people[14]. Onset of idiopathic retroperitoneal fibrosis most frequently occurs at and above the age of 50 years. Idiopathic retroperitoneal fibrosis is 2-3 times more common in men than in women[1,14]. About 30% of retroperitoneal fibrosis occurs secondary to a particular cause such as drug therapy, malignant tumors, infection, radiation therapy, or surgery[1,3] (Table 1).

Owing to the establishment of the concepts of AIP and IgG4-related disease, we now know that many previously diagnosed cases of idiopathic retroperitoneal fibrosis are IgG4-related (extrapancreatic lesions of AIP)[3,15]. However, the concept of IgG4-related disease is relatively new, and no large-scale epidemiological data are available to estimate what percentage of retroperitoneal fibrosis is actually IgG4-related. Thus, the exact frequency of IgG4-related retroperitoneal fibrosis is unknown. Corradi *et al*[3] reported that IgG4-positive cells were found in most cases of idiopathic retroperitoneal fibrosis. Neild *et al*[16] studied 12 patients with idiopathic retroperitoneal fibrosis and reported that the number of IgG4-positive plasma cells was > 20 per high power field in 7 of 9 patients whose retroperitoneal tissues were examined. Zen *et al*[15] reported that among 17 patients who had a histological diagnosis of retroperitoneal fibrosis, 10 patients (59%) had increased serum IgG4 levels and extensive IgG4-positive plasma cell infiltration, all of whom were men 50 years or older. Yamashita *et al*[17] reported that among 29 patients studied, the ratio of IgG4-positive plasma cells to IgG-positive plasma cells was > 20% in 9 patients (31%), and these 9 patients were considered to have IgG4-related retroperitoneal fibrosis. As described above, the proportion of IgG4-related retroperitoneal fibrosis among all cases of retroperitoneal fibrosis varies between the studies (30%-60%), and the scale of the studies is invariably small. Further studies at a larger scale need to be conducted.

On the other hand, most of the studies to assess the frequency of concurrent retroperitoneal fibrosis in IgG4-related disease were conducted in patients with AIP[18-27]. In many of the studies, concurrent retroperi-

RF: Retroperitoneal fibrosis; AIP: Autoimmune pancreatitis; IgG4: Immunoglobulin G4.

toneal fibrosis, represented by an extrapancreatic lesion, was reported in about 10% of patients with AIP. Takuma *et al*[18] reported that concurrent retroperitoneal fibrosis was found in 4 out of 56 patients with AIP (7%); of these, the onset of retroperitoneal fibrosis coincided with the onset of AIP in 2 patients, preceded the onset of AIP in 1 patient, and occurred 1 year after bypass surgery performed for AIP in 1 patient. Hamano *et al*[22] reported that concurrent retroperitoneal fibrosis was found in 8 out of 64 patients with AIP (12.5%). The onset of retroperitoneal fibrosis was heterochronic to the onset of AIP in 6 patients; the onset of retroperitoneal fibrosis preceded the onset of AIP in 3 patients and followed the onset of AIP in the other 3 patients[22]. Hirano *et al*[20] reported that concurrent retroperitoneal fibrosis was found in 8 out of 42 patients with AIP (19%). Ohara *et al*[21] reported that retroperitoneal fibrosis, as represented by an extrapancreatic lesion, was found in 8 out of 132 Japanese patients with AIP (6.1%). Moreover, the results of a Japanese multicenter study indicate that concurrent retroperitoneal fibrosis was found in 50 out of 459 patients with AIP who received steroid therapy (11%)[19]. The frequencies of concurrent retroperitoneal fibrosis reported in other countries are as follows: about 3%-4% in Asian countries including South Korea and China[23,24], about 8%-10% in the United States[25,26], and 3.6% in Europe[27]. In our experience, retroperitoneal fibrosis, as represented by an extrapancreatic lesion, was found in 8 of 51 patients (15.7%) diagnosed with AIP and treated at Kyushu University Hospital (Table 2). Of these, the onset of retroperitoneal fibrosis was synchronized with the onset of AIP in 5 patients (case presented in Figure 1), and was heterochronic to the onset of AIP in 3 patients. Regarding heterochronic onset of retroperitoneal fibrosis, the onset of retroperitoneal fibrosis preceded the onset of AIP in 2 patients (cases presented in Figure 2) and occurred 6.5 years after pancreatectomy in 1 patient with suspected pancreatic cancer.

There are reports on IgG4-related retroperitoneal fibrosis in diseases other than AIP. Ohta *et al*[28] reported concurrent retroperitoneal fibrosis in 1 out of 10 patients (10%) with IgG4-related sclerosing sialadenitis. Zen *et al*[29] reported concurrent retroperitoneal fibrosis in 13 out of 114 patients (11.4%) with histologically diagnosed IgG4-related sclerosing disease. Although further accumulation of case data is necessary to determine the accurate frequency of concurrent retroperitoneal fibrosis, the aforementioned studies suggest that concurrent retroperitoneal fibrosis occurs in about 10% of IgG4-related disease (Table 3). The concept of IgG4-related disease encompasses various disease conditions occurring in various organs; however, the primary cause of IgG4-related disease has not been elucidated. Moreover, it is unclear what clinical features determine the involvement of various organs, including the retroperitoneum. This needs to be elucidated in the future.

DIAGNOSIS

Retroperitoneal fibrosis has no specific symptoms. However, dull abdominal (flank) pain, back pain, general malaise, fever, and weight loss have been known to occur.

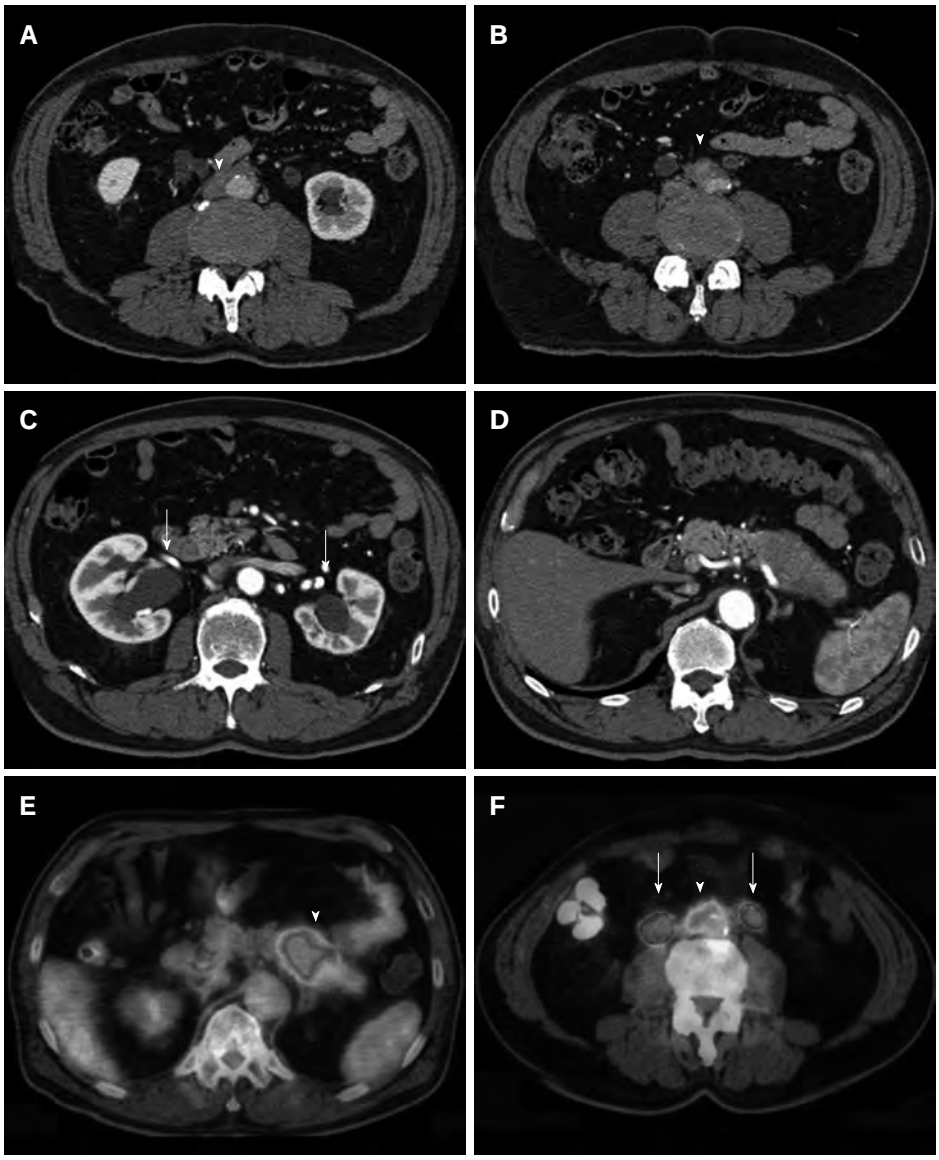

Figure 1 Typical retroperitoneal fibrosis associated with autoimmune pancreatitis. A, B: Soft tissue (arrow) surrounds the abdominal aorta and common iliac artery; C: Bilateral hydronephrosis (arrows); D: Swelling and capsule-like rim are seen in the body and tail of the pancreas. This case was diagnosed as autoimmune pancreatitis; E, F: Fluorodeoxyglucose positron emission tomography images from the same patient; high fluorodeoxyglucose uptake is seen in the body and tail of the pancreas (arrowhead) and in the retroperitoneal fibrosis lesions (arrowhead) surrounding the common iliac artery (arrows indicate dilated urinary ducts).

Retroperitoneal fibrosis often surrounds the urinary duct or inferior vena cava, and is often found in association with hydronephrosis or swelling of the lower extremities[1]. In recent times, retroperitoneal fibrosis is often detected during diagnostic imaging, such as a computed tomography (CT) scan, in asymptomatic patients undergoing a work-up for AIP (Figure 1). However, it should be noted that the onset of retroperitoneal fibrosis may or may not be synchronized with the onset of AIP. Furthermore, the onset of retroperitoneal fibrosis may either follow or precede the onset of AIP as described earlier. The histological features of retroperitoneal fibrosis associated with AIP (i.e., IgG4-related retroperitoneal fibrosis) include diffused fibrosis, infiltration of IgG4-positive plasma cells, obliterative phlebitis, eosinophilic infiltration, and the formation of lymphoid follicles; these are similar to other lesions of IgG4-related disease[15,16]. Zen *et al*[15] reported that obliterative phlebitis is significantly more frequent in IgG4-related retroperitoneal fibrosis than in non-IgG4-related retroperitoneal fibrosis. However, because surgery for retroperitoneal fibrosis is rarely performed and because a biopsy of the retroperitoneum cannot be easily carried out, it is often difficult to obtain the tissue specimens needed for diagnosis. Clinically, retroperitoneal fibrosis is diagnosed based on the results of diagnostic imaging such as CT scan and magnetic resonance imaging (MRI)[30]. Involvement of IgG4 is usually determined based on serum IgG4 levels and the presence/absence of other lesions such as AIP. Moreover, the effect of therapies is usually assessed using diagnostic imaging techniques.

There is no hematological parameter specifically associated with retroperitoneal fibrosis; however, an increased white blood cell count and increased C-reactive

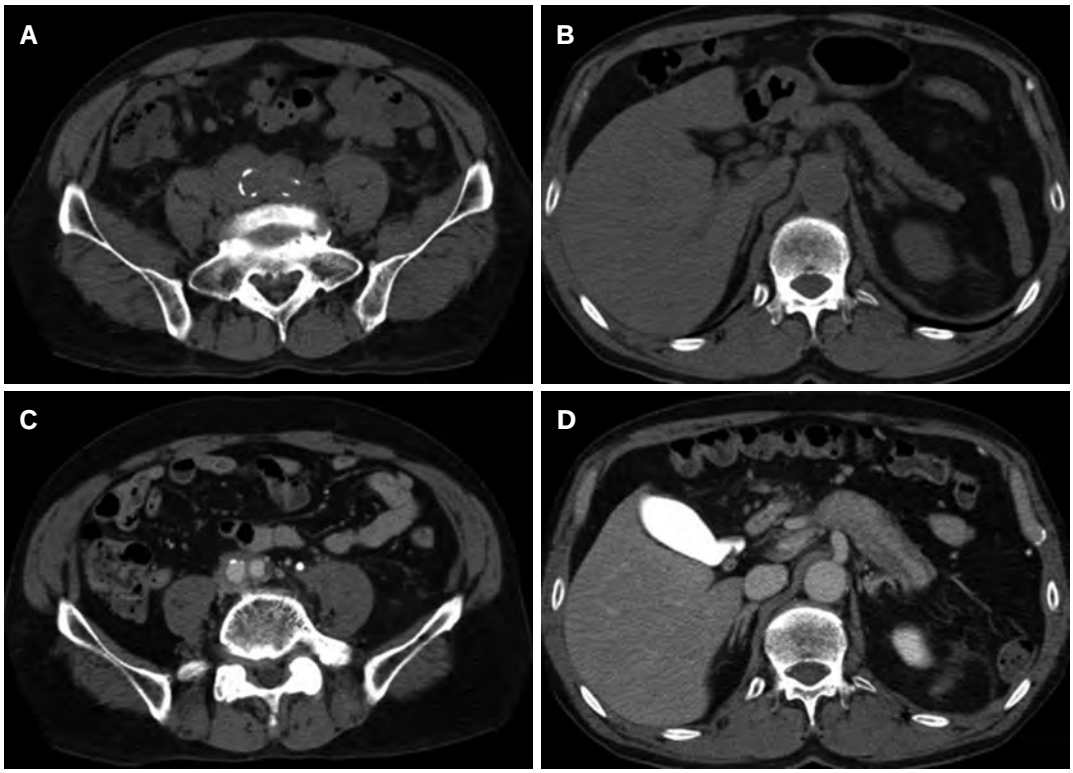

Figure 2 Retroperitoneal fibrosis occurring before the onset of autoimmune pancreatitis. A 65-year-old man developed hydronephrosis and renal failure. A, B: Soft tissue was observed surrounding the abdominal aorta and common iliac artery. No abnormality was found in the pancreas. The patient was diagnosed with idiopathic retroperitoneal fibrosis, and started receiving prednisolone (PSL) at the dose of 40 mg/d. The dose was gradually reduced over approximately 6 mo and discontinued. The hydronephrosis improved, and the patient continued to be followed up; C, D: Swelling of the pancreas observed on computed tomography images taken about 1 yr and 6 mo after the discontinuation of PSL. Compared with the initial observation, retroperitoneal fibrosis improved, but persisted. The serum immunoglobulin G4 level was 366 mg/dL. At that point, the patient was diagnosed with autoimmune pancreatitis, and started receiving PSL again at the dose of 40 mg/d. The swelling of the pancreas and retroperitoneal fibrosis were improved.

protein levels can be seen as a reflection of acute inflammation. Moreover, renal dysfunction may be observed due to ureteral obstruction. Diagnostic imaging techniques, such as ultrasound (US), CT, and MRI, are used to diagnose retroperitoneal fibrosis. US is usually performed first, because it is a simple and minimally invasive technique. Typically, retroperitoneal fibrosis is depicted as a hypo- to iso-echoic mass encasing an aorta; however, the sensitivity is low, and US is rather important in determining the presence/absence of concurrent hydronephrosis. The most useful diagnostic imaging techniques are CT and MRI. On CT images, retroperitoneal fibrosis is depicted as a soft tissue mass encasing an aorta, which often spreads laterally to involve the inferior vena cava and urinary duct[31] (Figure 1A-C). On MRI images, retroperitoneal fibrosis shows low signal intensity on T1-weighted images, and high signal intensity on T2-weighted images[1,31]. Moreover, although CT and MRI excel in their specificity, fluorodeoxyglucose positron emission tomography is also a useful tool for determination of the presence/absence of retroperitoneal fibrosis as well as other lesions of IgG4-related disease[1,32,33] (Figure 1D-F).

The retroperitoneum is also a site where tumor lesions, such as malignant lymphoma, desmoid fibromatosis, and liposarcoma, often develop. Thus, these diseases need to be differentiated from retroperitoneal fibrosis[1,3]. Although the onset of retroperitoneal fibrosis surrounding the pancreas is rare, this condition is sometimes difficult to distinguish from the invasion of pancreatic cancer to the area surrounding the superior mesenteric artery. In patients with previously diagnosed AIP in whom the onset of retroperitoneal fibrosis has occurred simultaneously with the onset (Figure 1) or relapse of AIP, retroperitoneal fibrosis can be relatively easily diagnosed based on the aforementioned characteristic findings on US/CT/MRI images and the presence of increased serum IgG4 levels. On the other hand, in some patients, the onset of retroperitoneal fibrosis precedes the onset of AIP (Figure 2); thus, the measurement of serum IgG4 levels is recommended for idiopathic retroperitoneal fibrosis[34]. When the IgG4 level is high, it should be treated and monitored as an IgG4-related disease.

TREATMENT AND PROGNOSIS

The first line of treatment for retroperitoneal fibrosis is steroid therapy, regardless of its cause. Although a few asymptomatic patients might need only monitoring, steroid therapy is usually necessary for patients with clinical symptoms (e.g., fatigue, weight loss, and abdominal or back pain) or those with hydronephrosis and acute renal

failure caused by ureteral obstruction[35]. The efficacy of immunosuppressants (e.g., azathioprine) and tamoxifen has been reported mainly in Europe and the United States[1,36,37]. However, a randomized controlled trial recently conducted in patients with idiopathic retroperitoneal fibrosis demonstrated that the efficacy of steroids in preventing the relapse of retroperitoneal fibrosis was significantly better than that of tamoxifen[35]. Moreover, Zen *et al*[15] reported that steroid therapy was effective regardless of the presence/absence of IgG4-related disease or serum IgG4 levels[15].

Steroid therapy is also recognized as a standard therapy for AIP[38]. The indications of steroid are symptoms such as obstructive jaundice due to sclerosing cholangitis, abdominal pain, and hydronephrosis due to associated retroperitoneal fibrosis[19]. Therefore, steroid therapy is strongly recommended for patients with concurrent AIP, that is, IgG4-related retroperitoneal fibrosis. The starting dose of steroid is usually 30-40 mg/d (0.6 mg/kg per day)[38]. The response to steroid therapy is generally favorable. In most cases, the pancreatic lesion and retroperitoneal fibrosis improve after the initial treatment. Among the 8 patients we studied, clinical improvement was achieved in 7 patients. In 1 patient, the disease condition did not change (Table 2). As mentioned earlier, the response to steroid therapy is generally good; however, some patients are resistant to steroid. Further, the mechanism of steroid resistance is unclear, and it is difficult to predict the efficacy of steroid therapy before treatment. In our patient who was refractory to steroid, soft tissue mass surrounding the abdominal aorta and hydronephrosis did not improve; however, his pancreatic lesion was improved and renal function was stabilized. Therefore, we continued with the maintenance steroid treatment. Zen *et al*[15] reported that 8 of 10 patients with IgG4-related retroperitoneal fibrosis received steroid therapy. One of these steroid-treated patients experienced relapse twice; however, remission of retroperitoneal fibrosis was achieved by re-administration of steroid. In some cases, relapse occurs after withdrawal from steroid therapy. In other cases, the ureteral stent cannot be removed because of inadequate response to steroid therapy. Thus, further study should be conducted to assess the long-term prognoses of retroperitoneal fibrosis. Although the use of immunosuppressants has been reported in patients with IgG4-related disease that is recurrent or non-responsive to steroid therapy, no consensus has been reached yet[26,27,39].

CONCLUSION

Owing to the newly emerged recognition of retroperitoneal fibrosis as an extrapancreatic lesion of AIP and the establishment of the concept of IgG4-related disease, diagnostic methods and therapies for retroperitoneal fibrosis have made great progress. Retroperitoneal fibrosis, as well as other lesions of IgG4-related disease, responds to steroid therapy in most cases. However, data from more cases need to be collected in order to assess the long-term prognoses of retroperitoneal fibrosis.

Abstract

Abnormal vasculature, termed tumor vessels, is a hallmark of solid tumors. The degree of angiogenesis is associated with tumor aggressiveness and clinical outcome. Therefore, exact quantification of tumor vessels is useful to evaluate prognosis. Furthermore, selective detection of newly formed tumor vessels within cancer tissues using specific markers raises the possibility of molecular targeted therapy *via* the inhibition of tumor angiogenesis. Nestin, an intermediate filament protein, is reportedly expressed in repair processes, various neoplasms, and proliferating vascular endothelial cells. Nestin expression is detected in endothelial cells of embryonic capillaries, capillaries of the corpus luteum, which replenishes itself by angiogenesis, and proliferating endothelial progenitor cells, but not in mature endothelial cells. Therefore, expression of nestin is relatively limited to proliferating vascular endothelial cells and endothelial progenitor cells. Nestin expression is also reported in blood vessels within glioblastoma, prostate cancer, colorectal cancer, and pancreatic cancer, and its expression is more specific for newly formed blood vessels than other endothelial cell markers. Nestin-positive blood vessels form smaller vessels with high proliferation activity in tumors. Knockdown of nestin in vascular endothelial cells suppresses endothelial cell growth and tumor formation ability of pancreatic cancers *in vivo*. Using nestin to more accurately evaluate microvessel density in cancer specimens may be a novel prognostic indicator. Furthermore, nestin-targeted therapy may suppress tumor proliferation *via* inhibition of angiogenesis in numerous malignancies, including pancreatic cancer. In this review article, we focus on nestin as a novel angiogenesis marker and possible therapeutic target *via* inhibition of tumor angiogenesis.

INTRODUCTION

A hallmark of solid tumors is abnormal vasculature, termed tumor vessels, which is adjacent to the tumor itself. Greater number of tumor vessels increases the risk that tumor cells will enter systemic circulation. The basement membranes of newly formed tumor vessels are highly permeable, enabling tumor cells to penetrate them more easily than mature vessels[1]. Furthermore, tumor angiogenesis enhances the supply of oxygen and nutrients to solid tumor cells. As a result, the tumor grows more rapidly and easily when tumor vessels are formed

in close proximity. After a tumor has attained a size of 1-2 mm, the induction of new blood vessel formation is required for further growth and expansion[2]. In fact, the degree of tumor angiogenesis reportedly correlates with clinical outcome, and angiogenic properties correlate with tumor aggressiveness in gastrointestinal (GI) cancers including colorectal cancers[3], gastric cancers[4], esophageal cancers[5], and pancreatic cancers[6,7]. These findings suggest that exact quantification of tumor vessels is useful to evaluate prognosis. Furthermore, selective detection of newly formed tumor vessels within cancer tissues using specific markers raises the possibility of molecular targeted therapy *via* the inhibition of tumor angiogenesis. Microvessel density (MVD), measured immunohistochemically in tumors, is often reported to correlate with prognosis in various malignancies[8,9], including GI cancers[10-14]. However, the clinical significance of MVD is controversial; for example, pancreatic cancer is characterized by hypovascularization[15,16]. For MVD analysis, CD34, CD31, and factor Ⅷ are commonly used as endothelial cell markers in tumor vessels (Table 1). CD34 and CD31 are cell surface markers, and factor Ⅷ is an essential blood clotting protein in vascular endothelial cells of normal tissues. However, these markers do not specifically identify newly formed tumor vessels, but also detect pre-existing large sized blood vessels[17]; therefore, they are not considered suitable for the sensitive analysis of tumor angiogenesis. Inclusion of pre-existing mature vessels in MVD of various tumors may cause controversial results when determining the relationship between tumor angiogenesis, clinicopathologic features, and prognosis.

Nestin, an intermediate filament (IF) protein, has recently been recognized as a more specific marker for newly formed blood vessels and as a therapeutic target *via* inhibition of angiogenesis. In this review, we summarize and emphasize recent research evidences concerning nestin in tumor angiogenesis in GI cancers, including pancreatic cancer.

BASIC CHARACTERIZATION OF NESTIN

Nestin is a class Ⅵ IF protein originally described as a neuronal stem cell marker. After cellular differentiation, nestin expression is downregulated and replaced by neurofilament, a tissue specific IF[18]. Nestin is also expressed in non-neuronal immature or progenitor cells in some normal tissues[19]. It is a large protein (> 1600 amino acids) containing a short N terminus and an unusually long C terminus. The C terminus interacts with other IFs including vimentin, desmin, or internexin, subsequently forming heterodimers and mixed polymers[19-21]. The long C-terminal portion of nestin protrudes from the filamentous body and may function as a link or cross-bridge between IFs and microtubules. Nestin is known to contribute to the disassembly of vimentin during mitosis, inactivation of cyclin-dependent kinase 5[22], and modulation of mitosis-associated cytoplasmic reorganization during mitosis *via* phosphorylation at Thr^{316} by cdc2 kinase[23]. Neural cell-specific expression is usually regulated by the second intron, whereas nestin expression in tumor endothelium is enhanced by the first intron[24]. Although nestin is expressed at the early stages of normal development, under pathological conditions, it is re-expressed in repair processes, various neoplasms, and proliferating vascular endothelial cells[25].

NESTIN IN ANGIOGENESIS DURING DEVELOPMENT

Much evidence has shown that nestin expression in vascular endothelial cells is associated with proliferation and angiogenesis[24,26-29]. Nestin expression was detected in endothelial cells of embryonic capillaries[28], capillaries of the corpus luteum, which replenishes itself by angiogenesis[30], and proliferating endothelial progenitor cells, but not in mature endothelial cells[24].

At the early stage of development, high levels of nestin are identified in endothelial cells lining all blood vessels of E14-15 rat fetuses and extraembryonic (chorion, placenta, umbilical cord) and intraembryonic blood vessels. Expression of nestin by vascular endothelial cells is greatly reduced in adult tissues[28].

These findings suggest that nestin plays important roles in vasculogenesis during development.

NESTIN IN ANGIOGENESIS IN NON-CANCEROUS DISEASES

Angiogenesis is a process of new blood vessel formation from pre-existing vessels; it is the mechanism mediating the growth and modification of a capillary network[31]. In non-cancerous diseases, nestin plays important roles in angiogenesis of wound healing in various tissues. In an adult rat necrotizing pancreatitis model, nestin is expressed in reactive stellate cells, or submesothelial cells, and endothelial cells during active angiogenesis[32], and nestin-positive cells may participate in tissue repair of the pancreas.

Nestin-expressing interfollicular blood vessel networks contribute to skin transplant survival and wound healing[33]. Scar formation following an ischemic insult to the heart is referred to as reparative fibrosis and represents an essential physiological response to damaged myocardium. Several studies reported that scar formation was associated with the recruitment of neural crest-derived cardiac resident nestin-positive cells that display characteristics consistent with a neural progenitor/stem cell phenotype[34,35]. During the reparative fibrotic response, these nestin-positive cells participate in neural remodeling and represent a novel cellular substrate of angiogenesis.

In the rat ovary, the endogenous luteinizing hormone surge induces nestin expression in capillary endothelial cells of the theca interna *via* the vascular endothelial growth factor (VEGF) signaling pathway[36]. Angiogenic induction of chorion-derived stem cells results in higher mRNA levels of pro-angiogenic protein, fibroblast growth factor-4, and stem cell markers ABCG-2, Sox-2, FZD9, BST-1, nestin, and Oct-4[37]. Endothelial precursors express nestin, and it participates in the formation of the cytoskeleton of newly formed endothelial cells.

Table 1 Angiogenesis markers for analysis of microvessel density

	Factor Ⅷ	CD 31	CD 34	Nestin
Roles	Glycoprotein Blood coagulation	Glycoprotein Endothelial cell intercellular junctions[57], migration	Glycoprotein Cell-cell adhesion factor, facilitate opening of vascular lumens[58]	Cytoskeletal protein Cell cycle[22,59], migration
Character of positive vessels	Large size Mature vessels	Small to large size Immature to mature vessels	Small to large size Immature to mature vessels	Small size[27] Immature vessels[26,30] High-proliferating activity[26,27]
Clinical outcome				
Esophageal cancer	Poor prognosis[60]	Poor prognosis[61,62]	Poor prognosis[63,64]	-
Gastric cancer	Advanced stage[65]	No relation[66]	No relation[45]	No relation[44]

Glioblastoma	Tumor grade[84]	No relation[85]	No relation[86]	Tumor grade[45]

VEGF is essential for the differentiation of the primitive embryonic vascular system and has been implicated in the vascularization of organs. VEGF is considered a modulator involved in neurogenesis as well as angiogenesis[38,39]. Human VEGF overexpressed transgenic mice showed an increased number of nestin positive cells after temporal ischemia of the central nervous system, as compared with wild type mice[40]. Therefore, VEGF is involved in nestin expression. Furthermore, pre-eclamptic human placenta showed higher nestin expression levels[41], thus hypoxia may be involved in expression of nestin.

NESTIN IN TUMOR ANGIOGENESIS

Expression of nestin by newly formed blood vessels in various tumor tissues, including pancreatic cancers, has been reported[26,27,30,42,43]. Its expression is not reported in mature vessels within cancer tissues. This suggests that nestin may be an angiogenesis-specific marker in malignant tumors[27,44]. Strongly nestin-positive MVD colorectal carcinomas[42] and prostate cancers[26] show a worse prognosis. In colorectal cancer, nestin is strongly localized to vascular endothelial cells, but not to cancer cells. Nestin-expressing vessels in colorectal cancer tissues are of smaller size and show greater positivity for proliferating cell nuclear antigen than CD34-expressing cells[42]. In glioblastomas, expression of nestin in both tumor cells and endothelial cells increased with tumor grade[45]. Similarly, nestin expression correlates with more advanced stage in melanoma[46]. In gastric cancers, there is no correlation between nestin-positive MVD and patient's clinical outcome, while in patients with larger carcinomas, MVD determined by nestin correlates better with longer survival than MVD determined by CD34[44]. We previously reported that nestin-positive blood vessels in pancreatic cancer exhibit high proliferating ability, but does not correlate with prognosis[27]. Tumor angiogenesis is essential for tumor progression, but increased angiogenesis may be influenced by variations in the existing vasculature of the host organ. Compared to MVD studies using other endothelial markers, only a limited number of investigations have used nestin. Large scale studies of various different malignancies using nestin as a MVD marker are needed to determine the efficacy of nestin as a predictive and prognostic marker.

The origin of nestin-positive vascular endothelial cells in tumor tissue is still controversial. Migration of mesenchymal stem cells from the bone marrow has been proposed[47]. Dong *et al*[48] showed that human glioma stem/progenitor cells transdifferentiate into vascular endothelial cells *in vitro* and *in vivo*. In skin angiogenesis, nestin-positive hair follicle cells form neovasculature[49]; therefore tissue stem cells are one possible origin of nestin-positive vessels.

Recent studies showed that nestin is an effective marker for *in vivo* imaging of tumor angiogenesis[50,51] and vascular formation in metastatic tumors[52].

NESTIN IN PANCREATIC CANCER

Pancreatic cancer is an aggressive malignancy with an overall five-year survival rate of less than 5%[53]. Since the majority of patients have locally advanced or metastatic disease at the time of diagnosis, there has been little progress in extending survival[54]. For over ten years, chemotherapy with gemcitabine, whose strategy is to inhibit tumor growth, has been the standard treatment for patients with advanced pancreatic cancer, prolonging survival by only five to six months.

To improve upon this modest benefit, several investigations explored other strategies aimed at inhibiting pancreatic cancer growth, including the use of anti-angiogenic agents. Tumor angiogenesis is an important factor in the proliferation, invasion, metastasis, and drug sensitivity of pancreatic cancers[6]. For a tumor to develop a highly malignant and deadly phenotype, it must first recruit and sustain its own blood supply. The process of angiogenesis is also sustained by secretion of specific angiogenic factors by cancer and non-cancer cells. Angiogenic factors can initiate a multi-step process that begins with vasodila-

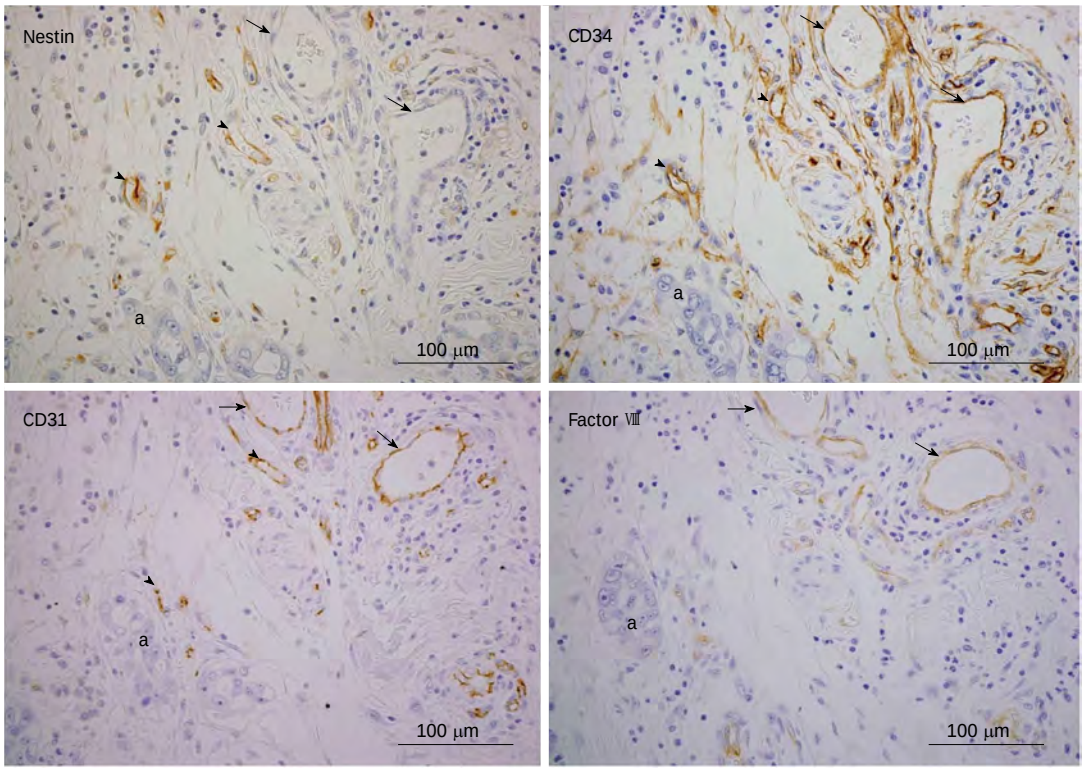

Figure 1 Immunohistochemical images of blood vessels in pancreatic cancer. Nestin was expressed in small vessels (arrowheads) and in the surrounding cancer cells (a), but not in large vessels (arrows). CD34 and CD31 were expressed in both small and large vessels (arrowheads and arrows), whereas factor Ⅷ was expressed only in large vessels (arrows).

tation, followed by the enhancement of vessel permeability and stroma degradation. Angiogenic factors can also promote endothelial cell migration and proliferation.

Several clinical agents have been developed to inhibit the angiogenesis process, including the VEGF pathway[55], and a number of phase Ⅱ and phase Ⅲ trials combined gemcitabine with novel anti-angiogenic agents with the hope of improving patient survival. Bevacizumab, which inhibits only the VEGF receptor, and sorafenib, which inhibits raf-1 kinase and the platelet-derived growth factor receptor tyrosine kinase in addition to the VEGF receptor, were studied in combination with gemcitabine. However, this approach has largely been unsuccessful and additional novel strategies are clearly needed.

In pancreatic cancers, we found that CD34, CD31, and factor Ⅷ, which are commonly used for MVD quantification by immunohistochemical analysis, were expressed in both newly formed small sized blood vessels and pre-existing vessels (Figure 1, arrows and arrowheads), whereas nestin was expressed only in newly formed blood vessels (arrowheads). Therefore, nestin is a potentially useful marker to distinguish newly formed blood vessels from pre-existing vessels in tumor tissues[27].

More importantly, we observed that knockdown of nestin in vascular endothelial cells suppresses cell growth and tumor formation of pancreatic cancers *in vivo*[27]. Therefore, nestin is a potential molecular target *via* inhibition of angiogenesis in pancreatic cancer.

Nestin is expressed in both pancreatic cancer cells and tumor vessels. Inhibition of nestin in cancer cells reduces tumor cell migration and metastasis[56] and down-regulation of nestin in tumor vessels also inhibits tumor formation[27]. These findings may indicate that nestin is a target not only for inhibition of tumor angiogenesis, but also within some cancers themselves that expression nestin, such as glioblastomas, melanomas, and pancreatic cancer (Figure 2).

CONCLUSION

More accurate estimation of MVD using nestin in GI cancers may reveal a strong relationship between tumor vessels and clinical outcome. Future studies on MVD with a large patient population are needed to clarify the efficacy of nestin as a predictive and prognostic marker. Nestin-targeting small interfering RNA (siRNA) has shown a tumor inhibitory effect *in vivo via* inhibition of tumor angiogenesis[27], thus nestin may be a novel therapeutic target for tumor angiogenesis. Treatment resistance often occurs with the isolated use of anti-VEGF therapy. Therefore, combination therapy that also includes nestin-targeting agents is a potentially effective therapeutic strategy. Nestin is expressed in some cancer cells, thus targeted therapy may exert inhibitory effects both on cancer cells and vascular endothelium in certain tumor types, including pancreatic cancers. In addition to small molecule compounds, emerging biotechnology including RNA aptamer and siRNA targeting nestin will possibly be adopted as new therapeutics for GI cancers, especially for pancreatic cancers.

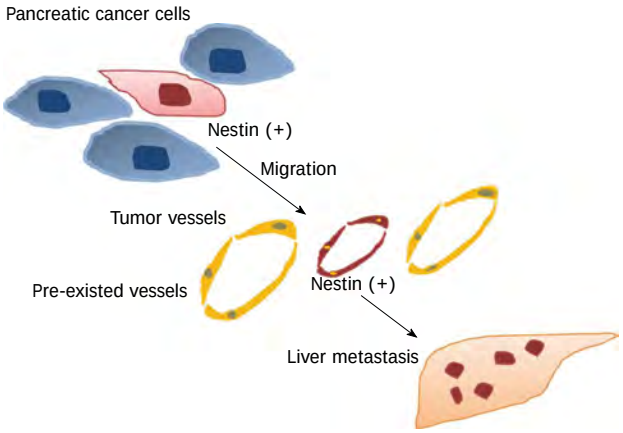

Figure 2 In pancreatic cancer, nestin is highly expressed in some pancreatic cancer cells and small proliferating tumor vessels.

ACKNOWLEDGMENTS

The authors thank Dr. Kosuke Narita from Departments of Pathology and Integrative Oncological Pathology for helpful discussion.

Abstract

AIM: To compare results of liver stiffness measurements by transient elastography (TE) obtained in our patients population with that used in a recently published meta-analysis.

METHODS: This was a single center cross-sectional study. Consecutive patients with chronic viral hepatitis scheduled for liver biopsy at the outpatient ward of our Infectious Diseases Department were enrolled. TE was carried out by using FibroScan™ (Echosens, Paris, France). Liver biopsy was performed on the same day as TE, as day case procedure. Fibrosis was staged according to the Metavir scoring system. The diagnostic performance of TE was assessed by using receiver operating characteristic (ROC) curves and the area under the ROC curve analysis.

RESULTS: Two hundred and fifty-two patients met the inclusion criteria. Six (2%) patients were excluded due to unreliable TE measurements. Thus, 246 (171 men and 75 women) patients were analyzed. One hundred and ninety-five (79.3%) patients had chronic hepatitis C, 41 (16.7%) had chronic hepatitis B, and 10 (4.0%) were coinfected with human immunodeficiency virus. ROC curve analysis identified optimal cut-off value of TE as high as 6.9 kPa for $F \geqslant 2$; 7.9 kPa for $F \geqslant 3$; 9.6 kPa for $F = 4$ in all patients ($n = 246$), and as high as 6.9 kPa for $F \geqslant 2$; 7.3 kPa for $F \geqslant 3$; 9.3 kPa for $F = 4$ in patients with hepatitis C ($n = 195$). Cut-off values

of TE obtained by maximizing only the specificity were as high as 6.9 kPa for $F \geqslant 2$; 9.6 kPa for $F \geqslant 3$; 12.2 kPa for $F = 4$ in all patients ($n = 246$), and as high as 7.0 kPa for $F \geqslant 2$; 9.3 kPa for $F \geqslant 3$; 12.3 kPa for $F = 4$ in patients with hepatitis C ($n = 195$).

CONCLUSION: The cut-off values of TE obtained in this single center study are comparable to that obtained in a recently published meta-analysis that included up to 40 studies.

INTRODUCTION

In chronic viral hepatitis, the degree of liver fibrosis affects both prognosis and treatment. Biopsy is still considered the reference standard for the assessment of liver fibrosis, even though it evaluates 1/50 000 only of the liver parenchyma and is subject to intra and inter-observer variability[1,2]. Moreover, it is an invasive procedure not well accepted by patients that is burdened by complications even though at a low rate[3,4]. For these reasons, in recent years imaging[5-8] or biochemical methods[9-13] for a noninvasive assessment of liver fibrosis have been tested. The imaging methods estimate elasticity of liver parenchyma, which is directly related to the amount of fibrosis. The method most widely used and validated is transient elastography (TE) (FibroScan Echosens, Paris)[9,14-17], which allows to evaluate the elasticity of a portion of liver parenchyma that is around 100 times greater than that examined by biopsy[18].

Several studies have shown significant positive correlation between TE and the stage of liver fibrosis[14-20]. The performance of TE is optimal for advanced stages of fibrosis[15,21-27].

A limitation of all the studies performed so far is that reference cut-off values of TE for each fibrosis stage were calculated from their own cohort of patients after data collection, and they are different across studies[8]. Few metanalysis have been carried out that have analysed the heterogeneity between studies and the overall performance of TE[5-8]. In the most recent one the cut-off values of 7, 9.5, and 12 kPa in stages F2, F3, and F4, respectively, were used[8].

The aim of this study was to compare the cut-offs of TE obtained by receiver operating characteristic (ROC) curve analysis in our series of consecutive patients, with chronic viral hepatitis referring to our center for liver biopsy, to those used in the recently published meta-analysis[8].

MATERIALS AND METHODS

Patients

This was a single center cross-sectional study. From June, 2009 through February, 2012, all consecutive patients with chronic viral hepatitis scheduled for liver biopsy at the outpatient ward of our Infectious Diseases Department were enrolled into the study.

Diagnosis of chronic hepatitis was based on the presence, at the time of the first observation, of active viral replication or detectable hepatitis C virus (HCV)-RNA in hepatitis B surface antigen or anti-HCV positive carriers, respectively, and, at least transiently, elevated serum alanine aminotransferase level. Patients characteristics, epidemiological data, and biochemical tests were recorded. Liver biopsy was performed on the same day as TE, as day case procedure.

The study protocol was approved by the institutional Ethics Committee. Participants gave their informed written consent.

Transient elastography

TE was carried out by using FibroScan™ (Echosens, Paris, France), a dedicated medical device which provides a quantifiable estimate of liver stiffness in kilopascal (kPa). Two physicians (Ferraioli G and Zicchetti M), with experience of at least 50 TE procedures as previously recommended[9], performed all the examinations. Measurements of liver stiffness were performed on the right lobe through intercostal spaces on patients lying in the dorsal decubitus position with the right arm in maximal abduction, following the examination procedure previously described[14]. Only patients with 10 validated measurements, a success rate of at least 60%, and interquartile range (IQR) of less than 30% of the median liver stiffness value were included. Values were expressed in kPa.

Liver biopsy and histology

Ultrasound-assisted percutaneous liver biopsy (LB) was performed by three experienced physicians (Filice C, Brunetti E, Michelone G) by using an intercostal approach. A disposable 1.4 mm-diameter modified Menghini needle (Hepafix; Braun, Melsungen, Germany) was used. All biopsy specimens were fixed in formalin and embedded in paraffin. The length of each LB specimen (in centimeters) was recorded.

Table 1 Patients demographics, and their biochemical and histological data at liver biopsy examination (%)

Characteristics	All patients (n = 246)	HCV patients (n = 195)	HBV patients (n = 41)
Sex (men)	171 (69.5)	139 (71.3)	30 (73.2)
Age (yr)	44.7 (11.8)[1]	45.3 (11.5)[1]	41.2 (13.7)[1]

AST (IU/L)	39 (24-78)[2]	40 (26-80)[2]	28 (21-48)[2]
ALT (IU/L)	65 (32-116)[2]	70 (35-120)[2]	50 (23-109)[2]
Platelets count (10^3/mm^3)	209 (171-262)[2]	212 (176-270)[2]	203 (172-253)[2]
Fibrosis score (Metavir)			
F0-F1	129 (52.3)	98 (50.3)	30 (73.2)
F2	54 (22.0)	46 (23.6)	6 (14.6)
F3	24 (9.8)	19 (9.7)	3 (7.3)
F4	39 (15.9)	32 (16.4)	2 (4.9)
Steatosis			
S0 (0%)	157 (63.8)	126 (64.6)	26 (63.4)
S1 (< 33%)	56 (22.8)	44 (22.6)	10 (24.4)
S2 (33%-66%)	19 (7.7)	15 (7.7)	4 (9.8)
S3 (> 66%)	14 (5.7)	10 (5.1)	1 (2.4)
HAI			
Mild	109 (44.3)	80 (41.0)	28 (68.3)
Moderate	102 (41.5)	89 (45.7)	7 (17.1)
Severe	35 (14.2)	26 (13.3)	6 (14.6)

[1]mean ± SD [2]Median value and interquartile range (IQR). BMI: Body mass index; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; HAI: Histological activity index; HCV: Hepatitis C virus; HBV: Hepatitis B virus.

The specimens were read on site by a single expert liver pathologist (Dal Bello B), blind to the TE results, but not to the patient's clinical and biochemical data. Fibrosis was evaluated semiquantitatively and staged according to the Metavir scoring system (F0, absent; F1, enlarged fibrotic portal tract; F2, periportal or initial portal-portal septa but intact architecture; F3, architectural distortion but no obvious cirrhosis; and F4, cirrhosis)[28]. For the purpose of this study, F0 and F1 scores were grouped in the subsequent statistical analysis. Necroinflammatory activity was evaluated using the histologic activity index (HAI) described by Knodell *et al* and classified as follows for statistical analysis: HAI score, 1-5 = mild; HAI score, 6-9 = moderate; HAI score, ⩾ 10 = severe[29]. Steatosis was expressed as a percentage of fat in the hepatocytes and classified as absent (S0), < 33% (S1), between 33% and 66% (S2), and > 66% (S3)[30].

Statistical analysis

Descriptive statistics were produced for demographic, clinical and laboratory characteristics for this study sample of patients. The Shapiro-Wilk test was used to test the normal distribution of quantitative variables. When quantitative variables were normally distributed, the results were expressed as mean values and SD, otherwise median and IQR (25th-75th percentile) were reported; qualitative variables were summarized as counts and percentages. Spearman rank coefficient was used to test correlation between two study variables. Quantile regression was used for multivariate model to assess the association between TE and fibrosis, HAI, steatosis, and biochemical tests. A frequency distribution was obtained for choosing optimal cut-off values of TE to maximize the sum of sensitivity and specificity for different fibrosis thresholds: F0-F1 *vs* F2- F4 ($F \geqslant 2$), F0-F2 *vs* F3-F4 ($F \geqslant 3$), F0-F3 *vs* F4 ($F = 4$). The diagnostic performance of TE was assessed by using ROC curves and the area under the ROC (AUC) curve analysis.

Data analysis was performed with STATA statistical package (release 11, 1, 2010, Stata Corporation, College Station, Texas, United States) and Medcalc (Version 11.2, 2011 MedCalc Software bvba , Be).

RESULTS

Patients

Two hundred and fifty-two patients met the inclusion criteria. Six (2%) patients were excluded due to unreliable TE measurements (no successful acquisitions in four patients; IQR > 30% in two patients). Thus, 246 patients were analyzed. Their characteristics are summarized in Table 1. There were 171 men and 75 women. One hundred and ninety-five (79.3%) patients had chronic hepatitis C, 41 (16.7%) had chronic hepatitis B, and 10 (4.0%) were coinfected with HIV. The mean length of the LB samples was 2.7 cm (± 0.8 cm). The fibrosis grade distribution was as follows: F0-F1, 129 patients; F2, 54 patients; F3, 24 patients; F4, 39 patients.

Liver stiffness measurements

All patients (n = 246): Medians and IQR of TE values for each fibrosis stage were 5.2 kPa (4.4-6.4) for F0-F1, 6.4 kPa (5.6-8.6) for F2, 9.0 kPa (7.8-14.8) for F3, and 17.8 kPa (12.9-23.7) for F4. Multiple comparison between groups provided an adjusted P value for significance of 0.004 and showed that there was a statistical significant difference for F0-F1 *vs* F2 (P = 0.000 026), and F2 *vs* F3 (P = 0.001), but not for F3 *vs* F4 (P = 0.02).

In univariate analysis, TE showed a good correlation with the degree of fibrosis (r = 0.72, P < 0.00 001), a moderate correlation with the degree of histological activity index (r = 0.49, P < 0.00 001) and the aspartate aminotransferase (AST) value (r = 0.40, P < 0.00 001), and a poor correlation with the degree of steatosis despite being statistically significant (r = 0.19, P = 0.002). TE also showed a moderate negative correlation with platelet counts (r = -0.41, P < 0.00 001). Multivariate regression analysis including fibrosis stage, histological activity index, steatosis, AST, platelet counts confirmed the correlation with fibrosis stage (P = 0.0001) but not with all other variables.

ROC curve analysis identified optimal cut-off values of liver stiffness measurements as high as 6.9 kPa for $F \geqslant 2$; 7.9 kPa for $F \geqslant 3$; 9.6 kPa for $F = 4$ (Figure 1). Corresponding values of sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), positive likelihood ratio (LR), negative LR and AUCs are shown in Table 2.

Table 2 Cut-off values of transient elastography obtained by receiver operating characteristic curve analysis for each Metavir fibrosis stage

	Sensitivity%	Specificity%	PPV%	NPV%	LR+	LR-	AUC
$F \geqslant 2$[1]							
7.0 kPa	70 (66-75)	81 (77-85)					
$F \geqslant 2$[2]

[1]Cut-off values of transient elastography from the paper of Tsochatzis *et al*[8]; [2]Cut-off values of transient elastography in all patients (n = 246); [3]Cut-off values of transient elastography in patients with chronic hepatitis C (n = 195); [4]Cut-off values obtained by maximizing specificity. PPV: Positive predictive value; NPV: Negative predictive value; LR+: Positive likelihood ratio; LR-: Negative likelihood ratio; AUC: The area under the receiver operating characteristic.

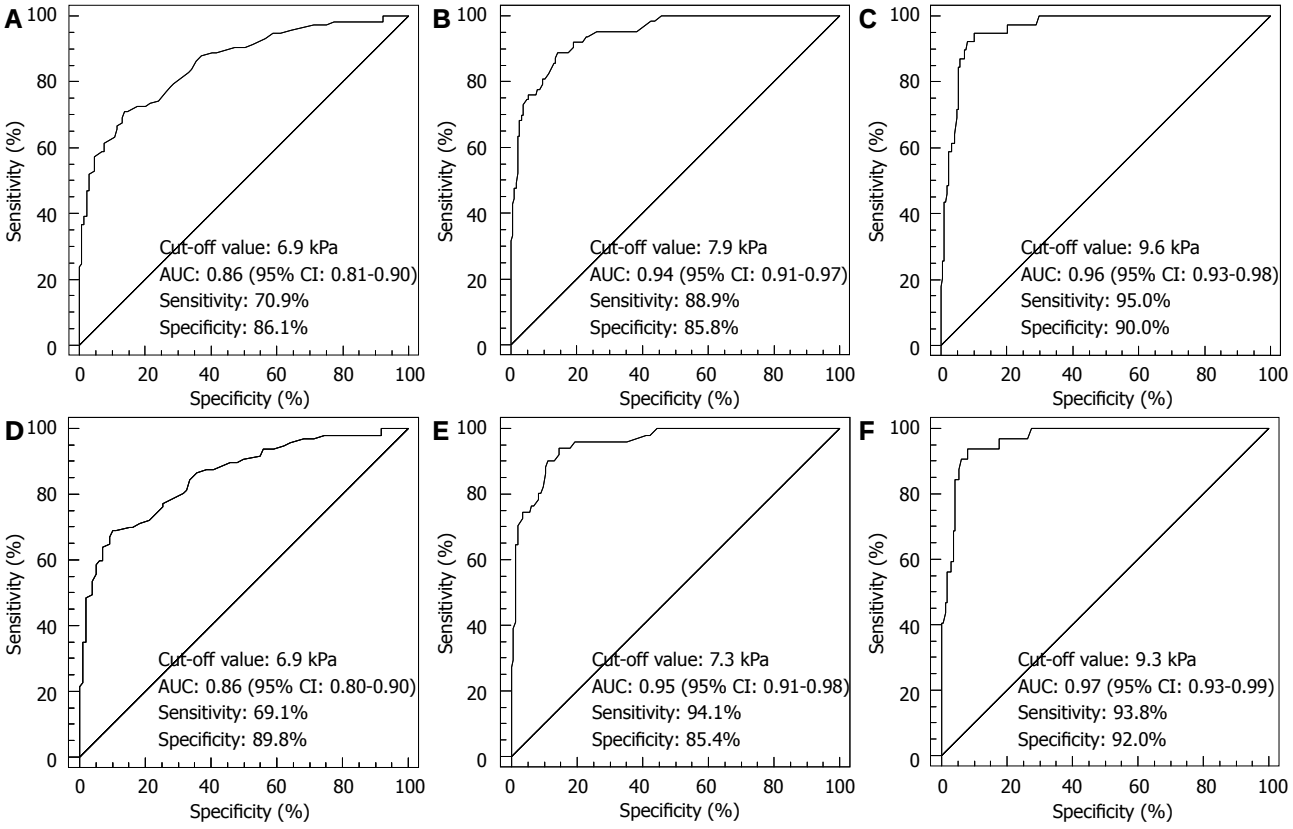

Figure 1 Receiver operating characteristic curve. A: F0-F1 *vs* F2- F4 (F > 2) in all patients (n = 246); B: F0-F2 *vs* F3- F4 (F > 3) in all patients (n = 246); C: F0-F3 *vs* F4 (F = 4) in all patients (n = 246); D: F0-F1 *vs* F2- F4 (F > 2) in patients with chronic hepatitis C (n = 195); E: F0-F2 *vs* F3- F4 (F > 3) in patients with chronic hepatitis C (n = 195); F: F0-F3 *vs* F4 (F = 4) in patients with chronic hepatitis C (n = 195).

Cut-off values of liver stiffness measurements obtained maximizing only the specificity were as high as 6.9 kPa for $F \geqslant 2$; 9.6 kPa for $F \geqslant 3$; 12.2 kPa for $F = 4$.

Patients with hepatitis C (n = 195): Medians and IQR of TE values for each fibrosis stage were 5.1 kPa (4.2-6.3) for F0-F1, 6.4 kPa (5.4-7.9) for F2, 8.9 kPa (8.0-13.3) for F3, and 17.4 kPa (12.8-22.2) for F4.

Multiple comparison between groups gave an adjusted P-value for significance of 0.004 and showed that there was a statistical significant difference for F0-F1 *vs* F2 (P = 0.0002), and F2 *vs* F3 (P = 0.001), but not for F3 *vs* F4 (P = 0.04).

In univariate analysis, TE showed a good correlation with the degree of fibrosis (r = 0.72, P < 0.00 001), a moderate correlation with the degree of histological activity index (r = 0.43, P < 0.00 001) and the AST value (r = 0.36, P < 0.00 001), and a poor correlation with the degree of steatosis despite being statistically significant (r = 0.19, P = 0.002). TE also showed a moderate negative correlation with platelet counts (r = -0.39, P = 0.002). Multivariate regression analysis including fibrosis stage, histological activity index, steatosis, AST, platelet counts confirmed the correlation with fibrosis stage (P < 0.0001) but not with all other variables.

ROC curve analysis identified optimal cut-off values of liver stiffness measurements as high as 6.9 kPa for $F \geqslant 2$; 7.3 kPa for $F \geqslant 3$; 9.3 kPa for $F = 4$ (Figure 1). Corresponding values of sensitivity, specificity, PPV, NPV, positive LR, negative LR and AUCs are shown in Table 2.

Cut-off values of liver stiffness measurements obtained maximizing only the specificity were as high as 7.0 kPa for $F \geqslant 2$; 9.3 kPa for $F \geqslant 3$; 12.3 kPa for $F = 4$.

Patients with hepatitis B (n = 41): Due to the small number of patients, only patients with F0-F1 stages *vs* F2-F4 stages were considered for statistical analysis. There was a statistical significant difference for F0-F1 *vs* F2-F4 (P = 0.0006).

In univariate analysis, TE showed a good correlation with the degree of fibrosis (r = 0.60, P < 0.00 001), a high correlation with the degree of histological activity index (r = 0.70, P < 0.00 001) and the AST value (r = 0.76, P < 0.00 001); no correlation was found with steatosis. Due to the small number of patients, multivariate regression analysis was not performed.

DISCUSSION

The results of this study show that the cut-off values of TE obtained for each fibrosis stage in a population of consecutive patients with chronic viral hepatitis from a single center are comparable to that obtained in the recent meta-analysis by Tsochatzis *et al*[8] that included up to 40 studies. In their study, the meta-analysis was conducted for cut-offs 7.0, 9.5 and 12 kPa in stages F2, F3, and F4, respectively.

In our series, when maximizing the sum of sensitivity and specificity for different fibrosis thresholds, the optimal cut-offs of TE were similar to those of the meta-analysis for the diagnosis of significant fibrosis ($F \geqslant 2$), and were lower for the diagnosis of advanced fibrosis ($F \geqslant 3$) and cirrhosis ($F = 4$). However, when maximizing specificity, the cut-offs were similar to those used by Tsochatzis *et al*[8], and showed specificity even higher with respect to those of the meta-analysis for all fibrosis stages.

In our series the results obtained in all patients with chronic viral hepatitis were almost similar to that obtained excluding patients with chronic hepatitis B. On the other hand, it should be underlined that our series included only 41/246 (16.7%) patients with chronic hepatitis B. Due to the small number, the statistical analysis of the data obtained in this group of patients was not performed.

An uneven distribution of patients over fibrosis stage, as observed in our study, is commonly found when consecutive patients undergoing liver biopsy are enrolled. Indeed, in our series the distribution of patients over fibrosis stages is almost similar to that observed in other studies[17,20,31,32], or when large series - as in the study of Degos *et al*[17] were enrolled.

Unlike to that reported by other authors[33,34], who found that the prevalence of liver steatosis in patients with hepatitis C was more than 50%, in our series the majority of patients had no to mild steatosis. On the other hand, it should be noted that, in our study, the mean value of BMI was within the normal range. This patient's characteristic could also explain the lower rate of TE unreliable results with respect to that reported in the literature[35,36].

In the seminal work of Sandrin *et al*[14] 93% of patients with TE values ⩽ 5.1 kPa were F0-F1, whereas 94% of patients with TE values ⩾ 7.6 kPa were F2 or more. On the other hand, patients with cirrhosis presented a very large range (from 14 kPa to 69 kPa). A limitation of that study is that liver biopsy and TE measurements were not performed in the same day; indeed, an inclusion criterion was liver biopsy performed less than one year before TE assessment. Since then , several studies have been published[15,31,37,38]. A wide range of TE cut-off value for F4 stage - from 11.8 kPa to 26.5 kPa - is found when comparing the results of several studies[5-9,15,17,31,35,37-39]. The different optimal TE cut-offs for F4 stage found in these studies by ROC curve analysis depend also on the fact that the characteristics of the patient population are not similar. Harada *et al*[37], that found a cut-off value of 26.5 kPa, enrolled patients with HCV recurrence after liver transplantation. In the study of Masuzaki *et al*[38], in which a cut-off of 15.9 kPa was found for F4 stage, there was a prevalence of patients with cirrhosis or pre-cirrhosis. In the study of Ziol *et al*[31], in which the optimal cut-off value for F4 stage was 14.5 kPa, liver biopsy was performed by the tran-

sjugular route in 63/251 (25.1%) of patients. It could be inferred that these patients presented already with clinical signs of cirrhosis, thus higher values of TE in the F4 stage - respect to patients without a clinical diagnosis of liver cirrhosis - could be expected[15,40]. Indeed, it has been demonstrated that there is an increase of TE values with liver disease progression beyond the F4 stage[15,19], and a highly positive correlation between TE values and portal pressure has been found[24,26]. Results similar to that obtained in our series were found in studies in which consecutive patients without clinical signs of liver cirrhosis were enrolled[39,41]. Cirrhosis should be regarded as a dynamic process, thus it is likely that patients in the initial stage of liver cirrhosis show lower values of TE respect to patients with compensated disease. Moreover, in the study of Foucher *et al*[15] liver stiffness was significantly correlated with Child-Pugh score. In their study, which included a large patient population with liver disease of different etiologies and also patients with decompensated cirrhosis, the optimal TE cut-off for F4 stage 17.6 kPa.

In conclusion, the results of our study show that the TE values used in the metanalysis of Tsochatzis *et al*[8] - namely 7.0, 9.5, and 12.0 kPa in stages F2, F3, and F4, respectively - could be used as given reference values in future studies aimed at evaluating the performance of TE in the assessment of liver fibrosis.

ACKNOWLEDGMENTS

The authors would like to thank Ms. Livia Astroni, Ms. Natali Calabrese, Mr. Filippo Cuda, Mr. Lorenzo Guioli, Ms. Maura Marchisoni, Ms. Giampiera Nava, Ms. Loredana Pavesi, Ms. Barbara Ricci, nurses in the outpatient ward of the Infectious Diseases Department, for their valuable help in complying with the study protocol.

COMMENTS

Background

Several studies have shown significant positive correlation between transient elastography (TE) and the stage of liver fibrosis. A limitation of all the studies is that the cut-off values for each fibrosis stage were calculated from their own cohort of patients after data collection, and they are different across studies.

Research frontiers

The aim of this study was to compare the cut-offs of TE obtained by receiver operating characteristic (ROC) curve analysis in their series of consecutive patients with chronic viral hepatitis to that used in a recently published meta-analysis.

Innovations and breakthroughs

The results of this study show that the cut-off values of TE obtained for each fibrosis stage in a population of consecutive patients with chronic viral hepatitis from a single center are comparable to that obtained in a recent meta-analysis that included up to 40 studies.

Applications

The values of TE obtained in the recently published meta-analysis could be used as reference values in future studies aimed at evaluating the performance of the technique in the assessment of liver fibrosis.

Terminology

Transient elastography is a technique that noninvasively quantify liver stiffness by estimating the velocity of propagation of a shear wave along an ultrasonic A-line. The harder the tissue, the faster the shear wave travels.

Peer review

The authors conducted this study to compare the cut-offs of TE obtained by ROC curve analysis in their series of consecutive patients, with chronic viral hepatitis referred to their center for liver biopsy, to that used in a recently published meta-analysis.

Abstract

AIM: To compare noninvasive methods presently used for steatosis detection and quantification in nonalcoholic fatty liver disease (NAFLD).

METHODS: Cross-sectional study of subjects from the general population, a subgroup from the First Israeli National Health Survey, without excessive alcohol consumption or viral hepatitis. All subjects underwent anthropometric measurements and fasting blood tests. Evaluation of liver fat was performed using four noninvasive methods: the SteatoTest; the fatty liver index (FLI); regular abdominal ultrasound (AUS); and the hepatorenal ultrasound index (HRI). Two of the noninvasive methods have been validated *vs* liver biopsy and were considered as the reference methods: the HRI, the ratio between the median brightness level of the liver and right kidney cortex; and the SteatoTest, a biochemical surrogate marker of liver steatosis. The FLI is calculated by an algorithm based on triglycerides, body mass index, γ-glutamyl-transpeptidase and waist circumference, that has been validated only *vs* AUS. FLI < 30 rules out and FLI ⩾ 60 rules in fatty liver.

RESULTS: Three hundred and thirty-eight volunteers met the inclusion and exclusion criteria and had valid tests. The prevalence rate of NAFLD was 31.1% according to AUS. The FLI was very strongly correlated with SteatoTest (r = 0.91, P < 0.001) and to a lesser but significant degree with HRI (r = 0.55, P < 0.001). HRI and SteatoTest were significantly correlated (r = 0.52, P < 0.001). The κ between diagnosis of fatty liver by SteatoTest (⩾ S2) and by FLI (⩾ 60) was 0.74, which represented good agreement. The sensitivity of FLI *vs* SteatoTest was 85.5%, specificity 92.6%, positive predictive value (PPV) 74.7%, and negative predictive value (NPV) 96.1%. Most subjects (84.2%) with FLI < 60 had S0 and none had S3-S4. The κ between diagnosis of fatty liver by HRI (⩾ 1.5) and by FLI (⩾ 60) was 0.43, which represented only moderate agreement. The sensitivity of FLI *vs* HRI was 56.3%, specificity 86.5%, PPV 57.0%, and NPV 86.1%. The diagnostic accuracy of FLI for steatosis > 5%, as predicted by SteatoTest, yielded an area under the receiver operating characteristic curve (AUROC) of 0.97 (95% CI: 0.95-0.98). The diagnostic accuracy of FLI for steatosis

> 5%, as predicted by HRI, yielded an AUROC of 0.82 (95% CI: 0.77-0.87). The κ between diagnosis of fatty liver by AUS and by FLI ($\geq$ 60) was 0.48 for the entire sample. However, after exclusion of all subjects with an intermediate FLI score of 30-60, the κ between diagnosis of fatty liver by AUS and by FLI either $\geq$ 60 or < 30 was 0.65, representing good agreement. Excluding all the subjects with an intermediate FLI score, the sensitivity of FLI was 80.3% and the specificity 87.3%. Only 8.5% of those with FLI < 30 had fatty liver on AUS, but 27.8% of those with FLI $\geq$ 60 had normal liver on AUS.

CONCLUSION: FLI has striking agreement with SteatoTest and moderate agreements with AUS or HRI. However, if intermediate values are excluded FLI has high diagnostic value *vs* AUS.

Comparison of fatty liver index with noninvasive methods for steatosis detection and quantification. *World J Gastroenterol* 2013; 19(1): 57-64 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/57.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.57

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is emerging as a significant health burden raising serious clinical and public health concerns. Liver steatosis may predispose the liver to inflammation, fibrosis and eventually cirrhosis and hepatocellular carcinoma[1,2]. Furthermore, it is regarded as the most prevalent chronic liver disease affecting as much as 30% of the adult western population[3-5].

Besides the hepatic damage, in recent years NAFLD has emerged as an independent risk factor for type 2 diabetes and cardiovascular disease[6,7]. Therefore, efforts to prevent NAFLD progression and extrahepatic manifestations must include screening and surveillance strategies. The occult nature of the disease has led to increased efforts in achieving simple and cost-effective diagnostic methods, preferably quantitative, that would be useful for screening, follow-up and evaluation of response to treatment in both clinical practice and research.

Liver biopsy is the gold standard for quantification of liver steatosis in NAFLD[8]. However, it is not routinely performed because it is an invasive procedure with a significant degree of sampling error[9]. In addition, due to the high prevalence of NAFLD in the general population using routine liver biopsy to diagnose NAFLD is unreasonable. Therefore, noninvasive methods including imaging techniques and blood-test-based formulas have been developed to qualify and quantify liver steatosis[10-12]. However, a widely accepted examination that is easy to perform, accurate and inexpensive has yet to be found.

The aim of this study was to compare the fatty liver index (FLI)[13], which has been validated only *vs* abdominal ultrasound (AUS) with two different reference noninvasive methods for steatosis quantification that were validated *vs* liver biopsy: the hepatorenal ultrasound index (HRI)[14], and the SteatoTest, a biochemical surrogate marker of liver steatosis[15], providing together a more complete picture of construct validity. We also aimed to compare FLI with regular AUS in a qualitative manner.

MATERIALS AND METHODS

Study population and measurements

A cross-sectional study was performed during 2003-2004, consisting of 375 participants, a subgroup from the First Israeli National Health Survey[16] as described in detail elsewhere[5,17]. Exclusion criteria were: alcohol consumption $\geq$ 30 g/d in men or 20 g/d in women, presence of hepatitis B surface antigen or anti-hepatitis C virus antibodies, fatty liver suspected to be secondary to hepatotoxic drugs, inflammatory bowel disease, prior surgery that could cause fatty liver, or celiac disease. All patients underwent measurements of weight, height, and waist circumference according to uniform protocols. Blood samples were drawn following a 12-h fast, and tested for liver enzymes, serum lipid profile, and fasting serum glucose and serum insulin levels. Frozen serum samples from all participants were stored at -80 ℃ until the analysis of SteatoTest (BioPredictive, Paris, France). Biomarkers components were analyzed according to published recommendations[18]. A face-to-face interview was carried out with a questionnaire that was assembled by the Israeli Ministry of Health[16] and included demographic data, health status and a detailed questionnaire on alcohol intake.

The study protocol was approved by the institution's human research committee and all participants gave signed informed consent.

AUS for detection of fatty liver and liver fat quantification

Fatty liver was diagnosed qualitatively by AUS using standardized criteria[19]. Ultrasound was performed in all subjects with the same equipment (EUB-8500 scanner; Hitachi Medical Corporation, Tokyo, Japan) and by the same operator (Webb M) as described previously[5,20]. The radiologist was blinded to the results of the blood tests and the clinical background of the participants, and the calculation of steatosis biomarkers was performed only after the radiological examination.

Furthermore, during AUS, the same single radiologist performed steatosis quantification using the HRI. The HRI has been validated *vs* liver biopsy and is an objective operator-independent examination[14] (available in 331 subjects). As previously described in detail[14], during ultrasonography, a graphic representation of echo

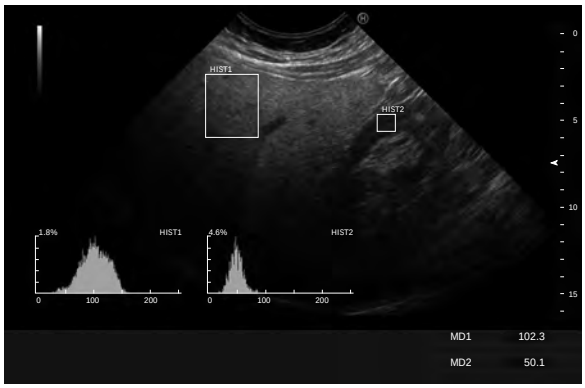

Figure 1 Ultrasound image of the liver and the right kidney cortex with graphic representation of the histogram in the region of interest rectangle. HIST1 is the histogram of the liver and HIST2 is the histogram of the right kidney cortex. The median histogram (MD) 1 of the liver is 102.3 and the MD2 of the kidney cortex is 50.1, yielding an HRI of 2.04.

intensity (histogram) within a region of interest in both the liver and the right kidney cortex was obtained on the same longitudinal sonographic plane. The ratio between the median brightness level of the liver and the right kidney cortex was calculated to determine the HRI (Figure 1). HRI $\geqslant$ 1.50 indicated fatty liver (parallel to steatosis > 5% on liver biopsy) with a sensitivity of 100% and specificity of 91% according to our validation study[14].

Surrogate measures of fatty liver

SteatoTest, the steatosis index, has been validated *vs* liver biopsy with a sensitivity of 0.90 and specificity of 0.54 at the 0.30 cut-off for the diagnosis of > 5% steatosis[15]. SteatoTest is calculated by the combination of the FibroTest with serum alanine amino transferase (ALT), body mass index (BMI), blood glucose, serum triglycerides and cholesterol adjusted for age and sex[15]. Two subjects had extremely low haptoglobin values, with suspected hemolysis and a high risk of false-positive FibroTest results, and therefore were omitted from our analysis. The definition of fatty liver was SteatoTest $\geqslant$ S2 (> 5% fat).

The FLI was calculated by an algorithm based on triglycerides, BMI, γ-glutamyl-transpeptidase and waist circumference. The FLI score range is 0-100 and estimates the percentage chance of having fatty liver. It has been validated *vs* fatty liver diagnosed qualitatively by ultrasound with a sensitivity of 0.61 and specificity of 0.86 for a cut-off of $\geqslant$ 60[13]. FLI < 30 rules out and FLI $\geqslant$ 60 rules in fatty liver. Our analyses referred to a cut-off with a value above 60 indicating NAFLD and a value below indicating no NAFLD.

Statistical analysis

Statistical analyses were performed using SPSS Version 17 (Chicago, IL, Unitd States). Continuous variables are presented as mean ± SD. The Pearson correlation coefficient was used for continuous variables. To test differences in continuous variables between two groups the independent samples *t* test was performed. For nominal variables, the Pearson χ^2 test was performed. To test the predictive value of the methods, receiver operating characteristic (ROC) curves were performed with SteatoTest ($\geqslant$ S2) or HRI ($\geqslant$ 1.5) as the reference methods, and the area under the ROC (AUROC) curve was recorded. κ was calculated for evaluation of agreement between diagnosis of fatty liver by SteatoTest ($\geqslant$ S2) or HRI ($\geqslant$ 1.5) compared to FLI ($\geqslant$ 60). κ values were interpreted by the following grades: very poor (0.00-0.20), poor (0.21-0.40), moderate (0.41-0.60), good (0.61-0.80), and excellent (0.81-1.00) agreement[21]. $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of the study population and comparison between subjects with FLI $\geqslant$ 60 and < 60

Three hundred and forty-nine volunteers met the inclusion criteria. Three hundred and forty serum samples were available for the SteatoTest (9 were either missing or hemolysed). Two subjects had a high risk of a false-positive FibroTest and thus were omitted from analysis, leaving a sample size of 338 subjects. Detailed information on the study population has been described elsewhere[5,17]. The main relevant characteristics of the study sample and comparison between the subjects with FLI $\geqslant$ 60 and and < 60 are depicted in Table 1. Subjects with FLI $\geqslant$ 60 were older, had a higher percentage of men, higher BMI, and higher serum fasting levels of liver enzymes, glucose, triglycerides, insulin and ferritin.

Distribution of steatosis as predicted by different methods in the entire sample and by FLI

Applying AUS as the reference method, most subjects with FLI $\geqslant$ 60 had fatty liver on AUS, yielding a positive predictive value (PPV) of 72.2%. Most subjects with FLI < 60 had normal liver on AUS, yielding a negative predictive value (NPV) of 81.5%. Applying HRI as the reference method, only 57.0% (PPV) of subjects with FLI $\geqslant$ 60 had HRI $\geqslant$ 1.50, but 86.1% (NPV) of the subjects with FLI < 60 also had HRI < 1.5. Applying the SteatoTest as the reference method, most subjects with FLI $\geqslant$ 60 had a SteatoTest of $\geqslant$ S2, yielding a PPV of 74.7%, and the majority of those with FLI < 60 had a SteatoTest < S2, yielding an NPV of 96.1%. Most subjects (84.2%) with FLI < 60 had S0 and none had S3-S4 (Table 1).

Correlation between FLI and SteatoTest or HRI

FLI was very strongly correlated with SteatoTest ($r = 0.91$, $P < 0.001$) and to a lesser but significant degree with HRI ($r = 0.55$, $P < 0.001$) (Figure 2). HRI and SteatoTest were also significantly correlated ($r = 0.52$, $P < 0.001$).

Furthermore, when testing the distribution of SteatoTest by FLI categories, FLI value above or below 60 discriminated the SteatoTest values with no overlap between the box plots (interquartile range). Similarly, the HRI values were discriminated by FLI categories, but to

Data are mean ± SD or proportion. BMI: Body mass index; ALT: Alanine amino transferase; AST: Abstract syntax tree; GGT: Gamma-glutamyl transpeptidase; FL: Fatty liver; FLI: Fatty liver index; AUS: Abdominal ultrasound; HRI: Hepatorenal ultrasound index; NA: Not avaliable.

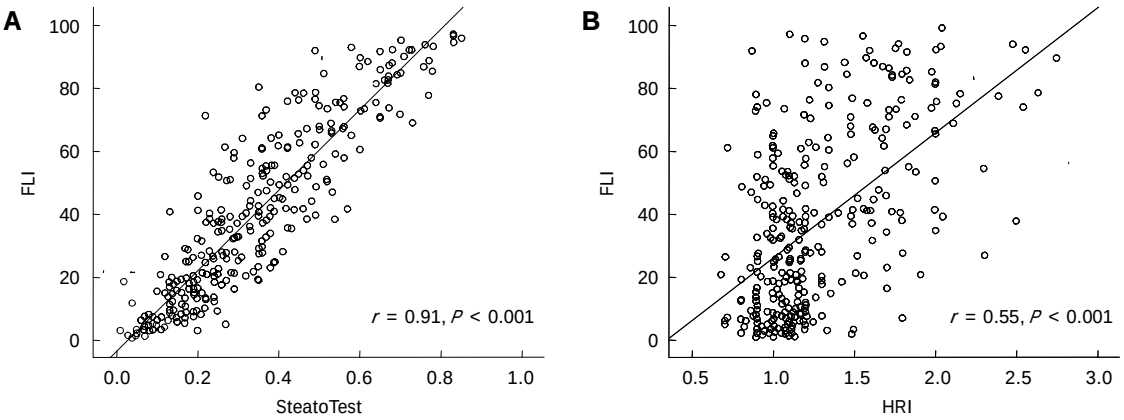

Figure 2 Correlation of fatty liver index with the reference methods. A: SteatoTest; B: Hepatorenal ultrasound index (HRI). FLI: Fatty liver index.

a lesser extent (Figure 3). The mean levels of SteatoTest and HRI were significantly different between FLI categories of above or below 60 (Table 1).

Concordance between FLI and SteatoTest or HRI in diagnosis of steatosis

The κ between diagnosis of fatty liver by SteatoTest (⩾ S2) and by FLI (⩾ 60) was 0.74, which represented good agreement (Table 2). The sensitivity of FLI *vs* SteatoTest was 85.5% (59/69) and the specificity 92.6% (249/269). The κ between diagnosis of fatty liver by HRI (⩾ 1.5) and by FLI (⩾ 60) was 0.43, which represented only moderate agreement (Table 2). The sensitivity of FLI *vs* HRI was 56.3% (45/80) and the specificity 86.5% (217/251).

Concordance between FLI and regular AUS in diagnosis of steatosis

The κ between diagnosis of fatty liver by AUS and by FLI (⩾ 60) was 0.48 (data not shown). A validation study of FLI has suggested that FLI < 30 rules out and FLI ⩾ 60 rules in fatty liver[13], therefore, further analysis was performed after exclusion of all subjects with an intermediate FLI score of 30-60 (27.8%). The κ between diagnosis of fatty liver by AUS and by FLI either ⩾ 60 or < 30 was 0.65, which represented good agreement (Table 2). The sensitivity of FLI was 80.3% (57/71) and the specificity 87.3% (151/173).

Only 8.5% of those with FLI < 30 had fatty liver on AUS, but 27.8% of those with FLI ⩾ 60 had normal liver on AUS.

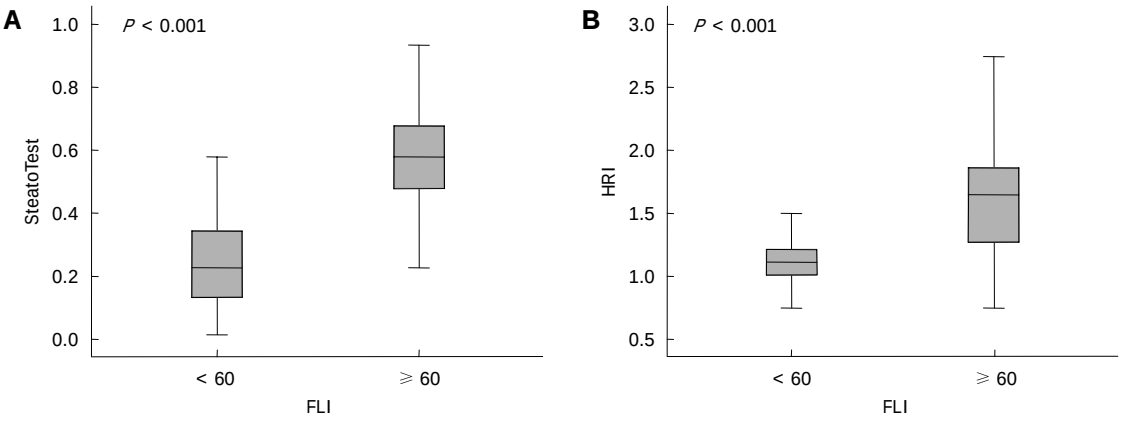

Figure 3 Distribution of SteatoTest and hepatorenal ultrasound index by fatty liver index above and below 60. A: SteatoTest; B: Hepatorenal ultrasound index (HRI). The box represents the interquartile range. The line across the box indicates the median. The "whiskers" are lines that extend from the box to the highest and lowest values, excluding outliers (defined as observations greater than 1.5 interquartile ranges). FLI: Fatty liver index.

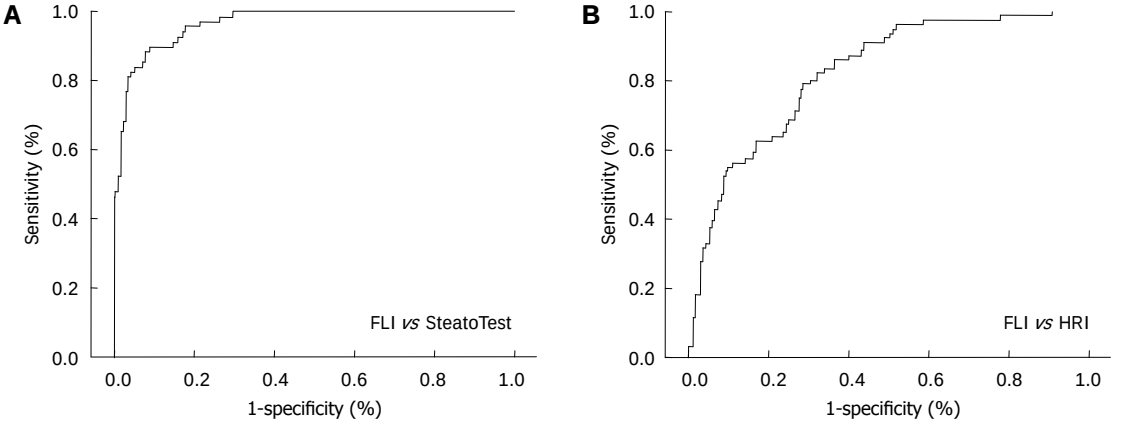

Figure 4 Receiver operating characteristic curves for diagnostic accuracy of fatty liver index *vs* SteatoTest or hepatorenal ultrasound index. A: SteatoTest; B: Hepatorenal ultrasound index (HRI). Comparing fatty liver index (FLI) to SteatoTest ⩾ S2, area under the receiver operating characteristic curve (AUROC) was 0.97 (95% CI: 0.95-0.98). Comparing FLI to HRI ⩾ 1.5, AUROC was 0.82 (95% CI: 0.77-0.87). Receiver operating characteristic curve of sensitivity (true-positive fraction) plotted against 1- specificity (false-positive fraction) of the FLI for diagnosis of steatosis.

Table 2 Diagnostic value of fatty liver index for predicting steatosis *vs* SteatoTest or hepatorenal ultrasound index or abdominal ultrasound

FLI ⩾ 60 *vs*	Sensitivity %	Specificity %	PPV %	NPV %	κ
SteatoTest ⩾ S2 (n = 338)	85.5	92.6	74.7	96.1	0.74
HRI ⩾ 1.50 (n = 331)	56.3	86.5	57	86.1	0.43
Abdominal ultrasound fatty liver (n = 244)	80.3	87.3	72.2	91.5	0.65

HRI: Hepatorenal ultrasound index; FLI: Fatty liver index; PPV: Positive predictive value; NPV: Negative predictive value.

Diagnostic accuracy of FLI for detection of steatosis > 5% in comparison to SteatoTest or HRI

The diagnostic accuracy of FLI for steatosis > 5%, as predicted by SteatoTest, yielded an AUROC of 0.97 (95% CI: 0.95-0.98). The diagnostic accuracy of FLI for steatosis > 5%, as predicted by HRI, yielded an AUROC of 0.82 (95% CI: 0.77-0.87) (Figure 4).

DISCUSSION

In view of the public health issue of the increasing prevalence of NAFLD and its hepatic and extrahepatic consequences, the development of simple cost-effective screening methods has become extremely important.

In the present study, the agreement between different potential noninvasive screening methods was evaluated. This is believed to be the first study to evaluate the agreement between FLI and steatoTest and between FLI and quantitative ultrasound methodology (HRI).

We found a striking agreement between SteatoTest and FLI, which were very highly correlated. A less impressive but still high correlation was found between FLI and HRI. The κ between diagnosis of fatty liver by SteatoTest and by FLI was 0.73, which represented good agreement. The κ between diagnosis of fatty liver by HRI and by FLI was 0.44, which represented only moderate agreement.

Although evaluation and quantification of steatosis does not provide a complete reflection of severity of

NAFLD, such evaluation is important for several reasons. As much as 23% of patients with simple steatosis may still develop nonalcoholic steatohepatitis (NASH) and fibrosis progression, as demonstrated in a recent 3-year follow-up of NAFLD patients[22]. Furthermore, recent literature indicates that NAFLD predicts the tendency to develop both diabetes mellitus[23,24] and cardiovascular disease[25-27]. Therefore, it is not surprising that patients with NAFLD have increased mortality and morbidity compared with the general population[28,29]. Moreover, NAFLD patients seem to have diminished quality of life[30], which is manifested by increased fatigue with impairment in physical function[31] and over-representation of depressive and anxiety disorders[32]. From the economic point of view, the health care costs were demonstrated to be significantly higher for individuals with NAFLD and increased serum ALT levels by 33%, controlling for BMI, lifestyle and comorbid conditions[33].

The limitation of this study was that it had no liver biopsy as a gold standard because it could not be obtained in a population-based screening study for NAFLD. Therefore, no inference can be made as for a criterion validity of the FLI. Two quantitative methods were developed and validated against liver biopsy; the HRI, a radiological method[14], and the SteatoTest[15], based on biochemical markers. Therefore, both methods were used as the best available reference for steatosis quantification, in the absence of biopsies, in the present population-based study. For that reason, the correlations presented here can only provide construct validity to the FLI. In fact, for a broader use of both SteatoTest and HRI, more validation studies including liver biopsy are warranted because only one has been performed for the HRI[14] and two for the SteatoTest in liver disease patients[15], and recently in patients with morbid obesity treated with bariatric surgery[34]. The HRI has been used in very few studies so far[35,36]; probably because it requires special ultrasonographic equipment, and a dedicated ultrasonographer. In contrast, there have been more studies using the SteatoTest[17,37-39] providing it with some construct validity.

The FLI is a continuous measure that has been validated against AUS for the qualitative detection of NAFLD and has never been validated *vs* liver biopsy. However, the presence of quantitative reference methods in the current study has enabled the testing of FLI also in a quantitative manner. The FLI has recently been used as a surrogate for NAFLD in large epidemiological studies. In a large European cross-sectional population-based study, FLI was associated with insulin resistance, higher Framingham risk score, and increased intima-media thickness[40]. More importantly, the predictive validity of FLI was demonstrated in two large cohorts. In the French general population cohort, FLI was an independent predictor for diabetes in a 9-year follow-up[41], as would be expected from ultrasound-diagnosed NAFLD[42]. In an Italian population cohort, after 15 years follow-up, FLI was independently associated with liver-related mortality[43].

The commonest noninvasive method for the evaluation of fatty liver is AUS[44,45]. AUS is the modern diagnostic test of choice for NAFLD in epidemiological surveys because it is noninvasive, safe, widely available, and with a reasonable sensitivity and specificity[4,46,47]. In a recent meta-analysis, the overall sensitivity and specificity of ultrasound for the detection of moderate-severe fatty liver compared to histology were 84.8% and 93.6%, respectively[48]. We demonstrated only moderate agreement between diagnosis of fatty liver by AUS and by FLI ($\geqslant$ 60) (κ = 0.48) , but after exclusion of all subjects with a intermediate FLI score of 30-60, κ increased to 0.65, representing good agreement, and the sensitivity and specificity of FLI were 80.3% and 87.3%, respectively. This however was at the cost of leaving almost 30% of the study population undiagnosed.

In summary, the present study provides construct validity to simple, inexpensive surrogate markers of NAFLD. FLI highly correlates and has good agreement with SteatoTest, perhaps because both are calculated measures based on overlapping parameters. FLI has moderate agreement with ultrasonographic methods; either regular AUS or HRI. These noninvasive diagnostic methods for liver steatosis should be further validated in different populations, preferably by criterion (*vs* liver histology) and predictive validity.

NAFLD has become one of the most important public health issues today. Although NASH is more relevant for the development of life-threatening liver disease, such as cirrhosis and hepatocellular carcinoma[49-51], it has now become clear from population studies that steatosis is relevant for the development of extrahepatic life-threatening diseases[52], such as diabetes[7,23,24] and cardiovascular disease[26,27]. Therefore, there is an urgent need for well-validated, quantitative, cost-effective, noninvasive methods for evaluation of steatosis in clinical practice, and epidemiological and clinical research when liver biopsy is not feasible.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) is regarded as the most prevalent chronic liver disease affecting as much as 30% of the adult western population. Besides hepatic damage, in recent years, NAFLD has emerged as an independent risk factor for type 2 diabetes and cardiovascular disease.

Research frontiers

Liver biopsy is the gold standard for detection and quantification of liver steatosis in NAFLD. However, it is not routinely performed because it is an invasive procedure with a significant degree of sampling error. In addition, due to the high prevalence of NAFLD, using routine liver biopsy to diagnose or screen for NAFLD is unreasonable and also unethical in epidemiological population-based studies. Therefore, noninvasive methods including imaging techniques and blood-test-based formulas have been developed to qualify and quantify liver steatosis. However, a widely accepted examination that is easy to perform, accurate and inexpensive has yet to be found.

Innovations and breakthroughs

In view of the increasing prevalence of NAFLD and its hepatic and extrahepatic consequences, the development of simple cost-effective screening methods has become extremely important. In the present study, the agreement between different potential noninvasive screening methods was evaluated. This is be-

lieved to be the first study to evaluate the agreement between fatty liver index (FLI) and two quantitative methods, the steatoTest and the hepatorenal index (HRI), which have been validated *vs* liver biopsy. This study also adds further validation to FLI as compared to regular abdominal ultrasound (AUS), which has been demonstrated so far only in one study.

Applications

Efforts to prevent NAFLD progression and extrahepatic manifestations must include screening and surveillance strategies. The present study provides validity to FLI, a simple, inexpensive surrogate marker of NAFLD. Validated, quantitative, cost-effective methods for evaluation of steatosis can help in repeated evaluation of treatment efficacy during follow-up in clinical practice and clinical trials. Furthermore, in large epidemiological population-based studies, when liver biopsy is not feasible, noninvasive methods may serve as an alternative. Knowing the agreement and disagreement between the different noninvasive methods would help in the interpretation of results from studies using different methods. Further validation of FLI in comparison with liver biopsy is still warranted.

Terminology

Steatosis is fatty infiltration of the liver, mainly triglycerides. Fatty liver is defined as steatosis exceeding 5%-10% of its weight. NAFLD may predispose the liver to inflammation, fibrosis and eventually cirrhosis and hepatocellular carcinoma. The HRI is a quantitative ultrasound methodology. The SteatoTest and the FLI are biochemical surrogate markers of liver steatosis based on calculated algorithms. All these are noninvasive methods presently used for steatosis detection and quantification.

Peer review

The subject of the article is of interest and importance. This was a good descriptive study in which the authors compared noninvasive methods presently used for steatosis detection and quantification in NAFLD. The results are interesting and suggest that FLI has striking agreement with SteatoTest and moderate agreements with AUS or HRI.

Abstract

AIM: To investigate the frequency and factors of prolonged QT dispersion that may lead to severe ventricular arrhythmias in patients with inflammatory bowel disease (IBD).

METHODS: This study included 63 ulcerative colitis (UC) and 41 Crohn's disease (CD) patients. Forty-seven healthy patients were included as the control group. Heart rate was calculated using electrocardiography, corrected QT dispersion (QTcd) and the Bazett's formula. Homeostasis model assessment (HOMA) was used to determine insulin resistance (IR). HOMA values < 1 were considered normal and values > 2.5 indicated a high probability of IR.

RESULTS: Prolonged QTcd was found in 12.2% of UC patients, and in 14.5% of CD patients compared with the control group ($P < 0.05$). A significant difference was found between the insulin values (CD: 10.95 ± 6.10 *vs* 6.44 ± 3.28, $P < 0.05$; UC: 10.88 ± 7.19 *vs* 7.20 ± 4.54, $P < 0.05$) and HOMA (CD: 2.56 ± 1.43 *vs* 1.42 ± 0.75, $P < 0.05$; UC: 2.94 ± 1.88 *vs* 1.90 ± 1.09, $P < 0.05$) in UC and CD patients with and without prolonged QTcd. Disease behavior types were determined in CD patients with prolonged QTcd. Increased systolic arterial pressure (125 ± 13.81 *vs* 114.09 ± 8.73, $P < 0.01$) and age (48.67 ± 13.93 *vs* 39.57 ± 11.58, $P < 0.05$) in UC patients were significantly associated with prolonged QTcd.

CONCLUSION: Our data show that IBD patients have prolonged QTcd in relation to controls. The routine follow-up of IBD patients should include determination of HOMA, insulin values and electrocardiogram examination.

INTRODUCTION

The most common extra-intestinal manifestations of Crohn's disease (CD) and ulcerative colitis (UC) are iridis, uveitis, primary sclerosing cholangitis, nodal erythema and pyoderma gangrenosum. Complications within the cardiovascular system seem to be uncommon, but there are no systematic investigations concerning the epidemiology of these manifestations. There have been more than 100 cases of pericarditis and perimyocarditis reported in patients with inflammatory bowel disease (IBD). Other patients with CD or UC suffer from vasculitis, representing a further mechanism of inflammatory diseases of the cardiovascular system. Some patients developed thrombotic complications due to activation of the coagulation system, which can result in atrial thrombi, embolism of the pulmonary arteries, myocardial infarction and disseminated intravascular coagulopa-

thy. Furthermore, a few cases of atrioventricular block, amyloidosis of the heart, dilated cardiomyopathy and endomyocardial fibrosis have been reported in patients with chronic IBD[1].

The most important causes of sudden death of cardiac origin are ventricular tachycardia and ventricular fibrillation cardiac arrhythmias. The action potentials in patients with long QT electrocardiographic (ECG) changes are not homogeneous, and as they result in the development of early and late repolarization facilitate the development of ventricular fibrillation[2]. The heterogeneity of QT dispersion (QTd) in ventricular repolarization is defined by the difference between the longest and shortest QT[3]. Increased QTd in many patients, and disease group were associated with the risk of serious arrhythmia and sudden death[2,4,5]. In patients with acute myocardial infarction, measurement of QT dispersion has shown little promise as a predictor of long-term mortality risk in individuals[6]. Cardiac involvement in IBD can cause serious ventricular arrhythmias with prolonged QTd, however, very little data is available on this subject[7]. In this study, QTd was prolonged in patients with IBD, and the relationships between disease characteristics and biochemical parameters were investigated.

MATERIALS AND METHODS

Ethics aspects

This study was formally authorized by the local Ethics Committee (approval date and number: 02-06-2009, No: 57). All of the patients gave written informed consent to the study protocol.

Study design

This was an observational, case-control study. Clinical, endoscopic, histologic, and radiologic findings showed that 63 patients had UC and 41 had CD. Forty-seven healthy control subjects were also included.

Selection of controls and patients

The control group had no chronic diseases, electrolyte imbalance and did not take regular medication. In addition, the controls were selected from persons with normal QT dispersion. IBD patients with known chronic disease, electrolyte imbalance, thyroid dysfunction or treated with drugs known to affect ECG findings were excluded from the study. Smoking status, alcohol habit, family history, use of medications, and physical examination were performed in all patients. After measurement of liver enzymes, blood count and blood levels of potassium, calcium and magnesium, those with abnormal findings were excluded from the study. To evaluate the clinical activity of CD, the Crohn's disease activity index (CDAI) was used. CDAI scores less than 150 indicated quiescence, while higher scores indicated active disease[8]. In UC patients, the Truelove-Witts clinical activity index was used to evaluate disease activity[9].

Anthropometric measurements

Anthropometric measurements (height, weight, waist circumference) were carried out by same person using standard instruments in patients wearing hospital clothing, while standing. Body mass index (BMI) was calculated by dividing the patient's weight by the square of his or her height (mass/height^2, kg/m^2). Waist circumference was measured while standing at the narrowest area of the waist midway between the anterior superior iliac spine and the lower rib margin on light expiration. Average systolic and diastolic blood pressure measurements were recorded. Systolic blood pressure (SBP) of 140 mmHg and over and diastolic blood pressure of 90 mmHg and over were accepted as hypertension[10]. Patients with hypertension were excluded.

QT interval calculation

All patients and controls underwent 12-lead surface ECG to determine QT interval, and the QRS complex was defined as the distance from the beginning to the end of the T wave. Heart rate, physiological causes of shortening of the QT interval, and reduction in speed will cause QT prolongation. Various formulations of the QT interval were corrected for heart rate. Corrected QT (QTc) was calculated according to the Bazett's formula (Bazett's formula QTc = QT × $\sqrt{RR}$). QTd and minimum mean QT as the difference between the average QT were also calculated. Corrected QT dispersion (QTcd) values were calculated in the same way. Extended QTc interval was defined as a duration of > 440 ms[11].

Biochemical analysis

After 12 h of night fasting, venous blood samples were taken, centrifuged (2500 cycle/min) and the serum separated to measure biochemical indices. Glucose, total cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol, triglyceride and uric acid levels were determined by enzymatic methods, and insulin level was determined by electrochemiluminescence immunoassay using a Roche E170 device. Insulin sensitivity was assessed by homeostasis model assessment of insulin resistance (HOMA-IR). Accordingly, IR was calculated using the following formula: Fasting insulin level (μIU/mL) × fasting plasma glucose (mmol/L)/22.5[12].

Statistical analysis

All data are presented as mean ± SE. Data were analyzed using descriptive statistical methods (mean, standard deviation, frequency). Differences between CD, UC, and controls, demographic, anthropometric, and laboratory values and the relationship between QT duration were calculated using the Kruskal-Wallis test, Mann-Whitney *U* test, and Chi-square test. Pearson correlation analysis was used to determine the relationship between variables. All analysis were performed using SPSS version 15.0 (SPSS Inc., United States). Statistical significance was accepted at $P \leq 0.05$.

RESULTS

Demographic characteristics

This study included 63 UC patients (33 female, 30 male; mean age 40.89 ± 12.25 years), 41 CD patients (16 female, 25 male; mean age 38 ± 7.79 years) and 47 healthy controls (25 female, 32 male; mean age 41.21 ± 10.55 years).

Descriptive analysis of patients

Of these patients; 12.2% UC and 14.5% CD patients had prolonged QTcd when compared with the control group ($P < 0.05$). Increased SBP ($P < 0.01$) and age ($P < 0.05$) in UC patients were significantly associated with prolonged QTcd. Disease group, disease duration, family history, smoking, alcohol use, history of surgery, disease activity, localization, and drug use were not related to prolonged QTcd ($P > 0.05$). Disease behavior type was determined to be involved in CD patients with prolonged QTcd ($P < 0.001$) (Tables 1 and 2).

Biochemical analysis and the relationship between prolonged QT intervals

Significant differences were observed in patients with UC and CD with respect to insulin values ($P < 0.05$) and HOMA ($P < 0.05$) values compared to patients without UC and CD (Tables 3 and 4). Both groups demonstrated HOMA values above 2.5 (Figure 1). Using Pearson cor-

relation analysis, a moderately significant positive relationship was observed between QT time in patients with CD and UC and insulin (CD: $r = 0.542$, $P = 0.023$; UC: $r = 0.560$, $P = 0.021$) and HOMA values (CD: $r = 0.618$, $P = 0.018$; UC: $r = 0.678$, $P = 0.011$).

DISCUSSION

Homogeneous ventricular resting time is believed to be protective against arrhythmias[13]. Easy and non-invasive methods to determine the risk of ventricular arrhythmia,

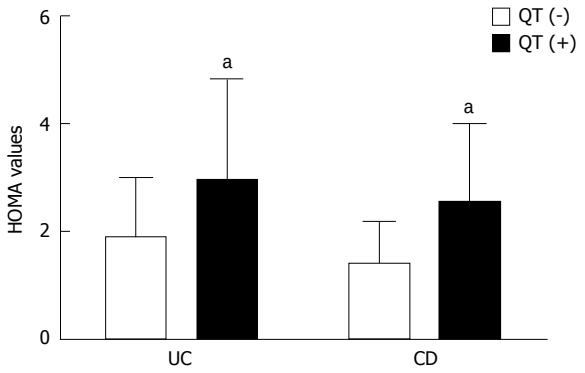

Figure 1 Homeostasis model assessment values in ulcerative colitis and Crohn's disease patient. Data are shown as mean ± SD. $^{a}P < 0.05$ *vs* QT prolongation (-) groups using Mann-Whitney *U* test. HOMA: Homeostasis model assessment; UC: Ulcerative colitis; CD: Crohn's disease.

are an advantage in patients with QTd. However, the frequency and prognostic value of IBD as an indicator of arrhythmia is not fully understood. In this study, the demographic data of patients with IBD and prolonged QT dispersion and the relationships with some cardiovascular risk parameters were investigated. Conflicting results were obtained in previous studies investigating the relationship between age and QT interval. Some studies in older healthy individuals showed a significant correlation between age and prolonged QTd[14-16]. In contrast, Merri *et al*[17] looked at descriptive ECG features of ventricular repolarization, and did not find a relationship between age and QT interval. The relationship between gender and QT interval has also been investigated. In the literature, some studies have reported long-QT dispersion in healthy women compared with men[18,19]. Mangoni and colleagues found no differences between QTd and gender[14]. In our study, UC patients showed a significant relationship between older age and prolonged QTd. Smoking may predispose to ventricular fibrillation and sudden cardiac death by altering ventricular recovery time dispersion indices. Some studies found a correlation between smoking in men and QT dispersion, this was not detected in the study by Mangoni and colleagues[14,20,21]. In our study, both UC and CD patients did not show a correlation between smoking and prolonged QTd. Drugs such as steroids and azathioprine can be cardiotoxic[22-27]. There was no correlation between QT dispersion and the use of 5-aminosalicylic acid, steroids and azathiopurine. In fact, although UC and CD are generally described as two expressions of a common pathophysiological process, they may be characterized by different autonomic alterations due to the diverse location of inflammatory lesions along the gastrointestinal tract[28]. Inflammation tends to be diffuse and uniform in UC, mainly affecting the superficial layers of the inner lining of the bowel, where autonomic neural fibers of the submucosal plexus are located[29], whereas in CD inflammation is concentrated in some areas more than in others, involving deeper layers of the bowel wall. The different location and structure of the lesions may therefore have different effects on autonomic gastrointestinal control, possibly reflected by differences in cardiovascular autonomic control[30]. In our study, prolonged QTd was significantly more frequent in patients with stricturing and penetrating CD. The relationship between physiologic BMI and QT interval confirms and extends the findings of previous reports which showed a positive relationship between these variables in human obesity[31-33]. Prolonged QTcd was observed in about 30% of subjects with impaired glucose tolerance in a report from the NHANES Ⅲ cohort, and a positive association was found between BMI and QTcd[34]. Some studies have also found a positive correlation between waist circumference and QTd[31,35,36]. In our study, prolonged QTd was found in UC and CD patients with higher BMI and waist circumference, although no statistically significant relationship was found. IR is a metabolic disorder characterized by a reduction in the use of glucose in skeletal muscle. Excess sodium retention, insulin-like cellular proliferation and matrix expansion causes vascular responses. Insulin, various growth factors, and vascular damage can accelerate atherosclerosis[37]. Nigro and colleagues found that HOMA and insulin concentrations were significantly correlated with QTd[33]. In our study, UC and CD patients with high insulin and HOMA values showed a statistically significant relationship with QT dispersion. The two groups demonstrated HOMA values above 2.5. According to JNC 7, subjects with systolic blood pressure of 120-139 mmHg are considered to have prehypertension[8]. Some studies showed a significant relationship between subjects with prehypertension and prolonged QTd[38,39]. In our study, SBP in UC patients with prolonged QTd was significantly higher than that in those without prolonged QTd, and the controls. QT dispersion seen before the development of hypertension and diabetes mellitus may be associated with IBD etiopathogenesis.

Simple, inexpensive and non-invasive methods can be used to identify QTd, ventricular arrhythmias, and the risk of cardiovascular diseases. These cardiovascular diseases may occur as a result of prolonged QTd, and IBD exacerbates ventricular arrhythmias and can cause sudden death. In IBD patients, prolonged QTd can be used to determine cardiovascular risk factors thought to be useful for the large patient groups in controlled trials.

COMMENTS

Background

Inflammatory bowel disease (IBD) involves two separate chronic idiopathic inflammatory diseases: Crohn's disease and ulcerative colitis. Increased QT dispersion (QTd) is a marker of myocardial electrical instability and predicts ventricular arrhythmias and sudden cardiac death.

Research frontiers

Easy and non-invasive methods to determine the risk of ventricular arrhythmia are an advantage in patients with QTd. However, the frequency and prognostic value of IBD as an indicator of arrhythmia is not fully understood. In this study, the demographic data of patients with IBD and prolonged QT dispersion and their relationship with some cardiovascular risk parameters were investigated.

Innovations and breakthroughs

Cardiac involvement in IBD can cause serious ventricular arrhythmias with prolonged QTd, however, very little data is available on this subject. QT disper-

sion is prolonged in patients with IBD. The relationship between QT dispersion, insulin, homeostasis model assessment (HOMA) and increased cardiovascular risk factors were investigated in this study.

Applications

Determination of the factors causing prolongation of the treatment of patients with IBD with QT dispersion and reorganization will provide additional benefit in the future prognosis of these diseases.

Peer review

The aim of the study was to investigate the whether prolonged QT dispersion as measured on the electrocardiographic, at risk of developing ventricular fibrillation, in adult patients with IBD. In addition, the authors determined the level of insulin resistance in these patients using HOMA.

Abstract

AIM: To evaluate the chemotherapeutic outcomes and confirm the recent improvement of prognosis for unresectable biliary tract cancer.

METHODS: A total of 186 consecutive patients with unresectable biliary tract cancer, who had been treated with chemotherapy between 2000 and 2009 at five institutions in Japan, were retrospectively analyzed. These patients were divided into three groups based on the year beginning chemotherapy: Group A (2000-2003), Group B (2004-2006), and Group C (2007-2009). The data were fixed at the end of December 2011. Overall survival and time-to-progression were analyzed and compared chronologically.

RESULTS: No patient characteristics were significantly different among the three groups. The gallbladder was involved in about half of the patients in each group, and metastatic biliary tract cancer was present in three quarters of the enrollees. In Group A, 5-fluorouracil-based chemotherapies were primarily selected as first-line chemotherapy, and only 24% were treated with second-line chemotherapy. In Group B, gemcitabine or S-1 monotherapy was mainly introduced as first-line chemotherapy, and 51% of the patients who were refractory to first-line chemotherapy were treated with second-line chemotherapy mainly with monotherapy. In Group C, the combination therapy with gemcitabine and S-1 was mainly chosen as first-line chemotherapy, and 53% of the patients refractory to first-line chemotherapy were treated with second-line chemotherapy mainly with combination therapy. The median time-to-progressions were 4.4 mo, 3.5 mo and 5.9 mo in Groups A, B and C, respectively (4.4 mo *vs* 3.5 mo *vs* 5.9 mo, $P < 0.01$). The median overall survivals were 7.1, 7.3, and 11.7 mo in Groups A, B and C (7.1 mo *vs* 7.3 mo *vs* 11.7 mo, $P = 0.03$). Induction rates of all three drugs (gemcitabine, platinum analogs, and fluoropyrimidine) in Groups A, B and C were 4%, 2% and 27% (4% *vs* 2% *vs* 27%, $P < 0.01$).

CONCLUSION: The prognosis of unresectable biliary tract cancer has improved recently. Using three effective drugs (gemcitabine, platinum analogs, and fluoropyrimidine) may improve the prognosis of this cancer.

INTRODUCTION

Biliary tract cancer (BTC) is the sixth leading cause of cancer-related death in Japan according to "Cancer Statistics in Japan (2009)". Surgery is still the only treatment that can cure this life-threatening disease. However, many patients are diagnosed at an advanced stage of disease. Therefore, chemotherapy is indispensable for the treatment of advanced BTC.

In the 21st century, many clinical trials have been conducted to investigate the use of chemotherapy for advanced BTC[1]. Regimens involving 5-fluorouracil were widely used around the year 2000. However, gemcitabine has now become a key drug based on the results of several retrospective analyses[2,3]. In Japan, gemcitabine and S-1 (an oral fluoropyrimidine) have been approved and are widely used for the treatment of BTC[4-8]. Combination therapy using gemcitabine and S-1 has produced promising results in phase Ⅱ studies and is considered as one of the regimen for advanced BTC, particularly in Japan[9,10]. Meanwhile, combination therapy with gemcitabine and cisplatin has become a standard chemotherapy regimen based on the results of recent randomized controlled studies reported in 2009[11,12].

BTC include the cancers of several biliary sites, therefore the results might have strongly been affected by the patient characteristics enrolled in the clinical trial. Moreover, most of these past trials also included both unresectable and recurrent cases; however, the prognoses of these two conditions are extremely different[12]. One of the reasons for this difference might be that the tumor volume of recurrent cases was usually smaller than that of unresectable cases. We have previously reported that tumor volume affects both the tumor response and prognosis in advanced BTC patients who received chemotherapy[13]. Another reason might be that the tolerance of chemotherapeutic agents was usually poorer in recurrent cases than in unresectable cases. It is sometimes difficult to treat recurrent cases with the same treatment dose and schedule as unresectable cases because metabolism of the anti-cancer agent is often influenced by major surgery[14]. Therefore, it is better to separate these two conditions when the treatment outcomes of chemotherapy for advanced BTC are analyzed. Thus, we conducted a retrospective study to clarify the treatment outcomes of chemotherapy and confirm the recent improvement of prognosis for the treatment of unresectable BTC patients.

MATERIALS AND METHODS

Patients and methods

A total of 186 patients with unresectable BTC, who had been treated with chemotherapy between 2000 and 2009 at five institutions in Japan, were retrospectively analyzed. The patients were divided into three groups: the patients who started chemotherapy between 2000 and 2003 were enrolled as Group A, the patients who started chemotherapy between 2004 and 2006 were enrolled as Group B and the patients who started chemotherapy between 2007 and 2009 were enrolled as Group C. The eligibility criteria of this retrospective study were as follows: (1) no previous chemotherapy; (2) an Eastern Cooperative Oncology Group performance score of 0 to 3; (3) adequate bone marrow function (white blood cell count > 3000/mm^3, hemoglobin > 9.0 g/dL and platelet count > 100 000/mm^3), liver function [total bilirubin < three times the upper limit of normal (ULN) and aspartate/alanine transaminase levels < five times the ULN] and renal function (creatinine < 1.2 mg/dL or creatinine clearance > 50 mL/min); (4) no serious complications; (5) no uncontrolled infections; and (6) written informed consent from the patient.

Treatment regimen

First-line chemotherapy: Because there was no standard chemotherapy or efficacious key drug for advanced BTC, several 5-fluorouracil-based chemotherapies were selected between 2000 and 2003 (Group A). Chemoradiation was primarily selected in cases of locally advanced BTC. The treatment regimen was chosen by the attending doctor during this period. Starting in the middle of 2004, gemcitabine monotherapy (1000 mg/m^2, days 1, 8, 15, q 4 wk) was introduced. Several clinical trials have been conducted since 2005. First, a feasibility study of S-1 monotherapy (80 mg/m^2, days 1-28, q 6 wk) was started in 2005[7]. A multicenter phase Ⅱ study of gemcitabine and S-1 combination therapy (gemcitabine: 1000 mg/m^2, days 1, 15; S-1: 80 mg/m^2, days 1-14, q 4 wk) started to enroll participants in 2007[9]. Furthermore, a randomized phase Ⅱ study comparing gemcitabine and S-1 combination therapy (gemcitabine: 1000 mg/m^2, days 1, 15; S-1: 80 mg/m^2, days 1-14, q 4 wk) with gemcitabine monotherapy (1000 mg/m^2, days 1, 8, 15, q 4 wk) started to enroll participants at the end of 2008. After the completion of this randomized study, gemcitabine and S-1 combination therapy became the first choice for clinical practice.

Second-line chemotherapy: Only certain patients were treated with second-line chemotherapy between 2000 and 2003 (Group A). Several clinical trials of second-line chemotherapy have also been conducted since 2007. A multicenter phase Ⅱ study of S-1 monotherapy (80 mg/m^2,

days 1-28, q 6 wk) as a second-line chemotherapy started to enroll participants in 2007[8]. Moreover, a feasibility study of gemcitabine and cisplatin combination therapy (gemcitabine: 1000 mg/m^2, days 1, 8; cisplatin: 25 mg/m^2, days 1, 8, q 3 wk) for refractory BTC was started in 2008[15]. Recently, gemcitabine and cisplatin combination therapy are chosen as second-line chemotherapy in clinical trial.

Statistical analysis

The Mann-Whitney *U* test was used to compare quantitative variables. The time to progression and overall survival were calculated using the Kaplan-Meier method. The time to progression was calculated from the start of the treatment to the first date of documented disease progression. The overall survival was defined as the time from the initiation of therapy to the final follow-up or until death from any cause. The final analysis was conducted using the follow-up data through the end of December 2011 to get enough follow-up periods. The JMP 8.0 statistical software program (SAS Institute Inc., Cary, NC, United States) was used for all statistical analyses.

RESULTS

Patient characteristics

A total of 186 patients with unresectable BTC were treated with chemotherapy between January 2000 and December 2009. Patient characteristics are shown in Table 1. The number of patients in Group A (2000-2003), B (2004-2006) and C (2007-2009) was 25, 54 and 107, respectively. No patient characteristics were significantly different among the three groups, although the median age of each group became slightly higher with time. There were no differences in either the primary biliary site or disease status. The gallbladder was involved in about half of the patients in each group and metastatic BTC was present in three quarters of the enrollees in each group.

Chemotherapy

Group A (2000-2003): The regimens for first-line and second-line chemotherapy are listed in Table 2. As first-line chemotherapy, 5-fluorouracil-based chemotherapies were primarily selected during this period (sixteen patients; 64%). Eight patients (32%) were treated with chemoradiation and intra-arterial infusions were delivered to four patients (16%). In this treatment group, all of the patients progressed with first-line chemotherapy. Only six patients (24%) were treated with second-line chemotherapy; two patients were treated with gemcitabine monotherapy and one patient was treated with S-1

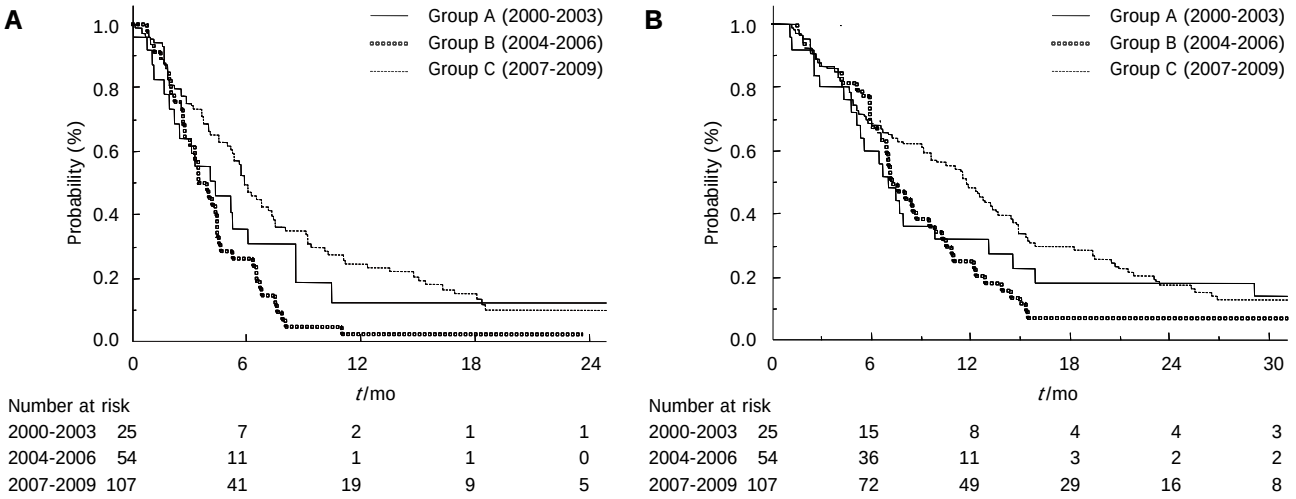

Figure 1 Time-to-progression curves (A) and overall survival curves (B) of patients with unresectable biliary tract cancer. A: The median time to progression was 4.4 mo, 3.5 mo and 5.9 mo in Groups A, B and C, respectively (log-rank test; $P < 0.01$). There was no difference between Groups A and B (log-rank test; $P = 0.20$); B: The median overall survival was 7.1 mo, 7.3 mo and 11.7 mo in Groups A, B and C, respectively (log-rank test; $P = 0.03$). There was no difference between Groups A and B (log-rank test; $P = 0.41$).

monotherapy, uracil-ftorafur monotherapy, 5-fluorouracil-based chemoradiation and intra-arterial infusion of gemcitabine. Of all, only one patient (4%) was treated with all three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) in this group.

Group B (2004-2006): During this period, gemcitabine or S-1 monotherapy was primarily selected for first-line chemotherapy (83%); twenty-five patients (46%) underwent gemcitabine monotherapy and twenty patients (37%) underwent S-1 monotherapy. In this treatment group, fifty-three patients progressed with first-line chemotherapy. Of the patients who were refractory to first-line chemotherapy, twenty-seven patients (51%) were treated with second-line chemotherapy, fourteen patients were treated with gemcitabine monotherapy and nine patients were treated with S-1 monotherapy. Sequential monotherapy of gemcitabine and S-1 was introduced during this period. Of all, only one patient (2%) was treated with all three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) in this group.

Group C (2007-2009): As first-line chemotherapy, combination therapy with gemcitabine and S-1 was introduced and used predominantly during this period (in 58% of patients). In this treatment group, ninety-nine patients progressed with first-line chemotherapy. Of these patients, fifty-two (53%) were treated with second-line chemotherapy; twenty-eight patients were treated with gemcitabine and cisplatin combination therapy, six patients were treated with gemcitabine monotherapy and thirteen patients were treated with S-1 monotherapy. During this period, sequential combination therapy using gemcitabine, S-1 and cisplatin was primarily prescribed. Of all, twenty-nine patients (27%) were treated with all three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) in this group.

Time-to-progression and overall survival

The median times-to-progression in Groups A, B and C were 4.4 mo (95% CI, 2.0-8.6 mo), 3.5 mo (95% CI, 2.8-4.5 mo) and 5.9 mo (95% CI, 5.2-7.3 mo), respectively (log-rank test; $P < 0.01$) (Figure 1A). There was no difference between Groups A and B (log-rank test; $P = 0.20$). The median overall survival times in Groups A, B and C were 7.1 mo (95% CI, 5.1-13.1 mo), 7.3 mo (95% CI, 6.6-9.5 mo) and 11.7 mo (95% CI, 9.2-13.7 mo), respectively (log-rank test; $P = 0.03$) (Figure 1B). There was also no difference between Groups A and B (log-rank test; $P = 0.41$).

After assessing the treatment outcomes of each primary biliary site, the median overall survival for patients with gallbladder cancer ($n = 46$), intrahepatic cholangiocarcinoma ($n = 40$) and extrahepatic cholangiocarcinoma ($n = 20$) in Group C (2007-2009) was 9.1 mo (95% CI, 5.2-12.5 mo), 12.4 mo (95% CI, 6.7-19.4 mo) and 14.9 mo (95% CI, 11.1 mo - not reached), respectively (log-rank test; $P = 0.049$).

DISCUSSION

Many clinical trials investigating the use of chemotherapy for advanced BTC have been reported since 2000, although most of these previous trials included both unresectable and recurrent cases[16]. However, the prognoses of these two conditions are extremely different[12]. In BT-22 study, the median overall survivals of unresectable and recurrent BTC, who were treated with the combination therapy of gemcitabine and cisplatin, were 9.4 mo and 16.1 mo, respectively. Thus, the patient characteristics strongly affect the results of clinical trial for advanced BTC, though most previous trial did not report the detail about the prognosis of unresectable BTC. In our retrospective study, we ascertained that the prognosis for unresectable BTC has actually improved in recent years

(Group C; 2007-2009) and the median overall survival has reached approximately one year. We also confirmed that the prognoses for unresectable BTC at several biliary sites are actually different and that the prognosis for unresectable gallbladder cancer is still extremely poor.

The median overall survival of Group C (2007-2009) was 11.7 mo (95% CI, 9.2-13.7 mo). The difference between the median overall survival and the median time to progression increased with time (Group A, 2.7 mo; Group B, 3.8 mo; Group C, 5.8 mo). The rate of second-line chemotherapy also increased in Group B (51%) and Group C (53%). However, greater improvement was observed only in Group C, which may have been caused by the use of three effective agents (gemcitabine, platinum analogs and fluoropyrimidine). In fact, induction rates of these three effective drugs in Groups A, B and C were 4%, 2% and 27% ($P < 0.01$). Therefore, using three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) may improve the prognosis of unresectable BTC.

One limitation of this retrospective study is that the regimens in each group were not uniform. However, the improvement of prognosis for unresectable BTC in clinical settings was confirmed because all of the patients who underwent chemotherapy in the past ten years were included in this retrospective study. Another limitation is that gemcitabine and S-1 had mainly been used for first-line chemotherapy because the efficacy of gemcitabine and cisplatin combination therapy was reported in 2009.

In conclusion, the use of chemotherapy for unresectable BTC has made recent advances and the median overall survival has reached approximately one year. However, the prognosis of unresectable gallbladder cancer is still exceedingly poor. Using three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) may improve the prognosis of unresectable BTC. Future assessments are needed to establish the best strategy for using these three effective drugs (gemcitabine, platinum analogs and fluoropyrimidine) for the treatment of unresectable BTC.

COMMENTS

Background

Biliary tract cancer (BTC) is a rare cancer worldwide. Obstructive jaundice and infection to the biliary system usually become obstacles to introduce chemotherapy. Thus, enrollment of clinical trial for advanced biliary tract cancer is more difficult than other common cancers.

Research frontiers

Previous clinical trials investigating the efficacy of chemotherapy for advanced biliary tract cancer enrolled both unresectable and recurrent cases. Recent reports showed the differences of prognoses between these two conditions. However, the details about the prognoses of each condition have not been evaluated sufficiently.

Innovations and breakthroughs

Although the prognoses of unresectable and recurrent cases were extremely different, previous studies included both conditions. Moreover, most of these previous reports only showed the overall efficacies. Therefore, the treatment outcomes of unresectable biliary tract cancer were not fully evaluated. In our retrospective analysis, they only included unresectable biliary tract cancer and confirmed the recent improvement of prognosis in patients receiving chemotherapy.

Applications

The prognosis of unresectable biliary tract cancer has improved recently and the median overall survival has reached approximately one year. Using three effective drugs (gemcitabine, platinum analogs, and fluoropyrimidine) may improve the prognosis of unresectable biliary tract cancer. Future assessments are needed to establish the best strategy for using these three effective drugs (gemcitabine, platinum analogs, and fluoropyrimidine) for the treatment of unresectable biliary tract cancer.

Terminology

Biliary tract cancer includes cholangiocarcinoma, gallbladder cancer, and ampullary carcinoma. 5-fluorouracil is a fluoropyrimidine analog used for chemotherapy. Gemcitabine is a nucleoside analog used for chemotherapy. S-1 is an oral fluoropyrimidine widely used in Japan. Cisplatin is a platinum alalog used for chemotherapy.

Peer review

This paper evaluates the chemotherapeutic outcomes of patients affected by unresectable BTC. The study retrospectively analyzed 186 consecutive patients with unresectable BTC between 2000 and 2009 at five institutions in Japan. The Authors concluded that the prognosis of unresectable BTC has improved during the years and reached approximately one year. Using three effective drugs in combination (gemcitabine, platinum analogs and fluoropyrimidine) could improve the prognosis of unresectable BTC. The authors possess an expertise about the topic since published some interesting papers about the treatment of biliary and pancreatic cancer. Moreover, this paper is well written and also the number of patients is relevant.

Abstract

AIM: To identify factors associated with prognosis of hepatocellular carcinoma (HCC) after initial therapy.

METHODS: A total of 377 HCC patients who were newly treated at Katsushika Medical Center, Japan from January 2000 to December 2009 and followed up for > 2 years, or died during follow-up, were enrolled. The factors related to survival were first analyzed in 377 patients with HCC tumor stage T1-T4 using multivariate Cox proportional hazards regression analysis. A similar analysis was performed in 282 patients with tumor stage T1-T3. Additionally, factors associated with the period between initial and subsequent therapy were examined in 144 patients who did not show local recurrence. Finally, 214 HCC stage T1-T3 patients who died during the observation period were classified into four groups according to their alcohol consumption and postprandial glucose levels, and differences in their causes of death were examined.

RESULTS: On multivariate Cox proportional hazards regression analysis, the following were significantly associated with survival: underlying liver disease stage [non-cirrhosis/Child-Pugh A *vs* B/C, hazard ratio (HR): 0.603, 95% CI: 0.417-0.874, $P = 0.0079$], HCC stage (T1/T2 *vs* T3/T4, HR: 0.447, 95% CI: 0.347-0.576, $P < 0.0001$), and mean postprandial plasma glucose after initial therapy (< 200 *vs* ⩾ 200 mg/dL, HR: 0.181, 95% CI: 0.067-0.488, $P = 0.0008$). In T1-T3 patients, uninterrupted alcohol consumption after initial therapy (no *vs* yes, HR: 0.641, 95% CI: 0.469-0.877, $P = 0.0055$) was significant in addition to underlying liver disease stage (non-cirrhosis/Child-Pugh A *vs* B/C, HR: 0649, 95% CI: 0.476-0.885, $P = 0.0068$), HCC stage (T1 *vs* T2/T3, HR: 0.788, 95% CI: 0.653-0.945, $P = 0.0108$), and mean postprandial plasma glucose after initial therapy (< 200 mg/dL *vs* ⩾ 200 mg/dL, HR: 0.502, 95% CI: 0.337-0.747, $P = 0.0005$). In patients without local recurrence, time from initial to subsequent therapy for newly emerging HCC was significantly longer in the "postprandial glucose within 200 mg/dL group" than the "postprandial glucose > 200 mg/dL group" (log-rank test, $P < 0.05$), whereas there was no difference in the period between the "non-alcohol group" (patients who did not drink regularly or those who could reduce their daily consumption to < 20 g) and the "continuation group" (drinkers who continued to drink > 20 g daily). Of 214 T1-T3 patients who died during the observation period, death caused by other than HCC progression was significantly more frequent in "group AL" (patients in the continuation and postprandial glucose within 200 mg/dL groups) than "group N" (patients in the non-alcohol and postprandial glucose within 200 mg/dL groups) ($P = 0.0016$).

CONCLUSION: This study found that abstinence from habitual alcohol consumption and intensive care for diabetes mellitus were related to improved prognosis in HCC patients.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most important diseases, with increasing numbers of patients worldwide in recent years[1]. The number of deaths from HCC has also increased steadily. In Japan, chronic viral infection, such as hepatitis C virus (HCV) or hepatitis B virus (HBV), is considered to be the most significant risk factor for the development of HCC[2]. It has been recognized that chronic infection with these viruses induces continuous or recurrent necroinflammatory reactions in the liver that lead to cirrhosis; in most cases, the cirrhotic stage facilitates the development of HCC[3].

In Japan, hepatitis B surface antigen (HBs-Ag)-positive or anti-HCV (HCV-Ab)-positive subjects have accounted for > 80% of HCC patients in the last decade[4]. Meanwhile, 5%-15% of patients with HCC have neither HBs-Ag nor HCV-Ab (non-B non-C)[5-7], and the proportion of non-B non-C HCC has been increasing in newly diagnosed subjects[8].

Alcoholic liver disease[9] and nonalcoholic fatty liver disease[10] have been proposed as possible major backgrounds associated with non-B non-C HCC. Moreover, diabetes mellitus (DM), which is frequently present in association with nonalcoholic steatohepatitis or alcoholic liver disease, has been identified as a risk factor for developing HCC[11-15].

As mentioned above, factors associated with the development of HCC have been well recognized. However, factors affecting the prognosis after treatment for HCC have not been extensively examined, except for HCC tumor stage and underlying liver function.

A large majority of HCC patients have been treated according to the "Japanese Guidelines for HCC"[16]. There have been numerous therapeutic strategies against HCC, including surgical resection, percutaneous ethanol injection therapy (PEIT), percutaneous radiofrequency ablation (RFA), and transhepatic arterial chemoembolization (TACE). The therapeutic strategy is determined based on liver function and HCC tumor stage, and aims to achieve the best prognosis[16]. However, there have often been obvious differences in clinical course even when HCC has been treated according to the "Japanese Guidelines for HCC"[16].

A relationship between HCC recurrence and the presence of DM in patients who are negative for markers of HBV and HCV[17] has been reported. The prognostic factors of HCC other than HCC tumor stage and underlying liver function have been evaluated[18]. However, there is no information about the relationship between HCC prognosis and general health management, including abstinence from alcohol drinking and intensive control of plasma glucose levels after therapy for HCC.

In the present study, the impact of plasma glucose levels and continuation of alcohol consumption on the prognosis after initial therapy for HCC was investigated.

MATERIALS AND METHODS

Patients

Of 475 consecutive HCC patients who were newly diagnosed and treated at the Jikei University Katsushika Medical Center from January 2000 to December 2009, we enrolled 377 who were treated based on the Japanese Guidelines for HCC[16]. Initial therapy consisted of surgical resection in five of 377 HCC patients, PEIT in 46 patients, RFA in 111 patients, TACE in 146 patients, transhepatic arterial infusion in 54 patients, and supportive care without therapy for HCC in 15 patients. Only 1.3% of patients underwent surgical resection, because patients who did not wish to undergo an operation tended to consult our department. Patients who received liver transplantation were not included in this study, because the number of deceased donors is small in Japan.

The diagnosis of HCC was based on the presence of characteristic imaging findings on computed tomography, magnetic resonance imaging, or ultrasonography. In subjects in whom the definite diagnosis of HCC could not be made by imaging, the diagnosis was confirmed by ultrasonography-guided tumor biopsy.

The characteristics of the 377 patients at the time of initial diagnosis of HCC, including age, sex, serum aspartate aminotransferase (AST)/alanine aminotransferase/α-fetoprotein (AFP)/protein induced by vitamin K absence or antagonist-Ⅱ (PIVKA-Ⅱ) level at the time of diagnosis, stage of underlying liver disease (cirrhotic or non-cirrhotic, Child-Pugh staging in cirrhotic patients), obesity [body mass index (BMI) > 25 kg/m^2], presence of DM, existence of malignant tumors other than HCC, habitual use of alcohol, and HCC tumor stage according to the tumor-node-metastasis staging classification system[19], are summarized in Table 1.

The presence or absence of serum HCV-Ab and HBs-Ag was determined in all patients using an enzyme immunoassay kit (AxSYM Abbott HCV; Axsym Co. Ltd., Tokyo, Japan, for HCV-Ab and AxSYM Abbott HBs-Ag; Axsym, for HBs-Ag).

The diagnosis of cirrhosis was made based on imaging findings, histological findings of liver biopsy specimens, and a combination of laboratory data[20]. Cirrhotic patients were then subdivided into A-C according to the Child-Pugh classification[21].

Habitual alcohol consumption was defined as cumulative consumption ≥ 320 kg ethanol in females or ≥ 480 kg in males, with daily alcohol consumption ≥ 20 g

ethanol. A history of alcohol consumption was obtained from interviews with patients, their families, or neighbors.

The definition of the presence of DM was as follows: fasting plasma glucose level > 126 mg/dL or postprandial plasma glucose > 200 mg/dL on at least two occasions, or the need for subcutaneous injection of insulin or oral hypoglycemic drugs to control glucose levels.

Enrolled patients were followed up after initial therapy for HCC for at least 2 years or until death during follow-up. No patients took drugs or foods containing carcinogenic substances. HCV-positive HCC patients did not undergo antiviral therapy after therapy for HCC, while all of the HBs-Ag-positive HCC patients were treated with nucleoside and/or nucleotide analogs including lamivudine, adefovir, dipivoxil, and entecavir.

Follow-up of patients after initial therapy for HCC

Survival after initial therapy and the period from initial therapy to subsequent therapy were recorded. Continuation of alcohol consumption and the mean postprandial plasma glucose values during almost monthly follow-up were examined.

The manner of drinking after initial therapy for HCC was classified into two groups: patients who did not drink regularly or habitual alcohol drinkers who were able to reduce their quantity of daily alcohol consumption to < 20 g ethanol (non-alcohol group), and habitual alcohol drinkers who continued to drink > 20 g ethanol daily (continuation group).

Patients defined as having DM were classified into the "postprandial glucose within 200 mg/dL group" or the "postprandial glucose > 200 mg/dL group". The postprandial glucose within 200 mg/dL group was defined as having a mean monthly postprandial plasma glucose level (plasma glucose measured about 2 h after taking the meal) ≤ 200 mg/dL during follow-up. Patients without DM were included in the postprandial glucose within 200 mg/dL group. The other HCC patients whose mean postprandial plasma glucose level was > 200 mg/dL despite treatment for DM were included in the postprandial glucose > 200 mg/dL group.

Education about abstinence from drinking was given to all habitual drinkers. For all patients with DM, education about appropriate caloric intake and standard drug therapy for DM, including insulin injection, was provided. This study complied with the standards of the Declaration of Helsinki and current ethical guidelines.

Statistical analysis

Data are expressed as means ± SD, and the parameters were categorized into two groups by the median value, except for the stage of underlying liver disease and the T stage of HCC. Factors associated with survival were examined by Cox proportional hazards regression analysis to elucidate factors associated with HCC prognosis. The differences in the survival period and in the period from initial therapy to subsequent therapy were evaluated by the Kaplan-Meier method with the log-rank test. Differences in the causes of death were evaluated by the χ^2 test with Yates's correction. All tests of significance were two-tailed, and a $P < 0.05$ was considered significant. All statistical analyses were carried out using Statistica for Windows Version 6.

RESULTS

Characteristics of HCC patients

The patients' median age was 69 years. The most common stage of underlying liver disease was Child-Pugh class A cirrhosis. The frequencies of HBs-Ag and HCV-Ab were 10.1% and 67.9%, respectively. The prevalence of habitual drinkers was 53.8%, and 21.1% had a BMI > 25 kg/m^2. DM was present in 35.0% of HCC patients (Table 1). The median survival period after initial therapy for HCC was 23 mo.

Factors related to survival after initial therapy for HCC

The factors associated with survival after initial therapy for HCC were investigated in 377 patients. On univariate analysis, the following 11 factors were significantly related to survival: stage of underlying liver disease (non-cirrhosis, Child A *vs* B, C cirrhosis, $P = 0.0001$), T stage of HCC (T1, 2 *vs* 3, 4, $P < 0.0001$), number of HCCs (solitary *vs* multiple, $P < 0.0001$), maximum size of HCCs (< 20 *vs* ≥ 20 mm, $P < 0.0001$), vascular invasion of HCCs (no *vs* yes, $P < 0.0001$), method of therapy (curative: surgical resection, PEIT, and RFA *vs* non-curative: other than surgical resection, PEIT, and RFA, $P = 0.0004$), serum AST (< 63 *vs* ≥ 63 IU/L, $P = 0.0089$), serum AFP (< 41 *vs* ≥ 41 ng/mL, $P < 0.0001$), serum PIVKA-Ⅱ (< 83 *vs* ≥ 83 mAU/mL, $P < 0.0001$), uninterrupted habitual drinking after initial therapy for HCC (no *vs* yes, $P = 0.0135$), and the mean postprandial plasma glucose level after initial therapy for HCC (< 200 *vs* ≥ 200 mg/dL, $P < 0.0001$).

These parameters were entered into the multivariate Cox proportional hazards regression analysis. Stage of underlying liver disease (non-cirrhosis, Child A *vs* B, C cirrhosis, $P = 0.0079$), T stage of HCC (T1, 2 *vs* 3, 4; $P < 0.0001$), and the mean postprandial plasma glucose level after initial therapy for HCC (< 200 *vs* ≥ 200 mg/dL, $P = 0.0008$) were extracted as independent factors affecting survival. However, uninterrupted habitual alcohol consumption was not related to survival (Table 2).

Factors related to period of survival after initial therapy for HCC in patients with stage T1-T3

The survival period is quite short in T4 stage HCC, therefore, T4 stage HCC was excluded to clarify the factors related to survival (Table 3). Univariate analysis of 282 patients with T1-T3 stage HCC identified the following seven factors as related to survival after initial therapy for HCC: stage of underlying liver disease (non-cirrhosis, Child A *vs* B, C, $P = 0.0009$), T stage of HCC (T1 *vs* 2, 3, $P = 0.0023$), number of HCCs (solitary *vs* multiple, $P = 0.0082$), serum AFP (< 41 *vs* ≥ 41 ng/mL,

T stage of hepatocellular carcinoma	Survival period (mo)
T1	43.3 ± 31.3
T2	39.8 ± 30.8
T3	23.6 ± 17.2
T4	8.7 ± 11.8

P = 0.0007), serum PIVKA-Ⅱ (< 83 *vs* ≥ 83 mAU/mL, *P* = 0.0101), uninterrupted alcohol consumption after initial therapy for HCC (no *vs* yes, *P* = 0.0002), and the mean postprandial plasma glucose level (< 200 *vs* ≥ 200 mg/dL, *P* = 0.0001).

On multivariate regression analysis using a stepwise Cox's hazard model, stage of underlying liver disease (non-cirrhosis, Child A *vs* B, C cirrhosis, *P* = 0.0068), T stage of HCC (T1 *vs* 2, 3, *P* = 0.0108), uninterrupted habitual alcohol consumption (no *vs* yes, *P* = 0.0055), and the mean postprandial plasma glucose level (< 200 *vs* ≥ 200 mg/dL, *P* = 0.0005) were extracted as independent factors related to survival after initial therapy for HCC (Table 4).

Period from initial curative to subsequent therapy for newly emerging HCC in patients without local recurrence

Of the 377 HCC patients, 144 (38.2%) patients did not show local recurrence after initial curative therapy for HCC. Of the 144 HCC patients who did not show local recurrence, 100 (69.4%) died during the observation period. Of the patients who did not show local recurrence, the period from initial curative therapy to subsequent therapy for newly emerging HCC was significantly longer in the postprandial glucose within 200 mg/dL group than the postprandial glucose > 200 mg/dL group (log-rank test, *P* < 0.05), although there was no difference in the period to second therapy between the non-alcohol group and continuation group (Figure 1).

Cause of death in HCC patients with stage T1-T3

A total of 214 T1-T3 stage HCC patients who died during the observation period were classified into four groups: "Group N", patients belonging to both the non-alcohol group and the postprandial glucose within 200 mg/dL group; "Group AL", patients belonging to both the continuation group and the postprandial glucose within 200 mg/dL group; "Group DM", patients belonging to both the daily alcohol < 20 g ethanol and the postprandial glucose > 200 mg/dL group; and "Group AD", patients belonging to both the continuation group and the postprandial glucose > 200 mg/dL group (Table 5). Death caused by other than HCC progression (hepatic failure, gastrointestinal bleeding, ischemic heart disease, cerebral vessel disease, bacterial infection, *etc.*) was significantly more frequent in "Group AL" than in "Group N" (*P* = 0.0016). On the other hand, the cause of death

[1]Curative therapies are surgical resection, percutaneous ethanol injection therapy, and percutaneous percutaneous radiofrequency ablation. TNM: Tumor, node, metastasis; HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; HBs-Ag: Surface antigen of the hepatitis B virus; HCV-Ab: Hepatitis C antibody; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; AFP: alpha-fetoprotein; PIVKA-Ⅱ: Proteins induced by vitamin KAbsense of antagonist-Ⅱ; BMI: Body mass index; HR: Hazard ratio.

in "Group DM" was the same as that in "Group N". Similarly, the cause of death was not different between "Group AD" and "Group AL" (Figure 2).

DISCUSSION

In the present study, stage of underlying liver disease, T stage of HCC, and the mean postprandial plasma glucose level after initial therapy for HCC despite standard treatment for DM were extracted as independent factors related to survival after initial therapy in 377 HCC patients who were newly diagnosed and treated according

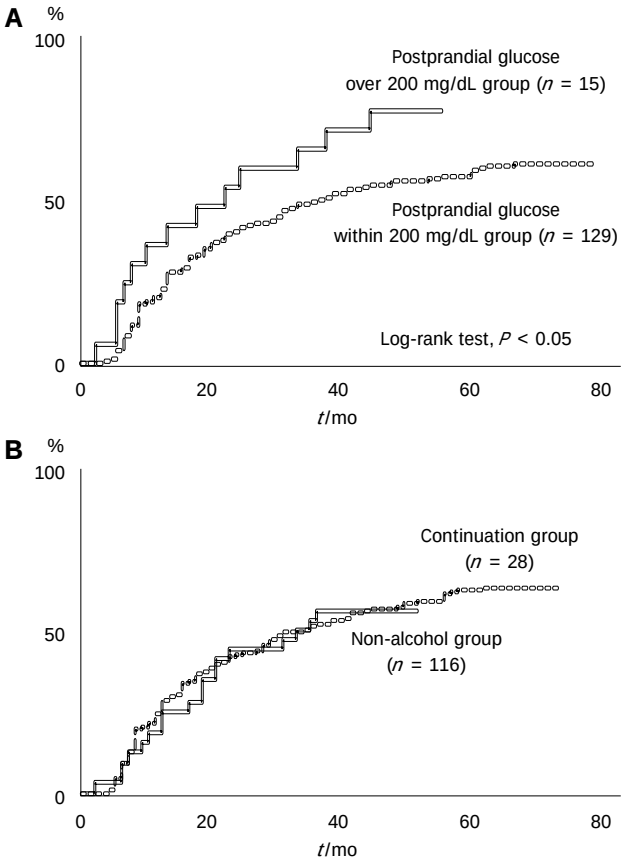

Figure 1 Duration from initial curative therapy for hepatocellular carcinoma to hepatocellular carcinoma recurrence in the different region. A: The period until developing a new lesion in a remote location of the liver was significantly longer in the postprandial glucose within 200 mg/dL group with diabetes mellitus than in the postprandial glucose > 200 mg/dL group without local recurrence after initial therapy for hepatocellular carcinoma (HCC) (log-rank test, $P < 0.05$); B: There was no difference in the period between the non-alcohol group with a history of drinking and the continuation group without local recurrence after initial curative therapy for HCC.

to the Japanese Guidelines for HCC[16]. Then, after T4 stage HCC patients were excluded, uninterrupted excess alcohol consumption was extracted as an independent factor along with the three factors described above.

Alcohol abuse provokes inflammatory and innate immune responses of Kupffer cells due to elevation of gut-derived endotoxin and increases reactive-oxygen-species-induced damage and profibrogenic factors such as acetaldehyde or lipid peroxidation products, which contribute to activation of hepatic stellate cells and progression of liver fibrosis[22]. Therefore, uninterrupted alcohol abuse may induce rapid worsening of hepatic dysfunction. Meanwhile, the presence of DM is related to HCC recurrence after potentially curative therapy in patients with non-B non-C HCC[17]. Furthermore, type 2 DM has consistently been identified as an independent predictor of hepatic fibrosis[10,23,24], faster fibrosis progression[24], and increased mortality[25]. In type 2 DM, insulin resistance may be observed in the majority of patients. Therefore, high levels of circulating insulin in type 2 DM may stimulate the proliferation of hepatic stellate cells and induce production of collagen, resulting in he-

TNM: Tumor, node, metastasis; M: Male; F: Female; LC: Liver cirrhosis; DM: Diabetes mellitus.

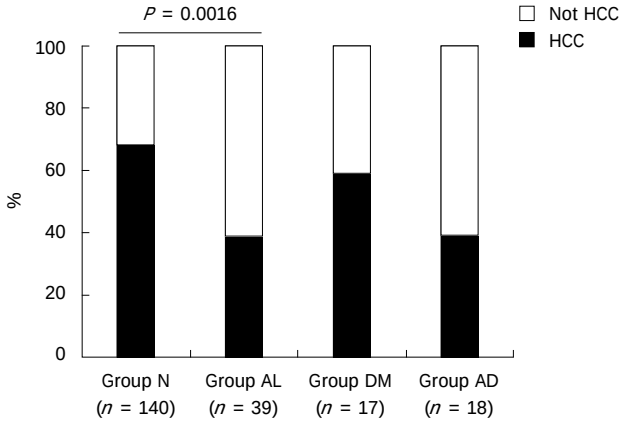

Figure 2 Cause of death in T1-T3 stage hepatocellular carcinoma. The rate of death from causes other than hepatocellular carcinoma (HCC), including hepatic failure, gastrointestinal bleeding, ischemic heart disease, cerebral vessel disease, and bacterial infection, was significantly higher in Group AL than Group N ($P = 0.0016$). The cause of death in Group diabetes mellitus (DM) was similar to that in Group N, and Group AD was similar to Group AL. Group N, patients belonging to both the non-alcohol group and postprandial glucose within 200 mg/dL group; Group AL, patients belonging to both the continuation group and postprandial glucose within 200 mg/dL group; Group DM, patients belonging to both the daily alcohol intake < 20 g ethanol and postprandial glucose > 200 mg/dL group; Group AD, patients belonging to both the continuation group and postprandial glucose > 200 mg/dL group.

patic fibrosis, as well as carcinogenesis of hepatocytes[26]. Therefore, the presence of DM may cause deterioration of hepatic function and carcinogenesis of the liver.

In the present study, the methods of initial therapy for HCC were varied, including surgical resection, PEIT, RFA and TACE. Therefore, selection bias of the therapeutic method could have affected the prognosis of HCC. However, we chose the therapeutic method according to the Japanese Guidelines for HCC[16], which guaranteed the equality of the therapeutic value of the various methods. Thus, it is not difficult to elucidate the factors related to the prognosis of HCC even though patients were treated with different methods, as long as the treatment was performed based on the Japanese Guidelines for HCC[16]. Therefore, patients treated in accordance with these guidelines were included in this study.

Although HCV and/or HBV infection is considered to be a strong carcinogenic factor, it was not extracted as a factor related to the period of survival after initial therapy for HCC. This finding suggested that the prognosis of non-B non-C HCC is no better than that of virus-related HCC, and that the prognosis is influenced by the T stage of HCC or the stage of underlying liver disease rather than the etiology of the liver disease. Non-B non-C HCC would be discovered at an advanced stage[7] compared with virus-related HCC because of the lack of periodic medical assessments[8]. Therefore, detection by means of periodic medical assessments in patients with chronic liver damage, even without HCV and/or HBV infection to diagnose early stage non-B non-C HCC, is crucial for long-term survival. Recently, the prevalence of non-B non-C HCC has been increasing. Thus, along with intensive surveillance of HCC, investigation of factors affecting the prognosis of non-B non-C HCC is urgently needed.

In the present study, the cause of death differed between patients with uninterrupted habitual alcohol consumption and those with higher postprandial plasma glucose levels. The most frequent cause of death in the postprandial glucose > 200 mg/dL group was recurrence of HCC in other locations of the liver, while hepatic failure without HCC recurrence was the most frequent cause of death in the continuation group among habitual alcohol drinkers. However, the rate of recurrence of HCC in other locations of the liver as a cause of death in the postprandial glucose > 200 mg/dL group was similar to that in Group N. These findings suggest that abstinence from alcohol did not affect the prevalence of new HCC but was related to rapid deterioration of hepatic function. Meanwhile, higher postprandial plasma glucose levels are considered to lead to both deterioration of liver function and enhanced carcinogenesis of the liver.

As shown in the period from initial curative therapy to subsequent therapy for HCC in patients without local recurrence, the period was significantly longer in the postprandial glucose within 200 mg/dL group than in the postprandial glucose > 200 mg/dL group. Therefore, the potential for carcinogenesis was considered to be enhanced in the postprandial glucose > 200 mg/dL group. In the postprandial glucose > 200 mg/dL group, the dose of insulin and the use of various oral hypoglycemic drugs, including drugs stimulating insulin secretion, tended to increase. Therefore, a higher level of circulating insulin may have an effect on the emergence of new HCC.

Control of glucose levels after therapy for HCC may be an important factor to improve the prognosis of HCC. However, it is unclear whether increasing the dose of insulin or the use of various drugs for good control of plasma glucose levels improves the prognosis of

HCC. Large prospective studies are needed to establish whether the prognosis of HCC after initial therapy is associated with the postprandial plasma glucose level in itself or other factors related to plasma glucose, including the type of hypoglycemic drug used, because the use of hypoglycemic drugs stimulating insulin secretion may affect the prognosis of HCC[27].

In conclusion, the present study provided clear evidence that uninterrupted alcohol drinking and high postprandial glucose levels after initial therapy for HCC worsen the prognosis of HCC patients. Education about abstinence from alcohol in the group having a history of habitual drinking and achieving good control of plasma glucose in the group having DM may improve the clinical course of HCC.

COMMENTS

Background

There are many factors other than hepatitis C virus or hepatitis B virus identified as risk factors for developing hepatocellular carcinoma (HCC). Among them, diabetes mellitus (DM) and habitual alcohol consumption have been considered significant risk factors for developing HCC. Meanwhile, factors affecting the prognosis after initial therapy for HCC have not been extensively examined, except for HCC tumor stage and underlying liver function.

Research frontiers

In T1-T3 stage HCC patients, uninterrupted alcohol consumption and the mean postprandial plasma glucose level (< 200 *vs* ⩾ 200 mg/dL) after initial therapy for HCC were independent significant factors affecting HCC prognosis. Uninterrupted alcohol consumption was associated with rapid deterioration of hepatic function, while the postprandial plasma glucose level was related to both early development of new HCC and rapid deterioration of hepatic function.

Innovations and breakthroughs

It is known from experience that continuation of alcohol consumption and postprandial plasma glucose levels after initial therapy for HCC greatly affect the prognosis of HCC. To the best of our knowledge, however, there have been few studies that have shown these findings.

Applications

Education about abstinence from alcohol in the group having a history of habitual drinking, and achieving good control of plasma glucose in the group having DM after HCC diagnosis may be critical for improving the clinical course of HCC.

Peer review

The authors investigated whether continuation of alcohol consumption and postprandial plasma glucose levels after initial therapy for HCC were related to the prognosis of HCC. The outcome of the study is interesting and important for the care of HCC patients after initial therapy for HCC.

Abstract

AIM: To investigate the short and long-term outcomes of endoscopic balloon dilatation (EBD) for Crohn's disease (CD) strictures.

METHODS: Between January 1995 and December 2011, 47 EBD procedures were performed in 30 patients (8 females and 22 males) with CD. All patients had strictures through which an endoscope could not pass, and symptoms of these strictures included abdominal pain, abdominal fullness, nausea, and/or vomiting. The 47 strictures included 17 anastomotic and 30 *de novo* strictures. Endoscopy and dilatation were performed under conscious sedation with intravenous diazepam or flunitrazepam. The dilatations were all performed using through-the-scope balloons with diameters from 8 mm to 20 mm on inflation and lengths of 30-80 mm. Each dilatation session consisted of two to four, 3-min multistep inflations of the balloon, repeated at intervals of 1 wk until adequate dilatation (up to 15-20 mm in diameter) was achieved. The follow-up data were collected from medical records and analyzed retrospectively. Primary success was defined as passage of the scope through the stricture after EBD. Long-term outcomes were analyzed focusing on intervention-free survival and surgery-free survival demonstrated by the Kaplan-Meier method. (Intervention-free meant cases in which neither endoscopic balloon re-dilatation nor surgery was needed after the first dilatation during the observation period). The log rank test was used to evaluate the difference in long-term outcomes between anastomotic and *de novo* stricture cases.

RESULTS: Primary success was achieved in 44 of the 47 strictures (93.6%). Balloon dilatations failed in 3 cases (6.4%). In 1 case, EBD was a technical failure because the guide-wire could not be passed through the stricture which showed severe adhesion and was a flexural lesion of the intestine. In 2 cases, unexpected perforations occurred immediately after balloon dilatation. Of the 47 treatments, complications occurred in 5 (10.6%). All 5 patients had *de novo* strictures. One suffered bleeding, two high fever and there were colorectal perforations. One of the patients with a colorectal perforation was treated surgically, the other was managed conservatively. These 2 cases correspond to the two aforementioned EBD failures. Long-term outcomes were evaluated for the 44 successfully-treated strictures after a median follow-up of 26 mo (range, 2-172 mo). During the observation period, re-strictures after EBDs occurred in 26 cases (60.5%). Fourteen of these 26 re-stricture cases underwent EBD again, but in two EBD failed and surgery was ultimately performed in both cases. Twelve of the 26 re-stricture cases were initially treated surgically when the re-strictures occurred. Finally, 30 of the 47 strictures (63.8%) were successfully managed with EBD, allowing surgery to be avoided. Intervention-free survival evaluated by the Kaplan-Meier method was 75% at 12 mo, 58% at 24 mo, and 43% at 36 mo. There was no significant difference between the anastomotic strictures (n = 16) and *de novo* strictures (n = 28) in the intervention-free survival as evaluated by the log-rank test. Surgery-free survival evaluated by the Kaplan-Meier method was

90% at 12 mo, 75% at 24 mo, and 53% at 36 mo. The 16 anastomotic strictures were associated with significantly better surgery-free survivals than the 28 *de novo* strictures (log-rank test: $P < 0.05$).

CONCLUSION: Anastomotic strictures were associated with better long-term outcomes than *de novo* strictures, indicating that stricture type might be useful for predicting the long-term outcomes of EBD.

Endo K, Takahashi S, Shiga H, Kakuta Y, Kinouchi Y, Shimosegawa T. Short and long-term outcomes of endoscopic balloon dilatation for Crohn's disease strictures. *World J Gastroenterol* 2013; 19(1): 86-91 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/86.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.86

INTRODUCTION

Crohn's disease (CD) is characterized by chronic or recurrent acute inflammation of the intestinal tract resulting in acute inflammatory changes of the intestinal wall, strictures and/or fistulas. Up to one-third of patients develop a stricture within 10 years after the diagnosis[1-3]. These strictures are mainly treated surgically. It is well known that up to 80% of CD patients will eventually require at least one surgical resection within 10 years of being diagnosed[4,5]. Although surgical resection can relieve the symptoms caused by these strictures, the strictures often recur after resection, sometimes necessitating another surgery and producing short bowel syndrome[6,7]. Therefore, surgical resection must be avoided whenever possible.

In recent years, endoscopic balloon dilatation (EBD) has offered a therapeutic alternative to surgery[8-12]. A recent systematic review estimated immediate success rates to be approximately 86%, and that long-term clinical efficacy was achieved in 58% of patients[9]. EBD has been regarded as a safe and effective procedure in the management of CD strictures. Many previous reports have shown short-term success rates of EBD to generally be high (80%-100%), while the long-term outcomes vary among studies. The factors which affect long-term outcomes of EBD have not been sufficiently clarified. A recent report by Mueller *et al*[12] showed that long-segment *de novo* strictures in the terminal ileum had poor long-term responses to EBD, raising the possibility that long-term outcomes of EBD could be affected by the characteristics of strictures. To assess this possibility, we hypothesized that long-term outcomes of EBD might differ between two types of strictures, anastomotic and *de novo*.

The aim of the present study was to evaluate the short- and long-term outcomes of EBD in our hospital and to compare the long-term outcomes of EBD for these two types of strictures affecting CD patients, anastomotic and *de novo* strictures.

MATERIALS AND METHODS

Patients

Between January 1995 and December 2011, 47 EBD procedures were performed in 30 patients (8 females and 22 males) with CD. The ages at dilatation ranged from 18 to 72 years (mean age, 32.5 ± 10.5). The average duration of CD was 12.8 (range, 1-35) years. Characteristics of these patients are summarized in Table 1.

All patients had strictures through which an endoscope could not pass, and symptoms of these strictures included abdominal pain, abdominal fullness, nausea, and/or vomiting.

The 47 strictures included 17 anastomotic and 30 *de novo* strictures. The locations of the anastomotic strictures were 1 at the gastro-jejunal, 5 at the ileo-ileal, 9 at the ileocolonic, and 2 at the ileorectal anastomosis. The locations of *de novo* strictures were 8 at the pyloric ring of the stomach, 1 in the duodenum, 8 in the ileum or at the ileocaecal valve, 7 in the colon, and 6 in the rectum.

Inclusion and exclusion criteria for EBD

EBD were performed on demand only when the patients presented with obstructive symptoms. Prior to endoscopy, all the patients received radiological assessment to confirm the clinically suspected stricture, to exclude intestinal fistulas and angulated strictures and to measure the length of the strictures. Detailed inclusion criteria for EBD were: (1) clinical symptoms of obstruction (abdominal pain, abdominal fullness, nausea, vomiting); (2) evidence of gut stenosis, detected by radiological examination, through which a standard colonoscope or gastrointestinal scope or enteroscope could not be passed; and (3) no or low inflammatory disease activity.

Exclusion criteria were strictures longer than 3 cm and those complicated by intestinal fistula, active ulceration, or abscess.

Dilatation protocol

Informed consent was obtained from all patients before the dilatation procedure. Endoscopy and dilatation were performed under conscious sedation with intravenous diazepam or flunitrazepam. Dilatation was performed using a standard gastrointestinal scope for 10 upper gastrointestinal strictures, a standard colonoscope for 36 lower gastrointestinal strictures, and an entroscope (double-balloon enteroscopy) for 1 ileo-ileal anstomotic stricture. The dilatations were all performed using through-the-scope balloons (Rigiiflex TTS™, or Controlled Radial Expansion Wireguided Balloon Dilatation Catheter™, Boston Scientific, Boston, MA, United States), with diameters from 8 mm to 20 mm on inflation and lengths of 30-80 mm. The balloon was introduced into the stricture using a guide-wire under radiological control. Each dilatation session consisted of two to four, 3-min multistep in-

Table 1 Patients characteristics

Number of patients	*n* = 30
Number of dilatations	47
Gender: male/female	22/8
Age at EBD (mean ± SD), yr	32.5 ± 10.5
Disease duration (mean ± SD), yr	12.8 ± 8.0
Median follow-up	26 mo (range, 2-172 mo)
Medical therapy at first dilatation (%)	
None	0
5-aminosalicylic acid:	86.7
Steroids:	13.3
Azathioprine/6-mercaptoprine:	20.0
Infliximab	13.3

Total parental nutrition:	16.7

EBD: Endoscopic balloon dilatation.

flations of the balloon, repeated at intervals of 1 wk until adequate dilatation (up to 15-20 mm in diameter) was achieved. Passage of the scope through the stricture was attempted in all patients and was used to define primary therapeutic success.

After the successful dilatation, patients were followed in our hospital as out-patients. Repeat dilatations were performed on demand when the patients had obstructive symptoms due to re-strictures confirmed by both radiological assessment and endoscopy.

Statistical analysis

The follow-up data were collected from medical records and analyzed retrospectively.

Primary success was defined as passage of the scope through the stricture after EBD. Long-term outcomes were analyzed focusing on intervention-free survival and surgery-free survival demonstrated by the Kaplan-Meier method. (Intervention-free meant cases in which neither endoscopic balloon re-dilatation nor surgery was needed after the first dilatation during the observation period). The log rank test was used to evaluate the difference in long-term outcomes between anastomotic and *de novo* stricture cases. A two-sided P value of < 0.05 was considered significant.

RESULTS

Rates of primary success

Primary success was achieved in 44 of the 47 strictures (93.6%). Balloon dilatations failed in 3 cases (6.4%). In 1 case, EBD was a technical failure because the guidewire could not be passed through the stricture which showed severe adhesion and was a flexural lesion of the intestine. In 2 cases, unexpected perforations occurred immediately after balloon dilatation.

Complications

Of the 47 treatments, complications occurred in 5 (10.6%). All 5 patients had *de novo* strictures. One suffered bleeding, two high fever and there were colorectal perforations. One of the patients with a colorectal perforation was treated surgically, the other was managed conservatively. These 2 cases correspond to the two aforementioned EBD failures.

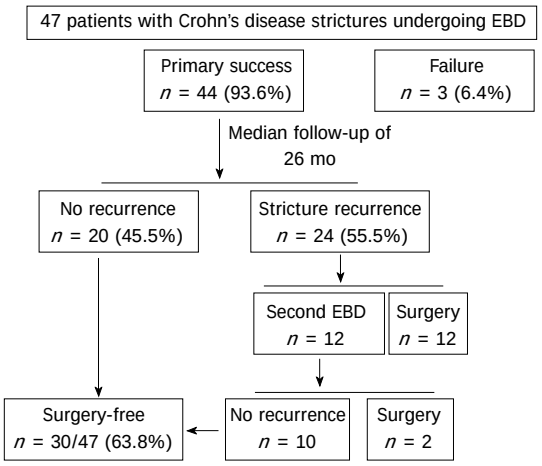

Figure 1 Overview of treatment outcomes for 47 strictures. Long-term outcomes were evaluated for the 44 successfully-treated strictures after a median follow-up of 26 mo (range, 2-172 mo). During the observation period, re-strictures after endoscopic balloon dilatations (EBDs) occurred in 26 cases (60.5%). Fourteen of these 26 re-stricture cases underwent EBD again, but in two EBD failed and surgery was ultimately performed in both cases. Twelve of the 26 re-stricture cases were initially treated surgically when the re-strictures occurred. Finally, 30 of the 47 strictures (63.8%) were successfully managed with EBD, allowing surgery to be avoided.

Long-term outcomes

An overview of the treatment outcomes for the 47 strictures is shown in Figure 1. Long-term outcomes were evaluated for the 44 successfully-treated strictures after a median follow-up of 26 mo (range, 2-172 mo). During the observation period, re-strictures after EBDs occurred in 26 cases (60.5%). Fourteen of these 26 re-stricture cases underwent EBD again, but in two EBD failed and surgery was ultimately performed in both cases. Twelve of the 26 re-stricture cases were initially treated surgically when the re-strictures occurred. Finally, 30 of the 47 strictures (63.8%) were successfully managed with EBD, allowing surgery to be avoided.

Intervention-free survival evaluated by the Kaplan-Meier method was 75% at 12 mo, 58% at 24 mo, and 43% at 36 mo (Figure 2). There was no significant difference between the anastomotic strictures ($n = 16$) and *de novo* strictures ($n = 28$) in the intervention-free survival as evaluated by the log-rank test (data not shown).

Surgery-free survival evaluated by the Kaplan-Meier method was 90% at 12 mo, 75% at 24 mo, and 53% at 36 mo (Figure 2). The 16 anastomotic strictures were associated with significantly better surgery-free survivals than the 28 *de novo* strictures (log-rank test: $P < 0.05$) (Figure 3).

DISCUSSION

EBD has become an alternative to surgery in the treatment of CD strictures in recent years. Many reports have shown good short-term success rates of EBD, while

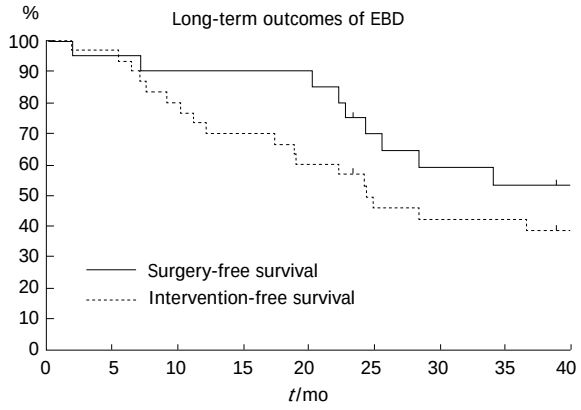

Figure 2 Long-term outcomes of endoscopic balloon dilatation by the Kaplan-Meier method. Intervention-free survival evaluated by the Kaplan-Meier method was 75% at 12 mo, 58% at 24 mo, and 43% at 36 mo. Surgery-free survival evaluated by the Kaplan-Meier method was 90% at 12 mo, 75% at 24 mo, and 53% at 36 mo. EBD: Endoscopic balloon dilatation.

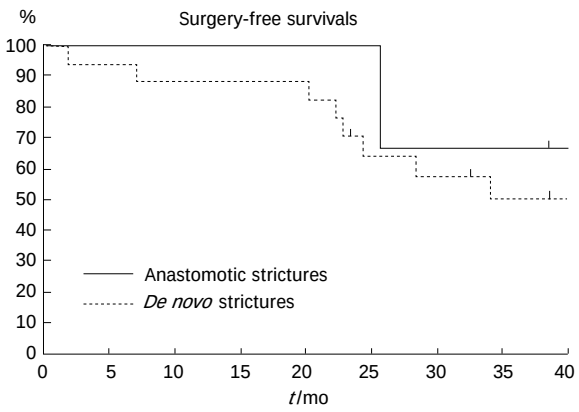

Figure 3 Surgery-free survivals-anastomotic *vs de novo* strictures. The 16 anastomotic strictures were associated with significantly better surgery-free survivals than the 28 *de novo* strictures (log-rank test: $P < 0.05$).

the long-term outcomes have varied among studies. Whether or not the stricture type, such as anastomotic or *de novo*, impacts long-term outcomes of EBD remains an open question. In this study, we evaluated short- and long-term outcomes of EBD for strictures associated with CD, in our hospital, and analyzed differences in long-term outcomes between anastomotic and de novo strictures.

As for short-term outcomes, primary success was achieved in 44 of the 47 strictures treated. EBD failed in only 3 cases. In 1 case, EBD was technically impossible and in 2 others unexpected perforations occurred immediately after EBD. Therefore, the primary success rate was 93.6% (44/47) in our study. The primary success rate was 86% in a systematic review[9] and 97% in a recent single-center cohort study[13]. Our primary success rate was thus similar to those reported previously. An important issue is the type of stricture, i.e., anastomotic versus de novo. In the aforementioned systematic review[9], 68% of the strictures treated by EBD were located at anastomotic sites, as were 84% of those in the recent single-center cohort study[13]. On the other hand, there were several more de novo (n = 28, 63.6%) than anastomotic strictures (n = 16, 36.4%) in our study. Despite the rather large percentage of *de novo* strictures, the primary success rate was very high. Mueller *et al*[12] also reported a primary success rate of 95% despite the majority of their patients presenting with de novo strictures (69%). These findings suggest that short-term outcomes might be not affected by the type of stricture.

In this study, we successfully performed EBD using double-balloon enteroscopy for one patient who had an ileo-ileal anastomtic stricture. In recent years, a few reports described the usefulness and efficacy of EBD for small intestinal strictures in CD patients using double-balloon enteroscopy[11,14]. This procedure may be potentially of significant benefit and should be considered as a useful and effective alternative to surgery. Further investigation should be necessary to confirm the benefit of this procedure.

In this study, 5 patients each experienced one complication (10.6%). All 5 patients had *de novo* strictures. The *de novo* strictures thus appeared to be associated with an increased risk of complications as compared with anastomotic strictures. One patient experienced bleeding (2.1%), 2 had high fever (4.3%), and 2 had colorectal perforations (4.3%). The perforation rate in this study was thus very similar to those in the literature[9,11,12,15-21] which have been in the 0%-10% range. We believe that it is important to perform multistep inflation with a gradually increasing diameter under minimal conscious sedation. This technique may have contributed to the low perforation rate in our study. A more aggressive endoscopic technique, general anesthesia, and using excessively large dilatation balloons are considered to be risk factors for perforation[8,22,23].

As for long-term outcomes, re-strictures after the first EBD occurred in 26 cases (60.5%) out of 44 successfully-treated strictures. Re-strictures did not seem to depend on the diameter of the first dilatation because dilatations were evenly achieved up to 15-20 mm in diameter in most of the successfully-treated strictures. Fourteen of these 26 cases were successfully treated with a second EBD during follow-up for re-strictures and surgery was avoided. Ultimately, 14 cases (31.8%) required surgery to treat re-strictures. These results compare favorably with those of the aforementioned systematic review which described 144 of 347 patients (42%) as ultimately needing surgery to treat re-strictures after EBD. In this study, we also estimated intervention-free and surgery-free survivals. Intervention-free survival was 75% at 12 mo, 58% at 24 mo, and 43% at 36 mo. Surgery-free survival was 90% at 12 mo, 75% at 24 mo, and 53% at 36 mo. These results are also similar to those of previous reports[12,13,22].

Little is known about prognostic factors that affect long-term outcomes after EBD. Smoking has been regarded as a prognostic factor increasing the risk of recurrence[20,24]. Hoffmann *et al*[24] indicated the presence of ulcers in strictures to be associated with poorer long-term outcomes, whereas Thienpont *et al*[13] reported that there

was no association between endoscopic activity, mainly determined by the sizes and number of ulcerations. Thienpont *et al*[13] also reported that increased levels of C-reactive protein did not influence long-term outcomes. As for the characteristics of strictures, Mueller *et al*[12] recently described the length and the location of strictures as affecting long-term outcomes. In their report, the patients who required surgery after EBD had longer strictures than those who did not, and all of the surgical patients had *de novo* strictures in the terminal ileum. In the present comparison of anastomotic and *de novo* strictures, we found the anastomotic type to be associated with significantly better surgery-free survival rates. Both our results and those of Mueller *et al*[12] suggested stricture type (anastomotic or *de novo*) to be useful for predicting long-term outcomes of EBD.

The effects of concurrent or subsequent therapy aimed at increasing the efficacy of EBD remain unclear. Local steroid injection into the strictures after EBD is controversial. Some studies have found this technique to improve outcomes of EBD[17,19,21-23,25,26], and a recent randomized double blind controlled trial showed this technique to effectively reduce both re-dilatation and surgery in pediatric CD patients with strictures[27]. However, opposite results were also obtained in a placebo controlled trial, although the number of patients was limited[28]. Further study is needed to clarify the utility of this technique. Little is known about the efficacy of subsequent administration of medications such as azathioprine or infliximab, and this topic also requires further study.

In summary, we examined short- and long-term effects of EDB for CD strictures. Although the complication rate was relatively low, *de novo* strictures may carry an increased risk of perforation. Our results also showed anastomotic strictures to be associated with better long-term outcomes than *de novo* strictures, indicating that stricture type (anastomotic *vs de novo*) might be useful for predicting the long-term outcomes of EBD.

COMMENTS

Background

In recent years, the efficacy of endoscopic balloon dilatation (EBD) for Crohn's disease (CD) strictures has been confirmed. Although EBD has been regarded as a safe and effective procedure in the management of CD strictures, the factors which affect long-term outcomes of EBD have not been sufficiently clarified.

Research frontiers

The authors hypothesized that outcomes of EBD might differ between two types of strictures, anastomotic and *de novo*. In this study, the authors evaluated the short- and long-term outcomes of EBD in the hospital and compared the outcomes of EBD for these two types of strictures affecting CD patients, anastomotic and *de novo* strictures.

Innovations and breakthroughs

The results showed that patients with anastomotic strictures had better long-term outcomes than those with *de novo* strictures. This is the first report to clarify that types of the strictures affect the long-term outcomes of EBD in CD patients.

Applications

When considering treatment for CD strictures, this study may indicate that the type of the stricture (anastomotic *vs de novo*) might be useful for predicting long-term outcomes of EBD.

Peer review

The study reported that EBD might be useful to treat the stricture of CD. The paper also observed the short and long-term outcomes of EBD for two different strictures in CD. The argument of the paper is new.

Abstract

AIM: To investigate the clinical usefulness of a newly developed index, the "index of convexity (IOC)", for evaluating liver functional reserve using technetium-99m-diethylenetriaminepentaacetic acid-galactosyl-human serum albumin (Tc-GSA scintigraphy).

METHODS: In total, 349 patients underwent Tc-GSA scintigraphy. Dynamic planner images were obtained, and time activity curves of the liver and heart were generated and analyzed. Our focus was on the convex shape of the liver accumulation curve. We developed a method for evaluating the extent of convexity and calculated an index that we named the IOC. Clearance index and receptor index were also calculated. The correlations between each GSA index with other liver function tests and liver histopathology were evaluated.

RESULTS: Among the 3 indices generated by Tc-GSA, the IOC had the highest correlation with all other liver function tests (indocyanine green R15, albumin, prothrombin time, cholinesterase level, platelet count, and total bilirubin level). IOC can also differentiate between normal liver, chronic hepatitis, and liver cirrhosis with highest *F* ratio among GSA indices as determined by one-way analysis of variance. Receiver operating characteristic analysis demonstrated high diagnostic performance of IOC in the diagnosis of cirrhosis.

CONCLUSION: IOC is a very simple and reliable index for assessing liver functional reserve, which may prove to be useful in combination with the indocyanine green test for preoperative assessment of hepatic resection.

INTRODUCTION

Preoperative assessment of liver functional reserve is crucial for hepatobiliary surgeons. Technetium-99m-diethylenetriaminepentaacetic acid-galactosyl-human serum albumin (Tc-GSA) is a radiopharmaceutical developed for evaluating liver function[1,2] and has been widely used for preoperative assessments[3,4]. This asialoglycoprotein (ASGP) analogue is specifically taken up by hepatocytes[5], and its rate of accumulation in the liver can be evaluated using a gamma camera[6]. The liver accumulation process can be assessed by generating a time activ-

ity curve (TAC) from dynamic planer images. Several indices of liver function have been reported through the analysis of dynamic planer images[7-11]. Clearance index (HH15) and receptor index (LHL15) have been widely used for almost 20 years[7,8], as they are easy to calculate. On the other hand, R_{max} or R_{total} are calculated using kinetic model analysis[9,10], which is highly complex and therefore not widely used. Index LU15 requires measurement of the radioactivity of the injection syringe[11], and the K_L index requires curve-fitting software[4]. The use of both of these methods is limited. Although HH15 and LHL15 have been widely used for a long time, both indices have several problems[12,13]. HH15 uses only the radioactivity counts of the heart pool, which is very low compared to liver counts. This index can thus be influenced by counts in the liver through scatter effects or body movements. Index LHL15 is directly influenced by the manner in which the heart regions of interest (ROI) is drawn, generating inter-operator or inter-institutional differences[13,14].

To overcome these problems, we focus on the shape of the liver TAC. Liver TACs have a convex shape in patients with good liver function. In contrast, liver TACs increase in a linear manner in patients with poor liver function. We developed a method for evaluating the convexity of the liver TAC and calculated an index that we have named the index of convexity (IOC).

In this study, we evaluated the significance and usefulness of this index for the assessment of the liver functional reserve.

MATERIALS AND METHODS

Patients

This study included 349 patients who received Tc-GSA scintigraphy at the University of Tokyo Hospital or Showa General Hospital between 1998 and 2011. Of these patients, 239 had hepatocellular carcinomas, 34 had metastatic liver tumors, and 39 had cholangiocarcinomas. Others were diagnosed with miscellaneous diseases. Liver histology in 236 patients confirmed a diagnosis of chronic hepatitis (48 patients), normal liver (45 patients), and liver cirrhosis (143 patients).

Tc-GSA scintigraphy

All patients received 3 mg of Tc-GSA (185 MBq) intravenously. After the injection, dynamic images were obtained with the patient in a supine position using a large-field view gamma camera. Digital images were acquired at 30 s intervals for 30 min. TACs were generated by drawing ROI over the whole liver [L(t)] and heart [H(t)] on the digital images.

Conventional parameters

The HH15 and LHL15 were defined as follows: HH15 = H(15)/H(3); LHL15 = L(15)/(L(15) + L(3).

IOC

The convexity of the liver TAC was evaluated by an index defined as follows: ΔABC was drawn over the liver TAC, where A and B were placed on the TAC at the data points corresponding to 3 min and 27 min after injection, respectively. Therefore, the coordinates of A, B, and C were A[3, L(3)], B[27, L(27)], and C[3, L(27)], respectively. D and E were set as the mid points of lines AB and BC, respectively. F was defined as the intersection of line DE and arc AB (Figure 1).

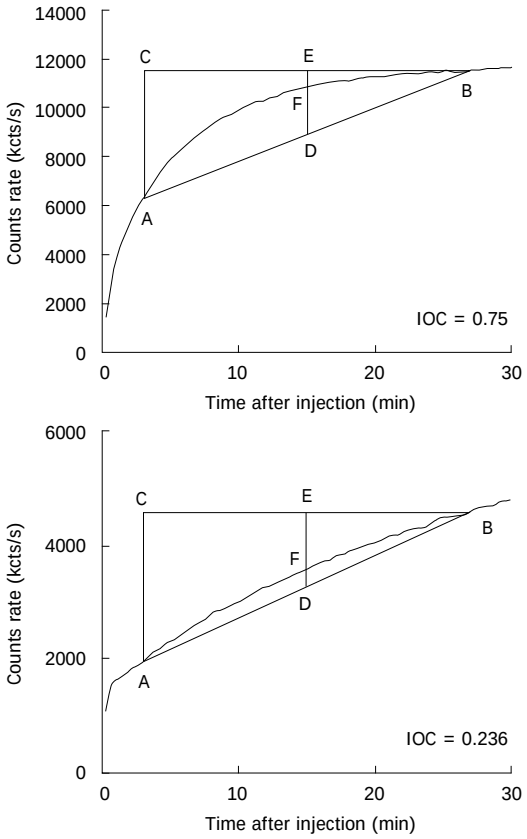

Figure 1 Representative time activity curves of a liver with good function (top) and poor function (bottom). ΔABC was drawn over the liver curve between the data points at 3 min and 27 min. D, E: The midpoints of lines AB and BC, respectively; F: The intersection of arc AB and line DE. The ratio of the length of DF to the length of DE is defined as index of convexity (IOC). High IOC values indicate good liver function.

IOC was defined as the ratio of the length of DF to the length of DE, where it is calculated as follows: IOC = [L(15) × 2 - L(3) - L(27)]/[L(27) - L(3)].

Possible values for this index range from 0 to 1.0. The better the liver function, the higher is the index value (Figure 1).

Other liver function tests

The indocyanine green (ICG) test was carried out, and 2 parameters (ICG R15 and ICG K value) were calculated using the standard methods. Serum albumin level (mg/dL), choline esterase level (IU/L), total bilirubin concentration (mg/dL), platelet counts (× 10^3/mm^3), and prothrombin time (%) were also measured.

Statistical analysis

Correlations between the 3 parameters of the Tc-GSA study (HH15, LHL15 and IOC) and other liver function

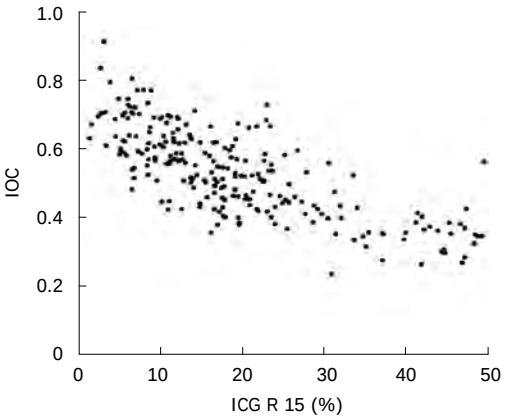

Figure 2 Scatter diagram of index of convexity and indocyanine green retention rate at 15 min. A strong correlation between the 2 parameters is observed (r = -0.761). IOC: Index of convexity; ICG R15: Indocyanine green retention rate at 15 min.

Table 2 Comparison of each index by liver histology

Index	Patient group (mean ± SD)			*F* ratio[1]	*P* value[2]
	Normal liver	Chronic hepatitis	Liver cirrhosis		
IOC	0.64 ± 0.09	0.60 ± 0.12	0.46 ± 0.12	57.8	< 0.0001
HH15	0.53 ± 0.08	0.57 ± 0.09	0.66 ± 0.10	48.2	< 0.0001
LHL15	0.94 ± 0.02	0.93 ± 0.03	0.89 ± 0.08	21.7	< 0.0001
ICG R15	11.7 ± 8.8	14.3 ± 8.3	23.7 ± 13.8	20.3	< 0.0001

[1]*F* ratio obtained by one way analysis of variance (ANOVA); [2]Probability value for the differences among the 3 groups, obtained by one-way ANOVA. IOC: Index of Convexity; ICG R15: Indocyanine green retention rate at 15 min; HH15: Clearance index; LHL15: Receptor index.

tests were estimated as Spearman's rank correlations. The differences in each Tc-GSA parameter between the 3 groups (normal liver, chronic hepatitis, and liver cirrhosis) were evaluated by one-way analysis of variance (ANOVA). The diagnostic performance for the diagnosis of cirrhosis was evaluated by receiver operating characteristic (ROC) analysis.

RESULTS

Spearman's rank correlation coefficients are listed in Table 1. IOC showed higher correlations than the other conventional indices of HH15 and LHL15. In particular, the IOC has a strong correlation to ICG R15 values compared to HH15 or LHL15 (Figure 2). The correlation coefficient between IOC and ICG R15 was statistically higher than that between HH15 and ICG R15 and that between LHL15 and ICG R15.

The results of one-way ANOVA also showed that IOC was significantly different between background liver groups with the highest *F* ratio (Table 2).

We performed ROC analysis to evaluate the diagnostic performance of IOC in diagnosing cirrhosis (Figure 3). The area under the curve (AUC) of ROC curves for IOC, HH15 and LHL15 were 0.851, 0.801 and 0.821, respectively. However, these differences were not statistically significant.

DISCUSSION

In this study, we developed a novel index to evaluate liver function using the dynamic images of Tc-GSA scintigraphy. This index is very simple to calculate and has stronger correlations to other liver function tests than do conventional indices such as HH15 or LHL15. This index also has a high diagnostic performance rating for diagnosing liver cirrhosis. IOC would thus be very useful to hepatobiliary surgeons in assessing preoperative liver function.

Tc-GSA is an ASGP analogue labeled with a radioisotope and developed for the assessment of liver functional reserve. Tc-GSA scintigraphy for assessing liver function has several benefits to consider. First, accumulation of Tc-GSA in the liver can be monitored continuously through dynamic planer images. The kinetics of ASGP have been investigated in detail in animals and humans[10,15,16], and several kinetic parameters have been proposed as candidates for indices of liver function[6,9,10]. Second, regional accumulation of Tc-GSA in the liver was measured separately to evaluate regional liver function *via* single photon emission computed tomography images[17-19], which can be used for the assessment of regional liver function after portal vein embolization[20,21]. Although many parameters of Tc-GSA scintigraphy have been reported, only HH15 and LHL15 are used widely.

Despite their widespread use, we found that both of these indices showed only moderate correlations to other liver functions, and we encountered some cases with a discrepancy between the values of both indices and their liver histology or liver functions[12], Since the TAC of the heart is influenced by background radiation or radioactivity in the liver adjacent to the heart, indicated Tc-GSA concentrations may deviate from the actual blood concentrations[22]. HH15, using only TAC of the heart and ignoring liver accumulation, is not suitable for the ideal index. LHL15 has been shown to be directly influenced by the manner in which the ROI is drawn over the heart[13,14]. The LHL15 index value was also found to be influenced by the shape of the liver and the size of the heart. These observations suggest that HH15 and LHL15 indices are prone to several measurement errors.

To overcome these problems, we focused on the shape of the liver accumulation curve. The shape of the liver accumulation curve seems universally consistent, even if the patients are stout or their liver is deformed.

The convexity of the liver curve seems to be a specific feature of good liver function. The liver curve increased rapidly and afterwards reaches a plateau in the case of good liver function. In contrast, the liver curve increases linearly throughout the examination period, with no plateau, in patients with poor liver function. In order to evaluate the convexity of the liver curve, we calculated the ratio of the length of line DF to line DE as described in Figure 1. IOC decreases as liver function deteriorates. This index correlated very strongly to other liver function tests, including ICG. IOC can be calculated quite easily as calculations require liver radioactivity data at only 3 time points. Results of one-way ANOVA indicate that IOC has a higher correlation to liver histology than does HH15 or LHL15. In fact, IOC seemed to be superior to HH15 or LHL15 in the diagnosis of liver cirrhosis as indicated by ROC analysis, although the differences between the AUC of ROC curves for IOC, HH15, and LHL15 were not statistically significant.

Makuuchi *et al* proposed that the criteria determining the extent of liver resection include ascites volume, bilirubin levels, and ICG tests[23]. Since then, the ICG test has been widely used in Japan for the preoperative assessment of liver functional reserve. It is well known that hyperbilirubinemia and large port-systemic shunts interfere with the results of ICG tests[24,25]. In addition, some patients are intolerant of ICG[26]. We have encountered many cases with large discrepancies between ICG results and conventional liver function tests. In these cases, Tc-GSA scintigraphy plays a complementary role in deciding on surgical procedures. In this study, IOC showed a stronger correlation with conventional liver function tests than did the ICG test. IOC is a simple and reliable index that is superior to HH15 and LHL15 indices and is a valuable parameter exceeding ICG tests in the preoperative assessment of liver functional reserve. We analyzed the Tc-GSA data retrospectively in this study. In order to prove the usefulness of this index, further prospective studies should be undertaken.

COMMENTS

Background

Technetium-99m-diethylenetriaminepentaacetic acid-galactosyl-human serum albumin (Tc-GSA) was a radiopharmaceutical developed in Japan to assess liver functional reserve. The liver uptake of Tc-GSA can be evaluated from dynamic images obtained using a gamma camera. Among the indices for the Tc-GSA scintigraphic analysis of liver functional reserve, only the receptor index (LHL15) and clearance indices (HH15) have been widely used. However, both indices are prone to measurement errors. To date, no appropriate methods have been developed that are superior to LHL15 and HH15 in terms of reliability and accuracy in the preoperative assessment of liver functional reserve.

Research frontiers

Several methods of evaluating liver function using Tc-GSA scintigraphy have been reported. In particular, methods using kinetic model analysis are highly complex, and another method requires radioactivity measurements of the injection syringe. Therefore, to overcome the limitations of these methods and increase the use of Tc-GSA scintigraphy for the assessment of hepatobiliary surgical outcomes, it is necessary to develop a simple but reliable index that is superior to LHL15 and HH15.

Innovations and breakthroughs

The authors focused on the shape of the liver time activity curve of Tc-GSA and found that the extent of the convexity correlated with liver function, Developing a new index, the index of convexity (IOC), that is very easy to calculate. The authors demonstrated that this index predicts liver functional reserve better than the conventional LHL15 and HH15 indices.

Applications

The IOC is a very simple but reliable index for assessing liver functional reserve, which is, in turn, very useful for preoperative assessment of hepatic resection. Therefore, it can be introduced in any institute without the need for special software.

Terminology

Tc-GSA is a radiopharmaceutical developed for evaluating liver function. This asialoglycoprotein analogue is specifically absorbed by hepatocytes, and its rate of accumulation in the liver is influenced by the liver functional reserve, which can be evaluated using a gamma camera.

Peer review

This is a very interesting and well-performed study evaluating the usefulness of a novel index of liver functional reserve based on dynamic Tc-GSA scintigraphic images. The authors developed a new method for analyzing the results of Tc-GSA scintigraphy based on the shape of the liver TAC and introduced the "IOC". They found that IOC had a strong correlation with conventional liver function test results and a good performance in the diagnosis of cirrhosis. The interesting conclusions of the study were that IOC is a simple but reliable index for assessing liver functional reserve and that it would be useful in deciding on surgical procedures. The study is well designed and written, with clinically relevant conclusions and appropriate data supporting the results.

Abstract

AIM: To investigate the relationship between *Helicobacter pylori* (*H. pylori*) seropositivity and the presence of microalbuminuria.

METHODS: Between December 2003 and February 2010, asymptomatic individuals who visited the Seoul National University Healthcare System Gangnam Center for a routine check-up and underwent tests for *H. pylori* immunoglobulin G antibodies and urinary albumin to creatinine ratio (UACR) were included. All study subjects completed a structured questionnaire, anthropometric measurements and laboratory tests. Anti-*H. pylori* immunoglobulin G was identified using an enzyme-linked immunosorbent assay kit. A random single-void urine sample, collected using a clean-catch technique, was obtained to determine the UACR. The presence of microalbuminuria was defined as a UACR from 30 to 300 μg/mg. The presence of diabetes mellitus (DM) was defined as either a fasting serum glucose level greater than or equal to 126 mg/dL or taking anti-diabetic medication. Multiple logistic regression analysis was performed to identify the risk factors. The dependent variable was microalbuminuria, and the independent variables were the other study variables.

RESULTS: A total of 2716 subjects (male, 71.8%; mean age, 54.9 years) were included. Among them, 224 subjects (8.2%) had microalbuminuria and 324 subjects (11.9%) had been diagnosed with DM. Subjects with microalbuminuria had a significantly higher *H. pylori* seropositivity rate than subjects without microalbuminuria (60.7% *vs* 52.8%, $P = 0.024$). Multivariate analysis after adjustment for age, body mass index (BMI), waist circumference, and glucose and triglyceride levels showed that *H. pylori* seropositivity was significantly associated with microalbuminuria [odds ratio (OR), 1.40, 95% CI, 1.05-1.89, $P = 0.024$]. After the data were stratified into cohorts by glucose levels (⩽ 100 mg/dL, 100 mg/dL < glucose < 126 mg/dL, and ⩾ 126 mg/dL or history of DM), *H. pylori* seropositivity was found to be significantly associated with microalbuminuria in diabetic subjects after adjusting for age, BMI and serum creatinine level (OR, 2.21, 95% CI, 1.20-4.08, $P = 0.011$). In addition, the subjects were divided into five groups. Those without microalbuminuria (an UACR of < 30 μg/mg) were divided into four groups in accordance with their UACR values, and subjects with microalbuminuria comprised their own group. Notably, *H. pylori* seropositivity gradually increased with an increase in UACR ($P = 0.001$) and was highest in subjects with microalbuminuria (OR, 2.41, 95% CI, 1.14-5.11). This suggests that *H. pylori* seropositivity is positively associated with microalbuminuria in diabetic subjects.

CONCLUSION: *H. pylori* seropositivity was independently associated with microalbuminuria, and the prevalence of *H. pylori* seropositivity was associated with the severity of UACR in diabetic subjects.

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection has been implicated in various extragastric conditions, including coronary heart disease and ischemic cerebrovascular disorder caused by predisposing chronic inflammation and atherosclerosis[1-5]. The association between *H. pylori* seropositivity and coronary artery calcium scores was recently reported[6]. Moreover, *H. pylori* infection was found to be associated with reduced high density lipoprotein and elevated low density lipoprotein levels in serum[7,8]. Furthermore, a prospective single-center study showed that *H. pylori* eradication had beneficial effects on insulin resistance, lipid abnormalities and low-grade inflammation[9]. These findings suggest a role for *H. pylori* infection in subjects with metabolic syndrome, including diabetes.

In contrast, microalbuminuria, which is defined as an increased urinary albumin to creatinine ratio (UACR) of 30-300 μg/mg[10], has been known to be a strong predictor of the development of diabetic nephropathy[11]. It has also been demonstrated that microalbuminuria is a risk factor for cardiovascular disease in the general and diabetic populations[12-14]. Although the mechanism linking microalbuminuria to cardiovascular morbidity remains unclear, one possible explanation is that the increased urinary leakage of albumin reflects vascular damage, i.e., endothelial dysfunction or low-grade chronic inflammation[15]. In addition, some studies have reported a relationship between microalbuminuria and metabolic syndrome, suggesting that insulin resistance underlies the pathogenesis of microalbuminuria[16-18].

Our hypothesis was that if *H. pylori* infection is involved in the pathogenesis of atherosclerosis, a significant association might exist between *H. pylori* infection and microalbuminuria, which is an early marker of atherosclerosis. Therefore, we aimed to investigate the relationship between *H. pylori* infection and microalbuminuria in subjects presenting for a routine health check-up.

MATERIALS AND METHODS

Study population

This cross-sectional study was conducted at the Seoul National University Hospital Gangnam Healthcare Center between March 2003 and February 2010. During the study period, a total of 2737 asymptomatic individuals visited our center for a routine check-up, including *H. pylori* serology and UACR tests. Among them, 21 subjects who showed macroalbuminuria exceeding 300 μg/mg were excluded. Accordingly, 2716 individuals comprised the study population. The presence of diabetes mellitus (DM) was defined as either a fasting serum glucose level greater than or equal to 126 mg/dL or taking anti-diabetic medication. This study was approved by the Institutional Review Board of Seoul National University Hospital, which waived the requirement for informed consent.

Clinical and laboratory assessments

All study subjects completed a structured questionnaire and underwent anthropometric measurements and laboratory tests. A current smoker was defined as a subject who had smoked 100 or more cigarettes during his lifetime and smoked daily at the time of the examination[19]. Height and body weight were measured using a digital scale, and body mass index (BMI) was calculated as follows: BMI = body weight (kg)/height squared (m^2). Systolic and diastolic blood pressures were measured in a sitting position after a 5-min rest, twice a day; mean values were used in the analysis. Blood samples were collected after at least a 12 h of fasting and used to determine glucose, triglyceride, high density lipoprotein cholesterol, and creatinine levels. Serum creatinine concentrations were determined using the Jaffe rate reaction. Anti-*H. pylori* immunoglobulin G was identified using an enzyme-linked immunosorbent assay kit (*H. pylori*-EIA-Well, Radim, Italy) and an automatic analyzer, Alisei® (Seac, Italy). The cut-off values were set according to the manufacturer's instructions.

A random single-void urine sample using a clean-catch technique after at least 12 h of fasting was obtained to determine the UACR (μg/mg). Urinary albumin excretion was measured using an immunoturbidimetric assay, and urinary creatinine was measured using the Jaffe rate reaction. Microalbuminuria was defined as a UACR from 30 μg/mg to 300 μg/mg.

Statistical analysis

Analyses were performed using the SPSS statistical package (Version 17.0, SPSS, Inc., Chicago, IL, United States). A Pearson χ^2 test was used to examine associations between microalbuminuria and the study variables, and P values of < 0.05 were considered statistically significant. Multiple logistic regression analysis was performed to identify risk factors. The dependent variable was microalbuminuria, and the independent variables were the other study variables. Odds ratios (OR) and the relevant 95% CI are presented for all of the potential risk factors.

RESULTS

Clinical characteristics of the study population

The mean age of the 2716 study subjects was 54.9 years, and 71.8% were men. Of the subjects, 224 (8.2%) had

H. pylori: *Helicobacter pylori*; OR: Odds ratio; BMI: Body mass index; WC: Waist circumference; HDL: High density lipoprotein; SBP: Systolic blood pressure; DBP: Diastolic blood pressure.

microalbuminuria, and 324 (11.9%) met the criteria for DM, either by taking diabetic medications or showing fasting serum glucose level in the diabetic range (≥ 126 mg/dL). BMI and the serum glucose, triglyceride and creatinine levels were found to be significantly higher in subjects with microalbuminuria than in those without microalbuminuria. In addition, subjects with microalbuminuria had a significantly higher *H. pylori* seropositivity rate than subjects without microalbuminuria (Table 1).

Risk factors of microalbuminuria

The results of the univariate and multivariate analyses of the risk factors for microalbuminuria are shown in Table 2. Multivariate analysis after adjustment for age, waist circumference, glucose, triglyceride and BMI showed that *H. pylori* seropositivity was statistically associated with microalbuminuria (OR, 1.40, 95% CI, 1.05-1.89, P = 0.024; Table 2). Because serum glucose level is the most well-known factor determining microalbuminuria, we performed the analysis after stratifying the cohort by glucose levels (≤ 100 mg/dL, 100 mg/dL < glucose < 126 mg/dL, and ≥ 126 mg/dL or history of DM) to reduce the confounding effect of serum glucose level. As a result, *H. pylori* seropositivity was significantly associated with microalbuminuria in diabetic subjects after adjusting for age, BMI and serum creatinine level (OR, 2.21, 95% CI, 1.20-4.08, P = 0.011). However, the relation between *H. pylori* seropositivity and microalbuminuria was not statistically significant in non-diabetic subjects.

Helicobacter pylori infection and microalbuminuria in diabetic subjects

The seropositivity rates for *H. pylori* in diabetic subjects and non-diabetic subjects were 50% (162/324) and 54% (1291/2392), respectively. Because *H. pylori* seropositivity was found to be significantly associated with an increased prevalence of microalbuminuria in diabetic subjects, we evaluated the relation between the severity of UACR and *H. pylori* seropositivity. The subjects were divided into five groups. Those without microalbuminuria (an UACR of < 30 μg/mg) were divided into four groups in accordance with their UACR values, and subjects with microalbuminuria comprised their own group. The percentage of *H. pylori* seropositivity was found to gradually increase with UACR (P = 0.001; Figure 1), and the highest rate was observed in subjects with microalbuminuria (OR, 2.41, 95% CI, 1.14-5.11; Table 3), suggesting that *H. pylori* seropositivity is positively associated with microalbuminuria in diabetic subjects.

DISCUSSION

This study shows that *H. pylori* seropositivity is independently associated with the presence of microalbuminuria, and the prevalence of *H. pylori* seropositivity shows a positive correlation with the severity of urine albumin creatinine ratio in diabetic subjects. These findings suggest that *H. pylori* infection might affect microvascular damage and possibly contributes to pathogenesis of early atherosclerosis in diabetes.

The mechanisms underlying increased urinary albumin excretion are complex, but endothelial cell dysfunction appears be a major pathogenic contributor[20]. Moreover, microalbuminuria is known to be associated with atherogenic risk factors, such as hypertension, hyperglycemia, central obesity and hyperinsulinemia[21]. In the present study, we consistently found that metabolic variables, such as glucose, triglyceride and BMI were significantly associated with microalbuminuria. In particular, *H. pylori* seropositivity was found to be positively related to microalbuminuria after adjusting for other variables, which suggests that *H. pylori* infection might participate in the pathogenesis of endothelial dysfunc-

Table 3 Relationship of the severity of the urine albumin to creatinine ratio to *Helicobacter pylori* seropositivity in diabetes subjects

Urine albumin-creatinine ratio (μg/mg)	*n*	*H. pylori* seropositivity (%)	OR (95% CI)	*P* for trend
Q1 (< 4.9)	64	50.0	Reference	0.001
Q2 (5.0-7.9)	63	46.0	0.86 (0.42-1.01)	
Q3 (8.0-13.9)	64	51.6	1.10 (0.36-2.23)	
Q4 (14.0-29.9)	65	61.5	1.55 (0.75-3.19)	
Microalbuminuria	68	72.1	2.41 (1.14-5.11)

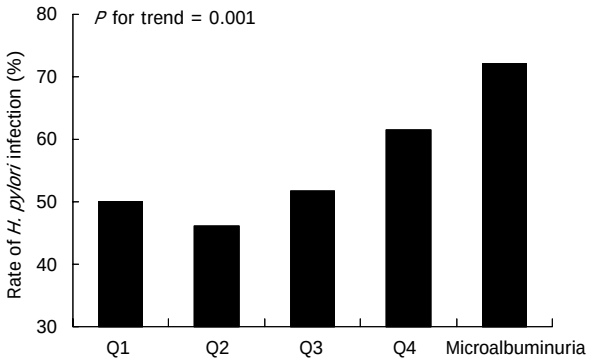

Figure 1 The rate of *Helicobacter pylori* seropositivity according to the urinary albumin to creatinine ratio in diabetic subjects. The subjects were divided into five groups: subjects without microalbuminuria were divided into four groups in accordance with their urine albumin to creatinine ratio values, and subjects with microalbuminuria comprised their own group: Q1, < 4.9 μg/mg; Q2, 5.0-7.9 μg/mg; Q3, 8.0-13.9 μg/mg; Q4, 14.0-29.9 μg/mg and microalbuminuria, > 30 μg/mg. *H. pylori*: *Helicobacter pylori*.

tion. There have been some studies suggesting the association between *H. pylori* infection and endothelial dysfunction; Oshima *et al*[22] reported that *H. pylori* seropositivity was associated with elevated C-reactive protein and soluble intercellular adhesion molecule-1. This indicates that chronic *H. pylori* infection might be involved in the pathogenesis of atherosclerosis. Prasad *et al*[23] showed that the immunoglobulin-G antibody response to pathogens was an independent risk factor for endothelial dysfunction and coronary atherosclerosis.

A possible mechanism linking *H. pylori* infection and endothelial dysfunction is the association between *H. pylori* infection and insulin resistance. Recently, a systematic review has reported a positive association between *H. pylori* infection and a homeostatic model of assessing insulin resistance[24]. *H. pylori* infection was significantly associated with metabolic syndrome in a large Japanese population[25]. Furthermore, Gunji *et al*[26] found that *H. pylori* infection significantly increases insulin resistance in the asymptomatic population. A recent prospective study showed the beneficial effect of *H. pylori* eradication on insulin resistance, serum lipid and low-grade inflammation[27]. It remains uncertain how the presence of *H. pylori* affects the pathogenic process of insulin resistance. The disturbance of proinflammatory and vasoactive substances, such as tumor necrosis factor-α, interlukin-6 and c-reactive protein, may be involved in the pathogenesis of insulin resistance[28,29]. Moreover, the reactive oxygen species caused by an *H. pylori* infection also affects insulin resistance[30,31].

Many studies have demonstrated that elevated blood pressure, poor glycemic control, older age and insulin resistance are associated with microalbuminuria in subjects with diabetes[32,33]. In this study, we stratified the study population according to glucose levels to reduce the confounding effect, and the association between *H. pylori* seropositivity and microalbuminuria was more potent in diabetic subjects than in non-diabetic and prediabetic subjects. Diabetic patients are known to have impaired function of cellular and humoral immunity, and consequently, the direct invasion of the arterial wall by bacteria might be more frequent in these patients than in non-diabetic ones. Indeed, some previous studies have found a higher prevalence of *H. pylori* infection among diabetic patients[34,35]. On the other hand, other studies did not detect an association between *H. pylori* infection and diabetes[36,37], and these contradictory results among studies might have resulted from differing methods used by the studies and from the uneven epidemiological distribution of *H. pylori* infection.

This study has several advantages. First, to the best our knowledge, this is the only study of the association between *H. pylori* infection and microalbuminuria. Second, it utilized a large study population, and we constructed a multiple regression model containing many metabolic confounding factors. Third, subjects in this study were an apparently healthy population that presented for screening, and such populations seems to approximate the general population.

Nevertheless, the study has several limitations. First, it does not provide details regarding the nature of the causative relation between *H. pylori* seropositivity and microalbuminuria because of the cross-sectional study design. Second, although the *H. pylori* seropositivity does not indicate current *H. pylori* infection, seropositivity for *H. pylori*-specific immunoglobulin G antibody was taken as a surrogate of *H. pylori* infection status in the present study. Thus, there might be some false-positive or false-negative subjects. Third, we did not evaluate *H. pylori*-induced inflammatory and virulence factors, such as the *cag A* gene, which could contribute to the pathogenesis of *H. pylori*-induced early atherosclerosis.

In conclusion, *H. pylori* seropositivity was independently associated with the presence of microalbuminuria, and the prevalence of *H. pylori* seropositivity was positively correlated with the severity of urine albumin creatinine ratio in diabetic subjects. Our findings suggest that *H. pylori* infection might be involved in the pathogenesis of early atherosclerosis in diabetes.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) infection has been implicated in various extragastric conditions including coronary heart disease and ischemic cerebrovascular

disorder, caused by predisposing chronic inflammation and atherosclerosis. On the other hand, microalbuminuria is a known early marker of renal and cardiovascular diseases. Their hypothesis was that if *H. pylori* infection is involved in the pathogenesis of atherosclerosis, a significant association might exist between *H. pylori* infection and microalbuminuria, which is an early marker of atherosclerosis.

Research frontiers

Recent studies have reported the association between *H. pylori* infection and endothelial dysfunction. *H. pylori* infection significantly increases insulin resistance in the asymptomatic population and it also associated with metabolic syndrome in a large Japanese population. Moreover, the beneficial effect of *H. pylori* eradication on insulin resistance was reported.

Innovations and breakthroughs

This study showed that *H. pylori* seropositivity is independently associated with presence of microalbuminuria and the prevalence of *H. pylori* seropositivity showed a positive correlation with the severity of the urine albumin creatinine ratio in diabetic subjects.

Applications

This study suggests that *H. pylori* infection might affect microvascular damage and possibly contributes to the pathogenesis of early atherosclerosis in diabetes.

Peer review

The authors have studied the relationship between the occurrence of *H. pylori* and microalbuminuria in a healthy population. The association between *H. pylori* and microalbuminuria has only recently been reported and has not been studied in a larger setting. Thus, the paper is of importance and novel. The paper is well written and well presented. Regarding ethics, the local review board had waived the need for written consent.

Abstract

AIM: To investigate the feasibility of a single-use endoscopy as an alternative procedure to nasogastric lavage in patients with acute gastrointestinal (GI) bleeding.

METHODS: Patients who presented with hematemesis, melena or hematochezia were enrolled in this study. EG scan™ and conventional esophagogastroduodenoscopy (EGD) were subsequently performed. Active bleeding was defined as blood in the stomach, and inactive bleeding was defined as coffee ground clots and clear fluid in the stomach. The findings were recorded and compared.

RESULTS: Between January and March, 2011, 13 patients that presented with hematemesis (n = 4), melena (n = 6), or bleeding from a previous nasogastric feeding tube (n = 3), were enrolled in this study. In 12 patients with upper GI bleeding, the EG scan device revealed that 7 patients had active bleeding and 5 patients had inactive bleeding, whereas conventional EGD revealed that 8 patients had active bleeding and 4 patients had inactive bleeding. The sensitivity and specificity of the EG scan device was 87.5% and 100% for active bleeding, with conventional EGD serving as a reference. No complication were reported during the EG scan procedures.

CONCLUSION: The EG scan is a feasible device for screening acute upper GI bleeding. It may replace nasogastric lavage for the evaluation of acute upper GI bleeding.

A pilot study of single-use endoscopy in screening acute gastrointestinal bleeding. *World J Gastroenterol* 2013; 19(1): 103-107 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/103.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.103

INTRODUCTION

Acute upper gastrointestinal (GI) bleeding is managed by early conventional endoscopy within 24 h of presentation[1-3]. In high-risk upper GI bleeding, urgent endoscopy reduces mortality; therefore, risk stratification is important[4,5]. Nasogastric lavage is a routine procedure used to evaluate acute upper GI bleeding and

to assess risk before performing conventional endoscopy. The findings of nasogastric lavage help doctors decide whether to perform an early conventional endoscopy[1,6-8]. However, the effect of nasogastric lavage on clinical outcomes and mortality remains controversial[3,9-12]. Nasogastric intubation and lavage is one of the most painful procedures performed in the emergency department[13,14].

A novel single-use endoscopy device (EG scan™: IntroMedic Co., Ltd., Seoul, South Korea) has been developed from the MiroCam® capsule endoscopy technology created by the IntroMedic company and Professor Si Young Song of Yonsei University College of Medicine[15,16]. The EG scan machinery (version I) is composed of an optical probe, a handle for control, and a display monitor. The optical probe is disposable (Figure 1), and the largest diameter is 6 mm, similar to a nasogastric tube with diameter of 16 French (Figure 2). The optical probe can be deflected to 60° upward or 60° downward, but not left or right. The optical probe is inserted though the mouth or nose using display monitor to visualize the process, and the probe can only be used once. The machinery of the full EG scan system is as small as a laptop computer and is portable. It can operate anywhere electric power is supplied. It is easy to use and is accessible for use by a non-GI endoscopist.

The EG scan has the potential to improve the easy and accuracy of diagnosis due to its visual monitoring capabilities for the evaluation of acute GI bleeding in decision making for early conventional upper endoscopy. It is also less painful and has a lower risk of complication than a blindly inserted nasogastric tube. We aimed to test the feasibility of the EG scan to assess GI bleeding for guidance of early conventional endoscopy in patients with acute GI bleeding as an alternative procedure to nasogastric lavage.

MATERIALS AND METHODS

Patients who were older than 18 years old and had clinical manifestations suspected of being acute GI bleeding were enrolled in this study. Acute GI bleeding was defined as presentation with hematemesis, melena, or hematochezia within 24 h. Patients who visited the emergency room for acute GI bleeding or in-patients who had been admitted to intensive care unit or general ward and presented with acute GI bleeding in Myongji Hospital were enrolled in this study. Patients with confirmed lower GI bleeding were excluded from this study.

When the patients were hemodynamically stable, an EG scan (version I) was immediately performed at the patients' bedside by one PGY-4 medical resident. The EG scan's optical probe was inserted through the mouth using the display monitor to visualize the process. The findings of the EG scan were recorded. Thereafter, conventional esophagogastroduodenoscopy (EGD) was instantly performed by one qualified endoscopist, who had not been informed of the findings from the EG scan.

Figure 1 EG scan device. The EG scan (version I) is composed of a disposable optical probe, a handle, and a display monitor.

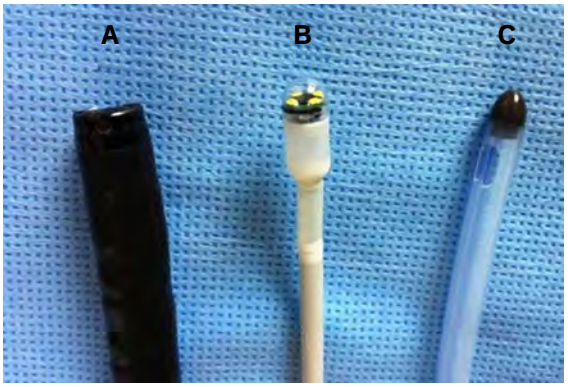

Figure 2 Comparison of diameters. A: The diameters of GIF-Q260 (Olympus) endoscopy; B: An optical probe of an EG scan device; C: An optical probe of a 16-Fr nasogastric tube.

The findings from the 2 procedures were compared.

Blood in the stomach was categorized into "active bleeding", and coffee ground clots and clear fluid were categorized into "inactive bleeding". In the EGD, high-risk lesions were defined as spurting, oozing of blood, or non-bleeding visible vessels, or by the Forrest classifications I a, I b, or II a[17,18].

Statistical analysis

To investigate the diagnostic efficacy of the EG scan device, the sensitivity, specificity, positive predictive value and negative predictive value for active bleeding were calculated, with conventional EGD serving as a reference.

RESULTS

Thirteen patients with acute GI bleeding were enrolled between January and March 2011 (Table 1). Of the 13 patients, 12 patients had symptoms suspicious of upper GI bleeding: 6 patients presented with melena, 3 patients presented with hematemesis, and 3 patients presented with bleeding from a previously located nasogastric tube for feeding or drainage. One patient presented with hematemesis, but the final focus of bleeding was identified as lung cancer.

Table 1 Clinical features and the findings of EG scan and esophagogastroduodenoscopy in all patients

No.	Age (yr)	Sex	Reason for endoscopy	Underlying disease/condition	EG scan		EGD		
					Performance location	Bleeding status	Bleeding status	Diagnosis	Risk
1	52	M	Hematemesis	Heavy alcoholics	ER	Active	Active	Mallory-Weiss syndrome	High
2	47	F	Hematemesis	Liver cirrhosis ESRD	ER	Active	Active	Gastric varix bleeding	High
3	87	M	Hematemesis	Old stroke	ER	Inactive	Active	Gastric ulcer with bleeding	High
4	79	M	Melena	Pneumonia Abdominal aorta aneurysm	ICU	Active	Active	Gastric ulcer with bleeding	High
5	88	M	Melena	Cardiac arrest Pneumonia	ICU	Active	Active	Gastric ulcer with bleeding	High
6	74	M	Melena	Old stroke	ER	Inactive	Inactive	Duodenal ulcer	Low
7	63	M	Melena	Valvular heart disease Coumadin toxicity	General ward	Inactive	Inactive	Gastric ulcer and duodenal ulcer	Low
8	85	F	Melena	Acute myocardial infarction	ICU	Active	Active	Gastric ulcer with bleeding	High

10	72	F	Blood clots from NG tube for feeding	Stroke Parkinson's disease	ICU	Inactive	Inactive	Multiple gastric hematin,	Low
11	89	F	Fresh blood from NG tube for feeding	Aspiration pneumonia	ICU	Active	Active	Gastric ulcer with bleeding	High
12	80	M	Fresh blood from NG tube for drainage	Postoperative state for gastric cancer	ICU	Active	Active	Anastomosis site bleeding	High
13	73	M	Hematemesis	COPD with acute exacerbation Lung cancer	ER	Active	Active	Hemoptysis (Ingestion of blood from lung cancer)	Not related

M: Male; F: Female; NG: Nasogastric; ER: Emergency room; ICU: Intensive care unit; Active: Blood; Inactive: Coffee ground or clear; COPD: Chronic obstructive pulmonary disease; ESRD: End stage renal disease; EGD: Esophagogastroduodenoscopy.

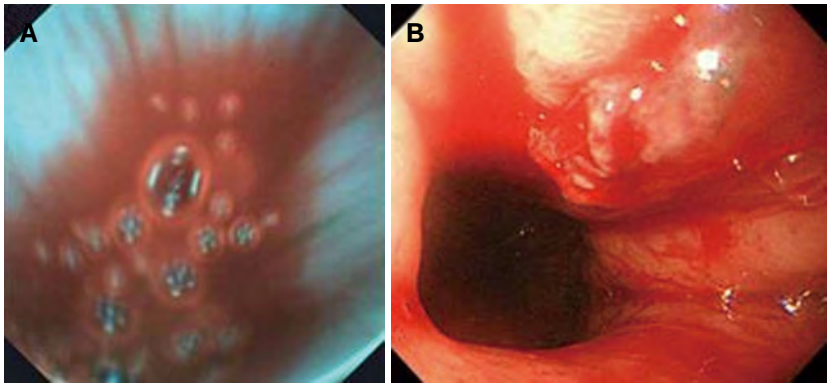

Figure 3 A concordant case of acute gastrointestinal bleeding from Mallory-Weiss syndrome. A: EG scan shows blood at the esophagogastric junction; B: Conventional esophagogastroduodenoscopy (GIF-Q260) shows oozing from the tear wound of the esophagogastric junction.

In the 12 patients with upper GI bleeding, 7 patients were diagnosed as having active bleeding by the EG scan, with the same finding by conventional EGD (Figure 3). In 5 patients diagnosed as having inactive bleeding by EG scan, 4 patients were confirmed as having inactive bleeding. The remaining patient was reported as active bleeding by conventional EGD. The sensitivity of the EG scan was 87.5% for active bleeding, and the specificity of the EG scan was 100% for inactive bleeding, with conventional EGD serving as a reference. The positive predictive value for active bleeding was 100%, and the negative predictive value for active bleeding was 80%, with conventional EGD serving as a reference. No complication were reported during the EG scan procedures.

DISCUSSION

In our small-scale pilot study, the EG scan was shown to evaluate acute upper GI bleeding before conventional EGD in a manner similar to nasogastric lavage. The sensitivity, specificity, and positive predictive values of the EG scan procedure were significant although the results are preliminary. Only one of 12 patients with upper GI bleeding had a discrepancy between the EG scan results and the EGD results. The cause of this discrepancy was possibly a gastric ulcer that had an inactive period of bleeding during the EG scan, whereas blood spurted from the ulcer during the EGD. Therefore, the result was not associated with the accuracy of the EG scan. In a large-scale study using a Canadian retrospective registry, a bloody nasogastric aspirate has a sensitivity of 48.4%, a specificity of 75.8%, and a negative predictive value of 77.9% of for high-risk endoscopic lesions[17]. In a prospective study, 73% of Greek patients with upper GI bleeding and a bloody nasogastric aspirate have active bleeding[19]. In a retrospective cohort study with GI

bleeding patients without hematemesis, the sensitivity of a positive nasogastric aspirate is 42%[10]. With respect to these findings, the EG scan is worth consideration of a large-scale controlled study as an alternative procedure to nasogastric lavage.

An EG scan probe can be inserted through a patient's mouth as it is in conventional EGD. This method can avoid pain during the nasal insertion of a nasogastric tube. The visual monitoring of the EG scan may prevent serious complications related to the blind insertion of a nasogastric tube, such as nasopharynx perforation, esophageal perforation and displacement into the trachea[11,20-22]. In addition, the EG scan's optical probe can be inserted through a patient's nose in the same manner in which a nasogastric tube is inserted. In our study, the pain related to the insertion of the EG scan was not investigated and should be part of the evaluation in a further study.

In critically ill patients with other morbidities such as acute myocardial infarction and COPD, conventional EGD has an increased complication rate[23-26]. When these patients are suspected of having acute GI bleeding, it is necessary to exactly assess the acuity, severity, and location of the GI bleeding. In these high-risk patients, the EG scan could play the role of a bridge to conventional EGD by assessing the exact status of GI bleeding. In our study, critically ill patients with acute myocardial infarction, cardiac arrest, and pneumonia received an EG scan with high performance and without any complications.

In Korea, the prices of a nasogastric tube and lavage are approximately 10 United States dollars and 20 United States dollars, respectively, whereas the price of a disposable optical probe of EG scan is approximately 100 United States dollars. The cost of performing EG scan is currently more expensive than nasogastric lavage. However, an EG scan may screen active bleeding more precisely than nasogastric lavage and may eventually reduce unnecessary emergency EGDs and costs. The cost and effectiveness of the EG scan must be confirmed through large-scale studies. Additionally, the price of an EG scan could be decreased by advancements in electronics in the future, and this technology could replace nasogastric lavage.

However, the EG scan has several weaknesses. First, EG scan version I does not provide air inflation; therefore, it is difficult to find the focus of the bleeding in the stomach. Recently, an EG scan version Ⅱ with an air inflation function has been released that could resolve this problem. Second, there is no method to clear the cover glass in front of the camera during the procedure, which means that vision can be impaired when secreted materials become stuck to the cover glass. Additionally, angulation of the head of the optical probe is limited up to 60° upward or 60° downward. Further development of the technique will compensate for these weak points when using the EG scan.

In conclusion, the EG scan was developed for single-use and as a portable device. It is feasible for screening acute upper GI bleeding with high sensitivity and specificity. If larger, controlled trials looking at the predictive value, the cost, patient discomfort, and the relative side effect profile of immediate endoscopy or nasogastric lavage in comparison to the EG scan prove positive, this device has the potential to replace nasogastric lavage or universal urgent EGD in an emergency room, ward or intensive care unit setting.

COMMENTS

Background

Nasogastric lavage is an important method to evaluate acute gastrointestinal bleeding. However, the findings of nasogastric lavage sometimes indicate false positive or false negative active bleeding, and nasogastric tube insertion is very painful to patients. A more precise and less painful procedure has been needed.

Research frontiers

The EG scan™ (IntroMedic Co., Ltd., Seoul, South Korea) is a novel disposable endoscopy tool using the mechanism of capsule endoscopy, and its machinery is small enough to be portable. It has been developed to be used in outpatient clinics quickly and comfortably.

Innovations and breakthroughs

This is the first study to investigate the diagnostic efficacy of the EG scan for screening active bleeding. The promising results suggest that the EG scan should be a candidate procedure as a substitute to nasogastric lavage, although this is a pilot study with a small sample size.

Applications

These preliminary findings suggest that the EG scan may be a substitute for nasogastric lavage. This device can also be used as esophagoscopy in outpatient clinics and as a flexible rectosigmoidoscopy. In the future, the portable nature of this device may enable EG scans to be used for patients in an emergency outside of a hospital.

Terminology

A single-use endoscopy tool is disposable after use. Early endoscopy is an endoscopic procedure used within 24 h of presentation to diagnose or treat diseases. Active bleeding is defined as the existence of blood in the stomach, and inactive bleeding is defined as the existence of coffee ground clots or clear fluid in the stomach. A high-risk ulcer is one with current bleeding or high risk of bleeding.

Peer review

This pilot study shows that the EG scan, a novel single-use endoscopy device, can screen active bleeding simply and easily. It is a portable system suitable for fast diagnosis in emergency rooms and intensive care units, although the efficacy should be confirmed in large-scale trials.

Abstract

AIM: To compare the outcomes between double-guidewire technique (DGT) and transpancreatic precut sphincterotomy (TPS) in patients with difficult biliary cannulation.

METHODS: This was a prospective, randomized study conducted in single tertiary referral hospital in Korea. Between January 2005 and September 2010. A total of 71 patients, who bile duct cannulation was not possible and selective pancreatic duct cannulation was achieved, were randomized into DGT (n = 34) and TPS (n = 37) groups. DGT or TPS was done for selective biliary cannulation. We measured the technical success rates of biliary cannulation, median cannulation time, and procedure related complications.

RESULTS: The distribution of patients after randomization was balanced, and both groups were comparable in baseline characteristics, except the higher percentage of endoscopic nasobiliary drainage in the DGT group (55.9% *vs* 13.5%, $P < 0.001$). Successful cannulation rate and mean cannulation times in DGT and TPS groups were 91.2% *vs* 91.9% and 14.1 ± 13.2 min *vs* 15.4 ± 17.9 min, $P = 0.732$, respectively. There was no significant difference between the two groups. The overall incidence of post- endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis was 38.2% *vs* 10.8%, $P < 0.011$ in the DGT group and the TPS group; post-procedure pancreatitis was significantly higher in the DGT group. But the overall incidence of post-ERCP hyperamylasemia was no significant difference between the two groups; DGT group *vs* TPS group: 14.7% *vs* 16.2%, $P < 1.0$.

CONCLUSION: When free bile duct cannulation was difficult and selective pancreatic duct cannulation was achieved, DGT and TPS facilitated biliary cannulation and showed similar success rates. However, post-procedure pancreatitis was significantly higher in the DGT group.

in difficult biliary cannulation. *World J Gastroenterol* 2013; 19(1): 108-114 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/108.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.108

INTRODUCTION

Selective biliary cannulation is an important step for therapeutic endoscopic retrograde cholangiopancreatography (ERCP). In the hands of experienced endoscopists, successful biliary cannulation rates are higher than 90%[1]. However, in some cases, bile duct (BD) cannulation can be difficult because of special anatomical features, inflammatory processes, and adenomas of the papilla or periampullary diverticulum. Large prospective studies have demonstrated that difficult cannulation is an independent risk factor for post-ERCP pancreatitis[2-4]. In the past few years, various efforts have been made to develop alternative endoscopic techniques, with the goal of increasing the rate of successful biliary cannulation. The use of a guidewire to physically occupy the pancreatic duct (PD), also known as the double-guidewire technique (DGT), was initially described by Dumonceau *et al*[5]. Since its first description, this method has been used with promising results in cases of complex biliary cannulation, especially in patients with a distorted BD anatomy caused by neoplasia or atypical morphology of the ampulla[6].

Transpancreatic precut sphincterotomy (TPS) using a guidewire, another technique for difficult biliary cannulation, was first described by Goff[7] in 1995. A sphincterotomy over the guidewire in the PD helps to cannulate the biliary orifice because the cut either opens the BD or runs along the side of the duct, thus exposing the duct's anatomy.

DGT and TPS might facilitate biliary cannulation. However, post-ERCP pancreatitis has been reported to occur with DGT and TPS in 0% to 25% of patients[6,8-11]. Most previous studies compared the performance of the new techniques with standard cannulation techniques or precut sphincterotomy. However, there has been no prospective, randomized study of the performance of DGT with TPS in patients with difficult biliary cannulation. Therefore, we designed this randomized, prospective study to compare the outcomes of DGT and TPS in patients with difficult biliary cannulation.

MATERIALS AND METHODS

Study design and patients

This was a prospective, randomized study conducted in the Tertiary Referral Hospital in South Korea. Between January 2005 and September 2010, a total of 1893 ERCPs were performed at Eulji University Hospital, and 71 patients were enrolled in this study. Consecutive patients were considered for inclusion if they underwent ERCP with clear indication of biliary access. Among these patients, those in whom free cannulation of the BD was not possible and selective PD cannulation was achieved without difficulty were enrolled in this study. Patients were excluded for any of the following reasons: (1) age of less than 18 years; (2) subjects who underwent prior biliary or pancreatic sphincterotomy or dilatation or stenting of either duct; (3) acute pancreatitis at the time of the procedure; and (4) intrauterine pregnancy.

Enrolled patients were randomly assigned to either the DGT group or the TPS group. A randomization list for group allocation was generated using computer-based pseudo-random number generators. We compared both techniques for a maximum of 10 extra attempts after randomization which are common BD (CBD) cannulation by each method. Thus, we did not impose a time limit for CBD cannulation. We received approval by our hospital's institutional review board and obtained written informed consent from all 1394 patients.

Endoscopic procedures and patient care after the procedure

Benzodiazepines, anti-spasmodic agents, and non-narcotic analgesics, alone or in combination, were administered routinely before the procedure. Therapy with antibiotics and analgesics was allowed to continue. One senior endoscopist directly performed all procedures using side-viewing endoscopes (JF-240, JF-260V, and TJF-240; Olympus Optical Co., Ltd., Tokyo, Japan).

Standard cannulation techniques were used to attempt biliary cannulation. However, if BD cannulation failed with standard techniques but the PD was successfully cannulated, patients were randomly assigned to either the DGT group or the TPS group, and selective BD cannulation was continued with those techniques.

The DGT was performed as follows. First, after PD cannulation had been achieved without difficulty, a guidewire (0.035-inch Tracer Hybrid® Wire Guide; Wilson-Cook Medical, Bloomington, United States) was left in the PD. Second, another cannula or sphincterotome was passed into the same working channel of the scope alongside the guidewire using the two-devices-in-one-channel method. The tip of the device was positioned in the papilla, and another guidewire (0.035-inch Tracer Metro® Direct™ Wire Guide; Wilson-Cook Medical, Bloomington, United States) was bent over the pancreatic wire to attempt cannulation of the BD (Figure 1A and B).

TPS was performed as follows. After a guidewire (0.035-inch Tracer Hybrid® Wire Guide; Wilson-Cook Medical, Bloomington, United States) had been inserted deeply into the PD without difficulty, the tip of a standard traction sphincterotome was wedged into the pancreatic orifice, and a sphincterotomy was performed with a cutting wire along the biliary direction at 11 o'clock. The incision was made through the septum between the pancreatic and biliary duct with the aim of exposing the BD orifice. The BD orifice was exposed to the left and either below or above the pancreatic orifice. After TPS, the guidewire placed in the PD was removed. Bili-

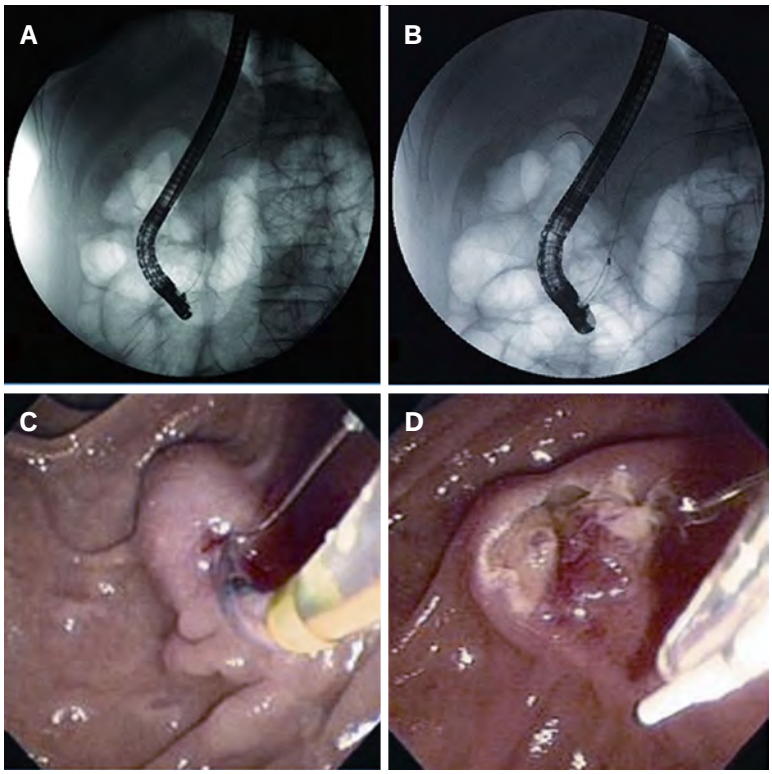

Figure 1 Radiologic images showing the use of double-guidewire technique and transpancreatic precut sphincterotomy. A: Guidewire inserted and left in the pancreatic duct (PD) [double-guidewire technique (DGT)]; B: Common bile duct cannulation with a guidewire after previous insertion of a guidewire in the PD (DGT); C: Sphincterotomy performed with a cutting wire along the biliary direction at 11 o'clock [transpancreatic precut sphincterotomy (TPS)] with guidewire inserted and left in the PD (TPS); D: The bile duct orifice exposed to the left and below the pancreatic orifice (TPS). And then common bile duct cannulation after transpancreatic sphincterotomy.

ary cannulation was then attempted using a catheter or sphincterotome, either with or without a guidewire at the discretion of the endoscopist (Figure 1C and D).

When cannulation of the BD was achieved with the DGT or TPS procedure, additional procedures were performed as necessary.

Serum amylase and lipase levels were checked before ERCP, 4 h and 24 h after ERCP, and when clinically indicated. The presence of abdominal pain attributable to the pancreas and the use and type of analgesic therapy were evaluated at those times.

Outcome measures

The primary outcome measure was the successful biliary cannulation rate. Secondary outcome measures were the median cannulation time and the rates of post-procedure-related complications, post-ERCP pancreatitis, bleeding, perforation, cholangitis, and cholecystitis.

Definition

The standard cannulation technique was defined as the use of a cannulation device (catheter or sphincterotome) preloaded with a guidewire, positioned in the ampullary orifice, and targeting the presumed entry of the CBD. Each cannulation attempt started when the device was inserted into the ampullary orifice and ended when the device was disengaged from the papilla; during the same attempt, while the cannulation device was still in contact with the papilla.

Cannulation success was determined as the achievement of deep biliary cannulation. Difficult biliary cannulation was defined as unsuccessful cannulation after 10 or more attempts with a cannula/sphincterotome or failure of cannulation after 10 min. Successful biliary cannulation at the time of DGT or TPS was considered to be an initial success. In cases in which the first biliary cannulation failed after DGT or TPS, ERCP was repeated within 2 d to 5 d with the consent of the patient, and the same cannulation technique was performed during the second ERCP attempt. Successful biliary cannulation on the first or second ERCP attempt was considered the final success.

The definition of post-ERCP pancreatitis was based on consensus criteria[12], as follows: newly developed or increased abdominal pain within 24 h after ERCP requiring analgesic agents, and the elevation of the serum amylase and/or lipase level by at least three times the normal upper limit at about 24 h after the procedure. Hyperamylasemia was defined as elevation of serum amylase levels to more than three times the normal upper limit at 4 and/or 24 h after the ERCP, without other symptoms. The severity of pancreatitis, bleeding, cholangitis, and perforation were defined as described elsewhere[12].

Sample size calculation

Our hypothesis was that the success rates of biliary cannulation were similar using either DGT or TPS; however, the post-ERCP pancreatitis rate may be lower in the TPS group than in the DGT group. Because an unrealistically large sample size would have been required to examine the biliary cannulation rates in the setting of an equivalence trial, the comparison of post-ERCP pancreatitis rates in a superiority setting was the basis for sample size calculation. Thirty-one patients in each group were needed to detect such a difference with a two-tailed χ^2 test, an a value of 0.05, and a statistical power of 80%.

ERCP: Endoscopic retrograde cholangiopancreatography; DGT: Double-guidewire technique; PD: Pancreatic duct; EST: Endoscopic sphincterotomy; CBD: Common bile duct; GB: Gallbladder; PADD: Periampullary duodenal diverticulum; EPBD: Endoscopic papillary balloon dilatation; ENBD: Endoscopic nasobiliary drainage; ERBD: Endoscopic retrograde biliary drainage; IQR: Inter-quartile range; PEP: Post endoscopic retrograde cholangiopancreatography pancreatitis; TPS: Transpancreatic sphincterotomy.

Statistical analysis

The data were analyzed with SPSS version 14.0 (SPSS Inc., Chicago, IL, United States). Continuous variables were described as median (interquartile range) and compared using Student's *t*-test. Categorical variables were tested using an χ^2 test. Statistical significance was indicated by a two-tailed *P* value of < 0.05. It is recognized that there was multiple testing of outcome data arising from individual patients. In that regard, there was no correction made to the *P* value for the comparison of post-ERCP pancreatitis rates because that comparison was considered to be the focal point when making sample size calculations. All other statistical tests of outcome results should be considered to be secondary, and their results should be taken as descriptive only.

RESULTS

Characteristics of patients

During the study period, 1893 ERCPs were performed at Eulji University Hospital. We excluded 499 patients for the following reasons: age of < 18 years (five patients); previous endoscopic sphincterotomy or endoscopic papillary balloon dilation (399 patients); acute pancreatitis before ERCP (222 patients); and pregnancy (three patients). After this exclusion, ERCP was attempted in the remaining 1394 patients with the native papilla of Vater with standard cannulation technique. In 1291 patients (92.6%), selective BD cannulation was achieved within 10 attempts and 10 min; difficult biliary cannulation occurred in 103 (7.4%) patients. Of these, PD cannulation was also not achieved in 32 patients. Finally, 71 patients in whom deep PD guidewire cannulation was achieved were enrolled in this study and randomly assigned to the DGT group (34 patients) or the TPS group (37 patients) (Figure 2).

The distribution of patients after randomization was balanced, and both groups were comparable in terms of their baseline characteristics, such as ERCP indication, devices used, ERCP findings, and maneuvers. The only significant difference was a higher percentage of endoscopic nasobiliary drainage (ENBD) in the DGT group (55.9% *vs* 13.5%, $P < 0.001$) (Table 1).

Successful BD cannulation rates and median cannulation time

Within the limit of 10 extra attempts, initial successful biliary cannulation was achieved in 27 of the 34 (79.4%) patients in the DGT group and 29 of the 37 (78.4%) patients in the TPS group. Additional successful biliary

cannulation was achieved in four and five patients using the initial technique in the second ERCP trial. Thus, the overall successful biliary cannulation rates, including the repeat ERCPs, were 91.2% (31/34) in the DGT group and 91.9% (34/37) in the TPS group. There was no significant difference in the initial and final cannulation rates of BD between the two groups (Table 1).

In patients who underwent successful biliary cannulation, the mean time of cannulation was 14.1 min in the DGT group and 15.4 min in the TPS group; the difference between the two groups was not statistically significant (Table 1).

Post-ERCP hyperamylasemia and pancreatitis

The overall incidence of post-ERCP hyperamylasemia was 14.7% (5/34) in the DGT group and 16.2% (6/37) in the TPS group. There was no significant difference between the two groups. Post-ERCP pancreatitis developed in 38.2% (13/34) of the DGT group and 10.8% (4/37) of the TPS group. Post-ERCP pancreatitis was significantly higher in the DGT group than in the TPS group ($P = 0.011$). However, most cases of pancreatitis were mild. Moderate or severe pancreatitis developed rarely in both groups (Table 1).

Other complications

One episode of bleeding occurred in the DGT group (2.9%), and two were detected in the TPS group (5.4%). Acute cholangitis developed in 20.6% (7/34) of the DGT group and 5.4% (2/37) of the TPS group. There was no statistically significant difference between the groups in the rates of procedure-related bleeding or cholangitis. However, the incidence of cholangitis in the DGT group was higher than that in the TPS group. Acute cholecystitis and perforation were not detected in any group (Table 1).

DISCUSSION

Several techniques of overcoming difficult biliary cannulation have evolved in the past few years. Needle-knife papillotomy is frequently used to open the biliary entrance and is highly successful when performed by an expert endoscopist. However, the disadvantage of this method is the higher rate of complications, including bleeding, perforation, and pancreatitis. Complication rates of 6% to more than 20% have been reported[2,12,13]. In the 1990s, new techniques for overcoming difficult biliary cannulation, such as DGT, TPS, and wire-guided biliary cannulation over the PD stent, were introduced.

The superior rate of biliary cannulation when using DGT has been attributed to the capability of the pancreatic guidewire to straighten both the PD and BD while at the same time occupying the PD, thus facilitating biliary cannulation and preventing repeated pancreatic cannulation[14,15]. One prospective randomized study reported by Maeda *et al*[8] compared DGT with standard methods, and indicated a higher cannulation success rate (93%) with DGT with no apparent added risk of post-ERCP pancreatitis. However, in the most recent prospective randomized multicenter study by Herreros de Tejada *et al*[6], DGT was not superior to standard cannulation techniques (success rates of 47% and 56%, respectively) and may have been associated with a higher risk of post-ERCP pancreatitis (17% and 8%, respectively).

TPS can facilitate cannulation of the biliary orifice because the cut either opens the BD or runs along the side of the duct, thus exposing the orifice. Akashi *et al*[16] published a prospective series in which TPS was successful in approximately 60% of the patients immediately and in 95% with repeated ERCP. However, the complication rates of TPS were significantly higher than those of standard biliary sphincterotomy (9.9% *vs* 0.8%, $P < 0.001$). In another prospective study by Kahaleh *et al*[17], the primary success rate of pancreatic sphincterotomy was 85%, which, when combined with the needle-knife technique, rose to 95%. The rate of post-ERCP pancreatitis was 8%, which was not different from that of conventional biliary sphincterotomy.

Our results show that the two techniques facilitate selective biliary cannulation with a similar success rate. The initial success rate of DGT in our study was 79.4%, and the final success rate, including the repeat ERCP, was 91.2%. This result is similar to that reported by Maeda *et al*[8] (92.6%), but higher than that reported by Herreros de Tejada *et al*[6] (47%). In the latter study, the difficult cannulation rates were as high as 49.5% and 22%. In comparison, the difficult biliary cannulation rate in our study was lower and more comparable with the experience in high-volume centers. Our difficult biliary cannulation rate was only 7.4%, which represented a truly difficult biliary cannulation group.

In our study, the initial success rate of TPS was 78.4%, and the final success rate was 91.9%. These results are similar to those reported elsewhere[16,17].

The incidence of post-ERCP pancreatitis after DGT was significantly higher than that after TPS (38.2% *vs* 10.8%, $P = 0.011$). Four patients in the DGT group needed special attention. Their total ERCP procedure time was more than 45 min. There were almost twice as many patients with periampullary duodenal diverticulum in the DGT group, but this difference was not statistically significant. Those patients needed more extensive manipulation; therefore, the longer procedure time and the more extensive manipulation might have had an effect on the development of post-ERCP pancreatitis. This may have been another reason for the higher pancreatitis rate in the DGT group. We kept the guidewire inserted into the PD for a longer period of time while attempting selective BD cannulation and removed the PD guidewire after BD cannulation. Conversely, TPS allowed for drainage of the pancreatic juice spontaneously *via* the PD opening, which may have helped decrease the rate of pancreatitis.

The overall post-ERCP pancreatitis rate in this study was 23.9% (17/71). This is similar to those of previous

studies, and most cases of pancreatitis were mild. However, in contrast to the other studies, we did not perform prophylactic PD stenting in any of the cases. The PD stent facilitates biliary cannulation and prevents post-ERCP pancreatitis, but is not usually used in Korea because the health insurance system does not cover the costs of PD stents for prevention of post-ERCP pancreatitis and the financial burden of patients is substantially increased by their use. Another difference is that we did not use any pharmacologic agents for post-ERCP pancreatitis, such as protease inhibitors, which are widely used by Japanese endoscopists. This might have lowered the frequency of post-ERCP pancreatitis in previous studies.

Problems with using a pancreatic guidewire include the potential for injuring branch ducts and the failure to place the guidewire deeply enough into a tortuous main duct. In our study, guidewire insertion into the PD was performed under the guidance of contrast and fluoroscopy to minimize branch duct injury. However, repeated PD injection of contrast is one of the risk factors of post-ERCP pancreatitis.

The incidence of cholangitis after DGT was almost four times higher than that after TPS (20.6% *vs* 5.4%, $P = 0.077$); however, this difference was not statistically significant. Patients with cholangitis had CBD stones or CBD stricture and underwent ENBD insertion. Therefore, we believe that the difference in cholangitis incidence was due to a difference not in methods, but in patients' characteristics. We believe that this is due to *post hoc* fallacy.

Our study has some limitations. First, the number of enrolled patients was relatively small, and the study was conducted in a single tertiary center. We enrolled only 71 patients with difficult cannulation from among a total of 1394 patients (5.1%) who presented for ERCP during the study period. This may have influenced the interpretation of the difference in success and post-ERCP pancreatitis rates. Therefore, a larger study is necessary to overcome this limitation. Second, information regarding the number of PD injections and patients with sphincter of Oddi dysfunction were not collected. This is one of the main limiting factors in drawing a firm conclusion regarding the role of guidewire insertion in the PD in post-ERCP pancreatitis.

In conclusion, we report here successful PD cannulation in cases of difficult BD cannulation. Both the DGT and TPS facilitated biliary cannulation and showed similar success rates. However, the incidence of post-procedure pancreatitis was significantly higher in the DGT group. Therefore, we suggest that the use of TPS when the standard biliary cannulation technique fails and PD cannulation is achieved is effective and has an acceptable complication profile. Further large-scale multicenter studies are needed.

COMMENTS

Background

Selective biliary cannulation is an important step for therapeutic endoscopic retrograde cholangiopancreatography (ERCP). In the hands of experienced endoscopists, successful biliary cannulation rates are higher than 90%. However, in some cases, bile duct (BD) cannulation can be difficult because of special anatomical features, inflammatory processes, and adenomas of the papilla or periampullary diverticulum.

Research frontiers

Double-guidewire technique (DGT) and transpancreatic precut sphincterotomy (TPS) might facilitate biliary cannulation. Most previous studies compared the performance of the new techniques with standard cannulation techniques or precut sphincterotomy. However, there has been no prospective, randomized study of the performance of DGT with TPS in patients with difficult biliary cannulation.

Innovations and breakthroughs

Authors designed this randomized, prospective study to compare the outcomes of DGT and TPS in patients with difficult biliary cannulation. They measured the technical success rates of biliary cannulation, median cannulation time, and procedure related complications.

Applications

Several techniques of overcoming difficult biliary cannulation have evolved in the past few years. Needle-knife papillotomy is frequently used to open the biliary entrance and is highly successful when performed by an expert endoscopist. The superior rate of biliary cannulation when using DGT has been attributed to the capability of the pancreatic guidewire to straighten both the pancreatic duct and BD. TPS can facilitate cannulation of the biliary orifice because the cut either opens the BD or runs along the side of the duct, thus exposing the orifice.

Peer review

Excellent prospective randomized study designed to compare the outcome between two different techniques for endoscopic biliary cannulation. Because this is a randomised controlled trial which showed differences in post ERCP pancreatitis between the 2 methods, it can be published.

Abstract

Vanishing bile duct syndrome (VBDS) is a group of rare disorders characterized by ductopenia, the progressive destruction and disappearance of intrahepatic bile ducts leading to cholestasis. Described in association with medications, autoimmune disorders, cancer, transplantation, and infections, the specific mechanisms of disease are not known. To date, only 4 cases of VBDS have been reported in human immunodeficiency virus (HIV) infected patients. We report 2 additional cases of HIV-associated VBDS and review the features common to the HIV-associated cases. Presentation includes hyperbilirubinemia, normal liver imaging, and negative viral and autoimmune hepatitis studies. In HIV-infected subjects, VBDS occurred at a range of CD4+ T-cell counts, in some cases following initiation or change in antiretroviral therapy. Lymphoma was associated with two cases; nevirapine, antibiotics, and viral co-infection were suggested as etiologies in the other cases. In HIV-positive patients with progressive cholestasis, early identification of VBDS and referral for transplantation may improve outcomes.

INTRODUCTION

Vanishing bile duct syndrome (VBDS) is a term that refers to a group of rare disorders characterized by progressive destruction and disappearance of the intrahepatic bile ducts leading to intrahepatic cholestasis[1]. VBDS has been described in association with autoimmune disorders, medications, cancer, transplantation, and infection, though idiopathic cases have also been described[2]. Immune mediated mechanisms have been proposed[3]. The prognosis is poor with progression to biliary cirrhosis in the majority of cases.

To date only 4 previous cases in human immunodeficiency virus (HIV) infected adults have been reported[2-5]. Antiretroviral therapy (ART) has been implicated as causal in three of the cases[2,4,5]. Here we report two additional cases of biliary ductopenia consistent with VBDS seen in HIV-infected adults cared for at two academic hospitals in 2010. The previously reported cases are reviewed and the potential etiologies, pathogenesis, management and prognosis for VBDS in HIV-infected adults are discussed.

CASE REPORT

Case 1

A 41-year-old man with HIV infection, diagnosed in 1989, was referred for evaluation of a 9-wk history of progressive jaundice. ART was initiated in 1999 with adherence to a regimen of tenofovir, didanosine, atazanavir, and ritonavir for at least 9 mo prior to presentation. CD4+ count was 304 cells/μL and HIV-1 viral load (VL) < 75 copies/mL two months prior to symptoms. He was taking no other medications and had no history of opportunistic infections (OI) or pancreatitis.

Eight weeks prior to referral he was evaluated for a one-week history of fatigue, nausea, abdominal pain, and scleral icterus. He denied new medications, alcohol or drug use. Laboratory studies revealed elevated alkaline phosphatase (AP), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and total bilirubin (TB) 4.7 mg/L. Lipase was elevated at 3571 U/L. All studies were within normal ranges two months earlier. Abdominal computed tomography (CT) scan showed pancreatic enlargement consistent with pancreatitis and a normal appearing liver. Because of concern for ART-associated pancreatitis and liver injury, ART was held and he received nothing by mouth. Magnetic resonance imaging and magnetic retrograde cholangio-pancreatography (MRI/MRCP) of the liver were normal. Subsequently, his nausea and abdominal pain improved, lipase trended down, and his diet was successfully advanced. He was discharged on the third day of hospitalization.

Five days later, he reported worsening fatigue and new generalized pruritus. Laboratory studies showed worsening hyperbilirubinemia (TB 14.3 mg/dL). He was referred to the National Institutes of Health (NIH) for further evaluation.

On admission to the NIH, he was febrile (38.2 ℃) with laboratory studies consistent with progressive cholestasis. CD4+ count was 164 cells/μL and HIV VL was 33 945 copies/mL. Viral hepatitis and autoimmune studies were negative. Epstein Barr virus (EBV) polymerase chain reaction (PCR) was low positive (660 genome equivalents/mL) and cytomegalovirus (CMV) PCR was low positive (< 250 genome equivalents/mL) in blood.

Liver biopsy revealed marked bile duct paucity associated with moderate inflammation, cholestasis, injury of residual ducts, and perivenular hepatocyte dropout with fibrosis (Figure 1B). Less than 10% of portal areas showed an intact duct, confirming the diagnosis of VBDS. No viral inclusions or granulomas were seen. Fungal and acid fast bacilli (AFB) staining were negative. Liver biopsy was negative for CMV by PCR and immunohistochemistry, and low positive for EBV by PCR, however in situ hybridization for EBV was negative. Electron microscopy showed mitochondrial injury, presumably secondary to the patient's prior ART (Figure 1D).

ART was reinitiated three weeks after admission with lamivudine, etravirine, raltegravir and enfuvirtide[6]. Four weeks later, his CD4+ count was 133 (12%) and HIV VL < 50. The patient's hospital course was complicated by pneumococcal sepsis, small bowel intussusception requiring surgical resection complicated by an anastomotic bleed, and renal failure. TB remained elevated, peaking at 45.6 mg/dL, and he was referred for liver transplant evaluation.

Due to poor nutritional and functional status, the patient was not deemed a candidate for liver transplant and was discharged to hospice care. He died two weeks later. Autopsy identified hepatomegaly with marked bile duct paucity, splenomegaly and bloody ascites. Classic Hodgkin's lymphoma, lymphocyte depleted subtype, was found in the lymph nodes of the neck and mediastinum as well as in the gallbladder and common bile ducts (Figure 1E).

Case 2

A 39-year-old African-American male with HIV, diagnosed in 1996, and a history of toxoplasmosis, disseminated *Mycobacterium avium* complex (MAC), seizure disorder, and medication non-compliance, presented with confusion. Evaluation revealed acute renal failure, hyperbilirubinemia and moderately elevated transaminases. Three months earlier, his CD4+ count was 190 cells/μL, HIV VL 136 copies/mL, AP 154 U/L, with normal serum transaminases and bilirubin. His medications included tenofovir, emtricitabine, lopinavir/ritonavir, dapsone, azithromycin, ethambutol, and divalproex. Two weeks prior, he received an unknown antibiotic for a sinus infection.

At presentation, he was awake but not following commands. Examination revealed jaundice and bibasilar rales. Laboratory studies showed pancytopenia, acute renal failure, elevated AP, AST and ALT, with TB 10 mg/dL. CT of the chest, abdomen and pelvis showed bibasilar lung infiltrates and hepatomegaly. He received

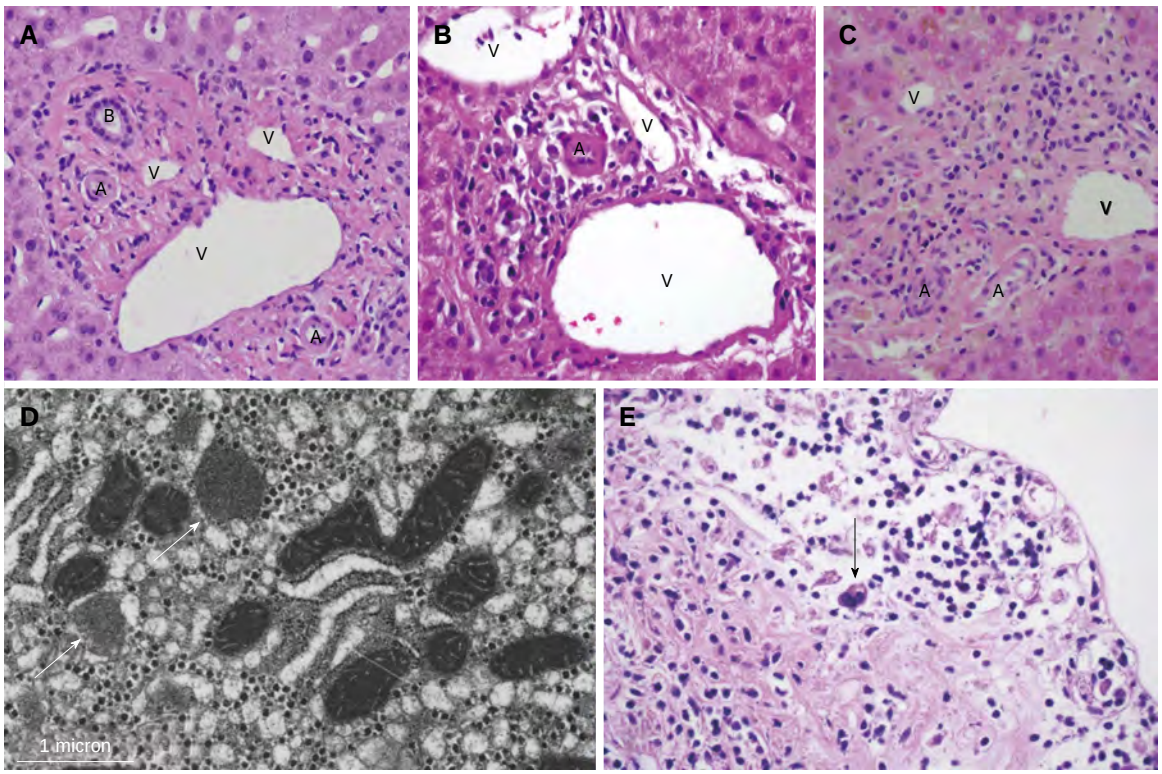

Figure 1 Liver core biopsy. A: Portal tract from normal liver for comparison; B: Portal inflammation and absence of bile duct from the portal area from case 1; C: Portal area showing absence of bile ducts and associated infiltration of lymphocytes and plasma cells from case 2 (HE, 600 ×); D: Electron microgram, case 1. Evidence of mitochondrial toxicity was noted on electron microscopy. Some mitochondria showed loss of cristae, as well as loss of inner and outer membranes, and an amorphous appearance to the mitochondrial matrix (arrows). Similar mitochondrial changes have been described previously in cases of nucleoside reverse transcriptase inhibitor-related hepatotoxicity. Courtesy of Dr. Maria Tsokos, National Cancer Institute Laboratory of Pathology; E: Involvement of the right hepatic bile duct by Hodgkin's Disease seen on autopsy from case 1. A Reed-Sternberg cell (arrow) is seen within the infiltrate beneath the autolysed bile duct (HE, 600×). V: Vein; A: Artery; B: Bile duct.

cefepime for pneumonia and hemodialysis for metabolic acidosis and uremia. His prior medications were held.

MRI/MRCP showed borderline small hepatic ducts with ductal irregularity in the right lobe without definitive obstruction. Liver biopsy showed ductopenia and intrahepatic and canalicular cholestasis. Of eleven portal tracts identified, none contained bile ducts. Where a bile duct would be expected, a mild lymphoplasmacytic infiltrate was seen without resultant expansion of the portal tract or associated piecemeal necrosis (Figure 1C). Fungal and AFB staining were negative. PCR for EBV DNA was low level positive, though no viral cytopathic effect was seen. Immunohistochemistry was negative for CMV or herpes simplex virus.

With supportive care, the patient's mental status improved. ART was reinitiated with etravirine, raltegravir, and ritonavir-boosted darunavir to improve his immune function and prevent recurrent or new OI. Secondary MAC and toxoplasmosis prophylaxis were restarted with ethambutol, azithromycin, and atovaquone. TB remained stable at 25 mg/dL. After discharge, he refused to take his medications and died 3 wk later of multisystem organ failure. Autopsy was not performed.

Summary of other reported cases

Case 3 was a 28-year-old African American female, 31-wk pregnant, who presented with jaundice four weeks after initiating ART with zidovudine, lamivudine, and nevirapine[4]. Prior to initiation of ART, CD4+ count was 234 cells/μL, and VL of 35 853 copies/mL. Liver biopsy showed marked ductopenia and cholestasis. ART was discontinued and the patient was treated with ursodeoxycholic acid. A repeat liver biopsy obtained 8 wk after presentation showed worsening cholestasis and persistent ductopenia. She was referred and listed for liver transplantation, however her cholestasis improved and she was ultimately removed from the transplant list (personal communication, Dr. Rajan Kochar, August 10, 2010). The authors felt that drug-induced liver injury from nevirapine was the likely cause of the VBDS.

Case 4 was a 39-year-old female with advanced acquired immunodeficiency syndrome (AIDS), hepatitis C (HCV) co-infection, and ongoing polysubstance abuse, who presented with one week of scleral icterus, pruritus, and abdominal pain[3]. She was not receiving ART and her CD4+ count was 7 cells/μL and VL 721 000 at presentation. CMV PCR in the blood was positive. Liver biopsy showed marked ductopenia and associated granulomatous inflammation. The authors imputed CMV as the culprit for VBDS, recognizing the potential contribution of HCV co-infection. The patient died one month after presentation

Table 1 Selected medications associated with chronic cholestasis and vanishing bile duct syndrome

Medication class	Medication
Antimicrobials	Penicillins
	Fluroquinolones
	Trimethoprim-sulfamethoxazole
	Azithromycin
	Tetracyclines
	Clindamycin
	Carbapenems
	Itraconazole
	Terbinafine
Antiretrovirals	Nevirapine
Anticonvulsants	Carbamazepine
	Valproic acid
NSAIDS	Ibuprofen
Sex steroids	Testosterone
Antidepressants	Amitriptyline
Antipsychotics	Risperidone
Immunomodulating	Interleukin-2
Anti-lipid Agents	Atorvastatin
	Fenofibrate

NSAIDS: Nonsteroidal antiinflammatory drugs.

Case 5 was a 25-year-old African male with advanced AIDS (CD4+ 108 cells/μL, VL 97 100 copies/mL) who presented with confusion, vomiting and jaundice two weeks after starting zidovudine, lamivudine and efavirenz[2]. ART was discontinued and he received ciprofloxacin and clarithromycin for pneumonia. Three weeks later, ART was reinitiated with tenofovir, lamivudine and nevirapine. One week later, he was readmitted with fever and worsening jaundice. Liver biopsy showed bile duct damage associated with minimal inflammation and absence of ducts in 40% of the visualized portal tracts. His clinical presentation, thought to be consistent with VBDS, was attributed to medications, especially nevirapine, since his clinical deterioration occurred after starting ART. He was referred for liver transplantation evaluation but died approximately one month after referral.

Case 6, available only in abstract form, was a 41-year-old male with HIV, previously well-controlled on a regimen of zidovudine, lamivudine, abacavir and tenofovir[5]. After his HIV RNA increased from < 50 to 454 copies/mL, his ART regimen was changed to abacavir, lamivudine and nevirapine. Liver enzymes prior to ART change were normal. Four weeks later, he developed jaundice and abdominal pain. Liver biopsy showed lack of bile ducts involving all portal tracts with lymphocytic infiltration without eosinophils. Given the temporal association with initiation of nevirapine, nevirapine-induced VBDS was imputed. In subsequent follow-up, the patient was diagnosed with lymphoma and died within a year of VBDS diagnosis (personal communication, Dr. Judith Berger, May 2, 2011).

DISCUSSION

VBDS is a rare cause of progressive cholestasis, most commonly described with drugs but also seen with infection, in cancer and cancer therapy, and in liver diseases such as allograft rejection, graft-versus-host disease, primary biliary cirrhosis and primary sclerosing cholangitis. Diagnosis is made by liver biopsy when interlobular and septal bile ducts cannot be identified in at least 50% of the portal tracts in a biopsy that contains at least 10 portal tracts for assessment[7].

Clinical presentation, similar in HIV-infected and non-HIV-infected patients, varies, with some cases presenting shortly after drug exposure with acute jaundice[4] and others appearing with cholestatic cirrhosis and complications of portal hypertension[7]. Evaluation should include a detailed medication history to identify possible drug causes of cholestasis, laboratory testing to rule out viral and autoimmune hepatitis and primary biliary cirrhosis, and imaging to rule out extrahepatic biliary obstruction. Liver biopsy is required for diagnosis.

The 6 cases in HIV-infected patients described to date share many risk factors for VBDS reported previously in non-HIV patients, including immunocompromise, multiple medication exposures, viral co-infection, and Hodgkin's lymphoma. Given the frequency of risk factors for VBDS in HIV-infected populations, it is perhaps surprising that the diagnosis is so rarely reported.

Remarkable features for the HIV-infected patients include near-total bile duct loss at the time of liver biopsy in 5 of the 6 patients described. The majority experienced irreversible progression with 5 of the 6 patients dying within months of diagnosis. Because diagnosis occurred over a range of CD4+ T-cell counts and levels of HIV viremia, it is difficult to conclude that advanced HIV disease is a predisposition. However, ART and associated immune reconstitution may play an underlying role in some cases, with 3 patients appearing shortly after antiretroviral regimen initiation or change.

Drugs

Many drugs with hepatic metabolism are known to cause hepatotoxicity and cholestasis and have been associated with VBDS[8]. The growing list of drugs associated with VBDS includes most antimicrobial classes, anticonvulsants, antipsychotics, antidepressants, antihistamines, NSAIDS, and sex steroids (Table 1). VBDS has also been described as a component of severe drug reactions, such as Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis[9,10].

The prognosis of drug-induced VBDS appears to be better than with other causes of VBDS with gradual improvement in liver test abnormalities and symptoms described in the majority of reports[11,12]. However, in a portion of patients, the disease is irreversible[10], as seen in 5 of the 6 HIV-positive patients described here.

Drug-induced ductopenia is thought to occur from direct damage caused by toxins or from an immunoallergic reaction where the drug or its metabolites act as haptens that induce an immune response against the biliary epithelium, destroying the intrahepatic bile ducts

and resulting in cholestasis[13]. Histologic descriptions of drug-induced VBDS include marked inflammatory infiltrates, including mononuclear cells, eosinophils, and neutrophils, surrounding bile ducts and accompanied by lobular cholestasis. Sequential biopsies demonstrate decreasing inflammation, increasing cholestasis and progressive ductopenia[13]. Interestingly, there does not appear to be any qualitative histologic difference between cases that improve and those that progress, though reports of ductopenia in allograft rejection suggest that a greater degree of bile duct loss was seen in irreversible cases[14].

Three of the HIV patients were treated with medications described in association with VBDS. Case 1 received empiric treatment for urethritis with ceftriaxone and azithromycin, two medications that could have potentially worsened his underlying liver disease. Case 2 received anti-MAC therapy and an unknown antibiotic for a respiratory infection. His antiepileptic, divalproex, is a pro-drug of valproic acid, a medication reported in association with VBDS. Case 5 received clarithromycin, ciprofloxacin, and ibuprofen. The role of these medications in causing or perpetuating the underlying liver damage is not known.

Though nevirapine has been associated with SJS and hepatoxicity, the 3 reports of VBDS in the setting of nevirapine use did not have features of SJS. However, given the temporal association of nevirapine with VBDS in cases 3 and 6, it has been added to the list of potentially causative agents.

Infection

Bile duct loss has been described in association with viral infections, most frequently HCV[15,16] and CMV,[17,18] less frequently HBV[19] and EBV[20], with most published cases occurring in the setting of transplant or other immunocompromised states.

Cholestatic presentation of HCV is well-described in liver transplant recipients[21], however ductopenia is infrequently observed in patients with chronic HCV. Rarely, this bile duct damage is associated with features of chronic cholestasis or progressive bile duct loss[16]. The mechanism of bile duct damage with HCV is not known. Proposed mechanisms include a direct cytopathic effect of HCV (HCV has been identified in bile duct epithelium[22]) and immune-mediated destruction[16]. Thus, HCV co-infection may have played a role in case 4, though other etiologies including advanced untreated HIV infection, CMV infection, and ongoing alcohol and substance abuse may also have contributed.

CMV infection is the best characterized viral cause of bile duct injury, both in neonates and adults[23,24], and is the most common viral cause of VBDS in liver transplants recipients[25]. The exact mechanism of CMV-related duct injury is not known; infection of the biliary epithelium or immune-mediated mechanisms have been proposed. Bile duct injury with CMV viral inclusions in the biliary epithelium has been shown in neonatal hepatitis and with epithelioid granulomas in adults[26]. One series of VBDS in liver transplant identified ongoing CMV replication in hepatocytes resulting in cholangiocyte death[25].

Case 4, a patient with advanced HIV disease not receiving ART and chronic HCV, had a positive CMV PCR in blood; no CMV studies were reported on the liver biopsy, however granulomatous inflammation was seen. The authors proposed CMV infection as the probable cause of the patient's VBDS. Cases 1 and 2 had low-level positive CMV PCR in blood, however liver biopsy found no evidence of CMV cytopathic effect. Cases 1 and 2 also presented with elevations in lipase consistent with pancreatitis, the etiology of which was not determined. CMV is a recognized cause of pancreatitis in immunocompromised and immunocompetent hosts[27,28], so CMV infection may have played a role in the development of VBDS in these cases.

A role for anti-CMV therapy for the treatment of CMV-associated ductopenic liver disease has not been established. Antiviral treatment in neonatal cholestatic hepatitis remains controversial[29]. The use of antiviral prophylaxis in transplant settings is associated with a decrease in early CMV disease and allograft rejection[30], however the impact on vanishing bile duct syndrome has not been shown.

Lymphoma

Many VBDS cases are associated with cancer and cancer therapy, frequently in association with Hodgkin's lymphoma[31]. Postulated mechanisms for VBDS in lymphoma include lymphoma-induced toxic cytokine release, resulting in bile duct damage either directly or through recruitment of other effector cells, or occult infiltration[31]. Though remission and improvement in cholestasis have been described with lymphoma therapy, the prognosis for VBDS and lymphoma is poor, in part because of chemotherapy dose reduction required to minimize further hepatotoxicity[31,32].

Two of the cases reported here, cases 1 and 6, were diagnosed with lymphoma after diagnosis of VBDS, a pattern of presentation described in non-HIV infected patients[32]. Lymphoma may have played a role in the other fatal HIV-related cases; however, post-mortem examination was not available for cases 2, 4 and 5. Given the high rate of lymphoma in HIV-infected adults[33], suspicion for incident lymphoma in HIV patients with VBDS should be high.

EBV infection could potentially contribute to the development of both lymphoma and VBDS. One patient with Hodgkin's lymphoma (case 1) was EBV DNA PCR positive in blood and liver, though EBV was not identified by in situ hybridization in liver.

Prognosis and treatment

Resolution of VBDS has been reported, both spontaneously[14,34] and in association with immunosuppressants[35,36] and ursodeoxycholic acid[9,37]. In cases of

possible drug-induced cholestasis, withdrawal of the drug is recommended, however in HIV-infected patients receiving ART, the risk of viral rebound and immune decline must be weighed against potential benefit of ART discontinuation. The majority of cases progress despite these interventions, however. In progressive cases, liver transplantation is the only potentially curative option. Successful transplantation has been described in idiopathic biliary ductopenia[38], however, recurrence of disease is frequently reported in patients undergoing liver transplant for chronic cholestatic conditions and with transplant-related ductopenia[39]. For HIV-infected adults access to liver transplant remains restricted, though data suggests that HIV-infected patients with non-viral hepatitis associated liver disease have a better prognosis than those with viral hepatitis[40].

In summary, VBDS is a rare cholestatic liver disease that is usually fatal in HIV-positive patients as a result of progressive destruction and disappearance of intrahepatic bile ducts leading to liver failure. Investigations should be aimed at potential associations of VBDS in HIV-positive patients, including medications, co-infection and lymphoma. Given the association of VBDS with Hodgkin's lymphoma, and the increased incidence of lymphoma in HIV-positive patients, evaluation for lymphoma is reasonable. In HIV-positive patients presenting with an acute cholestatic clinical picture, a high index of suspicion for VBDS, early diagnosis *via* liver biopsy, and referral to a liver transplant center, may improve clinical outcomes.

Abstract

Acute appendicitis, which requires immediate surgical intervention, is an important diagnosis in patients with acute abdomen. However, developmental abnormalities may interfere with the preoperative diagnosis and surgical treatment in some cases. Agenesis and atresia of the cecal vermiform appendix is an extremely rare clinical diagnosis. In addition, preoperative diagnosis may be difficult in some cases. Thus, diagnosis of the congenital absence of the vermiform appendix requires a thorough exploration of the retrocecal and ileocecal regions. A 59-year-old male was admitted from the emergency services with right lower abdominal pain. A celiotomy was performed with the suspicion of acute appendicitis. However, an atresia of the vermiform appendix was observed. The patient's appendix was thus removed. Pathological examination confirmed suppurative appendicitis. This case underlines the importance of the clinical entity for surgeons who may deal with a similar case.

INTRODUCTION

Acute appendicitis is an important diagnosis in patients with acute abdomen, and requires immediate surgical intervention. However, developmental abnormalities of appendix vermiformis may interfere with the preoperative diagnosis and surgical treatment in some cases. Although rare, duplication and agenesis of appendix vermiformis have been reported previously[1-3]. Clinical diagnosis of developmental abnormalities merits a thorough exploration of the abdominal cavity when clinical and surgical findings are atypical[2,4,5]. A definite diagnosis is essential, not only to control the ongoing inflammation due to an overlooked appendix, but also to exclude a cancer misdiagnosis. Here we present an atresia of the vermiform appendix in a patient with acute abdomen.

CASE REPORT

A 59-year-old male was admitted with acute abdomen. His past medical and surgical history was significant for coronary heart disease and a coronary by-pass surgery with two vessels replacement in 2005. His medication included oral anticoagulants and acetaminophen as needed for pain. He denied tobacco, alcohol, or intravenous drug use. He was afebrile and in mild distress at the time of presentation. His abdominal examina-

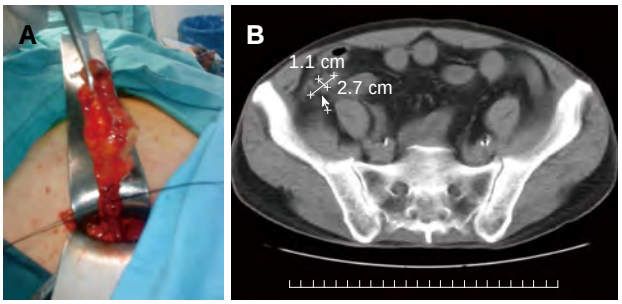

Figure 2 Appendix. A: Appendix; B: Computed tomography image.

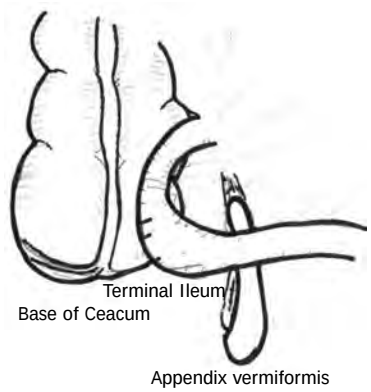

Figure 3 Illustration of the atresia of the appendix vermiformis.

tion was significant for tenderness at McBurney's point with voluntary guarding. Laboratory results revealed an elevated white blood cell count of 12.6 × 10^3/μL and a C-reactive protein level of 5.9 mg/L. Preoperative evaluation of the abdomen with computed tomography (CT) without contrast revealed mildly dilated loops of the small bowel, and questionable appendicitis with periappendiceal inflammation. The patient was thus scheduled for emergent diagnostic celiotomy. The preoperative diagnosis was suspicious for acute perforated appendicitis, and the intention was an appendectomy. Celiotomy was performed through a McBurney's incision. Purulent material in the pericecal and pelvic cavity was observed, and the surgical cavity was cleared with aspiration and irrigation. The cecum and retrocecal region were macroscopically normal in appearance without an appendix vermiformis (Figure 1A). A mass, with a free tip, was observed approximately 10 cm proximal of the ileocecal valve (Figure 2A). The tip of the mass was inflamed and the lumen was ending blindly without a connection to the cecum. The mass was removed after preparation of its mesoappendix-like pedicle (Figure 3). The vascular supply of the mass was the ileocecal artery. Meckel's diverticulum was excluded. After removal of the mass, the peritoneal and pelvic cavities were irrigated with saline, and a drain was placed in the pelvic cavity. Surgical incision was closed primarily. The drain was removed on the fifth postoperative day, and the surgical sutures were removed on the tenth day. Intravenous metronidazole (500 mg twice a day) was begun preoperatively and continued for five days. Analgesics were supplied as the patient needed. Pathological examination confirmed suppurative appendicitis. The initial surgical course was uneventful, but on the third day the patient was recognized to have a decrease in his speech ability and a loss of strength in his left leg. The end diagnosis was a transient ischemic attack from which the patient recovered after medical treatment with piracetam for five days and anticoagulation.

DISCUSSION

Developmental abnormalities of the appendix vermiformis, such as alterations in localization, duplication, or agenesis, may complicate the clinical and surgical presentation of patients with acute abdomen[2,3]. Thus, meticulous preoperative evaluation and surgical exploration of the abdominal cavity is essential in patients with atypical presentations[6-8]. Preoperative abdominal CT scanning may be helpful in some patients. In our case, an atresia of the appendix vermiformis was observed during surgical exploration. Preoperative abdominal CT images were reviewed with an experienced radiologist after surgery. Abdominal CT findings were found to be conclusive, with a focal increase in the thickness of the posteromedial wall of the cecum (Figure 1B). A tubular mass was noticed inferior to the cecum. There was no connection between this mass and the cecum (Figure 2B). In addition, the surrounding mesenteric fatty tissues were found to be dirty due to inflammation. Thus, this case also underlines the fact that a careful evaluation of abdominal CT images is the important part of the preoperative diagnosis. An experienced radiologist should be available to improve the preoperative diagnostic workup in the management of acute abdomen.

Previous reports with appendiceal developmental abnormalities have suggested an association with cancer[5]. In our experience, preoperative clinical presentation was suspicious for perforated appendicitis. However, a perforation was excluded with the presence of a healthy cecum and the observation of the inflamed mass in the ileocecal region. Cancer was excluded with histopathological examination of the resected mass. Routine histopathological examination should not be ignored in patients with appendicitis in order to exclude possible malign disorders[9].

In conclusion, this case is one of the first reports to demonstrate atresia of the appendix vermiformis. In such difficult cases, a surgeon should remember that a thorough exploration of the abdominal cavity is an essential part of the management of the patients with acute appendicitis. Preoperative diagnosis may be improved with the use of abdominal CT. Possible misdiagnoses may lead to inappropriate and inadequate treatment in patients with acute abdomen.

Abstract

Russell bodies are globular and eosinophilic inclusion bodies in the cytoplasm of mature plasma cells. Plasma cells whose cytoplasm is filled with Russell bodies are designated as Mott cells. Russell body duodenitis (RBD) is a unique form of chronic duodenitis that is characterized by infiltration of numerous Mott cells. RBD is very rare; only two cases have been reported to date. In this paper, we report a case of RBD in a patient with retroperitoneal metastasis of ureteral cancer. A 77-year-old man was admitted to our hospital complaining of appetite loss, vomiting, and upper abdominal distension. He had undergone left nephroureterectomy for ureteral cancer 4 years earlier. Upper digestive tract endoscopy revealed edema, stenosis, and punctate redness of the mucosa of the duodenum, and a biopsy was performed. Histological analysis showed that numerous Mott cells had infiltrated the lamina propria mucosae, and the condition was diagnosed as RBD. A mass lesion in the retroperitoneum adjacent to the duodenum was detected by abdominal computed tomography, and was diagnosed as metastatic urothelial carcinoma by biopsy. It is possible that chemokines produced by tumor cells caused RBD in this case.

Russell body duodenitis in a patient with retroperitoneal metastasis of ureteral cancer. *World J Gastroenterol* 2013; 19(1): 125-128 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/125.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.125

INTRODUCTION

Russell bodies are globular and eosinophilic inclusion bodies in the cytoplasm of mature plasma cells, and were first described by Russell[1] in 1890. They correspond to markedly dilated rough endoplasmic reticulum (rER) filled with produced proteins. Plasma cells whose cytoplasm is filled with Russell bodies are designated as Mott cells. Although the appearance of small numbers of Mott cells in chronic inflammation lesions is not rare, the appearance of numerous Mott cells in these lesions is very rare.

In 1998, Tazawa *et al*[2] reported a case of chronic gastritis with the appearance of numerous Mott cells and proposed that such a lesion be designated as "Russell body gastritis (RBG)". Since then, there has been a gradual increase in reported cases of RBG[3-9], and association with *Helicobacter pylori* (*H. pylori*) infection[2,4,6,7], human immunodeficiency virus (HIV) infection[5], and alcohol abuse[2,3,5,8] has been suspected. However, Russell body duodenitis (RBD), which has a similar histological appearance to RBG, is very rare, and only two cases have been reported to date[10,11]. A previously reported case of

RBD occurred in an HIV-positive patient[10]; however, the pathogenesis and clinicopathological characteristics of RBD remain to be determined. In this paper, we report a case of RBD that occurred in a patient with retroperitoneal metastasis of ureteral cancer and discuss the pathogenesis of RBD.

CASE REPORT

A 77-year-old man was admitted to our hospital complaining of appetite loss, vomiting, and upper abdominal distension. He had undergone left nephroureterectomy for ureteral cancer 4 years earlier, and 2 years later, he had undergone chemotherapy (methotrexate + vinblastine + doxorubicin + cisplatin) and radiation therapy (39.6 Gy in total) for paraaortic lymph node metastasis. He did not abuse alcohol, and was HIV-negative. He had not undergone any treatment for *H. pylori*. Edema, stenosis, and punctate redness of the mucosa were observed in the second portion of the duodenum by upper digestive tract endoscopy (Figure 1), and a biopsy was performed. Endoscopic visualization revealed no tumorous lesions in the upper digestive tract mucosa. Computed tomography showed a mass lesion in the retroperitoneum adjacent to the duodenum (Figure 2), and the clinical symptoms were attributed to duodenal obstruction by the mass. Gastrojejunal bypass surgery was performed 2 wk after admission. Biopsy of the retroperitoneal mass was performed during surgery, and the lesion was diagnosed as a metastasis of ureteral cancer. The retroperitoneal metastatic mass subsequently increased in size, and the patient died 2 mo after the surgery. Autopsy was not permitted.

Three biopsy fragments were taken from the second portion of the duodenum. Numerous plasmacytoid cells, whose cytoplasm was filled with eosinophilic inclusion bodies and whose nuclei were eccentrically located, had infiltrated the lamina propria mucosae of one biopsy fragment (Figure 3A and B). Neither nuclear atypia nor mitosis was observed in these cells. These inclusion bodies were positive for periodic acid-Schiff (PAS) staining. Immunohistochemically, the cells were positive for CD138 (Figure 3C), CD38, and CD79a and negative for cytokeratin, confirming that they were plasma cells containing Russell bodies (Mott cells). Although scattered lymphocytes and plasma cells without Russell bodies were also present, these cells showed no nuclear atypia, and no lymphoepithelial lesions were observed. Immunohistochemical staining for κ and λ chains revealed that the infiltrating plasma cells were of polyclonal origin (Figure 3D and E), although Russell bodies showed no obvious positive staining for either antibody. No gastric metaplasia was observed in the epithelium, and no *H. pylori* infection was detected by immunohistochemical staining. The other two duodenal biopsy fragments showed only non-specific chronic inflammation. No cancer invasion was observed in the biopsy fragments. The histological appearance of the biopsy specimen from the retroperitoneal mass was compatible with that of metastatic urothelial carcinoma.

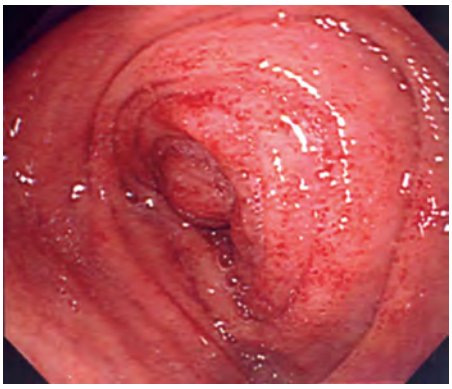

Figure 1 Endoscopic appearance of the duodenum. Edema, stenosis, and punctate redness of mucosa are observed.

Figure 2 Abdominal computed tomography image. A mass lesion is observed in the retroperitoneum adjacent to the duodenum (arrows).

DISCUSSION

The duodenal biopsy in this case helped us to reach a diagnosis of RBD. Differential diagnoses included B-cell lymphomas with plasmacytic differentiation, plasmacytoma, celiac disease, Whipple's disease, and lymphocytic gastroenteritis. Mott cells occasionally appear in B-cell lymphomas with plasmacytic differentiation (particularly mucosa-associated lymphoid tissue lymphoma) and plasmacytoma. However, RBD can be differentiated from B-cell lymphomas and plasmacytoma because no atypical lymphoid or plasmacytoid cells and lymphoepithelial lesions are present and the infiltrating plasma cells show a polyclonal pattern in immunohistochemical staining for κ and λ chains in RBD. In celiac disease, the endoscopy results indicate reduced or absent folds of the small intestinal mucosa, and the histological analysis indicates the accumulation of large fat globules in the surface epithelium. These features of celiac disease were not observed in the present case. In Whipple's disease, the inflammatory cells that aggregate in the lamina propria mucosae of the small intestine are not Mott cells, but large macrophages whose cytoplasm contains large amounts of a diastase-resistant, PAS-positive material. Lymphocytic gastroenteritis is characterized histologically by increased numbers of intraepithelial lymphocytes (mostly cytotoxic T-cells), which were not observed in the present case.

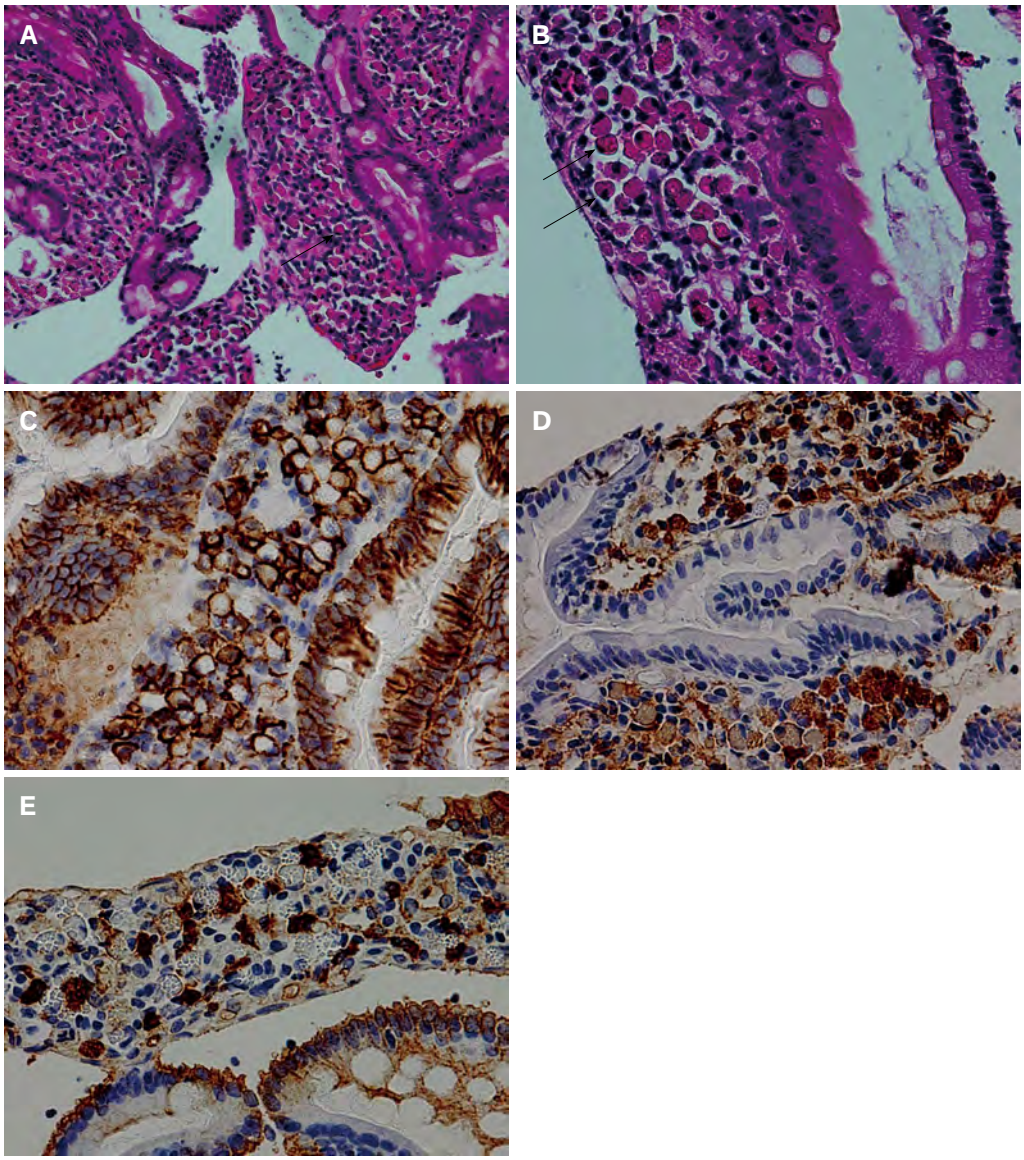

Figure 3 Histological appearance of the duodenal biopsy. A, B: Numerous Mott cells (arrows), whose cytoplasm is filled with eosinophilic inclusion bodies (Russell bodies), infiltrate the lamina propria mucosae (HE stain, A: × 200, B: × 400); C: Immunohistochemically, Mott cells are positive for CD138 (× 400); D, E: Infiltrating plasma cells show a polyclonal pattern upon the immunohistochemical staining for κ (D) and λ (E) chains (× 400).

Russell bodies are eosinophilic inclusions in the cytoplasm of plasma cells. They are situated within the cisternae of the rER and contain non-immunoglobulin molecules, by-products of immunoglobulin synthesis, or some altered form of immunoglobulins that can no longer be recognized by an anti-immunoglobulin antibody[12,13]. They may be formed by excessive production of, or failure in, the secretion of immunoglobulin molecules[12]. The appearance of numerous Mott cells in the lesion in cases of chronic inflammation is very rare, and the diagnosis of RBG/RBD is made when numerous Mott cells appear in a chronic gastritis/duodenitis lesion. RBG/RBD is thought to be a focal condition[2]; the fact that RBD was found in only one of three duodenal biopsy fragments in the present case is consistent with this hypothesis.

Although reported cases of RBG are gradually increasing in number[2-9], RBD is very rare, and only two cases have been reported to date[10,11]. The first reported case of RBD[10] was that of a 55-year-old HIV-positive man whose chief complaint was abdominal pain. The upper digestive tract endoscopy revealed non-specific gastritis and duodenitis. Histologically, gastric metaplasia was observed in the duodenal epithelium, although *H. pylori* infection was not detected. The second reported RBD case[11] was that of a 69-year-old woman. She complained of refractory dysphagia; however, this symptom was thought to be unrelated to the duodenal lesion. Using endoscopy, the RBD lesion was recognized as a nodule within the duodenal bulb. Histological analysis indicated gastric metaplasia in the duodenal epithelium, although neither *H. pylori* nor other discernible microorganisms were identified. The patient in our study was a 77-year-old HIV-negative man, and the clinical symptoms were appetite loss, vomiting, and upper abdominal distension; however, these symptoms were attributed to

obstruction of the duodenum by retroperitoneal metastasis of ureteral cancer. Endoscopic findings were nonspecific inflammation, and no *H. pylori* infection was detected. No gastric metaplasia was detected in the duodenal epithelium in the present case.

H. pylori infection was detected in more than half of the reported cases of RBG[2,4,6,7], and it is estimated that antigenic stimulation by *H. pylori* is an important factor in the etiology of RBG. Alcohol[3,5,8] or analgesic[3] abuse and/or HIV infection[5,10] were reported in the *H. pylori*-negative RBG/RBD cases, and stimulation or immunological abnormality caused by these factors may also be important in the pathogenesis of RBG/RBD. The present patient did not have any of these suggested etiological factors for RBG/RBD. It is noteworthy that metastatic urothelial carcinoma was present in the vicinity of the duodenum in the present case. Several cancer cases with prominent Mott cell proliferation have been reported[14,15], and it is speculated that chemokine production by tumor cells may be the cause of Mott cell accumulation in these cases[14]. Thus, chemokine production by tumor cells may be the cause of RBD in the present case, although cancer invasion was not present in the duodenal mucosa. It is possible that *H. pylori* infection is not important in the RBD pathogenesis, because no *H. pylori* infection has been detected in any of the reported RBD cases, including the present case. However, the pathogenesis of RBG/RBD should be further investigated using larger number of cases and molecular techniques.

In summary, this paper has described a case of RBD occurring in a patient with retroperitoneal metastasis of ureteral cancer. This is the third RBD case to be reported. It is possible that chemokines produced by tumor cells caused RBD in the present patient. It is important that pathologists maintain enough knowledge of the disease to avoid misdiagnosis of the condition as malignant diseases, such as B-cell lymphomas and plasmacytoma. The clinicopathological features of RBD should be further elucidated by continually accumulating and studying reported cases.

Abstract

Ring calcification in untreated hepatocellular carcinoma (HCC) is extremely rare, with only 3 previously reported cases in the English-language literature. A case of HCC with ring calcification was reported in this paper. Additionally, 3 previously reported cases of HCC with ring calcification were reviewed. In 3 of these 4 cases (including our case), surgery was performed. Although the size of the ring-calcified lesion ranged from 3.0-3.7 cm in previously reported cases, the size was only 1 cm in ours. The differentiation of the tumor was moderate in the 2 previously reported cases in the histological findings and poor in ours. In spite of their poor differentiation for their sizes, these tumors showed no early enhancement in dynamic computed tomography. All calcified tumors showed a thick fibrous capsule and extensive necrosis histologically. Ring calcification was considered to result from a circulatory disturbance caused by the imbalance between the less abundant arterial blood flow and high inner pressure induced by either the thick fibrous capsule or vigorous proliferation due to the poor differentiation. Ring calcification in untreated HCC may suggest a lower differentiation of the tumor. Even if its size is small, hepatic resection should be performed for any tumor with ring calcification because poor differentiation is considered to be one of the risk factors for recurrence after local ablation therapy, including radio frequency ablation.

Small hepatocellular carcinoma with ring calcification: A case report and literature review. *World J Gastroenterol* 2013; 19(1): 129-132 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/129.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.129

INTRODUCTION

Macroscopic calcification in untreated hepatocellular carcinoma (HCC) (the term "untreated HCC" is defined as HCC that was not treated with local ablation, local injection, or embolization prior to the development of calcification) is considered rare, and has reportedly been observed in only 1.9%-3.3% of cases[1-5]. Ring calcification in untreated HCC is extremely rare, with only 3 previously reported cases in the English-language literature[6,7]. We present a case of small HCC (1 cm in diameter) showing ring calcification. To elucidate the clinical and histological characteristics of this entity, we reviewed previously reported cases of HCC with ring calcification in the English-language literature.

CASE REPORT

A 68-year-old woman with a 19-year history of chronic hepatitis C was referred for surgery because of a hepatic

tumor in segment 4 (defined by Couinaud's nomenclature for liver segmentation) (Figure 1). Despite no elevation in either the serum alpha-fetoprotein (AFP) or des-γ-carboxy prothrombin (DCP) levels and no enhancement in the dynamic computed tomography (CT) study, the tumor was suspected to be HCC from the patient' s history of hepatitis C. The patient was offered surgery for the tumor but rejected the offer at that time. Six months after the first diagnosis of the tumor, the serum AFP level was elevated (128 ng/mL, but no elevation in DCP level) and the tumor showed ring calcification (Figure 1). Furthermore, an irregularly shaped tumor, which was broadly in contact with the calcified lesion and showed early enhancement in dynamic CT, was observed, whereas the calcified lesion showed no enhancement in any phase (Figure 1). After a detailed informed consent process explaining the necessity of surgery, the patient accepted the offer of surgery and underwent segment 4 segmentectomy 9 mo after the first diagnosis.

Macroscopically, a 10-mm tumor with ring calcification and an 18-mm tumor were identified in the same thick fibrous capsule (Figure 2A). Microscopic examination revealed findings of poorly differentiated HCC in the calcified lesion and moderately differentiated HCC in the non-calcified lesion (Figure 2B). Each lesion comprised only a single differentiated component and had a thick fibrous capsule (Figure 2A). With regard to the calcified tumor, extensive necrosis was diffusely observed in the tumor, suggesting that the necrosis was caused by a circulatory disturbance. The ring calcification formed inside the thick fibrous capsule (Figure 3).

The postoperative course was uneventful, and the patient is doing well without recurrence 30 mo after the surgery.

Review of the literature

A PubMed search on August 2012 for articles published since 1965 with the key words "hepatocellular carcinoma" and "calcification" yielded 62 articles published in English-language journals. These publications were all reviewed. There were only 2 articles describing 3 cases of untreated HCC with ring calcification[6,7], resulting in a total of 4 reported cases. The demographic data are shown in Table 1. The previously reported sizes of ring-calcified lesions ranged from 3.0 to 3.7, but ours was only 1 cm. Three of the four cases underwent hepatic resection. The remaining case did not receive any treatment for HCC because of markedly poor general condition, resulting in no histological confirmation for the diagnosis of HCC. Of the 3 cases for which histological findings were obtained, differentiation was moderate in the 2 previously reported cases and poor in our case. All 3 calcified lesions consisted of a single differentiated component. These 3 cases had a thick fibrous capsule, and the ring calcification formed inside the fibrous capsule. Additionally, in the previous 2 cases with histological findings, similar findings to our own case were observed; extensive necrosis was diffusely observed in the tumor[6,7].

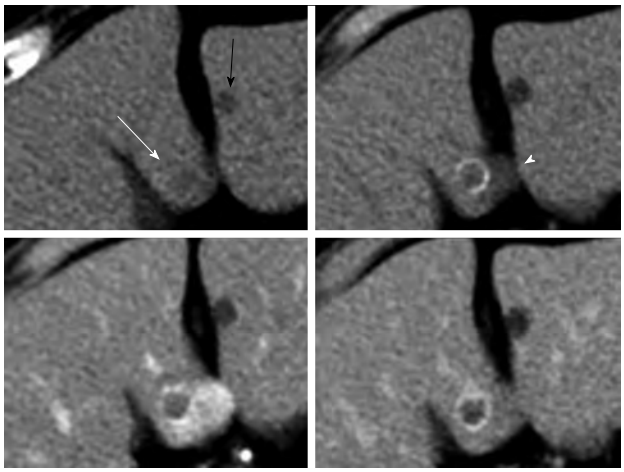

Figure 1 Findings of computed tomography. Upper left, plain abdominal computed tomography (CT) taken at the initial diagnosis revealed a 1-cm low-density lesion without calcification in liver segment 4 (white arrow). A small low-density area found in the left lateral section was a liver cyst (black arrow); upper right, plain abdominal CT taken 6 mo after the initial diagnosis revealed that the lesion had a ring calcification and an adjacent 1.8-cm lesion (white arrowhead); lower left and right, abdominal CT taken 6 mo after the initial diagnosis in the early phase (lower left) after a bolus administration of intravenous contrast material showed enhancement of the newly appeared lesion and the delayed phase (lower right) showed that it was hypoattenuated.

DISCUSSION

The cause of calcification in HCC is considered to be dystrophic calcification, in which deposition occurs locally in nonviable or dying tissues with normal serum levels of calcium and in the absence of a dysfunction in calcium metabolism[4-7]. Dystrophic calcification in untreated neoplasms is most commonly observed in meningioma, papillary thyroid carcinoma, and ovarian serous cystadenocarcinoma[8]. In such tumors, the mechanisms leading to the formation of calcifications in the tumors have been thoroughly analyzed[8]. Although the exact mechanism of calcification formation is not well understood, it has been suggested to be the following. In such tumors, spontaneous tumor necrosis occurs easily due to micro-infarction caused by their structural property, which predisposes microcirculatory disturbance. Matrix vesicles and matrix giant bodies derived from degenerated or necrotic cells sequester hydroxyapatite crystals to form seed crystals. Mineral deposition encrusts these crystals. Collagen and elastic fibers derived from degenerated basement membranes adjacent to necrotic cells are a prerequisite for the calcification to be identifiable because the expansion of hydroxyapatite deposition requires these connective tissues as nidi[8]. Namely, tumors with abundant stromal tissues, in which ischemic necrosis easily occurs, are likely to show identifiable dystrophic calcification. Therefore, the reason for why calcification in untreated HCC is rarely observed can be explained as the following. HCC is less abundant in stromal tissue and has a hypervascular structure, in which blood flow is primarily composed of arterial flow, which is less likely to cause spontaneous microcirculatory disturbance[9-11]. Converse-

Table 1 Summary of 4 cases of hepatocellular carcinoma with ring calcification

Case	No.	Age	Sex	Symptom	AFP (ng/mL)	Size of calcified lesion (cm)	Location	Early enhancement in dynamic CT	Viral infection	Background liver	Histology	Treatment
Fukuya *et al*[6]	1	72	F	No	178	3.0	S8	No	HCV	CH	Mod diff HCC	Partial hepatectomy
Fukuya *et al*[6]	2	77	F	No	9300	3.0	S8	Yes	HCV	LC	Not obtained	None
Kawada *et al*[7]	3	67	F	Abdominal pain Back pain	Not mentioned	3.7	S4	Yes	HCV	CH	Mod diff HCC	Left lobectomy
Our case	4	68	F	No	128	1.0	S4	No	HCV	CH	Poorly diff HCC	Left medial sectionectomy

AFP: Alpha-fetoprotein; CT: Computed tomography; F: Female; S8: Segment 8 (defined by the Couinaud's nomenclature for liver segmentation); S4: Segment 4; HCV: Hepatitis C virus; CH: Chronic hepatitis; LC: Liver cirrhosis; Mod diff: Moderately differentiated; Poorly diff: Poorly differentiated; HCC: Hepatocellular carcinoma.

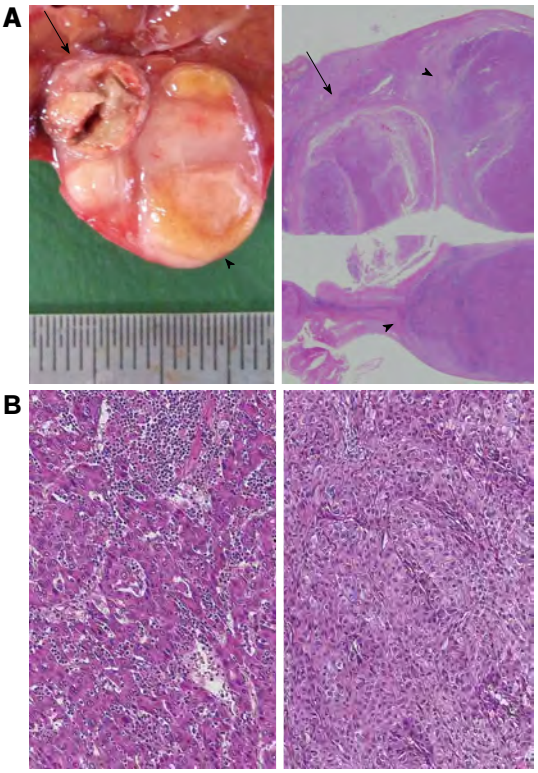

Figure 2 Macroscopic findings of the resected specimen, calcified and non-calcified lesions. A: Left, macroscopic examination showed a 10-mm tumor with ring calcification (arrow) and an 18-mm tumor (arrowhead) existing side-by-side and encapsulated within the same thick fibrous tissue; Right, a prepared specimen (loupe image, hematoxylin and eosin staining); B: Left, microscopic examination findings of the calcified lesion showed the poorly differentiated hepatocellular carcinoma (hematoxylin and eosin staining; original magnification, × 200); Right, microscopic examination findings of the non-calcified lesion showed moderately differentiated hepatocellular carcinoma (hematoxylin and eosin staining; original magnification, × 200).

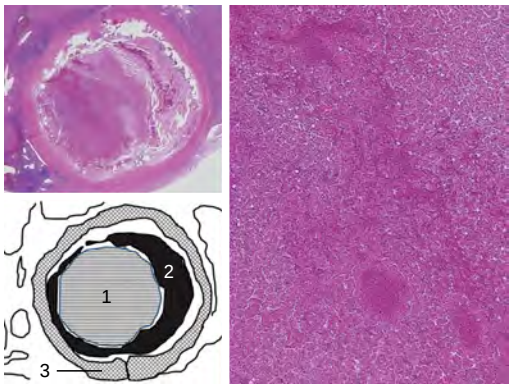

Figure 3 Schematic image of the structure of the calcified lesion. Upper left, loupe image of the calcified lesion (hematoxylin and eosin staining; original magnification, × 5); Right, microscopic findings of the calcified lesion showed that necrotic area was extensively observed in the tumor (hematoxylin and eosin staining; original magnification, × 40); Lower left, schematic of the structure of the calcified lesion. A poorly differentiated tumor, in which spotty necrosis and hemorrhagic necrosis were extensively observed, was surrounded by a fibrous capsule. Calcification was identified between the tumor and the fibrous capsule (1: Poorly differentiated tumor; 2: Calcification; 3: Fibrous capsule).

ly, calcification being observed often in HCC treated by trans-catheter arterial chemoembolization, which causes ischemic necrosis in tumors[4-7], suggests that extensive ischemic necrosis is essential for forming identifiable calcifications in neoplasms.

In the present study, tumors showing a ring calcification with histological findings revealed extensive necrosis histologically. A ring calcification formed in the marginal zone of relatively small tumors in contact with a thick fibrous capsule. Furthermore, these tumors consisted of a single relatively low-differentiation component. In fact, calcified lesions in the previously reported cases were composed of only a moderately differentiated component, whereas the calcified lesion in our case was only composed of a poorly differentiated component; all 3 tumors with histological findings showed poor differentiation for their sizes (1-3.7 cm)[6,7]. Furthermore, these tumors showed no early enhancement in dynamic CT study[6,7], suggesting that these tumors had less abundant arterial blood flow, unlike the usual cases of moderately or poorly differentiated HCC[9-11]. Furthermore, all 3 tumors had a thick fibrous capsule for their size. A fibrous capsule surrounding HCC is usually observed with relatively large and less histologically differentiated tumors[12-14]. It is not known exactly how the fibrous capsule is formed, but the formation is known to result from the interaction between the tumor and host liver and interferes with the growth and invasion of HCC[12-14]. The fibrous capsule is primarily composed of collagenous tissue produced principally

by stellate cells (the so-called fat-storing cell of Ito), which are present among the tumor cells in the vicinity of the boundary between the HCC and non-tumor liver[12-14]. Furthermore, it was reported that the fibrous capsule of HCC contains smooth muscle cells and has contractile ability, whereas the septa of multi-nodular HCC or hepatic cirrhosis does not have either[12]. Based on these findings, we hypothesize that ring calcification forms through the following process. Tumors with ring calcification in this series had less abundant arterial blood flow and had a high internal pressure induced by either the thick fibrous capsule or vigorous proliferation, as suggested by their low differentiation for their sizes. This imbalance between the blood flow and the internal pressure causes a circulatory disturbance in the tumor, resulting in extensive ischemic necrosis. Necrotic tumor cells cause mineral deposition that subsequently involves adjacent collagenous fibers produced by the stellate cell in the marginal zone and elastic fibers derived from the cytoskeleton of degenerated or necrotized tumor cells as the nidi to extend along the fibrous capsule, forming annular calcification. Identifiable calcification cannot be formed in the inner zone because of the absence of collagenous fiber as the nidus. In other words, the prerequisites for forming a ring calcification in untreated HCC are the following: small size, poor differentiation, a thick fibrous capsule, and less abundant arterial blood flow. These prerequisites are the reasons why a ring calcification in untreated HCC is extremely rare. On the other hand, tumors with ring calcification are considered to be likely to show poor differentiation for their sizes. Therefore, HCCs with ring calcification are likely to show a poorer prognosis than other tumors of their size when local ablation therapy is applied for treatment[15]. In treating these lesions, therefore, hepatic resection should be selected even if the size is small and ablation therapy seems feasible[15].

In conclusion, we present an extremely rare case of small HCC (1 cm in diameter) showing ring calcification and a review of the English-language literature including 3 other cases. We believe that ring calcification in untreated HCC is suggestive of the poorer differentiation of the tumors. Therefore, hepatic resection should be performed for these lesions because poor differentiation is considered to be one of the risk factors for recurrence after local ablation therapy.

Abstract

Phytobezoar is the most common type of bezoar. It is composed of indigestible vegetable matter and is usually found in the stomach. Biliary phytobezoar is extremely rare and difficult to diagnose preoperatively. The pathogenesis is not clear, and there have been only a few reports of biliary bezoars associated with sphincteric impairmentat the ampulla of Vater. Here, we present a report of biliary bezoar that resulted in jejunal obstruction. We were unable to identifythe bezoar in the extrahepatic bile duct until it obstructed the small bowel lumen. To our knowledge, this is the first report of small bowel obstruction resulting frommigration of a biliary bezoar.

INTRODUCTION

A bezoar is an intragastric mass consisting of accumulated ingested material. Phytobezoars, the most common type of bezoar, are masses of indigested vegetable matter including skin, seeds, and fruit and vegetable fiber, and are most commonly reported in patients who have had previous gastric surgery[1]. Although normally found in the stomach, a phytobezoar may pass into the small bowel. Primary small bowel bezoarsare very rare, but can form in patients with underlying small bowel disease such as diverticulum, stricture, or tumor[2]. Phytobezoars can also develop secondarily if there are areas of sufficient stagnation within a dilated small bowel loop, as may occur in patients with strictures caused by previous surgery, Crohn's disease, or tuberculosis[3].

We encountered a case of small bowel obstruction by a 'biliary' phytobezoar, which was formed in the extrahepatic bile duct and migrated into the small bowel resulting complete obstruction. Intestinal obstruction due to bezoars is rare, reportedly constituting only 0.44% of all small intestinal obstructions[4,5], and there is an even greater paucity of reports regarding small bowel obstructions caused by the migration of biliary bezoar. The first case report of bezoar-induced obstructive jaundice caused by an intradiverticular bezoar was published by Seryrig *et al*[6] in 1989, and to date, fewer than 5 cases of biliary bezoar have been reported in the English language literature[6-9].

This report concerns a rare case of biliary bezoar resulting intestinal obstruction, including imaging and clinicopathologic details.

CASE REPORT

A 72-year-old woman visited the emergency department with a 3-d history of abdominal pain. She had undergone open cholecystectomy with common bile duct (CBD) exploration for acute calculus cholecystitis 12 years previously. Since then, she had experienced recurrent episodes of obstructive jaundice and been hospitalized 3 years ago for recurrent pyogenic cholangitis. Multi-detector computed tomography (MDCT) at that time had shown diffuse and marked bile duct dilatation with pneumobilia (Figure 1A). Although the extent of dilatation was remarkable, there was no evidence of an obstructive mass within the bile ducts. The patient underwent endoscopic retrograde cholangio-pancreatography (ERCP), which revealed a choledochoduodenal fistula (Figure 1B). She was treated with endoscopic nasobiliary drainage and antibiotics and subsequently discharged after a few days of hospital stay.

A routine MDCT checkup 6 mo after discharge showed neither interval changes of the extensive biliary dilatation nor pneumobilia. The choledochoduodenal fistula was seen, along with a newly visible large mass at the extrahepatic bile duct with multiple internal air densities and low attenuation areas resembling impacted food material that was associated with luminal dilatation (Figure 1C). These MDCT features were suggestive of CBD stone or refluxed food material from the second portion of the duodenum (Figure 1D).

When the patient presented to the emergency room, MDCT confirmed small-bowel obstruction and showed proximal luminal dilatation of the jejunum with focal wall thickening of the transition zone of the mid-jejunum. In the transition zone, well-defined, thin-walled, ovoid food remnants were observed, consistent with bezoars, and these were assumed to be the cause of the obstruction (Figure 2A and B).

The patient underwent exploratory laparotomy with enterotomy, and the obstructing mass at the proximal jejunum was removed. Inflammation-induced segmental wall thickening was observed in the involved small bowel however, there was no sign of bowel perforation or ischemia. The resected mass was pathologically confirmed as a biliary bezoar (Figure 2D), and the histological evaluation indicated that theremoved objects were revealed as fibrinoid materials with some cellular debris.

When we retrospectively reviewed the preoperative computed tomography (CT) images, we concluded that the previously noted CBD mass, which was thought to be refluxed food or a stone, had disappeared. This mass had apparently migrated along the gastrointestinal tract until it reached the jejunal loop of the small bowel, where it resulted in obstruction (Figure 2C). The patient was discharged 1 wk after surgery without any postoperative complications.

DISCUSSION

Phytobezoar is a type of bezoar that consists of remnants of poorly digested food materials. Phytobezoars are usually reported in patients who have poor mastication, a vegetarian diet, have ingested persimmons, or have undergone previous gastric surgery and vagotomy resulting in diminished motility[10-12].

Biliary phytobezoar is extremely rare, and is reported to develop in patients who have had previous cholecystectomy. In 1995, Lamotte *et al*[6] were the first to describe a biliary bezoar, which developed in a patient 15 years after cholecystogastrostomy[13]. In other reports, including the present case, biliary bezoar shave developed in patients who have undergone cholecystectomy and had subsequent formation of choledochoduodenal fistulas[9]. Thus, development of biliary bezoar seems to be related to loss of the sphincteric mechanism due to previous biliary-enteric anastomosis or sphincterotomy, which allows reflux of undigested vegetable fibers or food particles from the alimentary tract into the bile ducts[7]. However, biliary bezoarhas also developed in the patients without any sphincteric disruption or impairment. Thus, it is conceivable that some vegetable matter can enter the bile duct through an intact sphincter[7,8].

It is reported that MDCT is the most useful method for diagnosing of small-bowel bezoars because it is able to reveal precise details including location, degree, and features of bezoars[14]. When a patient has a well-defined round or ovoid mass in the intraluminal space with mottled gas pattern causing small-bowel obstruction, bezoar should be considered as the cause of obstruction[14]. A study from France on CT findings that could differentiate small-bowel bezoars from small-bowel feces suggested'floating fat density debris', as a CT feature of bezoars, which can be defined in images showing fat-density debris in a region proximal to the obstruction site with dilated bowel loops[15]. The definition proposes that this unusual density arises from the sum of the tissue density of the debris and the negative density of trapped air. However, in our case, no such low-density feature was noted.

MDCT findings for biliary bezoars causing intestinal obstruction have not been previously reported. A biliary bezoar entrapped in the small bowel can be confused with an intraluminal gallstone associated with gallstone ileus or with other types of bezoars formed within gastrointestinal tract. The Rigler's radiologic criteria (evidence of an ectopic stone in the intestine, air in the biliary tree and gall bladder, and small-bowel obstruction) and direct visualization of choledochoduodenal fistula by MDCT are well known pathognomonic factors for the diagnosis of the gall stone ileus[16,17]. Although the present case fulfilled most criteria for the diagnosis of the gall stone ileus, mottled air densities of intraluminal mass in transition zone of intestinal obstruction was different from Rigler's criteria and this finding provided diagnostic clue for the final diagnosis as the bezoar rather than gall stone.

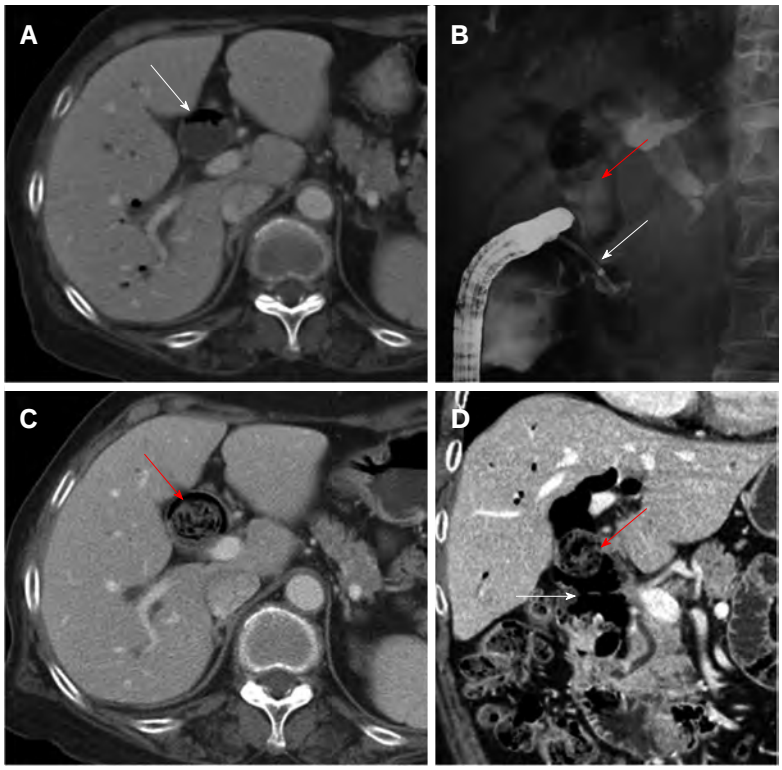

Figure 1 Development of a biliary phytobezoar in the extrahepatic bile duct. A: Axial portal venous-phase computed tomography (PVP CT) 3 years ago showing diffuse bile duct dilatation (white arrow) with pneumobilia; B: On endoscopic retrograde cholangiopancreatography, there was no abnormal filling defect except pneumobilia (red arrow) in the dilated extrahepatic bile duct (EHD). A choledochoduodenal fistula (white arrow) in the distal common bile duct which was cannulated by endoscopy; C and D: Axial PVP CT and its coronal reformatted image at 6-mo follow-up showed a dilated EHD and a newly developed intraductal ovoid mass with interstitial air (red arrows), as well as the choledochoduodenalfistula (white arrow).

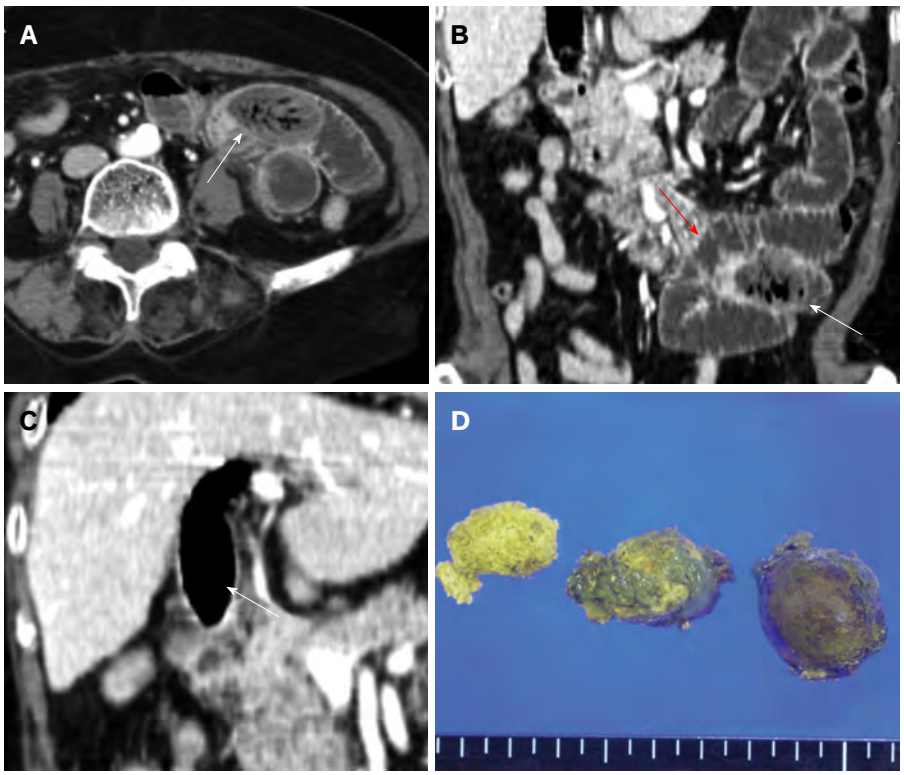

Figure 2 Migration of the biliary phytobezoar resulting in mechanical obstruction of the jejunum. A and B: Axial portal venous computed tomography and coronal reformatted image at admission showed the migration of the ovoid intraluminal mass (white arrows) with mottled gas pattern to the jejunal loop, as well as a dilated proximal loop (red arrow) containing air-fluid levels suggestive of obstruction; C: Empty extrahepatic bile duct (white arrow) with extensive residual pneumobilia after migration of the bezoar; D: Gross specimen and cut surface of the biliary bezoar.

It is not possible to classify biliary foreign bodies, including biliary bezoars, in patients who have not had previous surgery or who do not have a biliary enteric fistula, because the radiologic and macroscopic characteristics of biliary bezoarson MDCT and ERCP resemble those of bile duct stones[18]. Therefore, it is important to carefully check for the presence of biloenteric communication and predisposing factors related to bezoar formation ahead of a preoperative diagnosis of a biliary bezoar, because, as noted, most biliary bezoarsare associated with a previous history of biliary abnormality such as choledocho or cholecystoduodenal fistula or diverticula in the walls of the bile ducts and duodenum.

Surgical or laparoscopic excision is the treatment of choice for small bowel bezoars. The entire gastrointestinal tract must be explored to exclude synchronous bezoars and prevent recurrent bowel obstruction caused by residual bezoar[3]. Other non-surgical treatment options include sodium bicarbonate powder, a liquid diet, enzymatic digestion with various agents, endoscopic fragmentation, and oral intake (or endoscopic injection) of 'Coca-Cola'[19]. A study using combinations of the cola and the endoscopic treatment showed a relatively good response in terms of ability to dissolveor decrease the size of phytobezoars[20].

In conclusion, we have presented a case of small bowel obstruction caused by biliary phytobezoar. Although it is considered extremely rare, biliary bezoar can be one of the possible causes of the mechanical small bowel obstruction in patients with the previously mentioned predisposing factors. We have presented this case to promote further awareness of the interesting phenomenon of biliary bezoar formation associated with abilo digestive fistula, as well as the possibility of subsequent small bowel obstruction due tomigration of the biliary bezoar.

Abstract

Leiomyoma is the most common benign mesenchymal tumor of the esophagus. A small leiomyoma covered with endoscopically normal mucosa has a characteristic endoscopic ultrasonographic appearance, slow growth rate, and negligible risk of malignant transformation; therefore the histology does not need to be proven. Synchronous tumors such as an epithelial tumor and small subepithelial tumor in the upper gastrointestinal tract are uncommon. We describe a case with a co-existing small leiomyoma and severe dysplasia in the esophagus which were completely resected by endoscopic mucosal resection.

INTRODUCTION

Leiomyoma is the most common benign mesenchymal tumor in the esophagus[1,2]. A small and asymptomatic leiomyoma covered with endoscopically normal mucosa does not require surgical treatment such as resection because it has a characteristic endoscopic ultrasonographic appearance, slow growth rate, and negligible risk of malignant transformation[3]. A few cases involving co-existing tumors such as epithelial tumor and subepithelial tumor in the esophagus have been reported. However, in all of these reports the tumors were larger than 1 cm, were squamous cell carcinoma[4-8], and most were treated with surgery. A subepithelial lesion smaller than 1 cm combined with epithelial dysplasia is extremely unusual. We present a patient with an epithelial lesion of severe dysplasia overlying a small leiomyoma in the muscularis mucosa of the esophagus. Both lesions were completely removed simultaneously by endoscopic mucosal resection (EMR).

CASE REPORT

A 67-year-old male patient visited our hospital following the incidental finding of a subepithelial lesion at the mid-esophagus. He was a non-smoker, with no previous medical history and had good performance. Esophagogastroscopic examination showed a protruding mass, measuring 1 cm × 1 cm in dimension, without any ulcer or erosion, covered with normal mucosa (Figure 1A). We examined the lesion using narrow-band imaging (NBI) which showed scattered brown dots, and dilated and tortuous vessels on the top of the lesion (Figure 1B). We judged that the lesion might have dysplasia. Endoscopic ultrasonography was performed in order to determine the depth and nature of the tumor. Findings indicated

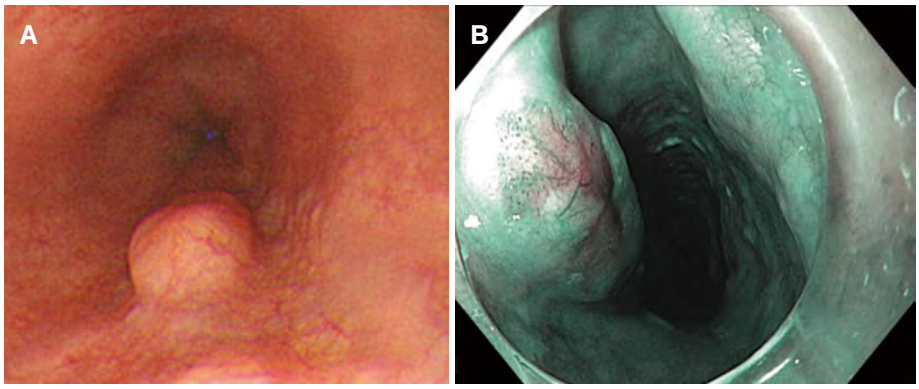

Figure 1 Endoscopic findings. A: Endoscopic findings demonstrate a subepithelial tumor with intact overlying mucosa; B: Chromoendoscopy with narrow band imaging showed scattered brown dots, and dilated and tortuous vessels on the top of the lesion.

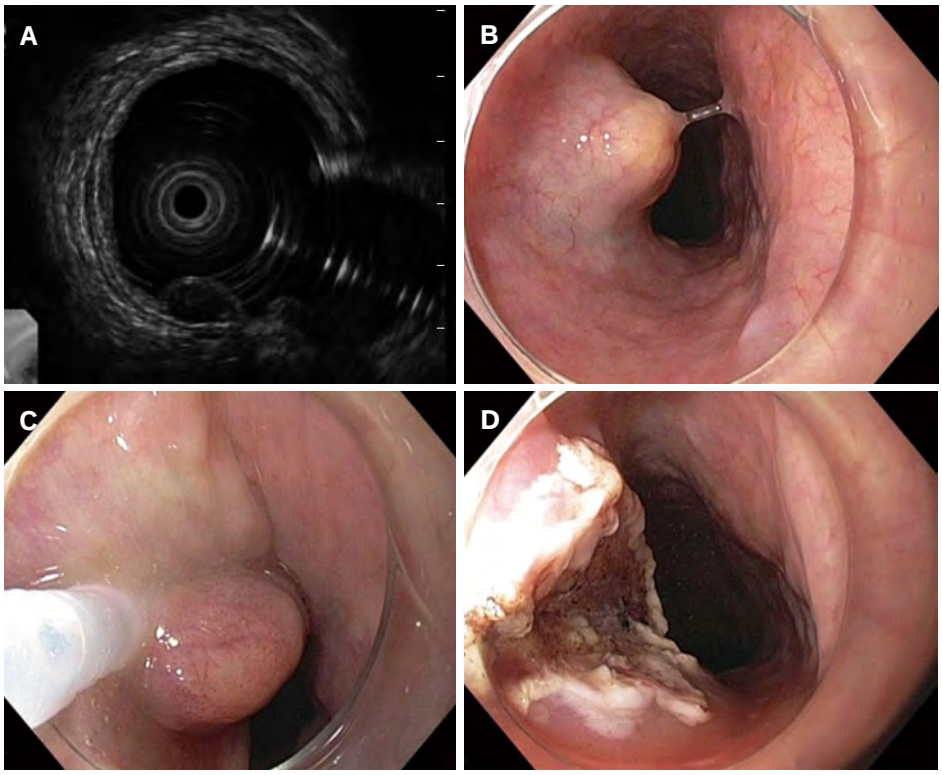

Figure 2 Endoscopic ultrasound findings and procedures for endoscopic mucosal resection. A: High frequency ultrasonic endoscopic findings showed a clear homogenous hypoechoic mass derived from the second layer of the esophagus; B: After making a submucosal bleb; C: The subepithelial lesion was captured using a snare; D: No immediate complications occurred after endoscopic mucosal resection.

that the lesion, which measured 5.0 mm × 4.0 mm in size, was a homogenous hypoechoic mass, confined to the second layer, the muscularis mucosa (Figure 2A). We performed a mucosal biopsy. Histological examination of the specimen indicated severe dysplasia. We diagnosed severe dysplasia overlying a small leiomyoma from the muscularis mucosa. Therefore, we planned *en bloc* resection by endoscopy for removal of the synchronous lesions. Endoscopic resection was performed using the EMR method. Following injection of hyaluronic acid into the submucosa, resection was performed using a snare (Figure 2B and C). No complications related to the procedure were observed (Figure 2D). Histopathological examination of the tumor revealed high-grade dysplasia with a clear resection margin and the results of immunohistochemical analyses revealed that the leiomyoma was negative for C-Kit and CD 34, and positive for smooth muscle actin (Figure 3).

DISCUSSION

The present case of severe epithelial dysplasia overlying a small subepithelial tumor was treated with EMR.

Due to improvements in diagnostic tools and prolonged lifespan rates, the diagnosis of esophageal subepithelial lesions is increasing. Leiomyoma is the most

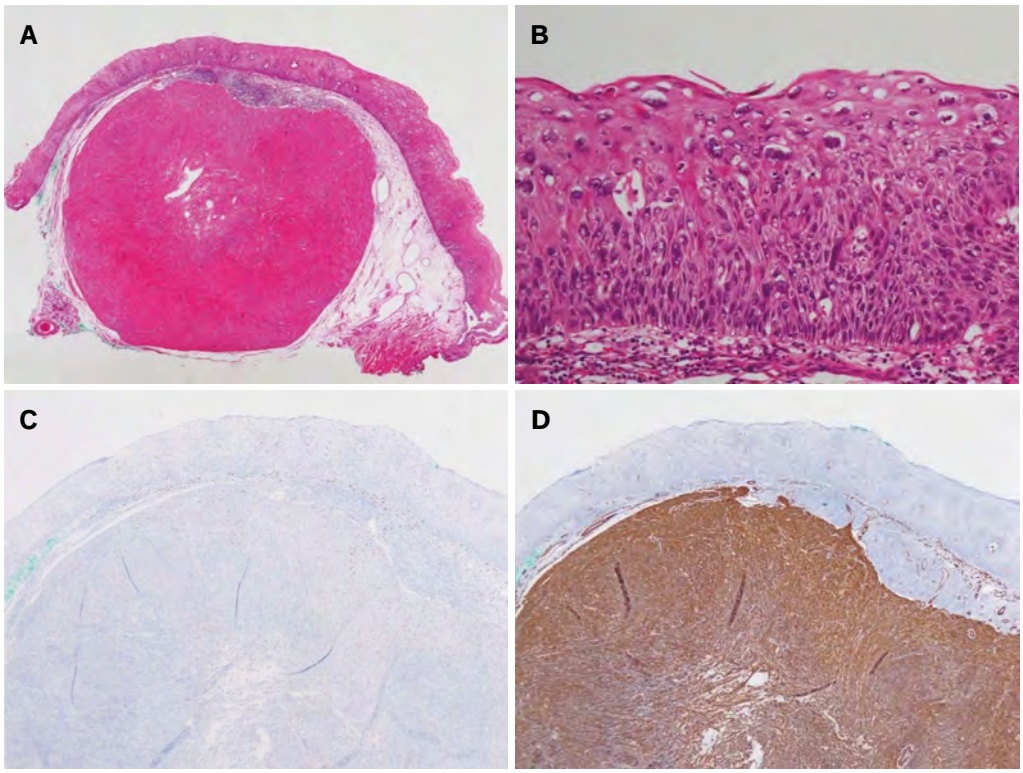

Figure 3 Histopathologic findings. A: Esophageal leiomyoma arising from the muscularis mucosa (HE, 20 ×); B: Atypical cells in all three areas of the epithelium, but not full thickness, showed severe dysplasia (HE, 200 ×); C: The esophageal leiomyoma was negative for CD117 (C-Kit); D: The esophageal leiomyoma showed strong and diffuse positive staining for smooth muscle actin (200 ×).

common subepithelial tumor of the esophagus. Esophageal leiomyomas account for approximately 12% of all gastrointestinal leiomyomas[9]. Esophageal leiomyomas may occur in the muscularis propria layer or the muscularis mucosa of the esophagus. With the development of the high frequency ultrasonic endoprobe, detection of the origin of leiomyomas, even in small lesions, appears to be easier[10]. On occasion, those arising from the muscularis mucosa can present as polypoid intraluminal tumors. In a review of 838 cases, only 1% were the polypoid intraluminal type[11]. The question of whether a leiomyoma can show malignant degeneration is controversial. If it were possible, the risk would be negligible. Thus, when a small leiomyoma covered with normal mucosa is encountered on endoscopy, a biopsy is not recommended[1].

The co-existence of an epithelial lesion and a subepithelial lesion is rare. Twelve patients in ten case reports with carcinoma located in the mucosa overlying a benign tumor have been reported[4-6,12]. All cases were squamous cell carcinoma and the subepithelial lesions were larger than 1 cm. Eight patients were treated surgically. However, this is the first case of epithelial dysplasia overlying a leiomyoma measuring less than 1 cm in the esophagus.

It is not clear whether both lesions occurred at the same time and whether there were any causative relationships. However, we suggest that there was synchronous development of the subepithelial and epithelial lesions. After development of a leiomyoma, external stimuli may change the mucosa. Epithelial dysplasia is the principal precursor lesion of esophageal squamous cell carcinoma. Studies have shown that esophageal squamous cell carcinoma develops through a progressive sequence from mild to severe dysplasia[13]. Predisposition to esophageal dysplasia may be related to certain carcinogenic stimuli, dietary factors, and individual genetic susceptibility[13]. The patient was a non-smoker and did not have any relevant medical history. He did not have any risk factors for esophageal cancer. We assume that focal mechanical stimuli might induce mucosa dysplasia. However, determination of a dysplastic lesion on conventional endoscopy is difficult, even when using an iodine stain. The prevalence of severe dysplasia derived from iodine-stained tissue is quite low (< 1%)[14]. The specificity of NBI for severe dysplasia performed by experienced endoscopists has been reported to be up to 100%[15]. Therefore, a subepithelial lesion presenting with an intraluminal polypoid mass should be examined closely using electronic chromoendoscopy with NBI and tissue biopsy. However, there is a risk of bleeding and scattering malignant cells with tissue biopsy. Furthermore, scarring after tissue biopsy can create problems in the complete removal of lesions. The examination of simultaneous lesions is important. If NBI findings suggest dysplastic change, it is better to resect the lesion without tissue biopsy. Severe dysplasia overlying a leiomyoma originating from the muscularis mucosa can be removed safely using an endoscopic technique[10].

In conclusion, a polypoid subepithelial tumor of the

esophagus is usually very small; however, it can occur with simultaneous epithelial dysplastic change. If the lesions are detected early using novel endoscopic imaging, they can be removed endoscopically.

Abstract

Polycystic liver diseases (PCLDs) are a heterogeneous group of genetic disorders characterized by the development of multiple fluid-filled cysts in the liver, which derive from cholangiocytes, the epithelial cells lining the bile ducts. When these cysts grow, symptoms such as abdominal distension, nausea, and abdominal pain may occur. PCLDs may exist isolated (i.e., autosomal dominant polycystic liver disease, ADPLD) or in combination with renal cystogenesis (i.e., autosomal dominant polycystic kidney disease and autosomal recessive polycystic liver disease). The exact prevalence of PCLDs is unknown, but is estimated to occur in approximately 1:1000 persons. Although the pathogenesis of each form of PCLD appears to be different, increasing evidences indicate that hepatic cystogenesis is a phenomenon that may involve somatic loss of heterozygosity (LOH) in those pathological conditions inherited in a dominant form. A recent report, using highly sophisticated methodology, demonstrated that ADPLD patients with a germline mutation in the protein kinase C substrate 80K-H (*PRKCSH*) gene mostly develop hepatic cystogenesis through a second somatic mutation. While hepatocystin, the PRKCSH-encoding protein, was absent in the hepatic cysts with LOH, it was still expressed in the heterozygous cysts. On the other hand, no additional trans-heterozygous mutations on the *SEC63 homolog* (*S. cerevisiae*/*SEC63*) gene (also involved in the development of PCLDs) were observed. These data indicate that PCLD is recessive at the cellular level, and point out the important role of hepatocystin loss in cystogenesis. In this commentary, we discuss the knowledge regarding the role of somatic second-hit mutations in the development of PCLDs, and the most relevant findings have been highlighted.

Banales JM, Munoz-Garrido P, Bujanda L. Somatic second-hit mutations leads to polycystic liver diseases. *World J Gastroenterol* 2013; 19(1): 141-143 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/141.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.141

TO THE EDITOR

We have read with great interest the recently publication by Janssen *et al*[1] in *Gastroenterology*. The manuscript nicely demonstrate that cystogenesis in polycystic liver diseases is mostly associated with a loss of heterozygosity (LOH) in the biliary epithelial cells, termed cholangiocytes[2]. In this study, the group of professor Drenth employed blood and liver cystic tissue from 8 female ADPLD

patients, who had a heterozygous germline mutation in the protein kinase C substrate 80K-H (*PRKCSH*) gene (5 patients with a c.1341-2A>G mutation and 3 with a c.292+1G>C mutation) resulting in premature stop codons. Moreover, no additional germline mutations in *SEC63* were detected in any of these patients. By using laser microdissection of hepatic cysts, they found that 76% of the liver cysts presented a secondary somatic mutation in the normal *PRKCSH* allele (i.e., LOH). In contrast, the surrounding liver tissue and blood of the patients showed heterozygosity for this gene (Figure 1). Additionally, no detectable somatic changes in the *SEC63 homolog*-(*S. cerevisiae*/*SEC63*) gene sequence were found in cystic epithelium compared to non-epithelial cells or blood DNA, excluding trans-heterozygous *SEC63* somatic mutations as a cause of cyst formation in cysts without somatic *PRKCSH* mutations.

The authors also indicated that hepatic cysts presented different somatic mutations extended through out the 70-kilo-base region in the majority (97%) of the cysts. These data support the concept that cyst formation results from a specific genetic event in a subset of cells. Although all known mutations in ADPLD are heterozygous, the fact that ADPLD bile ducts express hepatocystin and ADPLD cystic cholangiocytes do not express this protein *via* a 2-hit somatic genomic mutation support the hypothesis that this disease in recessive on a cellular level. Interestingly, sequencing of full *PRKCSH* gene in those 12 cysts without LOH showed that 2 of them, despite expressing hepatocystin, developed a somatic missense mutation. Therefore, the other cysts without LOH in the *PRKCSH* gene may represent all the other mutations in other genes that may lead to cyst formation.

We agree with the authors that it is important to remark that although somatic 2-hit mutations in *PRKCSH* may develop anywhere in the body, cyst formation is only seen in the liver. This observation indicates that the liver-specific phenotype of ADPLD patients is a consequence of a more sensitive response of cholangiocytes to the lack of hepatocystin. Because liver cysts display cholangiocyte features and no malignant transformation, the possibility that a somatic 2-hit mutation originating from a liver progenitor cell would explain the cyst development and the hyperproliferative properties of the cysts. There have been reports on the presence of 2-hit mechanisms in other non-malignant diseases including autosomal dominant polycystic kidney disease (ADPKD), where a somatic LOH was found in a proportion of both kidney and liver cysts[3,4].

Polycystic liver diseases (PCLDs) are genetic disorders characterized by the development of fluid-filled cysts in the liver derived from cholangiocytes[5-7]. The exact prevalence of PCLDs is unknown, but is estimated to occur in approximately 1:1000 persons. The most common symptoms are caused by enlargement of the liver, and include abdominal distension, dyspepsia, abdominal pain, and early satiety. Although not found

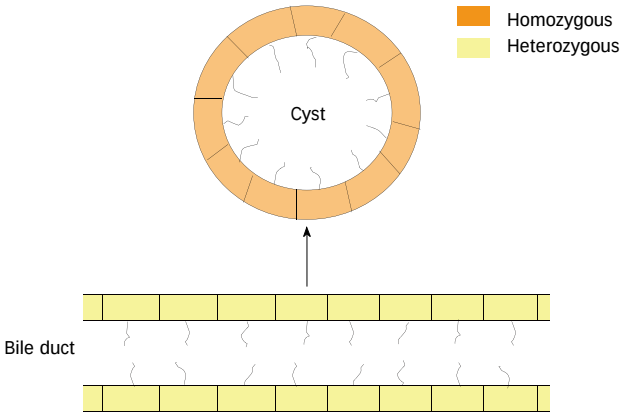

Figure 1 Chart representing the second somatic mutations occurring in the majority of cysts from autosomal dominant polycystic liver disease patients. Most of autosomal dominant polycystic liver disease cysts with a protein kinase C substrate 80K-H germline mutation develop over time a second somatic mutations in the same gene that result in the loss of heterozygosity and cyst formation.

frequently, serious complications such as portal hypertension and haemorrhage, or infections of cysts, may also occur[5-7]. The liver phenotype may exist isolated (i.e., ADPLD) or in combination with renal cystogenesis (i.e., autosomal dominant polycystic liver disease ADPLD, and autosomal recessive polycystic liver disease, ARPKD)[5-7]. ADPLD is a rare disease that can be caused by mutations in *PRKCSH* or *SEC63* genes, which encode for the endoplasmic reticulum (ER)-associated proteins hepatocystin and Sec63, involved in glycosylation and transport of glycoproteins into and out of the ER, respectively[5]. On the other hand, the genes responsible for the development of ADPKD (1:1000 prevalence) are *PKD1* and *PKD2*, which encode for polycystin-1 and polycystin-2, respectively[6,7]. Polycystin-1 is a mechanoreceptor involved in calcium signalling, and polycystin-2 a non-selective calcium channel. Finally, ARPKD (1:20.000 prevalence) is caused by mutations in the *PKHD1* gene, which encodes for fibrocystin, a protein with unknown function[6,7]. The pathogenesis of each form of PCLD appears to be different. However, alterations in different mechanisms such as proliferation, fluid secretion, and cell-matrix interactions seem to play an important role in all of them. Moreover, these altered events seem to be also associated with changes in the microRNA expression pattern, with increased levels of cyclic adenosine monophosphate levels, and with downregulation of the intracellular calcium levels[8,9]. Currently, there is no standard treatment for PCLDs. Pharmacological approaches include somatostatin analogues and mammalian target of rapamycin-inhibitors, but most clinical trials have only shown a small reduction of liver volume. On the other hand, the most frequently used surgical procedures are aspiration and sclerotherapy, fenestration, segmental hepatic resection, and liver transplantation, which have a better short term effect, but high recurrence and complication rate preclude wide spread use[5].

In summary, this article represents a milestone in the understanding of the molecular mechanisms involved in liver cystogenesis and leads to several questions such as the unknown mechanisms causing LOH in PCLDs, as well as the role of 2-hit somatic mutations in all forms of PCLDs, including ADPLD patients with a germline mutation in SEC63.

Abstract

Gastrointestinal stromal tumors (GISTs) are the most common soft tissue sarcoma of the gastrointestinal tract, resulting from an activating mutation of stem cell factor receptor (KIT), and an activating mutation of the homologous platelet-derived growth factor receptor alpha (PDGFRA) kinase. Most GISTs (90%-95%) are KIT-positive. About 5% of GISTs are truly negative for KIT expression. GISTs have been documented to resistant conventional chemotherapeutics. Due to the KIT activation that occurs in the majority of the cases, KIT inhibition is the primary treatment approach in the adjuvant treatment of metastatic GISTs. Imatinib mesylate is an oral agent that is a selective protein tyrosine kinase inhibitor of the KIT protein tyrosine kinase, and it has demonstrated clinical benefit and objective tumor responses in most GIST patients in phase Ⅱ and Ⅲ trials. The presence and the type of KIT or PDGFRA mutation are predictive of response to imatinib therapy in patients with advanced and metastatic disease. Molecular analysis in phase Ⅰ-Ⅱ trials revealed significant differences in objective response, progression-free survival, and overall survival between GISTs with different kinase mutations. The aim of this letter is to touch on the need for exon mutation analysis for adjuvant treatment with imatinib in GIST patients.

Şendur MAN, Özdemir NY, Akıncı MB, Uncu D, Zengin N, Aksoy S. Is exon mutation analysis needed for adjuvant treatment of gastrointestinal stromal tumor? *World J Gastroenterol* 2013; 19(1): 144-146 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i1/144.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i1.144

TO THE EDITOR

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms of the gastrointestinal tract. In general, 75% to 85% of GISTs have an activating mutation of stem cell factor receptor (KIT), 5% to 7% have an activating mutation of the homologous platelet-derived growth factor receptor alpha (PDGFRA) kinase, and approximately 12% to 15% of GISTs do not have a detectable mutation[1-3]. Imatinib mesylate is an oral agent that is a selective tyrosine kinase inhibitor of the KIT, PDGFRA, Abelson (ABL), and ABL activated by fusion with the *BCR* gene tyrosine kinases. Phase Ⅱ and Ⅲ trials have demonstrated that imatinib is effective against metastatic GIST in more than 50% of patients[4-7]. The presence and the type of KIT or PDGFRA

mutation are predictive of response to imatinib therapy in patients with advanced and metastatic disease. Molecular analysis in phase Ⅰ to Ⅱ trials revealed significant differences in objective response, progression-free survival (PFS), and overall survival (OS) between GISTs with different kinase mutations[8]. Previously published studies have shown that the outcomes of patients with KIT exon 11-mutant GIST were better than for patients with KIT exon 9-mutant GIST and tumors without a detectable KIT mutation[1,9]. In a recent trial, Joensuu *et al*[10] reported that in the adjuvant treatment of high risk of recurrence GIST patients, 36 mo of imatinib treatment improved recurrence-free survival (RFS) and OS compared with 12 mo of imatinib treatment. In this study, the KIT exon 11 mutation was found in nearly 65% of both groups. In exon 11 mutation-positive patients, RFS was statistically improved in the 36-mo imatinib treatment group compared with the 12-mo treatment group. However, RFS was not statistically significantly changed in all remaining patients who had a positive mutation other than exon 11, and who had extension of the treatment to 36 mo compared to 12 mo. The presence and the type of KIT or PDGFRA mutation are predictive of response to imatinib treatment. Heinrich *et al*[8] reported that the presence of the KIT exon 11 mutation in advanced GIST patients who were treated with imatinib correlated with improved objective response, time to tumor progression and OS, when compared with the presence of the KIT exon 9 mutation and wild-type genotypes. In the Finnish B2222 trial, assessing imatinib treatment in metastatic GIST patients, the partial response rate was 83.5% for those patients with positive exon 11 mutation, whereas it was 47.8% in exon 9 mutation-positive patients[1].

A randomized European Organisation for Research and Treatment of Cancer phase Ⅲ trial reported that treatment with imatinib 800 mg/d had a significantly superior PFS compared to imatinib 400 mg/d in advanced GIST patients with an exon 9 mutation[11]. Also, Heinrich *et al*[8] reported that imatinib 800 mg/d had improved response rates compared to imatinib 400 mg/d in advanced GIST patients with positive exon 9 mutation. DeMatteo *et al*[12] reported that adjuvant imatinib therapy compared to placebo treatment appears to prolong RFS following the resection of primary GIST, but the effect of mutation on RFS was not reported. On these grounds, the optimal duration of treatment and the optimal dose are not known for operable GIST with a high risk of recurrence, other than for exon 11 mutation patients.

In conclusion, analysis can disclose the type of exon mutation which can be predictive of response to adjuvant imatinib treatment in GIST patients.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access (OA) journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

Aims and scope

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

WJG is published by Baishideng Publishing Group (BPG) in both electronic and online forms. All *WJG* articles are published in *WJG* website and PubMed Central. The major advantages of OA journals are faster release and delivery, no page or graph restrictions, and increased visibility, usage and impact. Full-text PDF articles and electronic/online versions are freely available to global readers. After the paper is published, the author(s) can obtain high-quality PDF files, which contain the journal cover, a list of editorial board members, table of contents, text, and back cover of the journal. BPG has a strong professional editorial team composed of editorial board members, editors-in-chief, science editors, language editors, and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, *etc.*; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in gastroenterology and hepatology; (12) Brief

Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (13) Meta-Analysis: To evaluate the clinical effectiveness in gastroenterology and hepatology by using data from two or more randomised control trials; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Thomson Reuters, 2011 Impact Factor: 2.471 (32/74 Gastroenterology and Hepatology).

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc*. The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement
In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked

to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/…"), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list,

e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nihgov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

Examples for paper writing

All types of articles' writing style and requirement will be found in the link: http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade B certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Publication fee

WJG is an international, peer-reviewed, open access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 1365 USD per article. All invited articles are published free of charge.

APPENDIX	I-VI	Instructions to authors
ABOUT COVER		Editorial Board Member of *World Journal of Gastroenterology*, Dr. Mukaddes Esrefoglu, Professor, Department of Histology and Embryology, Inonu University, 44280 Malatya, Turkey

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Numerous techniques developed in medicine require careful evaluation to determine their indications, limitations and potential side effects prior to their clinical use. At present this generally involves the use of animal models which is undesirable from an ethical standpoint, requires complex and time-consuming authorization, and is very expensive. This process is exemplified in the development of hepatic ablation techniques, starting experiments on explanted livers and progressing to safety and efficacy studies in living animals prior to clinical studies. The two main approaches used are *ex vivo* isolated non-perfused liver models and *in vivo* animal models. *Ex vivo* non perfused models are less expensive, easier to obtain but not suitable to study the heat sink effect or experiments requiring several hours. *In vivo* animal models closely resemble clinical subjects but often are expensive and have small sample sizes due to ethical guidelines. Isolated perfused *ex vivo* liver models have been used to study drug toxicity, liver failure, organ transplantation and hepatic ablation and combine advantages of both previous models.

INTRODUCTION

Progress in science and medicine depends on new ideas being developed, tested and introduced into mainstream practice. Animal experimentation is used not only in medicine and surgery but also in science, the pharmaceutical industry, the military and educational establishments. In medicine it is essential to establish beyond doubt the safety of a drug, instrument or procedure before it even begins phase 1 of clinical trials. To establish the safety of this heterogeneous range of treatments the medical profession has frequently had no option but to the use of live animals. Although this practice is highly undesirable and many people are morally opposed to these experiments, unless and until viable alternatives are available legislation prevents the introduction of these new drugs and procedures without this prior testing. Indeed virtually all drugs and surgical treatments that are in use today have been tested on animals.

Although the best treatment for liver tumour remains surgical resection[1] the majority of patients are still affected by unresectable lesions. To these patients hepatic ablation provides an opportunity to increase survival[2]. Experimental research over the last twenty years has seen the development of a number of ablative modalities and

several of these have been applied clinically[3,4]. Ablation experiments are now focused to increase the diameter of the ablation zone to achieve better tumor margins[5-12], or to conduct safe ablations on lesions positioned close to major vessels[13-16]. Numerous experimental models are available, each with different advantages, disadvantages and ethical implications. It is therefore imperative that the researcher that wants to explore the field of experimental hepatic ablation is aware of their characteristics.

HISTORICAL BACKGROUND OF ANIMAL EXPERIMENTATION

The Greeks almost 2500 years ago described the earliest recorded animal experiments. Aristotle (384-322 BC), and Erasistratus (304-258 BC)[17,18] both performed studies on live animals and in 2nd century Rome Galen who is known as the father of vivisection dissected live goats and pigs[19]. These studies continued into the Roman era and were then passed on to medical schools in Arabia. The practice died out after this and was absent completely in the Dark Ages only being revived in Italy in the 16th century. Subsequently live animals have been used throughout history to study a wide range of problems and to assess new treatments particularly drugs and vaccines. In the 17th century, many pivotal discoveries came to light because of these studies including the understanding of lung function and the circulation of the blood. In the 1840's general anesthesia emerged (initially ether and chloroform) and it became possible to study unconscious animals. In 1881, 250 experiments were carried out in Britain, the first year that records were kept of the procedures carried out on animals. The following year (1822) the first animal protection law was passed in Britain and in 1876 the Cruelty to Animals Act came into being and was the first law specifically designed to regulate animal testing.

Many advances in our understanding did result from these animal studies including those in basic science and also medicine. These included Antoine Lavoisier demonstrating that respiration was a form of combustion using guinea pigs in calorimeters[20], Stephen Hales measuring blood pressure in the horses, and in the 1880's Louis Pasteur demonstrating the concept of "germs" by giving anthrax to sheep[21]. Also in the 1880's and 1890's Emil von Behring was able to isolate the diphtheria toxin and not only demonstrate its effects in guinea pigs but also, by 1898 produce immunity by the injection of a mixture of toxin and antitoxin, for which he was awarded the Nobel Prize in Physiology and Medicine in 1901. In 1921 Banting ligated the pancreatic duct of dogs and demonstrated that pancreatic isolates could be used to keep these diabetic animals alive, and by 1922 working with John Macloed he isolated insulin from bovine sources and famously treated Leonard Thompson, a 14-year-old diabetic boy with diabetes[22].

OBJECTIONS TO LIVE ANIMAL EXPERIMENTS

Despite these advances and those that took place subsequently many people remained understandably opposed to any form of live animal experimentation. Claude Bernard was known as the "prince of vivisectors" and the father of physiology[23] but ironically his wife Marie Francoise Martin founded the first anti-vivisection society in France in 1883 and famously wrote in 1865 that "the science of life is a superb and dazzlingly lighted hall which may be reached only by passing through a long and ghastly kitchen[23,24]. Opposition to animal experimentation continued and many eminent scientists voiced their disapproval. Charles Darwin in 1871 wrote to Ray Lancaster in reply and stated "You ask about my opinion on vivisection. I quite agree that it is justifiable for real investigations on physiology; but not for mere damnable and detestable curiosity. It is a subject which makes me sick with horror, so I will not say another word about it, else I shall not sleep tonight"[25].

Objections to live animal experiments emerged in the United States in the 1860's and Henry Bergh founded the American Society for the Prevention of Cruelty to Animals. The first movement which specifically opposed vivisection was the American Antivivisection Society, which was founded in 1883. The continued opposition to the use of animals together with the dramatic increase in the number of procedure that were being performed (in 2002 in the United Kingdom 2.7 million live animal experiments were authorized and in the United States, it is estimated that between 19 and 29 million experiments were performed although exact estimates were difficult because 90% of the animals were rats, mice and other species recently exempt from legislation) encouraged many researchers in science and medicine to seek other methods to test drugs and procedures and much of this ethos has been incorporated into legislation or guidelines. Although British law requires that any new drug be tested on at least two different species of animals (one must be a large non-rodent), United Kingdom regulations in respect of animal experimentation are very strict and the Animals Act of 1986 requires that no animal experiments be conducted if there is a realistic alternative. It also exhorts investigators to examine their research carefully to determine the smallest number of animals that may be used to answer the questions posed by the research.

There remains however a dilemma with both ethical and legislational dimensions. All scientists agree that animal experimentation is unacceptable if there is a viable alternative but legislation will not allow the introduction of new products without rigorous testing. In 1988, the American Medical Association published a white paper defending biomedical research in animals[26], and stated that "In fact, virtually every advance in medical science

in the 20th century, from antibiotics and vaccines to antidepressant drugs and organ transplants, has been achieved either directly or indirectly through the use of animals in laboratory experiments". In Europe European Centre for the Validation of Alternative Methods was established in October 1991 by a communication from the Commission to the Council and the Parliament. The aim was to try and organize research and exchange information to limit the need for animal experimentation. As defined in the communication it was felt that this could be achieved in four ways: (1) to coordinate the validation of alternative test methods at the European Union level; (2) to act as a focal point for the exchange of information on the development of alternative test methods; (3) to set up, maintain and manage a database on alternative procedures; and (4) to promote dialogue between legislators, industries, biomedical scientists, consumer organizations and animal welfare groups, with a view to the development, validation and international recognition of alternative test methods.

Although there has been considerable progress in these areas, notably with the use of fresh and cryo-preserved cells (particularly hepatocytes) problems remain when it is necessary to investigate a treatment prior to its use inpatients. The problem is particularly acute in the field of biotechnology in which many of the devices that are proposed and developed are potentially harmful and effects in living tissue are essentially unknown. Today it is certainly possible to computer model some of the effects (widely used in the pharmaceutical industry to predict the usefulness and safety of new drugs) but many results remain unpredictable. Fresh tissue can be used and will provide answers if the procedure takes a short time and its effects and results do not rely on changes (particularly at the cellular level) that require interaction with living cells or evolve over a significant time period (several hours or longer). Unfortunately many devices do produce changes due to interaction with normally vascularized tissue and frequently take prolonged periods to produce effects. With these the only way to date that the results could be examined in detail was in living animals. In addition although prototypes could be studied in small animals instruments that have been developed for human use because of their size can often only be studied in large animals.

LIVER ABLATION EXPERIMENTAL MODELS

The number of patients with liver lesions, which are potentially suitable for treatment, continues to rise with advances in critical care, anesthesia, surgery and oncology. At present, the gold standard remains surgical resection that produces long-term survivors and cure in a significant number of patients. The advent of laparoscopic resection has further widened the indications but by far the most attractive concept remains ablation of the liver (for primary or secondary tumors) containing the tumour. The ablation techniques currently in place for the treatment of liver tumors include radiofrequency ablation (RFA), microwave ablation (MWA), cryotherapy, percutaneous ethanol injection, high intensity focused ultrasound, interstitial laser photocoagulation, electrolysis and bimodal electric tissue ablation[4]. The additional availability of methods for real-time monitoring to ensure that a sufficient volume is ablated (to engulf the tumor and reduce the likelihood of local recurrence) has seen an upsurge in the number of procedures performed and the consequent emergence of survival data that are very encouraging. In addition there is evidence that ablative techniques produce immunologically active components that may confer some extra survival advantage but also systemic effects with potentially harmful consequences.

The development of any new hepatic ablative therapy is a long process that requires a detailed understanding of the basic physical and chemical properties of the ablative modality and their application in clinical settings. It includes designing equipment suitable for clinical application, identifying methods of assessing tissue response to ablation, optimizing treatment monitoring, exploring local and systemic effect of the ablation, and finally, demonstrating the safety and efficacy in humans. Understanding of the tissue temperature changes and radiological evolution of lesion generated by each ablative modality is crucial before it can be used in a clinical setting. Further problems occur with some of the techniques that rely on temperature changes for their effectiveness. Particularly with RFA and MWA the effect can be significantly attenuated in the vicinity of large blood vessels due to the "heat sink effect" where the large flow in the vessels conducts heat away sufficiently rapidly to interfere with the treatment and potentially leave viable tumor cells around these vessels. Flows within the hepatic vessels have been shown to reduce the ablative energy via heat sink effects resulting in a greater energy requirement when ablating in close proximity to larger vessels with an associated higher risk of vascular and bile duct complications[15,27]. For the same reasons, thermal ablation techniques particularly are influenced by the effects of the separate occlusion of the hepatic artery, portal vein or both (Pringle maneuver). This delicate balance between safety and efficacy of ablation has been the focus of many experimental studies[15,28,29].

One further attraction of ablative techniques is the fact that they can often be performed percutaneously or laparoscopically and considerable effort has been expended in the development of suitable probes. These probes can be complex and are generally modeled initially on computers to predict the likely outcome after the delivery of a set amount of energy. Unfortunately the alterations in tissue resistance and electrical and thermal conductivity consequent upon the use of the probes, together with the complex designs (and frequent use of multiple probes or probes that assume unpredictable

shapes after deployment) means that to date it has been essential to test the devices in animal models. These will also be necessary to "calibrate" all new devices and produce standard dose-response curves, so that in addition to real-time monitoring a prediction can be made about the amount of energy that needs to be delivered to ablate a predetermined volume.

The increasing popularity and deployment of these techniques means that to accomplish these aims would require the use of a large number of experimental animals, and because of this it is valuable to consider whether there is an alternative approach that can produce reliable data of sufficient quality to facilitate the incorporation of these methods into clinical practice without the need for subsequent large animal studies. *Ex vivo* perfused liver models have been developed recently for the study of the hepatic toxicity of new pharmacological agents[30-32], and in an attempt to improve the outcome from organ transplantation. Organ transplantation models, which use pulsatile perfusion after harvesting, would seem to offer an excellent alternative that could closely mimic the *in vivo* situation and allow data to be collected for up to 24 h. In a sufficiently well developed perfusion model in which parameters can be accurately controlled it seems likely that data generated would be genuinely useful and achieve the aim of avoiding the use of live animal models.

EX VIVO NON-PERFUSED MODELS

The most commonly used model for the study of hepatic ablation is liver explanted from animals. Bovine and porcine livers are most frequently used because of their similarity to human livers in terms of size and density, and because they are farm animals that are readily available and inexpensive. In addition long-term use has resulted in a familiarity with the animals' anatomy that is essential in studies on the liver where the lobulation and blood supply are an important determinants of outcome. Although the organ is not perfused the position of the ablation in respect of vessels and bile ducts remains important. Their size also allows a number of ablations to be carried out on each individual model, which minimizes the number of animals required.

These models can be used to examine the relationship between ablative energy and lesion size, to assess the effect of different antenna configurations on lesion size and to study the dielectric properties of liver tissues[33-36]. Crocetti *et al*[37] used *ex vivo* calf livers to assess the feasibility and validity of fusion imaging that combines ultrasound and computed tomography in the monitoring of RFA. Unfortunately the results of this study were not directly transferable to the clinical setting because of the absence of respiratory excursion and subject motions of this model. The absence of perfusion within *ex vivo* models also limits their ability to assess the effect of blood flow on the size of the lesion created by ablation with a set amount of energy. Furthermore detailed studies of the cellular changes in the ablated area cannot be conducted due to the ischemia produced by explantation and the rapid cessation of metabolic and physiochemical processes.

IN VIVO MODELS

In view of the limitation of *ex vivo* models particularly with respect to the absence of blood flow, *in vivo* animal models have been widely used for the study of hepatic ablation. Data generated from these studies are very reliable and the close similarity to results in humans allows the experience to be directly transferred to clinical practice. Small laboratory animal models such as murine models are easier to handle but have significant differences in organ size, function and anatomy compared to the human liver. The relatively small organ size also limits the number of ablations that can be carried out per liver. In contrast, *in vivo* porcine liver closely resembles human livers in size, vascularity and metabolic function and although the shape is different the organ is also lobulated in a similar way to the human liver. This allows comparisons to be drawn with respect of the positioning of probes, real dosage levels and consequences of treatment. The result is that the porcine model is by far the most commonly used at present for the final evaluation of all ablative techniques.

The two major approaches to date for the study of hepatic ablation in animals, *ex vivo* non-perfused liver models and *in vivo* animal studies, and their respective advantages and limitations are compared in Table 1. A number of studies have been carried out simultaneously on *in vivo* and *ex vivo* non-perfused models to try and assess the magnitude of the changes produced and also to evaluate the specific differences. The volume of the ablated regions is always significantly smaller in the *in vivo* models when similar energy of ablation is applied[5,38,39]. These findings can probably be attributed to the presence of vascular flow, which removes some of the energy (heat) during the treatment in the *in vivo* models and hence these models are used to examine the influence of vascular occlusion on the size of ablated area. *In vivo* models also allow histological study of different zones, and the evolution of these zones in lesions generated by thermal ablations.

Results generated from *in vivo* models are directly transferable to clinical practice and are at present the gold standard for pre-clinical experimental studies of hepatic ablation. However the use of living animals requires specific laboratory facilities and research teams with expertise in anesthetizing and handling different species. The size and temperament of larger animal models such as porcine and bovine models poses practical problems when animals need to be anesthetized, moved or examined post-procedure (particularly if blood sampling is required).

Table 1 Advantages and limitations of *ex vivo* and *in vivo* models for experimental study of hepatic ablation

Models	Applications	Advantages	Limitations
Ex vivo (non perfused) models	Compare the efficacy of different antenna configurations Trial of different energy setting	Allow histological examination of whole lesion to study zones of ablation Cheap Larger study sample size Easy to manipulate during experiment Does not require ethical approval/animal license	Non-physiological Homogenous parenchyma Absence of respiratory excursion and subject motions Lack of cooling effect secondary to tissue perfusion Unable to study heat sink effect
In vivo models	Study of lesion evolution over time Histological examination of lesion Study of heat sink effect and the effect of bile duct cooling Study of systemic responses to ablation Study of the effect of large volume ablation (in larger animals)	Small animals Easier to handle Cheaper Ability to have larger sample size	Small animals Small volume of liver Limit number of ablation on each liver Not suitable for the study of large volume ablation
		Large animals Closer resemblance to human liver in terms of size and physiology More ablations can be carried out in each liver	Large animals Size and temperament poses challenges during anesthesia Difficult vascular access in porcine models Also limited by strict ethic regulation Small study sample size
			Common limitations Expensive Expertise in animal handling and anesthesia is required Duration of study is limited to the lifespan of the model Absence of interacting organ systems which may have a role in generating systemic response Unable to assess the impact of ablation on end organs
Isolated perfused *ex vivo* liver models	Study of lesion evolution over time Study of heat sink effect and the effect of bile duct cooling Study of early inflammatory response	Cheaper than *in vivo* experiments Sophisticated and accurate manipulation of hepatic inflow (e.g., Pringle manoeuvre) Does not require ethical approval Greater control of perfusion characteristics (e.g., portal vein and hepatic arterial flows and pressures)	Perfusion circuit itself may activate some degree of systemic response

EX VIVO PERFUSED MODELS

Ex vivo non-perfused and *in vivo* models have significant advantages with respect to specific scientific questions but an alternative model, the isolated perfused *ex vivo* model, theoretically would have most of the advantages of both. A normothermic liver perfusion system using autologous blood maintains physiological and metabolic functions and the hemodynamic changes resemble those of *in vivo* models with good preservation of liver architecture[40-42]. The organ would be perfused over a number of hours, and within this period valuable data could be produced within a relatively inexpensive model with no ethical problems and no requirement for licensing (Table 1)[43-45]. This should permit the histological study of lesions generated by hepatic thermal ablation, real-time monitoring of the evolution of the lesions and experiments designed to study the "heat sink" effect with different modalities. In addition, with a sufficiently sophisticated and stable model it should also be possible (by venous sampling) to study the early inflammatory responses following hepatic ablation[44,46].

Liver perfusion studies date back as far as the 19th century when they were first performed for research on physiological function of the liver[47]. A number of studies have been conducted subsequently to establish valid models of liver perfusion using asanguineous perfusates or autologous blood[41,48-50]. These models have been used for physiological research, treatment of liver failure, studies of metabolism and toxicity of new pharmacological compounds and in transplant units for the recovery and preservation of organs, which are to be implanted[51-53]. Hildebrand *et al*[54] have advocated the use of a perfused *ex vivo* liver model for the training in laparoscopic RFA.

For the *ex vivo* perfused model the main limitation is the limited lifespan and the determination of intervals during this lifespan when valid data can be extracted. Nevertheless perfusion models, and particularly those using autologous blood and pulsatile perfusions, have become very sophisticated and physiological parameters can be very accurately maintained for many hours. The interaction of blood with non-biological surfaces of the perfusion circuit does activate a number of biological pathways producing some degree of systemic response and interpretation of responses to ablation will have to take these into account. However the response will be the same for each experiment and should not interfere with comparisons of different dose responses or different modalities[55]. The absence of other interacting

organs may also affect the extent of systemic responses following hepatic ablation but this model still potentially represents an exciting new method of studying these new devices while avoiding the need to use live animals. The true potential and weakness of an isolated perfused liver model for the study of hepatic ablation remain to be seen (and will be determined by future research) but recent advances have certainly developed the model to the stage that merits this research[56].

FUTURE DIRECTIONS AND ADVANCES

To overcome the limitations of disconnecting the liver from the remaining organs, Chung *et al*[56] recently created the first multiorgan *ex vivo* perfused model in which the liver was serially connected with the kidney. The viability of both organs and the inflammatory reaction elicited have been investigated in two separate studies[56,57]. The addition of the kidney to the circuit improved the biochemical milieu of the circuit and consented a more physiological environment for those experiments requiring strict conditions[57]. At the same time, the combination of two organs in the circuit did not increase the cytokine production compared to the classic "liver-alone" circuit[56] and therefore could be used to test the inflammatory reaction produced by ablative techniques[44] without significant interferences by the newly added organ.

CONCLUSION

The key advantages of isolated perfused liver models are the avoidance of live animal experiments, the ability to control accurately physiological parameters and to analyze morphological changes following hepatic ablation. In addition detailed study of the "heat sink" effect and changes consequent upon bile duct perfusion can be assessed. Other organs and tissues from the same animals from which the livers are procured can also be used in other research leading to an overall reduction in the number of animals required. Validation of the role of isolated perfused liver models for experimental studies of hepatic ablation is essential to establish their position in this field of research.

Abstract

Bowel preparation prior to colonoscopy is essential to maximize the benefits of colonoscopy. Numerous bowel preparations have been studied, ranging from 4 L polyethylene glycol (PEG) to split-dose regimens to 2 L PEG with an adjunct laxative (senna, bisacodyl, ascorbic acid). Due to the large volume of PEG required for adequate bowel preparation, many studies have focused on reducing this large volume to only 2 L PEG with the addition of an adjunct. Recently, a randomized controlled trial by Tajika *et al* showed that the addition of mosapride to only 1.5 L PEG was non-inferior to mosapride and 2 L PEG for bowel cleansing but did provide improvements in patient tolerance. This study offers yet another potential bowel preparation for patients undergoing colonoscopy and may trigger further studies with 1.5 L PEG with an adjunct. In this letter, we discuss the current state of bowel preparation prior to colonoscopy and offer information to guide clinicians on choosing the appropriate bowel preparation for their patients.

INVITED COMMENTARY ON HOT ARTICLES

As clinical gastroenterologists, we read the recent article by Tajika *et al*[1] describing a new lower volume bowel preparation prior to colonoscopy with considerable interest. This article examined the use of mosapride and only 1.5 L of polyethylene glycol (PEG) for bowel preparation prior to colonoscopy. Given the continued need and search for more options for bowel preparation, we recommend reading and possibly implementing the information in this article.

Colorectal cancer is a common and devastating disease which affects many patients worldwide. Being in top three of cancers and cancer-related deaths in the United States, colorectal cancer has become a focus of gastroenterology, with much of our practice being significantly impacted by colorectal cancer screening and surveillance[2].

Over the past 10 years, colonoscopy has become the screening test of choice for colorectal cancer. Unlike other non-invasive colorectal cancer screening tools, such as fecal occult blood testing and computed tomographic (CT) colonography, colonoscopy is the only modality which encompasses both diagnostic and therapeutic potential. However, colonoscopy is dependent on adequacy of bowel preparation for complete visualization of the

PEG: Polyethylene glycol.

colonic mucosa. If visualization is compromised, missed lesions, prolonged procedure time, and increased patient discomfort become increasingly possible, significantly impacting patients and healthcare costs[3,4]. Therefore, bowel preparation prior to colonoscopy is extremely important for an adequate colonoscopic examination.

The optimal bowel preparation prior to colonoscopy must adequately clear the fecal material to visualize the underlying mucosa but also must be tolerable to the patient. Even if the bowel preparation is exceptional at clearing the colon of feces, if it is not palatable, the patients will likely not complete the full preparation. Over the past few years, many studies have been performed with varying uses of PEG, such as split-dose PEG and PEG with adjuncts, in an effort to improve patient tolerability without decreasing the efficacy of the bowel preparation. A meta-analysis in *Gastrointestinal Endoscopy* in 2011 demonstrated that split-dose PEG (consisting of 2 L PEG the night prior and 2 L PEG the morning of the procedure), improved both the cleansing of the colon and patient tolerability as compared to full-dose PEG (4 L the night prior to colonoscopy)[5]. Subsequently, the split-dose PEG has become a very common bowel preparation and is the preferred bowel preparation of the American College of Gastroenterology. However, patients are still required to consume a large volume of PEG. Therefore, many studies have elected to reduce the volume of PEG to 2 L and add a laxative adjunct (ascorbic acid, bisacodyl, senna, magnesium, *etc*.) and monitor for bowel cleansing and patient tolerability[6-12]. However, these studies resulted in conflicting results.

In 2011, two meta-analyses were published as abstracts in the *American Journal of Gastroenterology* showing that 2 L PEG with ascorbic acid cleansed the colon as well as 4L PEG but was equally tolerated[13]; however, 2 L PEG with bisacodyl demonstrated equal bowel cleansing and improved patient tolerability[14]. Despite the results, limitations have been placed on using bisacodyl with PEG due to risk of ischemic colitis. Therefore, the search continues for an adequate low-dose PEG bowel preparation.

In the randomized controlled trial by Tajika *et al*[1] mosapride (15 mg) was utilized as an adjunct laxative to low-dose PEG (1.5 L *vs* 2 L). The study revealed that mosapride with 1.5 L PEG resulted in equal bowel cleansing and increased tolerability as compared to mosapride with 2 L PEG. Given these results, mosapride with 1.5 L PEG appears promising as an alternative bowel preparation prior to colonoscopy. However, given a few limitations within this study, the results need to be interpreted cautiously.

First, this study utilized a non-inferiority model for analysis. Most bowel preparation studies are performed using a superiority model due to limitations of the non-inferiority model. The non-inferiority model is dependent upon the margin at which non-inferiority is defined. If the margin is not accurate, the results may be significantly affected. In this study, mosapride with 1.5 L PEG was non-inferior to mosapride with 2 L PEG; however, it appears that 2 L PEG with mosapride group has many more excellent and good preparations as compared to 1.5 L PEG with mosapride group (right colon: 88 *vs* 60; left colon: 97 *vs* 82). Given this difference, especially in the right colon, it is difficult for us to believe that equality of cleansing exists for these two regimens. Therefore, this leads us to believe that the sample size estimation and the non-inferiority margin may not be as accurate as hoped. Second, although the Aronchick scale has been shown to be a valuable tool in assessing bowel preparation, it is designed for the entire colon[15]. This study used the Aronchick scale but divided it among right and left colon. Ideally, the Ottawa or Boston bowel preparation scales which utilize different segments of the colon with numerical scores may have been a better choice for bowel preparation assessment[16,17].

At this point, based upon the available literature, we believe the ideal bowel preparation prior to colonoscopy is the split-dose PEG given 2 L the night prior and 2 L the day of the colonoscopy (Table 1). However, given its large volume, it may not be suited for all patients. Furthermore, given the number of other potential options including the preparation described in this study, alternative bowel preparations are readily available and may be utilized in certain cases without adversely affecting bowel cleansing.

The choice of bowel preparation is extremely important for patients and practices. Adequate bowel preparation which is tolerable to patients will likely enhance satisfaction among patients, who would be more likely to return for another colonoscopy. It will also likely reduce the need for early repeat procedures due to poor prep quality and overall costs. Given the number of preparations available, bowel preparation prior to colonoscopy in the future may be tailored to the needs and desires of the patients. Although split-dose PEG seems to be the gold-standard at this time, other preparations may be utilized to enhance patient satisfaction without adversely affecting overall preparation quality. The choice is up to you and your patient.

Abstract

Even though the small intestine occupies a major portion of the abdominal space and is essential for life, in most pathology textbooks any chapter on small intestinal diseases, especially in human beings, is typically shorter than those for other gastrointestinal organs. Clinical and experimental investigations of the small intestine in various clinical situations, such as nutrition management, obesity interventions, and emergency care, have elucidated several important biological problems associated with the small intestine, the last frontier of gastroenterology. In this issue, a review by Professor Basson and his team at Michigan State University sheds light on the changes in the human small intestine under various conditions based on their clinical and surgical experience. With the advent of recent innovations in enteroscopy, a form of endoscopy used to examine deep within the small intestine, the issue that they highlighted, i.e., mucosal adaptation and atrophy of the human small intestine, has emerged as a major and manageable challenge for gastroenterologists in general, including the readers of the *World Journal of Gastroenterology*.

INVITED COMMENTARY ON HOT ARTICLES

Juan Rosai's Surgical Pathology (9th edition) contains 45 pages on the small intestine, compared with 80 pages on the large intestine[1]. The actual length of the small intestine is much longer than that of the large intestine, and the vital importance of the small intestine is well known. Why then are fewer pages devoted to diseases of the small intestine? Obviously, the access of surgical pathologists and gastroenterologists to the small intestine is limited, compared with access to the large intestine and appendix. Actually, the old version of Morson and Dawson's textbook Gastrointestinal Pathology[2] is fairer: the same number of pages is devoted to the small intestine and to the large intestine, probably because this book is a product of the century during which autopsies made major contributions to our knowledge base. This issue of the *World Journal of Gastroenterology* has a wide-ranging review article on the pathophysiology of the small intestine by Professor Basson and his colleagues[3]. These authors are surgeons, and a tremendous amount of data based on their own clinical experiences and those of others, as well as on animal experiments, are comprehensively discussed in their review. This review article addresses conditions such as starvation and parenteral nutrition in patients with severe trauma or pancreatitis and in patients with postoperative short-gut syndrome for various reasons including bariatric surgery for obesity. Although these

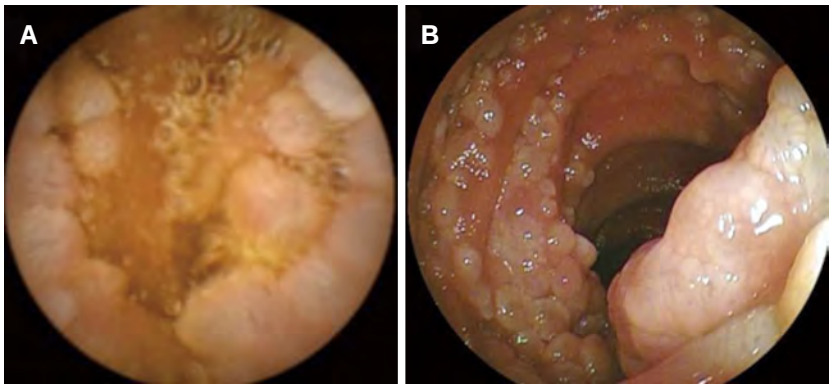

Figure 1 Endoscopy. Images obtained using capsule endoscopy (A) and double-balloon enteroscopy (B) in a 61-year-old man with follicular lymphoma who visited us because of gastrointestinal bleeding from an unknown cause and a hemoglobin concentration of 9.7 g/dL.

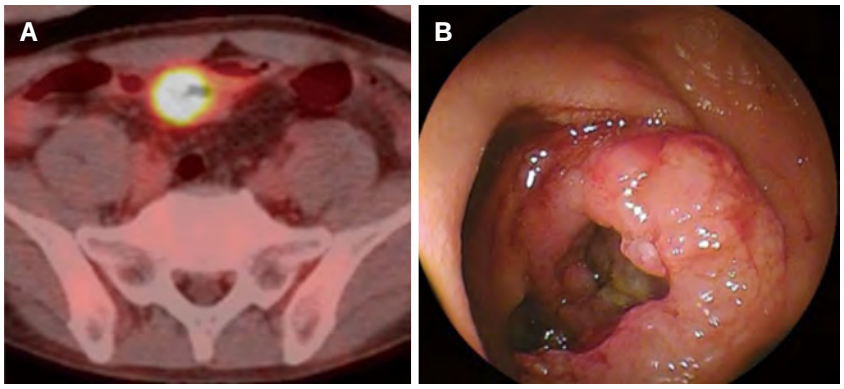

Figure 2 A mass positive by positron emission computed tomography actually was a tumor arising the mucosa of the small intestine of a 48-year-old woman who had suffered Crohn disease. A: Positron emission computed tomography/computed tomography showed an accumulation in site of wall thickening of ileum; B: Image obtained by double-balloon enteroscopy.

conditions are undoubtedly serious, recognition and explicit statements by medical professionals regarding the importance of the small intestine, and of its diseases as a "great burden of human distress", have only recently appeared in medical literature[4]. Most clinical conditions that highlight the importance of the small intestine are familiar only to experts in a particular area of medicine. These conditions are not typically a concern of non-surgical gastroenterologists, such as pathologists who are accustomed to diagnosing neoplasms of the large intestine, grading inflammatory bowel disease, and validating ischemic necrosis of the resected small intestine in cases with an acute abdomen. The small intestine is most often investigated because of its involvement in a disease originating from another organ, such as the mesothelium[5]. Changes in the mucosa of the small intestine itself are an exceptional category among the slides that pile up next to the microscope.

The situation is now changing. As avid readers of *World Journal of Gastroenterology* may have noticed[6-9], recent progress in enteroscopy has enabled areas deep within the small intestine to be reached, providing clinicians active in the wider branches of gastroenterology with the opportunity to evaluate changes in the small intestine, which have previously only been observed by surgeons. This also means that many non-surgeons must commit to the management of the small intestine, based on findings and evaluations associated with specimens of small intestine obtained using these newly developed modalities. For ordinary pathologists, for example, the concepts mainly discussed in this review, i.e., adaptation and atrophy of the small intestine, may be new and unfamiliar. These lesions were encountered only after specific "congenital or acquired disease or medical and surgical intervention" had occurred in the patients. When specimens obtained by enteroscopy become routine in the future, however, the concepts and knowledge of adaptation and atrophy of the small intestine will become an essential "must" for all practitioners including general pathologists.

One of the important conditions that the authors of this review addressed is the change in the small intestine in subjects receiving total parental nutrition. This lifesaving modality has many variations in terms of its nutritional regimen and the effects of these variations on pathophysiology, that is, on the grade of adaptation of the small intestine. These effects on the small intestinal mucosa and the consequent outcomes of individual patients have been thoroughly investigated and published in many scientific articles, but the scientific evidence in human beings remains insufficient according to the

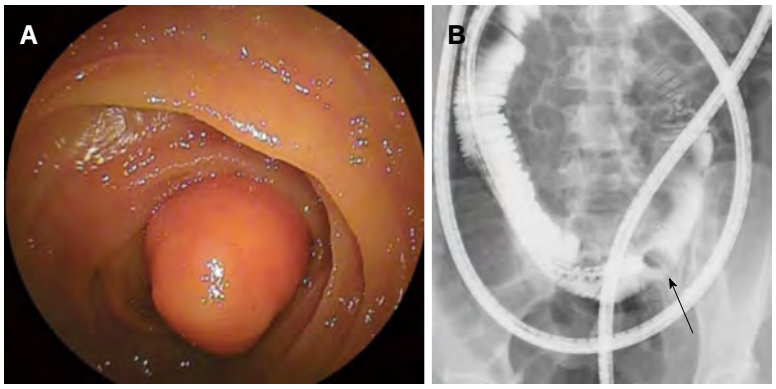

Figure 3 Identification of lipoma clarified the reason of intermittent abdominal discomfort in a 29-year-old female. Endoscopic finding (A) and selective small bowel series (B) obtained using double-balloon enteroscopy. This required surgical intervention. An arrow in the B indicates a defect by a lipoma.

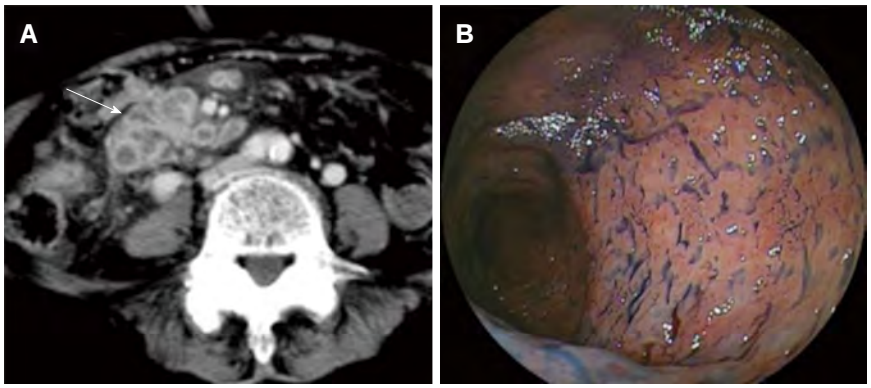

Figure 4 Intestinal tuberculosis is also revealed by double-ballon enteroscopy. A: Computed tomography showed wall thickening of the ileum with contrast enhancement (arrow); B: Double-balloon enteroscopy showed destruction of the small intestinal villi.

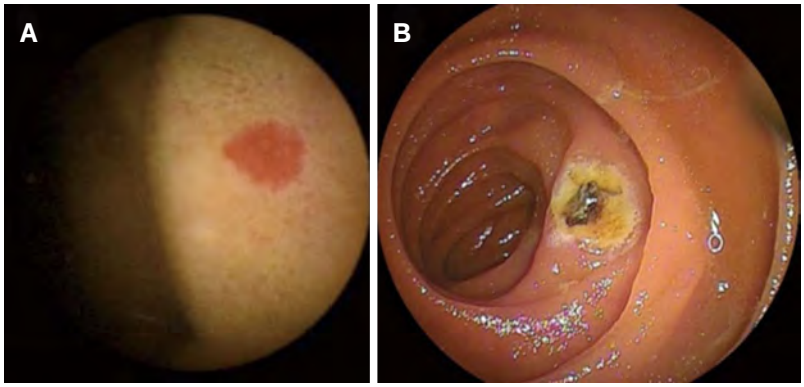

Figure 5 Angioectasia. A: Diagnosis of angioectasia was made by capsule endoscopy; B: Argon plasma coagulation successfully treated the lesion.

above-mentioned authors. The concept of mucosal adaptation[10] includes proliferation, functional augmentation, and cellular differentiation. Biochemical changes include alterations in molecules related to apoptosis, proliferation, signal transduction, and fatty acid metabolism. These meticulous frameworks in intestinal cells and tissues have so far been revealed by studies using *in vivo* and *in vitro* manipulative systems. From now on, in the era of enteroscopy, lingering questions such as "what is the reality and examples of mucosal adaptation in human clinical settings?" and "how can we validate the accumulated experimental findings in human beings and exploit them in clinical practice?" will be answered.

Small intestinal enteroscopy is now available in ordinary hospitals, thus facilitating the detection of previously unobserved pathological conditions. Capsular endoscopy, the latest wireless version of enteroscopy, has become a popular practical procedure since the publication of a seminal report on this modality a decade ago[11]. In the minds of laymen, this technique seems like a dream[12]. The use of capsular endoscopy and refined enteroscopy using a double-balloon method[13] in clinical practice have

revealed thousands of new anecdotal findings (Figure 1), and the rapid accumulation of this kind of basic knowledge of the small intestine will help to set up principles of surveillance for mucosal adaptation and atrophy of the small intestine (especially morphological changes) in various clinical conditions. For example, introduction of capsular endoscopy and a double-balloon method disclosed previously unrecognized lesions such as adenocarcinoma arising from Crohn disease in the small intestine (Figure 2)[14], submucosal lipoma (Figure 3), tuberculosis at the terminal ileum (Figure 4), and angioectasia (Figure 5). None of these lesions were accessible until the recent development of capsule endoscopy and the double balloon method. The morphology is new to pathologists and endoscopists, and these developments will critically influence the managements of the patients. The concepts that Professor Basson and colleagues have illuminated in their review will soon become an important guidepost for evaluating the histopathology of the small intestine in daily practice and for patient care by a broader range of gastroenterologists.

Abstract

Hepatitis C virus (HCV) is the leading indication for liver transplantation in the United States. It recurs universally after transplant but the rate of fibrosis and the development of graft failure is variable. Different donor and recipient features have been demonstrated to impact fibrosis. Plasma cell hepatitis, a histologic finding, is one feature associated with poor graft and patient outcomes. The pathogenic mechanism resulting in plasma cell hepatitis is poorly understood, with evidence suggesting a role for both the HCV and the immune system.A recent publication described plasma cell hepatitis in a larger context of immune medicated graft dysfunction in transplant recipients receiving interferon based therapy. This manuscript will highlight the topic of plasma cell hepatitis and provide commentary on the lack of recognition, the data regarding pathophysiologic mechanisms and the potential management options.

Kallwitz ER. Recurrent hepatitis C virus after transplant and the importance of plasma cells on biopsy. *World J Gastroenterol* 2013; 19(2): 158-160 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/158.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.158

INVITED COMMENTARY ON HOT ARTICLES

Hepatitis C virus (HCV) is the most common indication for liver transplantation in the United States. Recurrence of hepatitis C is nearly universal after transplantation and ensuing graft dysfunction occurs commonly. Ten percent of recipients progress to cirrhosis within 3 years of transplant[1] demonstrating that some patients develop aggressive recurrent HCV. Plasma cell hepatitis, diagnosed histologically, is one of a number of conditions associated with adverse outcomes and graft failure in patients with posttransplant HCV. Plasma cell hepatitis can develop in the context of interferon based therapy or in the absence of treatment with interferon. Levitsky *et al*[2] present a multicenter case-control study which included a large subset of patients found to have plasma cell hepatitis associated with interferon therapy for HCV.The manuscript should be read with interest by transplant hepatologists as it highlights important concepts regarding plasma cell hepatitis in patients with HCV after transplant. First, plasma cell hepatitis is under recognized. Second, the pathologic process resulting in plasma cell hepatitis is poorly understood. Finally, with a paucity of data, it is not possible to determine the best treatment for transplant recipients with this condition.

The case control series by Levitsky *et al*[2] reported that the incidence of any immune medicated graft dysfunction on interferon based therapy varied by center, ranging between 3.2%-16.3%. Persons found to have immune mediated graft dysfunction on HCV therapy had significantly worse survival, and more graft failure leading to higher rates of retransplantation. Plasma cell hepatitis was the most common manifestation of interferon induced immune mediated graft dysfunction. It is important to note that plasma cell hepatitis was also commonly identified prior to the use of interferon. The incidence of plasma cell hepatitis

Table 1 Generalized histologic and clinical features seen in post transplant patients with hepatitis C

Pathologic entity	Histologic features	Clinical and laboratory features
Plasma cell hepatitis	Plasma cells (often in sheets) Centrilobular necrosis	HCV PCR positive ANA or ASMA may be positive (often with low titers) Low level of immunosuppression Can be caused by interferon based therapy
De novo autoimmune hepatitis	Lymphoplasmacytic infiltrate Interface hepatitis	Positive ANA or ASMA Elevated immunoglobulins In persons on treatment HCV RNA often not detected (occurs in other settings in addition to HCV) Low level of immunosuppression Can be caused by interferon based therapy
Acute cellular rejection	Mixed inflammatory infiltrate Endotheliitis Nonsuppurative Cholangitis Centrilobular necrosis (variable)	Low level of immunosuppression Can be caused by interferon based therapy
Recurrent hepatitis C	Lymphocyte Aggregates Portal based fibrosis FCH is one variant (Cholestasis, Apoptosis, Fibrosis)	HCV PCR positive In FCH, markedly high viral load In FCH, high level of immunosuppression

HCV: Hepatitis C virus; FCH: Fibrosingcholestatic hepatitis; ANA: Antinuclear antibodies; ASMA: Anti-smooth muscle antibody; PCR: Polymerase chain reaction.

on pretreatment biopsies was much more common in persons who developed immune mediated graft dysfunction (36.5%) compared to the control group (7.7%, $P = 0.003$) on treatment[2]. Fourteen of the cases labeled as plasma cell hepatitis by the central pathologist were not recognized by the local pathologist who initially interpreted the liver biopsy[2]. The authors conclude that plasma cell hepatitis often predicts the development of immune mediated graft dysfunction occurring during interferon based treatment. In addition, the author's recommend that clinicians should not reduce immunosuppression doses and should not initiate interferon based therapy in those with immune features including plasma cell hepatitis on pretreatment biopsies.

The informative and interesting conclusions of this article deserve further comment. A main feature of the article from Levistky and colleagues is that plasma cell hepatitis is under recognized and is often mistaken for recurrent hepatitis C or other forms of rejection[2]. A histologic scoring system was developed in 2008[3]. Diagnostic features of plasma cell hepatitis include numerous plasma cells, often in sheets or clusters, accompanied by centrilobular necrosis. Despite the existence of standardized criteria, it is not surprising that plasma cell hepatitis is under recognized. With few publications describing plasma cell hepatitis, it is not topical to hepatologists and pathologists. Additionally, in post-transplant patients, other processes such as recurrent HCV, *de novo* autoimmune hepatitis and acute cellular rejection present alternative diagnoses. Table 1 highlights clinical and histologic features which might help distinguish the different diagnoses. It is important to realize significant overlap does exist between the pathologic process making a definite diagnosis impossible in some cases. The recent publication in a high profile journal will hopefully lead to better recognition of this disorder.

The pathogenesis of plasma cell hepatitis has yet to be defined. It has been described both as a manifestation of hepatitis C[4,5] and as a form of rejection[3]. Evidence exists for both possibilities. Prior series have shown that HCV plays a role. A two subject case series examined plasma cell hepatitis as a lymphoproliferative disorder[5]. Both patients in this series had serum or urine protein electrophoresis demonstrating a monoclonal protein and RNA probes for hepatitis C were positive within the plasma cell infiltrate[5]. An association between plasma cell hepatitis and mixed cryoglobulinemia has not been studied. In the current article, patient survival with plasma cell hepatitis was improved with a sustained virologic response to treatment for HCV[2]. Although graft failure and retransplantation occurred in some cases, five year survival was above 80% and similar to control subjects[2]. Additionally, there was a trend toward improved graft survival in cases of immune mediated graft dysfunction when hepatitis C was eradicated. In Kaplan-Meier analysis, the majority of graft loss occurred early after transplant with approximately 60% graft survival and no further graft loss occurring after two years in the group that achieved a sustained virological response (SVR)[2]. In contrast, the group that did not achieve an SVR continued to develop graft loss during the entire period of follow up and graft survival was less than 40% at five years[2]. It is additionally notable that SVR rates in series of patients with plasma cell hepatitis ranged between 40%-67%[2,3]. Given that poor outcomes are observed with plasma cell hepatitis in persons who never received interferon[3,6], prospective, randomized data are needed to compare outcome of interferon treatment versus no interferon treatment with respect to HCV eradication.

Other studies suggest the development of plasma cell hepatitis is an immune mediated event. Explanted livers of post transplant patients who later develop plasma cell hepatitis were more likely to have extensive plasma cell infiltrates[6] suggesting that immunologic predisposition exists even prior to transplant. However, not all persons with plasma cell infiltrates on explant will develop plasma cell hepatitis, and additional factors after transplant appear to play a role. There are data describing the development of plasma cell hepatitis in the setting of lowered immunosup-

pression[2,3]. In a series including 38 subjects with plasma cell hepatitis, 31 had either recently lowered immunosuppressant dosing or subtherapeutic drug levels[3]. In the series by Levitsky *et al*[2] significantly more patients with immune mediated graft dysfunction had a reduction in immunosuppression prior to interferon based therapy. Additionally, more subjects with immune mediated graft dysfunction had immunosuppression reduced during therapy[2]. One would expect interferon would have a role in the development of an immune mediated event and the contribution of interferon to the development of plasma cell hepatitis is not quite clear. In a retrospective series, interferon was not associated with the development of plasma cell hepatitis and its use did not impact outcome once plasma cell hepatitis developed[3]. In the series published by Levitsky *et al*[2] persons with existing plasma cell hepatitis had worsened immune mediated graft dysfunction after their immunosuppression was reduced and interferon was started. Increasing baseline immunosuppression prior to initiating interferon in patients with plasma cell hepatitis should be considered for future study, especially given data showing improved outcomes with augmenting immunosuppression alone[3].

With an immune predisposition, plasma cell hepatitis and *de novo* autoimmune hepatitis have overlapping features. They are nearly histologically indistinguishable, and some refer to them interchangeably[7]. A few subtle clues suggest that these processes have a different underlying pathophysiology. Case series have described *de novo* autoimmune hepatitis developing in conjunction with interferon based therapy with elevated autoimmune titers, undetected HCV RNA levels and pretreatment biopsies showing no plasma cells[8]. In addition, in transplant recipients for indications other than HCV, *de novo* autoimmune hepatitis has been shown to respond well to steroid therapy[9], whereas plasma cell hepatitis in HCV infected recipients typically does not[3].

Plasma cell hepatitis represents an important entity which is likely under reported as the result of poor recognition. Agreement on standardized nomenclature distinguishing plasma cell hepatitis from *de novo* autoimmune hepatitis in the post transplant setting may improve recognition. Plasma cell hepatitis best refers to plasma cell infiltration in the setting of post transplant hepatitis C. *De novo* autoimmune hepatitis best refers to plasma cell infiltration that occurs commonly with positive autoimmune titers, steroid responsiveness and, in the setting of interferon based therapy, may be best reserved when in a lymphoplasmacytic infiltrate develops without active viremia. As shown in Table 1, it must be recognized that overlap between the two conditions in both pathology and pathophysiologic mechanisms exist such that diagnostic certainty will not always occur.

Currently, the best management of plasma cell hepatitis that develops independent of HCV therapy is unclear. Limited data showed that augmentation of immunosuppression without the addition of prednisone may be of benefit[3]. Once on interferon based therapy, achieving an SVR was also shown to benefit patient survival[2]. The recommendation by Levitsky *et al*[2] that interferon should not be initiated in patients with plasma cell hepatitis may be overreaching based on the data presented. It also would suggest an alternate option with better outcomes existed. A practical approach may be augmenting baseline immunosuppression and a repeat liver biopsy. If the liver biopsy shows decreased immune features than interferon based therapy might be attempted. Ultimately, until there is better prospective data, responses to this entity will likely be reflective of single center experiences.

Abstract

Endoscopy is widely accepted as the first treatment option in the management of bile duct stones. In this review we focus on the alternative endoscopic modalities for the management of difficult common bile duct stones. Most biliary stones can be removed with an extraction balloon, extraction basket or mechanical lithotripsy after endoscopic sphincterotomy. Endoscopic papillary balloon dilation with or without endoscopic sphincterotomy or mechanical lithotripsy has been shown to be effective for management of difficult to remove bile duct stones in selected patients. Ductal clearance can be safely achieved with peroral cholangioscopy guided laser or electrohydraulic lithotripsy in most cases where other endoscopic treatment modalities have failed. Biliary stenting may be an alternative treatment option for frail and elderly patients or those with serious co morbidities.

INTRODUCTION

Common bile duct (CBD) stones are seen in approximately 7%-12% of patients who undergo cholecystectomy for symptomatic cholelithiasis and are a common indication for referral to a biliary endoscopist[1]. They vary in size ranging from rather small (approximately 1-2 mm) to very large (> 3 cm). Endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy (ES) and basket or balloon extraction are well established therapeutic procedures for the management of CBD stones. It is estimated that nearly 85%-95% of all CBD stones can be managed effectively by these conventional endoscopic methods[2,3]. Failure to clear the bile duct renders the patient vulnerable to biliary obstruction, cholangitis and pancreatitis, thereby increasing the morbidity[4,5]. The occurrence of acute cholangitis is associated with significant mortality, especially in the elderly, underscoring the need for early intervention to clear the bile duct of stones and to relieve the obstruction to achieve adequate biliary drainage. Extraction of CBD stones is one of the most commonly performed procedures by therapeutic endoscopists. With novel advances in extraction techniques and instruments emerging routinely, it is vital to keep abreast of the new developments in order to improve the outcome. This review focuses on the alter-

native endoscopic management options for the treatment of difficult to remove CBD stones.

REVIEW CRITERIA

In July 2011, we searched MEDLINE from 1982 to the present using the Medical Subject Headings terms common bile duct stone, endoscopic retrograde cholangiopancreatography, difficult stone, endoscopy, and the key word "common bile duct stone". Full papers and abstracts in English language were considered. Important developments in research, reports from centers of excellence, and our own clinical experience in managing them, form the basis of this review article.

FACTORS ASSOCIATED WITH DIFFICULT TO TREAT BILE DUCT STONES

Multiple factors have been postulated to govern the success or failure of endoscopic extraction of CBD stones. In approximately 10%-15% of patients, managing biliary stones becomes formidable primarily due to difficulties in accessing the bile duct (periampullary diverticulum, sigmoid shaped CBD, post-gastrectomy Billroth type Ⅱ anatomy, Roux-en-Y-gastrojejunostomy), large number of stones (greater than 10), large size of stones (stones with a diameter > 15 mm which cannot be grasped with a basket), unusually shaped stones (barrel-shaped) or location of the stones (intra hepatic, cystic duct, proximal to strictures)[6]. In addition, endoscopic management becomes challenging in Mirizzi syndrome, in which stones in the cystic duct cause obstruction of the main bile duct[7]. Kim *et al*[8] prospectively evaluated the factors contributing to technical difficulty during endoscopic clearance of CBD stones. They reported that older age (> 65 years), previous gastrojejunostomy, larger stone size (≥ 15mm), impaction of stones, shorter length of the distal CBD arm (≤ 36mm), and more acute distal CBD angulation (≤ 135 degrees) are all contributors to technical difficulty for endoscopic removal of bile duct stones[8].

MANAGEMENT OF DIFFICULT STONES

In high risk patients, the risks and benefits of alternative techniques for removal of bile duct stones not amenable to conventional endoscopic techniques must be carefully balanced against each other and with surgery. The individual decision concerning the appropriate therapy is also influenced by the local expertise and the availability of the technical equipment.

CBD stones up to 1.5 cm in diameter can be extracted intact after endoscopic sphincterotomy. The rate of successful retrieval progressively declines with increasing size of the stone[9]. Larger stones especially those with a diameter ≥ 2cm may need fragmentation before removal to reduce the risk of stone impaction.

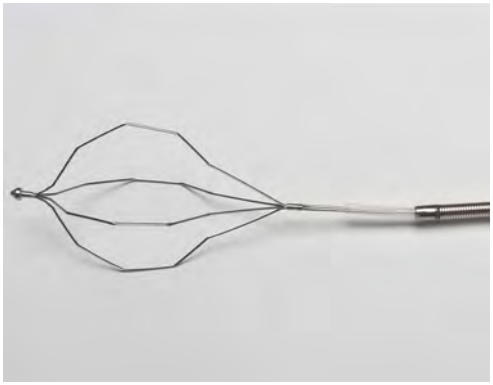

Figure 1 Example of a three-layered mechanical lithotripsy device with the basket, inner plastic sheath and an outer metal sheath. The stone is captured by the basket and crushed against the outer metal sheath.

Mechanical lithotripsy

In 1982, Riemann *et al*[10], first introduced mechanical lithotripsy (ML). ML is currently the most widely used technique for fragmentation of stones. Contemporary lithotripter baskets have a high breaking strengths and have improved the success rate of ML for extraction of large CBD stones (> 2 cm) to well over 90% without serious complications[11]. Broadly speaking, there are two types of baskets for ML. The type of basket used depends on whether lithotripsy is done on an elective ("through the scope") basis or on an emergent basis (salvage device) for basket impaction[12]. The 'through the scope' model is typically a three-layer system with the basket, inner plastic sheath, and an outer metal sheath (Figure 1). The stone is captured with the basket and the outer metal sheath is advanced to the stone which will be crushed against it. Sometimes, unexpectedly, stone and basket impaction can occur even during routine extraction of smaller stones. Under such circumstances, stone fragmentation can be done after removing the handle from the basket and the duodenoscope from the patient. An endotriptor (a spiral metal sheath) is introduced under fluoroscopic guidance, over the basket wires, and the stone is crushed after connecting the bare basket wires to the crank handle (Figure 2). The broken basket and the stone are then removed. The shaft of the endotriptor is generally shorter and thicker than that employed in standard ML[13]. Although basket impaction can occur with through the scope lithotripsy baskets; it is more commonly encountered with extraction baskets, which have thinner wires and weaker handles not suitable for fragmentation of stones.

In patients with multiple large stones, lithotripters with a sleeve system can be employed multiple times without withdrawal of the endoscope, facilitating stone fragmentation[14,15].

ML has been widely used as it is a readily available, cost effective, and simple procedure. Unfortunately the failure rate is high especially in patients with stones greater than 2.8 cm in diameter[15]. In a retrospective study the size of the stone was the only factor that significantly af-

Figure 2 Image of a mechanical lithotripter which can be used as a "salvage device" for removal of impacted baskets.

fected the success or failure of bile duct clearance. In this study of 162 patients, the cumulative probability of bile duct clearance ranged from > 90% for stones with a diameter less than 10 mm to 68% for those greater than 28 mm in diameter ($P < 0.02$)[15]. A subsequent prospective study by Garg *et al*[16] however reported that stone size alone may not be important unless considered together with the diameter of the bile duct. They concluded that the only important predictive factor that compromised the success of mechanical lithotripsy was stone impaction in the bile duct, with either an inability to pass the basket proximal to the stone or a failure of the basket to open fully around the stone to allow it to be grasped properly[16]. Although stone composition was not included in the study by Leung *et al*[12], some endoscopists believe that stones that are hard and densely calcified (visualized on a plain radiograph) resist mechanical fragmentation, resulting in an extraction failure with standard baskets. Although the stones which are molded to the shape of the bile duct may be softer, they are more difficult to crush because they may not be easily engaged by the lithotripter basket[12].

A multi-center study reported the rate of complications associated with ML to be around 3.6%[13]. Among the spectrum of complications, basket impaction or fracture of the basket wire are uniquely associated with ML. Non-surgical interventions that have been utilized in this setting include extension of sphincterotomy, awaiting spontaneous passage of the impacted basket and stone after successful stent placement, use of a second lithotripter, extracorporeal shock wave lithotripsy (ESWL), laser lithotripsy, electrohydraulic lithotripsy, and transhepatic lithotripsy and stone dislodgement[13-18]. Other complications include broken handle and perforation or injury to the bile duct[13-18].

In about 10% of the patients ML proves to be cumbersome, protracted and ineffective[6] wherein one has to resort to other methods such as electrohydraulic, or laser lithotripsy for stone fragmentation and subsequent removal.

Electrohydraulic lithotripsy

Initially used as an industrial tool for fragmenting rocks in mines, its application was extrapolated to medical use when Koch attempted fragmentation of biliary stones using this technology[19]. Electrohydraulic Lithotripsy (EHL) consists of a bipolar lithotripsy probe which discharges sparks with the aid of a charge generator in an aqueous medium. The sparks generated under water generate high-frequency hydraulic pressure waves, the energy of which is absorbed by nearby stones and results in their fragmentation[20]. The shock waves can cause inadvertent injury or perforation of the bile duct wall if the probe is not deployed close to the stone and away from the ductal wall. EHL can be performed under fluoroscopic guidance by using centering balloons or direct cholangioscopic vision[20]. The disadvantage of using only fluoroscopic guidance is related to the two dimensional imaging and the inability to confirm correct positioning of the probe. Therefore direct visualization is frequently preferred to avoid damage to the ductal wall[21]. A cholangioscope is inserted through the instrument channel of the mother scope. One or two dedicated biliary endoscopists are needed for this procedure. Continuous irrigation with water during the procedure generates a fluid medium for propagation of the shock waves and in addition offers a clear view of the stones by flushing away the debris[20].

The overall complication rate ranges from 7% to 9%[22,23], with most common complications being hemobilia, cholangitis, and less commonly, ductal perforation. Binmoeller *et al*[6], in one of the earlier large studies reported that EHL was successful in 63 of the 64 patients who had failed previous attempts of ML. Smaller published studies report stone fragmentation rates between 77%-100% for peroral EHL with minimal complications[22,24-28]. Arya *et al*[23], reported a stone fragmentation rate of 96% and final stone clearance of 90%. In a retrospective study of 94 patients who had failed stone extraction by conventional techniques, Hui *et al*[29], compared the outcomes of EHL with further endoscopy to stenting alone in a subset of elderly and infirm patients. They demonstrated that EHL and further ERCPs had a higher success rate (80%) with a low complication rate (7.7%) and recommended that elderly and frail patients should be referred to tertiary centers for EHL in order to prolong survival and decrease biliary complications[29].

The EHL equipment is compact, requires no special electricity, and is relatively inexpensive[30]. Other advantages are that the EHL procedure does not require special training or protective gear. In the United States, use of EHL for fragmentation and removal of biliary stones is quite common in centers with special interest in biliary disorders.

Laser lithotripsy

In laser lithotripsy (LL), laser light at a particular wavelength is focused on the surface of the stone to induce a wave-mediated fragmentation. The pulsed laser energy utilized in stone fragmentation is in contrast to the continuous laser energy used in tumor ablation[7]. The first successful use of pulsed laser for shock-wave lithotripsy of bile duct stones was reported in 1986[31]. Since then

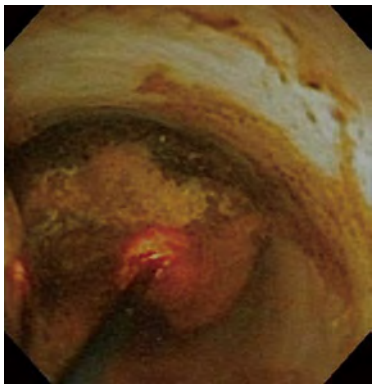

Figure 3 Laser lithotripsy of a bile duct stone under cholangioscopic guidance.

the technology has evolved and other laser types such as neodymium: yttrium-aluminum-garnet (Nd: YAG), flash lamp-pulsed dye (coumarin), the flash lamp-pulsed dye (rhodamine) with an automatic stone recognition system and the new Frequency Doubled Double Pulse Nd:YAG (FREDDY) system have been introduced[32-35]. LL is typically performed perorally under cholangioscopic or fluoroscopic guidance or by the transhepatic approach. As with EHL, LL under direct visualization using a cholangioscope is often preferred to avoid damage to the ductal wall (Figure 3).

Based on some reports, ductal clearance can be accomplished in 64% to 97% of patients by using[7,36] LL. In the majority of patients ductal clearance could be achieved in one session, although more sessions were required occasionally. LL has been demonstrated to be more effective than ESWL in terms of stone clearance rate and more rapid stone fragmentation with a shorter duration of treatment leading to a significant reduction in cost[37,38]. In some centers where the laser equipment is available, laser lithotripsy has gained popularity and has managed to replace EHL as the primary modality for fragmentation of difficult to remove stones.

A recent innovation worth mentioning is the introduction of a double-lumen basket which allows passage of a laser probe for effective laser lithotripsy after the stone is captured by the basket[39]. For a selected group of patients, this technique was shown to be feasible and effective, and the authors hope that continuous improvements in designs and construction materials would further enhance the success rate of this device.

Extracorporeal shockwave lithotripsy

In ESWL, high-pressure shock waves are generated outside the body (extracorporeal) by underwater spark gap (electrohydraulic) generated by piezoelectric crystals or electromagnetic membrane technology[30]. The shock waves are focused by elliptical transducers to the designated target through a liquid or tissue medium which prevents the energy attenuation. ESWL is performed under ultrasound or fluoroscopic guidance. Since most biliary stones are radiolucent and are not adequately visualized by fluoroscopy alone, placement of a nasobiliary tube for contrast instillation is required if ESWL is performed under fluoroscopy. In case of first generation lithotripters, the patients needed to be immersed in a water bath. Subsequent ESWL lithotripters employ water-filled compressible bags and a gel is applied to the skin surface for interface with the patient. Comparison between the lithotripters at a single center showed no significant difference in fragmentation of CBD stones[40]. General anesthesia is usually needed as the discomfort produced may not be adequately controlled by conscious sedation. The critical determining factor for success of single ESWL session is stone size and microcrystalline structure and architecture of the stone[41,42]. The presence or absence of bile duct stenosis can also influence the success of ESWL[43]. Sauerbruch *et al*[44], reported the efficacy of ESWL in achieving CBD stone fragmentation in over 90% of patients with minimal side effects.

In most institutions that already have access to ESWL for treatment of renal calculi, no other purchases of equipment needs to be made. For ESWL direct contact with the calculi is not needed, and multiple stones can be managed simultaneously[41]. ESWL can be of particular help in patients with abnormal anatomy such as those who have undergone Billroth-Ⅱ or Roux-en-Y surgeries in whom endoscopic access to the major papilla is difficult.

Although in general ESWL is tolerated well, it can be associated with adverse events such as transient biliary colic, subcutaneous ecchymosis, cardiac arrhythmia, self limited hemobilia, cholangitis, ileus and pancreatitis[7,45]. Perinephric hematoma, biliary obstruction, bowel perforation, lung injury and splenic rupture are among the rarely reported complications[42]. Multiple ESWL sessions may be required in a subset of patients to achieve ductal clearance, and endoscopic procedures between the ESWL sessions may become necessary to clear the bile duct of debris to assure drainage. The recurrence rate of CBD stones after ESWL clearance during a 1 to 2 year follow up was considerable and was around 14%[45,46]. In a randomized trial comparing fluoroscopic guided ESWL and LL, LL was preferable not only for successful stone free rate (73% *vs* 97%), but also in terms of the number of sessions needed to clear the duct (3 in ESWL *vs* 1.2 in LL) and the duration of treatment[30]. Another randomized trial comparing ultrasound guided ESWL and laser lithotripsy in the treatment of CBD stones refractory to conventional treatment clearly showed superior stone clearance rate and cost effectiveness in laser lithotripsy (52.4% *vs* 82%)[40]. However, a prospective trial comparing EHL *vs* ESWL showed no difference in success rates for clearing the CBD, duration and cost of hospitalization between the two modalities[24].

In the United States, ESWL is rarely performed for management of biliary stones and most centers prefer cholangioscopy-guided LL or EHL for this purpose.

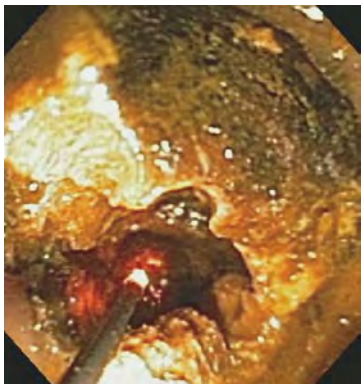

Figure 4 Direct peroral cholangioscopy guided laser lithotripsy of a bile duct stone. The red laser light makes targeting of the stone easier).

Cholangioscopy-guided lithotripsy

EHL or LL is ideally performed under direct visual control using a cholangioscope. The traditional cholangioscopy systems consist of a duodenoscope (also called "mother scope") and a dedicated cholangioscope (also called "baby scope" or "daughter scope") which is introduced into the bile duct through the accessory channel of the mother scope. The baby scope itself has an instrument channel through which the EHL or laser probe is introduced. Peroral cholangioscopy guided EHL or LL is cumbersome and can be labor intensive requiring an additional endoscopic unit and often participation of two skilled endoscopists, one to handle the duodenoscope and the other to maneuver the cholangioscope. The traditional cholangioscopes are capable of only 2-way steering, which may limit the field of view. These cholangioscopes are also extremely vulnerable to damage, requiring frequent expensive repairs. Furthermore, sharp angulations in the biliary tree may limit access into intrahepatic ducts or the cystic duct[47].

To negate these limitations, the Spyglass Direct Visualization System (Boston Scientific Corp, Natick, Mass) was designed for single operator examination of the bile ducts, 4-way steering, and dedicated irrigation channels[48,49]. In a large international multicenter study conducted at 10 centers in the United States and 5 centers in Europe, ductal clearance was successfully achieved in 71% of the patients using the Spyglass cholangioscopy system[50]. Despite its effectiveness, the spyglass system has been underutilized mainly due to its fiber optic image quality which is inferior to the video image quality offered by the new videocholangioscopes[51].

Direct peroral cholangioscopy

In direct peroral cholangioscopy (DPOC), an ultraslim upper endoscope is maneuvered across the biliary sphincter and into the bile duct for direct observation. With the introduction of high-definition ultraslim endoscopes with narrow band imaging capability, direct peroral cholangioscopy has gained popularity. This is mainly due to the many advantages of this technique. Compared to ductoscopy using a dedicated cholangioscope, direct cholangioscopy has several advantages. It offers a single operator platform, digital image quality and simultaneous irrigation and therapeutic capabilities. The most profound disadvantage of DPOC, however, is the difficulty associated with traversing the biliary sphincter to gain access to the bile duct. This is mainly due to looping of the ultraslim upper endoscope in the stomach or in the duodenum. To enhance the success rate of DPOC, specialized accessories or techniques are needed to advance the ultra slim endoscope into the proximal biliary system.

Larghi and Waxman[52] reported their experience in which the ultraslim upper endoscope was inserted with the aid of a guidewire placed during ERCP to maintain access. Additional use of manual pressure applied on the patient's abdomen has been shown to ease the passage of the ultraslim endoscope into the hilar area in some patients[53]. The main drawback encountered with passage of an ultraslim upper endoscope over a guidewire for gaining access to the bile duct is the dislodgement of the guidewire from the bile duct and also large loop formation hindering the entrance of the endoscope into the biliary system. Moon *et al*[54] demonstrated the ropeway technique using an intraductal balloon that can be anchored within an intrahepatic bile duct to advance an ultraslim upper endoscope into the biliary tree for performance of DPOC. However, withdrawal of the balloon may cause technical difficulties in maintaining access which underscores the need for other accessories to maintain the scope's position within the bile duct. The same group also reported use of an overtube balloon originally designed for double balloon enteroscopy to facilitate the introduction of an ultraslim upper endoscope into the biliary tree[55]. However the large inner diameter of the overtube (10.8 mm) compared to the outer diameter of the ultraslim upper endoscopes (5.2-6 mm), makes it difficult to manipulate both instruments and results in discomfort to the patient, looping of the endoscope in the duodenum, and difficulty in reaching the proximal bile duct[55,56].

In a recent study, we assessed utility of a novel anchoring balloon for performance of DPOC. Use of the anchoring balloon allowed consistent access to the biliary tree for performance of diagnostic and therapeutic DPOC distal to the confluence of the right and left hepatic ducts. More proximal access, however, was challenging owing to looping of the ultraslim endoscope after balloon removal.

Efforts are underway to develop the combined use of an intraductal anchoring balloon and an overtube especially designed for DPOC. Very recently, air embolism was reported following DPOC, resulting in a left sided hemiparesis[57]. Endoscopists must be conscious of the fact that air embolism could remain asymptomatic, as in regional embolism (portal venous gas) or manifest as hypoxia, shock, cardiac arrest or cerebral ischemia as noted in this case[57].

Once the hurdle of introducing an ultraslim upper endoscope into the bile duct has been overcome, a laser

Figure 5 Large diameter papillary balloon dilatation to remove bile duct stone.

or an EHL probe can easily be passed through the working channel of the ultraslim endoscope. Stones can be directly visualized before and during lithotripsy by DPOC (Figure 4). Lithotripsy is performed using this technique until the stones are satisfactorily fragmented to allow removal through the biliary sphincter. In a small study with 18 patients who had failed conventional endoscopic therapy including ML, DPOC guided EHL or LL was successful in approximately 90% of the patients with an average of 1.6 treatment sessions per patient[58].

Specialized ultraslim upper endoscopes are being designed to facilitate access to the biliary tree for DPOC[59]. Ultraslim upper endoscopes can be passed through the nasal cavity for performance of DPOC. Direct transnasal cholangioscopy has been reported for successful extraction of CBD stones[60].

Endoscopic papillary balloon dilatation

Endoscopic papillary balloon dilation (EPBD) was introduced as an alternative to endoscopic sphincterotomy for removal of bile duct stones in 1980's[61]. In an initial report involving 10 patients with CBD stones, biliary sphincteroplasty to 15 mm allowed removal of CBD stones in 6 patients[61]. In the other 4 patients, ductal clearance required a combination of biliary sphincterotomy and mechanical lithotripsy. The use of large diameter papillary balloon dilatation (up to 20 mm in diameter) for management of difficult to remove biliary stones was reported by Ersoz *et al*[62] in 2003. They reported a high success rate for stone removal. However, their complication rate was also high. Several reports have suggested that EPBD is associated with risk of severe pancreatitis which raises safety concern of this procedure[61,63]. In our institution, we use EPBD selectively and try to avoid its use in those with high risk of post ERCP pancreatitis (Figure 5).

Since those initial reports, multiple studies have shown that EPBD alone or in combination with other techniques can be of use for management of difficult to remove biliary stones[62-68]. EPBD is especially attractive in patients who are at risk for bleeding after endoscopic sphincterotomy or in those with altered anatomy in whom a full sphincterotomy cannot be successfully achieved.

Some authors have suggested that the stone recurrence rate may also be higher with EPBD than with endoscopic sphincterotomy and mechanical lithotripsy[69]. However the results of a Japanese multicentric trial with a mean follow up of 6.7 years demonstrated that there is lesser risk of stone recurrence following EPBD when compared with sphincterotomy[70]. Further, a recent meta-analysis which included 15 randomized trials comparing EPBD and endoscopic sphincterotomy showed reduced risk of bleeding and infections and is especially indicated in older patients, those who are at risk for infection and coagulopathy[71]. Despite its effectiveness, EPBD has been associated with serious complications[63]. A higher risk of post ERCP pancreatitis has been observed which has been attributed to the inadequately loosened sphincter of Oddi and the intra mucosal hemorrhage and inflammation/edema around the papilla. This may cause compression of the pancreatic duct and may accentuate the risk of pancreatitis[72]. In this regard, a randomized controlled trial demonstrated that a 5-min dilation time as opposed to the conventional 1-min time resulted in an adequately loosened sphincter of Oddi and consequently reduced the risk of post ERCP pancreatitis and improved its efficacy[73]. The rate of these complications can be reduced by strict patient selection, avoidance of forced procedures, optimal dilation duration and immediate conversion to an alternative procedure if any difficulty is encountered during EPBD.

Endoscopic biliary stenting

In very old patients and those with serious co-morbidities where other endoscopic or surgical procedures may confer unacceptably high risks, endoscopic biliary stenting is a useful alternative[69]. Biliary drainage by stenting is mandatory if ductal clearance cannot be achieved during ERCP or in between procedures in patients who require more than one session for ductal clearance. CBD stones have been reported to reduce in size in 60% of patients within one to two years after biliary stenting[69].

Mechanical irritation of the stent on the stone is postulated to be one of the mechanisms.

In a study involving 28 geriatric patients with CBD stones refractory to conventional endoscopic removal, endoscopic biliary stent placement combined with oral ursodeoxycholic acid and terpene therapy for a mean of six months led to significant reduction in the size of CBD stone[74]. Subsequently, endoscopic stone removal was successfully performed in 26 of 28 patients with a mean of 1.7 ERCP procedures. This combination therapy may be of use for treatment of difficult to remove CBD stones in a subset of patients with significant co-morbidities and intolerance to prolonged endoscopic treatment modalities.

In conclusion, the past several years have witnessed the emergence of new technologies and techniques for management of difficult to remove biliary stones. Treat-

ment of such stones is generally accomplished using a multimodal approach combining conventional techniques such as endoscopic sphincterotomy, use of extraction balloons and baskets and mechanical lithotripsy, with newer techniques such as cholangioscopy guided laser or electrohydraulic lithotripsy. Recent advances in the development of videocholangioscopes, single operator catheter-based cholangioscopes and specially-designed ultrathin upper endoscopes for DPOC have made lithotripsy under direct visual guidance safer, more reliable, and more routine. Future studies will certainly shed more light on the safety of different modalities for stone extraction and will help determine the best management approach for different subgroup of patients with difficult to remove bile duct stones.

Abstract

Colorectal cancer (CRC) remains one of the major public health problems throughout the world. Originally depicted as a multi-step dynamical disease, CRC develops slowly over several years and progresses through cytologically distinct benign and malignant states, from single crypt lesions through adenoma, to malignant carcinoma with the potential for invasion and metastasis. Moving from histological observations since a long time, it has been recognized that inflammation and immunity actively participate in the pathogenesis, surveillance and progression of CRC. The advent of immunohistochemical techniques and of animal models has improved our understanding of the immune dynamical system in CRC. It is well known that immune cells have variable behavior controlled by complex interactions in the tumor microenvironment. Advances in immunology and molecular biology have shown that CRC is immunogenic and that host immune responses influence survival. Several lines of evidence support the concept that tumor stromal cells, are not merely a scaffold, but rather they influence growth, survival, and invasiveness of cancer cells, dynamically contributing to the tumor microenvironment, together with immune cells. Different types of immune cells infiltrate CRC, comprising cells of both the innate and adaptive immune system. A relevant issue is to unravel the discrepancy between the inhibitory effects on cancer growth exerted by the local immune response and the promoting effects on cancer proliferation, invasion, and dissemination induced by some types of inflammatory cells. Here, we sought to discuss the role played by innate and adaptive immune system in the local progression and metastasis of CRC, and the prognostic information that we can currently understand and exploit.

INTRODUCTION

Despite progresses in our biological and clinical knowledge, colorectal cancer (CRC) remains one of the major public health problems throughout the world[1]. By its frequency, CRC ranks third in men and women worldwide[1]. In addition, CRC continues to be one of the most common fatal types of cancer. Originally depicted as a multi-step dynamical disease, CRC develops slowly over several years and progresses through cytologically distinct benign and malignant states, from single crypt lesions through

adenoma, to malignant carcinoma with the potential for invasion and metastasis[2,3]. According to the theory of multi-step carcinogenesis, colorectal epithelial cells accumulate a number of molecular changes to eventually become fully malignant[4,5]. In spite of unifying theories, genetic and epigenetic events during the carcinogenesis process differ considerably from tumor to tumor. Thus, CRC is not a single disease; rather it encompasses different molecular and pathological entities with a wide range of clinical behaviors[6]. At the molecular level, CRC is the tip of an iceberg the basis of which encloses a complex array of gene alterations, affecting supra-molecular processes. Essentially, like individual fingerprints, each tumor arises and behaves in a unique fashion that is unlikely to be exactly recapitulated by any other tumor. Nevertheless, molecular changes allows for a categorization of CRC, which is largely accepted, although likely to oversimplistic. It has been demonstrated that main genetic and epigenetic features, such as microsatellite instability (MSI), chromosomal instability, CpG island methylator phenotype (CIMP) or global DNA hypomethylation, lead to alterations of gene function on a genome-wide scale. It is known that activation of oncogenes, including *KRAS*, *BRAF*, *PIK3CA* and *TP53*, affects intracellular signaling pathways[6,7]. The suppressor pathway is disrupted in CRC with chromosomal instability occurring in the majority of CRCs (approximately 85%), which have a molecular profile characterized by specific chromosomal amplifications and transformations, aneuploidy, and loss of heterozygosity[6-8]. Differently, CRCs of the mutator pathway (approximately 15%) have a defective DNA mismatch repair system, which leads to accumulation of thousands of unrepaired mutations[8]. This inability to repair DNA slippage errors and mismatches can easily be demonstrated because it results in variability in the length of DNA microsatellites, formed by repetitive sequences, that is MSI. It is accepted that MSI CRCs have a heterogeneous histological appearance, better prognosis due to a reduced metastatic potential, and a different response to chemotherapy[9-14].

Histopathological examination reveals that likely other solid tumors, CRC are associated with diverse immune cell infiltrates[15-20], and that in the cancer context, epithelial cells coexist with extracellular matrix components and non-neoplastic cell types, including fibroblasts, myofibroblasts, adipocytes, endothelial cells, pericytes, which collectively form the tumor stroma. Several lines of evidence support the concept that tumor stromal cells, are not merely a scaffold, but rather they influence growth, survival, and invasiveness of cancer cells, dynamically contributing to the tumor microenvironment, together with immune cells[20-25]. The types of immune system cells that are found infiltrating CRC consist of cells of the innate immune system i.e., macrophages, neutrophils, mast cells and natural killer cells, as well as cells associated with an adaptive immune response i.e., T and B lymphocytes. Although it is commonly thought that an immune response localized to the tumor inhibit cancer growth, it is clear that some types of tumor-associated inflammation may also exert an opposite action, at least at some point of CRC natural history[26] (Figure 1). Here we sought to briefly review these two contradictory aspects of the immune response to CRC.

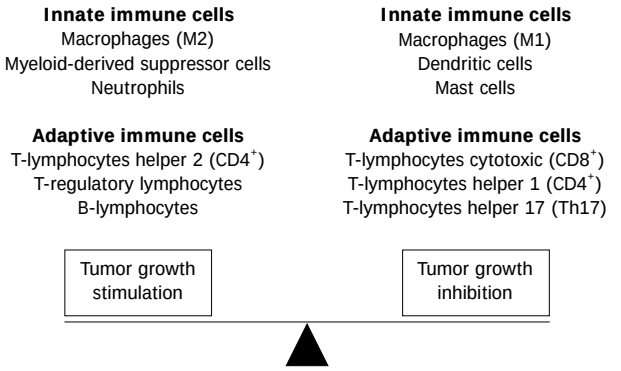

Figure 1 Immune cells have variable behavior controlled by complex interactions in the tumor microenvironment. Although it is commonly thought that an immune response localized to the tumor inhibit cancer growth, it is now clear that some types of tumor-associated inflammation can exert an opposite action.

INNATE IMMUNITY AND COLORECTAL CANCER

It is well known that innate immunity represents the body's first defense or "gut reaction" to an abnormal situation, such as cancer, and does not involve specific recognition of immunogenic peptides, or antigens[20]. Aside T and B lymphocytes , innate immune cells orchestrate an inflammatory environment that may function to either stimulate or inhibit cancer growth[20]. Various innate immune cells have been implicated in CRC development and progression[15,27,28]. Among these, macrophages, are a primary source of secreted pro-inflammatory cytokines, and are generally distinguished as type 1 (M1) or type 2 (M2)[29-31]. M1s generally have an interleukin (IL) 12^{low}IL-10^{high} phenotype, show impaired expression of reactive nitrogen intermediates, poor antigen presentation and have tumoricidal capacity, while show high expression of angiogenic factors [including Vascular-endothelial growth factor (VEGF) epidermal-growth factor (EGF) and semaphorin 4D], metalloproteases (MMPs) and cathepsins as well as of the growth arrest-specific protein 6 (GAS6)[29-32]. Additionally, M1s can support T-helper 1 (Th1) adaptive immunity[33]. Conversely, M2s secrete immunosuppressive cytokines and promote tumor growth[22,34]. It has been shown that cancer cells shape their interaction with macrophages by escaping phagocytosis and by promoting a M2-like polarization throughout chemokines and polarizing cytokines including chemokine (C-C motif) ligand 2 (CCL2), colony stimulating factor 1 (CSF1), macrophage slowing factor (MSF), tumor necrosis factor-alpha (TNF-α, IL-10 and transforming growth factor-β (TGF-β).

Among the cells with M2 phenotype, the tumor-associated macrophages (TAM) have been shown as capable of secreting proteases that enhance invasion and metastases, together with a range of cytokines inhibiting an adaptive tumor-specific immune response, and angiogenic factors that increase neovascularity. In patients with CRC, macrophages are usually found located around necrotic areas of tumor and the advancing tumor margin[28]. Their role in CRC still remains controversial. While, it was originally thought that the main function of TAMs was a direct cytotoxic effects on tumor cells, phagocytosis apoptotic/necrotic cell debris, and present tumor-associated antigens to T lymphocytes, current evidences suggest that inflammation and TAMs can also promote tumor growth and metastasis. Kang *et al*[35] have recently highlighted an association between intra-tumoral TAM densities with CRC malignant aggressiveness. Additionally, increased frequencies of intra-tumoral TAM have been associated with high levels of MMP type 2 and 9 expression in CRC cells[36,37]. These findings are in accord with a previous cell-line study showing that co-culturing of tumor cells with macrophages enhances cancer cell migration, invasiveness, and MMP-2 and MMP-9 secretion[35].

Kaler *et al*[38] have recently established that macrophages promote Wnt signaling pathway in CRC cells and thus enhance their proliferation, and demonstrated that macrophages exert their pro-tumorigenic activity mainly through the release of IL-1β. The same authors demonstrated that tumor necrosis factor related apoptosis inducing ligand (TRAIL) induced apoptosis of CRC cells is inhibited by macrophage derived IL-1β, and showed that macrophages and recombinant IL-1β counteract TRAIL-induced apoptosis through activation of Wnt signaling and stabilization of the nuclear transcription factor Snail in tumor cells.

A number of studies have also shown that macrophages can release a vast diversity of cytokines, proteolytic enzymes, growth factors, and inflammatory mediators that may directly influence and stimulate the growth and migration of tumor cells[29-33]. Li *et al*[39] first reported that IL-6 released by macrophage directly promotes CRC cell progression. They showed that monocyte/macrophage-derived IL-6 enhances migration of HT-29 CRC cells *in vitro*[39]. Although, how IL-6 enhances HT-29 cell migration still remains unknown, it has been suggested that TGF-β may be involved in this process. Using monoclonal antibodies to neutralize IL-10 in macrophage supernatant, Li *et al*[39] found that the IL-6-mediated effects on HT-29 CRC cells were all enhanced. Therefore, the interaction between IL-6 and IL-10 released from macrophage is indeed involved in CRC progression and prognosis. The above findings support the fact that TAMs play a regulatory role in the tumor microenvironment by modulating secretion of cytokines such as IL-6 and IL-10, thereby causing cancer cells to manipulate their microenvironment to facilitate cancer growth[40,41].

TAM activation and maturation is under the influence of the tumor microenvironment. TAMs retain a relatively immature phenotype, characterized by a low expression of differentiation-associated antigens in hypoxic microenvironments[35,42,43]. Conversely to an M2 phenotype with pro-tumoral functions in CRC[35], it has been shown that the macrophages, especially those secreting IL-12 and IL-23, infiltrating the tumor front are positively correlated with a favorable outcome, which implicates TAMs as possessing anti-tumor functions. Forssell *et al*[44] stained with the pan-monocyte/macrophage marker CD68 a series of CRC specimens and showed that the higher macrophage infiltration along the tumor invasive front correlated with improved survival in colon cancer compared to rectal cancer. They concluded that a dense macrophage infiltration at the tumor front positively influences prognosis in colon cancer and that the degree of cell-to-cell contact may influence the balance between pro-tumorigenic and anti-tumorigenic properties of macrophages. High levels of tissue macrophages have been also associated with earlier disease stage, absence of nodal and lymphovascular metastases and an overall better prognosis. Zhou *et al*[45] by analyzing the relationship between the density of TAMs and the potential of hepatic metastasis and survival have shown that a higher density of macrophages along the invasive front of CRC was associated with a higher 5-year survival rate. In addition, according to Forssell's scoring system that defines CD68 hot-spots as small areas among which the infiltration of macrophages was considerably above the average level of CD68-positive cells, the highest CD68 hot-spot was associated with both the incidence of hepatic metastasis and the interval between colon resection and the occurrence of hepatic metastasis[45].

The mechanisms behind the anti-tumor effects of TAMs have still not been fully elucidated, and seem potentially be ascribed to the M1 phenotype, which is in part controlled by the $CD4^+$T lymphocytes and the death of cancer cells[45-47]. It has been ascertained that recruitment of TAMs contributes to the development of an adaptive immune response against cancer, and the balance between antigen availability and clearance through phagocytosis and subsequent degradation of senescent or apoptotic cells.

It is undeniable that the discrepancies in results between different studies may be due to a number of factors related to the location of the TAMs and the assessment methods employed. Recent studies have reported that different macrophage phenotypes localized to different regions of the carcinoma have variable effects on tumor cells[18,19]. Furthermore, evidences have shown that the relationship between TAMs and tumor progression is tumor type-dependent.

Other innate immune system cells can be detected in CRC microenvironment, including mast cells (MCs), neutrophils, natural killer (NK) cells, and eosinophils.

Nagtegaal *et al*[48] have shown that peritumoral MCs prevent local and distant recurrence, with improved survival as a consequence. The significant benefit of MCs on

tumor progression in CRC was also highlighted by Gounaris *et al*[49] who reported that depletion of MCs, either by drugs either in MC-deficient mice, led to remission of existing polyps. Similar to other immune cell types, high numbers of MCs are associated with earlier CRC disease stage and have been proposed as an independent prognostic marker for improved survival[50]. It has also been reported that the number of MCs progressively decreases from normal mucosa through premalignant conditions and the lowest numbers are seen in cancers. Because of their location, MCs may prevent the metastasis of carcinomas that are restricted to the sub-mucosa. *In vivo* studies have observed that destruction of lymphatic vessels in the peritumoral infiltrate is always accompanied by MCs. This led to the hypothesis that MCs degranulate in the sub-mucosa when they come into contact with the inflammatory infiltrate or CRC cells, thus leading to the destruction of lymphatic vessels and thereby preventing further metastasis. Gulubova and Vlaykova[51] proposed the MCs density along the invasive front of the primary CRC as a helpful tool for prognosis of patients after surgical therapy. In their study, it has been shown that patients with low MCs density had significantly better prognosis compared to those with high MCs density. In addition, Blatner *et al*[52] reported that in CRC, MCs contribute to systemic regulatory T-cell dysfunction. MCs have an intricate interaction with T-regulatory cells that controls the functions of both cell types in a reciprocal manner. MCs play also an important role in allograft acceptance, where they are required to sustain the peripheral tolerance mediated by T-regulatory cells. These latter can inhibit MCs differentiation and hinder degranulation by contact-dependent mechanisms and production of soluble factors, such as IL-10. Conversely, the activation and subsequent degranulation of MCs breaks peripheral tolerance. MCs degranulation or direct cell contact and secretion of IL-6 promote Th-17 conversion of T-regulatory cells with loss of both forkhead box P3 transcription factor (Foxp3) expression and T-cell-suppressive properties.

Neutrophils may form up to 15% of the inflammatory infiltrate associated with CRCs and this proportion increases within areas of tumor necrosis[28]. In patients with rectal cancer, high concentrations of neutrophils have been shown as independent predictors of improved prognosis especially when microscopic abscesses form[28]. However, an elevated neutrophil/lymphocyte ratio was, however, found by Halazun *et al*[53] led to a poorer survival time and higher rate of recurrence in CRC patients undergoing surgery for liver metastasis.

NK cells are granular lymphocytes that form part of the innate cellular immune response[28]. In CRC, high numbers of NK cells in the inflammatory infiltrate has been associated with better prognosis[28]. The number of NK cells decreases with increasing cancer stage. Additionally, it has been shown that the ratio of NK cells in the peripheral blood is an important prognostic indicator in CRC patients and it is of interest to note that 5-fluorouracil-based chemotherapy increases the number of NK cells[54,55].

Aside the above innate immune cell types, dendritic cells (DCs), antigen-presenting cells that are critical to the stimulation of effective anti-tumor adaptive immune responses, can become defective in the tumor microenvironment and aid in tumor immune evasion by failing to stimulate T lymphocytes. It has been suggested that the presence of DCs may be of significant benefit in patients with CRC. Xie *et al*[56] also demonstrated that the presence of DCs was found predominantly in early compared to later disease stages and mostly located in tumor surrounding tissue. Suzuki *et al*[57] showed the presence of mature $CD83^+$ DCs at the cancer invasive front and by light and electron microscopy demonstrated their aggregation into clusters with lymphocytes, the majority of which were $CD45RO^+$ T lymphocytes. They concluded that mature $CD83^+$ DCs at the invasive margin promote T-cell activation for the generation of tumor specific immunity.

Although, there is growing evidence that the host innate immune system has a critical role in regulating carcinogenesis, the specific receptors involved and the importance of their interaction with commensal bacteria remain to be elucidated. Two major classes of innate immune receptors, the Toll-like receptors and Nod-like receptors, many of which are upstream of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), have been investigated[58,59]. Particularly, the toll-like receptors have been implicated in promoting colon tumorigenesis. Fukata *et al*[60] have shown that toll-like receptor-4 (TLR4) is over-expressed in human colitis-associated cancer and, that mice deficient in TLR4 are markedly protected against colitis-associated neoplasia. A high TLR4 expression in the tumor microenvironment has recently been reported as a possible marker of disease progression in CRC[60]. Conversely, the role of nod-like receptors in regulating colorectal tumorigenesis remains unclear. Chen *et al*[61] reported an increased intestinal permeability associated with enhanced inflammatory cytokine production and epithelial cell proliferation in Nod1-deficient mice. As the depletion of the gut microbiota suppressed tumor development in Nod1-deficient mice, a link should exist between commensal bacteria and host innate Nod1 signaling pathway involved in the development of inflammation-mediated CRC.

ADAPTIVE IMMUNITY AND COLORECTAL CANCER

It is today well recognized that cells of the adaptive immune system are recruited in CRC and colitis-associated tumours (CAC), where they have either pro- and anti-tumorigenic roles. T lymphocytes participate in inflammation, cancer development and progression, as well as in anticancer immunity[20-22]. In CAC the adaptive immune system seems to have mainly a pro-tumorigenic role, while in CRC it may play a double-faced role, being the

balance between immune-surveillance (carried out by $CD8^+$ and $CD4^+$ T lymphocytes) and tumour-promoting inflammation (by various sub-types of T lymphocytes) to change over time, and eventually dictating disease progression. It has been suggested that immune-surveillance might mediate the early recognition and elimination of transformed cells and aberrant crypt foci, keeping small tumours in a dormant state[62]. Immune-surveillance is retained important during the metastatic process, when small numbers or isolated tumoral cells travel and can be attacked by antitumor immune cells not inhibited by factors in the tumour microenvironment. Galon *et al*[18] suggested that once human CRC become clinically detectable, the adaptive immune response plays a role in preventing tumour recurrence and metastasis. Independently, Chiba *et al*[63] and Banerjea *et al*[64] reported that intra-tumoral T cells modify the tumour stroma or CRC cells in a way that attenuate the metastatic potential.

Cytotoxic T lymphocytes ($CD8^+$ T cells, or CTL) constitute one of the leading effector of antitumor immunity. In order for $CD8^+$ T cells to recognize antigens, these need to be exposed on the tumour cells in association with the human leukocyte antigen (HLA) class I proteins[65]. Upon encounter of a tumour cell antigen/HLA I complex for which their T cell receptor (TCR) is specific, $CD8^+$ T lymphocytes clonally expand and differentiate[65]. Once activated, cytotoxic T lymphocytes can mediate specific destruction of tumour cells through the release of lytic components *via* cell-cell interaction[65,66]. Perforin, a cytolytic protein found in the granules of CD8 T-cells and NK cells, and enzymatic proteases, including granzyme B, are secreted determining cell death by disruption of the cell membrane and activation of the apoptotic pathway respectively. $CD4^+$ T cells, which only respond to antigens presented by the HLA class Ⅱ proteins expressed by DCs, are important for antitumor immunity. On the peculiar cytokine profile induced, $CD4^+$ T lymphocytes are mainly subdivided in Th1 or Th2 lymphocytes[67]. Th1 cells secrete cytokines such as interferon-gamma (IFN-γ) and TNF-α, and support cytotoxic T lymphocytes by producing IL-2, required for $CD8^+$ T cells proliferation. Conversely, Th2 cells principally secrete IL-10, IL-4, and IL-5, and limit cytotoxic T lymphocytes proliferation.

Regulatory T cells (Treg cells) have been defined as a T-cell population that functionally suppresses an immune response by influencing the activity of another cell type[68]. Treg cells have been categorized into two main classes based on their ontogeny: naturally occurring Treg (nTreg), which develop in the thymus and are present in mice and healthy humans from an early postnatal period, and Treg which can arise in the periphery (or *in vitro*)[69]. nTreg are characterized by their high expression of CD25 ($CD4^+CD25^+$) and co-expression of the FOXP3[69]. Needham *et al*[70] reported that depletion of intra-tumoral Tregs enhances antitumor immunity and tumour rejection in mouse models. Clarke *et al*[71] have shown that depletion of Tregs in the peripheral blood of patients with CRC was recently shown to unmask $CD4^+$ T-cell responses to tumour antigens. It is known that self-tumour antigens may also induce the preferential proliferation of $CD4^+CD25^+FOXP3^+$ Treg cells. Tregs function to maintain immune homeostasis and limit acute inflammation. These cells interfere with T cell priming and can affect the antitumor function of effector cells *via* secretion of TGF-β and IL-10. A number of investigations suggest that Tregs infiltrating the tumour may adversely affect prognosis[72-75]. Increased levels of Treg cells have been, however, associated with a favourable prognosis in CRC[76-79]. The mechanisms of this dual effect, which seems dependent on the tissue type, are not well understood, although it is hypothesized that Tregs might suppress inflammation induced by growth promoting innate immune system cells.

Although the role of B lymphocytes in cancer has been overshadowed by the interest in developing T-cell-mediated cellular responses, it is now apparent that B lymphocytes can play a complementary role in the host response against tumour. B lymphocytes represent a cell population that express clonally diverse cell surface Ig receptors recognizing specific antigenic epitopes. In addition to the role of B lymphocytes in antibody production, these cells mediate/regulate several other functions fundamental for immune homeostasis. Of significant importance is the antigen-presenting role of B lymphocytes in the initiation of T-cell immune responses. Moreover, B lymphocytes can play a significant role in infection and autoimmunity as regulatory cells (indicated as Bregs) via the elaboration of suppressive cytokines, such as IL-10, TGF-β, or IL-4. The role played by B cells in cancer immunology remains still complex and somewhat controversial. Depending upon their state of activation, B lymphocytes have had divergent roles on T-cell differentiation and effector function. Oversimplifying, resting B lymphocytes have been reported to suppress T-cell-mediated antitumor immunity, by acting on both $CD4^+$ and $CD8^+$ T lymphocytes. In contrast, a number of reports suggest the efficacy of activated B lymphocytes in cellular immunotherapy of malignancies. In particular, activated B lymphocytes have been reported to enhance the ability to generate tumour-infiltrating lymphocytes in vitro involving anti-CD3 and IL-2.

The therapeutic targeting of tumours or components of the immune system with molecule-specific monoclonal antibodies (mAb) is now considered a viable treatment option for cancer patients. One of the currently applied antibodies in clinics is represented by rituximab (Rituxan) that targets B cells for elimination by binding the B cell-associated marker CD20. Interestingly, it has been recently developed a C57BL/6 TRAIL-sensitive tumour model with the aim of being able to use gene-targeted mice to better evaluate the innate and adaptive immune cells contributing to the tumoricidal activity of the MD5-1 mAb in more clinically relevant established tumours. C57BL/6 gene-targeted or immune cell-depleted mice were used to examine the antitumor activity of

MD5-1 against the TRAIL-sensitive mouse MC38 colon adenocarcinoma. It has been shown that an intact B cell compartment is critical for the therapeutic activity of MD5-1 against established tumours. B cells were confirmed to trigger tumour cell apoptosis by FcR-mediated cross-linking of the MD5-1 mAb *in vitro* and *in vivo* B lymphocytes were critical for directly triggering MD5-1-mediated tumour cell apoptosis.

Although the role of B-cells in human CRCs is still not completely characterized, B-cell-deficient mice exhibit spontaneous regression of MC38 colon carcinoma cells. Studies involving BCR transgenic mice indicated that B lymphocytes might inhibit antitumor T lymphocytes responses by antigen-nonspecific mechanisms. Shah *et al* investigated the role of B lymphocytes in tumour immunity by studying immune responses of mice genetically lacking B lymphocytes to primary tumours. They highlight that although the effects of B lymphocytes on anti-tumour response warrant further study, adoptive transfer of CD40(-/-) B lymphocytes into B lymphocytes-deficient mice resulted in restored growth of MC38 colon carcinoma cells suggesting additional factors other than CD40 are involved in dampening anti-tumour responses.

PROGNOSTIC INFORMATION OF IMMUNE CELL INFILTRATE

In contrast to infiltration of cells responsible for chronic inflammation, the presence of high numbers of T lymphocytes has been reported to be a positive prognostic factor in several cancers. The first reports on the beneficial effect of lymphocytic infiltration in CRC appeared already in the Eighties. They were later confirmed until recent most studies highlighting a prominent function for memory T lymphocytes and $CD8^+$ T lymphocytes in predicting disease-free survival and overall survival. In general terms, it has been suggested that prognosis in patients with cancer is positively affected by (1) the presence of a tumour gene signature consistent with a type I adaptive immune response (i.e., increased antigen presentation, IFN-γ signalling, and TCR signalling); and (2) the presence of T cells that penetrate through tumour stroma and deeply infiltrate the parenchyma to become intra-tumoral T cells[20]. Thus, besides a Th-1 response signature, the other key feature of an effective immune response is the ability of T cells to reach the site of the tumour and to infiltrate it. Because T-cell infiltration is not spatially homogeneous in CRC, attention has been focused on the predictive values of T lymphocytes located in the center of the tumor (CT), along the invasive margin (IM) and in lymphoid aggregate mainly detectable in proximity of the tumor (these aggregates are called tertiary lymphoid structures)[80,81].

In a large series of CRCs, Pagès *et al*[82] assessed the immune component of the tumoral microenvironment by a combination of high-throughput gene expression and immunophenotypic analyses, and evaluated its possible influence on tumour dissemination. They found an association between evidence of an immune reaction within the tumour and the absence of tumour local invasion of vascular, lymphatic, and neural structures (collectively referred to as VELIPI). CRCs without VELIPI were associated with an enhanced immune cell infiltration and an increase of mRNA expression of adaptive Th1 effector T-cell markers [CD8, T-box transcription factor 21 (T-bet), IFN regulatory factor-1 (IRF-1), IFN-γ, granulysin, and granzyme B]. The immunohistochemical analysis of adaptive immune markers i.e., CD3, CD8, granzyme B, and CD45RO, by tissue microarrays prepared from the CT and from its IM revealed a statistically significant correlation between the density of these immune cells and outcome for all patients but those with metastatic disease at diagnosis. Further, the combined analysis of both tumour regions improved the accuracy of survival prediction compared with single-region analysis[18].

Independently, Deschoolmeester *et al*[83] showed that the presence of a pronounced lymphocytic infiltration within the tumour is associated with improved survival. They found that $CD3^+$ and $CD8^+$ T lymphocytes within tumour nests and of $CD3^+$ in the stroma had a major impact on the patients' overall survival. The improved survival associated with infiltration of T lymphocytes has been suggested to result from the effective suppression of micrometastases. Therefore, the densities of $CD8^+$ T cells within the primary tumour might be a potential marker of the presence of a systemic immunosurveillance mechanism. In addition, tumour cells secrete substances in the stromal compartment, which might be recognized by the immune system that subsequently attack the tumour. A weak adaptive immune reaction correlated with a very poor prognosis even in patients with early tumour invasion. Conversely, a high density of adaptive immune cells correlated with a highly favourable prognosis whatever the local extent of the tumour and the regional lymph node invasion.

In mice, targeted disruptions of genes that encode critical components of the immune system (i.e., mice lacking: IFN-γ or its receptor, signal transducer and activator of transcription-1 mediating IFN-γ receptor signalling, perforin, recombination activating gene-2, or IL-12) induce an increased susceptibility of the host to tumours[84]. These findings make it possible to hypothesize an immune-mediated control of tumour development by the adaptive compartment.

A number of studies have reported that MSI, CIMP, BRAF mutation, PIK3CA mutation, and tumour LINE-1 hypomethylation are associated with CRC prognosis and that lymphocytic infiltration is associated with many of these molecular variables. The associations of a prognostic biomarker with a given disease, strongly suggests its stage-dependency as outcome predictor. This is best exemplified by MSI CRC, whose overall prognostic advantage is associated with a low frequency of stage Ⅲ and Ⅳ cases at diagnosis as compared to microsatellite stable counterpart. Most MSI CRCs show a pronounced

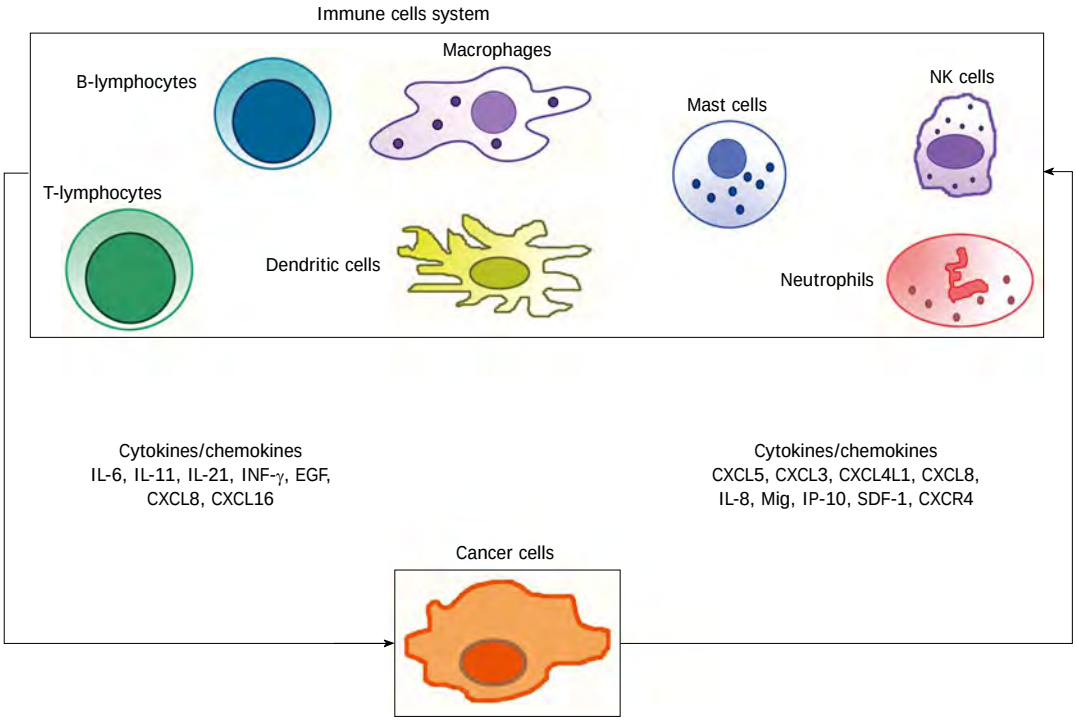

Figure 2 Anti- and pro-tumor immune response involves the interaction of several cell types of the adaptive as well as of the innate immune system, and an intricate network of products (i.e., cytokines and chemokines). IL: Interleukin; INF-γ: Intracellular interferon-γ; EGF: Epidermal-growth factor; NK cells: Natural killer cells.

intra-tumoral inflammatory reaction (in fact a criterion for MSI testing), the mechanistic explanation of which, however, is still incompletely understood. Within these tumours, infiltrating lymphocytes have been identified as predominantly activated $CD8^+$ T cells. The presence of these cytotoxic T lymphocytes has been attributed to the inherently greater production of abnormal peptides as a result of unreliable DNA repair in MSI-positive tumours. It is known that truncated peptides produced by frameshift mutations due to MSI may be immunogenic and contribute to the host immune response. However, little is still known about the interrelationship between tumour-infiltrating T lymphocytes, MSI status, and other tumour molecular features. It is indubitable that to define the prognostic effect of tumour-infiltrating T-cells independently of those potential confounders, large studies of CRC with extensive molecular characterization are needed. Additionally, caution is needed before incorporating tumour-infiltrating T cells into tumour staging. To minimise the risk of inappropriate tumour down-staging at diagnosis, survival data need to be confirmed in independent series of patients studied in the past decade. Moreover, the association has to be conclusively proven between low densities of tumour-infiltrating T cells and the clinical detection of metachronous metastases, which remains the most appropriate outcome measure for recognising a role of the local immune response in micrometastasis suppression. Recently, Laghi *et al*[85] investigated the relationship between the density of $CD3^+$ T infiltrating lymphocytes along the tumour invasive margin, and the occurrence of metachronous distant-organ metastases after potentially curative resection, in a large, consecutive series of patients with deeply invading (pT3 or pT4) MSI-typed CRC, and no evidence of distant organ metastasis at diagnosis. They found that large areas of $CD3^+$ cells at the invasive front of pT3 or pT4 CRCs are associated with a low risk of metachronous metastasis and consequently a survival advantage, only in patients with node-negative cancers, but not in patients whose cancers involved lymphnodes. Of interest, the prognostic advantage conferred by a high density of $CD3^+$ cells was independent of tumour microsatellite status in patients with stage Ⅱ CRC. CD3-immunostaining of CRC tissue might therefore be useful for selecting stage Ⅱ patients who, because they are at very low risk for cancer progression, could be spared adjuvant treatments.

Nosho *et al*[86] examined the prognostic role of tumour-infiltrating T-cell subsets in a database of 768 CRCs from two prospective cohort studies. They concurrently assessed the densities of $CD3^+$, $CD8^+$, $CD45RO^+$, and $FOXP3^+$ lymphocytes as well as other relevant molecular and pathological features, therefore making possible to evaluate the independent effect of each T-cell subset density on patient survival. They found that the density of $CD45RO^+$ cells, but not that of $CD3^+$, $CD8^+$, or $FOXP3^+$ cells, was an independent prognostic biomarker of longer survival in CRC patients. In contrast, Salama *et al*[76] by analysing T-cell infiltrates in 967 CRCs including 593 stage Ⅱ and 374 stage Ⅲ cases, reported that $FOXP3^+$ lymphocytes density had stronger prognostic significance than $CD8^+$ and $CD45RO^+$ cells, and predicted a better outcome. $FOXP3^+$ lymphocytes were

found not associated with any histopathologic features. At multivariate analysis, stage, vascular invasion, and $FOXP3^+$ cell density in tumoral tissue were independent prognostic indicators. These results led Salama *et al*[76] to conclude that the inclusion of $FOXP3^+$ cell density may help to improve the prognostication of early-stage CRC, although these authors do not explored this parameter with tumor stage.

CONCLUSION

It is accepted that human cancer is a complex dynamical disease[87,88]. It is also now well recognized that cancers are not just composed of malignant cells, but that they are microenvironment consisting of many cell types, including a range of immune cells. It is indubitable that the antitumor immune response involves the interaction of several cell types and products (Figure 2), of the adaptive as well as of the innate immune system. It is also clear that CRC can escape immune surveillance using several strategies. The molecular profiles of the function and interaction of innate and adaptive immune cells, and the definition of tumor antigens have all led to build the basis of the knowledge of how the immune system modulates tumor growth and inhibition. The challenge remains to determine not only how the "rejection" pathway initiates in human malignancy, but also how that rejection is maintained. It is indubitable that the analysis of the type, quantity, location and the functions of the immune infiltrate becomes a primary step in understanding CRC natural history, and, in a clinical perspective, its prognostic determinants. A comprehensive analysis of all components of the lymphocytic infiltrates in the context of their localization, organization and impact at various steps of tumor progression remains largely, if not entirely, to be reported to prospective studies. In parallel, understanding the mechanisms of efficient immune reactions, the place where they are initiated, the cells and key cytokines and chemokines involved (Figure 2), and their impact at different stages of the disease should provide new tools and goals for more effective and less toxic targeted therapies.

Abstract

Ionising radiation therapy is a common treatment modality for different types of cancer and its use is expected to increase with advances in screening and early detection of cancer. Radiation injury to the gastrointestinal tract is important factor working against better utility of this important therapeutic modality. Cancer survivors can suffer a wide variety of acute and chronic symptoms following radiotherapy, which significantly reduces their quality of life as well as adding an extra burden to the cost of health care. The accurate diagnosis and treatment of intestinal radiation injury often represents a clinical challenge to practicing physicians in both gastroenterology and oncology. Despite the growing recognition of the problem and some advances in understanding the cellular and molecular mechanisms of radiation injury, relatively little is known about the pathophysiology of gastrointestinal radiation injury or any possible susceptibility factors that could aggravate its severity. The aims of this review are to examine the various clinical manifestations of post-radiation gastrointestinal symptoms, to discuss possible patient and treatment factors implicated in normal gastrointestinal tissue radiosensitivity and to outline different mechanisms of intestinal tissue injury.

INTRODUCTION

Radiation delivery methods

Radiation therapy can be delivered by three main methods. External beam radiotherapy is a method in which radiation beam is delivered from outside the body to the target tumour through two or three-dimensional beam arrays using linear accelerators. Advances in planning and delivery techniques such as 3-dimensional simulation and intensity modulated radiation therapy are associated with a reduced risk of normal tissue toxicity and allow a higher radiation dose to be used compared to conventional two dimensional methods[1-4]. Enhanced target definition of both tumours and surrounding normal tissues and combining beams of varying intensity in intensity modulated radiation therapy allow for better dose delivery and improved tumour control with less toxicity[5,6]. Quantitative dose tracking to both normal tissues and tumors in the form of dose-volume histograms[7] provide a graphic display of a simulated radiation treatment plan and generate valuable information on the dose distribution within the volume of interest[8]. These are now common planning

tools in modern external beam radiation delivery. Brachytherapy is an internal form of radiation therapy where the radiation sources are implanted within or in close proximity to the target tumour to deliver a high dose of localized radiation. This procedure is a highly effective dose delivery method for certain tumours such as prostate and gynaecological cancers. The third method of the radiation therapy is the systemic administration of radioactive particles which is termed radioisotope therapy. In this method radioactive particles (radionuclides) are injected into the blood stream to be adsorbed specifically by the targeted tissue such as thyroid gland[9]. Gastrointestinal radiation injury most commonly occurs following external beam therapy.

A highly precise radiation delivery can be achieved through newer techniques such as image guided radiotherapy techniques which allow verification of the target position on a daily basis to account for internal target motion[10]. Stereotactic radiation therapy[11] can focus a narrow radiation beams on a small target such as early cancer or metastatic lesions[12].

TREATMENT RELATED RISK FACTORS FOR GASTROINTESTINAL INJURY

Radiation dose, fractionation and field size

Radiation dose is a major determinant of the severity of acute and late normal tissue toxicity[13-20], the desired optimal radiation dose is defined as the dose that maximizes the difference between "tumor" and "normal tissue" damage within the sigmoid shape dose-effect relationship curve[11]. With respect to the gastrointestinal tract, the severity of toxicity is reported as Grades of severity to different symptoms or clinical manifestations ranging from minor symptomatic changes to severe life threatening complications. Multiple toxicity grading systems have been developed to assess adverse events of cancer treatment[21]. Generally, Grade 1 and 2 radiation injury are frequent and they are often requiring no treatment although they can cause a considerable effect on patient quality of life. Examples of commonly used toxicity grading system to assess radiation injury severity are the Radiation Therapy Oncology Group[22] and the Common Terminology Criteria for Adverse Events grading system (Table 1)[21]. Radiation dose per fraction and altered fractionation schedules are important factors linked to increased risk of intestinal radiation toxicity[23]. The radiosensitivity of the cell depends on two factors, the intrinsic radiosensitivity which is linearly related to the radiation dose and it is represents the initial slope of the cell survival curve (alpha). The second factor is (beta) which represents the curvature of the cell survival curve and it is a factor of dose-per fraction and dose-rate variations in radiobiology[24].

The alpha/beta ratio represents the dose at which the linear and quadratic components of the Linear-Quadratic model contribute equally to cell killing and has been shown to have a connection to early and late radiation response[25]. In radiotherapy of tumors with long turnover time such as prostate cancer, the alpha/beta ratio is smaller than that of early reacting normal tissues. In this case, hypo-fractionation will be a better strategy for radiotherapy than the many small fractions used for other tumors[24,26,27].

A data analysis of 918 head and neck cancer patients reported a variable prevalence of mucositis between patients treated with continuous hyperfractionated accelerated radiotherapy (CHART) and patients received conventional fractionation radiotherapy. The incidence of Grade 3 confluent mucositis reported after CHART was 75% compared to 44% following conventional fractionation radiotherapy[28].

Modification of the radiation delivery regimes through

Table 1 Example of some gastrointestinal symptoms grades following radiation injury

Grade	Gastrointestinal symptoms
	Nausea
1	Loss of appetite without alteration in eating habits
2	Oral intake decreased without significant weight loss, dehydration or malnutrition; IV fluids indicated < 24 h
3	Inadequate oral caloric or fluid intake; IV fluids, tube feedings, or TPN indicated ⩾ 24 h
4	Life-threatening consequences
5	Death
	Anorexia
1	Loss of appetite without alteration in eating habits
2	Oral intake altered without significant weight loss or malnutrition; oral nutritional supplements indicated
3	Associated with significant weight loss or malnutrition (e.g., inadequate oral caloric and/or fluid intake); IV fluids, tube feedings or TPN indicated
4	Life-threatening consequences
5	Death
	Haemorrhage-GI
1	Mild, intervention (other than iron supplements) not indicated
2	Symptomatic and medical intervention or minor cauterization indicated
3	Transfusion, interventional radiology, endoscopic, or operative intervention indicated; radiation therapy (i.e., hemostasis of bleeding site)
4	Life-threatening consequences; major urgent intervention indicated
5	Death
	Ulceration-GI
1	Asymptomatic, radiographic or endoscopic findings only
2	Symptomatic; altered GI function (e.g., altered dietary habits, oral supplements); IV fluids indicated < 24 h
3	Symptomatic and severely altered GI function (e.g., inadequate oral caloric or fluid intake); IV fluids, tube feedings, or TPN indicated ⩾ 24 h
4	Life-threatening consequences
5	Death
	Incontinence anal
1	Occasional use of pads required
2	Daily use of pads required
3	Interfering with ADL; operative intervention indicated
4	Permanent bowel diversion indicated
5	Death

According to the Common Terminology Criteria for Adverse Events system v 3.0. IV: Intravenous; GI: Gastrointestinal; ADL: Activities of daily living; TPN: Total parenteral nutrition.

Table 2 Summary of risk factors for gastrointestinal radiation injury

Risk factors	
Radiation techniques	Treatment volume, total dose, fractionation dose and schedules
Combined modality therapies	Surgery Chemotherapy: Particularly concurrent
Medical co-morbidities	Vascular disease, connective tissue disease, inflammatory bowel disease, HIV
Genetic susceptibility	Single nucleotide polymorphism, ataxia telangiectasia

HIV: Human immunodeficiency virus.

hypofractionation was also suggested to be safer than conventionally fractionated conformal radiotherapy in a randomized study of prostate cancer radiotherapy[29].

Treatment field size and intestinal volume irradiated are important factor and a key determinant of radiation toxicity. Bowel toxicity was found to be directly related to the volume of small intestine irradiated[13]. Moreover, irradiation to a larger volume of small intestine was reported to increase the operative mortality in rectal cancer patients treated with anterior and posterior field irradiation technique[30,31]. Furthermore, the impact of the field volume has been demonstrated in a randomized study of prostate cancer radiotherapy. Patients who were treated with conformal shielding with 48% less volume irradiation had less rectal toxicity at 5 years than patients treated with conventional radiotherapy, despite identical radiation dose[32,33] (Table 2).

Combined modality approaches

Combined modality therapy increases the risk of radiation toxicity. Surgery or concurrent chemotherapy is linked to an increased incidence of radiation toxicity. Previous abdominal surgery increases the risk of radiation toxicity[34]. Anatomical changes that increases intestinal exposure to radiation such as postoperative small intestine prolapse into the pelvic cavity[13,35] or surgical adhesions that fix intestinal segments within the radiation field can all predispose part of the intestine to receive higher doses of radiation[36]. Combining prostatectomy with radiotherapy can increase rectal toxicity during prostate cancer treatment[37]. An analysis of acute toxicity was performed in 405 prostate patients in The European Organization for Research and Treatment of Cancer randomized trial 22863. In those patients it was reported that among other factors, previous genitourinary surgery was found to be predictive of lower gastrointestinal radiation toxicity[38].

Combining chemotherapy with radiation has been reported to increase the rate of acute intestinal toxicity, while the long term effect of this combination is not clear[20,39]. Oral mucositis was reported in more than 90% of patients treated with a combined chemo-radiotherapy regime for head and neck cancer[40,41] in comparison to another study which reported an incidence of oral mucositis in 62% of patients treated with radiotherapy alone[42]. Concurrent chemotherapy with radiation has also been reported to increase the risk of oesophageal radiation injury by 12-fold[43].

In a study of cervical cancer patients treated with chemoradiotherapy, the incidence of Grade 3 late intestinal toxicity increased from 10% to 26% in patients treated with both mitomycin and fluorouracil compared to a fluorouracil alone group, suggesting a possible role for the type of chemotherapeutic agent used as determinant of severity of gastrointestinal toxicity[44].

Different mechanisms have been suggested to explain the sensitizing effect of adding chemotherapy in increasing the risk of intestinal radiation injury. Examples of possible mechanisms are alterations in cell cycle kinetics, or synchronization of replicating cell populations. Halopyrimidines such as fluorouracil, fluorodeoxyuridine and iododeoxyuridine may sensitize tumors both by inhibiting effective DNA repair and by increasing the amount of radiation induced DNA damage[45-47].

SYMPTOMS RESULTING FROM RADIATION INJURY TO THE GASTROINTESTINAL TRACT

Acute and chronic gastrointestinal radiation injury

During external beam radiotherapy, ionising radiation enters and exits the body and therefore affects normal tissues surrounding the target tumour. The gastrointestinal tract which extends over a large surface area and any part of the gastrointestinal tract that falls within the radiation field can be affected, resulting in acute and chronic symptoms of gastrointestinal radiation injury (Table 3).

Clinical manifestations of gastrointestinal radiation injury can present during or soon following radiotherapy. These symptoms are related to acute mucosal injury and inflammation. Delayed symptoms occur a few months or years after radiotherapy and are attributed to a chronic process of transmural fibrosis and vascular sclerosis. Typically symptoms are considered "acute" if they occur within the course of treatment or up to 90 d following treatment. These are generally reversible. Chronic side effects are much less common and occur more than 90 d post radiation; they are less likely to reverse. The onset of delayed symptoms has been reported as much as after 30 years following radiotherapy[48].

Mouth, pharynx, and oesophagus

During radiotherapy for head and neck or thoracic cancer, the upper gastrointestinal tract falls within the radiation field. Irradiation to this area results in acute mucosal injury causing mucositis and ulceration which manifests within the first two weeks in 30%-60% of patients, causing dysphagia and odynophagia[49]. In a study of 254 non-small-cell lung cancer patients, acute toxicity of Grade 2 or worse has been reported in 78% of patients[50]. Mucositis is debilitating, can be a dose limiting side effect and

Table 3 Acute and chronic manifestations of gastrointestinal radiation injury

Clinical manifestations	Radiation tolerance dose TD5/5, TD50/5 (Gy)	Gastrointestinal organ
Oral mucositis occurs in > 90% of patients with concurrent chemotherapy[40] Xerostomia and altered saliva composition	Parotid gland: TD5/5 (32) TD50/5 (46)[60,179,180]	Mouth, salivary glands, hypopharynx, parotid
Acute Grade 3-4 oesophageal injuries occur in 46%with concurrent chemotherapy[181]	TD5/5 (55-60)	
Dose > 58 Gy predicts Grade 3-5 acute oesophagitis[54] 60 Gy resulted in Grade 3 toxicity in 42%[182] Radiation can lead to late stricture and/or perforation of the oesophagus[53,60]	TD50/5 (68-72)[60,179]	Oesophagus
40 Gy: Severe late toxicity in 7% including ulceration, gastritis and small-bowel obstruction/perforation[183]	TD5/5; (50-60) TD50/5 (65-70)[60,179]	Stomach
Elevated liver enzymes in 5%[184]	TD5/5; (30-50)	Liver Small intestine
(31.3-37 Gy resulted in RILD in 9.4%[66,185]	TD50/5; (40-55)[60,179]	
45 Gy cause 5% Grade 3-4 toxicity and 14% with concurrent chemotherapy[71]	TD5/5; (40-50)	
Diarrhoea, abdominal pain in 20-70%[72] Transmural fibrosis leading to obstruction in 5%-10%[68,77-78]	TD50/5; (55-60)[60,179,180]	
Intestinal fistulation occurs at a rate of 0.6% to 4.8%[68,79] 50 Gy 5 year estimate of small bowel obstruction is 11%[186]		Colon and rectum
Colitis in 25%-50% of patients[186]	Colon	
Grade 2-3 acute proctitis 40%[91]	TD5/5; (45-55)	
Chronic rectal symptoms in 6.7%-31%[91]	TD50/5 (55-65)[60,179,180]	
Acute symptoms of anus and rectal injury occur in up to 75% of patients during radiotherapy[187]	Rectum TD5/5; (60-61.38) TD50/5 (80-81.38)[60,179,180]	

TD5/5: Radiation dose associated with 5% of patients' risk of delayed toxicity in 5 years; TD50/5: The radiation dose associated with 50% of patients' risk of delayed toxicity in 5 years. RILD: Radiation-induced liver disease.

is difficult to treat. Severe symptoms may require therapy interruption, or the provision of an alternative nutritional route to avoid dehydration and malnutrition. Therefore, elective percutaneous endoscopic gastrostomy tube insertion before radiotherapy is a recognized practice and it is associated with improved quality of life and a lower rate of hospital admissions[51,52]. In severe cases, acute radiation oesophagitis can lead to more serious complications such as significant bleeding or oesophageal perforation[53].

Clinical predictors for acute oesophageal toxicity include maximum radiation dose. A maximum dose of > 58 Gy was reported to predict the risk of Grade 3-5 oesophageal toxicity in 207 non-small-cell lung cancer patients treated with 3-dimensional conformal radiotherapy[54] while a dose of 50 Gy was significantly associated with Grade 2 or worse oesophagitis in another cohort 36 non-small-cell lung cancer patients[55]. In both studies patients received concurrent chemotherapy which is also a risk factor for oesophageal toxicity. The volume of the irradiated oesophagus has also been suggested to predict acute oesophageal toxicity[55]. In another series of 208 non-small-cell lung cancer patients treated with three dimensional conformal radiotherapy, concurrent chemotherapy and maximal point dose to the oesophagus > 60 Gy were found to be significantly associated with the risk of Grade 3-5 oesophageal injury[56]. The Quantitative Analyses of Normal Tissue Effects in the Clinic paper by Werner-Wasik *et al*[57] published in 2010 reviewed the published data on the dose-volume effect and concluded that it was not possible to identify the best threshold volumetric parameter for oesophageal irradiation given the variety of the volumetric metrics in the published data.

Delayed symptoms of oesophageal injury can manifest after several months following radiotherapy and include chronic ulceration, fistulisation or chronic dysphagia. Dysphagia can be secondary to tissue fibrosis and stricture formation or due to motility disorder induced by muscular or nerve injuries. Delayed oesophageal toxicity has been reported in 17% of non-small-cell lung cancer patients[50] and the median and maximal time to the onset of late toxicity was 5 and 40 mo respectively after radiotherapy.

Stomach and duodenum

Gastric injury during radiotherapy occurs when the stomach falls within the radiation field of an adjacent tumour. Nausea, vomiting, dyspepsia and abdominal pain has been reported to occur early after radiotherapy to the upper abdomen in 50% of patients[58]. These symptoms result from acute mucosal injury causing erosions and ulceration of gastric and duodenal mucosa.

Later symptoms include chronic dyspepsia and abdominal pain due to chronic ulceration secondary to mucosal injury[59]. Rarely, gastric wall fibrosis can lead to gastric outlet obstruction. The radiation dose associated with 5% and 50% of patients risk of delayed gastric toxicity in 5 years (TD5/5 and TD50/5) have been estimated at 50 Gy and 65 Gy respectively for gastric ulceration or perforation. An accurate data on dose-volume constrain for partial gastric irradiation is not available. However, the threshold dose of 45 Gy to the whole stomach has been associated with ulceration in 5%-7% of patients[60,61].

Liver injury

Following irradiation to the liver, radiation induced liver disease can occur in patients with normal pre-radiotherapy liver function, causing anicteric hepatomegaly and mild alkaline phosphatase serum level elevation. A more

severe derangement of liver function occurs in patients with pre-existing liver disease[62]. Radiation induced liver disease can progress to fibrosis, cirrhosis, and liver failure[63]. Abdominal imaging with computed tomography scan or magnetic resonance imaging can be helpful to show low-attenuation injury areas or areas of atrophy in the irradiated liver segment[64].

Risk factors for radiation induced liver disease include baseline liver dysfunction, Hepatitis B virus carrier status[65], mean dose > 30 Gy for partial liver radiotherapy, concurrent chemotherapy and volume of liver irradiated[66,67].

Small intestine

The small intestine receives irradiation during radiotherapy of pelvic or abdominal malignancies. The degree of injury depends on the radiation dose and the volume of intestinal segment that falls within the radiation field[68,69]. Significant correlation has been suggested between the volume of irradiated small bowel and the likelihood of acute toxicity, regardless of the radiation dose delivered[70]. Other predictors of acute small intestine toxicity include the use of concurrent chemotherapy. This effect has been reported in 186 cervical cancer patients who received 45 Gy preoperative pelvic radiotherapy alone where 5% of patients experienced Grade 3-4 toxicity in comparison to 14% of 183 patients who received radiotherapy and weekly cisplatin[71]. The relatively fixed portions of the small intestine such as the duodenum and the terminal ileum are at increased risk of radiation toxicity as they are more susceptible to receive higher doses of radiation than the mobile parts of small intestine.

The radiation dose associated with delayed small bowel toxicity have been estimated by Emami *et al*[60]. The TD5/5 and TD50/5 doses for one third of small bowel irradiation were estimated at 50 Gy and 60 Gy respectively. The TD5/5 and TD50/5 for the whole-organ irradiation were 40 Gy and 55 Gy respectively. These doses estimates remained as a guide for two decades and more recent data were consistent with these ranges[60,61].

Clinically, nausea, vomiting and abdominal pain are early symptoms that can occur during the first two weeks following abdominal radiotherapy, and may be mediated by the release of inflammatory cytokines following radiotherapy. Diarrhoea and abdominal pain occur during the first two weeks of radiotherapy to abdominal or pelvic malignancies in 20% to 70% of patients[72]. This may be a result of direct radiation injury to the small intestinal mucosa causing epithelial atrophy, and reduced mucosal blood flow[73].

The acute symptoms usually settle within three weeks after completion of radiotherapy and the intestinal epithelium regenerates from stem cells at the base of the crypts.

Delayed symptoms of radiation small intestinal injury manifest months to years after radiotherapy with symptoms of diarrhoea, recurrent abdominal pains and malabsorption.

Chronic diarrhoea following radiotherapy can result from different pathophysiological processes such as bile salt malabsorption, bacterial overgrowth, fat malabsorption, rapid intestinal transit or lactose intolerance[74]. More chronic symptoms occur as a result of pathological abnormalities to the intestinal vascular compartment resulting in intestinal ischemia as well as progressive intestinal fibrosis leading to structural abnormalities such as strictures and fistulation. Bacterial overgrowth contributes to malabsorption and diarrhoea, particularly in patients with intestinal strictures[73,75].

Intestinal obstruction can complicate 5% to 10% of severe small intestinal radiation injury[76]. The rate of severe small intestinal complications following radiotherapy for rectal cancer can vary considerably depending on the tumor and treatment characteristics, Reports indicate rates of 0.8% to 13% for small intestinal obstruction[68,77,78] and 0.6% to 4.8% for intestinal fistulation[68,79]. Patients with severe small intestinal injury have a poor prognosis since surgery to manage strictures is complex and has been associated with poor outcomes[73,80].

Colon and rectum

During abdominal and pelvic radiotherapy, the colon and rectum are commonly affected as their anatomical locations fall within the radiation field of a variety of cancers. The fixed portions of the colon, the caecum and the rectum are at greater risk of receiving higher doses of radiation than the remainder of the colon.

Acute radiation injury to the rectum and anal canal can result in a diversity of symptoms such as abdominal pain, diarrhoea, tenesmus, rectal pain, urgency, rectal discharge, incontinence, and fresh rectal bleeding. These symptoms occur primarily as a consequence of direct mucosal damage[81-83]. Acute radiation injury to the colon can be severe and in 5%-15% can lead to therapy interruption or treatment plan alteration[84].

A recent study showed that 47% of women who received radiotherapy for cervical or endometrial cancer reported symptoms of radiation intestinal injury affecting quality of life within 3 mo following therapy completion[85]. These results are consistent with a previous structured questionnaire study[86] which showed that 53% of patients had reported bowel symptoms significantly affecting their quality of life, whilst 81% of patients in the study described new-onset gastrointestinal problems after receiving radiotherapy.

The recent data on dose-volume effect in radiation induced rectal injury was reviewed by Michalski *et al*[87]. The incidence of Grade > 2 injury from different studies was variable according to dose, treatment parameters and scale used in each study. Among the recent studies reported, an incidence of 13.5% and 16% of Grade > 2 rectal injury. Identified predictors for Grade > 2 rectal injury or rectal bleeding include the volume of the rectum irradiated and a total radiation dose > 60 Gy during 3-dimensional conformal radiotherapy. The effect of concurrent chemotherapy has been observed in the

European Organization for Research and Treatment of Cancer study where patients received 45 Gy preoperative radiotherapy or radiotherapy and 5-flurouracil (5-FU). Grade > 2 diarrhoea occurred in 17% of radiotherapy alone group compared to 38% of radiotherapy and 5-FU group[88].

Delayed symptoms of radiation colonic injury are insidious and usually follow a progressive course. They can manifest after a latent period of few months or years. One study has reported a 15% incidence of bowel toxicity 20 years after receiving radiotherapy in a cervical cancer cohort[89]. Severe life threatening complications occur after radiotherapy such as fistulation, sepsis, perforation or bleeding at a rate between 4%-8% within 5-10 year time after radiotherapy[90]. Patients suffer from a variety of symptoms, such as abdominal pain, changing bowel habits with intermittent diarrhoea. Constipation can result from altered colonic motility due to fibrosis and stricture formation. An abnormal bowel transit can manifest as recurrent pain and increased risk of obstruction or pseudo-obstruction secondary to fecal loading. Excessive fibrosis can cause loss of ano-rectal compliance and manifests as urgency and frequency[73]. Faecal incontinence has been reported in up to 20% of patients and significantly reduces patients' quality of life[86,91].

Unlike radiation injury to the small bowel, radiation injury to the colon does not compromise nutrient absorption and malabsorption is uncommon[73].

Adverse effects of radiation to the pelvis primarily affect the colon and the rectum. However, other organs can be irradiated causing increased morbidity for example injury to the urinary tract or the genital system resulting in symptoms affecting quality of life were reported in 30% of patients[92-95]. A rare but serious complication of prostate brachytherapy is recto-vesical fistula which occurs with a low frequency of 1 in 250 to 1 in 1000 patients implanted[96-98].

Radiation exposure increases the risk of a secondary malignancy. Patients who received radiotherapy were shown to have significantly higher risk of developing second cancers both overall and in the areas that were exposed to the radiation field[99]. In an analysis of testicular cancer survivors which included 28 843 men, the risk of a second cancer was estimated. The patterns of second cancer suggested that many factors may be involved, including previous treatment received, but the precise roles of different factors is still to be clarified. It has been reported that secondary leukaemia was associated with both radiotherapy and chemotherapy, whereas excess cancers of the stomach, bladder, and possibly pancreas were associated mainly with radiotherapy[100]. This risk also includes colorectal cancer, which can occur more than 10 to 20 years after radiation exposure[99,101].

PATIENT RELATED RISK FACTORS

Patient factors and individual variations

Individual patient phenotypic factors have been suggested to influence the susceptibility to intestinal radiation injury. It was reported that older patient age is associated with an increased risk of developing reduced organ function after radiotherapy[102-104]. Body habitus has been reported as another susceptibility factor, where thin patients with narrow antero-posterior diameter can suffer an increased risk of intestinal radiation toxicity compared to normal individuals[36]. Smoking status has been associated with risk of chronic intestinal toxicity[20,105] as well as previous history of surgery[13,35,36].

Medical co-morbidities

Vascular disease: Co-morbid vascular disease such as hypertension, diabetes mellitus and atherosclerosis were suggested to predispose patients to an increased vascular injury following radiation and subsequent intestinal wall ischemia and impaired tissue repair[74]. The microocclusive vascular disease in addition to increased blood viscosity in diabetes mellitus were suggested to predispose to intestinal tissue ischemia[106,107]. One study investigated the possible effect of diabetes mellitus during prostate cancer radiotherapy. The study reported higher rates of late genitourinary/gastrointestinal toxicities in diabetic patients than in non-diabetics (34% and 23% respectively). It was also noticed that diabetics developed complications earlier than the non-diabetics (10 mo and 24 mo respectively)[108].

Inflammatory bowel disease: Co-morbid inflammatory bowel disease (IBD) is considered in some institutions as a relative contraindication to radiotherapy for concerns of greater risk of acute and late side effects[109-111]. Intolerance to radiotherapy in IBD patients has been demonstrated in case reports[112,113] and in a larger retrospective analysis where the incidence of severe acute and late events was 21% and 29% respectively[114,115]. However, in a large retrospective analysis in patients with colorectal cancer, the data on treatment modality received for 170 colorectal cancer patients with history of IBD found no significant difference in cancer treatment modalities between patients with or without history of IBD. This observation points out that a history of IBD was not a barrier to receive radiotherapy treatment in this patient group[116].

It has been postulated that co-morbid IBD and intestinal inflammation may alter the acute tissue response to radiotherapy through inflammatory mediators, growth factors and cytokine cascades produced at the site of intestinal injury. Some mediators and cytokines were suggested to decrease the sensitivity to radiation injury e.g., fibroblast growth factor 2, prostaglandin-E2, tumor necrosis factor-α and interleukin (IL)-1 and IL-11. However, others were suggested to have mixed effects e.g., IL-12 protecting bone marrow-derived cells but sensitizing intestinal epithelial cells to radiation injury[117-123].

Collagen vascular diseases: Collagen vascular diseases (CVD) increases the risk of both acute and chronic radia-

tion toxicity, as has been reported by Chon *et al*[105] in 4 different studies in patients with and without CVD. On the other hand, radiation may cause an acute exacerbation of systemic symptoms in patients with CVD[124], possibility through release of fibroblast-triggering mediators by the inflammatory cells[105].

Human immunodeficiency virus infection: It has been reported that human immunodeficiency virus (HIV) infection induces a state of radiosensitivity because severe mucositis was observed in HIV patients who received radiotherapy for the treatment of Kaposi sarcoma[125,126]. Support for this hypothesis was found by an increased radiosensitivity of skin fibroblasts of HIV patients with Kaposi sarcoma compared to healthy control[127]. It was also noted in a study involving 59 HIV positive patients that T-lymphocytes of HIV infected individuals were considerably more sensitive to X-rays compared to that of HIV negative donors[128]. Housri *et al*[129] reviewed the recent evidence and suggested recommendations for radiotherapy in HIV patients, based on the strength of the best available evidence, and classified according to Strength of Recommendation Taxonomy. There was no conclusive evidence to support the need for special precautions for HIV patients during radiotherapy[130].

Genotypic variations

It has been suggested that patient's genotype may impact their individual susceptibility to radiation toxicity. This can occur through inherited germ-line mutations in genes involved in DNA damage detection, DNA repair or cell cycle regulation[131-133]. Recently the term Radiogenomics has been introduced to refer to the science that aims to predict clinical radiosensitivity and to optimize radiotherapy treatment from individual genetic profiles[134].

Genetic variations are thought to be a key determinant of normal tissue radiosensitivity and may account for up to 80% of the inter-individual variations in normal tissue reaction to radiotherapy[135,136]. Support for this hypothesis was provided in a study of breast cancer radiotherapy, which reported the incidence and time to development of radiation-induced telangiectasia[137]. The results of the study revealed a wide range of variation suggesting that patient-related factors can explain 81%-90% of the patient-to-patient variation in telangiectasia level seen after radiotherapy despite similar radiation treatment given. The results further supported reports of other studies[138,139].

The state of extreme tissue radiosensitivity which has been identified in patients with germ-line mutations in genes involved in DNA damage detection or DNA repair e.g., Nijmegen breakage syndrome, Fanconi's anemia and Ataxia telangiectasia has supported the potential role of genetic variations as an important determinant of individual's radiation response. Nevertheless, this risk is probably confined to patients and carriers of those mutant genes and is not known to be relevant to other patients receiving radiotherapy[31,45,140,141].

Candidate gene studies, [single nucleotide polymorphism (SNP) association studies] have investigated the role of many genes which have been linked to different elements of the mechanisms related to the pathogenesis of radiation toxicity. Genes investigated include those involved in DNA repair such as *ATM*, *BRCA1*, *BRCA2*[142,143], apoptosis such as *TP53, BCL2*[144,145], antioxidant enzymes such as *SOD1*[146], and growth factors *FGF2*[147,148] and *VEGF*[147,148]. In this regard, an association has been suggested between candidate SNPs in the genes *TGFB1*, *SOD2*, *XRCC3*, *XRCC1* and late radiation toxicity in breast cancer patients[133,149]. Similarly, SNP association studies in pelvic tissue have suggested correlations between some risk genes such as *XRCC1*, *XRCC3*, *TGFB1*, *OGG1* and an increased risk of developing late gastrointestinal and genitourinary radiation toxicity following radiotherapy[150-152].

MECHANISMS OF RADIATION INJURY

Ionising radiation induces double strand breaks in DNA. This triggers activation of a signalling pathway that leads to activation of tumour suppressor p53. Depending on the extent of the DNA damage, which depends on the radiation dose, and on other factors in the cellular milieu, p53 activation leads to cell cycle arrest and DNA double strand break repair, or apoptosis. In cancer radiotherapy, apoptosis of tumour cells is the desired outcome. However, intestinal crypt epithelial cells are quite sensitive to radiation and the killing of these cells leads to mucosal injury[153,154]. Specifically, when the dose of radiation is sufficient to kill all of the epithelial stem cells in a crypt, then as the epithelial cells migrate up the crypt and are eventually shed into the intestinal lumen; the crypt cannot be repopulated with epithelial cells, and consequently involutes. When this happens to a large proportion of crypts in a region of intestine, normal barrier function is lost which leads to the exposure of the normally sterile lamina propria to luminal microbes. This triggers an acute inflammatory response associated with immune cellular infiltrates; T lymphocytes, macrophages and neutrophils causing loss of epithelial cells as well as degradation of the extracellular matrix in the lamina propria due to enzymes and mediators released by the immune cells[155]. A further damage to the mucosal and submucosal tissues are caused by reactive oxygen metabolites which are produced in large amounts by activated leukocytes in the inflamed mucosa and this can induce significant damage to various cellular components, including structural and regulatory proteins, carbohydrates, lipids, DNA, and RNA[31].

During radiotherapy, ionising radiation kills crypt epithelial stem cells. As a result, crypts involute and epithelial barrier integrity is lost. This provides access of luminal microbes and their products to innate immune cells in the lamina propria, with activation of immune cells. An impaired recognition of bacterial translocation can further exacerbate the inflammatory process and promote

stricture formation by two possible mechanisms. The bacterial wall antigens could causes a secondary excessive up regulation of pro-inflammatory transcription factors, such as nuclear factor kappaB[156]. This might be followed by prolonged macrophage activation and induction of NADPH oxidase expression[157] leading to a further increased in oxygen radical secretion to eradicate bacteria leading to further tissue destruction[155]. Meanwhile translocated bacteria could directly stimulate neighboring mesenchymal cells via pattern recognition receptors leading to increased activation of immune cells[156,158].

The acute inflammatory process continues but eventually, after the cessation of radiation, through poorly understood mechanisms, crypts start to regenerate and this restores normal epithelial barrier function, which is followed by resolution of inflammation[159]. In some patients this inflammatory process becomes exaggerated for unknown reasons with severe ulceration and inflammatory process runs a chronic course characterised by extensive fibrosis and intestinal ischemia[160,161]. Recent observations in animal models of radiation injury indicate that repair after radiation may depend on the recruitment of mesenchymal stem cells from the bone marrow to the site of radiation injury. Mesenchymal stem cell mobilization and engraftment is thought to be induced by cytokines and potentially specific homing induced by chemokines, all of these are released by inflammation[162,163].

The final pathological outcome of the radiation injury in the intestinal tissue will depend on a complex crosstalk between various cellular components of the tissue within the extracellular matrix which eventually determine the process of tissue recovery or long term complications[73,164].

Radiation injury to the vascular compartment is thought to be a key feature in the pathological processes of intestinal radiation injury as well as an important determinant of both acute and chronic effects after radiotherapy[165,166]. It has been regarded as a major component in the initiation, progression and maintenance of delayed intestinal tissue damage and enhanced fibrosis which lead to loss of mucosal function and stricture formation[167,168].

Endothelial cell apoptosis has been implicated as the primary lesion leading to epithelial stem cell dysfunction and subsequent intestinal tissue damage following radiotherapy. Support for this hypothesis was found by identifying a state of radioresisitance following inhibition of endothelial apoptosis in experimental mice. Radiation-induced crypt damage, organ failure, and death from radiation injury were all prevented when the endothelial apoptosis was inhibited pharmacologically, by the administration of fibroblast growth factor or genetically by deletion of the acid sphingomyelinase gene[169]. However, subsequent studies challenged this concept by demonstrating an epithelial cell apoptosis at lower radiation doses which is insufficient to cause endothelial cell death. This result has been enforced further by experiments using high dose Boron therapy radiation, specifically targeted to the endothelium. The results showed no effect on epithelial stem cell survival[168,170].

Formation of new blood vessels (angiogenesis) is a crucial requirement for tumour growth and survival[171]. The tumour vasculature is prone to hypoxia which results in further production of proangiogenic factors by tumour cells. Angiogenesis inhibitors target tumour endothelial cells and cause inhibition of new vessel formation and a transient tumour hypoxia[172,173]. Although tumour hypoxia has been linked to increasing tumour radio-resistance, studies have shown that the administration of angiogenesis inhibitors improves tumour oxygenation and response to radiotherapy[174-177]. Different mechanism has been suggested for the radio-sensitising effect of combining angiogenesis inhibitors with radiotherapy[173]. Mazeron *et al*[178] has recently reviewed the clinical trials on angiogenesis inhibitors, but despite the promising value of these new agents, the biological basis for their synergistic effect and the safety and efficacy of these agents are still to be determined.

CONCLUSION

Intestinal radiation injury is a significant clinical issue which is expected to increase in prevalence due to improved survival of cancer patients as well as to increased availability of radiotherapy as an affordable treatment option. Radiotherapy treatment can cause a wide variety of gastrointestinal side effects. Following radiation injury to the gastrointestinal tract, symptoms can present acutely or after a long period of time. Although severe intestinal injury is less common with the development of advanced radiotherapy planning and delivery techniques, a less severe degree of injury is common and continues to affect a considerable proportion of patients, significantly reduces their quality of life, ands an extra burden to the cost of health care. The accurate diagnosis and management of intestinal radiation injury represents a clinical challenge to practicing physicians in both gastroenterology and oncology. Despite the growing recognition of the problem and some advances in understanding the cellular and molecular mechanisms of radiation injury, relatively little is known about the pathophysiology of intestinal radiation injury or the exact factors that aggravate it. Patient and treatment related risk factors have been suggested although the exact influence posed by these factors is still to be better characterized. Combined modality therapies for cancer are commonly used and they increase the risk of radiation toxicity and further add to the problem. Medical co-morbid diseases such as vascular disease, inflammatory bowel disease and collagen vascular disease can pose a significant risk that can affect patient suitability to receive radiotherapy treatment. Genotypic variations can influence the risk of gastrointestinal radiation injury but future research findings on this area are needed to assess their clinical importance. A better understanding of the pathophysiology of radiation injury may provide the opportunity to develop more effective preventive and therapeutic strategies.

Abstract

With the recent advances in detection and treatment of cancer, there is an increasing emphasis on the efficacy and safety aspects of cancer therapy. Radiation therapy is a common treatment for a wide variety of cancers, either alone or in combination with other treatments. Ionising radiation injury to the gastrointestinal tract is a frequent side effect of radiation therapy and a considerable proportion of patients suffer acute or chronic gastrointestinal symptoms as a result. These side effects often cause morbidity and may in some cases lower the efficacy of radiotherapy treatment. Radiation injury to the gastrointestinal tract can be minimised by either of two strategies: technical strategies which aim to physically shift radiation dose away from the normal intestinal tissues, and biological strategies which aim to modulate the normal tissue response to ionising radiation or to increase its resistance to it. Although considerable improvement in the safety of radiotherapy treatment has been achieved through the use of modern optimised planning and delivery techniques, biological techniques may offer additional further promise. Different agents have been used to prevent or minimize the severity of gastrointestinal injury induced by ionising radiation exposure, including biological, chemical and pharmacological agents. In this review we aim to discuss various technical strategies to prevent gastrointestinal injury during cancer radiotherapy, examine the different therapeutic options for acute and chronic gastrointestinal radiation injury and outline some examples of research directions and considerations for prevention at a pre-clinical level.

Shadad AK, Sullivan FJ, Martin JD, Egan LJ. Gastrointestinal radiation injury: Prevention and treatment. *World J Gastroenterol* 2013; 19(2): 199-208 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/199.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.199

INTRODUCTION

External beam radiotherapy is a common treatment modality for wide varieties of cancers. Approximately 70% of all cancer patients receive radiotherapy during the course of their disease, while radiotherapy plays a central role in 25% of all cancer cures[1-2]. Radiotherapy is a cost effective treatment, accounting for only 5% of the total cancer care expenditure[3]. This estimate has increased over the last decade with the wide use of modern technological innovations in simulation, delineation, dose calculation and radiation treatment delivery[4].

Gastrointestinal radiation injury is an important problem for two main reasons. First, it causes morbidity associated with a significant economic burden[5] and a significant reduction in patient's quality of life[6,7]. Second, it limits the dose of radiation that can be used to control cancer, as radiotherapy-related side effects often limit the tolerability for patients. Clinical manifestations of gastrointestinal

radiation injury can present acutely during or soon following radiotherapy due to acute mucosal injury and inflammation or they can present insidiously within few months or years after radiotherapy due to a chronic process of transmural fibrosis and vascular sclerosis.

Radiation toxicity to the gastrointestinal tract can be reduced by either of two strategies: technical strategies, which aim to physically shift the radiation dose away from the normal tissues or through biological strategies which aim to modulate the cellular and tissue response to ionising radiation.

TECHNICAL STRATEGIES FOR PREVENTION

Attention to detail regarding both radiotherapy planning and radiation delivery methods can minimise the risk of intestinal toxicity during pelvic radiotherapy. Multiple field planning and delivery can reduce the radiation dose to normal intestine as well as minimise the volume of small intestine exposed to radiation in the pelvis[8].

Physical manoeuvres and tissue expander techniques

The impact of different physical measures such as patient position during pelvic radiotherapy have been evaluated in a randomized trial of supine and prone positioning in patients undergoing conformal radiotherapy for prostate cancer. There were significant improvements for small bowel, rectal wall and bladder wall doses in the supine position[9].

Another study utilised combined manoeuvres to displace the small intestine from the pelvis during radiotherapy by bladder distension, lower abdominal wall compression with the patient in prone position using two-field and four-field planning radiographs of contrast-enhanced small bowel[10]. The results demonstrated in 50% of patients the four-field volume of pelvic small bowel was significantly less in the prone position than in the supine position. Similarly, other techniques such as the use of a "belly board" while the patient is in the prone position where the opening in the table allows the abdomen to fall below the level of the table, displaces the small bowel by the effect of the gravity during radiotherapy. These technique were found to reduce the volume of the small intestine within the pelvis by a mean of 66%[11].

Pre-treatment small bowel contrast studies can assess the location and mobility of the small bowel and hence, determine the optimum treatment position that could minimise the volume of small intestine within the pelvis[12]. Tissue expander techniques have been used to minimise the volume of exposed small bowel within the irradiation field during abdominal and pelvic external beam radiotherapy. Studies have shown a reduction of 50% in the risk of chronic intestinal complications with the use of intra-pelvic tissue expander[13]. Other techniques used to minimise the radiation dose to the rectum include transperineal injection of human collagen to increase the distance between the prostate gland and anterior rectal wall. The mean reduction in dose to the anterior rectal wall was 50% with no rectal toxicity reported[14].

Prophylactic surgical techniques

Various prophylactic surgical therapies were also employed to reduce the small intestinal exposure during pelvic radiotherapy such as insertion of biodegradable mesh slings, intra-pelvic breast prostheses or omentoplasty during operative resection whenever postoperative radiotherapy may be indicated[15-20]. Mesh slings were found to reduce the volume of small intestine exposed by 50%[21,22] while other techniques such as pelvic reconstruction, omentoplasty and transposition of the large bowel were found to reduce the volume of bowel at risk by 60%[22,23]. Prostate gland immobilization and rectal wall sparing has been suggested by the use of endorectal balloons during prostate cancer radiotherapy. Endorectal balloons are reported to be well tolerated by patients and showed a significant rectal wall sparing effect during three-dimensional conformal radiotherapy and intensity-modulated radiotherapy for prostate cancer[24,25].

Optimised planning and delivery techniques

A significant improvement in the safety of radiotherapy treatment has been achieved through the use of optimised planning and delivery techniques which aim to reduce the field size, focus the radiation beam into the lesion and minimise the volume of exposed surrounding tissues in the radiation field[10]. Multiple field arrangements may also reduce normal tissue toxicity during pelvic radiotherapy.

The dose-volume histogram is a plot of a cumulative dose-volume frequency distribution, that graphically summarizes the simulated radiation distribution within a volume of interest of a patient which would result from a proposed radiation treatment plan[26]. It provides a graphic display of a simulated radiation treatment plan and generates valuable information on the dose distribution within the volume of interest[27]. The dose-volume histogram is used to predict the development of radiation toxicity and to identify low and high risk patient groups[28]. Careful review of the dose-volume histogram of both the intended targets as well as the structures of avoidance constitutes a standard part of the assessment of the radiation treatment plans in modern radiation therapy.

Three-dimensional conformal techniques which comprise computerised tomography scanning simulation techniques and intensity modulated radiation therapy are associated with a reduced risk of normal tissue toxicity and allow a higher radiation doses to be used compared to conventional two dimensional methods[29-32]. Computerised tomography scan simulation techniques were found to reduce the volume of the bowel unintentionally irradiated by 5% compared to conventional radiotherapy[33].

Intensity modulated radiation therapy allows clear definition of both target lesions and surrounding normal tissues and hence the ability to apply two different inten-

sities of radiation (high and low) within the same treatment field[34,35]. It represents the ultimate combination of treatment planning and delivery which provides the most flexible delivery of radiation to complex targets while minimising radiation doses to surrounding critical structures. It does so by utilizing sophisticated planning algorithms such as inverse planning and multiple small beams of varying intensity, to optimally deliver the treatment. Intensity modulated radiation therapy was associated with a significant reduction in toxicity following pelvic radiotherapy in prostate cancer patients[36]. It was also associated with a reduction of 15%-18% in intestinal volume unintentionally irradiated compared to conventional two dimensional radiotherapy, and a 10%-13% reduction in intestinal volume unintentionally irradiated compared to three-dimensional computerised tomography simulation techniques[33]. Furthermore, intensity modulated radiation therapy has been found to reduce acute and late toxicity and maintains good long term quality of life even when high radiation doses are administered to prostate cancer patients[37-39]. In 208 head and neck cancer patients treated with intensity modulated radiation therapy it was found that intensity modulated radiation therapy was associated with reduced late toxicities without jeopardising local cancer control and overall survival[40]. The long-term quality of life has been compared among survivors of head and neck cancer patients whom were treated with either intensity modulated radiation therapy or three-dimensional conformal radiotherapy. The study results have shown that the early improvement in quality of life associated with intensity modulated radiation therapy was maintained and become more magnified over time[41].

Brachytherapy is another advanced technique in which the source of radiation is implanted within the malignant tissues (interstitial brachytherapy) or within a cavity in its immediate vicinity (intra-cavitary brachytherapy). The sources can be permanently inserted and emits their radiation over a prolonged period of time (low dose rate) or temporary and emit over a short period (high dose rate). In this fashion, a high radiation dose is limited to the target lesion sparing the surrounding normal tissues. Brachytherapy alone or in combination with external beam radiotherapy can reduce normal tissue toxicity without compromising treatment efficacy in prostate cancer[42,43]. Brachytherapy can be an option for patients with history of inflammatory bowel disease and it is well tolerated in low risk prostate carcinoma[44].

Combining target definition on a daily basis and adjusting the treatments to account for target motion is referred to as image guided radiotherapy techniques[45]. Stereotactic radiation therapy can focus an extremely narrow ionizing radiation beam on a small target from different directions using an immobilisation system. The high accuracy of this technique has enabled targeting a small lesions such as brain metastatic lesions[46]. Stereotactic radiation therapy uses a small number of high doses of radiation to target small lesions. It has been used in the treatment of early-stage non-small-cell lung cancer, prostate cancer, renal-cell carcinoma, and liver cancer, and in the treatment of oligometastases in the lung, liver, and spine[47]. Stereotactic radiation therapy is associated with high local control rates of cancer[48] and it was evaluated in the treatment of prostate cancer using an accelerated form of hypofractitionation through fewer but larger treatment fractions. The early results of this new technique suggest that it may induce an initial prostate specific antigen response similar to that seen with conventional fractionation radiotherapy but with fewer acute side effects. Disease control and chronic toxicity have not yet been fully evaluated[49]. The use of higher (often > 10 Gy) daily radiation doses in stereotactic radiation therapy needs to be carefully considered in view of the potential for more severe side effects[50]. The impact of the image guided radiotherapy techniques has been shown in a large study with 331 patients treated with high-dose intensity modulated radiation therapy with fiducial marker-based position verification for prostate cancer which allowed daily correction of the prostate position using the fiducial markers. The results showed that high dose was well tolerated with lower rate of acute toxicity, which provide possibilities for further dose escalation[37].

High-energy proton beams stop abruptly in the tissue at the end of their range and deposit most of their energy there, in this fashion, they provide dose distributions that are superior to X-rays when used in comparable beam configurations[51] In addition, they are more densely ionising along their treatment path, and therefore a higher quantum of energy to kill the cancer cell and high linear energy transfer. With proton beam radiation therapy a smaller volume of normal tissues is irradiated at high dose levels for most anatomic sites than is feasible with any photon technique[52]. Clinical studies have shown that proton beam therapy in patients with hepatocellular carcinoma has been shown to be effective, safe and well tolerable[53]. Proton beam therapy allows large tumour volumes to be irradiated to high doses without significant dose exposure to surrounding normal tissue which make it a promising modality for the treatment of large-volume tumours[54]. However, they have yet to show significant advantages in comparison with the conventional radiation therapy.

MEDICAL THERAPY FOR GASTROINTESTINAL RADIATION INJURY

Although technical strategies have achieved a significant degree of normal tissue protection during radiotherapy delivery, biological strategies may offer additional future promise. A wide variety of pharmacological agents, nutritional supplements, biological response modifiers, and dietary measures have been investigated for potential benefit to prevent or minimize the severity of intestinal tissue injury induced by ionising radiation exposure.

SUPPORTIVE TREATMENT

Patient selection for radiotherapy

Patient risk profile for developing radiation toxicity merits a careful consideration while assessing individual patient for radiotherapy treatment. Co-morbid diseases such as vascular disease, hypertension, diabetes mellitus and atherosclerosis[55], inflammatory bowel disease[56-58], collagen vascular disease[59] and human immunodeficiency virus (HIV) infection[60,61] have been linked to an increased risk of toxicity following external beam radiotherapy.

Nutritional status and effect of diet during radiotherapy

Patient general health and nutritional status during radiotherapy may affect outcomes. Measures to improve patient nutrition such as dietary counselling, oral supplements and intensive nutrition intervention have been associated with an improved outcome in terms of body weight, morbidity, and quality of life during and after radiotherapy[62,63]. McGough *et al*[64] reviewed the efficacy of nutritional intervention on bowel symptoms during pelvic radiotherapy in data from 2646 patients. They found no evidence base for nutritional interventions identified to mitigate bowel symptoms following radiotherapy. However, the role of probiotic supplements, low fat diet and elemental diet was recommended for further evaluation. Subsequent studies on elemental diet identified the difficulty of patients tolerance to large volumes of elemental diet regimen during radiotherapy period[65,66]. The effect of high-potency probiotic preparation VSL3 has been investigated in double-blind, placebo-controlled trial of 490 pelvic radiotherapy patients. The results showed more diarrhoea and daily bowel movements in the placebo group compared with VSL3 recipients[67].

Biological, chemical and pharmacological therapy

Biological, chemical or pharmacological interventions to ameliorate the effect of radiation injury on gastrointestinal tract can be categorized according to the time of administration with respect to radiation exposure. Agents administered prior to radiotherapy for normal tissue prophylaxis are described as radioprotectors. Agents administered during the course of radiotherapy to minimize the injury are called mitigators, while agents administered to ameliorate an established injury are called treatment[68].

The complexity of the pathophysiology of intestinal radiation injury along with the increasing prevalence of the problem has attracted significant research interest in exploring the effectiveness of many agents. Treatment of delayed radiation injury is challenging as it is often refractory to different therapeutic modalities[69].

At the pre-clinical level, there has been a significant interest to test the efficacy of different agents to modulate the biological process implicated in radiation induced tissue injury and normal tissue damage (Table 1).

At the clinical level, there are no formal trials to reliably assess the effectiveness of most of the suggested therapies; hence most of the evidence is obtained from small studies which are often from a single centre. In addition, the results reported in many studies are often directly related to the radiation toxicity scale in use and its sensitivity, specificity as well as to methods of interpretation and grading of symptoms reported by patients.

Topical therapy

Topical therapy for radiation proctitis has been tried with different agents. Local instillation of formalin has been reported to be effective in the treatment of severe haemorrhagic radiation proctitis[70]. Sodium butyrate enemas were reported to improve the acute symptoms of radiation proctitis with no impact on the incidence and severity of late proctitis[71]. Steroid enemas and other topical steroid preparations, commonly prescribed for other anorectal inflammatory conditions have also been in use for symptom relief in radiation proctitis, but without conclusive evidence of efficacy.

Hyperbaric oxygen was suggested to exert its therapeutic role in chronic radiation proctitis through induction of neovascularization that reverses tissue hypoxia[72,73] with trophic effect on vasculogenic stem cells[74]. Treatment of chronic radiation proctitis with hyperbaric oxygen has shown promising results in a large randomized double-blind trial with 120 patients with long term follow up. Hyperbaric oxygen therapy significantly improved the healing responses in patients with refractory radiation proctitis with enhanced bowel-specific quality of life[75].

A recent systematic review demonstrated the therapeutic benefit of hyperbaric oxygen based on the evidence and expert consensus opinion. The review demonstrated its efficacy in patients with radiation damage to the anus and rectum and refractory chronic radiation injury[73].

Anti-inflammatory agents

Anti-inflammatory agents were suggested to reduce the severity of acute intestinal inflammation following irradiation. 5 aminosalicylic acid (5-ASA) has been studied, but most have reported no benefit or even worse symptoms with the use of 5-ASA compared to placebo[76-79]. Sulphasalazine showed clinical improvement in symptoms in a case series of four patients[80]. Balsalazide has been suggested to improve proctitis and toxicity grade in patients undergoing prostate cancer radiotherapy, in a study of 27 patients[81]. Taken together, the clinical evidence on therapeutic role of 5-ASA are not sufficient to recommend routine use in radiation injury.

Antioxidants

Antioxidants were suggested to have cytoprotective effects by reducing cellular oxidative stress following radiation injury to intestinal tissue. A sustained therapeutic benefit after 4 wk therapy with vitamin E and C has been reported in a study involving twenty patients with chronic radiation proctitis[82]. More studies will be required to assess the therapeutic role of different antioxidant agents.

Table 1 Examples of putative intestinal radioprotectants tested in pre-clinical studies

Biological agent	Suggested effect/mechanism	Suggested radioprotection
Glutamine, arginine enriched diet[103]	Enhanced mucosal healing	Protective effect on rat intestine compared to control
Vitamin- E[104]	Reduction of oxidative stress	Protective effect on rat intestine compared to control
Captopril[105]	Inhibition of pro-inflammatory enzyme angiotensin-1-converting enzyme	Protective effect on mouse intestine compared to control
Rofecoxib[106]	Selective Inhibition of cyclooxygenases -2 enzyme	Protective effect on rat intestine compared to control
Clopidogrel[107]	Inhibition of platelets aggregation with reduced vascular sclerosis	Protective effect on rat intestine
Thalidomide[108]	Protection to microvascular bed	Attenuated injury to rat endothelial cells of micro vascular bed compared to control
Simvastatin[109]	Attenuate endothelial cell injury	Attenuated delayed intestinal injury in rats
Glucagon-like peptide-2 (GLP-2)[110]	Increased mucosal mass	Intestinal trophic and protective effect to rat intestine
Octreotide[111,112]	Modulation the inflammatory effects mediated by over expression of NFκB	Ameliorated inflammation and injury in rat intestine
Prostaglandin E-2[113]	Pro-proliferative and anti-apoptotic effect on intestinal epithelium	Increased crypts survival
Anti-Transforming growth factors beta receptor[114]	Biological inhibition of extracellular remodeling	Reduced intestinal injury and fibrosis compared to IgG treated control mice
Toll like receptor 5 agonist derived from Salmonella flagellin[115]	Activation of intestinal immune response *via* NFκB signalling pathway	Protective effect to mice intestine
Intestinal sterilisation[116] Germ-free raised mice	Reduced number of translocated bacteria, sepsis and inflammation	Reduced intestinal cell apoptosis
Probiotic bacteria[117] (*Lactobacillus species*)	Restored intestinal microbiota imbalance	Reduces intestinal damage, sepsis and death in rodents

Amifostine

Amifostine is a scavenger of reactive oxygen species. Its protective effects have been related to its ability to minimise the injurious effects of free radicals on intestinal cells[83]. Amifostine has been investigated for both systemic and topical routes of administration during radiotherapy. Intravenous amifostine administered daily before radiotherapy has been shown to reduce the incidence of radiation proctitis during pelvic radiotherapy[84,85]. Similarly, rectal suspension of amifostine in two doses (1 g in 18 patients and 2 g in 12 patients) administrated daily before radiation therapy for prostate cancer has resulted in significant improvement in acute and late bowel quality of life toxicity parameters, more noticeable with higher doses[86]. Despite the results of these studies and that of many others, the updated clinical practice guidelines for the prevention and treatment of mucositis published in 2007[87] concluded that data on amifostine are mostly obtained from small, single-centre studies with conflicting results. The group concluded that intravenous amifostine daily administration prior to radiotherapy may prevent radiation proctitis in patients who are receiving standard-dose radiotherapy for rectal cancer (Level Ⅲ evidence, grade B recommendation)[87].

In previous studies, amifostine has been shown to reduce the incidence of xerostomia in patients during head and neck radiotherapy[88]. The American Society for Clinical Oncology recommended its use in 2002 published guidelines[89]. However, the recommendation has been subsequently withdrawn in the guidelines update in 2008 due to an insufficient data[90].

Sucralfate

Protection of mucosal cells has been suggested with sucralfate (aluminium sucrose octasulfate). A beneficial effect of sucralfate has been previously reported in two double-blind placebo-controlled studies in patients who received pelvic radiotherapy. It reported that the frequency of defecation and stool consistency were improved by sucralfate[91,92]. Sucralfate enemas have been evaluated in 26 patients with radiation-induced proctitis with persistent rectal bleeding and the results showed a reduction in the severity of rectal bleeding in all patients with sucralfate enemas after four weeks treatment[93]. However, in another study the therapeutic effect of sucralfate rectal enemas were evaluated compared to placebo, both administered during the course of prostate cancer radiotherapy. The results showed no difference in the rate of rectal bleeding between sucralfate and placebo treated group after a median follow-up of five years[94]. The therapeutic benefits of oral sucralfate have also been assessed in a prospective randomised placebo-controlled study on fifty one patients receiving pelvic radiotherapy. Results from 44 study subjects showed significantly increased diarrhoea in the sucralfate group which led to cessation of the trial. The study concluded that sucralfate cannot be recommended for prophylaxis of acute radiation to the rectum and may even worsen the symptoms[95]. Similarly, the lack of effect of micronized sucralfate mouthwash has been reported in a randomized, controlled trial in radiation-induced oral mucositis patients[96]. Despite extensive investigation, clinical data on sucralfate have shown variable results, which do not support its protective role

for routine clinical use.

ENDOSCOPIC MANAGEMENT, BIOPSY AND LASER CAUTERY

A variety of endoscopic therapies have been tried for the treatment of chronic radiation injury such as the heater probe, bipolar electrocoagulation and argon plasma coagulation with newer methods of endoscopic ablation such as radiofrequency ablation and cryotherapy[97]. Endoscopic treatment has been used primarily aimed to treat bleeding rectal telengectasia. Argon plasma coagulation therapy has been shown to be effective and safe treatment for treatment of rectal bleeding resulting from chronic radiation injury[98,99]. Caution should be applied however when considering the use of these invasive techniques following high dose treatment delivery. For instance the use of rectal wall biopsy and laser cautery has been associated with the development of recto-urinary fistulae[100-102] in men treated with brachytherapy for prostate cancer.

CONCLUSION

Prevention of gastrointestinal toxicity starts with a thorough assessment of patient risk profile before radiotherapy. There is no prophylactic or therapeutic agent available to radiotherapy patients proven to mitigate the acute and chronic symptoms of gastrointestinal radiation injury or to allow safe radiation dose escalation for better control of cancer. Many therapeutic agents are in use, but often with little evidence base. The recent advances in radiotherapy planning and delivery techniques provide a considerable degree of protection to the gastrointestinal during external beam radiotherapy. Newer techniques such as image guided radiotherapy techniques, stereotactic therapy and proton beam therapy may confer additional protection. On the other hand, a better understanding of the pathophysiology of intestinal radiation injury will allow the development of more effective biological strategies that could increase the end organ resistance to radiation toxicity. In this regard, modulation of various cellular and cytokine pathways that have been implicated in the development of the acute pathological process of radiation injury can give future promise. In addition to targeting different mechanisms mediating chronic inflammatory and fibrotic process that underlie the delayed pathological changes in the gastrointestinal tract, such approaches may provide new therapeutics insights to this problem.

Abstract

AIM: To investigate the effect of local intestinal perfusion with hypertonic saline (HTS) on intestinal ischemia-reperfusion injury (IRI) in both *ex vivo* and *in vivo* rat models.

METHODS: All experiments were performed on male Wistar rats anesthetized with pentobarbital sodium given intraperitoneally at a dose of 60 mg/kg. *Ex vivo* vascularly perfused rat intestine was subjected to 60-min ischemia and either 30-min reperfusion with isotonic buffer (controls), or 5 min with HTS of 365 or 415 mOsm/L osmolarity ($HTS^{365mOsm}$ or $HTS^{415mOsm}$, respectively) followed by 25-min reperfusion with isotonic buffer. The vascular intestinal perfusate flow (IPF) rate was determined by collection of the effluent from the portal vein in a calibrated tube. Spontaneous intestinal contraction rate was monitored throughout. Irreversible intestinal injury or area of necrosis (AN) was evaluated histochemically using 2.3.5-triphenyltetrazolium chloride staining. *In vivo*, 30-min ischemia was followed by either 30-min blood perfusion or 5-min reperfusion with $HTS^{365mOsm}$ through the superior mesenteric artery (SMA) followed by 25-min blood perfusion. Arterial blood pressure (BP) was measured in the common carotid artery using a miniature pressure transducer. Histological injury was evaluated in both preparations using the Chui score.

RESULTS: *Ex vivo*, intestinal IRI resulted in a reduction in the IPF rate during reperfusion ($P < 0.05$ *vs* sham). The postischemic recovery of the IPF rate did not differ between the controls and the $HTS^{365mOsm}$ group. In the $HTS^{415mOsm}$ group, postischemic IPF rates were lower than in the controls and the $HTS^{365mOsm}$ group ($P < 0.05$). The intestinal contraction rate was similar at baseline in all groups. An increase in this parameter was observed during the first 10 min of reperfusion in the control group as compared to the sham-treated group, but no such increase was seen in the $HTS^{365mOsm}$ group. In controls, AN averaged 14.8% ± 5.07% of the total tissue volume. Administration of $HTS^{365mOsm}$ for 5 min after 60-min ischemia resulted in decrease in AN (5.1% ± 1.20% *vs* controls, $P < 0.01$). However, perfusion of the intestine with the HTS of greater osmolarity ($HTS^{415mOsm}$) failed to protect the intestine from irreversible injury. The Chiu score was lower in the $HTS^{365mOsm}$ group in comparison with controls (2.4 ± 0.54 *vs* 3.2 ± 0.44, $P = 0.042$), while intestinal perfusion with $HTS^{415mOsm}$ failed to improve the Chiu score. Intestinal reperfusion with $HTS^{365mOsm}$ in

the *in vivo* series secured rapid recovery of BP after its transient fall, whereas in the controls no recovery was seen. The Chiu score was lower in the $HTS^{365mOsm}$ group *vs* controls (3.1 ± 0.26 and 3.8 ± 0.22, $P = 0.0079$ respectively,), although the magnitude of the effect was lower than in the *ex vivo* series.

CONCLUSION: Brief intestinal postischemic perfusion with $HTS^{365mOsm}$ through the SMA followed by blood flow restoration is a protective procedure that could be used for the prevention of intestinal IRI.

INTRODUCTION

Acute mesenteric ischemia (AMI) is a life-threatening vascular emergency with a mortality rate as high as 60%-80%[1]. It can be caused by local arterial obstruction, impairment of venous outflow, or a systemic hemodynamic disorder resulting in severe intestinal hypoxic injury. The rather non-specific clinical presentation of AMI can be an obstacle to its early recognition, thus delaying the proper treatment, namely revascularization[2]. However, if AMI can be diagnosed unambiguously prior to the development of intestinal infarction, either embolectomy or the intra-arterial infusion of thrombolytic agents can materially improve the outcome[3]. Unfortunately, even after timely revascularization, the positive effect can be compromised, at least in part, by the development of reperfusion injury, including edema, the no-reflow phenomenon, and the progressive death of mucosal cells[4]. In experimental models, intestinal ischemia-reperfusion injury (IRI) has been shown to be alleviated by a variety of pre- and postconditioning procedures[5,6], while various antioxidants, anesthetics, vasodilators, anti-inflammatory agents, and cytokine receptor blockers can also be helpful[7,8]. Furthermore, the systemic administration of hypertonic saline (HTS) has given clearly positive results[9,10]. The protective effect of HTS in these experiments is believed to be based on the following mechanisms: arteriolar vasodilation, osmotic stress-induced inhibition of inflammatory cells, and prevention of intestinal edema[10-12]. It is to be noted that the application of either HTS or some of the above-mentioned drugs may have certain limitations, such as an increased risk of electrolyte imbalance[12] and the development of adverse drug reactions, in either case as a result of systemic administration. It has been hypothesized, therefore, that perfusion of the intestine with HTS through the superior mesenteric artery (SMA) might prove to be a more advantageous strategy, given its greater efficacy in delivering the hypertonic solution to the target.

The present study was an experimental investigation of the effect of local intra-arterial HTS administration during the early reperfusion phase on the functional and structural manifestations of intestinal injury. To the best of our knowledge, this approach has not yet been attempted.

MATERIALS AND METHODS

Chemicals and materials

2.3.5-triphenyltetrazolium chloride (TTC) was obtained from Sigma-Aldrich (St. Louis, MO, United States). Pentobarbital sodium was purchased from Apoteket (Umea, Sweden). Bovine serum albumin was obtained from Biowest (Nuaille, France). Dextran 60 000 was obtained from Biochemist (Saransk, Russian Federation). Other chemicals used for the preparation of both Krebs-Henseleit buffer and HTS were purchased from Acros Organics (Geel, Belgium).

Animals

All experiments were performed on male Wistar rats weighting 250-300 g. The animals were fed regular chow, and water was available *ad libitum*. The procedures were performed in accordance with the Guide for the Care and Use of Laboratory Animals and were approved by the local Ethics Committee. The animals were anesthetized with pentobarbital sodium given intraperitoneally at a dose of 60 mg/kg. Core body temperature was maintained at 37.0 ± 0.5 ℃ by a feedback-controlled heating pad (TCAT-2LV controller, PHYSITEMP Instruments Inc., United States).

Ex vivo experiments

Isolated perfused small intestine preparation: The intestine was isolated and perfused according to a previously described technique[13]. Briefly, the abdominal cavity was opened by a midline incision. To prevent blood coagulation, 50 units of heparin sodium were injected into the inferior vena cava. The abdominal aorta was exposed from the level of the celiac trunk (CT) to the aortic bifurcation. The intestinal segment between the pyloric sphincter and the distal portion of the ileum was cut using an electrocautery unit. The branches of the SMA that supply the cecum and proximal part of the colon were exposed, ligated, and cut, followed by the removal of the proximal colon. The intestinal lumen was rinsed with warm (37 ℃) saline. The aorta was cannulated through its infrarenal segment with subsequent advancement of the cannula tip to the SMA level. The aorta was then ligated immediately above the CT, and perfusion of the small

intestine with oxygenated (95% O_2 and 5% CO_2) Krebs-Henseleit buffer (KHB) was initiated through the SMA and CT at a pressure of 80 mmHg. KHB solution was modified to contain high molecular weight compounds (1.0% bovine serum albumin and 3.0% dextran 60 000) plus (all in mmol/L) 118.5 NaCl, 25.0 $NaHCO_3$, 4.7 KCl, 1.2 KH_2PO_4, 1.2 $MgSO_4$, 1.5 $CaCl_2$, 5.0 glucose, 2.0 lactate, 0.2 pyruvate. The portal vein was cannulated to ensure outflow of the perfusion fluid. After ligation of the splenic and gastric vessels, the exposed part of the intestine was placed into the water-jacketed bath filled with normal saline to maintain the temperature at 37 ℃ during the experiment. All surgical procedures described were performed within 50-60 min and were followed by a 20-min stabilization period.

Experimental protocol: After stabilization, ischemia of the intestine was induced by cessation of the perfusate flow for 60 min, followed by reperfusion. During the initial 5-min reperfusion, the perfusion was resumed with the modified KHB of either normal (physiological) or increased osmolarity (315 *vs* 365 or 415 mOsm/L, designated as $HTS^{365mOsm}$ or $HTS^{415mOsm}$, respectively), in each case delivered under a pressure of 80 mmHg, followed by perfusion with normotonic KHB for 25 min. The experiments were randomized and allocated to the following 4 groups**:** (1) Sham (n = 6): the intestine was continuously perfused for 110 min; (2) Controls (n = 6): 60-min intestinal ischemia, followed by 30-min reperfusion with normotonic KHB (osmolarity 315 mOsm/L); (3) $HTS^{365mOsm}$ (n = 5): 60-min intestinal ischemia, followed by 5-min reperfusion with HTS having an increased osmolarity of 365 mOsm/L (KHB supplemented with 50 mmol NaCl), followed by 25-min reperfusion with normotonic KHB; and (4) $HTS^{415mOsm}$ (n = 6): the same sequence of procedures as in the previous group, but using HTS with osmolarity increased to 415 mOsm/L.

Assessment of vascular intestinal perfusate flow rate: The vascular intestinal perfusate flow (IPF) rate was determined each 5 min during both the stabilization and reperfusion periods by collection of the effluent from the portal vein in a calibrated tube.

Determination of luminal intestinal flow: The outflow from the intestinal lumen was determined in all experiments during the stabilization period. Luminal flow exceeding 0.5 mL/min is indicative of pathological intestinal secretion, which is usually due to ischemic injury of the intestine during surgical manipulations. Thus, the experiments with luminal flow exceeding 0.5 mL/min were excluded from the final analysis.

Histochemical analysis: We used the technique of visualizing the area of necrosis (AN) with 2.3.5-triphenyltetrazolium chloride (TTC), a method generally considered to be a "gold standard" for AN delineation in the heart in other studies, including our own[14,15]. Briefly, immediately after the end of reperfusion into the SMA, 10 mL of 0.5% TTC solution were administered for 30 s. Fifteen minutes after that, 3 equally spaced segments of the intestine with a total length of 3 cm were excised and fixed in 4% buffered formaldehyde solution for 24 h at room temperature. The samples were cut into 7-8 transverse slices, each 1.5 mm thick, which were photographed for further analysis using Adobe Photoshop CS. TTC-positive tissue, brick red in color, was considered to be viable, in contrast to the necrotic tissue, which had a pale appearance. The AN volume in each sample was calculated by multiplying the TTC-negative area by the slice thickness. The AN volume of the whole intestinal segment was calculated by summing the AN volumes of the slices and was expressed as the percentage of AN in relation to the total volume of the intestinal tissue being analyzed.

Evaluation of spontaneous intestinal motility: According to the original technique described by Hoffman *et al*[16], this parameter is assessed by recording the movement of fecal pellets down the intestine. We used a different approach to register the spontaneous intestinal contraction rate. In brief, a pair of soft rubber rings, hand-crafted from a black tube with a diameter close to that of the intestine, were cut at one point and carefully placed around the intestine to signify equally spaced anatomical locations throughout the experiments. Sixty-second video recordings (5 frames per second) were taken every 10 min during the stabilization and reperfusion periods and were digitized with VirtualDub software (Avery Lee, United States). Based on the distances between the rings, the values were plotted against time, followed by a Fourier transform and probability plotting of the frequency distribution. The data were presented as the rates of low-frequency intestinal contractions (Hz).

In vivo experiments

For the investigation of the effect of HTS perfusion on the intestinal IRI, we developed a technique for perfusion through the SMA, which, in our opinion, offers some advantages over the systemic administration of HTS used before. The infrarenal aorta was occluded with a microclip and cannulated with an 18G polyethylene cannula (Figure 1A). The micro clip was then removed and placed on the aorta between the SMA and the CT, after which the cannula was advanced up to the SMA level, where its tip was fixed by ligation (Figure 1B). The next step included 2 manipulations: the occlusion of the distal part of the superior mesenteric vein (SMV) and the incision of the ileocecal SMV branch to secure the outflow of the perfusate from the intestinal circulation. The oxygenated HTS maintained at 37 ℃ was delivered through the SMA with an infusion pump (SPACE infusion system, B. Braun, Germany) at a constant rate of 15 mL/min. The flow rate was selected on the basis of our pilot experiments showing that the mean blood flow in the SMA of animals of comparable weight, having blood pressure (BP) in the range between 100 and 120 mmHg,

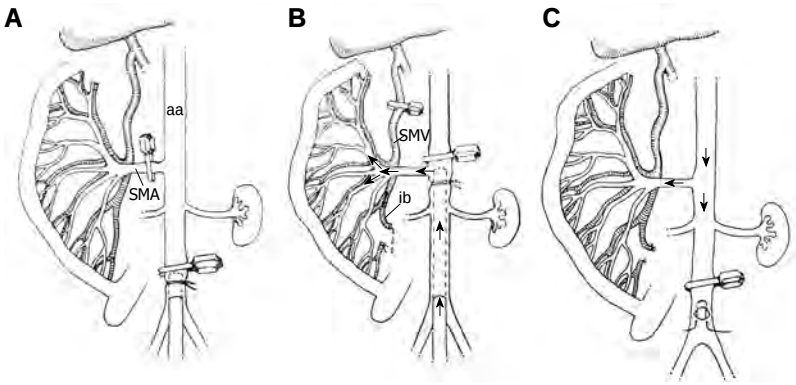

Figure 1 The sequential steps of the intestinal perfusion *in vivo*. A: The abdominal aorta (aa) is occluded by a clip, followed by cannulation of the vessel; the superior mesenteric artery (SMA) is clipped; B: The aortic clip is positioned above the SMA; the cannula is positioned at the level of SMA to allow its perfusion with hypertonic saline; the perfusate outflow is secured through the opened ileocecal branch (ib) of the superior mesenteric vein (SMV); the main trunk of SMV is clipped; C: The cannula is removed to allow blood flow through the SMA to resume simultaneously with the following procedures: the aortic clip is positioned as in Figure 1A; the clip occluding the SMV is removed, and bleeding from the ileocecal branch of the SMV is prevented by ligation.

was approximately 10% higher than 15 mL/min. Any appearance of blood in the perfusate was checked by visual inspection. At the end of the perfusion, the ileocecal SMV branch was ligated and the main trunk of the SMV was reopened. The aortic cannula was removed and the aortic incision closed with a suture (Figure 1C), so that blood flow was restored in both the aorta and the mesenteric vascular bed.

Experimental protocol: The animals were randomly allocated into 2 groups: (1) Controls (n = 6): intestinal ischemia by SMA occlusion for 30 min, followed by 30-min reperfusion with blood; and (2) HTS^{365mOsm} (n = 5): intestinal ischemia by SMA occlusion for 30 min, followed by 5-min reperfusion with HTS^{365mOsm}, followed by 25-min reperfusion with blood.

Blood pressure measurement: Arterial BP was measured in the common carotid artery using a miniature pressure transducer (Baxter, United States), to be monitored using PhysExp X4 software (Cardioprotect Ltd., St. Petersburg, Russian Federation). BP values were registered under the following conditions: at baseline, prior to SMA occlusion, 15 and 30 min after SMA occlusion, and at the 15th and 30th min of reperfusion.

Histological studies: At the end of reperfusion, intestinal samples were taken and routinely fixed in 10% buffered formaldehyde solution, embedded in paraffin, cut into 5 μm sections, and stained with hematoxylin and eosin. The slides were analyzed under a light microscope by the pathologist blinded to the treatment mode used in each group. The results were scored from 0 to 5 according to the scale of Chiu *et al*[17]. The method is based on the well established relationship between the grade of intestinal injury, if any, and its structural manifestation (grade 0: normal villi; grade 1: development of subepithelial space; grade 2: moderate lifting of subepithelial layer; grade 3: massive epithelial lifting with a few tips denuded; grade 4: denuded villi with lamina propria and dilated capillaries exposed; grade 5: digestion and disintegration of lamina propria with ulceration). In the present study, we rigorously followed this gradation as applied in similar trials by several groups[10,18,19].

Statistical analysis

Data were analyzed with SPSS 11.0 (SPSS Inc. Software, Chicago, IL, United States). All values are expressed as mean ± SD. Differences in the intestinal motility and IPF rate were tested by repeated-measures analysis of variance, followed by a Tukey post-hoc test. The non-parametric Mann-Whitney U test was used to determine the inter-group differences in AN value and histopathological score. $P \leqslant 0.05$ were considered significant.

RESULTS

Ex vivo experiments

Exclusions: Two animals were excluded from the final analysis (one in the control group and one in the HTS^{415mOsm} group) because the luminal flow exceeded 0.5 mL/min.

Intestinal perfusate flow rate: There were no inter-group differences in the IPF rate during the stabilization period (Figure 2). The IPF values remained unchanged over the entire 110-min perfusion period in the sham-treated group. In contrast, intestinal ischemia-reperfusion resulted in a reduction in the IPF rate during reperfusion (P < 0.05 *vs* sham). This reduction could have been due to IRI in the intestinal microcirculatory bed, resulting in no-reflow. The postischemic recovery of the IPF rate did not differ between the controls and the HTS^{365mOsm} group. In the HTS^{415mOsm} group, postischemic IPF rates were lower than in the controls and the HTS^{365mOsm} group (P < 0.05).

Area of necrosis: TTC-negative intestinal tissue was not present in the samples obtained from the sham-treated group. In the controls, AN averaged 14.8% ± 5.07% of the total tissue volume within the analyzed intestinal seg-

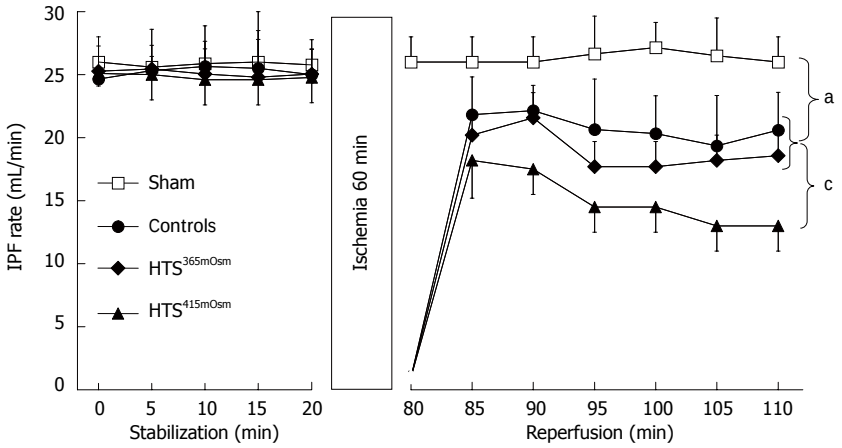

Figure 2 Intestinal perfusate flow rate in the *ex vivo* rat experiments with 60-min ischemia followed by varying conditions of reperfusion. The groups tested were: sham-operated (no ischemia at all, $n = 6$); controls (30 min reperfusion with normotonic buffer, $n = 5$); 2 groups with either HTS^{365mOsm} ($n = 5$) or HTS^{415mOsm} ($n = 5$), both subjected to 5-min reperfusion with the respective hypertonic solution followed by 25 min reperfusion with normotonic buffer. The pre-ischemic values of Intestinal perfusate flow (IPF) rate were similar in all groups. No changes were apparent in the shams over the whole period, whereas IPF values were lower in all the ischemia-reperfusion groups, although the groups showed different patterns. HTS^{415mOsm} resulted in the most prominent decrease in the IPF rate, with a further progressive fall to the end of the experiment. In contrast, IPF rate was less affected in the control and HTS^{365mOsm} groups, to a similar degree in both, while an appreciable degree of stabilization took place towards the end of the postischemic period. Postischemic IPF rate recovery did not differ between the controls and the HTS^{365mOsm} group, whereas postischemic IPF rate values were significantly lower in the HTS^{415mOsm} group, compared to both the controls and the HTS^{365mOsm} group. Data are mean ± SD. $^{a}P < 0.05$ *vs* sham; $^{c}P < 0.05$ *vs* controls.

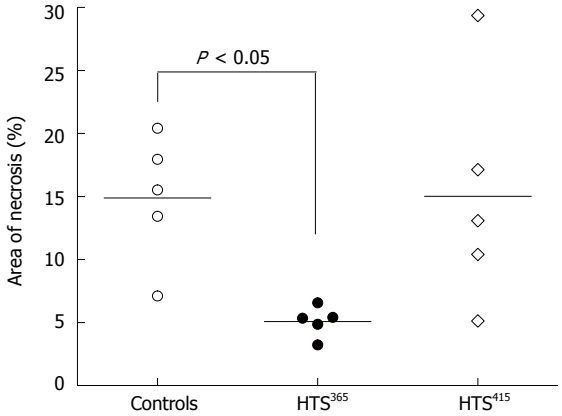

Figure 3 Area of necrosis within the isolated rat intestine after 60-min ischemia followed by the varying conditions of reperfusion. The area of necrosis (AN) is defined as the percentage of 2.3.5-triphenyltetrazolium chloride-negative in relation to the total intestinal tissue volume. Controls (reperfusion with normotonic saline) and the HTS^{415mOsm} group did not differ statistically regarding AN volume, whereas HTS^{365mOsm} administration resulted in a significantly lower value of AN. In both hypertonic saline (HTS) groups, the 5-min reperfusion with the appropriate hyperosmotic saline was followed by 25-min normotonic reperfusion. The data are presented as dot plots with median values.

ment (Figure 3). Administration of HTS^{365mOsm} for 5 min after 60-min ischemia resulted in decrease in AN (5.1% ± 1.20% *vs* controls, $P < 0.01$). However, perfusion of the intestine with the HTS of greater osmolarity (HTS^{415mOsm}) failed to protect the intestine from irreversible injury (AN = 15.0% ± 9.12% *vs* controls, $P > 0.05$).

Intestinal motility: The rate of intestinal contraction-relaxation pulses, which was used as a measure of intestinal motility in the present study, was similar at baseline in all groups (Figure 4). An increase in this parameter was observed during the first 10 min of reperfusion in the control group as compared to the sham-treated group, but no such increase was seen in the HTS^{365mOsm} group.

Histological data: Histological data from the intestinal samples obtained after 30-min reperfusion *ex vivo* are shown in Figure 5A. Sham-treated animals had normal or near-normal histology. The Chiu score was lower in the HTS^{365mOsm} group in comparison with controls (2.4 ± 0.54 *vs* 3.2 ± 0.44, $P = 0.042$, Figure 5A), while intestinal perfusion with HTS^{415mOsm} failed to improve the Chiu score (3.6 ± 0.54 *vs* controls, $P > 0.05$).

In vivo experiments

Exclusions: Although the experimental model suggested is highly invasive and complex, the extensive training prior to the beginning of the main experimental series has minimized the number of animals excluded due to technical reasons. Only one rat was excluded in the control group because of the severe bleeding and low BP.

Blood pressure values during intestinal perfusion *in vivo*: Baseline BP values did not differ between the controls and the HTS^{365mOsm} group (Table 1, Figure 6). SMA occlusion did not cause appreciable changes in BP level in either group. Aortic occlusion during the 5-min SMA perfusion period in the HTS^{365mOsm} group resulted in a trend to BP elevation. Reinstitution of blood flow in the aorta caused a temporary decrease in BP that lasted for only 2-3 min before it returned to the baseline values (Table 1). In contrast, SMA reperfusion in controls caused a decrease in BP level that persisted during the entire reperfusion period (Table 1, Figure 6A).

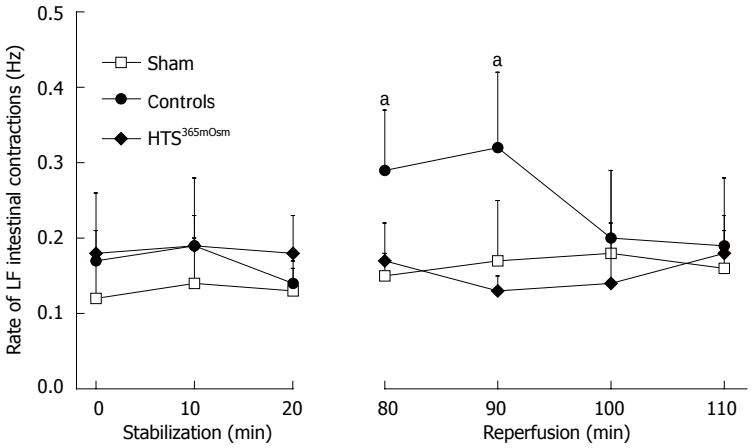

Figure 4 The rate of low frequency intestinal contractions in the *ex vivo* experiments. In shams, the intestine was continuously perfused for 110 min. In controls (60-min ischemia followed by 30-min reperfusion), intestinal contraction rate was significantly higher over the initial 10 min of reperfusion in comparison with the shams. Intestinal reperfusion with hyperosmotic saline in the HTS^{365mOsm} group prevented the increase in postischemic intestinal contraction rate. Data are mean ± SD. $^{a}P < 0.05$ *vs* sham. LF: Low frequency.

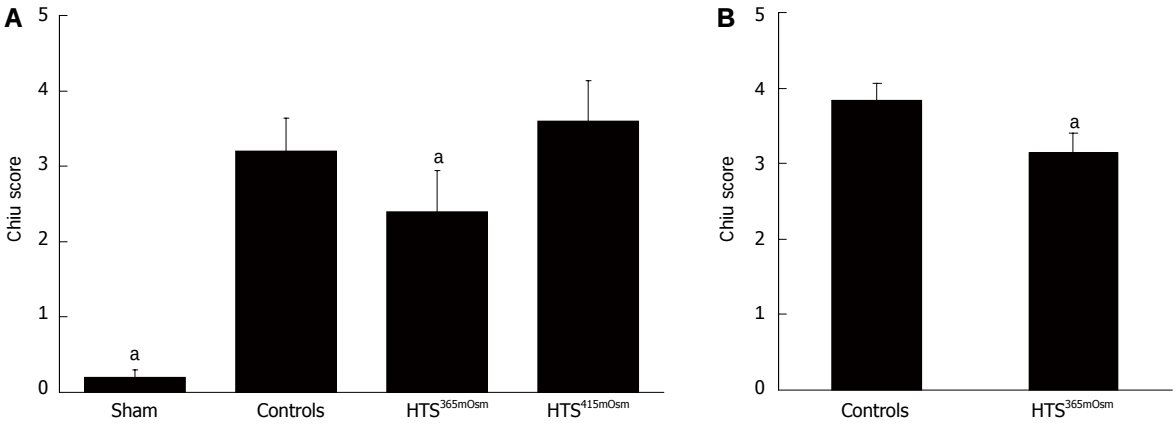

Figure 5 Histologically defined scores in the *ex vivo* (A) and *in vivo* (B) experiments. A, B: In the sham group (no ischemia at all, A) slight injury only is evident, probably due to the prolonged perfusion in the extracorporeal environment. Sixty-minute ischemia followed by 30-min normotonic reperfusion (controls) resulted in a significant injurious effect, which, however, was substantially less expressed in the HTS^{365mOsm} but not in the HTS^{415mOsm} group. The analogous difference between the controls and the HTS^{365mOsm} group is apparent in the *in vivo* experiments (B). The data are expressed as mean ± SD; $^{a}P < 0.05$ *vs* controls.

Table 1 Arterial blood pressure (mmHg) in the *in vivo* experiments (mean ± SD)

	Controls (n = 5)	HTS^{365mOsm} (n = 5)
Baseline	125 ± 8	132 ± 12
Before SMA occlusion	127 ± 10	128 ± 9
SMA occlusion		
15 min	118 ± 11	125 ± 7
30 min	121 ± 9	123 ± 6
SMA reperfusion		
15 min	68 ± 12	118 ± 13[a]
30 min	74 ± 8	126 ± 11[a]

SMA: Superior mesenteric artery. $^{a}P < 0.05$ *vs* controls.

Histology: Histological data from the intestinal samples obtained after 30-min reperfusion *in vivo* are shown in Figure 5B. The Chiu score was lower in the HTS^{365mOsm} group *vs* controls (3.1 ± 0.26 and 3.8 ± 0.22, $P = 0.0079$, respectively, Figure 5B), although the magnitude of the effect was lower than in the *ex vivo* series.

DISCUSSION

The results of this study indicate that the technique of isolated *in vivo* vascular perfusion of the intestine is reproducible and reliable. Using this approach, intestinal perfusion with HTS^{365mOsm} over the initial 5 min of reperfusion resulted in significant protection of the intestine from IRI, as demonstrated using morphological data (per both TTC and Chiu *et al*[17]). In order to evaluate both the experimental and also the possible clinical implications of this strategy, it seems appropriate to review in detail the relevant findings from systemic HTS administration. A salvation effect on the intestinal IRI, as well as limitation of remote organ injury, were observed in rats that were subjected to 60-min SMA occlusion followed by 6-h reperfusion, when intravenous administration of HTS was performed during the last 5 min of ischemia[10]. In parallel, an improvement in intestinal transit time, a reduction in mucosal injury, and limitation of intestinal myeloperoxidase activity were demonstrated using the same model; all effects were considered to be dependent on heme oxygenase-1 activity[18]. In addition, HTS infusion performed within the first 5 min of reperfusion after 120 min of SMA occlusion in pigs resulted in a better recovery of both mean arterial blood pressure and intestinal microvascular perfusion in comparison with conventional isotonic resuscitation[9]. In a somewhat different rat mod-

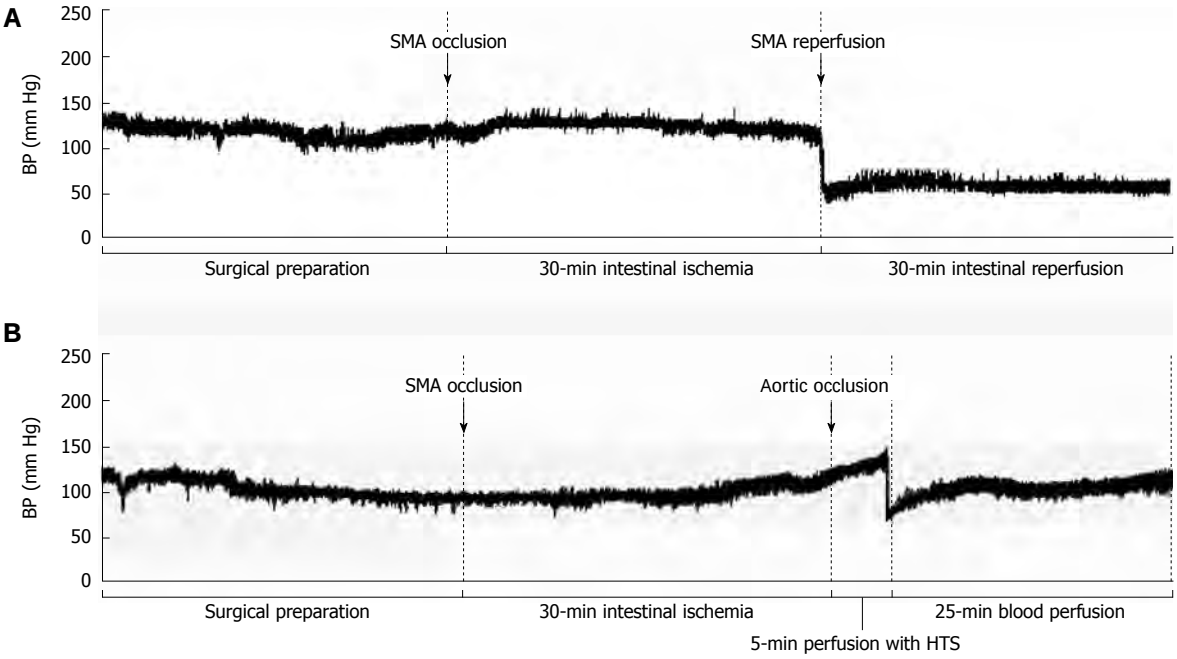

Figure 6 Representative samples of arterial blood pressure recordings in anesthetized rats subjected to intestinal ischemia-reperfusion *in vivo*. A: Thirty-minute superior mesenteric artery (SMA) occlusion followed by 30-min reperfusion (controls) resulted in a persistent blood pressure (BP) decrease over the entire reperfusion period; B: Thirty-minute SMA occlusion finalized by aortic clamping followed immediately by 5-min SMA perfusion with hypertonic saline (365 mOsm/L), with a subsequent 25-min reperfusion with blood, resulted in a transient drop with a rapid restoration of BP up to the initial values. HTS: Hypertonic saline.

el of intestinal IRI, this time induced by hemorrhagic shock followed by blood reinfusion, the administration of HTS for 25 min after the return of shed blood into circulation resulted in better post-resuscitation blood flow and improved endothelial function of the intestinal vasculature[12]. It also suppressed the apoptotic death of intestinal epithelial cells[20] and prevented intestinal mucosal injury[21]. As to the remote effects of systemic HTS treatment, a more complete and stable restoration of BP[12] as well as the prevention of systemic oxidative stress[21] have been observed. However, in general, systemic HTS administration has several intrinsic drawbacks, including an increased risk of hypernatremia, plasma hyperosmolarity, cardiac arrhythmias, and heart failure[12]. Apart from being free of the limitations inherent to systemic HTS administration, the technique of local HTS delivery seems to have 2 more additional advantages over a variety of protocols attempted previously[22,23]. First, the delivery of perfusate directly into the SMA, with outflow from the opened vein, completely prevents the otherwise inevitable generalized spread throughout the systemic circulation of the metabolites and bacterial toxins accumulated during ischemia. Second, the pharmacological agents recommended for strengthening the protective effect of HTS[24,25]-which could thus be potentially helpful to HTS administration *via* a local route-could be used at higher doses and therefore with higher efficiency, analogously with the strategy applied for regional perfusion in chemotherapy for certain neoplasms[26].

The question might arise as to whether the HTS osmolarity value used in the present study was optimal. While the osmolarity of HTS for hypertonic resuscitation averages approximately 7.5% NaCl, in our local delivery model we tested solutions with much lower osmolarities. Previous studies have tried values ranging from normal (300-310 mOsm/L) to nearly 400 mOsm/L for local organ anti-ischemic protection, particularly the heart; the optimal osmolarity was found to be 334 mOsm/L[27]. Interestingly, in *ex vivo* experiments, osmolarity values above 400 mOsm/L apparently produced a negative effect; that is, HTS delivery resulted in a significant deterioration in postischemic IPF rate recovery as compared to controls (Figure 2). Although different mechanisms might be involved in the observed effect, the most likely are endothelial injury and impaired microvascular function; however, this matter requires further investigation. Based on these findings, in this study a solution with a lower osmolarity ($HTS^{365mOsm}$) was preferred and was found to be effective for the preservation of intestinal viability, not only *ex vivo*, but also in the *in vivo* model. A higher HTS osmolarity value than that optimal for the heart could be justified by the higher hydrophilicity of the intestinal tissue, which would thus also require more potent anti-edema protection. It should be noted, however, that further experimentation will be needed in order to determine more precisely the optimal HTS parameter(s) for the anti-IRI protection of intestinal tissue.

Although not fully understood, the mechanism of the intestine protection with HTS may include such factors as dilatation of precapillary arterioles[12], inhibition of neutrophil-mediated reperfusion injury[11], or prevention of intestinal edema due to reperfusion-induced water influx into the cells[28]. At the molecular level, the major factor underlying the removal of excess water from the cells

has been shown to be the up-regulation of aquaporin 4 within the plasma membrane of the mucosal cells[29].

As mentioned before, protective effects of local HTS delivery on reperfusion injury have also been found in the heart, suggesting that common mechanisms may be involved. The concept of controlled cardiac reperfusion was originally proposed in the late 1980s to protect the myocardium from IRI by modifying the composition and/or delivery rate of the perfusion fluid[30]. One of the major modifications was the increased osmolarity of the perfusate, which was shown to decrease the incidence of reperfusion-induced arrhythmias, to attenuate tissue injury, and to reduce edema in the isolated hearts of pig and rabbit[27,31]. This promising approach is still awaiting implementation in clinical practice, initially in open heart surgery.

Local infusion of saline before reperfusion was also found to be protective in the brain. It was found that flushing the ischemic area of the brain with isotonic saline prior to reperfusion resulted in a reduced infarct volume and improved cerebral blood flow in the rat model[32]. Since normotonic saline was used in this study, the authors attributed its protective effect to the local clearance of proinflammatory cytokines and metabolic end-products.

In the present study, the spontaneous intestinal motility was assessed with a technique that has not yet been employed in the experiments simulating IRI. The observation of significant augmentation of the intestinal contraction rate over the first 10 min of intra-arterial perfusate reflow after 60-min *in vitro* ischemia (Figure 4) is in general agreement with data showing a transient increase in both the contraction rate and baseline tension observed upon reoxygenation of the jejunal rings after they were subjected to 60-min *in vitro* hypoxia[33]. In both situations, the increased motor activity of the intestine within the early postischemic period might be explained, in gross analogy with the postischemic heart response[34], by sudden oxygen-evoked re-energizing of the cells immediately after severe hypoxia. The subsequent excessive activation of contractile machinery might, in turn, contribute to the progression of mucosal injury, most likely due to the adverse effect of hypermotility. Its complete prevention with HTS perfusion (Figure 4) may point to the solution of the relevant clinical problem.

One obvious limitation of our *in vivo* model is the need to advance the perfusion cannula through the infrarenal aorta, rather than directly into the SMA. As a result, the kidneys and hindlimbs were exposed to an additional 5 min of ischemia. However, this limitation is imposed by the small size of the animal and the need to restore blood flow in the mesenteric vascular bed. In order to make the results comparable, control animals also received 5-min occlusion of the infrarenal aorta. Future studies are needed to verify the protective effect of local HTS infusion in large animal models. For instance, the study might be repeated in pigs using an endovascular approach with percutaneous puncture in the femoral artery and balloon occlusion of the SMA.

As to further extrapolations useful for clinical practice, the findings from the present study imply that intra-arterial HTS administration could contribute to the prevention, or at least amelioration, of 2 seemingly inevitable negative effects that would otherwise arise; that is, if "unprotected" reperfusion is applied. The first of these is reperfusion-induced intestinal damage, while the second includes whole-body disturbances, such as the systemic inflammatory response syndrome[4], hemodynamic impairments[35], and remote organ injuries[36], all of which are associated with the massive washout of metabolites and bacterial toxins from the ischemia-affected intestine into the systemic circulation. Our *in vivo* model could lead to the development of a novel therapy that combines local perfusion of the ischemic region with mechanical restoration of the blood flow and/or the administration of pharmacological agents. As to the clinical translation of the model, it might be speculated that perfusion of the SMA in patients with AMI could be performed after laparotomy, either *via* a catheter directly placed in the SMA or during percutaneous intervention. The perfusate outflow could be ensured through the punctured SMV. It should be noted that the suggested technique delayed restoration of blood flow to the intestine by 5 min; however, it is unlikely that perfusion with an oxygen- and glucose-enriched solution could cause any ischemic/hypoxic injury to the intestine during this period. It is also of importance to determine the optimal osmolarity value of the HTS, since the results of the present study have demonstrated the negative effect of HTS with excessive osmolarity, i.e., 415 mOsm/L.

In conclusion, the results of our experiments show that isolated intestinal perfusion with HTS at the beginning of the reperfusion period can appreciably protect the intestine from IRI. Despite the positive effect of intra-arterial HTS delivery, aimed in the present study at establishing the validity of this approach in principle, its further improvement by optimization of the particular parameters during all steps of the procedure will be required before clinical trials can be contemplated.

COMMENTS

Background

Acute mesenteric ischemia (AMI) is a life-threatening vascular emergency with high mortality rate. The major treatment approach for AMI is rapid intestinal revascularization. Unfortunately, even after timely revascularization, its positive effect can be compromised, at least in part, by the development of intestinal reperfusion injury.

Research frontiers

Systemic administration of hypertonic saline (HTS) was shown to be protective in the experimental models of AMI. In the present study, the authors investigated the effect of local intra-arterial HTS administration during the early reperfusion phase on the functional and structural manifestations of intestinal injury.

Innovations and breakthroughs

The authors showed for the first time that isolated intestinal perfusion with HTS at the beginning of the reperfusion period can appreciably protect the intestine from ischemia-reperfusion injury. In addition, the technique of isolated *in vivo* vascular perfusion of the intestine is suggested and experimentally validated.

Applications

This *in vivo* model could lead to the development of a novel therapy that combines local perfusion of the ischemic intestine with mechanical restoration of the blood flow and/or the administration of pharmacological agents.

Terminology

Intestinal ischemia-reperfusion injury (IRI) develops because of the temporal complete or partial cessation of blood supply to the intestine. HTS is crystalloid or colloid solution with osmolarity value exceeding physiological. Potential benefits of HTS in the settings of AMI include prevention of edema, improvement in the microcirculation, and washout of potentially toxic metabolites.

Peer review

This paper investigated the effect of local intestinal perfusion with HTS on intestinal IRI in both *ex vivo* and *in vivo* rat models, to find that brief intestinal postischemic perfusion with $HTS^{365mOsm}$ through the SMA followed by blood flow restoration was a protective procedure that could be used for the prevention of intestinal IRI. It is well written and organized.

Abstract

AIM: To investigate the diagnostic performance of acoustic radiation force impulse (ARFI) elastography for characterizing focal liver mass by quantifying their stiffness.

METHODS: This prospective study included 62 patients with a focal liver mass that was well visualized on conventional ultrasonography performed in our institution from February 2011 to November 2011. Among them, 12 patients were excluded for ARFI measurement failure due to a lesion that was smaller than the region of the interest and at an inaccessible location (deeper than 8 cm) (n = 7) or poor compliance to hold their breath as required (n = 5). Finally, 50 patients with valid ARFI measurements were enrolled. If a patient had multiple liver masses, only one mass of interest was chosen. The masses were diagnosed by histological examination or clinical diagnostic criteria. During ultrasonographic evaluation, stiffness, expressed as velocity, was checked 10 times per focal liver mass and the surrounding liver parenchyma.

RESULTS: After further excluding three masses that were non-diagnostic on biopsy, a total of 47 focal mass lesions were tested, including 39 (83.0%) malignant masses [24 hepatocellular carcinomas (HCC), seven cholangiocellular carcinomas (CCC), and eight liver metastases] and eight (17.0%) benign masses (five hemangiomas and three focal nodular hyperplasias, FNH). Thirty-seven (74.0%) masses were confirmed by histological examination. The mean velocity was 2.48 m/s in HCCs, 1.65 m/s in CCCs, 2.35 m/s in metastases, 1.83 m/s in hemangiomas, and 0.97 m/s in FNHs. Although considerable overlap was still noted between malignant and benign masses, significant differences in ARFI values were observed between malignant and benign masses (mean 2.31 m/s *vs* 1.51 m/s, P = 0.047), as well as between HCCs and benign masses (mean 2.48 m/s *vs* 1.51 m/s, P = 0.006). The areas under the receiver operating characteristics curves (AUROC) for discriminating the malignant masses from benign masses was 0.724 (95%CI, 0.566-0.883, P = 0.048), and the AUROC for discriminating HCCs from benign masses was 0.813 (95%CI, 0.649-0.976, P = 0.008). To maximize the sum of sensitivity and specificity, an ARFI value of 1.82 m/s was selected as the cutoff value to differentiate malignant from benign liver masses. Furthermore, the cutoff value for distinguishing HCCs from benign masses was also determined to be 1.82 m/s. The diagnostic performance of the sum of the ARFI values for focal liver masses and the surrounding liver parenchyma to differentiate liver masses improved (AUROC = 0.853;

95%CI, 0.745-0.960; P = 0.002 in malignant liver masses *vs* benign ones and AUROC = 0.948; 95%CI, 0.896-0.992, P < 0.001 in HCCs *vs* benign masses).

CONCLUSION: ARFI elastography provides additional information for the differential diagnosis of liver masses. However, our results should be interpreted in clinical context, because considerable overlap in ARFI values existed among liver masses.

Characterization of focal liver masses using acoustic radiation force impulse elastography. *World J Gastroenterol* 2013; 19(2): 219-226 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/219.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.219

INTRODUCTION

Focal liver masses are being discovered at increasing rates due to the wide accessibility of modern high resolution imaging procedures. Conventional ultrasonography (US) is typically used as a first imaging modality to evaluate a focal liver mass. The differential diagnosis of a focal liver mass using imaging studies is based on the characteristics of the surrounding liver parenchyma and underlying clinical conditions such as cirrhosis and the characteristics of the mass itself. Although contrast-enhanced US, computed tomography (CT), and magnetic resonance imaging (MRI) can assess the morphology of a focal liver mass and its vasculature with a high level of diagnostic accuracy[1-5], patients are exposed to potential risks, including contrast medium-induced side-effects and irradiation hazards[6], particularly when repeated examinations are required.

Acoustic radiation force impulse (ARFI) elastography has been introduced as a new ultrasound imaging modality to evaluate tissue stiffness using the radiation forced-based imaging method. The tissue response to the radiation force is observed using conventional B-mode imaging pulses, and it is possible to display the quantitative shear wave velocity (m/s) of the ARFI image[7,8]. Because velocity is directly related to tissue stiffness, ARFI imaging can be applied to evaluate tissue elasticity. Generally, the stiffer the tissue, the faster the shear wave propagates[6,9-13]. Although several reports have indicated a good correlation of ARFI elastography with the other elastography systems such as transient elastography[14,15] and with histological fibrosis grade[14,16,17], ARFI elastography differs from other elastography systems which apply pressure manually to the surface of the organs or a mechanical vibration to induce an elastic shear wave with only M-mode US imaging. Instead, ARFI uses short-duration acoustic pulses generated from a probe under real-time B-mode imaging to produce localized displacements in tissue[18-20]. Furthermore, because ARFI elastography uses elastography with a flexible metering box of the region of the interest (ROI), it is the only elastography method suitable for quantifying focal liver mass stiffness.

Few reports have investigated the applicability of ARFI elastography to evaluate focal liver masses[6,20-25]. Thus, we prospectively recruited patients with a focal liver mass and investigated the diagnostic performance of ARFI elastography to discriminate malignant liver masses and hepatocellular carcinoma (HCC) from benign masses by quantifying their stiffness.

MATERIALS AND METHODS

Subjects

From February 2011 to November 2011, a total of 62 patients with a focal liver mass that was well visualized on conventional US were prospectively recruited for this study. The subjects were referred to our institute for further evaluation of a focal liver mass from primary or secondary clinics, or had been diagnosed with a focal liver mass during a surveillance examination at our institute. Of these, 12 patients were excluded for the following reasons: (1) ARFI measurement failure due to a lesion that was smaller than the ROI and at an inaccessible location (deeper than 8 cm) (n = 7) or (2) poor compliance or inability to hold their breath as required (n = 5). Finally, 50 patients with valid ARFI measurements were enrolled. If a patient had multiple liver masses, only one mass of interest was chosen.

This study was approved by the institutional review board at Severance Hospital in Seoul, South Korea, and conformed to the ethical guidelines of the 1975 Declaration of Helsinki. Written informed consent was obtained from all participants.

Histological confirmation of the liver masses

We performed a targeted biopsy on masses when a confirmatory histological diagnosis was needed or the radiological diagnosis was not confirmative. Among the 50 masses in our study, 37 (74.0%) received targeted biopsy for histological confirmation. Masses that had any component of cholangiocellular carcinomas (CCC) or combined HCC (CHCC) were classified as CCC and the others as HCC.

Clinical diagnosis of the liver masses

A clinical diagnosis of HCC was made according to the American Association for the Study of Liver Disease recommendation[26]. Briefly, patients were diagnosed with HCC if they had a tumor with a maximum diameter > 2 cm and exhibited typical features of HCC on dynamic CT, defined as enhancement in the arterial phase, early washout on the portal phase, and an α-fetoprotein level

Figure 1 Measurement of acoustic radiation force impulse value within the region of interest of a focal liver mass. The shear wave velocity measured when the region of interest box was placed within the mass.

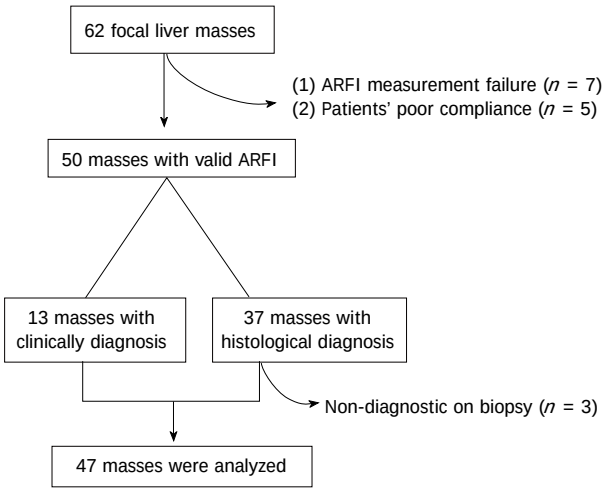

Figure 2 Recruitment algorithm.

> 200 ng/mL. Overall, nine patients satisfied these criteria sufficiently to be diagnosed with HCC without a histological examination.

The presence of a hemangioma was diagnosed clinically in four patients, based on a combination of typical findings, determined using CT or MRI, and a lack of growth for at least 12 mo[22]. A hemangioma appears as a mass with hypoattenuation on unenhanced CT, very high signal intensity on T2-weighted images, peripheral nodular enhancement in the arterial phase, and progressive filling-in of enhancement with no washout in later phases[20].

ARFI elastography

ARFI elastography was performed with an Acuson S2000 ultrasound system (Siemens, Erlanger, Germany), using a 4-1 MHz curved array probe. ARFI elastography was performed by a single physician in all patients (2 years of experience with US and more than 100 examinations with ARFI elastography) who was blinded with regard to the clinical and biochemical data. For patients who underwent liver biopsy, ARFI elastography was performed just before the biopsy, on the same day. For patients with a solitary liver mass that was clinically diagnosed, ARFI elastography was performed at the time of enrollment in this study.

Details of the technical background and examination procedure have been described previously[27]. Briefly, a B-mode US image of the lesion was identified utilizing a ROI, characterized by a box with a fixed dimension of 1 cm × 0.5 cm and a maximum depth of 8 cm. The ROI was entirely located in the lesion, and the ROI location was changed to cover large masses as much as possible without including any vascular or biliary structures (Figure 1). The potential presence of degeneration, such as necrotic, cystic, or calcified portions, was not included in the ROI. To evaluate background liver status of the focal mass, measurements were also taken in the surrounding liver parenchyma with the ROI within 2-3 cm from the target mass, taking care not to comprise any vascular or biliary structure. To ensure quality of the ARFI measurement, 10 measurements were performed for each mass and surrounding liver parenchyma.

Statistical analysis

Continuous variables are expressed as medians and ranges. The χ^2 test or Fisher's exact test and the Mann-Whitney test were used to compare categorical and continuous variables, respectively. Receiver operating characteristics (ROC) curves and areas under the ROC curves (AUROC) were used to estimate diagnostic performance. The cutoff ARFI value for maximal diagnostic accuracy was selected by considering the highest sum of sensitivity and specificity. A P-value < 0.05 was considered statistically significant. The statistical analysis was performed using SPSS software ver. 18.0.0 (Chicago, IL, United States).

RESULTS

Final diagnosis of focal liver masses

We further excluded three masses that were non-diagnostic on biopsy due to a lack of sufficient tissue or ineffective targeting of the mass. Thus, 47 masses (34 histologically confirmed and 13 clinically diagnosed) were evaluated (Figure 2).

Overall, 15 HCCs, eight metastases (three from colorectal cancers, two from gallbladder cancer, one from pancreatic cancer, one from a gastrointestinal stromal tumor, and one from cervical cancer), seven CCCs, three focal nodular hyperplasias (FNH), and one hemangioma were diagnosed. Figure 3 describes pre-biopsy and post-biopsy diagnoses: 21 (61.8%) masses were consistent with the pre-biopsy diagnosis, and 10 masses diagnosed as HCC or CHCC at the time of pre-biopsy were finally confirmed as six HCCs and four CCCs through the biopsy. The histological diagnosis of the other three masses changed (two FNHs to one hemangioma and one HCC; one poorly-differentiated malignancy or metastatic mass to CCC).

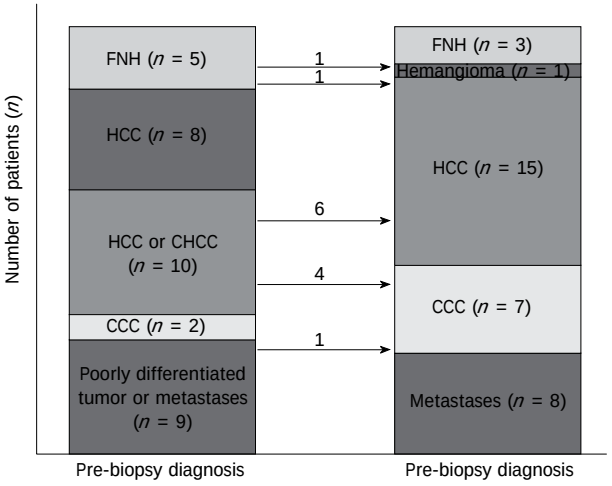

Figure 3 The flow of histological diagnosis. The values on arrows indicate the number of patients who obtained diagnoses differing from those pre-biopsy diagnoses after liver biopsy.

Characteristics and ARFI values of focal liver masses

The depth, location (right *vs* left lobe), and size of each focal liver mass are described in Table 1. ARFI values of HCCs and metastases were higher (2.48 and 2.35 m/s) than those of hemangiomas (1.83 m/s), CCCs (1.65 m/s), and FNH (0.97 m/s). ARFI values for CCCs, hemangiomas, and metastases were significantly higher than those for their surrounding liver parenchyma (mean 1.65 *vs* 1.07 m/s in CCCs; 1.83 m/s *vs* 1.10 m/s in hemangiomas; 2.35 m/s *vs* 1.45 m/s in metastases; all $P < 0.05$), whereas ARFI values for HCCs were similar to those of surrounding liver parenchyma (2.48 m/s *vs* 2.14 m/s, $P = 0.134$).

When HCCs, CCCs, and metastases were categorized into a malignant liver mass group ($n = 39$) and the others were stratified into a benign mass group ($n = 8$), a significant difference appeared in the between the malignant and benign liver masses (2.31 ± 1.05 m/s *vs* 1.51 ± 0.69 m/s, $P = 0.047$) (Figure 4A). However, considerable overlap in ARFI values was noted between malignant and benign masses. Additionally, a significant difference in the ARFI values was observed between the HCCs and the benign masses (2.48 ± 0.84 m/s *vs* 1.51 ± 0.69 m/s, $P = 0.006$) (Figure 4A). To address this overlap, we attempted further analysis taking into consideration the ARFI values of surrounding liver parenchyma as well as those of focal liver masses. When ARFI values of focal liver masses and their surrounding liver parenchyma were combined, the differences in ARFI values for each tumor type became more prominent (4.29 ± 1.22 m/s *vs* 2.92 ± 0.35 m/s for malignant masses *vs* benign masses, $P < 0.001$; 4.62 ± 0.96 m/s *vs* 2.92 ± 0.35 m/s for HCCs *vs* benign masses, $P < 0.001$) (Figure 4B).

Discrimination of malignant liver masses and HCCs from benign masses

The AUROC for discriminating the malignant masses from benign masses was 0.724 (95%CI, 0.566-0.883, $P = 0.048$), and the AUROC for discriminating HCCs from benign masses was 0.813 (95%CI, 0.649-0.976, $P = 0.008$) (Table 2). To maximize the sum of sensitivity and specificity, an ARFI value of 1.82 m/s was selected as the cutoff value to differentiate malignant from benign liver masses. Furthermore, the cutoff value for distinguishing HCCs from benign masses was also determined to be 1.82 m/s (Table 2). Additionally, the diagnostic performance of the sum of the ARFI values for focal liver masses and the surrounding liver parenchyma to differentiate liver masses improved (AUROC = 0.853; 95%CI, 0.745-0.960; $P = 0.002$ in malignant liver masses *vs* benign ones and AUROC = 0.948; 95%CI, 0.896-0.992, $P < 0.001$ in HCCs *vs* benign masses) (Table 2).

DISCUSSION

ARFI elastography has been proposed as a new method for assessing liver stiffness[7-9]. Although ARFI elastography uses shear wave velocity (m/s) to assess liver stiffness, which is similar to FibroScan®, it exhibits several unique properties. First, ARFI elastography allows for the evaluation of deep tissue by generating a shear wave without the need for exertional compression[7,28]. Second, ARFI elastography has the distinct advantage of being integrated into a conventional US system and can provide additional real-time information during a conventional US study[14,15]. Third, ARFI elastography can be performed regardless of the presence of impediments such as ascites, although the reproducibility in this setting should be further investigated[19,29]. Finally, ARFI elastography offers a flexible metering box at variable depths, allowing the examination of specific liver areas[21,30]. Due to these characteristics, the clinical applicability of ARFI elastography has expanded to characterize and distinguish focal liver masses beyond a simple assessment of liver fibrosis[6,20-25].

According to previous studies[22,24,25], malignant liver masses are stiffer than benign masses, as reflected by higher ARFI values. Consistent with this finding, the ARFI values of malignant liver masses (2.31 m/s) or HCCs (2.48 m/s) in our cohort were significantly higher than those of benign masses (1.51 m/s) (all $P < 0.05$). However, when we consider that two types of malignant liver masses (HCCs and CCCs) with different ARFI values were stratified into one malignant mass group in our study, the accuracy of ARFI elastography for identifying malignant liver masses would change according to the proportion of HCCs and CCCs. Thus, an exact comparison between the ARFI values of HCCs and CCCs as well as those of benign masses should be performed in future, larger-scale studies. Additionally, the respective ARFI values of HCCs and metastatic masses in our study were 2.48 m/s and 2.35 m/s, which were similar to data from previous studies (2.45 to 2.63 m/s in HCC and 2.18 to 2.88 m/s in metastasis)[22,23].

ARFI values for hemangiomas vary among reports[6,20,22,23]. The ARFI values of hemangiomas reported

Table 1 Characteristics and acoustic radiation force impulse values of focal liver masses

in two previous studies (1.51 and 1.75 m/s, respectively) were comparable to our data (1.83 m/s)[20,22,23], whereas the ARFI value for a hemangioma in another study was rather higher (2.36 m/s)[22,23]. The variability in hemangioma ARFI values has been explained based on the amount of fibrotic septa that divide the dilated vascular spaces[22]. That is, hemangiomas are composed of multiple vascular channels filled with blood so they would not be expected to be stiff, and therefore would have low ARFI values; in contrast, those including pathological patterns such as sclerosis, thrombosis of the vessels, or calcification, would be stiff and have high ARFI values[20]. Because relatively few hemangioma cases were analyzed in these studies, this discrepancy will need to be investigated *via* further study including a larger number of cases.

Some researchers have attempted to suggest a cutoff ARFI value for distinguishing malignant liver masses from benign masses. We obtained a high PPV (malignant masses *vs* benign masses, PPV 93.3%; HCC *vs* benign masses, 90.5%) using the cutoff ARFI value of 1.82 m/s, which maximized the sum of the sensitivity and specificity for distinguishing masses. Our cutoff value of 1.82 m/s for identifying malignant liver masses was slightly lower than those in previous studies (2.0 to 2.5 m/s)[22,24,25],

which can be partially explained by the different methods used to categorize the masses. In one study, which reported a rather high cutoff value of 2.5 m/s, only metastases that had a high ARFI value of 4.18 m/s were categorized into a malignant group and compared with benign masses[24], whereas another study that reported 2.22 m/s as a cutoff value for discriminating malignant masses from benign masses included FNHs, adenomas, and focal fatty change lesions in the benign mass group as well as hemangiomas[25]. Thus, in this regard, further study is needed to prevent potential bias due to heterogeneity of the masses and to confirm the clinically applicable cutoff values for ARFI elastography. Although our cutoff value may be useful to physicians who encounter focal liver masses during routine US evaluation, it should be interpreted cautiously in the clinical context for several reasons. First, although our cutoff value would correctly characterize HCC and metastasis, it would mischaracterize CCC with a relatively low ARFI value and hemangioma with a relatively high ARFI value. Second, there was considerable overlap of ARFI values between malignant and benign masses.

Underlying fibrosis of the liver is a consideration for the differential diagnosis of a focal liver mass. Several previous studies have proposed that HCCs generally appear softer (lower ARFI values) than the surrounding liver[21], whereas metastases and hemangiomas generally appear harder than that of the surrounding liver despite some controversies among studies[21]. Similarly, we found that CCCs, hemangiomas, and metastases had higher ARFI values than those of surrounding liver parenchyma, whereas ARFI values of HCCs were statistically equivalent to those of the surrounding liver parenchyma. Because hemangiomas and metastases were evaluated in patients without chronic liver disease in most studies[6,25], ARFI values seemed consistently higher than those of a background liver. In contrast, because HCCs were evaluated in patients with chronic liver disease and diverse degrees of background liver fibrosis, the comparative results between ARFI values of HCCs and those of background liver differed among studies based on the characteristics of each study cohort[6,21,25]. That is, simultaneously measuring ARFI values of focal liver mass and the surrounding liver should focus on assessing the respective characteristics of the hepatic mass and surrounding fibrosis to prevent a misdiagnosis of the hepatic mass using the correlation of ARFI values between the liver mass and background liver parenchyma. However, when we used the sum of ARFI values of focal liver mass and the surrounding liver parenchyma, the diagnostic performance in terms of distinguishing liver mass improved. Thus, these controversial findings concerning the simultaneous measurement of liver masses and their surrounding liver parenchyma should be further investigated in future larger-scale studies.

Although most cases (72.3%) were histologically confirmed in our study, the relative small sample size of our cohort and inclusion of patients with high ALT, which has the potential of overestimating influences on ARFI values[30,31], are potential limitations. Although ARFI elastography can freely locate the ROI box in a specific area within a mass and measure its stiffness, morphological characteristics of liver masses including heterogeneous components such as HCC with hemorrhage and fatty metamorphosis[6,20,32] and lesion shapes were not considered in our study, which is a limitation of this study. Further investigation of how to evaluate such heterogeneous or morphologically varying liver masses using ARFI elastography and their influences on ARFI values of liver masses should be conducted.

In our study, we demonstrated the potential clinical utility of ARFI elastography for characterization of focal liver masses. Although this study had limitations and should be interpreted cautiously, our findings provide a useful reference for the differential diagnosis of a focal liver mass and will provide additional information to clinicians who are confronted with a need for an immediate diagnosis of a focal liver mass during a routine US examination before a further diagnostic imaging study such as contrast-enhanced US, CT or MRI. However, further studies with larger numbers of cases are warranted to assess the utility of ARFI elastography in the clinic.

COMMENTS

Background

Acoustic radiation force impulse (ARFI) elastography can quantify tissue elasticity. Compared to previous elastography techniques, one of the distinguishing advantages of ARFI elastography is that it offers a flexible metering box at variable depths, which allows an examination of specific liver areas. With using this characteristic of ARFI elastography, authors investigated its applicability to evaluate focal liver masses.

Research frontiers

According to previous studies, malignant liver masses are stiffer than benign masses, as reflected by higher ARFI values. However, previous studies have showed somewhat controversial results with various median ARFI values for each focal liver mass and they have had limitations, such as most subjects not being supported by adequate histological confirmation.

Innovations and breakthroughs

Authors prospectively investigated 50 focal liver masses found during routine ultrasonography (US) study, and measured the stiffness of each focal liver mass using ARFI elastography. Focal liver masses included hepatocellular carcinomas (HCCs), cholangiocellular carcinomas, metastases, hemangiomas, and focal nodular hyperplasia. The advantage of our study over other previous studies is that majority of our subjects (72.3%) are confirmed with histological examinations.

Applications

Using ARFI elastography, physicians who are confronted with a need for an immediate diagnosis of a focal liver mass during a routine US examination can get additional information for the differential diagnosis of liver masses in clinical practice. Further future studies with larger numbers of cases are warranted to assess the utility of ARFI elastography.

Terminology

ARFI elastography is an emerging examination which can quantify tissue elasticity. ARFI elastography has the distinct advantage of being integrated into a conventional US system and can be checked simultaneously during a conventional US study. Furthermore, because ARFI elastography uses elastography with a flexible metering box of the region of the interest, it is suitable for quantifying focal liver mass stiffness.

Peer review

Although this study had limitations and should be interpreted cautiously, their results show the clinical applicability of ARFI elastography as a complementary diagnostic tool for the differential diagnosis of liver masses.

Abstract

AIM: To investigate the role of inositol-requiring enzyme 1α (IRE1α) in gut development of *Xenopus lavies* embryos.

METHODS: *Xenopus* embryos were obtained with *in vitro* fertilization and cultured in 0.1 × MBSH. One and half nanogram of IRE1α, 1 ng of IRE1α-GR mRNA, 1 ng of IRE1αΔC-GR mRNA, and 50 ng of IRE1α morpholino oligonucleotide (MO) or XBP1(C)MO were injected into four blastomeres at 4-cell stage for scoring the phenotype and marker gene analysis. To rescue the effect of IRE1α MO, 1 ng of IRE1α-GR mRNA was co-injected with 50 ng of MO. For the activation of the GR-fusion proteins, dexamethasone was prepared as 5 mmol/L stock solutions in 100% ethanol and applied to the mRNA injected embryos at desired stages in a concentration of 10 μmol/L in 0.1 × MBSH. Embryos were kept in dexamethasone up to stage 41. Whole-mount *in situ* hybridization was used to determine specific gene expression, such as IRE1α, IRE1β, Xbra and Xsox17α. IRE1α protein expression during *Xenopus* embryogenesis was detected by Western blotting.

RESULTS: In the whole-mount *in situ* hybridization analysis, xenopus IRE1α and IRE1β showed quite different expression pattern during tadpole stage. The relatively higher expression of IRE1α was observed in the pancreas, and significant transcription of IRE1β was found in the liver. IRE1α protein could be detected at all developmental stages analyzed, from stage 1 to stage 42. Gain-of-function assay showed that IRE1α mRNA injected embryos at tailbud stage were nearly normal and the expression of the pan-mesodermal marker gene Xbra and the endodermal gene Xsox17α at stage 10.5 was not significantly changed in embryos injected with IRE1α mRNA as compared to uninjected control embryos. And at tadpole stage, the embryos injected with IRE1α-GR mRNA did not display overt phenotype, such as gut-coiling defect. Loss-of-function assay demonstrated that the IRE1α MO injected embryos were morphologically normal before the tailbud stages. We did not observe a significant change of mesodermal and endodermal marker gene expression, while after stage 40, about 80% of the MO injected embryos exhibited dramatic gut defects in which the guts did not coil, but other structures outside the gastrointestinal tract were relatively normal. To test if the phenotypes were specifically caused by the knockdown of IRE1α, a rescue experiment was performed by co-injection of IRE1α-GR mRMA with IRE1α MO. The data obtained demonstrated that the gut coiling defect was rescued. The deletion mutant of IRE1α was constructed, consisting of the N-terminal part without the C-terminal kinase and RNase domains named IRE1αΔC, to investigate the functional domain of IRE1α. Injection of IRE1αΔC-GR mRNA caused similar morphological alterations with gut malformation by interfering with the function of endogenous xIRE1α. In order to investigate if IRE1α/

XBP1 pathway was involved in gut development, 50 ng of XBP1 MO was injected and the results showed that knockdown of XBP1 resulted in similar morphological alterations with gut-coiling defect at tadpole stage.

CONCLUSION: IRE1α is not required for germ layer formation but for gut development in *Xenopus lavies* and it may function *via* XBP1-dependent pathway.

INTRODUCTION

The endoplasmic reticulum (ER) plays a central role in the synthesis and modification of secretary and membrane proteins in all eukaryotic cells[1-3]. Under normal conditions, these proteins are correctly folded and assembled in the ER. However, when cells are exposed to disturbed environment, such as overproduction of ER proteins, viral infection, and glucose deprivation, these proteins accumulate as unfolded or misfolded forms in the ER lumen and, consequently, cause ER stress. To maintain cellular homeostasis, cells induce some adaptive responses to ER stress. One of them is the unfolded protein response (UPR), which up-regulates the transcription of various genes to increase the protein-folding and protein-degradation activity in the ER[4-7]. Inositol requiring enzyme-1 (IRE1) is an ER-located type I transmembrane protein with a kinase domain and RNase domain in the cytosolic region and has a unique function of relieving ER stress in cells. When the amino-terminal luminal region senses perturbations in the ER environment, *via* trans-autophosphorylation and activation of its RNase domain, IRE1 induces unconventional splicing of mRNA coding, a specific transcription factor for activating the UPR[8-10]. IRE1 is highly conserved from yeast to humans, and two IRE1 paralogues have been reported in mammals: IRE1α and IRE1β[11-13]. Upon activation by ER stress, IRE1 performs an unconventional cytoplasmic splicing of XBP1 pre-mRNA, thus allowing the synthesis of active XBP1, which activates UPR target genes to restore the homeostasis of the ER[10,14,15]. The spliced XBP1 mRNA is translated into a functional transcription factor to up-regulate gene expression for ER quality control. IRE1 is also reported to activate proapoptotic JNK signaling under ER stress conditions[16].

IRE1α is also known to be expressed ubiquitously in fetal and adult mice and to be essential for mammalian developmental processes[17]. Therefore, IRE1α inactivation results in widespread developmental defects, leading to embryonic death after 12.5 d of gestation in mice[18]. However, the cause of this embryonic lethality is not fully understood. These lines of evidence suggest that IRE1α has a unique function in mammalian developmental processes, but it has been hitherto unclear in which tissues and how IRE1α functions during embryogenesis.

Xenopus lavies is an excellent model system for studying organ development[19]. However, little information is available about the function of the IRE1/XBP1 pathway during embryogenesis, although loss of function studies revealed that IRE1 or XBP1 is absolutely required for embryonic development of C. elegans[20], Drosophila[21] or mouse[22]. In *Xenopus*, although the transcripts of two isoforms of IRE1, IRE1α and IRE1β show similar spatial expression in pre-neurula embryos, they are also differentially expressed following the onset of neurulation[23]. IRE1α is localized to the nervous system and mesoderm or endoderm-derived organs, such as pronephros and pancreas. However, the role of IRE1α in organogenesis is still unclear. In the present study, both gain and loss of function analyses revealed that IRE1α is required for gut development in *Xenopus*.

MATERIALS AND METHODS

Embryos

Wild type *Xenopus lavies* eggs were obtained by injecting 1000 IU of human chorionic gonadotrophin into the dorsal lymph sacs of adult females 6-8 h before egg collection. Eggs were fertilized *in vitro* with minced testes, dejellied with 2% cysteine hydrochloride (pH 7.8-8.0) 30 min after fertilization, and cultured in 0.1 × MBSH (8.8 mmol/L NaCl, 0.24 mmol/L $NaHCO_3$, 0.1 mmol/LKCl, 0.082 mmol/L $MgSO_4$, 0.041 mmol/L $CaCl_2$, 0.033 mmol/L $Ca(NO_3)_2$, 1 mmol/L HEPES, pH 7.4). Staging of *Xenopus lavies* embryos was according to Nieuwkoop and Faber (1967).

Plasmids and constructs

IRE1α ORF was amplified from a cDNA pool consisting of st.1, st.8, st.10, st.15, st.20 and st.28 cDNAs and subcloned to $pCS2^+$ vector. The construct was named $pCS2^+$-IRE1α. To make expression constructs, complete coding region and the N-terminal region (aa 1-479) were amplified from the $pCS2^+$-IRE1α using PCR and subcloned to the BamHI-EcoRV sites on $pCS2^+$-GR. The resulting constructs were designated as $pCS2^+$IRE1α-GR and $pCS2^+$IRE1αΔC-GR.

In vitro RNA synthesis, antisense morpholino oligonucleotides and microinjection

Plasmids $pCS2^+$IRE1α, $pCS2^+$IRE1α-GR and $pCS2^+$IRE1αΔC-GR were linearized with *Not*I. Capped mRNA for microinjection was synthesized with SP6 mMessage mMachine™ kit (Ambion) and cleaned up with RNeasy kit (Qiagen). The antisense morpholino

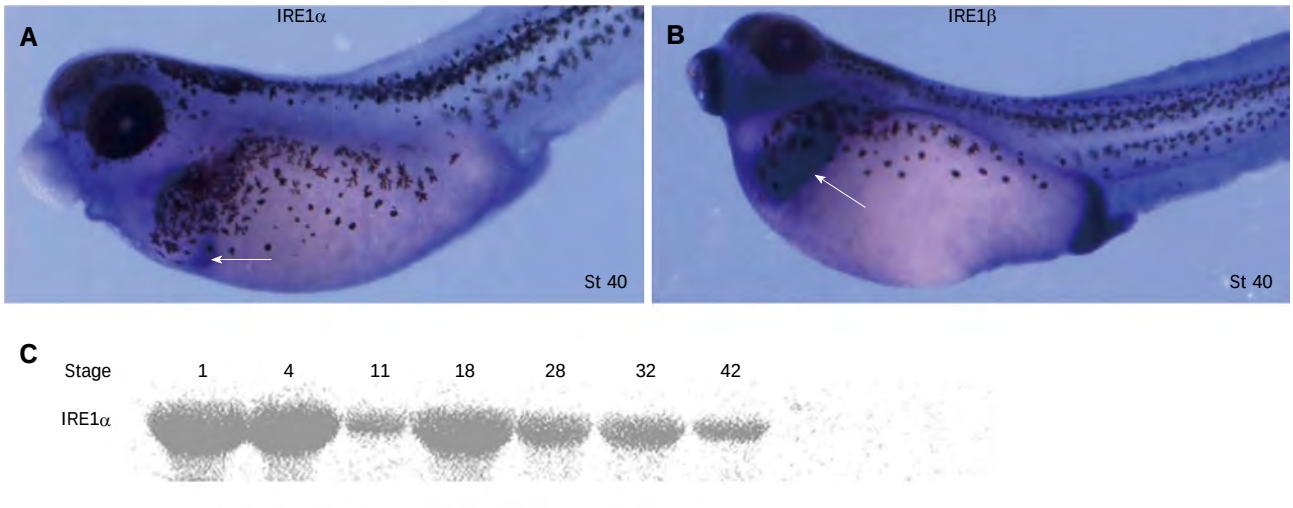

Figure 1 Expression pattern of xIRE1 in *Xenopus lavies* during development. A, B: Whole-mount *in situ* hybridizations revealed relatively high expression of inositol-requiring enzyme (IRE) 1α in pancreas (white arrow in A) and relatively high expression of IRE1β in liver (white arrow in B); C: Western blotting revealed temporal expression of IRE1α during *Xenopus* embryogenesis.

oligonucleotide (Gene Tools) used for IRE1α functional knockdown (IRE1α MO) was: 5'-AAGAGAACCGC-CAGAGGC GCCATG T-3'; and an antisense morpholino oligonucleotide XBP1(C) MO designed to inhibit the cytoplasmic splicing of xXBP1 was: 5'-GACATCT-GGGCCTGCTC CTGC TGCA-3'. One and half nanogram of IRE1α, 1 ng of IRE1α-GR mRNA, 1 ng of IRE1αΔC-GR mRNA, and 50 ng of IRE1α MO or XBP1(C)MO were injected into four blastomeres at 4-cell stage for scoring the phenotype, whole-mount *in situ* hybridization and marker gene analysis. For the activation of the GR-fusion proteins, dexamethasone (Sigma) was prepared as 5 mmol/L stock solutions in 100% ethanol and applied to the control and mRNA injected embryos at desired stages in a concentration of 10 μmol/L in 0.1 × MBS. Embryos were kept in dexamethasone up to stage 41. To rescue the effect of blocking xXBP1 splicing by IRE1α MO, 1 ng of IRE1α-GR mRNA was co-injected with 50 ng of MO.

In vitro translation

In vitro protein translation was performed with TNT coupled Reticulocyte Lysate Systems (Promega) to test the efficiency of IRE1α MO for blocking protein translation. One μg of pCS2$^+$IRE1α plasmid was used either alone or together with 20 μg IRE1α MO for *in vitro* translation. Translation products were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and chemiluminescent detection.

Whole-mount in situ hybridization

Whole-mount *in situ* hybridization was performed according to the protocol described elsewhere[24]. The digoxigenin-labeled antisense probes were prepared as follows: pDrive-IRE1α cut with *Hin*dⅢ, transcribed with T7 RNA polymerase; pCS2$^+$XIRE1β cut with *Xba*I, transcribed with T3 RNA polymerase; pBS-Xbra cut with *Sal*I, transcribed with T7 RNA polymerase; and pCS2$^+$XSox17α cut with *Cla*I, transcribed with T7 RNA polymerase.

Protein extraction and Western blotting

Embryos were homogenized in RIPA lysis buffer (20 mmol/L Tris, pH 8; 2 mmol/L EDTA, pH 8; 0.5% NP-40; 25 mmol/L β glycerophosphate; 100 mmol/L NaF; 100 mmol/L PMSF and phosphatase inhibitor cocktail). Lysates were centrifuged at 4 ℃, 15 000 × *g*, for 20 min, and the supernatants were added to 5 × SDS loading buffer. Proteins were separated by 10% SDS-PAGE and transferred to nitrocellulose membrane (Millipore, Billerica, MA). Immunoblotting membranes were blocked with 5% milk in TBST. After several washes in TBST, membranes were incubated overnight with the first antibody [anti-IRE1α antibody (Santa Cruz Biotechnology, Santa Cruz, CA), 1:500]. Loading controls of presumably constantly expressed proteins such as β-actin were used; however, their variability and increase in development precluded their use[25]. Detection was then done with HRP-labeled secondary antibodies and enhanced chemiluminescence (ECL).

RESULTS

Expression of xIRE1α in Xenopus lavies during development

Two forms of IRE1 genes, IRE1α and IRE1β, exist in *Xenopus lavies*. Whole-mount *in situ* hybridization revealed that IRE1α and IRE1β were expressed in a similar pattern from egg to gastrulation. In tailbud embryos, IRE1α was detected in a domain that probably represented the dorsal pancreas anlage. IRE1β was only observed in the hatching gland and cement gland until the hatched tadpole stage[23]. To further explore the spatial expression patterns of IRE1α and IRE1β in *Xenopus* embryos at later stages, whole-mount *in situ* hybridizations were carried out. During tadpole stages, relatively high expression of IRE1α was observed in the pancreas (Figure 1A), and significant transcription of IRE1β was observed in the

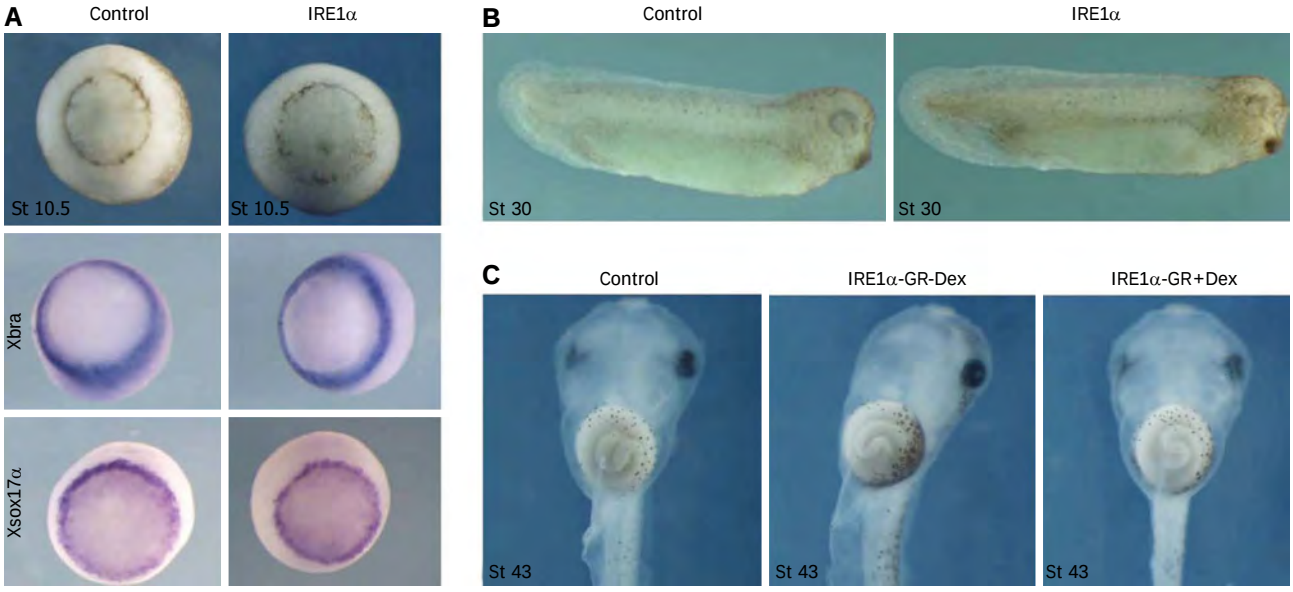

Figure 2 Overexpression of inositol-requiring enzyme 1α affected neither mesoderm and endoderm formation nor gut development. A: Overexpression of inositol-requiring enzyme (IRE) 1α did not change the phenotype and the expression of Xbra and Xsox17α at stage 10.5; B: IRE1α mRNA injected embryos at tailbud stage were nearly normal; C: Embryos injected with IRE1α-GR mRNA did not display any defect until tadpole stage.

Figure 3 Inositol-requiring enzyme 1α morpholino oligonucleotide blocks inositol-requiring enzyme 1α translation in an *in vitro* transcription/translation assay. In this assay, xIRE1α was effectively transcribed/translated from a pCS2+xIRE1α construct. However, translation was dramatically decreased by addition of IRE1α morpholino oligonucleotide (MO). IRE: Inositol-requiring enzyme.

liver (Figure 1B). IRE1α protein could be detected at all developmental stages analyzed (Figure 1C).

IRE1α gain of function

Different doses of IRE1α mRNA were injected into all blastomeres at 4-cell stage. Even at a dose of 1.5 ng, injected embryos at tailbud stage were nearly normal (Figure 2B). Whole-mount *in situ* hybridization of embryos injected with IRE1α mRNA revealed that the expression of the pan-mesodermal marker gene Xbra and the endodermal gene Xsox17α at stage 10.5 was not significantly changed as compared to uninjected control embryos (Figure 2A). To test the function of IRE1α in the later stage of development, the mRNA encoding a dexamethasone inducible variant of IRE1α, referred to as IRE1α-GR, was injected into all four blastomeres at 4-cell stage *Xenopus* embryos. For the activation of the GR-fusion proteins, dexamethasone treatment was administered at embryonic stage 27. No apparent change of phenotype was observed even at tadpole stage (Figure 2C). Therefore, gain of function of IRE1α did not lead to an apparent change of phenotype and we did not observe a significant change of mesodermal and endodermal marker gene expression.

IRE1α MO blocking IRE1α translation

To further explore the function of xIRE1α during embryonic development, we performed a loss of function (LOF) analysis using an antisense morpholino oligonucleotide (IRE1α MO) directed against xIRE1α. *In vitro* protein translation was performed with TNT coupled Reticulocyte Lysate Systems to test the efficiency of IRE1α MO for blocking protein translation. As shown in Figure 3, IRE1α MO totally blocked IRE1α translation.

IRE1α loss of function

The IRE1α MO-injected embryos were morphologically normal before the tailbud stages (Figure 4B) and we did not observe a significant change of mesodermal and endodermal marker gene expression (Figure 4A), but after stage 40, about 80% of the MO (50 ng)-injected embryos exhibited dramatic gut defects in which the guts did not coil, while other structures outside the gastrointestinal tract developed normally (Figure 4). To test if the phenotypes were specifically caused by the knockdown of IRE1α, a rescue experiment was performed by co-injection of IRE1α-GR mRMA with MO. The results indicated that the phenotype could be rescued (Figure 5). Taken together, these data indicate that IRE1α is re-

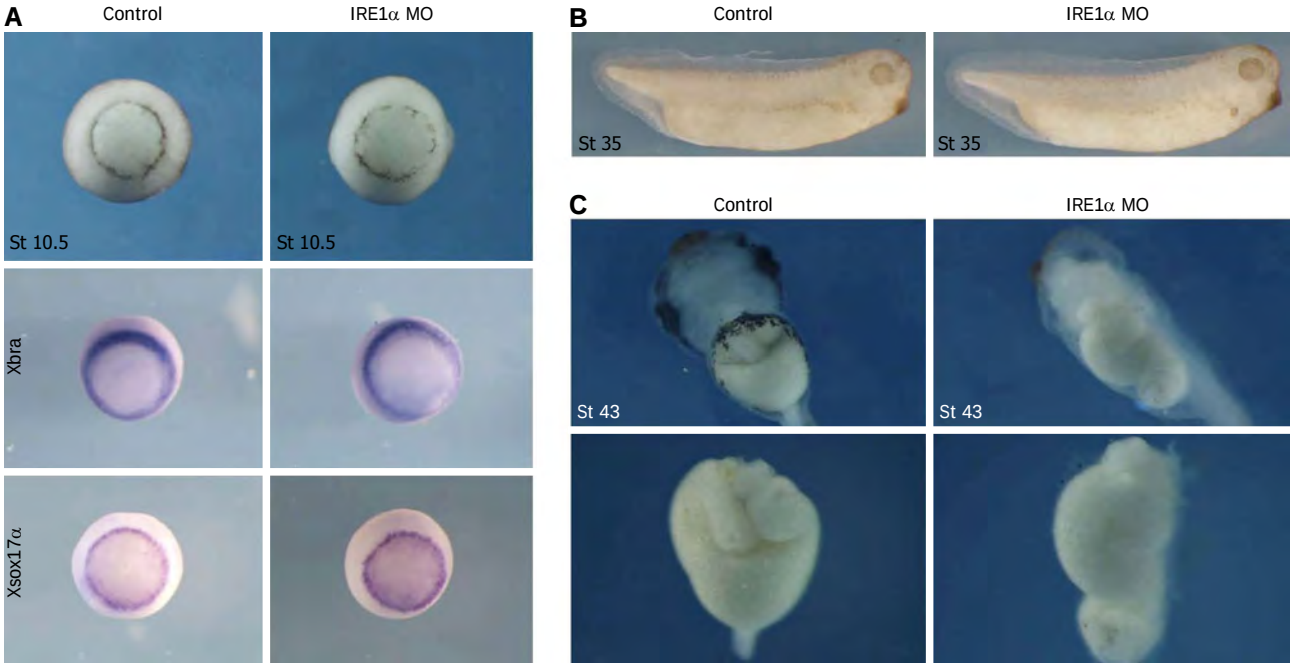

Figure 4 ***Xenopus*** **inositol-requiring enzyme 1α is required for gut development.** A: Knockdown of x IRE1α did not change the phenotype and the expression of Xbra and Xsox17α at stage 10.5; B: The inositol-requiring enzyme (IRE) 1α morpholino oligonucleotide (MO)-injected embryos were morphologically normal before the tailbud stages; C: IRE1α knockdown upon injection of 50 ng of MO resulted in a gut defective phenotype. Surgically-resected guts from embryos were shown in C under panel. Coiled structure of gut was not detected in IRE1α MO-injected embryos at stage 43. MO injection was repeated 5 times in a total of 278 embryos.

Figure 5 **Rescue of xIRE1α knockdown with IRE1α-GR mRNA.** Gut defective phenotype caused by 50 ng of morpholino oligonucleotide (MO) could be rescued by co-injection of 1 ng of inositol-requiring enzyme (IRE) 1α-GR mRNA. Co-injection was done 3 times in a total of 258 embryos.

quired for proper gut development in *Xenopus*.

Deletion mutant of IRE1α

IRE1α is a Ser/Thr protein kinase and endoribonuclease that, upon activation, initiates the unconventional splicing of the mRNA of XBP1[12]. The deletion mutant was constructed consisting of the N-terminal part without the C-terminal kinase and RNase domains (Figure 6A). Injection of IRE1αΔC-GR mRNA caused similar morphological alterations with gut malformation by interfering with the function of endogenous xIRE1α (Figure 6B-D). These data further confirmed the notion that IRE1αΔC represents a dominant-negative form of IRE1α.

XBP1 loss of function

IRE1α is the most evolutionarily conserved branch of the UPR, and upon activation, initiates the unconventional splicing of the mRNA encoding the transcriptional factor XBP1 to attenuate ER stress by mediating UPR. In other words, IRE1α mediates XBP1 splicing. IRE1α MO could knockdown IRE1α expression, and then XBP1 splicing would be repressed. To test if knockdown of XBP1 might cause similar phenotype with IRE1α knockdown, 50 ng of XBP1(C)MO was injected into four blastomeres at 4-cell stage for scoring the phenotype. As shown in Figure 7, injection of XBP1(C)MO caused similar phenotype with gut-coiling defect.

DISCUSSION

In eukaryotic cells, ER is responsible for the early steps in the maturation of most proteins in the secretory pathway, such as folding of the newly synthesized polypeptide chains and post-translational modifications that are essential for protein function[26,27]. Nascent polypeptides are translocated to the ER lumen in an unfolded state, where

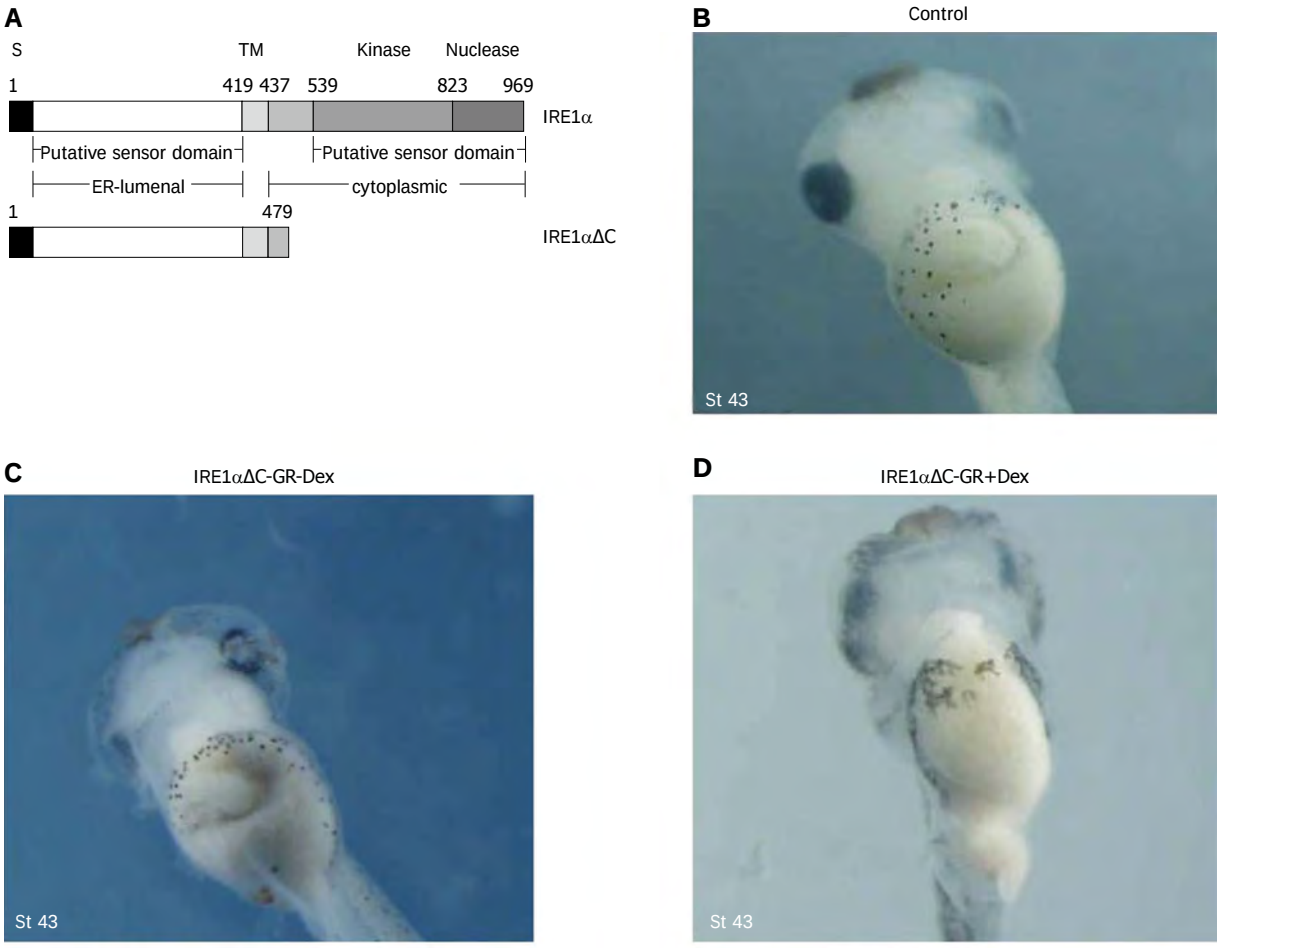

Figure 6 Injection of IRE1α**ΔC-GR mRNA caused morphological alterations with gut malformation.** A: Diagram depicting the construction of deletion mutants. S and TM denote the signal peptide and the transmembrane domain; B-D: Gut defects were also observed with a dominant-negative mutant, IRE1αΔC, lacking the cytoplasmic kinase and RNase domains.

Figure 7 XBP1 knockdown affected gut development. Injection of XBP1(C) morpholino oligonucleotide (MO) caused similar phenotype with gut-coiling defect at stage 43.

they are processed for folding. However, the function of ER will be disrupted when the inflow of unfolded polypeptide chains exceeds the folding or processing capacity of the ER[28,29]. This ER stress in turn leads to the activation of a series of adaptive pathways known as UPR to maintain ER homeostasis[30]. The adaptive process, UPR, has at least two distinct components[4]. The first consists of the rapid and transient attenuation of new protein synthesis and can be considered to be an attempt on the part of the cell to limit the load on the folding apparatus in the ER. The second component consists of the upregulation of expression of genes whose products promote protein folding in the ER and degradation of malfolded proteins. The latter UPR signaling pathways are transduced by three ER resident transmembrane proteins IRE1, PERK and ATF6 upon activation[14], among which IRE1 functions as an endoribonuclease (RNase) to process XBP1 pre-mRNA to a mature form. Spliced XBP1 is a transcriptional activator that plays a fundamental role in the activation of a wide variety of UPR target genes[31,32]. Two mammalian homologues of yeast IRE1 have been identified: IRE1α and IRE1β. IRE1α is expressed in most cells and tissues, with highest levels of expression in the pancreas and placenta[17]. IRE1β expression is prominent only in intestinal epithelial cells[13].

Accumulation of malfolded proteins in the ER occurs under many pathophysiological conditions, in addition, it also takes place during embryonic development. During embryogenesis of vertebrates, such as *Xenopus*, germ layer induction, pattern formation, and morphoge-

netic movement are known to be mediated by secreted proteins, including fibroblast growth factors (FGFs)[33], TGF-β/nodal/BMPs, and Wnts[34,35]. Therefore, dysfunction of the ER should also interfere with the secretion of these proteins and consequently disrupt early embryonic development[36].

Although the effect of ER stress on cellular physiology has been extensively investigated, little is known so far about how it affects early embryonic development. The previous study has verified the conservation of IRE1/XBP1 pathway in *Xenopus* embryos and the importance of IRE1β for mesoderm formation in *Xenopus* embryos[23]. In this study, we demonstrated that (1) IRE1α mainly expressed in pancreas at tadpole stages and IRE1α protein could be detected at all developmental stages analyzed (Figure 1); (2) although it did not cause overt phenotypes upon overexpression (Figure 2), specific knockdown of IRE1α (Figure 4) or XBP1 (Figure 7) led to a gut-coiling defect, and injection of xIRE1αΔC-GR mRNA caused similar morphological alterations with gut malformation (Figure 6); and (3) IRE1α-GR mRNA can rescue IRE1 knockdown phenotypes (Figure 5).

In conclusion, our loss and gain of function data support the notion that IRE1α is required for gut development in *Xenopus* embryos. Our results demonstrate that homeostasis of ER and xIRE1α functions are required for gut development in *Xenopus* embryos. We infer from our results that IRE1 regulates gut development through IRE1α-XBP1 pathway.

COMMENTS

Background

Inositol-requiring enzyme 1α (IRE1α) is an endoplasmic reticulum (ER)-located type I transmembrane protein with a kinase domain and RNase domain in the cytosolic region. IRE1α induces the unconventional splicing of XBP1 mRNA under ER stress condition. However, a XBP1-independent IRE1α function also exists. IRE1α is expressed ubiquitously in fetal and adult mice and is essential for mammalian developmental processes. However, the function of IRE1α in specific organs and tissues remains incompletely understood.

Research frontiers

IRE1α is confirmed to be essential during mammalian development. However, the IRE1α conventional knockout mice showed embryonic lethality, and it has been reported that during development IRE1α is required for B-cell differentiation, placental development and embryonic viability. And the function of IRE1α in specific organs and tissues deserves to be illustrated.

Innovations and breakthroughs

Compared with previous studies, this study used the *Xenopus lavies* as animal model to study the function of IRE1α during their development. After overexpressing and knockdown of the IRE1α, the phenotype could be analyzed. And the results showed that at early stage, IRE1α did not play a significant role in germ layer formation, however, at the stage of organogenesis, knockdown of IRE1α or XBP1 caused gut-coiling defect. The results suggested that IRE1α is not required for germ layer formation, but for gut development in *Xenopus lavies* and it may function *via* XBP1-dependent pathway.

Applications

The results in this study showed that IRE1α does play a role in organogenesis, however, two questions remain to be answered: which organs or tissues in gut are affected and what is the underlying mechanism.

Peer review

This is an interesting article. The authors show in a systematic manner that the role of IRE1a in the gut development of *Xenopus*. They also show that it acts through the XBP1 processing.

Abstract

AIM: To assess the effects of partially hydrolyzed guar gum (PHGG) diet supplement in pediatric chronic abdominal pain (CAP) and irritable bowel syndrome (IBS).

METHODS: A randomized, double-blind pilot study was performed in sixty children (8-16 years) with functional bowel disorders, such as CAP or IBS, diagnosed according to Rome Ⅲ criteria. All patients underwent ultrasound, blood and stool examinations to rule out any organic disease. Patients were allocated to receive PHGG at dosage of 5 g/d (n = 30) or placebo (fruit-juice n = 30) for 4 wk. The evaluation of the efficacy of fiber supplement included IBS symptom severity score (Birmingham IBS Questionnaire), severity of abdominal pain (Wong-Baker Face Pain Rating Score) and bowel habit (Bristol Stool Scale). Symptom scores were completed at 2, 4, and 8 wk. The change from baseline in the symptom severity scale at the end of treatment and at 4 wk follow-up after treatment was the primary endpoint. The secondary endpoint was to evaluate compliance to supplementation with the PHGG in the pediatric population. Differences within groups during the treatment period and follow-up were evaluated by the Wilcoxon signed-rank test.

RESULTS: The results of the study were assessed considering some variables, such as frequency and intensity of symptoms with modifications of the bowel habit**.** Both groups were balanced for baseline characteristics and all patients completed the study. Group A (PHGG group) presented a higher level of efficacy compared to group B (control group), (43% *vs* 5%, P = 0.025) in reducing clinical symptoms with modification of Birmingham IBS score (median 0 ± 1 *vs* 4 ± 1, P = 0.025), in intensity of CAP assessed with the Wong-Baker Face Pain Rating Score and in normalization of bowel habit evaluated with the Bristol Stool Scale (40% *vs* 13.3%, P = 0.025). In IBS subgroups, statistical analysis shown a tendency toward normalization of bowel movements, but there was no difference in the prevalence of improvement in two bowel habit subsets. PHGG was therefore better tolerated without any adverse effects.

CONCLUSION: Although the cause of pediatric functional gastrointestinal disorders is not known, the results show that complementary therapy with PHGG may have beneficial effects on symptom control.

INTRODUCTION

Functional gastrointestinal disorders (FGIDs) are defined as a variable combination of chronic or recurrent gastrointestinal (GI) symptoms; they are age dependent and not explained by structural or biochemical abnormalities[1]. Chronic abdominal pain (CAP) is the most common condition in FGIDs. It is usually functional without objective evidence of an underlying organic disorder. Apley *et al*[2] introduced the term recurrent abdominal pain (RAP) for the first time in pediatric literature, using it to describe a condition whereby children have experienced at least 3 bouts of pain, severe enough to affect activities, over a period of at least 3 mo. In 1999, the Pediatric Rome Working Group introduced standardized symptom-based criteria for pediatric FGIDs with the publication of the Rome Ⅱ criteria[3]. In 2006, the "Rome Committee"[4] defined new diagnostic criteria (Roma Ⅲ) for pediatric FGIDs, differentiating functional abdominal pain (FAP) from dyspepsia and irritable bowel syndrome (IBS) in that the pain is at a different site with normal bowel habits. The exact prevalence of CAP in children is not known. It seems to account for 2%-4% of all pediatric office visits[5]. Several studies suggested that 13% of middle-school students and 17% of high school students have weekly experience of abdominal pain[6,7]. According to these criteria, IBS is an FGID characterized by abdominal pain or discomfort, accompanied by altered bowel habits (constipation, IBS-c or diarrhea, IBS-d or alternating)[8]. It has been shown that some factors, especially psychological factors, dietary habits, and frequency of exercise, are associated with onset and course of IBS[9-11]. The term "functional" is not real but conceptual and the pathogenesis can be correlated with alterations of visceral sensitivity, increased intestinal permeability, chronic inflammation and presence of a genetic predisposition[12]. Pharmacotherapy generally cannot be recommended for children with FAP, except in the context of clinical trials. Drugs should only be given in exceptional cases[13,14]. Up to 40% of children undergo alternative or complementary therapy such as reassurance, phytotherapy, dietary restrictions or homeopathy[15]. The putative benefit of such methods has not been documented by controlled clinical trials.

The beneficial effects of water-soluble dietary fibers have received attention as complementary therapy in FGIDs, especially in FAP and IBS, for their ability to modify bowel pattern, accelerate oral-to-anal transit and decrease intracolonic pressure and alleviate pain[16,17]. Partially hydrolyzed guar gum (PHGG) is a vegetal, water-soluble, non-viscous, non-gelling dietary fiber that is derived from guar gum, a water-soluble, viscous, gelling polysaccharide found in the seeds of the guar plant. The saccharide component of guar gum is galactomannan[18]. Parisi *et al*[19] showed, in an adult open trial, that PHGG supplementation is followed by a decrease of IBS symptoms, such as abdominal pain and bowel habit. Feldman *et al*[20], in a small, prospective, randomized, double-blind, controlled trial, have revealed that fiber supplementation can improve symptoms in children with FAP. Despite this, there have been no recently available published randomized controlled trials (RCTs) to support the use of fiber in the treatment of CAP in a pediatric population.

The aim of this study was to assess the effect of PHGG diet supplement on CAP and IBS symptoms in paediatric population.

MATERIALS AND METHODS

Sixty patients were prospectively enrolled in the study and randomly assigned to one of 2 study arms (PHGG group or group A: 30 patients; placebo group or group B: 30 patients). Median age was 12.8 years (range 8-16 years) with a greater predominance of females (62% girls and 38% boys). CAP and IBS patients were defined according to the Rome Ⅲ criteria.

All patients were identified into two subgroups: 21/30 (70%) and 19/30 (63%) with constipation-predominant IBS in group A and B respectively; 9/30 (30%) and 11/30 (37%) with diarrhoea-predominant IBS in group A and B respectively. At baseline, the two groups were not statistically different, with respect to age, sex, alterations in bowel movements, incidence and intensity of self-reported symptoms. Subjects' overall baseline demographic and clinical characteristics are summarized in Table 1. All patients underwent ultrasound, blood and stool examinations to exclude organic disease. Seven days before joining the study, patients were asked to not use any medication. The study was performed in accordance with the Declaration of Helsinki and was approved by the local ethics committee. Informed consent was obtained for each patient. All patients completed the trial without any dropouts. Figure 1 is a flow diagram showing the subjects' progression through the study. Patients were consecutively recruited from November 2010 to May 2011, in the Pediatric Gastroenterology Unit of the University of Messina, and randomly assigned to two groups (1:1, PHGG group or group A: 30 patients; placebo group or group B: 30 patients) to receive either a beverage of PHGG (Benefibra, Novartis Consumer Health) at a dosage of 5 g/d in 50 mL of fruit-juice (n = 30) or matching placebo (fruit-juice, n = 30) for 4 wk. For technical reasons of non-laboratory reproducibility of an inert and odorless powder, the placebo consisted of a fruit juice. As in other studies, PHGG was mixed with fruit juice during meals or between meals.

The manufacturer had no role in the conception, design or conduct of the study or in the analysis or interpretation of the data. Randomization was based on a computer-generated list. Supplementation was stopped after 4 wk and patients were followed up for a further 4 wk. GI symptoms were assessed with the "Birmingham IBS Symptom Questionnaire", "Wong Baker Faces Pain Rating Score" and "Bristol Stool Scale". The Birmingham IBS symptoms score consists of 11 questions based

Table 1 Baseline demographic and clinical data

	PHGG group A	Placebo group B	*P* value
n	30	30	
Age (yr)	12.3 ± 2.0	13.1 ± 1.5	0.16
Sex (male/female)	12/18	11/19	0.88
Self-reported pain	3.7 ± 1.2	3.5 ± 1.5	0.15
c-IBS	21/30 (70%)	19/30 (63%)	0.75
d-IBS	9/30 (30%)	11/30 (37%)	0.64

Values are mean ± SD or *n* (%). PHGG: Partially hydrolyzed guar gum; IBS: Irritable bowel syndrome.

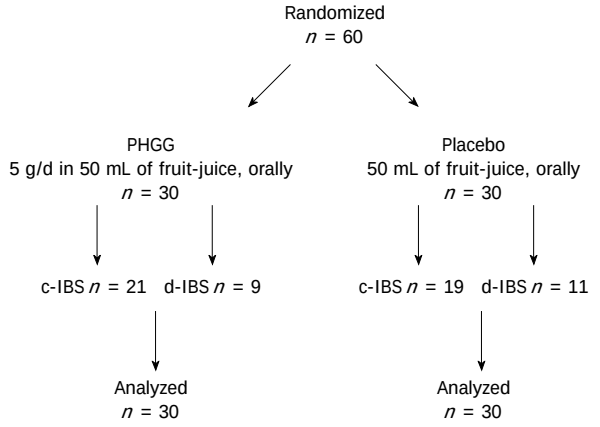

Figure 1 Flow diagram of the progress through the study. PHGG: Partially hydrolyzed guar gum; IBS: Irritable bowel syndrome.

on the frequency of IBS related symptoms. Each question had a standard response scale with symptoms all being measured on a 6-point Likert scale ranging from 0 = none of the time, to 5 = all of the time (Table 2). Wong-Baker Faces Pain Rating Score was used to evaluate CAP severity with a variable score from 0 = no hurt, to 5 = hurts worst. The Bristol Stool Scale classifies the form and consistency of stools into 7 categories (from separate hard lump to entirely liquid stools).

All patients were assessed clinically at 2, 4, and 8 wk (T1, T2, T3) by means of a physical examination and the scoring systems from baseline (Table 3). At T2, compliance with treatment (worse, unchanged, better) was also assessed. Adverse events or any use of other drugs were recorded. Primary outcome was reduction in the frequency and intensity of clinical symptoms and correlation with the improvement of character of stool. Secondary outcome was the evaluation of compliance and safety of PHGG in children.

Statistical analysis

Data are given as mean ± SD. Differences between groups were evaluated by the Kruskall-Wallis one-way analysis of variance (ANOVA). Nominal variables were analyzed with Pearson's chi-square test and Fisher's exact test when, in a 2 × 2 table, one cell had an expected frequency ⩽ 5. Differences within groups during the treatment period and follow-up were evaluated by the Wilcoxon signed-rank test. The statistical level of significance was set at the 5% level ($P < 0.05$). The system utilized was IBM SPSS Statistics Processor.

Table 2 Modified by Birmingham Score Questionnaire[36]

Constipation	Diarrhoea	Pain
Hard bowel motions	Loose, mushy or watery bowel motions	Discomfort or pain
Straining	Diarrhoea	Discomfort or pain after eating
Constipation	Leaked or soiled	Sleep problem
	Urgency	
	Mucus or slime	

Each question had a standard response scale with symptoms all being measured on a 6-point Likert Scale ranging from 0 = none of the time to 5 = all of the time.

RESULTS

The results of the study were assessed considering some main variables, such as improving frequency and intensity of the symptoms and modifications of the bowel habit.

Overall rating of frequency symptoms

At the enrolment visit (T0), mean score evaluation of principal IBS related symptoms (Birmingham Score) confirmed that symptoms were present almost every day, together with a strong functional disability in both groups. Overall, 15 of the 60 (24%) participants with IBS reported treatment success. Those in the PHGG group were more likely to have treatment success than those in the control group (43% *vs* 5%, $P = 0.025$). Responders with significant reduction of Birmingham IBS score (median 0 ± 1 *vs* 4 ± 1, $P = 0.025$) was shown in the PHGG group *vs* placebo at both 4 wk and 8 wk (Table 3). The total score and the three subscale scores for constipation, diarrhoea and pain symptoms of the Birmingham score were significantly improved at the 4 and 8 wk evaluations compared to the baseline in the PHGG group. The supplementation response was comparable both in IBS-d and IBS-c subgroups. In group B, no significant difference was found in comparisons at any evaluation time point for any subscale score.

Bowel habits

At baseline all patients were shown a wide range of alterations in bowel movements, evaluated with Bristol Stool Scale, without any difference in the two treatment groups. Effects of PHGG supplementation (5 g/d) for 4 wk on fecal output in IBS-d and IBS-c subsets *vs* placebo were also evaluated. In group A, there was a tendency toward normalization of bowel movements, which is highlighted by the progressive normalization of Bristol Stool Scale at type 3 or 4 (Table 3). In particular, 16 (26.6%) of 60 patients had normalized bowel habits: in the PHGG group the prevalence of improvement was 40% (12 patients), while it was 13.3% (4 patients) in the placebo group ($P = 0.025$). This result remained constant during the follow-up 4 wk. There was no difference in the prevalence of

Table 3 Outcome measures at baseline (T0), at 4 wk of supplementation (T2) and after 8 wk (mean ± SD)

	Group A PHGG 5g/d (n = 30)			Group B Placebo (n = 30)		
	Baseline	4 wk (T2)	8 wk (T3)	Baseline	4 wk (T2)	8 wk (T3)
Birmingham Score[a]	28.5 ± 7.16	24.3 ± 6.02	23.0 ± 6.15	29.5 ± 6.94	28.4 ± 8.39	28.7 ± 7.54
Bristol Stool Score[a]						
IBS-c	1.00 ± 1.02	2.02 ± 1.50	2.32 ± 1.50	1.16 ± 0.89	1.76 ± 1.04	1.65 ± 1.08
IBS-d	5.02 ± 0.63	4.01 ± 0.16	4.07 ± 0.12	5.54 ± 0.32	4.86 ± 0.96	4.89 ± 0.73
Wong-Baker Score[a]	2.15 ± 0.14	1.86 ± 0.14	1.63 ± 0.16	2.16 ± 0.17	2.04 ± 0.17	2.05 ± 0.19

[a]$P < 0.05$ *vs* placebo (Wilcoxon 2-sample test). PHGG: Partially hydrolyzed guar gum; IBS: Irritable bowel syndrome.

improvement in two bowel habit subsets ($P > 0.05$).

Intensity of the abdominal pain

There was no difference in pain intensity reported at baseline between the groups as Wong-Baker Face Pain Rating Score. During the course of study, there was a decrease in the intensity of pain in the group of children given PHGG, which was not seen in the placebo-supplemented group (Table 3). However, this result was not statistically significant ($P > 0.05$), compared with baseline at wk 4 and 8. Improvement of clinical symptoms in group A was correlated with a change of bowel habit and persisted 4 wk (T8) after cessation of PHGG supplementation. The clinical response was comparable both in IBS-d and IBS-c subgroups (Table 3). Analysis of the data confirmed optimal compliance and safety of PHGG dietary supplementation.

DISCUSSION

CAP is common in children and adolescents. In most children, CAP is functional without objective evidence of an underlying organic disorder. Children with CAP are more likely than children without CAP to have headache, joint pain, anorexia, vomiting, nausea and altered bowel habit assignable to IBS[21]. Physicians must decide whether to order diagnostic tests or use conservative management. The presence of alarm symptoms or signs suggests higher pretest probability and prevalence of organic disease and may justify the performance of diagnostic tests. CAP can cause long absences from school and markedly worsens quality of life of the children and parents[22,23].

In a recent American study, the diagnostic evaluation of CAP in a tertiary center in United States was found to cost approximately $6000 per patient[24]. The first treatment step is an age-appropriate assessment through the reassurance of the child and family on the absence of organic causes, but this does not mean that abdominal pain is not a real problem. Cognitive behavioral therapy, however, is an effective form of alternative treatment[25,26].

A thorough review of literature, with a focus on RCTs, revealed a paucity of studies examining effectiveness of pharmacologic and dietary interventions. Definitive statements concerning therapeutic efficacy are quite limited. Huertas-Ceballos *et al*[15], in a meta-analysis, failed to reveal any therapeutic benefit from a low-lactose or high-fiber diet for children with CAP. Therapeutic trials in adults with CAP associated with IBS symptoms have revealed a high rate of the placebo-response, confirming that non-pharmacological therapies alone are often adequate for many patients. PHGG is a soluble fiber with important properties, such as non-viscous texture, normal fermentation, non gelling, high hydrophilic potential and no interference with micronutrient absorption[27]. There is clear evidence that fiber decreases whole gut transit time, accelerates oral-to-anal transit, and decreases intracolonic pressure reducing abdominal pain. Fiber may represent a mainstay in the FAP and IBS therapeutic algorithm. Results of fiber supplementation in the adult population in patients with FAP and IBS has produced contrasting results, and the main reason for the variation is correlated with different types of fiber used[28,29]. The main distinction between soluble and insoluble fiber is essential as only soluble fiber such as PHGG dissolves in water and is widely metabolized in the large bowel, thus producing short-chain fatty acids, leading to selective stimulation of microbial growth[30,31]. PHGG may also act as prebiotic, thus modulating intestinal microbiota. Weaver *et al*[32], in experimental studies in rats, demonstrated that PHGG administration was accompanied by a rise in butyrate concentrations of colonocytes. Tuohy *et al*[33] showed that PHGG supplementation in healthy volunteers caused selective increase in the percentage of *Bifidobacteria* and *Lactobacilli* with beneficial modulation of microbiota that has been reported to ameliorate IBS symptoms, with a decrease in pain and flatulence[34].

Bijkerk *et al*[35] observed in an adult population that, although general fiber supplementation globally alleviates IBS symptoms, the beneficial effect is mainly associated with the use of soluble fiber rather than insoluble fiber. This study demonstrated that soluble fiber is effective in decreasing global IBS symptoms[36] but was no better than a placebo. Some of these above mentioned studies on the use of fiber in adult populations were biased as they confirmed that the placebo response in IBS patients ranged from 20%-50%. In our study, the placebo response was much lower than expected.

In 2012, a systematic review identified 3 RCTs evalu-

ating fiber supplementation in children with FGIDs. Patients were supplemented with different dietary fiber types for 4-6 wk[57]. Among these, the Feldman[20] study, a randomized, double-blind, placebo-controlled trial, is the only study in children with CAP (26 for group) recruited from primary care practices and supplemented with soluble fibers. Improvement of symptoms in treated patients with fiber not was significant *vs* the placebo-group. In patients with IBS symptoms with modification of the bowel habit, water-soluble fibers, such as PHGG, decrease symptoms also with a prebiotic effect, beneficial modification of the intestinal microflora and selective increase of *Lactobacilli* and *Bifidobacteria*[38]. PHGG was therefore tolerated and preferred by patients, indicating higher success of soluble fiber than bran or insoluble fiber. The present findings confirm the beneficial effects of PHGG at 5 g/d and in the short term (4 wk). Our study can be considered the first prospective, randomized, controlled, single-blind, clinical trial conducted with this particular fiber supplementation (PHGG) in pediatric CAP and IBS. Some limitations should caution against generalizing from the results of this study, such as the classification at baseline of CAP according to severity of symptoms (mild, moderate and severe) and lack of knowledge of dietary habits in patients enrolled. Given the good results obtained for the first time, it is important to confirm these preliminary data on a greater number of patients and also to consider the active role of liquid fiber in improvement of symptoms. The efficacy of this approach has proven how dietary management is more effective than pharmacological therapy in children with CAP and IBS.

In summary, fiber supplementation can be considered an important option in pediatric CAP and IBS. Water-soluble fiber, such as PHGG, is preferable to insoluble fiber. Moreover, initial studies have shown that fiber may act as a prebiotic, thus increasing the therapeutic benefits. Further placebo-controlled studies are needed to evaluate whether PHGG can also be seen as a maintenance therapy of CAP.

COMMENTS

Background

Functional bowel disorders, such as chronic abdominal pain (CAP), are frequent in children and similar to adult irritable bowel syndrome (IBS). Some children with CAP develop substantial disability and limitations in physical and psychosocial functions. There is little evidence of the efficacy of conventional medical treatment while there is a moderate evidence for the efficacy of complementary therapy (diet, fibers, low-lactose intake) in the adult population. Water-soluble fibers, such as oats, barley and gums in psyllium, can be safe in IBS symptoms.

Research frontiers

Water-soluble fibers are known for their ability to modify bowel patterns, accelerate oral-to-anal transit, decrease intracolonic pressure and alleviate pain. Functional abdominal disorders, such as abdominal pain and IBS, are frequent also in pediatric populations and should stimulate the trend to conservative therapy.

Innovations and breakthroughs

To date, there has been a limited number of studies regarding specific optional treatment in CAP and IBS. This is the first study in a pediatric population that showed a clinically significant improvement of the symptoms in pediatric functional gastrointestinal disease with dietary manipulation. The small sample size and a low placebo effect may indicate a requirement for request powered and well designed randomized controlled trials on the clinical effectiveness and safety of dietary treatment.

Applications

The findings in this study indicate that fiber supplementation can be considered an important therapeutic option in pediatric IBS.

Peer review

It is very well written and the topic is very interesting for the readers. This is an important topic for gastroenterologists, clinicians, surgeons, Critical Care doctors and nutritionists.

Abstract

AIM: To examine whether the administration of atorvastatin and rosuvastatin would prevent experimentally-induced hepatic cirrhosis in rats.

METHODS: Liver cirrhosis was induced by injections of thioacetamide (TAA). Rats were treated concurrently with TAA alone or TAA and either atorvastatin (1,10 and 20 mg/kg) or rosuvastatin (1, 2.5, 5, 10 and 20 mg/kg) given daily by nasogastric gavage.

RESULTS: Liver fibrosis and hepatic hydroxyproline content, in the TAA-treated group was significantly higher than those of the controls [11.5 ± 3.2 *vs* 2.6 ± 0.6 mg/g protein (P = 0.02)]. There were no differences in serum aminotransferase levels in the TAA controls compared to all the groups treated concomitantly by statins. Both statins used in our study did not prevent liver fibrosis or reduce portal hypertension, and had no effect on hepatic oxidative stress. Accordingly, the hepatic level of malondialdehyde was not lower in those groups treated by TAA + statins compared to TAA only. *In vitro* studies, using the BrdU method have shown that atorvastatin had no effect of hepatic stellate cells proliferation. Nevertheless, statin treatment was not associated with worsening of liver damage, portal hypertension or survival rate.

CONCLUSION: Atorvastatin or rosuvastatin did not inhibit TAA-induced liver cirrhosis or oxidative stress in rats. Whether statins may have therapeutic applications in hepatic fibrosis due to other etiologies deserve further investigation.

Shirin H, Sharvit E, Aeed H, Gavish D, Bruck R. Atorvastatin and rosuvastatin do not prevent thioacetamide induced liver cirrhosis in rats. *World J Gastroenterol* 2013; 19(2): 241-248 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/241.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.241

INTRODUCTION

Liver cirrhosis is one of the leading causes of morbidity and mortality worldwide. Hepatic stellate cells (HSC) play a major role in the pathogenesis of hepatic fibrosis[1]. Injury to hepatocytes results in generation of lipid peroxides, which may have a direct stimulatory effect on matrix production by activated HSC[2]. It has been suggested that aldehyde-protein adducts, including products of lipid peroxidation, modulate collagen gene expression in human fibroblasts[3,4] and may be a link between tissue injury and hepatic fibrosis[2,5]. Several

studies demonstrated that activation of HSC in culture is provoked by generation of free radicals and is blocked by anti-oxidants. This activation may involve the transcription factor c-myb and nuclear factor kappa B (NF-κB)[6,7]. Accordingly, antioxidants have been suggested as therapeutic modalities in experimental models[8-10], and in patients with chronic liver injury[11].

3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are used extensively to reduce serum cholesterol in an effort to reduce atherosclerotic cardiovascular morbidity and mortality. In addition to their cholesterol-lowering effect, statins demonstrate other biological effects (pleiotropic effects) that some of them may lead to clinical benefits. Those include anti-inflammatory[12] and antioxidant effects[13], inhibition of PDGF-stimulated proliferation and upregulation of tumor growth factor (TGF)-β signaling in murine mesangial cells and cultured heart cells[14-16].

Over the past decade the potential effect of statins as anti-fibrotic agents has received increasing attention. The rationale for the anti fibrotic efficacy is based on the ability of statin compounds to: (1) decrease the growth of human Ito cells in vitro, independently of their effect on cholesterol synthesis[17]; (2) inhibit the proliferation rate of HSC and reduction of the collagen protein steady state levels by both simvastatin and lovastatin[18]; (3) inhibit steatosis, hepatic fibrosis and carcinogenesis in a rat model of non-alcoholic steatohepatitis (NASH)[19]; and (4) enhance hepatic nitric oxide production and decrease hepatic vascular resistance in patients with cirrhosis and portal hypertension[20]. In addition to inhibiting stellate cell activation, the anti-oxidative activity and the attenuation of inflammation by specific statin derivatives may also contribute to the inhibition of fibrosis. Despite the existing data suggesting that statin derivatives can inhibit fibrosis by various mechanisms, treatment with simvastatin or pravastatin did not decrease fibrosis-induced by bile duct ligation (BDL) or carbon tetrachloride (CCl_4) in rats[21,22]. However, one recent study showed that very early atorvastatin treatment inhibits HSC activation and fibrosis in the BDL model *in vivo*[23].

To further elucidate the anti-fibrotic activity of statins in the liver, we examined the effects of both atorvastatin and rosuvastatin in a well characterized model of chronic thioacetamide (TAA)-induced administration in which cirrhosis is mainly produced *via* the formation of reactive oxygen species. TAA undergoes an extensive metabolism to acetamide shortly after administration, and to the hepatotoxic reactive metabolite thioacetamide-S-oxide by the mixed function oxidase system[24-26]. We hypothesized that inhibition of HSC activity in addition to the anti inflammatory and anti oxidative effects induced by statins may prevent the hepatic damage induced by TAA in rats.

Our results indicate that both atorvastatin and rosuvastatin did not diminish neither oxidative stress nor the development of TAA-induced cirrhosis in rats, and also had no effect on the proliferation of cultured HSC.

MATERIALS AND METHODS

Materials and animals

TAA, atorvastatin and rosuvastatin was purchased from Sigma (Sigma Chemical Co., St. Louis, MO). Male Wistar rats (250-300 g), obtained from Tel-Aviv University Animal Breeding Center, were kept in the animal breeding house of the E. Wolfson Medical Center and fed a Purina chow *ad libitum*. Animals were kept with a 12-h light-dark cycle at constant temperature and humidity and the rats had free access to tap water during the study period. Use of animals was in accordance with the National Institutes of Health Policy on the care and use of laboratory animals and was approved by the Animal Use and Care Committee of the E. Wolfson Medical Center.

Induction of liver cirrhosis

For induction of liver cirrhosis, rats were given intraperitoneal injections of thioacetamide, 200 mg/kg, twice a week for 12 wk, as previously described[27]. Control rats were treated with intraperitoneal injections of NaCl 0.9%.

Analysis of liver histopathology

The rats were sacrificed at the completion of the treatment protocols, their livers were removed, and midsections of the left lobes of the livers were processed for light microscopy. This processing consisted of fixing the specimens in a 5% neutral formol solution, embedding the specimens in paraffin, making sections of 5 μm thickness, and staining the sections with hematoxylin and eosin and Masson Trichrome. The tissue slices were scanned and scored blindly by two expert pathologists. The degree of fibrosis was expressed as the mean of 10 different fields in each slide, which had been classified on a scale of 0-4 according to Batts and Ludwig[28].

Measurement of hepatic hydroxyproline levels

Quantitative determination of hepatic hydroxyproline content was performed as previously described[29].

Measurement of hepatic malondialdehyde

For the determination of the hepatic content of malondialdehyde, liver tissue (5 g) was cut into small pieces using a razor blade, and homogenized after dilution in H_2O 1:10 w/v. Liver homogenate was centrifuged in 900 g for 5 min, and then the supernatant was collected and centrifuged in 20 000 rpm in Sorvall for 30 min using plastic tubes. The clear supernatant was obtained and malondialdehyde was measured and expressed as nmole/g wet tissue using the thiobarbituric acid method[30]. Briefly, to 1 mL of 10% liver homogenate with 1.15% KCl were added 2 mL of fresh solution 15% w/v TCA, 0.375% w/v thiobarbituric acid, 0.25 mL/L HCl. The mixture was heated at 95 ℃ for 15 min. The solution was cooled to room temperature using tap water and centrifuged at 300 rpm for 10 min. Absorption of the pink supernatant was determined spectrophoto-

metrically at 532 nm.

Effect of atorvastatin on proliferation of primary hepatic stellate cells

Hepatic stellate cells were isolated from male rat using sequential pronase-collagenase digestion followed by Nycodenz (Sigma-Aldrich, Inc., St. Louis, MO, United States) density gradient centrifugation essentially as described previously with minor modifications[1]. Briefly, the liver of male rat Wistar (300-400 g) was minced with scalpels and incubated with 100 mL of freshly prepared and filtered-GBSS with 65 mg pronase (Roche Molecular Biochemicals, Indianapolis, IN, United States), 50 mg collagenase (Worthington Biochemical Corporationv, Lakewood, NJ, United States), and 0.5mL 2.7%$CaCl_2$ for 15 min at 37 ℃ with 200 rpm shaking. Then 50 mL of freshly prepared and filtered-GBSS was added containing 12.5 mg pronase, 12.5 mg collagenase, 20 μg/mL DNAse I (Sigma-Aldrich, Inc., St. Louis, MO, United States) and 0.25 mL 2.7% $CaCl_2$ for 30 min at 37 ℃ with 200 rpm shaking. The digested tissue was filtered through a sterile 150-μm metal mesh, and the cells were centrifuged at for 2000 rpm for 7 min. The digested liver hepatic stellate cells were isolated on a 17.5% Nycodenz gradient centrifuged at 2700 rpm for 20 min. A stellate cell-enriched fraction was present in the upper layer. Cells were washed twice by centrifugation (1200 rpm, 4 ℃, 5 min) in DMEM with 10% fetal calf serum (FCS), 100 μg/mL penicillin and 100 μg/mL of streptomycin.

Reagents

Atorvastatin (Sigma-Aldrich, Inc., St. Louis, MO, United States) stock solution was dissolved in DDW to a concentration of 5×10^{-4} mol/L. PDGF-BB (Peprotech Inc. NJ, United States) was dissolved in DDW to a concentration of 1μg/mL. All the reagents were aliquot and stored in -20 ℃ until use.

Proliferation assays

The proliferation of HSC was examined by BrdU method (Exalpha biological, Inc. Watertown, MA, United States). Primary HSC were cultured for 14 d, after which they were trypsinized and plated at a density of 20 000 cell/well in 96 well plates in DMEM containing 10% FCS. The cells were incubated for 24 h, and then they were serum starved in DMEM + 0.5% FCS overnight. At the following day, the various stimuli were added in medium containing 0.5% FCS. HSC were exposed to either 30 ng/mL of PDGF (Peprotech, Inc. NJ, United States), and different concentration of Atorvastatin (5×10^{-8} mol/L, 10^{-7} mol/L, 5×10^{-7} mol/L) alone, or combination of the two. After 24 h the cells were tested for proliferation according to the manufacture instruction.

Western blotting

HSCs were plated on 100 mm plates at a density of 2×10^6 cells/plate. After 24 h, the medium was changed to starvation medium (DMEM + 0.5% FCS) overnight. The following day, cells were incubated for 24 h with the different treatments according to which experiments were performed. Total proteins were extracted by incubating the cells for 30 min on ice in RIPA buffer containing a 1:100 dilution of a protease inhibitor cocktail (Sigma-Aldrich, Inc., St. Louis, MO, United States). After 20 min centrifugation at 14 000 rpm at 4 ℃, extracts were normalized to total protein content, determined using the BCA Reagent (Sigma-Aldrich, Inc., St. Louis, MO, United States). Equal amounts of total protein-were separated in 4%-12% bis-tris (BT) gels (NuPAGE, Gibco-BRL Life Technologies, Grand Island, NY), blotted onto Hybond C extra membranes, blocked overnight in 5% milk, and incubated with antibodies against α smooth muscle actin (αSMA), glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Santa Cruz Biotechnology, Santa Cruz, CA, United States) and then incubated with horseradish peroxidase-conjugated secondary antibody. Afterwards, signals were detected by chemiluminescent. Expression of proteins was normalized to the expression of GAPDH.

Experimental design (in vivo experiments)

Control groups: (1) normal controls: injections of NaCl 0.9%; and (2) cirrhotic controls: TAA (200 mg/kg *ip*, twice weekly) injections for 12 wk.

Atorvastatin groups: (1) TAA + Atorvastatin 1 mg/kg daily; (2) TAA + Atorvastatin 10 mg/kg daily; and (3) TAA+ Atorvastatin 20 mg/kg daily.

Rosuvastatin groups: (1) TAA + Rosuvastatin 2.5 mg/kg daily; (2) TAA + Rosuvastatin 5 mg/kg daily; (3) TAA + Rosuvastatin 10 mg/kg daily; and (4) TAA + Rosuvastatin 20 mg/kg daily.

Each subgroup included 6-7 rats. The statins were given *po*, started concurrently with TAA and continued during the study. When the treatments were completed after 12 wk the rats were sacrificed, their livers were removed and the weights of their spleens measured.

Statistical analysis

The data are presented as median (range). The significance of differences among different groups was determined by a student's *t*-test.

RESULTS

Induction of liver cirrhosis by thioacetamide

Intraperitoneal administration of TAA for 12 wk, resulted in a uniform coarse granulation of the surface of the rats' liver. Microscopic analysis revealed liver cirrhosis, characterized by mixed-sized fibrotic nodules in these TAA-treated rats. Neither atorvastatin nor rosuvastatin had any effect on liver enzymes when given alone or in addition to TAA.

Table 1 Effects of rosuvastatin and atorvastatin treatment on oxidative stress and liver fibrosis in thioacethamide-treated rats

n = 7, in the groups that received thioacethamide (TAA), n = 4 in the control, rosuvastatin only treated groups and atorvastatin only treated groups. TAA, 200 mg/kg *ip* twice weekly for 12 wk. Rosuvastatin and atorvastatin had given daily by nasogastric gavage. Ros: Rosuvastatin; ALT:Alanine transaminase; MDA: Malondialdehyde.

Inhibition of thioacetamide-induced liver cirrhosis by statins

Compared to the rats which received TAA only, neither atorvastatin nor rosuvastatin had protective effect on the histopathologic score after 12 wk and TAA-induced liver cirrhosis was not inhibited by all the doses that were examined. Hepatic fibrosis was also quantitated by the measurement of hepatic hydroxyproline levels. The mean hydroxyproline levels of the TAA-treated group were similar to those of the TAA plus atorvastatin or rosuvastatin at all doses used.

Spleen weights

An indirect measure of portal hypertension was obtained by measuring the weights of the rats' spleens at the end of the experiment. Characteristic hemodynamic changes have previously been shown after 3 mo of TAA administration, i.e., upon TAA-induced liver cirrhosis[27]. These changes include portal hypertension and hyperdynamic circulation which are accompanied with a significant increase in spleen weight. After 12 wk, the mean spleen weight of rats receiving TAA was about 30% higher than those receiving injections of 0.9% NaCl or statins only. The mean spleen weight of rats that received statins in addition to TAA was not lower than that of TAA alone (Table 1).

Hepatic levels of malondialdehyde and lipid peroxides

The hepatic levels of malondialdehyde measured after 12 wk, were not significantly different in the rats treated with TAA and statins compared to TAA only. Table 1 summarize the rosuvastatin and atorvastatin treatment effects on oxidative stress and liver fibrosis in TAA-treated rats [median (range)], n = 6-7.

Effect of Atorvastatin on hepatic stellate cells proliferation and smooth muscle actin expression

Atorvastatin in different concentrations had no effect on HSC proliferation as examined by the BrdU method (Figure 1) and no effect on the expression of smooth muscle actin determined by western blot analysis (Figure 2).

DISCUSSION

Our major finding in the present study is that atorvastatin and rosuvastatin do not have a therapeutic value as a potential anti-oxidant or anti-fibrotic agents targeting increased oxidative stress or liver fibrosis induced by TAA in rats.

There are various experimental observations regarding the direct anti-fibrotic activity of the statins by the inhibition of stellate cell proliferation; lovastatin inhibits pancreatic stellate cell activation and alpha-smooth muscle actin expression[31] and both simvastatin and lovastatin interferes with HSC activation in vitro[20,21]. Fluvastatin reduces renal fibroblast proliferation and collagen type Ⅲ production[32] and suppresses oxidative stress and kidney fibrosis after ureteral obstruction[33]. It is also possible that the anti-fibrotic effects of statins are mediated through mechanisms that stimulate fibroblast apoptosis *in vitro* and *in vivo* as it was shown in lung and renal fibroblasts[32,34]. Alternatively, the anti-fibrotic effects of statins may be mediated through their newly recognized anti inflammatory[12] and antioxidant mechanisms[35-37]. These include the inhibition of myeloperoxidase derived and nitric oxide derived oxidants[36],

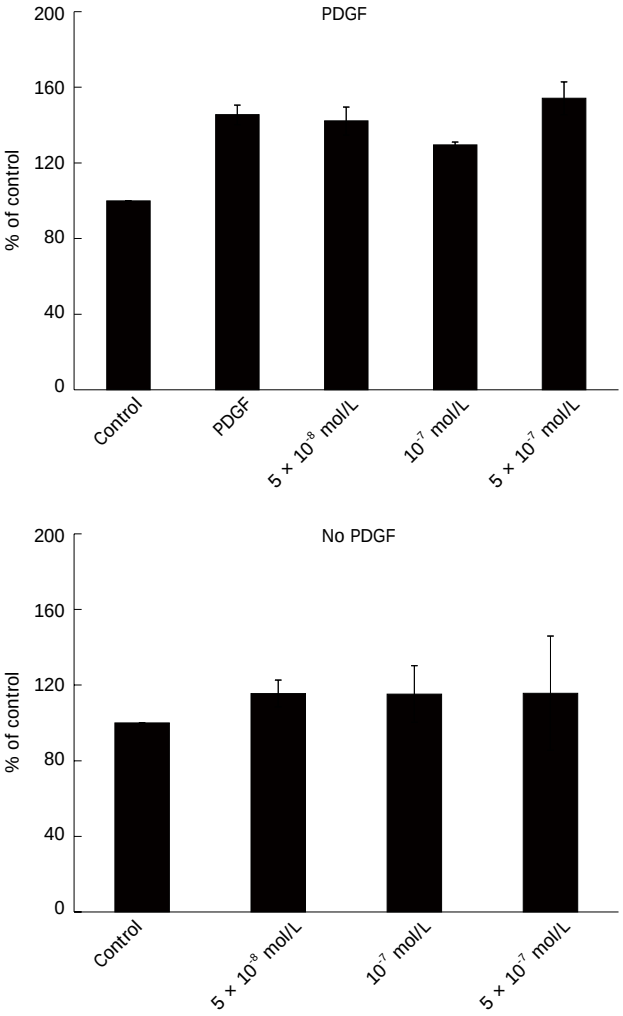

Figure 1 Effect of atorvastatin on hepatic stellate cells proliferation. PDGF: Platelet derived growth factor.

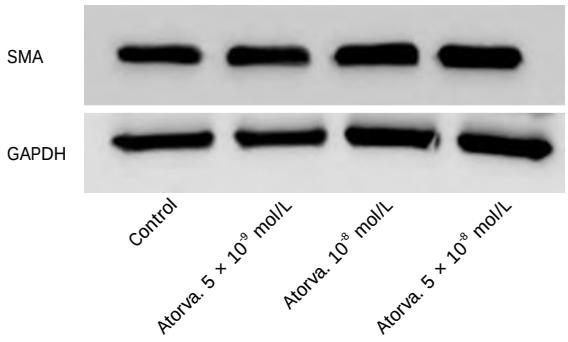

Figure 2 Atorvastatin effect on the expression of smooth muscle actin. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; SMA: Smooth muscle actin.

S-nitrosylation and activation of thioredoxin in endothelial cells[37], decreased expression of essential NAD(P)H oxidase subunits and upregulation of catalase expression in vascular smooth muscle cells[35]. Statins also induce the expression of a protein with antioxidant and anti-inflammatory functions, heme oxygenase-1 (HO-1), *in vitro* and *in vivo*[33,38]. However, this effect is tissue specific demonstrating significant increase in liver HO-1 with simvastatin and lovastatin but not atorvastatin and rosuvastatin. The involvement of hydroxyl radicals and oxidative stress in TAA induced cirrhosis[39], the anti-oxidative effects of different statins, including atorvastatin, and the antifibrotic effect of atorvastatin in a rat model if BDL as was reported recently by Trebicka *et al*[23], provided a good rationale for the assumption that statins may reduce or prevent fibrogenesis in this specific animal model.

The explanation for the unexpected failure of atorvastatin and rosuvastatin to inhibit fibrosis in this model of cirrhosis are not clear. Two studies demonstrated anti fibrogenic effects of atorvastatin in a CCl_4 induced fibrosis[40,41]. Gardner *et al*[41] have shown that atorvastatin exhibited statistically significant, although modest, suppression of CCl_4-induced fibrogenesis after 3 wk of treatment. This was shown only using a novel technique for measuring hepatic collagen synthesis *in vivo* through metabolic labeling with heavy water (^2H_2O). Histopathology of the same tissues revealed no significant differences in fibrosis scores among groups that received co-treatment with atorvastatin, emphasizing the importance of the fibrosis measuring method.

Nevertheless the evidence that fibrosis was not inhibited by atorvastatin and with a more potent cholesterol metabolism pathway inhibitor, rosuvastatin, suggests that this effect is not selective and occurs independently of their HMG-CoA inhibition. Since we used much higher doses than those used clinically (up to 20 mg/kg) it does not seem that we are dealing with under dose treatment. Appropriate timing for the administration of the statins may also be critical. Later therapy in the BDL model, for example, lacked significant effects on fibrosis with no change in hepatic inflammation[23]. The statin treatment in our study began in parallel to the administration of TAA. Although, it is possible that pretreatment by statins would be more effective, the fact that there was no improvement, neither in MDA levels nor in fibrosis after three months, do not support this hypothesis. Another possibility to explain these negative results might be the selection of the wrong statins. Indeed, the two statins that inhibited HSC proliferation in vitro were lovastatin and simvastatin[18] and atorvastatin *in vivo*. In addition pitavastatin was the one that inhibited hepatic fibrosis in a choline-deficient L-amino acid defined diet liver fibrosis[19]. However, despite these effects, even the latter mechanisms were not efficient to prevent or inhibit liver fibrosis, as it was demonstrated with simvastatin or pravastatin in two different animal models of cirrhosis (bile duct ligation and CCl_4), in rats[21,22]. Moreover, antioxidant therapy in human clinical trials also lack or have minimal effect in chronic liver disease[42,43]. Finally, statin-induced protein kinase C (PKC) activation in activated HSCs may interrupt statin-induced HSC apoptosis, thereby reducing its antifibrotic efficacy. Indeed Yang *et al*[44] recently demonstrated that simultaneous treatment with pravastatin and PKC inhibitor may

synergistically enhance antifibrotic efficacy in hepatic fibrosis induced by intraperitoneal injection of carbon tetrachloride or thioacetamide in mice. Finally, we also have to consider the possibility that the negative results may be due to the small numbers (type 2 error).

To further explore the effect of statins on liver fibrosis we examined the effect of several atorvastain concentrations on the proliferation of primary HSC. We observed that atorvastatin had no inhibitory effect on HSC proliferation either in the presence or in the absence of PDGF (Figure 1). This finding is in discordance with several previous studies that demonstrated decreased HSC activation by statins[17,18]. Moreover, using western blot analysis we found that atorvastatin (5×10^{-8}-10^{-9} mol/L) had no effect on the expression of α smooth muscle actin further supporting the lack of effect shown in the proliferation assay.

It is of interest that treatment with atorvastatin or rosuvastatin in all doses did not reduce spleen weights, a parameter of portal hypertension. This is in contrast to the recently described therapeutic effects of simvastatin in patients with cirrhosis and portal hypertension. In patients with cirrhosis and portal hypertension simvastatin enhanced hepatic nitric oxide production and decreased hepatic resistance[20]. Similarly, in cirrhotic rats, induced by BDL, atorvastatin has been shown to lower intrahepatic resistance and to decrease portal hypertension[45].

Finally, oral atorvastatin and rosuvastatin were both well tolerated with no side effects, toxicity or mortality. Furthermore, transaminase levels, hepatic MDA and hydroxyproline and liver histopathology score did not aggravate. These data suggest that the use of atorvastatin and rosuvastatin is not associated with an increased risk of hepatoxicity in damaged liver.

In summary, our results show that atorvastatin and rosuvastatin have no effect on TAA-induced liver cirrhosis. Obviously further studies are required to evaluate whether statins may have therapeutic applications, in the development of hepatic fibrosis induced by other etiologies.

COMMENTS

Background

Liver cirrhosis is one of the leading causes of morbidity and mortality worldwide. Hepatic stellate cells (HSC) play a major role in the pathogenesis of hepatic fibrosis. Several studies demonstrated that activation of HSC in culture is provoked by generation of free radicals. Accordingly, antioxidants have been suggested as therapeutic modalities in experimental models, and in patients with chronic liver injury.

Research frontiers

Previous studies mainly focused on the potential effect of statins as anti-fibrotic agents. However, whether the anti-oxidative activity and the attenuation of inflammation by specific statin derivatives may also contribute to the inhibition of stellate cell activation and fibrosis remain unclear. The authors hypothesized that inhibition of HSC activity in addition to the anti inflammatory and anti oxidative effects induced by statins may prevent the hepatic damage induced by TAA in rats.

Innovations and breakthroughs

To further elucidate the anti-fibrotic activity of statins in the liver, the authors examined the effects of both atorvastatin and rosuvastatin in thioacetamide (TAA)-induced liver fibrosis in which cirrhosis is mainly produced *via* the formation of reactive oxygen species. The major finding was that both statins do not have a therapeutic value as a potential anti-oxidant or anti-fibrotic agents targeting increased oxidative stress or liver fibrosis induced by TAA.

Applications

The results show that atorvastatin and rosuvastatin have no effect on cirrhosis induced mainly by oxidative stress. Further studies are required to evaluate clarify the mechanism by which statins may have therapeutic applications, in hepatic fibrosis induced by other etiologies.

Terminology

3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are used extensively to reduce serum cholesterol in an effort to reduce atherosclerotic cardiovascular morbidity and mortality. In addition to their cholesterol-lowering effect, statins demonstrate also anti-inflammatory and antioxidant effects. TAA-induced cirrhosis is mainly produced *via* the formation of reactive oxygen species. TAA undergoes an extensive metabolism to acetamide shortly after administration, and to the hepatotoxic reactive metabolite thioacetamide-S-oxide by the mixed function oxidase system.

Peer review

Well written manuscript which presented that atorvastatin or rosuvastatin did not inhibit the formation of TAA-induced liver cirrhosis in rats. Further, no induction of oxidative stress or effect on HSC proliferation have been noted. The model is well presented, the experiments seems to be correct. Even if results are negative, and in partial or total contrast with previous studies, the study appears well conducted and the results discussed with honesty, and caution.

Abstract

AIM: To evaluate whether metabolic factors are related to distant recurrence of hepatocellular carcinoma (HCC) and survival after curative treatment.

METHODS: This retrospective study included 344 patients whose HCC was treated curatively by radiofrequency ablation (RFA) therapy. The mean age was 67.6 years and the mean observation period was 4.04 years. The etiological background of liver disease was hepatitis B virus infection in 30, hepatitis C virus infection in 278, excessive alcohol drinking in 9, and other in 27 patients. The Child-Pugh classification grade was A (n = 307) or B (n = 37). The number of HCC nodules was one in 260, two in 61, and three in 23 patients. For surveillance of HCC recurrence after curative therapy with RFA, patients were radiologically evaluated every 3 mo. Factors associated with distant recurrence of HCC or survival were studied.

RESULTS: Inadequate maintenance of blood glucose in diabetic patients was associated with higher incidence of distant recurrence. The 1-, 2-, and 3-year recurrence rates were significantly higher in diabetic patients with inadequate maintenance of blood glucose compared with the others: 50.6% *vs* 26.8%, 83.5% *vs* 54.4%, and 93.8% *vs* 73.0%, respectively (P = 0.0001). Inadequate maintenance of blood glucose was an independent predictor of distant recurrence [adjusted relative risk 1.97 (95%CI, 1.33-2.91), (P = 0.0007)] after adjustment for other risk factors, such as number of HCC nodules [2.03 (95%CI, 1.51-2.73), P < 0.0001] and initial level of serum alpha fetoprotein (AFP) [1.43 (95%CI, 1.04-1.97), P = 0.028]. Obesity was not an independent predictor of recurrence. The incidence of distant recurrence did not differ between diabetic patients with adequate maintenance of blood glucose and non-diabetic patients. Among 232 patients who had HCC recurrence, 138 had a second recurrence. The 1-, 2-, and 3-year rates of second recurrence were significantly higher in diabetic patients with inadequate maintenance of blood glucose than in the others: 9.0% *vs* 5.9%, 53.1% *vs* 24.3%, and 69.6% *vs* 42.3%, respectively (P = 0.0021). Inadequate maintenance of blood glucose in diabetic patients [1.99 (95%CI, 1.23-3.22), P = 0.0049] and presence of multiple HCC nodules [1.53 (95%CI, 1.06-2.22), P = 0.024] were again significantly associated with second HCC recurrence. Inadequate maintenance of blood glucose in diabetic

patients was also a significant predictor of poor survival [2.77 (95%CI, 1.38-5.57), P = 0.0046] independent of excessive alcohol drinking [6.34 (95%CI, 1.35-29.7), P = 0.019], initial level of serum AFP [3.40 (95%CI, 1.88-6.18), P < 0.0001] and Child-Pugh classification grade B [2.24 (95%CI, 1.12-4.46), P = 0.022]. Comparing diabetic patients with inadequate maintenance of blood glucose *vs* the others, the 1-, 2-, and 3-year survival rates were significantly lower in diabetic patients with inadequate maintenance of blood glucose: 92% *vs* 99%, 85% *vs* 96%, and 70% *vs* 92%, respectively (P = 0.0003).

CONCLUSION: Inadequate maintenance of blood glucose in diabetic patients is a significant risk factor for recurrence of HCC and for poor survival after curative RFA therapy.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide[1] and its incidence has been increasing in many countries[2]. Surgical resection, liver transplantation, and local ablation therapy, such as radiofrequency ablation (RFA) therapy, have been considered as efficient curative therapies for HCC. RFA therapy is now widely performed in patients with small HCC[3] and a randomized controlled study demonstrated that the survival rates were similar in patients with small HCC receiving RFA or surgical resection[4]. A characteristic of HCC is its high rate of recurrence after curative resection or local ablation therapy, reaching approximately 80% within 5 years[5-7]. Identification of factors related to recurrence of HCC and therapeutic intervention targeting these factors may lead to prevention of frequent recurrence of HCC and improved survival.

Tumor factors, such as the number of HCC nodules and their size, are associated with the recurrence of HCC and survival prognosis[8-10]. Another factor that is associated with the recurrence of HCC and survival is the hepatic reserve function at the time of HCC therapy[8,10,11]. Hepatitis C virus (HCV) and hepatitis B virus (HBV) infection are the major causes responsible for 80% of HCC cases[2] and antiviral therapy targeting HCV[12,13] or HBV[14] has been shown to decrease HCC recurrence, and improve hepatic reserve function and survival. Non-alcoholic steatohepatitis (NASH) has also received attention as a cause of HCC[15]. Metabolic factors, such as obesity and diabetes, are closely linked to the etiology of NASH. These metabolic factors have also been identified as risk factors for several other types of cancer. Obesity is associated with increased mortality rates of several cancers[16,17] and diabetes is also reported as a risk factor for liver, pancreatic, renal, and colon cancers[18,19]. If these metabolic factors are related to the recurrence of HCC, therapeutic intervention targeting these factors may lead to prevention of frequent recurrence of HCC and improved survival. The impact of diabetes on the recurrence of HCC after treatment has been discussed, but with conflicting results[20-23].

In this study, factors contributing to the recurrence and prognosis of HCC after curative treatment were analyzed. We found that inadequate maintenance of blood glucose was related to the high rate of HCC recurrence and poor survival.

MATERIALS AND METHODS

Patients whose HCC was treated by RFA at the Musashino Red Cross Hospital were studied retrospectively for factors associated with recurrence of HCC and survival. The inclusion criteria were as follows: (1) HCC treated curatively with RFA at the Musashino Red Cross Hospital between 1999 and 2007; (2) maximum diameter of HCC nodule $\leqslant$ 3 cm; (3) number of HCC nodules $\leqslant$ 3; (4) no previous history of treatment for HCC; and (5) follow-up observation for at least 6 mo after RFA therapy. 344 patients met these criteria, including 140 women and 204 men, with a mean age of 67.6 years and mean observation time of 4.04 years. The clinical characteristics of the patients are summarized in Table 1. The etiological background of liver disease was HBV infection in 30, HCV infection in 278, excessive alcohol drinking (intake of ethanol $\geqslant$ 60 g/d for $\geqslant$ 5 years continuously) in 9, and non-B non-C non-alcoholic etiology in 27 patients. The Child-Pugh classification grade was either A (n = 307) or B (n = 37). The number of HCC nodules was one in 260, two in 61, and three in 23 patients. Thus, 260 patients had a single lesion, and 84 had multiple lesions. The maximum diameter of HCC nodules was 19.9 $\pm$ 0.3 mm.

Obesity was defined as a body mass index > 25 kg/m^2 according to the definition of the Japan Society for the Study of Obesity[24]. Blood glucose was measured monthly for 6 mo after HCC treatment and the average value was determined. Inadequate maintenance of blood glucose was defined as an average value of blood glucose $\geqslant$ 200 mg/dL. The level of hemoglobin A1c (HbA1c) was not used in the present study because the lifespan of erythrocytes is shortened due to hypersplenism in patients with chronic hepatitis or cirrhosis, leading to lower HbA1c levels relative to the blood glucose level[25]. Diagnosis of type 2 diabetes was made according to the

Table 1 Characteristics of patients undergoing curative radiofrequency ablation for hepatocellular carcinoma *n* (%)

Variable	Value
Sex (male/female)	204/140
Age(yr)	67.6 ± 8.4
Etiology of liver disease: HBV/HCV/NBNC	30/278/36
AST (IU/L)	84.0 ± 34.5
ALT (IU/L)	73.2 ± 36.5
GGT (IU/L)	82.9 ± 96.8
T-Chol (mg/dL)	157.8 ± 32.0
TG (mg/dL)	112.3 ± 55.7
Mean blood sugar (mg/dL)	139.3 ± 44.0
Diabetes mellitus	159 (48)
BMI > 25 kg/m^2	86 (25)
Maximum diameter of HCC nodule (mm)	19.9 ± 0.3
Number of HCC nodules: single/2 or 3	260/84
AFP (ng/mL)	214 ± 1025
Alcohol drinking > 60 g/d	9 (2.6)
Child-Pugh grade: A/B	307/37

HBV: Hepatitis B virus; HCV: Hepatitis C virus; NBNV: Neither HBV nor HCV; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: γ-glutamyltransferase; T-Chol: Total cholesterol; TG: Triglyceride; BMI: Body mass index; AFP: α-fetoprotein; HCC: Hepatocellular carcinoma.

American Diabetes Association criteria of a fasting blood glucose level ≥ 126 mg/dL (≥ 7.0 mmol/L) and/or HbA1c level ≥ 6.5[26]. After initial treatment of HCC by RFA, the ablated area was confirmed by contrast-enhanced computed tomography (CT) within one week. If the ablated area was not sufficient, then RFA therapy was repeated until the HCC nodule was completely ablated.

HCC surveillance and diagnosis of recurrence

Diagnosis of HCC was based on abdominal ultrasonography, contrast-enhanced CT, magnetic resonance imaging (MRI), or angiography. Classical HCC was diagnosed for tumors showing vascular enhancement with washout on at least two types of diagnostic imaging. Tumor biopsy was used to diagnose tumors with non-classical imaging findings.

For surveillance of HCC recurrence after curative therapy with RFA, patients were evaluated by abdominal ultrasonography, contrast-enhanced CT, or contrast-enhanced MRI every three months. Recurrence of HCC was diagnosed based on a new lesion detected by ultrasonography showing vascular enhancement with washout on CT or MRI. If the tumor was not hypervascular, a tumor biopsy was performed to confirm the diagnosis.

Statistical analysis

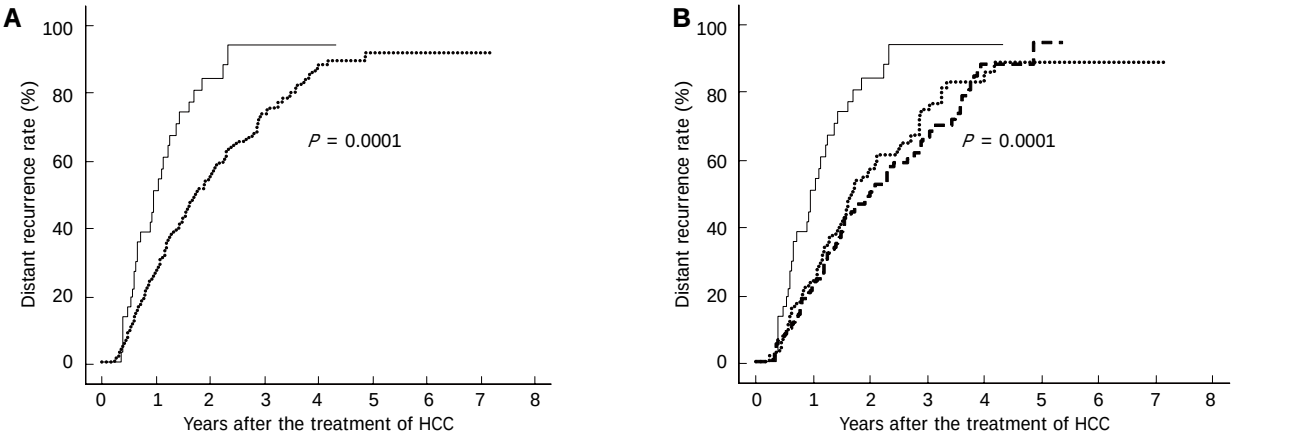
For analysis of survival and recurrence, the time of initial RFA treatment was defined as day zero. Survival rate and recurrence rate were analyzed by the Kaplan-Meier method and log rank test. Multivariate analysis was performed using a Cox proportional hazard model. Data were analyzed using StatView Version 5.0 (SAS Institute Inc, Cary, North Carolina, United States) and IBM-SPSS statistics version 18 (IBM SPSS Inc, Chicago, IL, United States). Statistical significance was set at $P < 0.05$.

RESULTS

Factors associated with HCC recurrence

Of the 344 patients whose HCC was curatively treated by RFA, 232 had HCC recurrence. The 1-, 2-, and 3-year recurrence rates were 29.3%, 57.5%, and 75.2%, respectively. On univariate analysis, inadequate maintenance of blood glucose, higher initial level of serum AFP and multiple HCC nodules were significantly associated with HCC recurrence. Obesity ($P = 0.06$) and diabetes ($P = 0.65$) were not significantly associated with HCC recurrence.

Thirty-seven patients had diabetes with inadequate maintenance of blood glucose, 122 patients had diabetes with adequate maintenance of blood glucose, and 185 patients did not have diabetes. The HCC recurrence rate was significantly higher in diabetic patients with inadequate maintenance of blood glucose than in the others ($P = 0.0001$) (Figure 1A).



Comparing patients with diabetes ($n = 159$) and patients who did not have diabetes ($n = 185$), there was no significant difference in the recurrence rate ($P = 0.65$). Upon comparison of the three groups, i.e., the diabetes with inadequate maintenance of blood glucose group, the diabetes with adequate maintenance of blood glucose group, and the non-diabetes group, the recurrence rate was significantly higher in the diabetes with inadequate maintenance of blood glucose group than in the other two groups ($P = 0.0001$) (Figure 1B). On the other hand, there was no significant difference in the HCC recurrence rate between the diabetes patients with adequate maintenance of blood glucose group and the non-diabetes group.

In terms of the number of HCC nodules, namely, single ($n = 260$) *vs* multiple ($n = 84$), the recurrence rate was significantly higher in patients with multiple HCC nodules ($P = 0.0001$). Within each subgroup of patients with single and multiple HCC nodules, diabetes with inadequate maintenance of blood glucose was significantly associated with recurrence of HCC (single, $P = 0.006$; multiple, $P = 0.025$) (Figure 2A, B). In terms of the initial level of serum AFP ≥100 ng/mL ($n = 70$) *vs* < 100 ng/mL ($n = 274$), the recurrence rate was significantly higher in patients with AFP ≥ 100 g/mL ($P = 0.018$). Within each subgroup of patients with AFP ≥ 100 ng/mL and < 100 ng/mL, diabetes with inadequate maintenance of blood glucose was associated with a higher rate of recurrence (AFP ≥ 100 ng/mL, $P = 0.005$; AFP < 100 ng/mL, $P = 0.017$) (Figure 2C, D).

Independent risk factors for distant recurrence of HCC on multivariate analysis were inadequate maintenance of blood glucose in diabetic patients [adjusted relative risk, 1.97 (95%CI, 1.33-2.91), $P = 0.0007$], multiple HCC nodules [2.03 (1.51-2.73), $P < 0.0001$], and AFP ≥ 100 ng/mL [1.43 (1.04-1.97), $P = 0.028$] (Table 2).

Factors associated with second recurrence

Among the 232 patients who had HCC recurrence, 138 had a second recurrence. Regarding second recurrence, inadequate maintenance of blood glucose in diabetic pa-

Recurrence rate at	1-year	2-year	3-year
Inadequate maintenance of blood glucose	50.6%	83.5%	93.8%
Others	26.8%	54.4%	73.0%

Recurrence rate at	1-year	2-year	3-year
Diabetes with inadequate maintenance of blood glucose	50.6%	83.5%	93.8%
Diabetes with adequate maintenance of blood glucose	21.9%	48.7%	66.5%
Non-diabetes	23.6%	55.5%	74.4%

Figure 1 Kaplan-Meier curves showing a higher rate of hepatocellular carcinoma recurrence in diabetic patients with hyperglycemia. A: The cumulative incidence of the recurrence of hepatocellular carcinoma (HCC) was significantly higher in diabetic patients with inadequate maintenance of blood glucose (blood glucose ⩾ 200 mg/dL solid line) than in the others (dotted line) (P = 0.0001); B: The HCC recurrence rate was significantly higher in diabetic patients with inadequate maintenance of blood glucose (solid line) than in diabetic patients with adequate maintenance of blood glucose (blood glucose < 200 mg/dL, broken line) or non-diabetic patients (dotted line) (P = 0.0001). There was no significant difference in HCC recurrence rate between diabetic patients with adequate maintenance of blood glucose and non-diabetic patients.

Table 2 Multivariate analysis of factors associated with recurrence of hepatocellular carcinoma

Factors	Odds ratio (95%CI)	*P*-value
First recurrence		
Inadequate maintenance of blood glucose	1.97 (1.33-2.91)	0.0007
Multiple HCC nodules	2.03 (1.51-2.73)	< 0.0001
AFP ⩾ 100 ng/mL	1.43 (1.04-1.97)	0.028
Second recurrence		
Inadequate maintenance of blood glucose (mg/dL)	1.99 (1.23-3.22)	0.0049
Multiple HCC nodules	1.53 (1.06-2.22)	0.024

Inadequate maintenance of blood glucose was defined as an average of casual blood glucose of ⩾ 200 mg/dL. HCC: Hepatocellular carcinoma; AFP: α-fetoprotein.

tients and multiple HCC nodules were again significantly associated with HCC recurrence. Obesity (P = 0.18), diabetes (P = 0.31) and initial level of serum AFP (P = 0.08) were not associated with second recurrence. In terms of the number of HCC nodules, namely, single *vs* multiple, the 1-, 2-, and 3-year recurrence rates were significantly higher in patients with multiple lesions (6.4% *vs* 6.1%, 39.3% *vs* 23.1%, and 52.5% *vs* 42.3%, respectively, P = 0.013). Upon comparing diabetic patients with inadequate maintenance of blood glucose *vs* the others, the rate of second recurrence was significantly higher in diabetic patients with inadequate maintenance of blood glucose (P = 0.0021) (Figure 3A). Upon comparing patients with diabetes *vs* patients who did not have diabetes, the rates of second recurrence were not significantly different (P = 0.31). Upon comparison of the three groups, i.e., the diabetes with inadequate maintenance of blood glucose group, the diabetes with adequate maintenance of blood glucose group, and the non-diabetes group, the second recurrence rate was again significantly higher in the diabetes with inadequate maintenance of blood glucose group than in the other two groups (P = 0.0035) (Figure 3B). On the other hand, there was no significant difference in the second recurrence rate between the diabetes with adequate maintenance of blood glucose group and the non-diabetes group.

Independent risk factors for second recurrence of HCC on multivariate analysis were inadequate maintenance of blood glucose [1.99 (95%CI, 1.23-3.22), P = 0.0049] and multiple HCC nodules [1.53 (95%CI, 1.06-2.22), P = 0.024] (Table 2).

Factors associated with survival

There were 52 HCC-related or hepatic failure deaths. On univariate analysis, inadequate maintenance of blood glucose, excessive alcohol drinking, higher initial level of serum AFP and Child-Pugh classification grade B were significantly associated with survival. Obesity (P = 0.81) and diabetes (P = 0.11) were not significantly associated with survival.

Upon comparing diabetic patients with inadequate maintenance of blood glucose *vs* the others, the survival rate was significantly lower in patients with inadequate maintenance of blood glucose (P = 0.0003) (Figure 4A). Upon comparing diabetic patients *vs* non-diabetic patients, the survival rates were not significantly different

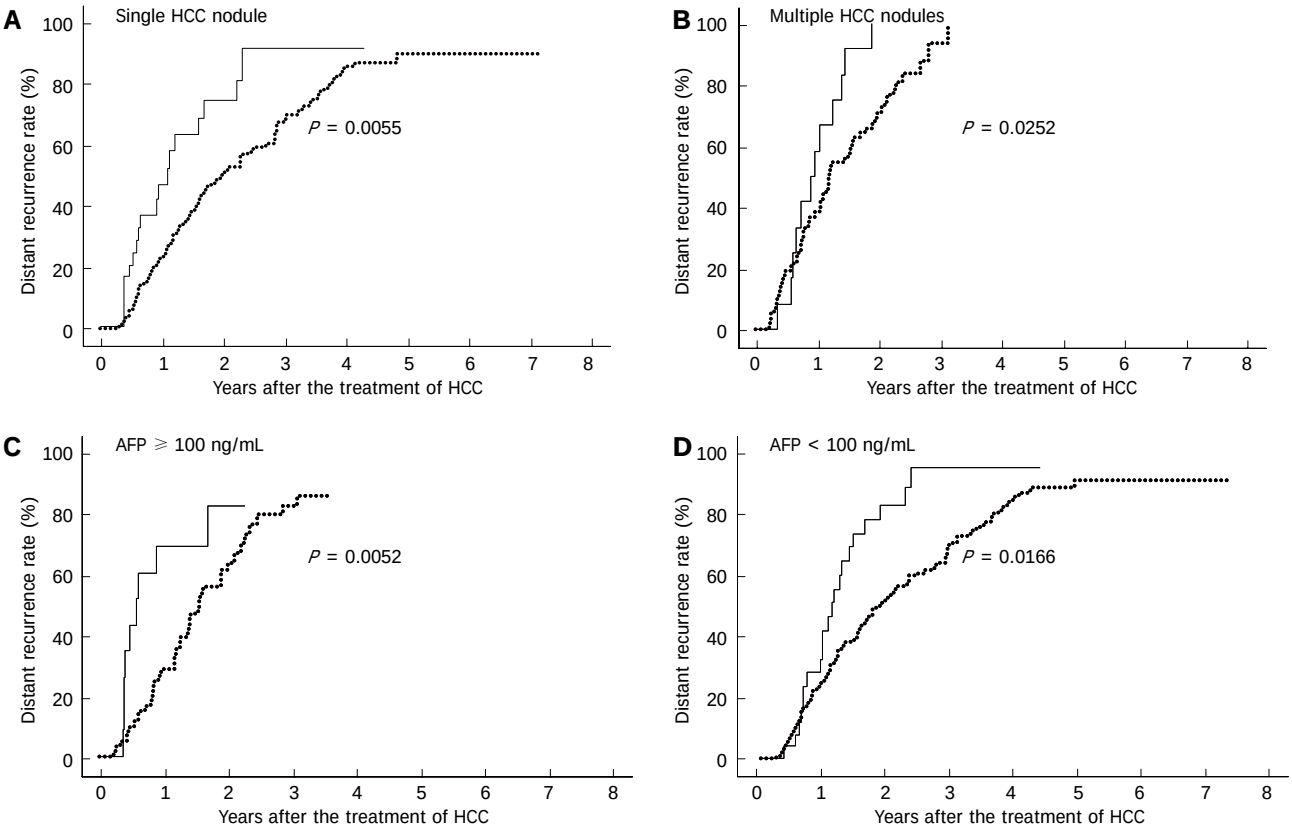


Figure 2 **Diabetic patients with inadequate maintenance of blood glucose have higher rate of hepatocellular carcinoma recurrence after stratification by other risk factors.** A: $P = 0.006$ for single hepatocellular carcinoma (HCC) nodule; B: $P = 0.025$ for multiple HCC nodules; C: $P = 0.005$ for AFP ⩾ 100 ng/mL; D: $P = 0.017$ for α-fetoprotein (AFP) < 100 ng/mL. The cumulative incidence of the recurrence of HCC was significantly higher in diabetic patients with inadequate maintenance of blood glucose (solid line) than in the others (dotted line). after stratification by number of HCC nodules and by initial level of AFP.

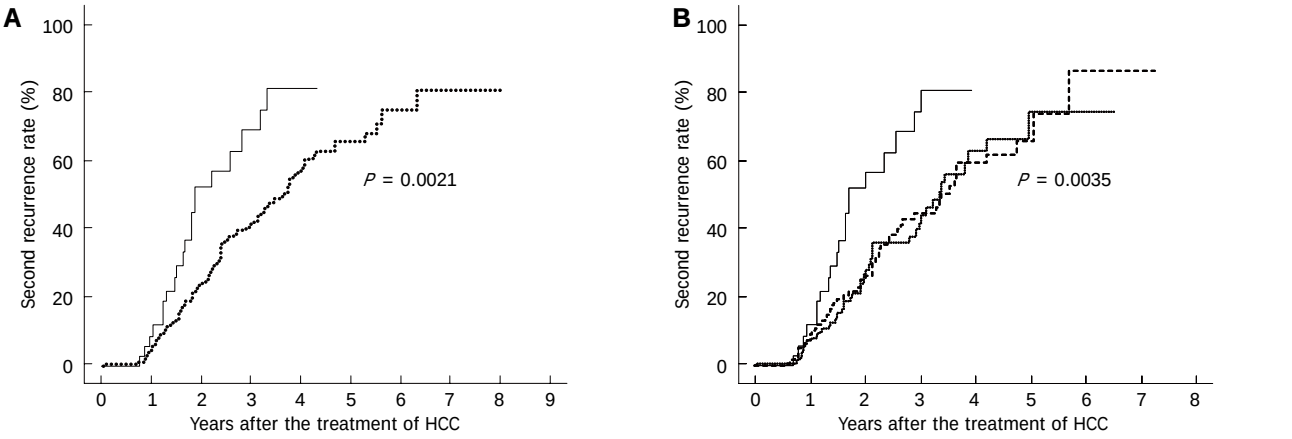
Table 3 Multivariable analysis of factors associated with survival

Factors	Odds ratio (95%CI)	*P*-value
Inadequate maintenance of blood glucose	2.77 (1.38-5.57)	0.0046
Alcohol drinking ⩾ 60 g/d	6.34 (1.35-29.7)	0.019
Child Pugh grade B	2.24 (1.12-4.46)	0.022
AFP ⩾ 100 ng/mL	3.40 (1.88-6.18)	< 0.0001

Inadequate maintenance of blood glucose was defined as an average of casual blood glucose of ⩾ 200 mg/dL. AFP: α-fetoprotein.



($P = 0.11$). of the survival rate was compared among the three groups, i.e., the diabetes with inadequate maintenance of blood glucose group, the diabetes with adequate maintenance of blood glucose group, and the non-diabetes group. The survival rate was significantly poorer in the diabetes with inadequate maintenance of blood glucose group than in the other two groups ($P = 0.0003$) (Figure 4B), while it did not differ between the diabetes with adequate maintenance of blood glucose group and the non-diabetes group.

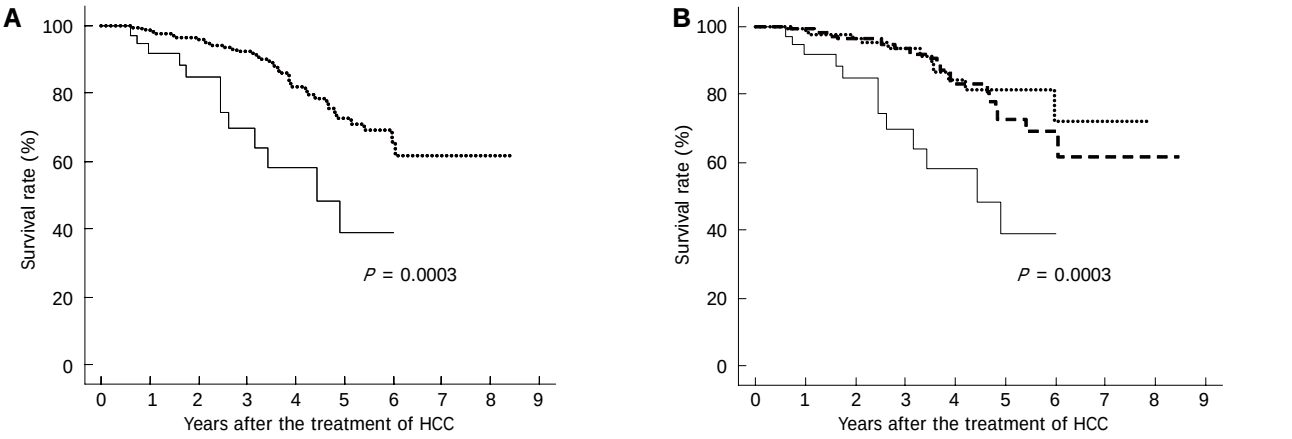
The number of HCC nodules, which was a significant factor for HCC recurrence, was not related to survival ($P = 0.34$). Patients with excessive alcohol drinking had poor survival prognosis compared to those with non-excessive or no alcohol drinking ($P = 0.046$). Survival was better in patients in Child-Pugh A class than in patients in Child-Pugh B class ($P = 0.0082$). AFP ⩾ 100 ng/mL was associated with poor survival compared with AFP < 100 ng/mL ($P < 0.0001$).

On multivariate analysis, inadequate maintenance of blood glucose was a significant predictor of poor survival [2.77 (95%CI, 1.38-5.57), $P = 0.0046$] independent of excessive alcohol drinking [6.34 (95%CI, 1.35-29.7), $P = 0.019$], initial level of serum AFP ⩾ 100 ng/mL [3.40 (95%CI, 1.88-6.18), $P < 0.0001$] and Child-Pugh classification grade B [2.24 (95%CI, 1.12-4.46), $P = 0.022$] (Table 3).

DISCUSSION

The impact of metabolic factors, such as hyperglycemia, diabetes and obesity, on distant recurrence and survival after curative RFA therapy for HCC was analyzed retrospectively. We identified that inadequate maintenance of blood glucose in diabetic patients was a significant and independent risk factor for early recurrence of HCC and a risk factor for poor survival, whereas obesity and diabetes were not. Diabetic patients with inadequate maintenance of blood glucose had a higher rate of HCC recurrence and poorer survival compared with diabetic patients with adequate maintenance of blood glucose and non-diabetic patients. In other words, even in patients with diabetes, if

Second recurrence rate at	1-year	2-year	3-year
Inadequate maintenance of blood glucose	9.0%	53.1%	69.6%
Others	5.9%	24.3%	42.3%



Second recurrence rate at	1-year	2-year	3-year
Diabetes with inadequate maintenance of blood glucose	9.0%	53.1%	69.6%
Diabetes with adequate maintenance of blood glucose	5.9%	22.1%	43.7%
Non-diabetes	5.6%	21.5%	36.5%

Figure 3 Kaplan-Meier curves showing a higher rate of second recurrence of hepatocellular carcinoma in diabetic patients with inadequate maintenance of blood glucose. A: The cumulative incidence of the second recurrence of hepatocellular carcinoma (HCC) was significantly higher in diabetic patients with inadequate maintenance of blood glucose (blood glucose ⩾ 200 mg/dL solid line) than in the others (dotted line) (P = 0.002); B: The rate of second recurrence of HCC was significantly higher in diabetic patients with inadequate maintenance of blood glucose (solid line) than in diabetic patients with adequate maintenance of blood glucose (blood glucose < 200 mg/dL, broken line) or non-diabetic patients (dotted line) (P = 0.004). There was no significant difference in the rate of second recurrence of HCC between diabetic patients with adequate maintenance of blood glucose and non-diabetic patients.

the blood glucose was adequately maintained, the HCC recurrence rate and survival did not differ significantly compared with those in non-diabetic patients. These results indicate the possibility that adequate management of hyperglycemia may lead to reduction in the risk of HCC recurrence and improvement of overall survival.

The contribution of diabetes to the development of HCC has been confirmed in several reports[27-30]. The impact of diabetes on the recurrence of HCC after treatment has also been discussed, but with conflicting results[20-22]. A recent study from Taiwan demonstrated that diabetes may not affect the intra-hepatic HCC recurrence and survival after RFA[23]. The results of the present study also indicated that diabetes itself is not a significant risk factor if the level of blood glucose is adequately managed. Rather, hyperglycemia was a significant risk factor for the recurrence of HCC. There may be several mechanisms involved in the relationship between hyperglycemia and HCC recurrence. Hyperglycemia promotes cancer cell proliferation in pancreatic cancer cells and breast cancer cells[31-33] through accelerated cell cycle progression or through the production of reactive oxygen species, leading to activation of protein kinase C and increased DNA synthesis in cancer cells[34]. A previous study in hepatitis C patients indicated that hyperglycemia after challenge with 75-g oral glucose tolerance test was associated with the risk for HCC while hyperglycemia at fasting was not[35]. A possible reason for this result may be that patients with post-challenge hyperglycemia may have higher fluctuations in daily glucose levels that lead to oxidative stress[35], because it was reported that acute fluctuations in blood glucose levels cause greater oxidative stress than sustained chronic hyperglycemia[36]. Taken together, a possible mechanism for the relationship between higher level of casual blood glucose and development of HCC in the present study may be that daily fluctuations in serum glucose levels caused greater oxidative stress. Alternatively, hyper-insulinemia or increased level of insulin-like growth factor, which are caused by hyperglycemia, may be related to carcinogenesis[37-39]. Insulin levels were not measured in our study; therefore, the effects of insulin could not be identified.

Discussions are now taking place on methods of treating diabetes from the standpoint of cancer prevention. Control of hyperglycemia could reduce cancer incidence, which means that hyperglycemia could directly contribute to the development of cancer[39]. The results of our study also showed that adequate management of hyperglycemia may lead to reduction in the risk of HCC recurrence and improvement of overall survival. Improvement in insulin resistance is undoubtedly the most important factor for the treatment of diabetes, but glycemic control is often difficult to achieve with dietary therapy, exercise, or insulin resistance-improving drugs alone. It was reported that metformin may be associated with a lower risk of cancer[38] and there is a theoretical concern that exogenous insulin may be associated with an increased risk of cancer[40]. In fact, a recent study reported that insulin therapy in patients with HCV infection is linked with the development of HCC[41]. On the other hand, with insulin treatment, concomitant use of metformin has been reported to offset the carcinogenic risk of insulin[42]. Whether glycemic control should be a priority, or whether avoiding hyper-insulinemia because

Second recurrence rate at	1-year	2-year	3-year
Inadequate maintenance of blood glucose	91.7%	84.6%	69.7%
Others	98.7%	95.9%	92.4%

Second recurrence rate at	1-year	2-year	3-year
Diabetes with inadequate maintenance of blood glucose	91.7%	84.6%	69.7%
Diabetes with adequate maintenance of blood glucose	99.2%	96.3%	93.7%
Non-diabetes	99.2%	96.4%	93.3%

Figure 4 Patients with inadequate maintenance of blood glucose have a lower survival rate. A: The survival rate after curative local ablation therapy for hepatocellular carcinoma (HCC) was significantly lower in diabetic patients with inadequate maintenance of blood glucose (blood glucose ≥ 200 mg/dL solid line) than in the others (dotted line) (P = 0.0003); B: The survival rate was significantly lower in diabetic patients with inadequate maintenance of blood glucose (solid line) than in diabetic patients with adequate maintenance of blood glucose (blood glucose < 200 mg/dL, broken line) or non-diabetic patients (dotted line) (P = 0.0003). There was no significant difference in survival rate between diabetic patients with adequate maintenance of blood glucose and non-diabetic patients.

of therapy should be a priority, is an issue for future investigation.

In terms of survival of HCC patients, associations with liver function and tumor factors have been reported[10], but conflicting results have been reported for the relationship with diabetes[20,21]. These two studies involved heterogeneous groups of HCC patients treated with various therapies, including surgery, local ablation therapy and transcatheter arterial embolization. This heterogeneity may have led to the conflicting results, because the survival of HCC patients may be strongly affected by the initial treatment. Our study involved a homogeneous patient population, i.e., all patients were initially treated curatively by RFA. The results of our study suggest that glycemic control in diabetic patients, more so than diabetes itself, plays a role in survival. The mechanism by which glycemic control and survival are related is unknown, but frequent recurrence of HCC in hyperglycemic patients and the accumulation of damage in liver function because of repeated treatment intervention for HCC may lead to worsening survival.

In conclusion, inadequate maintenance of blood glucose in diabetic patients was a significant and independent risk factor for early recurrence of HCC and for poor survival. Adequate management of hyperglycemia in diabetic patients may lead to reduction in the risk of HCC recurrence and improvement in overall survival.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common cancers worldwide. Radiofrequency ablation (RFA) therapy is an efficient curative therapy for HCC, but long-term survival is limited because of the high rate of distant recurrence of approximately 80% within 5 years. Identification of factors related to recurrence of HCC and therapeutic intervention targeting these factors may lead to prevention of frequent recurrence of HCC and improved survival.

Research frontiers

Metabolic factors, such as obesity and diabetes, have been identified as risk factors for several types of cancer, such as cancer of the liver, pancreas, kidney, and colon. These metabolic factors may be related to recurrence of HCC. The impact of diabetes on the recurrence of HCC after treatment has been discussed, but with conflicting results.

Innovations and breakthroughs

The authors identified that inadequate maintenance of blood glucose in diabetic patients was a significant and independent risk factor for early recurrence of HCC and a risk factor for poor survival, whereas diabetes was not. In other words, even in patients with diabetes, if the blood glucose was adequately maintained, then the HCC recurrence rate and survival did not differ significantly from those in non-diabetic patients.

Applications

The results of the present study indicate the possibility that adequate management of hyperglycemia in diabetic patients may lead to reduction in the risk of HCC recurrence and improvement of overall survival.

Peer review

This is an important study in which the effect of inadequate maintenance of blood glucose in diabetes has been shown as a significant risk factor for distant recurrence of hepatocellular carcinoma and poor survival after curative radiofrequency ablation therapy.

Abstract

AIM: To evaluate the effect of proton pump inhibitors (PPIs) on the development of gastrointestinal tuberculosis.

METHODS: All patients who were more than 20 years old and who had received a prescription for PPIs among those who visited Seoul National University Hospital from January 1, 2005 to December 31, 2009 were identified. Due to the low sensitivity of the microbiologic test and the nonspecific pathologic findings, the diagnosis of gastrointestinal tuberculosis was confirmed through the presence of active ulcerations and the responses to anti-tuberculosis medications. The patients were divided into two groups according to treatment duration (group 1: ⩽ 3 mo; group 2: > 3 mo) and were followed up from the time they took the first prescription of PPIs until their last visit. Logistic regression analysis was used to calculate the relative risks (RR) and 95%CI, adjusting for covariates.

RESULTS: Among the 61 834 patients exposed to PPIs (50 534 in group 1; 11 300 in group 2), 21 patients were diagnosed with PPI-associated gastrointestinal tuberculosis during 124 274 person-years of follow-up. Of 21 patients, the 12 who revealed only scar changes in the colonoscopy were excluded from the statistical analyses. Of those who remained, 2 were excluded because they underwent gastrointestinal endoscopy within 4 wk of the first prescription for PPIs. Longer exposure to PPI was associated with a higher mean age (55.0 ± 14.5 in group 1 *vs* 58.2 ± 13.3 in group 2, $P < 0.001$) and a higher Charlson co-morbidity index (0.50 ± 0.93 in group 1 *vs* 0.77 ± 1.14 in group 2, $P < 0.001$). The true incidence of active gastrointestinal tuberculosis was 0.65 per 1000 person-years in group 1 and 0.03 per 1 000 person-years in group 2. Like the less-than-three-month PPI treatment period in group 1, the over-three-month PPI therapy period in group 2 was not associated with increased risk of acquiring gastrointestinal tuberculosis, after adjusting for age and co-morbidities, whereas the Charlson co-morbidity index was associated with increased risk of acquiring gastrointestinal tuberculosis based on the score [RR: (reference 1) in group 1 *vs* 1.518 in group 2; 95% CI: 1.040-2.216, $P = 0.03$].

CONCLUSION: Long-term PPI therapy does not seem to be associated with increased risk of acquiring gas-

trointestinal tuberculosis, but a higher Charlson comorbidity index is associated with such.

Hong KS, Kang SJ, Choi JK, Kim JH, Seo H, Lee S, Jung JW, Kang HR, Cho SH, Kim JS. Gastrointestinal tuberculosis is not associated with proton pump inhibitors: A retrospective cohort study. *World J Gastroenterol* 2013; 19(2): 258-264 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/258.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.258

INTRODUCTION

Gut flora is closely related to human health and disease[1]. The intestinal microflora is assumed to be affected by a series of factors that determine the intraluminal environment: the pH in the gastrointestinal tract, oxygen tension, nutrient availability, colonic physiology, bacterial interference, *etc.*[2]. One of the major factors controlling the bacterial distribution in the gastrointestinal tract is the gastric acid barrier, which may be affected by the use of inhibitors of gastric acid secretion, gastrectomy, and dietary indiscretion and stress[3]. The establishment of enteric infection has been considered directly related to gastric acidity reduction[4,5]. Several recent studies associated proton pump inhibitors (PPIs) with a two- to three-fold increase in the risk of *Clostridium difficile* infection[6-8].

PPIs are currently the most powerful gastric acid suppressants and the drug of choice for the treatment of gastroesophageal reflux disease and peptic ulcer. PPIs are very powerful acid suppressants whose effects mean the percentage time intragastric pH > 4 may increase from 20% at baseline to over 60% within a week[9]. Today's life expectancy is longer than ever before, and the number of patients who take antiplatelet agents to prevent the onset of vascular diseases is increasing. Along with this, more and more patients are obliged to take prophylactic gastric acid suppressants, including PPIs, to prevent severe complications, such as peptic ulcer bleeding.

Tuberculosis is still an important health problem in many developing countries, including South Korea[10]. Unlike in developing countries, the disease used to be uncommon in developed countries, but it has re-emerged in the Western countries as a result of the acquired immunodeficiency syndrome (AIDS) epidemic therein as well as the influx of immigrants from developing countries[11-13]. Gastrectomy has been known to be a potential risk factor for tuberculosis for decades[14-16]. To these authors' knowledge, however, there has been no report about a possible association between PPI use and gastrointestinal tuberculosis. This study was thus conducted to evaluate the effect of PPIs on the development of gastrointestinal tuberculosis.

MATERIALS AND METHODS

Setting and design

This study is part of a hospital-based longitudinal cohort study entitled "Seoul National University Hospital (SNUH) PPI Safety Study," in which these authors analyzed the data regarding patients who visited SNUH and who were treated with PPI between January 1, 2005, and December 31, 2009. SNUH is a large urban tertiary care center in Seoul, South Korea. The hospital's institutional review board approved the study with a waiver of informed consent.

Data sources

Data were obtained from a clinical data warehouse fully synchronized with the electronic medical recording (EMR) system created as part of the usual care. SNUH Clinical Data Warehouse (CDW) contains all the information from each visit, not only routine clinical data such as the demographics, diagnosis, medication profiles, laboratory results, and lengths of stay of inpatients since 2001 but also the electronic charts since 2004.

Patients and case definitions

All patients who were at least 20 years old at their first visit and who ingested PPI on prescription during the five-year screening period were included in the study. According to a large retrospective study including 225 Korean patients, histological examination of the colonoscopic biopsy specimens revealed caseous necrosis in only 11.1% of the patients, and acid-fast bacilli (AFB) in 17.3% of the patients. *Mycobacterium tuberculosis* was isolated from the culture of biopsy specimens in 29.3% of the patients[17]. Even though granulomas were observed in 72.4% of the patients, granuloma is not a specific finding in intestinal tuberculosis. Due to the low sensitivity of the microbiologic test and the nonspecific pathologic findings, the diagnosis of active gastrointestinal tuberculosis was confirmed through both an endoscopic finding of active transverse ulcerations and a good response to anti-tuberculosis treatment, which was confirmed through a follow-up colonoscopy within three months from the initiation of the treatment. The definition of good therapeutic response was complete or near-complete healing of all the ulcerations in the follow-up colonoscopy.

The patients in whom colonoscopy revealed only scar changes were excluded from the statistical analysis for two reasons: (1) the exact temporal relationship between PPI ingestion and the development of gastrointestinal tuberculosis could not be verified; and (2) the diagnosis of tuberculosis could not be confirmed as there was no need for anti-tuberculosis treatment and due to the low sensitivity of the histological evaluation of the biopsy specimens. As tuberculosis is a chronic inflammatory disease, the patients who were diagnosed with gastrointestinal tuberculosis within four weeks of their first prescription for PPIs were also excluded from the statistical analyses.

The primary exposure of interest was receipt of PPIs. PPI

Table 1 Clinical information of the patients who were endoscopically diagnosed with suspicious tuberculosis

21	F/46	1	28	Epigastric pain	Ulcers, mid-esophagus	Non-caseating granuloma, positive PCR[2]	Included	

[1]Patients with PPI treatment for three months or less as group 1, and patients with more-than-three-month PPI treatment as group 2; [2]Polymerase chain reaction (PCR) for *Mycobacterium tuberculosis*. PPI: Proton pump inhibitor; M: Male; F: Female.

exposure was classified by overall dosing period before the first endoscopy showing suspicious gastrointestinal tuberculosis or the last prescription date in patients without gastrointestinal tuberculosis. The patients with less than three months of PPI treatment were defined as group 1, and those with three or more months of PPI treatment were defined as group 2. To normalize the different acid-suppressive capacities among the PPI regimens, omeprazole 20 mg, lansoprazole 30 mg, rabeprazole 20 mg, pantoprazole 40 mg, and esomeprazole 40 mg were defined as standard daily doses of PPI. To calculate the adjusted dosing period, the period of the half-dose regimen was multiplied by 0.5, and the period for the double-dose regimen was multiplied by 2.

Statistical analysis

The covariates that may influence the risk of acquiring gastrointestinal tuberculosis and those that may influence the exposure to PPIs were included in the analysis. These variables were age, sex, and co-morbidities. The co-morbidities were determined from the registered diagnosis by the attending physician using the International Classification of Diseases 10th Revision code. Quan's algorithm was used to define the 17 Charlson co-morbidities, and the Charlson index was calculated[18,19].

Unadjusted comparisons were performed using the *t*-test, ANOVA test, Mann-Whitney test, χ^2 test, or Fisher exact test, as appropriate. Logistic regression modeling was used to estimate the relative risk of acquiring gastrointestinal tuberculosis in multivariate analyses. Statistical analysis was performed using the SAS software, version 9.2 (SAS Institute Inc., Cary, North Carolina).

RESULTS

Among the patients who visited SNUH during the five-year study period, 61 834 patients received PPIs and 7 gastrointestinal tuberculosis cases were identified. After excluding the patients who were diagnosed with suspicious gastrointestinal tuberculosis through endoscopy prior to the first prescription of PPIs, a total of 21 patients were screened. Of these, 12 patients who revealed only scar changes in colonoscopy were excluded from the statistical analyses. Of those who remained, 2 were excluded because they underwent gastrointestinal endoscopy within 4 wk of the first prescription of PPIs (Table

Table 2 Summary of descriptive statistical analysis *n* (%)

	Group 1	Group 2
Patients (*n*)	50 534	11 300
Cases	6 (0.012)	1 (0.009)
Esophageal tuberculosis	1	0
Gastric tuberculosis	0	1
Colonic tuberculosis	5	0
Total follow-up (person-mo)	1 102 947	388 345
Average follow-up (mo)	21.8	34.4
Incidence per 1000 person/yr	0.65	0.03

1). Anti-tuberculosis medications (isoniazid, rifampicin, ethambutol, and pyrazinamide) were prescribed to the finally selected 7 patients. Follow-up endoscopy was performed 2 or 3 mo after the start of the anti-tuberculosis treatment, and revealed complete healing or almost-healed ulcerations in all 7 patients.

The true incidence of gastrointestinal tuberculosis was 0.65 per 1000 person-years in group 1 and 0.03 per 1000 person-years in group 2 (Table 2). The characteristics of each group are shown in Table 3. The mean age (± SD) was 55.0 ± 14.5 years in group 1 and 58.2 ± 13.3 years in group 2. Longer exposure to PPI was associated with a higher Charlson co-morbidity index and a higher age (Table 3).

Table 4 presents the demographic and clinical characteristics of the active-gastrointestinal-tuberculosis and non-tuberculosis groups. Due to the small number of patients in the active-tuberculosis group, there was no significant difference between the two groups.

Table 5 shows the results of the multivariable analysis using logistic regression. A longer PPI treatment period (over three months) was not associated with increased risk of acquiring active gastrointestinal tuberculosis. The Charlson index was associated with significantly increased risk of acquiring active gastrointestinal tuberculosis by over 50% per score 1.

DISCUSSION

This cohort study was conducted not only to evaluate the possible role of more-than-three-month PPI treatment but also to calculate the incidence rate of, and to find the risk factors for, acquiring active gastrointestinal tuberculosis in all the at-least-20-year-old patients who visited SNUH and who were treated with PPI between January 1, 2005 and December 31, 2009. As a result, more-than-three-month PPI treatment was found not to be associated with increased risk of acquiring active gastrointestinal tuberculosis. The annual incidence rate of tuberculosis was reported to be 97 per 100 000 in 2010 in the South Korean general population[10]. The calculated incidence rate of active gastrointestinal tuberculosis seems to be much lower in PPI-treated patients in the present study (Table 2), even considering the reportedly small proportion of gastrointestinal tuberculosis in the whole tuberculosis population[20].

A diagnosis of gastrointestinal tuberculosis can be confirmed if a characteristic caseous granuloma, positive smear of AFB, or positive culture of mycobacterium is observed in the biopsy specimen[12]. Compared to pulmonary tuberculosis, however, there is a relatively small absolute number of AFB in gastrointestinal tuberculosis[21], and caseous granuloma is infrequently observed in patients with an early-stage disease or who have been treated with anti-tuberculosis medications[22]. Many studies have been performed to assess the diagnostic accuracy of such histological markers, and there have been a number of reports showing granuloma in 41%-48%[23-25], caseous granuloma in 8%-18%[24-26], positive smear of AFB in 0%-100%[24,25,27,28], and positive culture of AFB in 0%-69%[24-26,28] of gastrointestinal-tuberculosis patients. As there have been many reports showing variable results, it seems impossible to set universal standards for diagnosing gastrointestinal tuberculosis. There are adjunct diagnostic modalities, such as polymerase chain reaction (PCR) for *Mycobacterium tuberculosis*, and endoscopic findings. Although PCR is a method that shows over 50% diagnostic sensitivity, its substantial false positivity limits its role to that of an adjunctive test for the diagnosis of gastrointestinal tuberculosis[29]. In the present study, both non-caseating granuloma and positive PCR were observed in two patients with gastroesophageal

tuberculosis, but non-caseating granuloma was observed in only 2 of the 7 patients with intestinal tuberculosis, and PCR was positive in 1 of the 2 patients who showed granuloma.

The endoscopic findings of gastrointestinal tuberculosis are often nonspecific[12,30]. Intestinal tuberculosis and Crohn's disease are chronic inflammatory bowel disorders that are difficult to differentiate from each other[31,32]. A study on colonoscopic findings reported that four parameters (involvement of fewer than 4 segments, a patulous ileocecal valve, transverse ulcers, and scars or pseudopolyps) were more frequently observed in intestinal tuberculosis patients than in Crohn's disease patients. Four parameters (anorectal lesions, longitudinal ulcers, aphthous ulcers, and cobblestone appearance) were significantly more common in Crohn's disease patients than in intestinal tuberculosis patients. A systematic analysis of the 8 parameters of colonoscopy was very useful in the differential diagnosis as it could differentiate between intestinal tuberculosis and Crohn's disease with 87.5% accuracy[33]. In the endemic areas of tuberculosis, it seems reasonable to prescribe anti-tuberculosis medications for patients with endoscopic findings favoring intestinal tuberculosis even if there is no specific histological finding from the biopsy specimens[12]. In the present study, anti-tuberculosis medications were also prescribed for 5 patients with only nonspecific chronic inflammations found through biopsy. Intestinal tuberculosis was confirmed in all 5 patients through follow-up colonoscopy, which revealed good therapeutic responses as well as symptom relief.

This study has a number of strengths. First, to these authors' knowledge, this study is the first study that evaluated PPI's role in the development of gastrointestinal tuberculosis. Second, all the data in this study were extracted from the SNUH CDW system that is fully synchronized with the EMR system and is optimized for research. Using the SNUH CDW system, 61 834 patients among the over one million patients who visited SNUH during the 5-year study period were rapidly screened, and the patients with gastrointestinal tuberculosis were sensitively sought out *via* browsing endoscopy and pathology reports. Most of all, compared to cohort studies using a public database, through which only the cumulative incidence rate could be estimated, it is notable that the true incidence rate of gastrointestinal tuberculosis in PPI-treated patients was calculated. The calculated incidence rate was as low as 0.65 per 1000 person-years in group 1 and 0.03 per 1000 person-years in group 2, and anti-tuberculosis medications were shown to be effective in all the patients with active gastrointestinal tuberculosis. Therefore, the risk of acquiring gastrointestinal tuberculosis does not seem to be clinically significant in PPI-treated patients.

This study, however, has several key limitations. First, the study was performed with patients from a single urbanized tertiary care hospital. In general, a hospital cohort is vulnerable to selection bias, and the results have poor generalizability. In South Korea, a single compulsory medical insurance takes effect. Due to the open medical delivery system, all the patients are practically free to visit tertiary care hospitals. In this study, 64% of the patients fall under Charlson index 0. Therefore, their possible difference from primary care patients in the aspect of clinical severity does not seem substantial. Another limitation of a hospital cohort is its dynamic nature, which enables the members to easily join or drop out. Fortunately, even if this study was performed in PPI-treated patients during a 5-year period, the patients could be followed up for 21.8 mo in group 1 and for 34.4 mo in group 2. Therefore, the adherence of the patients in this study seems to have been good.

The second limitation is the potentially different diagnostic sensitivity. This study is an observational study. Therefore, the patients did not necessarily undergo gastrointestinal endoscopy. The implementation of endoscopy was determined according to the patient's symptoms/signs, patient's will, and doctor's decision. There might have been differences in these factors between group 1 and group 2. In this study, most of the 12 patients with only ileo-colonic scars were females and underwent colonoscopy due to mild symptoms or as a routine check. Half of them belonged to group 2, showing a relatively higher incidence in group 2 compared to 1 in the patients with active gastrointestinal tuberculosis (Table 1). Presumably, this may be due to the more frequent requests for routine check-up from or the

stricter adherence to the hospital of female patients than male patients. In the 9 patients diagnosed with active gastrointestinal tuberculosis, however, there were nearly equal numbers of male and female patients. Endoscopy was performed to assess bloody diarrhea, anemia, and severe pain, which seemed to be symptoms suggesting active gastrointestinal tuberculosis (Table 1). In this study, statistical analysis was performed in the patients with active gastrointestinal tuberculosis, which could suggest that the results of this study were not highly biased by the patients' will or adherence.

In conclusion, long-term PPI therapy does not seem to be associated with increased risk of acquiring gastrointestinal tuberculosis whereas a higher Charlson comorbidity index is associated with such. These results, however, may not exempt further monitoring due to the small case number.

COMMENTS

Background

Proton pump inhibitors (PPIs) are currently the most powerful gastric acid suppressants. Several studies have associated acid suppression with increased risk of acquiring gastrointestinal infectious diseases, such as *Clostridium difficile* infection.

Research frontiers

Gastrectomy has been known to be a potential risk factor for tuberculosis, and gastric-acid suppression may play a role in its pathogenesis. There has been no report about a possible association between PPI use and gastrointestinal tuberculosis.

Innovations and breakthroughs

Seoul National University Hospital Clinical Data Warehouse is a database that is fully synchronized with an electronic medical recording system. Using the high-quality dataset, gastrointestinal-tuberculosis patients were efficiently screened, and the true incidence and relative risk of longer PPI treatment were calculated.

Applications

Long-term PPI therapy does not seem to be associated with increased risk of acquiring gastrointestinal tuberculosis.

Peer review

The response to therapy must be evaluated very strictly as this was adopted as a diagnostic criterion.

Abstract

AIM: To evaluate the clinical outcomes and prognostic factors after intravenous corticosteroids following oral corticosteroid failure in active ulcerative colitis patients.

METHODS: Consecutive patients with moderate to severe ulcerative colitis who had been treated with a course of intravenous corticosteroids after oral corticosteroid therapy failure between January 1996 and July 2010 were recruited at Severance Hospital, Seoul, South Korea. The disease activity was measured by the Mayo score, which consists of stool frequency, rectal bleeding, mucosal appearance at flexible sigmoidoscopy, and Physician Global Assessment. We retrospectively evaluated clinical outcomes at two weeks, one month, three months, and one year after the initiation of intravenous corticosteroid therapy. Two weeks outcomes were classified as responders or non-responders. One month, three month and one year outcomes were classified into prolonged response, steroid dependency, and refractoriness.

RESULTS: Our study included a total of 67 eligible patients. At two weeks, 56 (83.6%) patients responded to intravenous corticosteroids. At one month, complete remission was documented in 18 (32.1%) patients and partial remission in 26 (46.4%). Eleven patients (19.7%) were refractory to the treatment. At three months and one year, we found 37 (67.3%) and 25 (46.3%) patients in prolonged response, ten (18.2%) and 23 (42.6%) patients in corticosteroid dependency, 8 (14.5%) and 6 (11.1%) patients with no response, respectively. Total 9 patients were underwent elective proctocolectomy within 1 year. The duration of oral corticosteroid therapy (> 14 d *vs* ⩽ 14 d, $P = 0.049$) and lower hemoglobin level (⩽ 11.0 mg/dL *vs* >11.0 mg/dL, $P = 0.02$) were found to be poor prognostic factors for response at two weeks. For one year outcome, univariate analysis revealed that only a partial Mayo score (⩾ 6 *vs* <6, $P = 0.057$) was found to be associated with a poor response.

CONCLUSION: The duration of oral corticosteroid therapy and lower hemoglobin level were strongly associated with poor outcome.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory disease of the colon with unknown etiology and is characterized by a typical natural course with recurrent flares of mucosal inflammation. About 15% of patients with UC have been reported to have an overall chance of acute exacerbation and require admission to hospital and treatment with systemic corticosteroids[1,2]. Systemic corticosteroids remain as the gold standard treatment of acute moderate to severe UC. However, about 15%-57% of UC patients remain steroid-dependent or refractory even after steroid treatment[3]. Before the mid-1990s, proctocolectomy was the only treatment in steroid-unresponsive UC patients. Recently, intensive drug therapies have been shown to be effective in reducing and delaying the need for colectomy[4,5].

For UC patients who fail to improve with a maximal dosage of 5-aminosalicylic acids, oral steroid therapy should be considered. Moreover, for those who also do not respond to orally administered steroids, hospital admission is usually required for intensive intravenous treatment[6,7]. However, to the best of our knowledge, there has been no published study describing the clinical course of patients with acute attack of UC who were treated first with oral corticosteroids and subsequently with intravenous corticosteroids due to oral steroid failure. Before demonstrating the efficacy of second line drugs, the response and the clinical outcomes of intravenous corticosteroid therapy after oral administration need to be clarified. In addition, identification of early predictors of intravenous corticosteroid responsiveness could facilitate appropriate patient selection and well-timed administration of second line therapies in such UC patients. Clinically, earlier detection of response is important to help estimate risks, benefits, and duration of treatment, as this will enable the use of alternative drugs before complications of long term use of systemic corticosteroids can develop. However, data on predictive response factors of intravenous corticosteroids following oral corticosteroid therapy are lacking.

Here we sought to identify predictive clinical or biological factors associated with intravenous corticosteroid responsiveness in UC patients that initially did not respond to oral corticosteroids, as well as two week, one month, three month, and one year clinical outcomes of such treated patients with acute attack of UC.

MATERIALS AND METHODS

Patients

The clinical records of patients with active UC who were treated with intravenous corticosteroids immediately after treatment failure of oral corticosteroids at the Yonsei University College of Medicine, Seoul, South Korea between January 1996 and July 2010 were retrospectively evaluated. The diagnosis of ulcerative colitis was based on the accepted clinical, endoscopic, and histopathological criteria[8]. The criteria for eligibility were male or female patients with a diagnosis of UC followed regularly for at least 1 year. The exclusion criteria were patients with a history of corticosteroid therapy at other hospitals, corticosteroid use for diseases other than UC and a follow-up duration of less than 1 year. All enrolled patients were initiated intravenous corticosteroid therapy after admission after failure of oral steroid therapy which was done at outpatient clinic.

Intravenous corticosteroid therapy was initiated with intravenous administration of 100 mg of hydrocortisone every eight hours. Intravenous corticosteroid therapy was continued for 1-2 wk, with the treatment duration depending on the individual patient conditions, followed by gradual tapering of corticosteroids. After clinical improvement of UC, the dose of intravenous hydrocortisone was reduced to 200 mg daily. If the patients had no clinical exacerbation of UC, they were administered 30 mg/d of oral corticosteroid therapy before discharge. Our oral corticosteroid tapering policy was to reduce prednisolone by 5 or 10 mg weekly for patients with improved clinical symptoms but to sustain the current dose of prednisolone for one week for patients with lasting clinical symptoms[9,10]. All patients who were concomitantly taking sulfasalazine (2-4 g/d) or mesalamine (1.5-4 g/d) at the time of flare up continued therapy. Patients who took immuomodulators at the time of acute flare up also maintained their initial immuomodulator therapy while taking corticosteroids.

Our study is a retrospective study from a prospectively collected database. The data are stored in a form of Assess file as well as paper form. After then, the questionnaire including Mayo or partial Mayo scores including Physician Global Assessment (PGA) is updated every visit of the patient to outpatient clinics.

The disease activity was measured by the Mayo score, which consists of stool frequency, rectal bleeding, mucosal appearance at flexible sigmoidoscopy, and PGA[11,12]. Each component was scored 0 to 3 points, and the total score ranged from 0 to 12 points. However, a measurement of this score necessarily requires invasive flexible sigmoidoscopy, which limits repeated measurement. Therefore, most actual disease activity was measured on a nine-point partial Mayo score, which excluded the mucosal appearance at endoscopy[13]. At the initiation of oral corticosteroid therapy, demographic data including age, age at diagnosis, duration, gender, number of acute attacks, extent of disease, concomitant medications, duration of oral corticosteroid therapy, Mayo score, and partial Mayo score were collected. Partial Mayo score and laboratory parameters were also recorded at two weeks, one month, three months, and one year after the time of initiation of intravenous corticosteroid therapy. This study was approved by the institutional board of Severance Hospital.

Definitions

Clinical outcome was measured at two weeks, one month,

three months, and one year after the initiation of intravenous corticosteroids. The classification of response to intravenous corticosteroid therapy was adopted from previous studies with minor modification[3,11,14,15]. Patients at two weeks were classified as responders or non-responders. Non-responder of intravenous therapy after oral corticosteroid therapy was defined as persistent active disease despite administration of intravenous corticosteroids over two weeks, death due to UC attack before day 14, proctocolectomy before day 14, or secondary alternative drug use such as cyclosporine and infliximab before day 14. Proctocolecctomy was performed when the patient had intractable bloody diarrhea, a continued PGA score of 3, severe anemia, persistent abdominal pain, or severe malnutrition despite intensive medical treatment. One month outcomes were classified as complete remission, partial remission, or refractoriness. Complete remission was defined as a stool frequency ≤ 2/d with no rectal bleeding, stool urgency, fever, or any other systemic symptoms, and a PGA score of 0. Partial remission was defined as stool frequency ≤ 4/d or ≤ 50% of initial stool frequency with regression of other clinical symptoms and a PGA score of 1 or 2. Refractoriness was defined as persistent active status despite administration of prednisolone up to 30 mg/d or the equivalent dose over the period of four weeks[14]. Three month outcomes were classified into prolonged response, steroid dependency, and refractoriness. Prolonged response was defined as sustained complete or partial remission during the planned dose reduction or after the completion of corticosteroids[3]. Steroid dependency was defined as need for the same corticosteroid dose for more than two weeks despite clinical improvement, requiring an increased dose, or restarting corticosteroid therapy within two weeks because of exacerbation of symptoms[11,14]. Refractoriness was defined as no improvement of clinical symptoms despite continued corticosteroid use. Similarly, outcomes at one year were subdivided into three groups. Prolonged response was characterized by two conditions: maintaining complete or partial remission after discontinuation of corticosteroid therapy and requiring the same dose for more than two weeks or an increasing dose of corticosteroids only in the first three months. Steroid dependency was defined as restart of corticosteroid therapy due to recurrent flare-up of UC after the first three months or being unable to reduce prednisolone to 10 mg/day within three months. Non-response was defined in the same way as for the intermediate outcomes.

Statistical analysis

Continuous variables were presented as the mean ± SD or median (range) and were compared using two-sample *t* tests. Categorical variables were compared by χ^2 tests or Fisher's exact test. Logistic regression analysis was performed to identify predictive variables of clinical outcomes. *P* values less than 0.05 were considered statistically significant. All the statistical analyses were performed using the statistical software package SPSS 12.0 for Windows (SPSS Inc., Chicago, IL).

Table 1 Baseline characteristics of patients with active ulcerative colitis receiving intravenous corticosteroids after oral corticosteroid therapy failure

	Total patients (*n* = 67)
Gender (male/female)	39/28 (58.2/41.8)

RESULTS

Patient characteristics

A total of 67 patients, 39 men and 28 women, with active UC were included in this study (Table 1). The median age at diagnosis was 31 years (range: 11-78 years), and median disease duration at the time of oral corticosteroid therapy was 24 mo (range: 0-132 mo). The median length of oral corticosteroid use before intravenous therapy was 13 d (range: 3-50 d). Forty-one (61.2%) patients had extensive disease, and 32 (47.8%) had their first attack of active UC.

Clinical outcomes after intravenous corticosteroid therapy

Clinical outcomes of patients were organized in a flow chart (Figure 1). At two weeks after treatment, 56 (83.6%) patients responded to intravenous systemic corticosteroids. Seven of the 11 non-responders underwent proctocolectomy before day 14. Three patients were treated with an intravenous tumor necrosis factor-α blocker, and one patient was treated with intravenous cyclosporine. At one month after treatment, 18 (32.1%) patients were in complete remission, 26 (46.4%) in partial remission, and 12 (21.5%) had no response. Collectively, 21.5% of

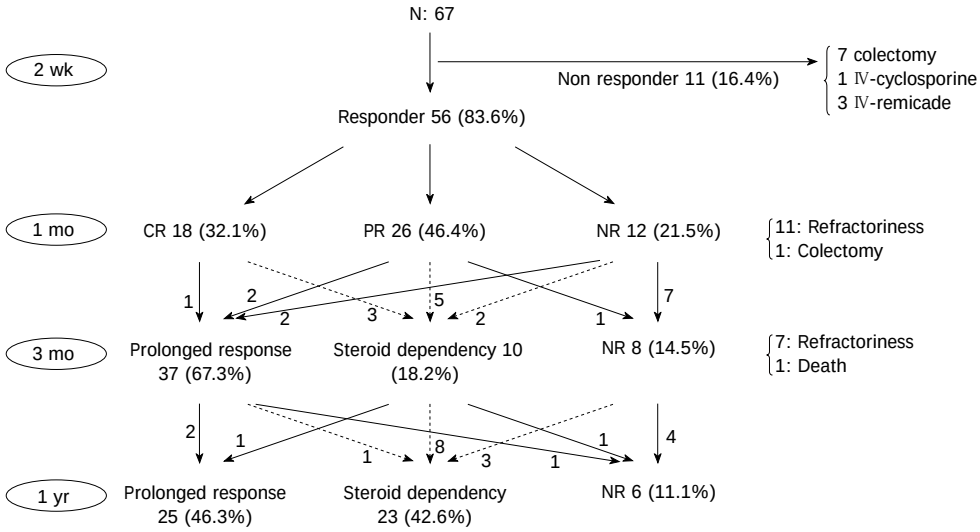

Figure 1 Clinical outcomes of patients with active ulcerative colitis treated with intravenous corticosteroids in oral corticosteroid refractory patients. CR: Complete remission; PR: Partial remission; NR: Non-response.

patients showed treatment failure to systemic corticosteroid therapy, and the other 78.5% of patients showed a partial or complete response to intravenous corticosteroid therapy. At three months, 37 patients had prolonged response, ten had steroid dependency, and seven showed no response. Of the 11 patients who were refractory to corticosteroid therapy at one month, two were in partial remission, two were steroid-dependent, seven had persistent refractoriness at three months, and one patient, a 59-year-old man who underwent proctocolectomy, died of pneumonia and sepsis. At one year, 25 of the 67 patients (37.3%) were categorized with prolonged response, 23 as steroid-dependent (34.3%), and six as non-responders (9.0%).

In our study, cytomegalovirus infection was detected in 5 patients. All were diagnosed by histologic examinations and were treated with ganciclovir. Of these, one patient underwent proctocolectomy within 14 d after the treatment. The rest of them responded to ganciclovir treatment. Finally, three patients were in partial remission and one patient was steroid dependent at one year.

Predictive factors for favorable outcomes

We performed univariate and multivariate analyses to detect clinical or laboratory factors capable of predicting poor outcomes of intravenous corticosteroid therapy after oral corticosteroid therapy failure. For the evaluation of intravenous corticosteroids at two weeks, we divided all patients into two groups: responders and non-responders who experienced death, proctocolectomy, or secondary medical treatment before two weeks. Patients were also divided into good responders and poor responders at one month, three months, and at one year after the corticosteroids therapy: good responders were those who showed a prolonged response, and poor responders were steroid-dependent or non-responsive. Multivariate analysis was carried out using the factors that were found to be statistically significant by univariate analysis.

For two weeks outcomes, univariate analysis of predictors for non-responders showed that disease duration (> 24 mo), duration of oral corticosteroids use (> 14 days), and lower hemoglobin level (≤ 11 mg/dL) were associated with poor prognosis. According to multivariate analysis, the duration of oral corticosteroids use (> 14 d *vs* ≤ 14 d, $P = 0.049$) and lower hemoglobin level (≤ 11.0 mg/dL *vs* > 11.0 mg/dL, $P = 0.02$) remained predictive factors for non-responders (Table 2). No predictive factors for poor responders at one month or three months were identified (Tables 3 and 4). For one year outcome, univariate analysis revealed that only a partial Mayo score (≥ 6 *vs* < 6, $P = 0.057$) was found to be associated with a poor response (Table 5).

DISCUSSION

We analyzed the clinical outcomes and identified predictive factors associated with corticosteroid responsiveness of patients who had an acute attack of UC and had been administered intravenous corticosteroids after a previous course of systemic oral corticosteroid therapy. There have been many previous studies that have reported the predictors of clinical response to systemic corticosteroid treatment in moderate to severe active UC patients[16-19]. However, there are few reports of outcomes of a conservative approach of intravenous steroid treatment in moderate to severe active UC patients after oral corticosteroid therapy failure.

In our study, intravenous corticosteroid therapy following a failure after oral corticosteroid therapy was successful at inducing response at two weeks of treatment in 83.6% of patients. This result implies that intravenous corticosteroids could be administered when a lack of response to oral corticosteroid therapy is shown. This

result was partly explained by previous pharmacokinetic studies, which demonstrated delayed prednisolone absorption after an oral dose in patients with acute colitis as compared to healthy controls and higher plasma levels after intravenous steroid administration[20,21]. In addition, intravenous steroid administration in the hospital ensures good treatment compliance.

The rate of failure of intravenous corticosteroid therapy in moderate to severe UC attacks was quite high, accounting for 30%-40% in recent studies investigating Western populations[16-19,22,23]. Moreover, Meyers *et al*[24] showed a better clinical improvement of intravenous corticotrophin therapy for acute UC in steroid-naïve patients than in patients who had already received steroid treatment. Considering that our enrolled patients were an oral corticosteroid failure group and approximately half of them were non steroid-naïve patients, our results at two weeks showed a much higher response rate to intravenous corticosteroid therapy compared with previous studies[16-19,22,23]. Moreover, In our study, 13.4% of patients underwent proctocolectomy or experienced death within one year, while the incidence of cumulative proctocolectomy was reported to be about one-fifth that of exacerbation of UC[25-27]. This difference in the results of steroid treatment reaffirms the previous report that UC patients in the Korean population have a lower cumulative probability of proctocolectomy compared to those in Western countries[28,29]. Taken together, these results suggest that Korean patients with UC might have a more favorable prognosis compared to Western counterparts. In order to investigate the clinical application of our results in the treatment of UC patients, further prospective studies are warranted.

One month after the initiation of intravenous corticosteroid therapy, 78.5% of patients (32.1% with complete response and 46.4% with partial response) showed clinical improvement, whereas 42.6% were dependent on steroids at one year. It has been previously reported that 22% of patients in a western study became steroid-dependent[3]. Recently, Yoon *et al*[10] reported that a steroid-naïve Korean UC patient showed a good response to steroid treatment, while 40% of UC patients eventually became steroid-dependent or refractory. Our study showed that the responses to intravenous corticosteroids following a failure after oral corticosteroid treatment were similarly favorable in the short term period. However, more than half of patients eventually became steroid-dependent or refractory in the long term.

Reports evaluating predictive factors for poor clinical outcomes have shown different and controversial results. Some found no predictive factors[15,24,30] while others showed several factors related to clinical outcomes[16-19,22,23]. In our study, the UC duration, the duration of oral corticosteroid use, and lower hemoglobin level were associated with failure of steroid treatment on univariate analysis. Of these variables, only duration of oral corticosteroid therapy and lower hemoglobin level were found to be independently associated with failure of corticosteroid therapy on multivariate analysis. Knowledge of the clinical factors associated with non-response to intravenous corticosteroid therapy after oral therapy may be useful in clinical decision-making. Our study was such an attempt to explain this situation. Our results showing the relationships between simple clinical factors, such as lower hemoglobin or duration of oral steroid use, and intravenous treatment outcome might help in predicting poor responders. Lower hemoglobin level as a risk factor for poor response in our study is in accordance with an earlier reports, which reflects that initial severity of disease might be a significant predictor of poor clinical outcome after steroid treatment[19,31,32]. Also, anemia is a common and important complication of IBD with a prevalence rate ranging from 8.8% to 66.6% in UC patients[33,34]. The quality of life, an ability of work, and cognitive function can be impaired because of anemia in IBD patients[35,36]. Impaired quality of life by anemia in UC patients could influence patient well-being sense and PGA. For this reason, lower hemoglobin level could be a risk factor for poor response in our study. However, none of the previous studies have evaluated duration of oral corticosteroid use before intravenous corticosteroids to predict outcome of corticosteroid therapy in patients with UC. We found that the duration of oral corticosteroid administration was an independent predictor of non-response to intravenous corticosteroid therapy on multivariate analysis in patients with acute exacerbation

[1]Good responders included patients with prolonged response that maintained complete remission or partial remission after corticosteroid therapy had finished; [2]Poor responders included patients with steroid dependence and non-response. M/F: Male/female; UC: Ulcerative colitis; CRP: C-reactive protein; ESR: Erythrocyte sedimentation rate.

of UC. Patients with UC with more severe disease activity achieved remission less often than who tended to achieve remission earlier[37]. The duration of oral corticosteroid therapy was likely to reflect the severity nature of UC in these non-responding patients. Additionally, prolonged oral corticosteroid therapy might be associated with mortality and morbidity such as infection and sepsis in UC patients undergoing surgery. With regard to the duration of intravenous corticosteroid treatment, the limit of 7-10 d for certifying the criteria of steroid resistance was based on historical series, which showed that the median time of remission of UC was 7.5 d and that prolonged treatment beyond 10 d did not increase the remission rate[37]. In contrast with this point of view, a large retrospective study of single experienced hospital was in favor of more conservative approach, which entered into remission within the 21 d of treatment[38]. Therefore it is difficult to define resistance to corticosteroid which day after treatment is used as a limit marker. None of the previous studies have shown duration of oral corticosteroid administration was an independent predictor of non-response to intravenous corticosteroid therapy. This result demonstrates that optimal timing of intravenous corticosteroids after oral therapy was an important clinical factor of medical treatment response. In other words, use of oral corticosteroids for more than two weeks appears to be less effective in terms of clinical outcome. Additionally, long term oral corticosteroids use could lead to worse clinical outcomes and complications. An extended pre-operative use of steroids might increase the risk of surgical complications[39,40]. UC patients undergoing an elective surgery have been shown to be at an increased risk of postoperative infectious complications in patients treated with corticosteroids[40]. In our study, a total of 9 patients underwent elective proctocolectomy within 1 year. Among of them, one patient died of pneumonia and sepsis after proctocolectomy. Therefore, in the management of UC, the optimal timing of administration of intravenous corticosteroids after oral corticosteroid failure should be determined within two weeks after oral corticosteroid therapy. However, the optimal time limit with oral corticosteroid therapy in the face of response has not been clearly defined by randomized controlled trials. Therefore, large scaled, prospective studies are needed to confirm this result.

Yoon *et al*[10] reported that partial Mayo score was a predictive factor of steroid dependency in steroid-naïve patients with UC. In our study, we also showed that initial higher partial Mayo score might be associated with long term poor prognosis of corticosteroid therapy. Considered overall, the partial Mayo scores could help to predict long term potential corticosteroid dependency or refractoriness in active UC patients who are treated with systemic corticosteroid therapy.

Our study on clinical outcomes and factors for response prediction after intravenous therapy after oral corticosteroids failure in active UC patient has clear clinical significance. There have been no previously published studies describing the clinical course of patients with acute attack of UC who were treated first with oral corticosteroids and subsequently intravenous corticosteroids. This study may provide valuable clinical data that can be used in the management of UC patients receiving oral corticosteroids therapy. Such studies could also be used to suggest optimal timing for administration of intravenous corticosteroids in UC patients who are treated with oral corticosteroids. Moreover, our enrolled UC patients possessed the quality of comparatively homogenous corticosteroid therapy indication and same dose of corticosteroids. These facts might be advantageous in terms of eliminating confounding factors.

There were several limitations in our study. Our study was a retrospective study in a single tertiary hospital. Mucosal healing has emerged as an important treatment goal in UC because evidence is accumulating that it can alter the clinical course of UC. However, evidence of cortico-

steroid's ability to promote mucosal healing is limited. A considerable portion of a period in this study was at moment before mucosal healing has emerged as an emerging parameter in UC. Then we could not evaluate the mucosal healing as a parameter of clinical outcomes in this study. Moreover, our study was not a placebo-controlled comparative study. Finally, the sample size was relatively small.

In conclusion, our study showed that most Korean patients with active UC responded well to intravenous corticosteroid therapy after oral corticosteroid therapy failure. However, a considerable number of patients turned out to be refractory to or dependent on this therapy. The duration of oral corticosteroid therapy and lower hemoglobin level were strongly associated with poor outcome. Further prospective studies are warranted to confirm these results and to determine the optimal timing and dose of corticosteroids.

COMMENTS

Background

Ulcerative colitis (UC) is a chronic inflammatory disease of the colon with unknown etiology and is characterized by a typical natural course with recurrent flares of mucosal inflammation. Systemic corticosteroids remain as the gold standard treatment of acute moderate to severe UC. For those who also do not respond to orally administered steroids, hospital admission is usually required for intensive intravenous treatment. However, there has been no published study describing the clinical course of patients with acute attack of UC who were treated first with oral corticosteroids and subsequently with intravenous corticosteroids due to oral steroid failure.

Research frontiers

This study showed that the duration of oral corticosteroids use (> 14 d *vs* ⩽ 14 d, $P = 0.049$) and lower hemoglobin level (⩽ 11.0 mg/dL *vs* > 11.0 mg/dL, $P = 0.02$) was predictive factors for non-responders. Lower hemoglobin level and duration of corticosteroids may be useful in clinical decision-making as the clinical factors associated with non-response to intravenous corticosteroid therapy after oral therapy.

Innovations and breakthroughs

These results showing the relationships between lower hemoglobin or duration of oral steroid use, and intravenous treatment outcome might help in predicting poor responders. Low hemoglobin level as a risk factor for poor response is in accordance with an earlier report which reflects that initial severity of disease might be a significant predictor of poor clinical outcome. However, none of the previous studies have evaluated duration of oral corticosteroid use before intravenous corticosteroids to predict outcome of corticosteroid therapy in patients with UC. This result demonstrates that optimal timing of intravenous corticosteroids after oral therapy was an important clinical factor of medical treatment response.

Peer review

This paper is well written and the authors highlight the limitation of the study appropriately in their discussion: Retrospective design, not strictly comparative in terms of therapies, and small numbers. Nonetheless, there is an important observation in terms of better management of patients with UC. Some of the findings have been previously reported (low hemoglobin as a risk factor for refractoriness) but it is valuable to see the principles applied to a different population. The comparative data is compelling and statistically significant using appropriate methods. Duration of oral steroid administration may be a very useful predictor of outcome in these cases. The authors are right to emphasize the need for further study in this area.

Abstract

AIM: To investigate the effect of novel probiotics on the clinical characteristics of high-fructose induced metabolic syndrome.

METHODS: Male Wistar rats aged 4 wk were fed a 70% w/w high-fructose diet (n = 27) or chow diet (n = 9) for 3 wk to induce metabolic syndrome, the rats were then randomized into groups and administered probiotic [*Lactobacillus curvatus* (*L. curvatus*) HY7601 and *Lactobacillus plantarum* (*L. plantarum*) KY1032] at 10^9 cfu/d or 10^{10} cfu/d or placebo by oral gavage for 3 wk. Food intake and body weight were measured once a week. After 6 wk, the rats were fasted for 12 h, then anesthetized with diethyl ether and sacrificed. Blood samples were taken from the inferior vena cava for plasma analysis of glucose, insulin, C-peptide, total-cholesterol, triglycerides and thiobarbituric acid-reacting substances. Real-time polymerase chain reaction was performed using mouse-specific Taqman probe sets to assess genes related to fatty acid β-oxidation, lipogenesis and cholesterol metabolism in the liver. Target gene expression was normalized to the housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase.

RESULTS: Rodents fed a high-fructose diet developed clinical characteristics of the metabolic syndrome including increased plasma glucose, insulin, triglycerides, total cholesterol and oxidative stress levels, as well as increased liver mass and liver lipids compared to chow fed controls. Probiotic treatment (*L. curvatus* HY7601 and *L. plantarum* KY1032) at high (10^{10} cfu/d) or low dosage (10^9 cfu/d) lowered plasma glucose, insulin, triglycerides and oxidative stress levels. Only high-dose probiotic treatment reduced liver mass and liver cholesterol. Probiotic treatment reduced lipogenesis *via* down-regulation of SREBP1, FAS and SCD1 mRNA levels and increased β-oxidation *via* up-regulation of PPARα and CPT2 mRNA levels.

CONCLUSION: Probiotic *L. curvatus* HY7601 and *L. plantarum* KY1032 combined suppressed the clinical characteristics of high-fructose-induced metabolic syndrome, therefore, may provide a natural alternative for the treatment of diet-induced metabolic syndrome.

INTRODUCTION

Metabolic syndrome is a rapidly growing worldwide pandemic, which is associated with a greater risk of multiple chronic pathologies including cardiovascular disease and Type 2 diabetes. Metabolic syndrome is characterised by a cluster of metabolic abnormalities including insulin resistance, elevated fasting glucose, elevated plasma triglycerides, elevated blood pressure, low-grade inflammation, abdominal obesity and reduced high-density lipoprotein (HDL)-cholesterol[1,2]. There is no universal cause of metabolic syndrome, although major underlying risk factors include abdominal obesity, physical inactivity or diabetogenic diets[1].

Diabetogenic diets with high fructose content have been strongly implicated in the development of metabolic syndrome, cardiovascular disease and Type 2 diabetes[3]. Food manufacturers are increasingly using fructose corn syrup to increase sweetness, as well as the palatability of food and beverages. However, there is growing experimental evidence that excessive fructose intake can lead to metabolic abnormalities, including insulin resistance, dyslipidemia as well as abdominal adiposity in both animals and humans[4]. Animals fed a high-fructose diet develop clinical characteristics of metabolic syndrome, therefore, high-fructose fed animals are particularly useful for assessing potential therapeutic interventions against metabolic syndrome[5]. Excess dietary fructose can be converted to triglycerides through *de novo* lipogenesis, resulting in increased lipid accumulation in the liver and elevated blood lipid levels. Over a period of time prolonged high intracellular and systemic lipid levels can cause increased oxidative stress and inflammation, both of which can trigger insulin resistance, leading to increased blood glucose levels. Due to the lack of effective drugs to treat metabolic syndrome, there is growing interest in natural therapeutics to prevent or manage metabolic syndrome.

Over the past five years, probiotics have rapidly emerged as natural therapeutics with potential to target key risk factors associated with metabolic syndrome[6,7]. Probiotics consist of single or multiple live bacterial species, which may directly or indirectly modulate gut microbial activity and improve host health. The human gut harbours between 10^{14} bacterial species collectively forming the gut microbiota[8]. Gut microbial communities are proposed to provide the host with the ability to harvest otherwise inaccessible energy from the diet[9-11] and modulate host genes associated with energy storage in adipose tissue[2,12]. Probiotics have been widely assessed *in-vivo* in diet-induced obesity models[13-17], however, different probiotic species even from the same family can exert variable effects on lipid accumulation and obesity[18], therefore, it remains essential to assess the effectiveness of probiotic strains in different animal disease models *in-vivo*. Probiotic yogurt containing multiple *Lactobacillus* strains has been reported to alleviate fasting blood glucose, plasma insulin and triglyceride in high-fructose fed rats[19]. However, few other studies have considered the impact of probiotics on high-fructose diet-induced metabolic syndrome. To our knowledge, the dose-dependent and metabolic effects of probiotic treatment in high-fructose-induced metabolic syndrome remain to be established.

The aim of this study was to assess the dose-dependent effects of a probiotic consisting of *Lactobacillus curvatus* (*L. curvatus*) HY7601 and *Lactobacillus plantarum* (*L. plantarum*) KY1032 on hyperlipidemia, hyperglycemia, insulin resistance, oxidative stress and hepatic metabolism related gene expression in high-fructose fed rats with metabolic syndrome. We hypothesized that probiotic treatment may protect against dysregulated metabolism induced by a high-fructose diet in a dose-dependent manner.

MATERIALS AND METHODS

Animals, diets and experimental design

Male Wistar rats (n = 36) aged 4 wk were purchased from Jackson Laboratories (Bar Harbor, United States). All rats were individually housed under a constant temperature and humidity (22 ± 1 ℃, 55% ± 10%) with a 12 h light/12 h dark cycle. The experimental design consisted of a pretreatment phase (0-3 wk) and a treatment phase (3-6 wk). During the pretreatment phase, male Wistar rats were fed a 70% w/w high-fructose diet (n = 27) to induce metabolic abnormalities or a chow diet (n = 9) for 3 wk. The composition of the high-fructose diet was formulated according to Table 1. During the treatment phase, the placebo (HF) group (n = 9), low dose probiotic (LP) group (n = 9) and high dose probiotic (HP) group (n = 9) were fed the same high-fructose diet with placebo, 10^9 cfu probiotics or 10^{10} cfu probiotics, respectively, administered orally each day for a further 3 wk. The chow control group was fed the same chow diet with placebo administered orally each day for a further 3 wk. Freeze-dried *Lactobacillus* strains were produced by Culture Systems Inc. (United States), and packed with lactose according to Table 2. Each pack was resuspended in 500 μL distilled water prior to administration. Food intake and body weight were measured once a week. Before sacrifice, rats were fasted for 12 h and anesthetized with diethyl ether. Blood samples were taken from the inferior vena cava for plasma analysis. Epididymal adipose tissue and liver tissue were removed, rinsed with phosphate buffered saline, weighed and immediately frozen at -70 ℃. The experimental design was approved by the Ethics Committee of Korea Yakult Company Limited R and D Center.

were determined using the glucose assay kit (Cayman, United States), insulin enzyme-linked immunosorbent assay (ELISA) kit (Millipore, United States) and rat C-peptide ELISA kit (EIAab, China), respectively, according to the manufacturer's instructions. Insulin resistance was assessed based on homeostasis model assessment of insulin resistance (HOMA-IR), calculated as the product of fasting plasma glucose (FPG) and insulin (FPI), divided by a constant[20]. The equation was [FPG (mg/dL) × FPI (μU/mL)]/2430. Plasma total-cholesterol and triglyceride concentrations were determined using commercial kits (AsanPharm, South Korea). Plasma thiobarbituric acid-reacting substances (TBARS) were measured to assess oxidative stress as described previously[21].

Hepatic lipid profile analysis

Hepatic lipids were extracted as previously reported[22]. The dried lipid residues were dissolved in 1 mL of isopropanol for the triglyceride and cholesterol assays. Hepatic triglyceride and cholesterol concentrations were measured using the same commercial kits (AsanPharm, South Korea) used for the plasma analysis.

RT-qPCR

Total RNA was extracted from liver (15 mg) tissue using an RNAqueous kit (Ambion, United States). DNA was removed with a Turbo DNA-free kit (Ambion, United States). RNA integrity was verified and RNA quantified using a GeneQuant Pro spectrophotometer (GE Healthcare, United States). Total RNA (2 μg) was reverse-transcribed into cDNA with a high-capacity RNA-to-cDNA kit (Applied Biosystems Inc., United States). Then cDNA was amplified on a 7500 Real Time PCR System (Applied Biosystems Inc., United States) using mouse-specific Taqman probe sets (Table 3) under the following conditions: 95 ℃ for 10 min, followed by 40 cycles at 95 ℃ for 15 s, and 60 ℃ for 1 min. Target gene expression was normalized to the housekeeping gene, glyceraldehyde-3-phosphate dehydrogenase (catalog number Rn01775763_g1). Data was analyzed using the ABI 7500 System Sequence Detection software (Applied Biosystems Inc., United States) and presented as mean ± SE.

Table 3 Catalog numbers of Taqman probes

Taqman probe	Catalog number

Sterol regulatory element binding protein-1	Rn01495769_m1
Fatty acid synthase	Rn00569117_m1
Stearoyl-CoA desaturase 1	Rn00594894_g1
Cholesterol 7 alpha-hydroxylase	Rn00564065_m1
Low density lipoprotein receptor	Rn00598442_m1

Statistical analysis

All data were presented as mean ± SE. Statistical analysis was performed using SPSS software (SPSS Inc., United States). Data were analyzed by one way analysis of variance, and the differences between experimental groups were evaluated using Duncan's multiple range test at the $P < 0.05$ level. Significant differences between chow control and HF control groups were determined using unpaired Student's *t*-test. Significant differences between week 3 and week 6 in each parameter were determined using the paired Student's *t*-test, and the values were considered statistically significant when $P < 0.05$.

RESULTS

Effects of probiotic treatment on food intake, body weight and tissue mass

Metabolic syndrome was induced in rodents by feeding them a high-fructose diet over 3 wk, while a control group was fed a chow diet. Rodents with metabolic syndrome were then randomized into three treatment groups and fed a high-fructose diet for a further 3 wk, with daily treatment of either probiotic (HP) at a dose of 1×10^{10} cfu/d, probiotic (LP) at a dose of 1×10^9 cfu/d or placebo administered by oral gavage. The chow control group were fed the same diet for the same period and administered placebo by oral gavage. Average food intake was suppressed in the high-fructose diet fed rodents compared to the chow fed controls (Figure 1A). However, low or high dose probiotic treatment had no significant effect on food intake (Figure 1A). Body weight gain and epididymal fat mass were not significantly affected by high-fructose feeding or probiotic treatment regardless of dosage (Figure 1B and C). Importantly, average liver

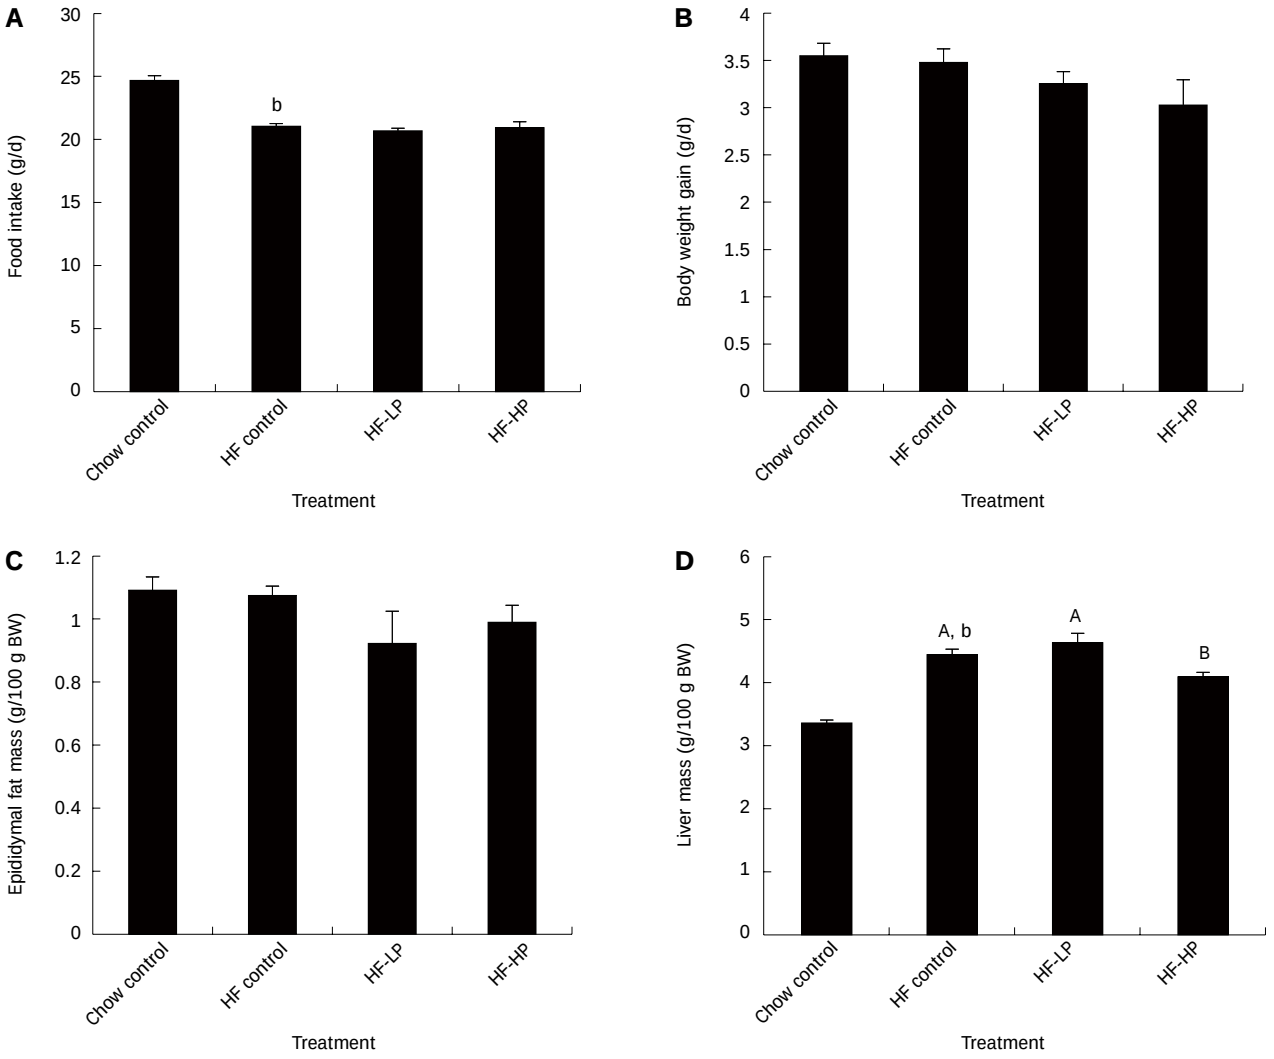

Figure 1 Effects of probiotic treatment on food intake (A), body weight gain (B), epididymal fat mass (C) and liver mass (D) in high-fructose diet-fed rats. Results are expressed as mean ± SE. $^{b}P < 0.01$ *vs* chow control by unpaired Student's *t*-test; ^{AB}Bars with different capital letters are significantly different at $P < 0.05$ by Duncan's multiple range tests. HP: High dose probiotic; HF: High fructose diet; LP: Low dose probiotic; BW: Body weight.

mass, which was significantly increased by high-fructose diet, was significantly lower following HP treatment by 10% ($P < 0.01$) compared to high-fructose fed controls (Figure 1D).

Effects of probiotic treatment on dyslipidemia

Hypertriglyceridemia was effectively induced by a high-fructose diet within 3 wk (163.91 ± 6.50 mg/dL *vs* 49.26 ± 3.99 mg/dL, HF and chow group, respectively). However, subsequently 3-wk of probiotic treatment significantly reduced average plasma triglyceride levels by 46% compared to placebo treatment in the high-fructose fed rodents (Figure 2A). The probiotic treatment had no influence on either total cholesterol or HDL cholesterol levels, which were increased by high-fructose diet intake (Figure 2B and C).

Effects of probiotic treatment on hyperglycemia, insulin resistance and oxidative stress

The average plasma glucose levels of the high-fructose fed rats were significantly higher than that of the chow fed controls at week 6, but were effectively reduced following LP and HP treatment by 24% ($P < 0.05$) and 14% ($P < 0.05$), respectively, (Figure 3A). The average plasma insulin levels of the high-fructose fed rats were significantly higher at both weeks 3 and 6 compared to the chow fed controls. However, after HP treatment plasma, insulin levels were substantially lower (31%, $P < 0.05$) compared to the high-fructose fed rats. Moreover, the plasma insulin levels following LP and HP treatment were reduced by 33% ($P < 0.01$) and 29% ($P < 0.05$), respectively, compared to before treatment (Figure 3B). The HOMA-IR, a representative index of insulin resistance, was significantly higher in the high-fructose fed rats compared to the chow fed controls at week 6, but was significantly reduced by LP (35%) and HP (34%) treatment (Figure 3C). Furthermore, HOMA-IR following LP treatment was 25% ($P < 0.05$) lower compared to before treatment (Figure 3C). Plasma C-peptide is another biomarker associated with insulin resistance.

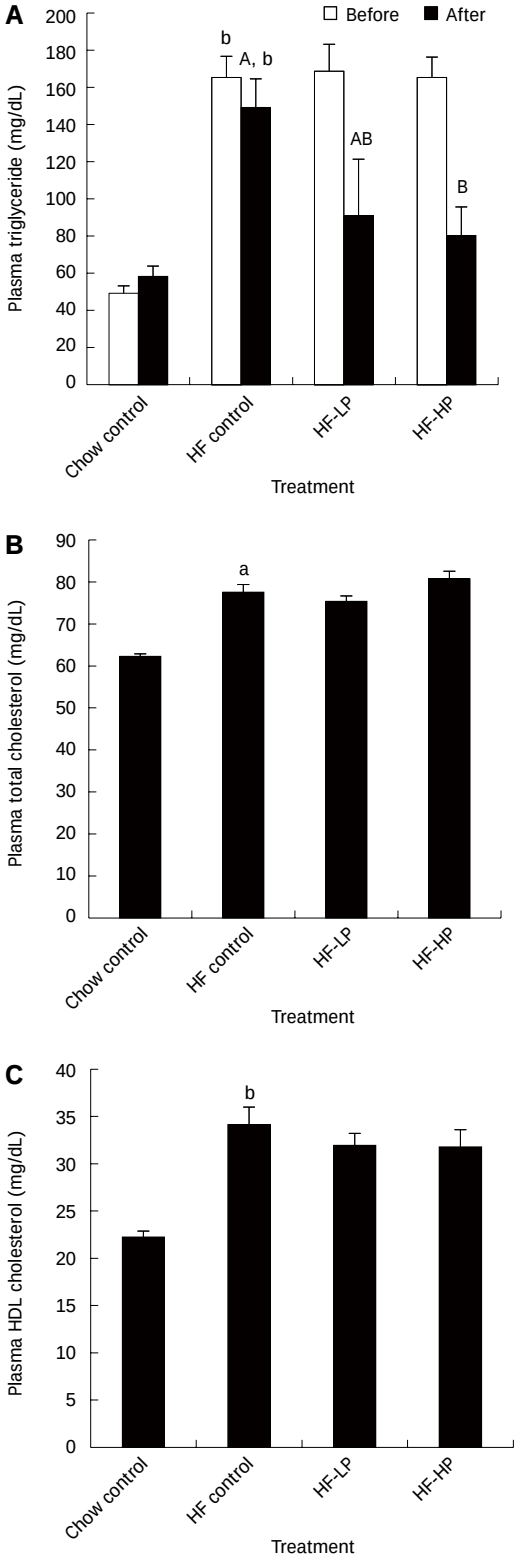

Figure 2 Effects of probiotic treatment on plasma triglyceride (A), plasma total cholesterol (B) and plasma high-density lipoprotein cholesterol (C) in high-fructose diet-fed rats. Results are expressed as mean ± SE. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* chow control by unpaired Student's *t*-test; ^{AB}Bars with different capital letters are significantly different at $P < 0.05$ by Duncan's multiple range tests. HF: High fructose diet; HP: High dose probiotic; LP: Low dose probiotic; HDL: High-density lipoprotein.

Plasma C-peptide level was 24% ($P < 0.05$) lower following HP treatment compared to placebo treatment in high-fructose fed rats (Figure 3D). Moreover, plasma C-peptide levels after HP treatment were 28% ($P < 0.05$) lower compared to before treatment (Figure 3D). In addition, probiotic treatment of either LP or HP decreased plasma TBARS levels by 37% ($P < 0.01$) and 50% ($P < 0.001$), respectively (Figure 3E).

Effects of probiotic treatment on hepatic lipid content and gene expression

Both hepatic triglyceride and cholesterol levels in the high-fructose fed rats were significantly higher than those in the chow fed controls. Probiotic treatment with either LP or HP tended to reduce hepatic triglyceride levels (Figure 4A), and HP significantly reduced (27%, $P < 0.05$) hepatic cholesterol levels compared to the high-fructose fed controls (Figure 4B).

In order to determine the mechanisms underlying the probiotic effect on hepatic lipid homeostasis, we examined the mRNA levels of hepatic genes associated with lipid metabolism (Figure 5A-C). High-fructose diet intake altered gene expression compared to chow diet intake. The changes in gene expression in the high-fructose group indicated decreases in fatty acid β-oxidation (PPARα, CPT1, CPT2 and ACOX1), cholesterol uptake (LDLR) and bile acid synthesis (CYP7A1), and increases in fatty acid synthesis (SREBP1, FAS, SCD1). Importantly, HP treatment significantly reversed high-fructose-induced gene expression changes including up-regulation of PPARα (+76%), CPT2 (+66%) and CYP7A1 (+71%), and down-regulation of SREBP1 (-30%), FAS (-54%) and SCD1 (-23%), although LP treatment did not cause any significant changes in hepatic lipid metabolism gene expression.

DISCUSSION

Recent studies indicate that the gut microbiota plays an important role in host lipid and glucose metabolism. Therefore, therapeutic probiotics which can manipulate the gut microbiota may also prevent some of the risk factors underlying the development of metabolic syndrome including dyslipidemia, elevated fasting glucose levels and insulin resistance[23]. In the present study, we used a novel probiotic consisting of *L. curvatus* HY7601 and *L. plantarum* KY1302 isolated from Korean fermented cabbage. We showed that probiotic administered to high-fructose fed mice reversed the risk factors underlying the metabolic syndrome. Previous evidence from high-fructose diet-fed rat studies indicated that a probiotic-cultured yogurt called Dahi can also improve metabolic abnormalities[19,24]. Importantly, in the present study, we established the dose-dependent effects of a novel combination of probiotic strains on metabolic syndrome.

High-fructose intake is reported to promote lipogenesis and suppress glucose intake[25-27]. Consistent with other studies of high-fructose fed animals, hepatic gene expression analysis indicated that lipogenesis was increased *via*

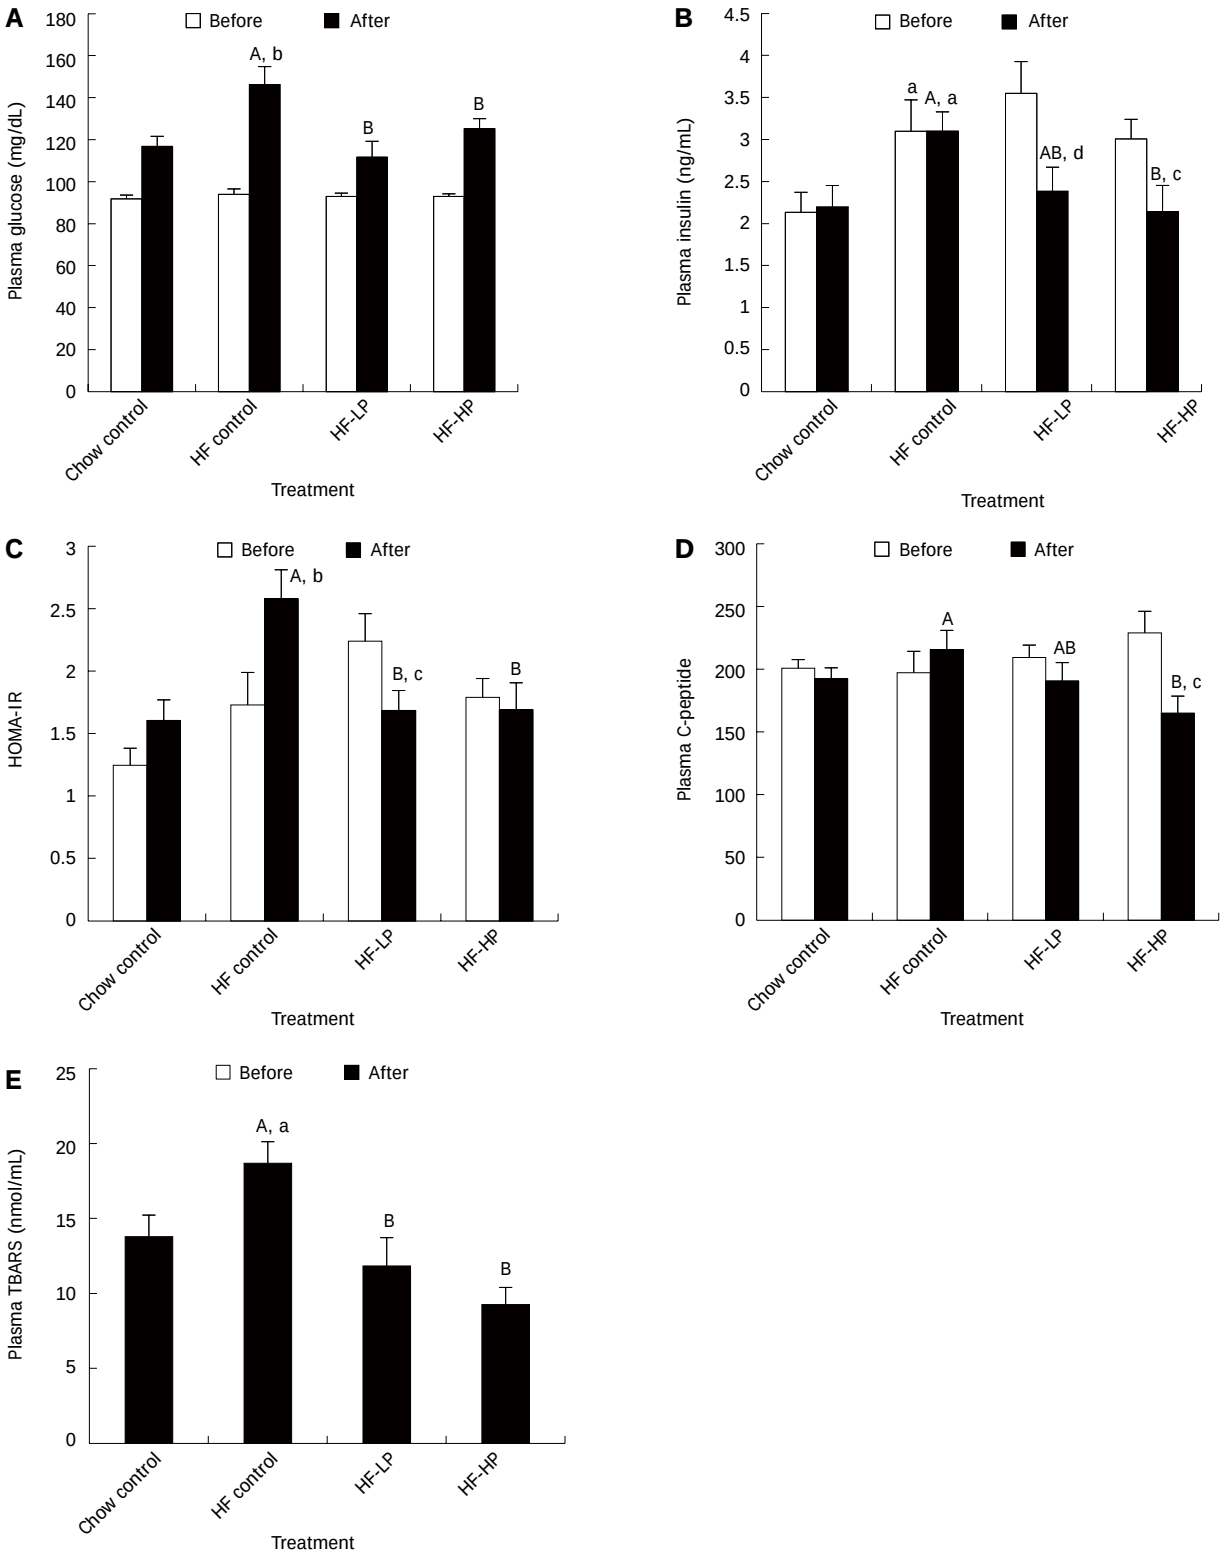

Figure 3 Effects of probiotic treatment on plasma glucose, plasma insulin, insulin resistance, plasma C-peptide and plasma thiobarbituric acid-reacting substances in high-fructose diet-fed rats. Results are expressed as mean ± SE. [a]*P* < 0.05 and [b]*P* < 0.01 HF control *vs* chow control by unpaired Student's *t*-test; [c]*P* < 0.05 and [d]*P* < 0.01 week 6 *vs* week 3 by paired Student's *t*-test; [AB]Bars with different capital letters are significantly different at *P* < 0.05 by Duncan's multiple range tests. HF: High fructose diet; LP: Low dose probiotic; HP: High dose probiotic; TBARS: Thiobarbituric acid-reacting substances.

upregulation of SREBP1, FAS and SCD1, conversely β-oxidation was decreased *via* downregulation of PPARα and PPARα-regulated CPT1, CPT2 and ACOX1 expression[25-27]. Increased lipogenesis and decreased β-oxidation lead to excess accumulation of cellular lipids, as shown by the liver enlargement and hypertriglyceridemia in the high-fructose fed rats in the present study. Hypertriglyceridemia is known to be an important predictor of car-

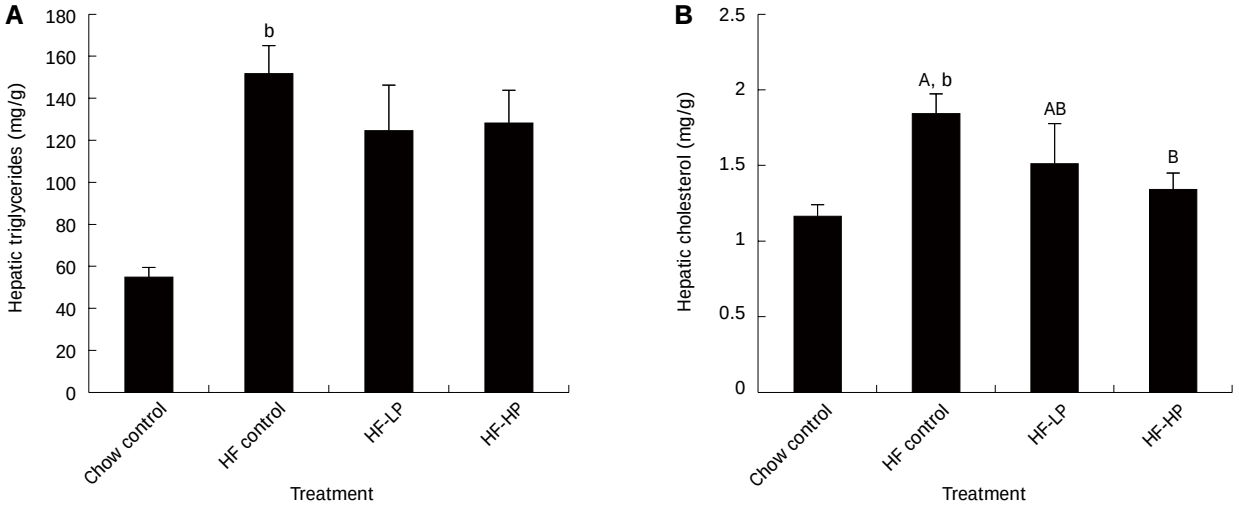

Figure 4 Effects of probiotic treatment on hepatic triglyceride and hepatic total cholesterol in high-fructose diet-fed rats. Results are expressed as mean ± SE. $^{b}P < 0.01$ HF control *vs* chow control by unpaired Student's *t*-test; ^{AB}Bars with different capital letters are significantly different at $P < 0.05$ by Duncan's multiple range tests. HF: High fructose diet; LP: Low dose probiotic; HP: High dose probiotic.

diovascular disease mortality in subjects with diabetes or impaired glucose tolerance[28], therefore, reducing plasma triglyceride levels may improve long-term health.

Previous studies have shown that probiotics can alter the gut microbiota[29], and direct gut microbiota manipulations in germ-free mice significantly affect host lipid metabolism[2,12]. Here we showed that 10^{10} cfu/d probiotic treatment led to upregulated PPARα and CPT2 expression reflecting activation of β-oxidation, and downregulated SREBP1, FAS and SCD1 expression reflecting suppression of lipogenesis. Moreover, these probiotics induced transcriptional changes which resulted in a significant reduction in liver mass and plasma triglyceride levels. These findings are consistent with a previous report which showed that *L. plantarum* KY1032 inhibits lipid droplet accumulation during adipocyte differentiation. In contrast to plasma triglyceride levels, hepatic triglyceride levels were only slightly reduced by probiotic treatment. We hypothesized that the probiotic-induced increase in hepatic β-oxidation related gene expression was partly to clear excess hepatic triglycerides generated through high-fructose-induced *de novo* lipogenesis.

Contrary to hepatic triglyceride levels, cholesterol levels were significantly reduced by probiotic treatment, whereas plasma cholesterol levels were unchanged. We assessed whether the reduction in hepatic cholesterol following probiotic treatment was due to altered hepatic cholesterol metabolism related gene expression. High-fructose diet suppressed CYP7A1 expression, which encodes cholesterol 7 α-hydroxylase, the rate-limiting enzyme involved in the formation of bile from cholesterol. However, 10^{10} cfu/d probiotic treatment upregulated CYP7A1 expression indicating increased bile synthesis activity. Some probiotics are also reported to increase bile salt hydrolase activity[30]. Hepatic LDLR expression remained unchanged, suggesting that probiotic treatment did not enhance uptake of plasma cholesterol into the liver, which is consistent with the absence of changes in plasma cholesterol levels. However, the effect of probiotics on liver cholesterol metabolism may be partly dependent on the diet regime used, because in high-fat or high-cholesterol diet fed animals, probiotics are reported to decrease plasma and hepatic cholesterol levels together.

The probiotic effect on host lipid levels may also contribute to the observed improvement in glucose homeostasis. Excess intracellular lipids can inhibit insulin signalling, hence reduce insulin-stimulated glucose uptake leading to hyperglycemia and hyperinsulinemia as shown in this study. We observed that probiotic treatment at 10^{9} or 10^{10} cfu/d significantly lowered plasma glucose, insulin and C-peptide concentrations, and reduced insulin resistance indicated by the reduced HOMA-IR index[20,31]. Excess fructose intake is also reported to promote lipid peroxidation and oxidative stress is implicated in the pathogenesis of insulin resistance[32,33]. In the present study, probiotic treatment at 10^{9} or 10^{10} cfu/d significantly reversed the oxidative stress present in the high-fructose fed rats with metabolic syndrome, indicated by lower plasma TBARS levels. Some *Lactobacillus* strains are also reported to possess anti-oxidative activity. For example, probiotics have been reported to reduce exercise-induced oxidative stress, *via* increases in anti-oxidative activity, which helps neutralize reactive oxygen species[34]. Furthermore, studies in human Type 2 diabetes show probiotic supplementation can increase superoxide dismutase and glutathione peroxidase activities[35], which are anti-oxidants that help protect against oxidative stress.

While evidence is growing on the effects of probiotic treatment on many chronic pathologies, some issues remain to be addressed. Probiotics are widely assumed to modulate the gut microbiota, and exert health benefits *via* direct modification of gut microbial communities[8]. Studies on diet-induced mice indicate that probiotics alter the gut microbiota[29], similar to our recent experience with the same probiotic used in this study (unpublished observations). However, in another study using germ-

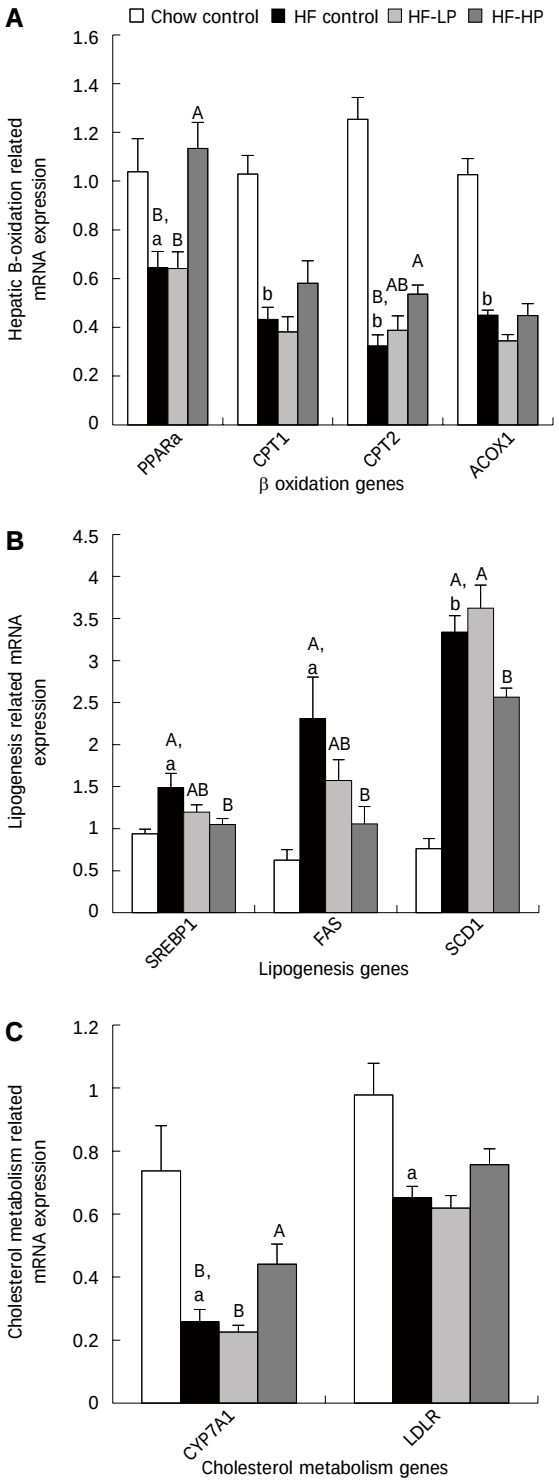

Figure 5 Effects of probiotic treatment on hepatic B-oxidation, lipogenesis and cholesterol metabolism related gene expression in high-fructose diet-fed rats. Results are expressed as mean ± SE. $^{a}P < 0.05$ and $^{b}P < 0.01$ HF control *vs* chow control by unpaired Student's *t*-test; ^{AB}Bars with different capital letters are significantly different at $P < 0.05$ by Duncan's multiple range tests. HF: High fructose diet; LP: Low dose probiotic; HP: High dose probiotic; FAS: Fatty acid synthase; SREBP1: Sterol regulatory element-binding protein-1; PPARα: Peroxisome proliferator-activated receptor α; CPT: Carnitine palmitoyltransferase; ACOX: Acyl-coenzyme A oxidase; SCD: Steaoryl-CoA desaturase; CYP7A1: Cholesterol 7α-hydroxylase gene; LDLR: Low-density lipoprotein receptor.

free mice transplanted with a small artificial gut microbial community, a multi-species probiotic failed to change the gut microbiota[36]. Whether multi-species probiotics are more effective than single-species probiotics is not clear, because few studies make this comparison. We used a two species probiotic in the present study, and based on our preliminary data the results suggest that combined species are more effective than either species alone. Finally, whether probiotics exert dose-dependent effects against metabolic syndrome has not been evaluated, nor has the minimum amount of live bacteria that is necessary for functional health benefits. Evidence from the present study indicates that probiotics containing 10^{10} cfu/d showed the greatest effectiveness against high-fructose-induced metabolic syndrome over a relatively short period, without any adverse effects. In contrast, probiotic treatment at 10^{9} cfu/d exerted minimal effects on hypertriglyceridemia, but effectively improved hyperglycaemia and insulin resistance. In the case of hepatic gene expression, 10^{9} cfu/d probiotic treatment had no modulatory effect on any of the genes tested, but probiotic treatment at 10^{10} cfu/d modulated lipogenesis and β-oxidation related genes.

In conclusion, probiotic *L. curvatus* HY7601 and *L. plantarum* KY1032 combined can suppress the clinical characteristics of high-fructose-induced metabolic syndrome, therefore, may provide a natural alternative for the treatment of diet-induced metabolic syndrome.

COMMENTS

Background

Metabolic syndrome is a growing health problem characterised by elevated blood sugar and blood lipid levels, insulin resistance, high blood pressure and abdominal obesity. Poor diet consisting of high sugar or high fat content is a major risk factor for metabolic syndrome. There is no universal treatment for metabolic syndrome. Probiotics found in fermented foods have emerged as a natural way of protecting against metabolic syndrome, but many probiotic strains have varying metabolic effects. Therefore, a major challenge for scientists is discovering probiotic strains, which may help protect against metabolic syndrome.

Research frontiers

Probiotic strains identified in kimchi, a traditional Korean fermented cabbage consumed regularly in South Asian countries, are reported to have various beneficial properties. Current research aims to determine whether these probiotic strains are effective in different animal models of disease including metabolic syndrome, Type 2 diabetes and obesity.

Innovations and breakthroughs

The authors showed that two probiotic strains, *Lactobacillus curvatus* (*L. curvatus*) HY7601 and *Lactobacillus plantarum* (*L. plantarum*) KY1032, can suppress metabolic abnormalities such as hypertriglyceridemia, hyperglycemia and insulin resistance in high-fructose-induced metabolic syndrome. These probiotic health benefits were associated with decreased lipogenesis and increased β-oxidation-related gene expression in the liver.

Applications

Probiotic with *L. curvatus* HY7601 and *L. plantarum* KY1032 may provide a natural supplement for the management of the underlying risk factors of metabolic syndrome.

Terminology

Probiotics consist of live micro-organisms which confer beneficial effects on host health. Hypertriglyceridemia is prolonged elevated triglyceride levels in blood. Hyperglycemia is prolonged elevated glucose levels in the blood. Insulin resistance is the inability of insulin to stimulate glucose uptake pathways in fat, skeletal muscle and the liver.

Peer review

This paper investigated the effect of novel probiotics on the clinical characteristics of high-fructose induced metabolic syndrome. The authors were suggesting a mechanism. One novel thing of this paper is that no one has looked at these specific microbes in this combination. It is well written.

Abstract

AIM: To investigate tumor response and survival in patients with postembolization fever (PEF) and to determine the risk factors for PEF.

METHODS: Four hundred forty-three hepatocellular carcinoma (HCC) patients who underwent the first session of transcatheter arterial chemoembolization (TACE) between January 2005 and December 2009 were analyzed retrospectively. PEF was defined as a body temperature greater than 38.0 ℃ that developed within 3 d of TACE without evidence of infection. The tumor progression-free interval was defined as the interval from the first TACE to the second TACE based on mRECIST criteria. Clinical staging was based on the American Joint Committee on Cancer tumor, node, metastases (TNM) classification of malignant tumors. All patients were admitted before their 1st TACE treatment, and blood samples were obtained from all patients before and after treatment. Clinicoradiological variables and host-related variables were compared between two groups: patients with PEF *vs* patients without PEF. Additionally, variables related to 20-mo mortality and tumor progression-free survival were analyzed.

RESULTS: The study population comprised 370 (85.4%) men and 73 (14.6%) women with a mean age of 62.29 ± 10.35 years. A total of 1836 TACE sessions were conducted in 443 patients, and each patient received between 1 and 27 (mean: 4.14 ± 3.57) TACE sessions. The mean follow-up duration was 22.23 ± 19.6 mo (range: 0-81 mo). PEF developed in 117 patients (26.41%) at the time of the first TACE session. PEF was not associated with 20-mo survival (P = 0.524) or computed tomography (CT) response (P = 0.413) in a univariate analysis. A univariate analysis further indicated that diffuse-type HCC (P = 0.021), large tumor size (≥ 5 cm) (P = 0.046), lipiodol dose (≥ 7 mL, P = 0.001), poor blood glucose control (P = 0.034), alanine aminotransferase (ALT) value after TACE (P = 0.004) and C-reactive protein (CRP) value after TACE (P = 0.036) served as possible risk factors correlated with PEF. The ALT value after TACE (P = 0.021) and lipiodol dose over 7 mL (P = 0.011) were independent risk factors for PEF in the multivariate analysis. For the 20-mo survival, poor blood sugar control (P < 0.001), portal vein thrombosis (P = 0.001), favorable CT response after TACE (P < 0.001), initial aspartate aminotransferase (P = 0.02), initial CRP (P = 0.042), tumor size (P < 0.001), TNM stage (P < 0.001) and lipiodol dose (P < 0.001) were possible risk factors in the univariate analysis. Tumor size (P = 0.03), poor blood sugar control (P = 0.043), and portal vein thrombosis (P = 0.031) were significant predictors of survival in the multivariate analysis. Furthermore, the tumor progression-free interval was closely associated with CRP > 1 mg/dL (P = 0.003), tumor size > 5 cm (P < 0.001), tumor type (poorly defined) (P < 0.001), and lipiodol dose (> 7 mL, P < 0.001).

CONCLUSION: PEF has no impact on survival at 20 mo or radiologic response. However, the ALT level after TACE and the lipiodol dose represent significant risk factors for PEF.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the seventh most common carcinoma worldwide and the third most common cause of cancer-related mortality[1]. In South Korea, the age-standardized incidence rate of HCC is 46.5 per 100 000 individuals[2]. Recent advances in treatment, including liver transplantation, surgical resection, percutaneous ethanol injection therapy, radiofrequency ablation and transcatheter arterial chemoembolization (TACE) have improved the prognosis for patients with HCC[3,4]. In addition, beneficial therapeutic options that may affect long-term cure include surgical resection, liver transplantation, and percutaneous ablation[5]. However, these curative therapies are feasible only for a small subset of patients with HCC[6]. Among the noncurative therapies, only chemoembolization, the most widely used treatment for unresectable HCC, has demonstrated a positive effect on survival[7]. In contrast, TACE can be employed for any type of HCC irrespective of tumor size, location, or number[8].

However, TACE inevitably results in a hypoxic insult to the HCC and the surrounding liver tissue[9], and postembolization syndrome is common[10]. Postembolization syndrome, which consists of temporary fever, ileus, and abdominal pain, is the most common side effect of chemoembolization, affecting 60% to 80% of patients with HCC[5,11]. Postembolization fever after TACE is the most significant adverse effect, and it frequently affects the duration of hospitalization and causes the needless administration of antibiotics, although the fever is self-limited in most cases. However, few data about postembolization fever have been reported. Therefore, we evaluated the risk factors and prognostic significance of postembolization fever in patients with HCC.

MATERIALS AND METHODS

Patients and methods

Four hundred forty-three HCC patients who underwent the first session of TACE between January 2005 and December 2009 were analyzed retrospectively. The diagnosis of HCC was confirmed histologically or based on consistent findings obtained from at least two imaging techniques: ultrasonography, computed tomography (CT), magnetic resonance imaging, and/or selective hepatic arterial angiography[12,13]. Clinical staging was determined based on the American Joint Committee on Cancer tumor, node, metastases (TNM) classification of malignant tumors[14].

Clinicoradiological variables were compared between two groups (patients with PEF *vs* patients without PEF). The host-related variables included age, sex, viral status, cause of HCC, Child-Pugh score, Eastern Cooperative Oncology Group (ECOG) performance status, white blood cell counts, aspartate aminotransferase (AST), alanine aminotransferase (ALT), α-fetoprotein (AFP), and 20-mo mortality. The tumor-related variables included maximal tumor size, number of tumors, TNM stage, radiological findings (poorly defined or well defined), portal vein thrombosis, and CT response after 1st TACE.

All patients were admitted before their 1st TACE, and blood samples were obtained from all patients before and after treatment. Serum AFP, CRP, blood chemistry and ECOG score at admission were measured. After the 1st TACE, the patients were carefully followed. Dynamic CT was performed after 4 wk and then every 3 to 6 mo (Figure 1).

Our institutional review board did not require approval because the procedures were performed for clinical reasons. Informed consent was obtained from all patients after the nature and purpose of the TACE procedure had been fully explained.

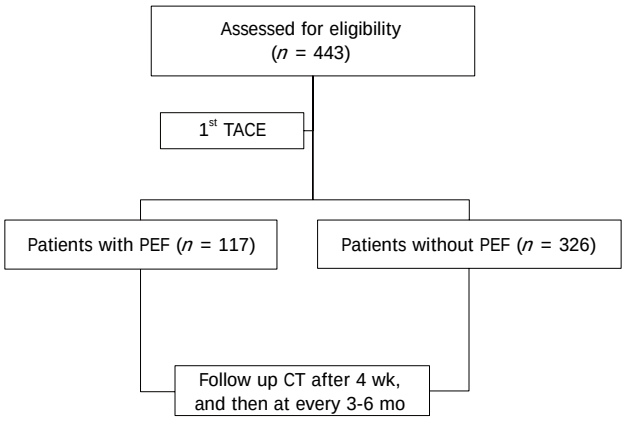

Figure 1 Flowchart of study patient enrollment. PEF: Postembolization fever; TACE: Transcatheter arterial chemoembolization; CT: Computed tomography.

Chemoembolization procedure

An arterial catheter was inserted into the femoral artery using the Seldinger method and placed in the hepatic artery. Tumor-feeding vessels were superselected whenever possible, and a solution containing 10 to 40 mg of doxorubicin hydrochloride (ADM; Dong-A Pharmacy, Seoul, Korea) and 0 to 40 mL of iodized oil (Lipiodol; Guer-

Table 1 Comparison of transcatheter arterial chemoembolization sessions with or without postembolization fever

Variables	Patients with PEF (n = 117)	Patients without PEF (n = 326)	P-value

Favorable tumor response	61 (52.5%)	155 (48.5%)	0.516
20-mo mortality	60 (51.7%)	172 (53.4%)	0.828
Initial WBC/mm^3	5969 ± 3497	5547 ± 2535	0.194
Initial AST U/L	68.87 ± 45.49	64.11 ± 44.79	0.358
Initial ALT U/L	50.84 ± 41.58	43.89 ± 33.16	0.129
Initial CRP mg/dL	1.23 ± 1.66	0.86 ± 0.93	0.116
Initial AFP IU/mL	2778 ± 8014	2600 ± 8656	0.857
Child-Pugh score	5.66 ± 0.72	5.77 ± 0.97	0.296
TNM stage	1.95 ± 1.05	1.83 ± 1.07	0.305
Interval from 1st TACE to 2nd TACE (d)	157 ± 225	180 ± 270	0.412
Total TACE sessions	1.48 ± 3.45	4.02 ± 3.62	0.230

TACE: Transcatheter arterial chemoembolization; AFP: α-fetoprotein; PEF: Postembolization fever; TNM: Tumor, node, metastases; CRP: C-reactive protein; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; HCC: Hepatocellular carcinoma; M: Male; F: Female; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

bet, Aulnay-sous-Bois, France) with absorbable gelatin particles (Gelfoam; Upjohn, Kalamazoo, Michigan) was injected through the catheter (5F) or microcatheter (2.8 or 3F). The doses of doxorubicin and iodized oil were individually determined according to tumor size, tumor extent, and the patient's underlying liver function.

Monitoring and management of postembolization fever

For the purpose of this study, we defined postembolization fever as a body temperature greater than 38.0 ℃ during the 3 d after TACE. Body temperature was measured *qid* by nurses using an axillary thermometer. Bacterial cultures from blood and urine and chest X-rays were performed for patients who had fevers after TACE to detect any potential infectious agents. Empirical broad-spectrum intravenous antibiotics were used to treat potential infections if there was fever but were discontinued when bacterial cultures did not reveal any causative agent and the fever had subsided. Ultrasonography or CT scans were performed if the fever persisted despite the use of antibiotics to detect the possible formation of an abscess. Acetaminophen or nonsteroidal anti-inflammatory drugs were used for symptom control, if necessary.

Response assessment

The efficacy of TACE was evaluated by comparing the CT scans obtained before and after chemoembolization in terms of iodized oil uptake patterns in the tumor that could be considered necrotic[12] and tumor extent. The iodized oil uptake was considered compact if the oily contrast medium was clearly dispersed through all viable target tumors but was noncompact in all other cases[8]. Tumor response to TACE was defined as a compact uptake of iodized oil or at least a 30% decrease in the sum of the largest diameters of viable tumors, despite noncompact iodized oil uptake.

Definitions

PEF was defined as a body temperature greater than 38.0 ℃ that developed within 3 d of TACE without evidence of infection. Poor blood glucose control was defined as a mean blood glucose level > 200 mg/dL. Poorly defined tumor type was defined as diffuse-type HCC, whereas well-defined tumor type was defined as nodular HCC. Tumor progression-free survival was defined as the interval during and after treatment in which a patient remained alive and the disease did not worsen (in this case, the interval from the 1st TACE to the 2nd TACE).

Statistical analysis

Comparisons were performed using the student's t test for continuous variables and Pearson's χ^2 test. Factors that were significant in the univariate analysis were entered into a stepwise multivariate analysis to identify the most significant risk factors. The hazard function data were estimated using the Kaplan-Meier curve and compared using the log-rank test. Multivariate analyses were performed using the Cox proportional hazards model to identify prognostic factors. We performed statistical analyses using SPSS 17.0 (SPSS Inc., Chicago, United States). A P-value less than 0.05 was considered statistically significant.

RESULTS

Fever after TACE and clinical features

The study population consisted of 370 (85.4%) men and 73 (14.6%) women with a mean age of 62.29 ± 10.35 years. A total 1836 sessions of TACE were conducted in 443 patients between January 2005 and December 2009. Each patient received between 1 and 27 (mean, 4.14 ± 3.57) sessions of TACE. The mean follow-up duration was 22.23 ± 19.6 mo (range: 0-81 mo).

One hundred seventeen episodes of postembolization fever (26.41%) occurred in 443 HCC patients after the 1st TACE session. Most of the postembolization fever episodes peaked within the first two days after TACE. The post-TACE fever was usually self-limiting, with durations ranging from 1 to 10 d (mean: 1.72 ± 1.11 d). The infectious complication rate was 0.16% (3/1836 cases). Two cases of bacteremia and one case of liver abscess developed after 1836 TACE sessions. A comparison of the TACE sessions with and without fever is presented in Table 1.

Association of PEF with clinical variables

A univariate analysis indicated that diffuse-type HCC (P < 0.05), large tumor size (≥ 5 cm) (P < 0.05), lipiodol

Table 2 Multivariate and univariate analysis for postembolization fever, 20-mo mortality, and tumor progression-free survival

Variables	HR	95%CI	*P*-value
Multivariate analysis[1]			
ALT value after TACE	1.002	1.00-1.005	< 0.05
Lipiodol dose (< 7 mL)	0.539	0.329-0.881	< 0.05
Univariate analysis[2]			
Poor BS control	2.673	1.77-4.034	< 0.01
Portal vein thrombosis	3.048	1.536-6.06	< 0.01
Poor CT response	2.638	1.785-3.891	< 0.01
Initial AST	1.006	1.001-1.011	< 0.05
Initial CRP	1.348	1.011-1.796	< 0.05
Tumor size	1.31	1.198-1.433	< 0.01
TNM	1.555	1.26-1.92	< 0.01
Lipiodol dose	1.12	1.058-1.185	< 0.01
Multivariate analysis[3]			
Tumor size	1.252	1.108-1.414	< 0.01
Poor BS control	2.442	1.310-4.55	< 0.01
Portal vein thrombosis	3.344	1.021-10.98	< 0.05
Cox regression analysis[4]			
Poor CT response after TACE	0.302	0.192-0.765	< 0.01
Lipiodol dose (≥ 7 mL)	0.494	0.279-0.874	< 0.05

[1]Predictors for postembolization fever; [2]Risk factors for 20-mo mortality; [3]Predictors for 20-mo mortality; [4]Predictors for tumor progression-free survival. HR: Hazard ratio; CRP: C-reactive protein; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TNM: Tumor, node, metastases; TACE: Transcatheter arterial chemoembolization; BS: Base of support.

dose (≥ 7 mL) ($P < 0.01$), poor blood glucose control ($P < 0.05$), ALT value after TACE ($P < 0.01$) and CRP value after TACE ($P < 0.05$) were possible risk factors correlated with postembolization fever in patients with HCC.

A multivariate analysis using logistic regression showed that the ALT value after TACE ($P < 0.05$) and the lipiodol dose (≥ 7 mL) ($P < 0.05$) were independent predictive factors of postembolization fever (Table 2).

PEF was not associated with 20-mo survival ($P = 0.754$), 10-mo survival ($P = 0.524$) and CT response ($P = 0.461$) in the univariate analysis.

20-mo mortality

The univariate analysis revealed that poor blood sugar control ($P < 0.01$), portal vein thrombosis ($P < 0.01$), favorable CT response after TACE ($P < 0.01$), initial AST ($P < 0.05$), initial CRP ($P < 0.05$), tumor size ($P < 0.01$), TNM stage ($P < 0.01$) and lipiodol dose ($P < 0.01$) were possible risk factors correlated with 20-mo mortality (Table 2). A multivariate analysis using logistic regression showed that tumor size ($P < 0.01$), poor blood glucose control ($P < 0.01$) and portal vein thrombosis ($P < 0.05$) were independent risk factors for 20-mo mortality (Table 2).

Tumor progression-free survival

The progression-free survival in the poorly defined tumor (diffuse) type group was significantly shorter than in the well-defined (nodular) tumor type group ($P < 0.01$). Additionally, large size (size ≥ 5 cm, $P < 0.01$), no antiviral treatment ($P < 0.05$), poor CT response ($P < 0.01$), lipiodol dose (dose ≥ 7 mL, $P < 0.01$), antibiotic use

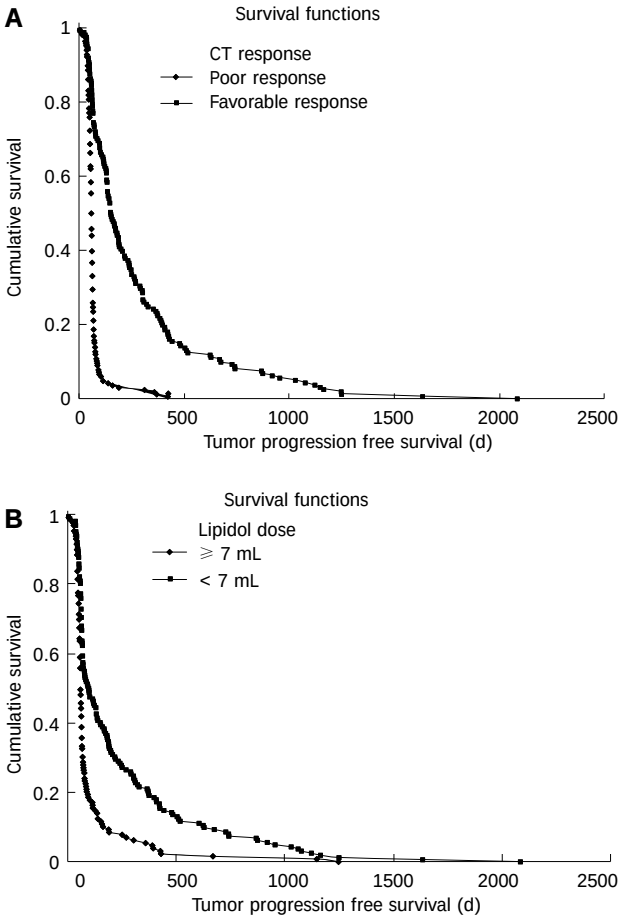

Figure 2 Kaplan-Meier curves of progression-free survival. A: According to computed tomography response (log-rank test, $P < 0.001$); B: According to lipiodol dose (log-rank test, $P < 0.001$).

($P < 0.05$) and CRP (CRP ≥ 1 mg/dL, $P < 0.01$) were statistically significant factors in the univariate analysis (Figure 2A and B). In the multivariate Cox proportional hazard model for progression-free survival, CT response ($P < 0.01$) and lipiodol dose (≥ 7 mL) ($P < 0.05$) were identified as independent factors (Table 2).

DISCUSSION

TACE is one of the major treatment methods for unresectable HCC and has demonstrated survival benefits[4,10-15]. Chemoembolization acts by obstructing the hepatic artery with embolization agents, usually gelatin, and introducing antitumor agents (e.g., cisplatin, doxorubicin, and mitomycin C) emulsified in iodized oil, thereby inducing extensive necrosis in large vascularized HCC tumors[7]. TACE complications can be categorized as hepatic injuries, including deterioration of hepatic function, hepatic infarction, or intrahepatic biloma, and liver abscess; extrahepatic complications, including gastrointestinal bleeding, gallbladder or spleen infarction, and pulmonary embolism; and systemic complications, including postembolization syndrome and septicemia[16]. The most frequent complication of chemoembolization is postembolization fever, which can typically be satisfactorily

alleviated with symptom treatment[11,16]. Nevertheless, PEF frequently troubles patients, family members and physicians, and few data have been published concerning postembolization fever; therefore, we investigated the risk factors and clinical significance of PEF that developed after TACE in patients with HCC.

Infectious complications are very rare because of the standard antiseptic procedures associated with TACE. Another study reported that only 0.26% of HCC patients developed liver abscesses after TACE[17]. Thus, antibiotic prophylaxis is usually not necessary in patients with HCC who are undergoing TACE[10]. Although fevers were common (27%) in this study, they were generally not caused by an infectious process because very few patients had bacterial infections (0.16%). These fevers can often be adequately controlled with antipyretics, and in most cases, antibiotics are not necessary.

The pathogenesis of PEF remains unclear and complicated. The main aspects are as follows: (1) lipiodol-induced embolisms may result in ischemia, hypoxia, and necrosis in some normal hepatic cells; (2) chemotherapeutic drugs themselves have toxicities[18]; (3) the procedure itself can lead to a considerable release of inflammatory factors[19]; and (4) such stimuli as injury and drugs can contribute to stress responses in the human body. In the present study, the occurrence of PEF was closely associated with several clinical and laboratory variables, including poor blood glucose control, large tumor size (> 5 cm), poorly defined tumor type, post-TACE CRP level, lipiodol dose higher than 7 mL, and post-TACE ALT level in a univariate analysis. However, the multiple regression analysis showed that a lipiodol dose over 7 mL and the post-TACE ALT level were independent risk factors, which is similar to the result of another recent study[20]. No difference was found between favorable CT responses and unfavorable CT responses regarding the presence of PEF, which is in concordance with another study showing that post-TACE fever was not associated with an enhanced tumor response in patients with HCC[20-22].

PEF is thought to reflect extensive tumor necrosis, thereby representing the efficacy of chemoembolization[22-24]. However, we observed no other robust association between PEF and survival in this study. Moreover, PEF did not independently affect progression-free survival, which may be an indirect indicator of treatment efficacy. These findings suggest that the previously described correlation between PEF and the extent of tissue necrosis cannot always be justified because the extent of tissue necrosis after chemoembolization is proportional to tumor mass, a factor that is independently associated with PEF.

Raoul *et al*[25] suggested that factors associated with poor TACE outcomes included Child-Pugh score, reduced liver function, AFP level, tumor size, tumor number, tumor type, portal vein thrombosis, multiple TACE sessions and lobar embolization. In our study, large tumor size, poor blood glucose control and portal vein thrombosis were independent risk factors for 20-mo mortality. However, unlike in other studies, the Child-Pugh score was not a significant prognostic factor in our study. It was likely that most of the patients enrolled in our study had Child A (the Child score for patients with PEF was 5.66 *vs* 5.77 for those without PEF), and as a result, liver function did not affect the prognosis. According to Shim *et al*[22], hepatitis B virus infection, modified UICC stage (Stage 1), and response to chemoembolization are independent predictive factors for the tumor progression-free interval. In good agreement with other studies, we found that the TACE response and lipiodol dose (< 7 mL) were closely associated with tumor progression-free survival. Because the lipiodol dose was dependent on tumor size, progression-free survival was closely associated with tumor size and response to TACE.

This study had several limitations, including its retrospective design. Although we performed laboratory and culture studies of blood, urine, and ascites to detect hidden infections, it was impossible to rule out all infective complications in patients with PEF. In addition, the tumor response to chemoembolization may have been overestimated in patients with poorly defined HCC, particularly those with the diffuse infiltrative type of HCC, because of the difficulty of evaluating the degree of viable tumor. Finally, it may be difficult to determine whether the development of PEF after a single session of TACE was exclusively associated with overall survival because the mortality of TACE-treated HCC patients is subject to many other factors.

In conclusion, ALT levels after TACE and lipiodol dose were independent risk factors for postembolization fever in HCC patients. However, postembolization fever after TACE had no impact on survival at 20 mo or on the radiologic response.

COMMENTS

Background

Postembolization fever (PEF) is thought to reflect extensive tumor necrosis and thereby represent the efficacy of transcatheter arterial chemoembolization (TACE) in hepatocellular carcinoma (HCC). The aim of this study was to assess the tumor response and survival of patients with PEF after TACE and to determine the risk factors for PEF.

Research frontiers

TACE has improved the prognosis of patients with HCC. However, TACE inevitably results in a hypoxic insult to the HCC and the surrounding liver tissue, and postembolization fever is common. However, the clinical meaning of and the risks factor for PEF are not known.

Innovations and breakthroughs

PEF has been associated with overall survival in HCC patients. However, there is limited published data about PEF and the risk factors for PEF. Unlike other studies, their demonstrated that PEF was not associated with overall survival or radiological tumor response. Furthermore, this study demonstrated that alanine aminotransferase (ALT) levels after TACE and lipiodol doses were risk factors for PEF.

Applications

The results of this study imply that PEF is associated with lipiodol dose and ALT levels after TACE but does not affect prognosis; therefore, patients undergoing TACE who have risk factors for PEF should receive active or prophylactic antipyretics for PEF control.

Terminology

Postembolization fever was defined as a body temperature greater than 38.0 ℃

that developed within 3 d of TACE without evidence of infection. Poorly defined tumor type was defined as diffuse-type HCC, whereas well-defined tumor type was defined as nodular HCC. Tumor progression-free survival was defined as the interval of time during and after treatment in which a patient remained alive and the disease did not worsen (in the case of this study, the interval from the 1st TACE to the 2nd TACE).

Peer review

Postembolization fever is a clinically relevant problem in the treatment of patients with HCC. The authors addressed potential causes and risk factors and found that the ALT level after TACE and the lipiodol dose served as independent risk factors for PEF after TACE and that PEF had no impact on 20-mo survival in HCC patients. These results were extracted and calculated from a large group of 443 patients who were treated and observed within a 5-year period.

Abstract

AIM: To test whether the status of positive cytomegalovirus (CMV) DNA detection adds to the predictive value of IL28B and to further categorize C/T allele carriers.

METHODS: This study included 166 chronic hepatitis C (CHC) patients who received combined interferon and ribavirin therapy for 48 wk, 84 spontaneous hepatitis C virus (HCV) resolvers who were positive for IgG anti-HCV antibody and negative for HCV RNA, and 100 healthy subjects who were negative for both HCV antibodies and RNA as controls. Genomic DNA from peripheral blood was used for IL28B rs.12979860 single nucleotide polymorphism (SNP) and CMV DNA detection. A 139 bp fragment containing IL28B SNP was amplified in all subjects by polymerase chain reaction using a specifically designed primer. Then the IL28B rs.12979860 SNP was detected by restriction fragment length polymorphism (RFLP) genotyping. The presence of CMV DNA was tested by amplification of the *gB1* gene using nested polymerase chain reaction. The role of CMV and IL28B rs.12979860 SNP genotypes in determining the response rate to combined interferon therapy and clinical status of patients were statistically analyzed.

RESULTS: Current data showed that 67% of patients carrying the IL28B 12979860 C/C allele had a sustained viral response (SVR) while the genotypes C/T and TT were associated with lower SVR rates, 50% and 48%, respectively. SVR rates for the C/C allele were lower than other HCV genotypes and/or other populations. Genotype CC was associated with the response to interferon (P = 0.025). Genotype C/C was reduced from 48% in controls to 14% in CHC patients suggesting its protective role against progression to chronicity. The majority of spontaneously cleared subjects (86%) were C/C, confirming its protective role. The C/T allele was present in 71% of CHC patients compared with 38% of controls, so the use of IL28B SNP genotyping only in these patients may be of little value as a predictor of response. CMV reactivation occurred in 40% of CHC patients. Co-infection with CMV seriously diminished the response to interferon (IFN) therapy, with SVR rates in C/C genotypes 87.5% in CMV-negative patients and 12.5% in CMV-positive patients (P < 0.0001). SVR rates among C/T carriers were reduced to < 50% in patients with positive CMV DNA while the non-response rate doubled. These data indicate that a supplemental assay for CMV viremia adds to the prognostic value of IL28B genotyping.

CONCLUSION: The results suggest that both genetic (i.e., spontaneous) and therapeutic (IFN-based therapy) arms are complementary in the battle against HCV. CMV DNA testing may be of value to better predict the response to IFN, particularly in IL28B C/T carriers.

IL28B polymorphism and cytomegalovirus predict response to treatment in Egyptian HCV type 4 patients. *World J Gastroenterol* 2013; 19(2): 290-298 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/290.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.290

INTRODUCTION

The current standard-of-care for chronic hepatitis C virus (HCV) infection includes weekly injections of pegylated interferon-α (peg-IFN) combined with daily oral ribavirin[1,2] for 48 wk[3]. During the first 3 mo of therapy, HCV viral loads usually fall to undetectable levels in response to interferon-α. However, in non-responder (NR) patients, HCV viral loads persist at or near pretreatment levels. Among those patients with an initial response to treatment, known as early virological responders, up to 50% will relapse after treatment is discontinued and are known as relapsed responders, whereas the remainder will have a sustained virological response (SVR) as determined by the absence of detectable viremia 6 mo after treatment has stopped[4]. In Egypt, several reports stated that approximately 50% of patients infected with genotype 4, the most common among Egyptian HCV patients, achieve a SVR to this regimen. Genome-wide association studies have recently revealed that single nucleotide polymorphisms (SNPs) within or adjacent to IL28B (19q13) that codes for interferon-λ3, predict spontaneous resolution of HCV[5,6] and a likely SVR to IFN-based treatment in chronic hepatitis C (CHC) patients infected with genotypes other than type 4[4,5,7-9]. Therefore, IL28B SNPs may have strong predictive value for the outcome of IFN-based therapy in the difficult to treat HCV genotype 4 patients, with the hope that IL28B SNPs will improve future decision-making in the management of CHC in Egypt. Nevertheless, it was estimated that IL28B variations account for about 15% of the inter-individual variability of SVR, thus supporting the necessity for additional predictor(s) of the response to treatment. Recent predictors include vitamin D deficiency, IFN-c-inducible protein-10 serum levels, steatosis/insulin resistance[10-17], or IFN-stimulated genes (ISGs) such as OAS1[18] and MxA[19]. Therefore, biological models for the prediction of SVR should include a variety of parameters besides IL28B genotyping, as this would offer better accuracy compared with IL28B typing alone[13]. Recently two predictors for SVR in genotype 4 patients were reported; first, reactivation of CMV infection[20] and second, SNP at exon 7 splice acceptor site of 2' 5'OAS gene[18]. The role of several genetic factors that influence spontaneous or treatment-induced HCV clearance, such as ISGs and genes encoding the natural killer cell receptor KIR2DL3 and its ligand, and human leukocyte antigen C group 1[21-23] should be re-analyzed parallel with the IL28 genotype. A major difficulty in decision-making for prediction of the response at the start of treatment is the high frequency of heterozygous carriers rs 12979860 C/T among chronic HCV patients, ranging from 45% to 70% of the CHC populations and provide vague predictive results. This means that the predictive value of rs 12979860 SNP will not be useful in almost half the patient population. The search for additional predictive factors for response is mandatory. Co-infection with other pathogens is, in some instances, an interfering factor against host genotype-based prediction. Several studies revealed comparable associations between IL28B variations and treatment-induced HCV clearance in patients co-infected with human immunodeficiency virus (HIV)[5,24-26]. For example, one study in HIV co-infected patients reported 2-3-fold higher SVR rates for HCV genotypes 1 and 4 according to rs12979860 C/C *vs* C/T, T/T, but no difference for HCV genotype 3 according to rs12979860 C/C *vs* C/T, T/T[26]. Recently, active CMV infection was shown by our laboratory[20] to dramatically interfere with SVR rates in genotype 4 CHC patients, probably by inhibiting the JAK-STAT cascade. We, therefore, hypothesize that the role of CMV in the IL28B association with SVR should be a strong candidate for further categorization of C/T genotype carriers.

MATERIALS AND METHODS

Subjects

The present study comprised 350 subjects, including 166 CHC patients, 84 spontaneous HCV resolvers and 100 healthy control subjects.

Chronic HCV patients: All 166 patients had mild liver disease F0-F3 according to the Metavir classification[27]. All subjects had undetectable HBV surface antigen (HBsAg), Anti-schistosoma antibodies (Abs), and autoimmune Abs. None of the patients had a history of long-term drug use, aflatoxins consumption or alcohol intake. All patients were infected with HCV genotype 4. Patients included 105 males and 61 females, with an age range of 19-57 years. None had uncontrolled type II diabetes mellitus, thyroid dysfunction or obesity. All patients received weekly injection of peg-IFN-α plus daily oral ribavirin treatment for 48 wk. Eighty six patients achieved a SVR, namely undetectable HCV RNA 24 wk after the end of

the treatment response that was achieved after 48 wk, i.e., a total of 72 wk. The remaining 80 patients were NR who failed to achieve a SVR, i.e., either did not respond to therapy after 12 wk or achieved undetectable viremia but failed to maintain the state of no viremia till 48 wk (breakthrough) or post 48 wk (viral relapse).

Spontaneous HCV resolvers: Eighty four subjects who tested positive for IgG anti-HCV Abs (3rd generation) and negative for HCV RNA were enrolled in the study. Patients included 53 males and 31 females, with an age range of 18-55 years.

Controls: One hundred healthy subjects who tested negative for both IgG anti HCV Abs and HCV RNA served as controls for the IL28B SNP and CMV reactivation studies. Also, they were negative for HBsAg, anti-schistosoma Abs, autoimmune Abs and CMV DNA. Subjects included 50 males and 50 females, with an age range of 18-64 years. None of subjects had a history of liver insult, either viral, metabolic or drug exposure.

Methods

Extraction of peripheral blood DNA: Peripheral blood was withdrawn from all subjects into EDTA solution and DNA was extracted using genomic DNA extraction kit (Qiagen, Milan Italy). Plasma samples were separated before DNA extraction and utilized for testing HBsAg, anti schistosomiases Abs and autoimmune Abs (ANA, AMA, LKM1, ASMA). Purified genomic DNA was used for IL28B SNP analysis and for testing the presence of CMV DNA.

Detection of IL-28B rs12979860 C/T polymorphism: Genotyping for the IL-28B rs12979860 C/T polymorphism was performed according to Fabris *et al*[24] with minor modification by polymerase chain reaction based restriction fragment length polymorphism (PCR-RFLP). Using purified genomic DNA, a 139 base-pair (bp) product was obtained with the forward primer 5'-CCAGGGCCCCTAACCTCTGCA-3' and the reverse primer 5'-GGGAGCGCGGAGTGCAATTCA-3', newly designed with the aid of NCBI Primer-Blast Tool (http://www.ncbi.nlm.nih.gov/tools/primer-blast/). Amplification was carried out in a total volume of 10 μL containing 10 mmol/L Tris-HCl (pH 8.3), 50 mmol/L KCl, Tween-20 0.01%, 0.2 mmol/L deoxyribonucleotides, 2-4 pmol of each primer, 2.0 mmol/L MgCl2, 0.5 units hot-start Taq DNA polymerase (Righ Taq, Euroclone, Milan, Italy) and ~10 ng of genomic DNA. The thermal protocol for amplification included 35 cycles of denaturation (at 95 ℃ for 60 s), annealing (at 64 ℃ for 60 s), and polymerization (at 72 ℃ for 60 s). Ten μL of the amplicons were digested with 1 unit of the BstU-I restriction endonuclease (New England Biolabs, Hitchin, UK) in a total volume of 20 μL at 37 ℃ for 4-6 h or overnight. The fragments were resolved by electrophoresis in 4% agarose gel after staining with ethidium bromide. A band of 139 bp indicated the TT genotype, 109 bp indicated the CC genotype; 139 + 109 bp indicated the CT genotype.

PCR amplification of the CMV *gB* gene: Primers for the first-round PCR were derived from the *gB* region of CMV, and PCR protocols were followed as described previously[28,29] The amplification mixture contained 10 pmol of each primer (CMV1 and CMV2), 0.2 mmol/L from each dNTP (Promega, Madison, WI, United States), 0.1 U Taq polymerase (Promega, Madison, WI, United States), 1 μL Taq buffer, 5 μL template, and distilled water to a final volume of 20 μL. A negative control tube (in which water replaced the DNA sample) was incorporated into each run. A sample from the first PCR product was used as a template in a second-round PCR (nested). Briefly, 1 μL of first round product was added to the reaction mixture, which is the same as the first-round reaction mix except for use of CMV3 and CMV4 as nested primers. The thermal cycling protocol was as follows: 1 min at 94 ℃, 1 min at 55 ℃ and 1 min at 72 ℃ for 30 cycles. Then, the nested PCR products were analyzed with 3% agarose gel electrophoresis and stained with ethidium bromide. A result was considered positive when a clear 100 bp product was visible on the gel.

Primers used for the first and the second-round PCR were CMV1: 5'-GAGGACAACGAAATCCTGTTGGGCA-3'; CMV2: 5'-GTCGACGGTGGAGATACTGCTGAGG-3'; CMV3: 5'-ACCACCGCACTGAGGAATGTCAG-3'; and CMV4: 5'-TCAATCATGCGTTTGAAGAGGTA-3'.

Assessment of SVR status (real-time and RT-PCR of HCV RNA: As reported in our previous study[20,29]. Disappearance of viremia was confirmed by a variety of tests including RT-PCR using nested primers derived from the highly conserved HCV 5'UTR and real-time PCR. These tests were done 3, 6, 12 and 18 mo after the start of IFN therapy. HCV RNA was extracted using the BIOZOL-total RNA extraction reagent kit (Hangzhou Bioer Technology, Hangzhou, China). Nested RT-PCR performed in a 25 μL reaction mixture containing 20 units of avian myeloblastosis virus reverse transcriptase (Clontech, Mountain View, CA, United States), 200-400 ng of total cellular RNA as template, 40 units of RNAsin (Clontech), 0.2 μmol/L from each dNTP (QBIOGENE, Carlsbad, CA, United States), and 50 pmol of the reverse primer P2. The reaction was incubated at 42 ℃ for 60 min and denatured at 98 ℃ for 10 min. Amplification of the highly conserved 5'-UTR sequences was done using two rounds of PCR with two pairs of nested primers. First-round amplification was done in 50 μL of reaction containing 50 pmol from each of the P1 forward primer and P2 reverse primer, 0.2 mmol/L from each dNTP, 10 μL from RT reaction mixture as template and two units of Taq DNA polymerase (Finnzyme, Woburn, MA, Unit-

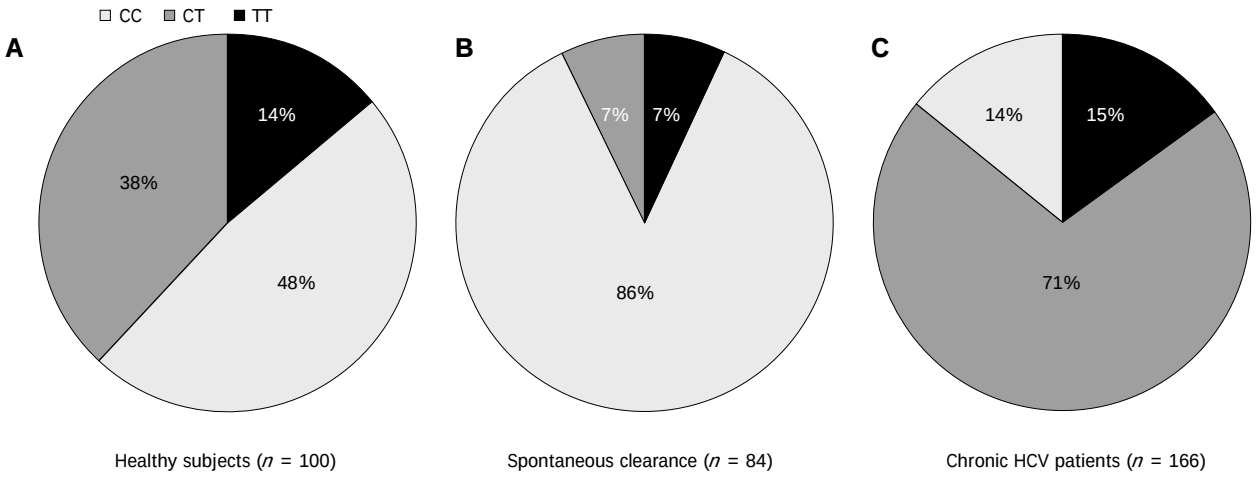

Figure 1 Distribution of LI28B rs12979860 single nucleotide polymorphism alleles among a healthy Egyptian population, spontaneous clearance and chronic hepatitis C patients. A: A hundred healthy subjects representing ethnic backgrounds of the Egyptian population were typed for IL28B single nucleotide polymorphism (SNP) rs 12979860. The distribution of different allele frequencies is depicted as a pie chart; B: Eighty four patients with spontaneous clearance from hepatitis C virus (HCV) infection were typed for IL28B SNP rs 12979860. The distribution of different allele frequencies is depicted as a pie chart; C: A hundred and sixty six chronic hepatitis C (CHC) patients with low F scores (F0-F2) were typed for IL28B SNP rs 12979860. The distribution of different allele frequencies is depicted as a pie chart.

ed States) in a 1 × buffer supplied with the enzyme. The thermal cycling protocol was as follows: 1 min at 94 ℃, 1 min at 55 ℃ and 1 min at 72 ℃ for 30 cycles. The second round of amplification was done similar to the first round, except for use of the nested reverse primer p4 and forward primer p3 at 50 pmol each. A fragment of 171 bp length was identified in positive samples. Primer sequences were as follows: P1: 5'-AACTACTGTCTTCACGCAGAA-3'; P2: 5'-GGTGCACGGTCTACGAGACCTC-3'; P3: 5'-GTGCAGCCTCCAGGACCC-3'; and P4: 5'-ACTCGGCTAGCAGTCTCGCG-3'.

HCV quantitation was performed using the Fluorescence Quantitative Detection kit (Hangzhou Bioer Technology, Hangzhou, China). HCV RNA was reverse transcribed and a specific fragment was amplified with specific primers in a one-step RT-PCR reaction. The products were detected using specific Taqman-MGB Probes. The real-time RT-PCR reaction was done in 50 μL of reaction containing 25 μL RT-PCR mix, 2.5 μL Mn^{2+}, 1.5 μL HCV probe mix, and 1 μL internal control. Then 20 μL of the corresponding HCV RNA template were added. For the standard, 20 μL of the standards control 1-4 were added. All PCR tubes were placed in the real-time PCR Detection Instrument. The thermal cycling protocol was as follows: one cycle (30 s at 90 ℃, 20 min at 61 ℃ and 1 min at 95 ℃) followed by 30 cycles and 50 cycles (15 s at 95 ℃, 1 min at 60 ℃).

Statistical analysis

The significance of the response to IFN therapy was investigated by multivariate logistic regression analysis. CMV significantly affected the HCV response rate in C/T heterozygous carriers. The frequency of rs 12979860 SNP was compared in the control group *vs* the CHC patient group. All statistical analyses were performed using SPSS 9.0 statistical software (SPSS Inc., Chicago, IL, United States). The odds ratio (OR) and 95% confidence interval (CI) were calculated to assess the relative risk confidence. A two tailed *P*-value 0.05 was considered statistically significant.

RESULTS

IL 28 C/C frequency in spontaneous resolvers of HCV infection

To test the hypothesis whether patients who spontaneously cleared HCV infection during or shortly following the acute phase bear the protective C/C allele more frequently than healthy subjects, we typed the IL28 B SNP (rs 12979860) in 84 spontaneous resolvers and 100 healthy subjects. The results of this study were previously described by our laboratory and are shown in Figure 1A and B, which clearly indicate the protective role of the C/C allele in patients who spontaneously cleared the virus, where C/C was present in 86% of spontaneous resolvers *vs* 48% of healthy subjects.

IL28B C/C frequency in chronic HCV patients

To examine the allele frequencies of the C/C genotype according to progression to chronic HCV infection, we compared the IL28B typing data derived from 166 chronic HCV patients with 84 subjects with spontaneous clearance of HCV. The results showed that the frequency of the protective C/C allele was markedly decreased from 86% in spontaneous resolvers to 48% in healthy controls to 14% in CHC patients regardless of their response to IFN therapy (Figure 1A-C). This decline was associated with a comparable increase in the heterozygous C/T from 7% in spontaneous resolvers to 38% in healthy subjects and to 71% in CHC patients.

Table 1 Statistical analyses of the different IL28B genotypes and alleles in non-responder and sustained viral response patients *n* (%)

	Non-responders (NR = 79)	Responders (SVR = 87)	Odds ratio	95%CI	*P* value
CC (*n* = 24)	8 (33.3)	16 (66.7)	4.575	1.376-7.846	0.025
CT (*n* = 117)	58 (49.6)	59 (50.4)	0.858	0.538-1.449	0.589
TT (*n* = 25)	13 (52)	12 (48)	0.978	0.758-1.759	0.464
C (*n* = 165)	74 (44.8)	91 (55.2)	1.636	0.773-3.465	0.198
T (*n* = 167)	84 (50.3)	83 (49.7)	0.798	0.598-1.349	0.604

Frequencies of genotypes and alleles at IL28B SNP were compared between SVR and NR patients. Genotype CC were associated with SVR (*P* = 0.025). SVR: Sustained viral response; NR: Non-responder.

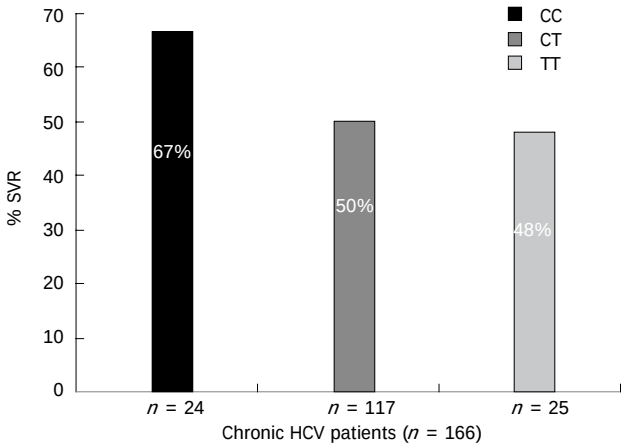

Figure 2 Rate of sustained viral response in IL28B variants. Among 166 chronic hepatitis C (CHC) patients treated with combined interferon (IFN) and ribavirin therapy, 80 patients did not achieve a sustained viral response (SVR) while 86 patients achieved a SVR. Among the 14% (24) of CHC patients bearing the C/C allele, 67% (16 patients) achieved a SVR, while the other two genotypes C/T and TT were associated with lower SVR rates; 50% and 48%, respectively. Genotype CC was associated with response to IFN (*P* = 0.025). HCV: Hepatitis C virus.

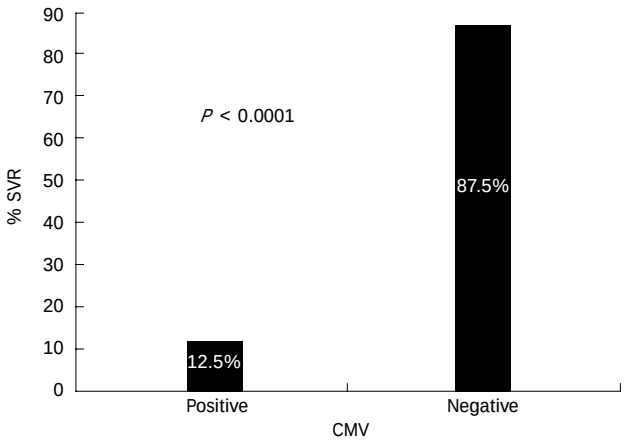

Figure 3 Association of cytomegalovirus reactivation with sustained viral response rates in C/C patients. The data shown clearly demonstrate that cytomegalovirus (CMV) reactivation has dramatically reduced the sustained viral response (SVR) rates in C/C genotypes as represented by a 12.5% SVR rate in CMV-positive patients compared with 87.5% in CMV-negative patients (*P* < 0.0001).

Rate of SVR in patients with the rs12979860 C/C allele

Among 166 CHC patients treated with combined IFN and ribavirin therapy, 79 patients did not achieve a SVR while 87 patients achieved a SVR. The effect of different IL28B genotypes and alleles on the HCV response to IFN treatment are shown in Table 1. The genotype CC was associated with response to IFN ($P = 0.025$). Of the 24 CHC patients bearing the C/C allele, 16 (67%) achieved a SVR, while the other two genotypes C/T and TT were associated with lower SVR rates: 50% and 48%, respectively (Figure 2).

Association of CMV reactivation with SVR rates in C/C patients

The PCR results of the CMV *gB* gene showed that 66/166 (40%) of chronic HCV patients have detectable CMV DNA. Since we have previously shown that coinfection with CMV seriously diminished the response to IFN therapy, it was tempting to examine whether this co-infection is associated with lower SVR rates in C/C holders. The data shown in Figure 3 clearly demonstrate that positive CMV DNA dramatically reduced the SVR rates in C/C genotypes as represented by a 12.5% SVR rate in CMV-positive patients compared with 87.5% in CMV-negative patients ($P < 0.0001$).

Sorting of C/T genotype according to association with CMV infection

Since the C/T allele represents the majority of CHC patients (117/166) (71%), the use of IL28B SNP genotyping may be of little value as a predictor of response prior to starting the treatment regimen. Therefore, there is a great need to include another factor that was previously known to affect SVR rates. Table 2 shows the results of CMV testing in CT genotype patients. Specifically, CMV DNA was detected in 71% of NR patients and in 29% of SVR patients. In Figure 4, the SVR rates among C/T carriers was reduced to < 50% of its value in cases where patients had positive CMV DNA On the other hand, the NR rate doubled in cases of positive CMV DNA. These data indicate that a supplemental assay for CMV viremia adds to the prognostic value of IL28B genotyping.

DISCUSSION

Several predictive factors have been reported recently for SVR rates for combination therapy in HCV infection. Viral factors, other than viral loads and genotypes were reported, including substitutions at core amino acids 70 and 91[30,31], IFN sensitivity determining region variations[32] and IFN and ribavirin response determining region variations[33]. SNPs within a number of host genes were found to be associated with different treatment outcomes to therapy. These include IFN-α pathway genes[34] and IFN-stimulated genes such as OAS[18]

Table 2 Influence of cytomegalovirus infection on response rate to interferon combined therapy in chronic hepatitis C virus infected patients with IL28B CT genotype *n* (%)

HCV response to treatment (*n* = 117)	IL 28B genotype (CT) +ve CMV patients (*n* = 45)	IL 28B genotype (CT) -ve CMV patients (*n* = 72)
NR (*n* = 59)	32 (71)	27 (38)
SVR (*n* = 58)	13 (29)	45 (62)

Reactivation of cytomegalovirus (CMV) was assessed by amplification of viral genome in all patients. Association of IL28B genotype CT and CMV emia with response to interferon based therapy is illustrated in this table. SVR: Sustained viral response; NR: Non-responder.

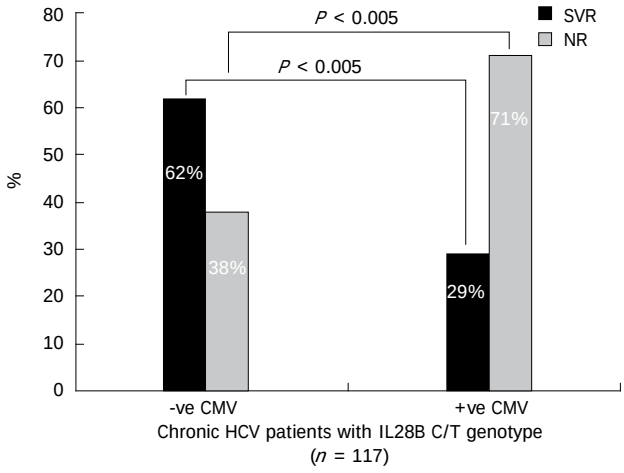

Figure 4 Sorting of C/T genotype according to association with cytomegalovirus infection. The sustained viral response (SVR) rates among C/T carriers, is reduced to < 50% of its value in cases where patients had cytomegalovirus (CMV) reactivation. On the other hand, the non-response rate is increased 2-fold in cases of CMV reactivation. HCV: Hepatitis C virus.

and MxA[19]. The widely studied IL28B SNP allele was reported to correlate with a favorable therapeutic response and was also associated with spontaneous clearance of HCV[6]. Thomas *et al*[6] reported that the allele related to HCV clearance, namely rs 12979860 C/C, was the major allele in the majority of Asian and European countries. Conversely, patients of African ancestry had lower C/C allele frequency and SVR rates. The current data indicate that the Egyptian population infected mainly with genotype 4 has an intermediate response between that of the populations of African and European ancestries, i.e., the C/C allele frequency in normal subjects was 48% *vs* > 50% in Europeans and ~35% in Africans while SVR rates in the currently studied CHC patients were 67% *vs* ~80% in Europeans and ~50% in Africans. One of the most interesting aspects of the current study is the dramatic decline in C/C frequency in CHC patients (from 48% in controls to 14% in genotype 4 infections), thus allowing speculation that protective IL28B variations provide a more substantial advantage in acute HCV genotype 4. In a similar study on a German cohort, the rs12979860 C/C genotype was found in 49% of uninfected subjects and declined in chronic infection to 42.7% of HCV genotype 2 and 3 patients and 33.9% of HCV genotype 1 patients[35]. Taking together the data from the German cohort and the data of the current study, we may speculate that HCV genotype 4 has the highest advantage of viral clearance during acute infection followed by genotype 1 and lastly genotypes 2 and 3.

Strong evidence from the current data on the significant protective effect of the IL28 B variant in acute HCV 4 is the high percentage of the C/C genotype among spontaneously cleared individuals, i.e., positive HCV Abs and negative HCV RNA compared with controls and CHC patients (86% *vs* 48 and 14%, respectively). The lack of a protective role of the C/C genotype in 14% of CHC patients suggests that, in CHC patients with the C/C genotype, other factors are involved in development of chronic infection. It is tempting to hypothesize that IL28B C/C in those 24 CHC patients was not sufficient to provide substantial tendency towards viral clearance and consequently explains the relatively lower figure for the C/C association with SVR rate in the present cohort compared with Asian and European studies. In a recent study from our laboratory co-infection with active CMV viremia induced severe failure to achieve acceptable rates of SVR[20]. Infection with CMV has evolved multiple mechanisms for disrupting the IFN-stimulated JAK/STAT signal transduction. It appears to inhibit IFN-α responsiveness by decreasing JAK1 protein, which is an essential component of IFN-α signaling[36]. It was reported that CMV blocks IFN-stimulated gene factor 3 (ISGF3)-dependent (MHC class I, 2',5'-OAS, and MxA) and ISGF3-independent gene expression in infected cells. Moreover, the essential component of ISGF3, p48, is significantly decreased by CMV. Therefore decreased JAK1 and p48 protein would inhibit IFN-α stimulated signal transduction, transcription factor activation, and gene expression, thus it is likely to globally block IFN-stimulated responses in CMV-infected patients[37]. The dual analysis of both roles of IL28B SNP and CMV co-infection clearly showed that C/C carriers not infected with CMV have a 7-fold higher rate of SVR than those C/C patients co-infected with CMV. One of the major problems in decision-making on an individual patient basis is the overwhelming preponderance of the IL28B C/T genotype among the current CHC cohort as well as other cohorts[38,39]. The present results indicate that the IL28B SNP is not the only factor that influences the IFN-induced antiviral activities of host cells against viral infection. The present results showed a 2-fold increase in SVR rate in CMV-negative over CMV-positive C/T carriers and clearly highlight the significance of additional testing for CMV viremia besides IL28 genotyping to set a model for accurate prediction of response to combined therapy in C/T carriers.

In conclusion the current results allow us to speculate that both genetic (i.e., spontaneous) and therapeutic (IFN-based therapy) arms are complementary in the battle against HCV where poor spontaneous clearance is

associated with higher IFN-mediated response as in genotypes 2 and 3. On the other hand, the difficult to treat genotypes 1 and 4 have clearly better chances for spontaneous resolution. Furthermore, CMV DNA testing may be of value at the moment to make better prognostication on response to IFN particularly in heterozygous carriers. Needless to say the search for supplemental predictive host factors will never stop at least in the near future.

COMMENTS

Background

The current recommended treatment for chronic hepatitis C virus (HCV) infection is the combination of pegylated α-interferon (IFN) and ribavirin given for 48 wk. Both viral and host factors may contribute to the phenomenon that some patients with chronic hepatitis C respond well to IFN therapy but others do not. The host genetic factors mediate the vigor of the immune response of the host through the control of inter-individual differences in the production of intracellular antiviral proteins or some cytokines. Different studies revealed that single nucleotide polymorphisms (SNPs) within or adjacent to IL28B (19q13) that codes for interferon-λ3, predict spontaneous resolution of HCV and likely SVR to IFN based treatment in chronic HCV patients infected with genotypes other than type 4. Since more than 93% of patients in Egypt are infected with HCV genotype 4, the authors investigated whether IL28B SNPs may be of predictive value for the outcome of IFN-based therapy in the difficult to treat HCV genotype 4 patients. Also the authors tested whether the status of positive cytomegalovirus (CMV) DNA detection added to the predictive value of IL28B and to further categorization of C/T allele carriers.

Research frontiers

HCV is a global health problem that infects more than 170 million people around the world and more than 15% of the Egyptian population. The response rate to combined IFN therapy does not exceed 50% of patients infected with HCV genotype 4, the most prevalent subtype in Egypt. Timing and rules for this therapy without major complications are not very well defined, so that infected patients not only suffer from severe adverse effects but there is also a contribution to evolution of more resistant strains of the virus. A research focus is how to determine and understand which HCV patients are likely to develop persistent infection, progressive liver disease or do not respond significantly to IFN therapy. These criteria are of utmost importance in disease control programs and treatment strategies. Therefore, there is an urgent need for biological models containing a variety of prognostic parameters to predict the response to IFN treatment in HCV-infected patients and to help make better decisions on treatment strategy.

Innovations and breakthroughs

The use of IL28B SNP analysis in predicting the response to combined IFN therapy is informative only in cases of CC or TT genotypes. Since the heterozygous genotype CT represents more than 70% of chronic HCV patients, there is a need for supplemental markers for making a decision on whether the HCV patient is a potential responder to combined IFN therapy or not. The authors' data clearly improve the decision-making by detecting CMV reactivation in the CT genotype group. CMV reactivation has been shown to dramatically interfere with the response to combined IFN treatment. The data presented in this manuscript are indeed important for hepatologists regarding the anticipated response to standard combined therapy for HCV genotype 4 patients.

Applications

The data of this manuscript help hepatologists make better decisions on response rate to combined interferon therapy for HCV genotype 4 patients.

Peer review

In this manuscript, the authors aimed to investigate whether the status of positive cytomegalovirus (CMV) DNA detection increases the predictive value of IL28B and to further categorize C/T allele carriers. The authors have found that CMV DNA testing might be valuable at the moment to make better decisions on response to IFN particularly in IL28B C/T carriers. Overall, this topic is very interesting.

Abstract

Ischemic colitis accounts for 6%-18% of the causes of acute lower gastrointestinal bleeding. It is often multifactorial and more commonly encountered in the elderly. Several medications have been implicated in the development of colonic ischemia. We report a case of a 54-year old woman who presented with a two-hour history of nausea, vomiting, abdominal pain, and bloody stool. The patient had recently used lubiprostone with close temporal relationship between the increase in the dose and her symptoms of rectal bleeding. The radiologic, colonoscopic and histopathologic findings were all consistent with ischemic colitis. Her condition improved without any serious complications after the cessation of lubiprostone. This is the first reported case of ischemic colitis with a clear relationship with lubiprostone (Naranjo score of 10). Clinical vigilance for ischemic colitis is recommended for patients receiving lubiprostone who are presenting with abdominal pain and rectal bleeding.

INTRODUCTION

Ischemic colitis in patients with nonocclusive vascular disease is thought to result from a transient low flow state through an inadequate vascular system. Advanced age, aortic surgery, diabetes mellitus, hypertension, and peripheral vascular disease have been also suggested to be predisposing factors for ischemic colitis[1]. It occurs more often in the splenic flexure and rectosigmoid junction which are known as the watershed areas. These areas are the distributions of the superior mesenteric artery and the inferior mesenteric artery for the splenic flexure and between the inferior mesenteric artery and the internal iliac artery for the rectosigmoid junction[1].

The pathophysiology of developing ischemic colitis includes transient hypoperfusion that involve segments of the colon. Affected patients are often elderly or have a cardiovascular condition (congestive heart failure or an arrhythmia) which puts them at risk to develop a transient reduction in bowel perfusion. Less common causes of ischemic colitis include hypercoagulable states, vasculitis, embolus, colonic obstruction (strictures, colon cancer, diverticulitis)[1,2]. Other causes include medications and substances such as amphetamines, alosetron, catechol-

amines (epinephrine, norepinephrine), cocaine, digitalis, nonsteriodal anti-inflammatory drugs, pseudoephedrine and triptans, *etc*[3].

Lubiprostone was initially approved in 2006 by the US Food and Drug Administration for the treatment of idiopathic chronic constipation at a dose of 24 mcg twice daily[4-6]. In 2008, it was approved for women with constipation predominant irritable bowel syndrome at dose of 8 mcg twice daily[4,5,7]. Lubiprostone is a prostaglandin E1 derivative which acts by activating chloride channel type-2 (CLC-2) in the apical membrane of the intestinal epithelial cells. Consequently, it produces chloride rich fluid into the intestinal lumen with a passive sodium and water shift which increases the liquidity of the stool and promotes the gastrointestinal tract motility which in turn accelerates the bowel transit[8]. Lubiprostone acts locally on the bowel epithelium and is minimally absorbed. It is well known to cause nausea, diarrhea, abdominal distention, and abdominal pain. Here we describe the first case report of ischemic colitis associated with lubiprostone usage.

CASE REPORT

A 54-year old female presented with a two-hour history of nausea, non-bloody, non-bilious vomiting associated with crampy generalized abdominal pain located to the epigastrium and left upper quadrant. She did not have any bowel movements 3 d prior to her presentation. In the emergency department, she had one bowel movement with hard stool followed by 6 watery, bloody stools. She did not have a fever or urinary symptoms. She did not have a history of recent antibiotic use, travel outside the United States, recent diet changes, or history of symptoms suggestive of inflammatory bowel disease. She suffers from diabetes mellitus, hypertension, hypercholesterolemia, hypothyroidism and chronic constipation. Her current medications included metformin (taking for 8 years), lisinopril (taking for 3 years), atorvastatin (taking for 4 years) and replacement thyroxin (taking for 4 years). She did not smoke or use illicit drugs.

On admission, her vital signs were essentially normal with a blood pressure of 134/70 mmHg without orthostatic changes, a heart rate of 61 bpm, temperature of 97.7 F°, respiratory rate of 16/min, oxygen saturation of 97% on room air, height of 162 cm, weight of 60.8 kg, and body mass index of 23.2. She did not have any episodes of hypotension either in the emergency department or during her hospitalization. Physical examination revealed a soft abdomen with mild epigastric and left upper quadrant tenderness. There was no distension, guarding, rebound tenderness, or organomegaly. The bowel sounds were normal. Rectal exam was unremarkable except for positive occult blood. The remainder of physical exam revealed no findings.

The laboratory studies were unremarkable including complete blood count, comprehensive metabolic panel, amylase, lipase, urinalysis, and urine toxicology. The stool studies were negative for ova, parasites, clostridium difficile, and pathogenic bacteria. The hemoglobin A1c was 6.5%. A plain abdominal X-ray was unremarkable. A computed tomography (CT) scan of the abdomen and pelvis revealed thickening of the colonic wall involving the transverse and the proximal portions of the descending colon near the splenic flexure (Figure 1A). A colonoscopic examination showed mucosal changes consistent with ischemic colitis (mucosal edema and hyperemia with areas of hemorrhage, erosions, and frank ulcerations) affecting the descending colon, between 30 to 40 cm from the anal verge (Figure 1B-D). The histopathology examination showed ischemic loss of crypts with acute hemorrhage in lamnia propria associated with acute fibrinopurulent exudate at colonic epithelial surface, consistent with ischemic colitis (Figure 1E, F).

A diagnosis of ischemic colitis was made based on the above findings. To clarify the etiology, a detailed history was taken including the use of over the counter and herbal medications. She stated that she had been taking lubiprostone for a period of 2 mo prior to her admission after she failed to respond to conventional laxatives for chronic constipation. The patient was initially started on 24 mcg of lubiprostone, but several hours after taking the drug, she developed nausea, vomiting and abdominal pain with bloody diarrhea which lasted for two days. She did not undergo any investigations, but her dose of lubiprostone was changed to 8 mcg daily as needed after she called her primary care physician. Twenty-four hours prior to her current admission she had taken a total of 24 mcg of lubiprostone. Her symptoms developed two hours after the last dose. This temporal relationship between the recurrence of her symptoms and the rechallenging of the drug confirms the diagnosis of ischemic colitis in the light of absence of other causes of ischemic colitis. This case scored a 10 on the Naranjo Nomogram for adverse drug reactions which places lubiprostone as a definitive cause of ischemic colitis in this case (definitive $\geqslant$ 9). The patient was treated with discontinuation of lubiprostone, intravenous fluids, bowel rest and intravenous antibiotics. Her hospitalization course was uneventful and she was discharged home without any complications 4 d later.

DISCUSSION

Ischemic colitis accounts for 6%-18% of the causes of acute lower gastrointestinal bleeding[2]. The causes of ischemic colitis vary from systemic hypotension, aortoiliac surgery, atherosclerosis, thromboembolic events, vasculitis, and medications[9].

The medications that have been implicated in the development of ischemic colitis have different mechanisms including decreasing blood flow *via* systemic hypotension with angiotensin-converting enzyme inhibitors, vasospasm with pseudoephedrine, thromboembolic events with oral contraceptives, vasculitis secondary to gold salts, and increasing intracolonic pressures with alos-

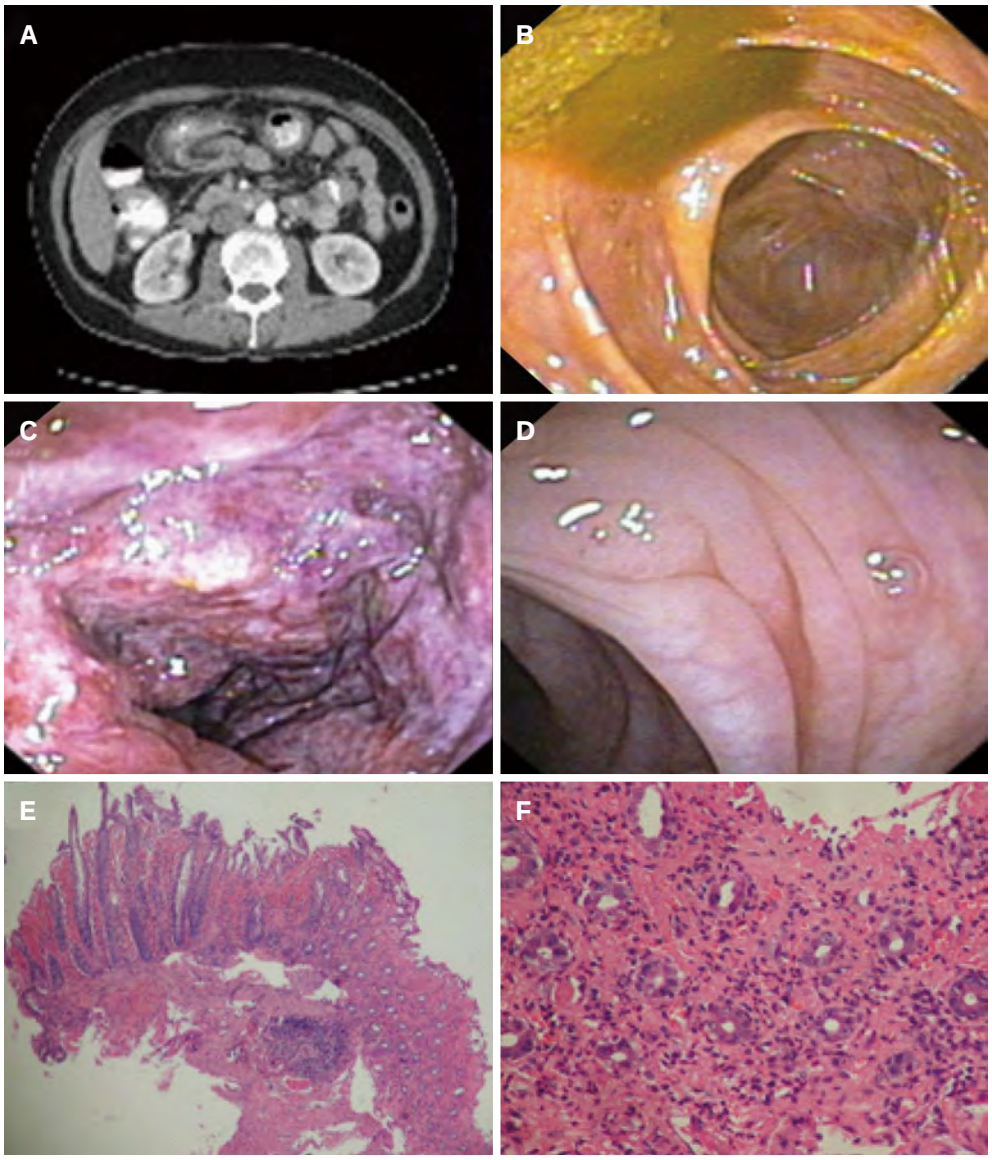

Figure 1 The laboratory studies results. A: Computed tomography scan shows thickening of the colonic wall involving the splenic flexure of the colon; B: Normal mucosa in the right colon (appendiceal orifice); C: Ischemic colitis features in the splenic flexure of the colon; D: Normal mucosa in sigmoid with a small polyp; E, F: Histopathology shows ischemic loss of crypts and acute hemorrhage in lamnia propria (acute hemorrhagic necrosis replacing glands) associated with acute fibrinopurulent exudate at colonic epithelial surface, consistent with ischemic colitis.

etron[3]. The mechanism of some drugs reported to cause ischemic colitis has not yet determined. Table 1 shows a list of medications and their mechanisms for causing ischemic colitis[3].

Many case reports have linked ischemic colitis and other unusual associations such as herbal remedies (ma huang/ephedra), weight loss medications such as phentermine, following screening colonoscopies, certain chemotherapy agents such as bevacizumab and irinotecan, hepatitis C therapy with peginterferon and ribavirin, scuba diving, flying, snake bites, acute carbonic monoxide poisoning, using electrical muscle stimulation devices on the abdominal wall, and following long distance running[3].

Lubiprostone has been shown to improve symptoms in patients with chronic idiopathic constipation. In a 48 wk prospective, multicenter, open-labeled trial performed by Lembo *et al*[10] patients with chronic idiopathic constipation were taking lubiprostone 24 mcg twice daily as needed and the most common side effects were nausea (19.8%), diarrhea (9.7%), abdominal distension (6.9%), headache (6.9%), and abdominal pain (5.2%).

Lubiprostone has also been approved for the treatment of constipation predominant irritable bowel syndrome (IBS-C). In a randomized, placebo controlled trial, the overall rate of response based on a patient ranked assessment tool was significantly higher in the lubiprostone group using 8 mcg twice daily compared to placebo. The side effects were similar in both groups[11].

In a phase 2, placebo controlled trial by Johanson *et al*[12] lubiprostone was superior to placebo in IBS-C regarding the severity of constipation, stool consistency,

Table 1 Medications associated with ischemic colitis

Agent	Mechanism
Amphetamines	Vasoconstriction
Alosetron	
Catecholamines (epinephrine, norepinephrine)	
Cocaine	
Cyclosporine

frequency, straining, bloating, and abdominal pain in 1, 2, and 3 mo follow ups. Both diarrhea and nausea occurred more often in the lubiprostone group, especially with 24 mcg twice daily compared to 8 mcg twice daily.

Lubiprostone is a bicyclic fatty acid, derived from prostaglandin E1. It is a member of a class of drugs called prostones which, unlike prostaglandins, are not believed to cause direct smooth muscle contraction. It is metabolized in the upper part of the gastrointestinal tract by the microsomal carbonyl reductase system. Lubiprostone acts locally in gastrointestinal epithelium and its active metabolite, M3, absorbs systemically. The half-life of M3 is 0.9-1.4 h. M3 is used for the pharmacokinetic parameters of lubiprostone because the drug itself has limited systemic absorption and low bioavailability[4,8].

Lubiprostone mainly acts on CLC-2 activators in the intestinal epithelium which is one of the nine types of chloride channels in the body which also includes the cystic fibrosis transmembrane conductance regulator (CFTR) (Figure 2)[13].

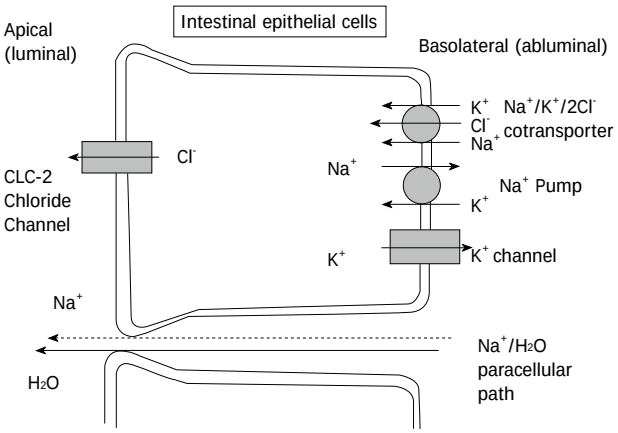

Figure 2 Mechanism of action of lubiprostone across epithelial intestinal cells[8].

Activation of CLC-2 in the apical membrane of intestinal epithelial cells causes an active secretion of chloride ions from cells into the intestinal lumen followed by a passive secretion of sodium ions and water which results in increased isotonic fluid in the lumen which promotes small bowel and colonic transit by stimulating stretch receptors and smooth muscles in the intestine (Figure 2)[8].

There is now controversy whether lubiprostone activates CLC-2 in be basolateral or apical aspect of intestinal epithelium, whether it activates mainly CFTR or CLC-2, or whether it directly stimulates smooth muscles *via* prostaglandin receptors[8]. Bao *et al*[14] showed in an experimental study that lubiprostone activates CLC-2 at low concentrations but activates CFTR at higher concentrations. It has also been shown that lubiprostone weakly activates prostaglandin receptors in different levels of the GI tract which could be responsible for some side effects such as nausea[15].

In our patient, despite having other risk factors for ischemic colitis such as chronic constipation which has been shown to increase the risk of ischemic colitis by 2.7 folds in some studies[16], the close temporal relationship between lubiprostone and occurrence of the symptoms of ischemic colitis makes the drug the most likely culprit of this event. When applying the Naranjo Nomogram in our patient, a score of 10 was obtained indicating a definite likelihood of lubiprostone as the cause of ischemic colitis in this case (Table 2).

To the best of our knowledge, this is the first report of lubiprostone induced ischemic colitis. We report that a direct causal relation by exclusion of other causes, the disappearance of symptoms after cessation of lubiprostone, recurrence of symptoms with self rechallenge, and a Naranjo Nomogram score of 10 all go in favor of the drug-induced ischemic colitis. The actual mechanism of lubiprostone causing ischemic colitis is not known, however, fast fluid shift into the intestinal lumen causing local hypoperfusion, rapid increase of the intracolonic pressure due to rapid fluid secretion into the bowel, or direct vasoconstriction caused by lubiprostone in higher doses

Table 2 Naranjo adverse drug reaction nomogram in our patient

	Yes	No	Our patient
Are there previous conclusive reports on this reaction?	1	0	0
Did the adverse event appear after the suspected drug was administered?	2	-1	2
Did the adverse reaction improve when the drug was discontinued or a specific antagonist was administered?	1	0	1
Did the adverse reaction reappear when the drug was readministered?	2	-1	2
Are there alternative causes (other than the drug) that could have, on their own, caused the reaction?	-1	2	2
Did the reaction appear when a placebo was given?	-1	1	1
Was the drug detected in the blood (or other fluids) in concentration known to be toxic?	1	0	0
Was the reaction more severe when the dose was increased or less severe when dose was decreased?	1	0	0
Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	1	0	1
Was the adverse event confirmed by any objective evidence?	1	0	1
			10

by stimulating prostaglandin receptors are the proposed pathophysiological mechanisms. In conclusion, lubiprostone may cause ischemic colitis, especially in some susceptible persons and greater awareness of this side effect is warranted with the increasing use of lubiprostone.

Abstract

Cryoglobulinemia is a pathological condition usually associated with hepatitis C virus (HCV) chronic liver disease and less commonly with autoimmune or lymphoproliferative disorders. The possible association of cryoglobulinemia with hepatitis B virus (HBV) infection is not widely accepted. In our patient, serum negativity for HCV markers initially led us to consider two other causes of cryoglobulinemia. Myelodysplastic disorders were excluded on the basis of hematological studies, while serum markers for active HBV infection were positive. Surprisingly, the detection of HCV RNA in the cryocrit, even in the absence of anti-HCV antibodies, suggested a pathogenetic role of HCV in this case of cryoglobulinemia. Negative "first level" tests for HCV in the serum do not completely exclude HCV involvement in the pathogenesis of cryoglobulinemia. Analysis of the cryoprecipitate is always essential for diagnosis.

INTRODUCTION

Cryoglobulinemia is a pathological condition usually associated with hepatitis C virus (HCV) chronic liver disease[1,2]. Cases of cryoglobulinemia associated with autoimmune or lymphoproliferative diseases are less common[2], while the association with hepatitis B virus (HBV) infection is not widely accepted, the HBV virus being mostly associated with other immunocomplex-related disorders[3-5].

Cryoglobulins are proteins that can precipitate at low temperatures (< 4 ℃). The final product of this precipitate, termed the cryocrit, can be characterized on the basis of its composition: polyclonal immunoglobulins, monoclonal immunoglobulins or the presence of rheumatoid activity (RA). Three types of cryoglobulinemia have been identified, namely: type 1, including monoclonal cryoglobulins (IgM, IgG and IgA) without any RA; type 2, that includes a monoclonal component (usually IgM with RA) and a polyclonal component (usually IgM/IgG); type 3, that includes several polyclonal components and a component with RA (usually IgG/IgM)[6].

Normally, cryoglobulinemia type 1 is associated with lymphoproliferative/myelodysplastic diseases such as multiple myeloma, Waldenstrom macroglobulinemia, chronic lymphatic leukemia, non-Hodgkin lymphoma, *etc.* Cryoglobulinemia type 2 is associated not only with lymphoproliferative diseases and plasma cellular dyscrasias but also with infectious and autoimmune diseases (rheumatoid arthritis, Sjogren's syndrome, *etc.*). Finally, cryoglobulinemia type 3 is frequently associated with autoimmune or infectious diseases. The mechanism responsible

for cryoglobulin formation during lymphoproliferative or autoimmune diseases is known, but the etiopathogenesis of the forms defined as "essential cryoglobulinemias", which occur as isolated events, has still to be clarified. Among the essential forms, the most common variant is cryoglobulinemia type 2[2]. The amount of cryoglobulins, expressed as a percentage of the serum volume, can vary significantly among patients and may change over time. It is therefore useful to evaluate the cryocrit, also during follow-up, in order to assess prognosis and treatment. Cryoglobulinemia characterization by protein electrophoresis and immunofixation is equally important to define the type[2]. In 1966, Meltzer *et al*[7] described a clinical triad characterized by palpable purpura, arthralgia and asthenia associated with nephropathy and neuropathy. It is widely accepted that presentation of the complete triad is rare in clinical practice. In fact, most patients are asymptomatic and purpura, often fleeting, is the only clinical manifestation. The frequent association of HCV infection with the great majority of cryoglobulins, initially defined as essential, suggested the involvement of this virus in the pathogenesis of mixed cryoglobulinemia. Actually, mixed cryoglobulinemia (type 2 or 3) is found in 50% of patients with chronic HCV infection[1,4]. Therefore, in patients with mixed cryoglobulinemia, the possibility of HCV infection should always be considered, and serum tests should be performed for the detection of anti-HCV antibodies and HCV RNA.

CASE REPORT

Our patient was in apparent good health until the age of 73 when he underwent percutaneous angioplasty for acute non-Q myocardial infarction, after which he was prescribed anticoagulant and antihypertensive therapy. At the age of 77, he had an outpatient medical visit because of the first manifestation of purpura of the lower limbs, arthralgia and a sense of postural instability, raising the suspicion of a cryoglobulinemic syndrome. At this time, the cryocrit was positive (35%), and the patient underwent several serological and molecular investigations that excluded HCV (negative anti-HCV and HCV RNA) and HIV infection and demonstrated chronic HBV infection (surface antigen of the hepatitis B virus (HBsAg) 11 700 IU/mL, anti-HBsAg negative, hepatitis B core antibody positive, anti-hepatitis Be antibody positive, HBV-DNA 2 410 000 IU/mL, anti-HDV negative). Immediately after, he was admitted to our unit because of the onset of a hypertensive crisis that was not controlled by the administration of calcium antagonists, beta-blockers and loop diuretics. Renal function monitoring demonstrated the following values: creatinine 1.85 mg/dL, creatinine clearance 20 mL/min and 24-h proteinuria 1.3 g/24 h. Echotomographic examination showed ultrasonographic signs of cirrhosis, and hepatic elastometry yielded a stiffness value of 47.2 kPa. Other laboratory tests demonstrated aspartate aminotransferase × 6.7 upper limit of normal (ULN), alanine aminotransferase × 4.9 ULN and gamma-glutamyl transpeptidase × 5.2 ULN, and total bilirubin 1.8 mg/dL. On the basis of these data, the patient was started on antiviral treatment (0.5 mg entecavir every 72 h) and prednisone, 50 mg/d, to be tapered to 10 mg/d. Although the hypertensive crisis could presumably be ascribed to a cryoglobulin-induced nephropathy attributable to HBV, considering that the serum β2-microglobulin levels were markedly increased (7.2 mg/L, < 2 ULN) and gamma-globulin showed a monoclonal peak, we also considered the possibility of cryoglobulinemia associated with a myeloproliferative disorder. The characteristics of the cryoprecipitate were therefore evaluated in order to define the type of cryoglobulinemia. We found rheumatoid factor positivity, lower C3 and C4 levels, 24% cryocrit, while serum immunofixation showed a K monoclonal IgM component, and cryocrit immunofixation a K monoclonal IgM component with polyclonal IgG. On the basis of these elements we made a diagnosis of mixed cryoglobulinemia type 2, that did not exclude a myeloproliferative disorder, so a peripheral blood smear and bone marrow biopsy were performed, and these excluded a myeloproliferative disease. During the period of hospitalization we observed an improvement in renal function (creatinine decreased to 1.4 mg/dL, 24-h creatinine clearance increased to 35 mL/min, and 24-h proteinuria decreased to 0.9 g) and a striking reduction of the cryocrit (6.1%). Surprisingly, cryoprecipitate characterization demonstrated the presence of HCV RNA (807 copies/mL, by m2000 Real Time System, Abbott, IL, United States, Figure 1) and for this reason, we rechecked the serum anti-HCV antibodies and HCV RNA, and the absence of both was confirmed (HCV RNA undetectable using 50 IU/mL as cut-off).

DISCUSSION

In the present case, the detection of HCV components in the cryocrit cast some doubt on the pathogenesis of the cryoglobulinemia that we initially attributed to HBV infection.

It has been reported that in chronic HCV patients with mixed cryoglobulinemia, HCV RNA may be undetectable in the plasma (due to the entrapment of HCV RNA in the cryoprecipitate) and the diagnosis of HCV infection is based on the presence of anti-HCV antibodies[8]. However, in our patient anti-HCV antibodies were undetectable in the serum. This could be explained by interference between the two viruses that may even lead to inhibition of HCV replication in patients with chronic hepatitis C with a superimposed HBV infection[9,10].

This experience suggests that negative tests for HCV detection in the serum (anti-HCV antibodies and HCV RNA) do not completely exclude the involvement of HCV in the pathogenesis of cryoglobulinemia, and show that analysis of the cryoprecipitate is always essential, since detection of HCV RNA in the cryoprecipitate is the most sensitive method. Once HCV infection has been excluded, investigations must take into account other causes

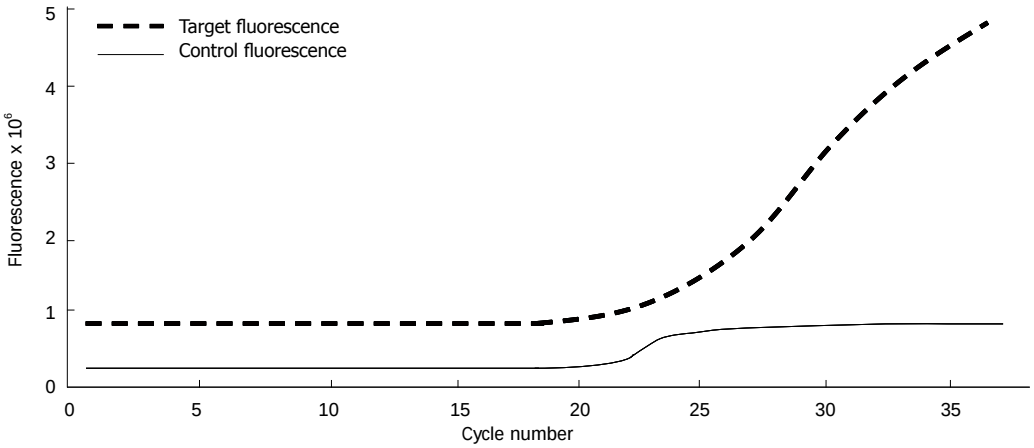

Figure 1 Real time polymerase chain reaction amplification plot for hepatitis C virus RNA. The presence of viral RNA started to become evident after 19.4 cycles and the amount of RNA was 807 copies/mL.

of cryoglobulinemia, such as autoimmune and myelo- or lymphoproliferative disorders and HBV infection.

Abstract

A 53-year-old male developed cervical esophageal stenosis after esophageal bypass surgery using a right colon conduit. The esophageal bypass surgery was performed to treat multiple esophageal strictures resulting from corrosive ingestion three years prior to presentation. Although the patient underwent several endoscopic stricture dilatations after surgery, he continued to suffer from recurrent esophageal stenosis. We planned cervical patch esophagoplasty with a pedicled skin flap of sternocleidomastoid (SCM) muscle. Postoperative recovery was successful, and the patient could eat a solid meal without difficulty and has been well for 18 mo. SCM flap esophagoplasty is an easier and safer method of managing complicated and recurrent cervical esophageal strictures than other operations.

INTRODUCTION

A variety of total esophageal reconstruction procedures have been described; however, there is no universally-accepted method[1]. Cervical reconstruction for esophageal stenosis of any etiology is complicated and can be more challenging in cases of recurrent cervical stenosis with previous colon conduit failure. Recently, we successfully treated upper cervical stenosis caused by corrosive strictures using colon conduits. However, these operations have been followed by recurrent stenosis. Many different approaches have been utilized in the treatment of cervical stenosis. These include local fasciocutaneous flaps, pedicled myocutaneous flaps, pedicled visceral flaps, free flaps, and free fasciocutaneous flaps[2]. We present a successful patch-plasty with myocutaneous flap of sternocleidomastoid (SCM) muscle for treatment of recurrent cervical esophageal stenosis.

CASE REPORT

A 53-year-old male developed recurrent cervical esophageal stenosis 1.5 years after undergoing esophageal bypass surgery using a right colon conduit. He had received corrosive esophageal strictures three years earlier after a suicide attempt by potassium hydroxide ingestion. His presentation was complicated, with multi-level stenotic segments down the entire esophagus. He underwent

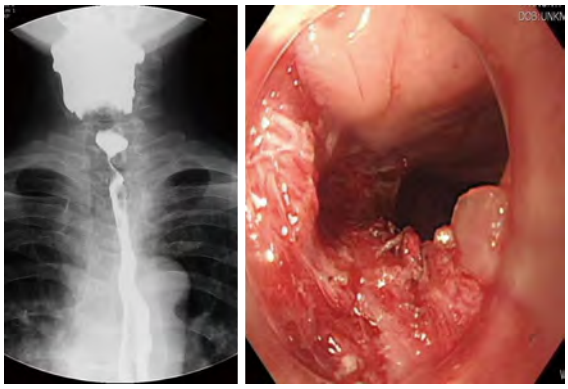

Figure 1 Esophagogram and endoscopic findings before patch esophagoplasty. The native esophagus was visualized with the esophagogram, but the colon conduit from bypass surgery was not visible. After insertion of an Endoscopic Varix Ligation tube, a stenotic lesion of the esophago-colonic anastomosis site was opened. Focal luminal stenosis by fibrosis was evident. Endoscopic dilatation was repeated using electrocauterization.

repeated balloon dilatation, but one cervical stricture progressed to near-complete obstruction just below the entrance of the esophagus as seen on endoscopy and barium esophagogram. The severity of stenosis below the proximal esophagus could not be evaluated. He had severe weight loss of 15 kg and required total parenteral nutrition, afterwards gaining back about 2.5 kg (43 kg and 173 cm, body mass index 14.37). Instead of feeding gastrostomy insertion, esophageal bypass surgery using a segment of the right colon was performed one year later. At surgery, the ileum was anastomosed with the cervical esophagus in a side-to-end manner, and its blood supply was preserved. Postoperative esophagogram showed that barium passed through the native esophagus and newly constructed colon conduit. The patient began to eat 7 d after surgery and returned home 14 d after surgery with a weight gain of 3 kg. On follow-up, he gained weight by additional 3 kg, but suffered from painful swallowing of solid food three mo after discharge. Follow-up endoscopy revealed cicatricial stenosis in the native esophagus proximal to the interposed colon, though the site of gastro-colon anastomosis was patent. Barium esophagogram showed mild stenosis at the level of the thoracic inlet and severe stenosis just above the anastomosis of the esophagus. The patient underwent repeated 7 times esophageal dilatation using Savary-Guillard or balloon dilators, and an episode of electrocauterization ablation to improve swallowing before the 2nd operation. Despite endoscopic dilatation using electrocauterization, he again developed pain on swallowing. Finally, he was admitted for surgical correction. We reviewed the esophagogram and endoscopic findings (Figure 1). The stenotic segment was 3 cm long and located in the proximal esophagus near the site of the previous esophago-colonic anastomosis. Fortunately, the lesion was easily opened with a dilator or balloon. This finding suggested that the stenotic segment was not caused by mechanical stenosis resulting from circumferential fibrosis, but was caused by twisted axis of esophageal anastomosis site possibly due to cicatricial obstruction resulting from colon conduit failure. We planned to perform a patch enlargement operation with a myocutaneous flap of SCM muscle. Under endotracheal anesthesia, the patient was placed supine with neck extension and slight rotation for better exposure. A skin incision in the neck was made along the previous incision while preserving an elliptical skin island over the SCM muscle (Figure 2). Improved exposure of the stenotic cervical esophagus was obtained after SCM division with a skin island near the clavicle. There was a fibrotic band near the proximal esophagus instead of near the colon. The proximal esophagus and hypopharynx were exposed, and a small esophagotomy at the level of the cricoid cartilage was initially made and extended upward to the hypopharynx with a longitudinal incision of about 5 cm (Figure 2). The attached skin island of the SCM myocutaneous flap was rotated medially over the esophagopharyngeal opening and sutured in interrupted fashion with 3-0 black silk. The SCM muscle attached to the skin flap was then tacked into place around the esophagus and pharynx. A drain was placed, and the neck wound was closed after a skin tension-releasing procedure (Figure 2). Seven days later, an esophagogram showed good passage without tracheal aspiration (Figure 3). The patient could eat a solid meal without pain or resistance and returned home in ten days. He then returned to work and has been well with a gradual weight gain about 10 kg for 18 mo after the esophagoplasty.

DISCUSSION

Graft necrosis is the most dangerous complication of colon graft interposition with a reported mortality approaching 90% or more[3]. Most instances of colonic graft ischemia are secondary to arterial insufficiency[3]. Ischemic complications are expressed as frank colon necrosis, anastomotic leakage, and colonic stricture[3]. Colonic segment necrosis and anastomotic leakage usually occur in the first postoperative week[4], but in our case, localized strictures of the cervical region developed 1.5 years after the first bypass operation. The slow course is likely explained by slowly progressive ischemia from graft torsion, resulting in a non-necrotic colonic cicatricial stricture rather than colonic necrosis. This may be the cause of esophageal obstruction in our case. This cicatricial change in the esophageal anastomosis site might twist the esophageal axis, and cause painful swallowing. Also this lesion was easily dilated with esophageal ballooning.

Although dilatation is the primary method of treating esophageal strictures[5], alimentary tract reconstruction is necessary for correction of severe and extensive strictures. Invasive surgeries like stomach pull-up, colon bypass, and free jejunal flap are not always possible when the prior operation was similarly invasive[6].

In our case, the right colon had already been used during the previous bypass operation, and the graft stricture of the neo-esophagus resulted from ischemia. Thus, patch dilative strictureplasty with viable tissue was

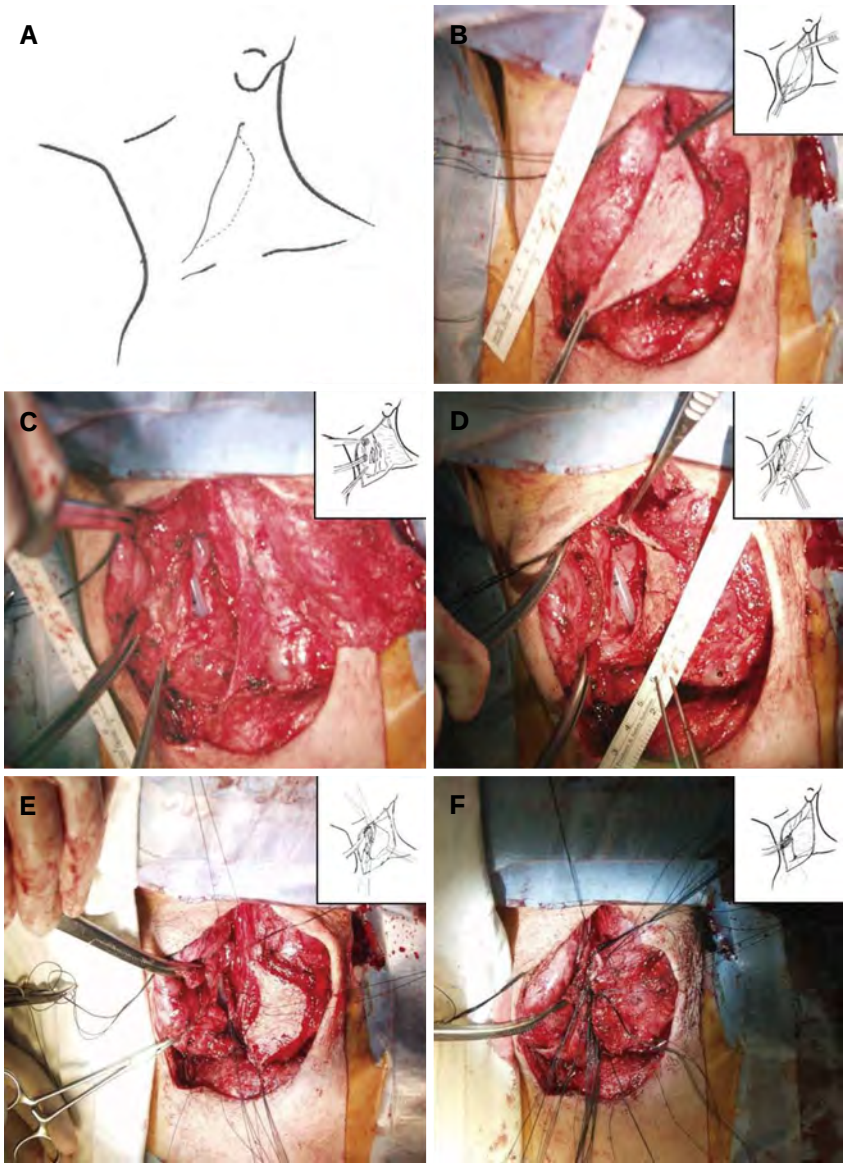

Figure 2 Photograph of the musculocutaneous sternocleidomastoid flap and esophagotomy during the operation. A: A skin incision was designed for an elliptical skin island based on the sternocleidomastoid muscle; B: A skin island (6 cm × 4 cm) on the sternocleidomastoid (SCM) muscle was prepared; C, D: Esophagotomy at the level of the cricoid cartilage was extended upward to pharynx and downward; E: The SCM muscle was severed near the clavicle and rotated. The skin flap was fixated to esophagus with interrupted silk sutures; F: The esophagoplasty site was covered with SCM muscle *via* multiple fixation sutures.

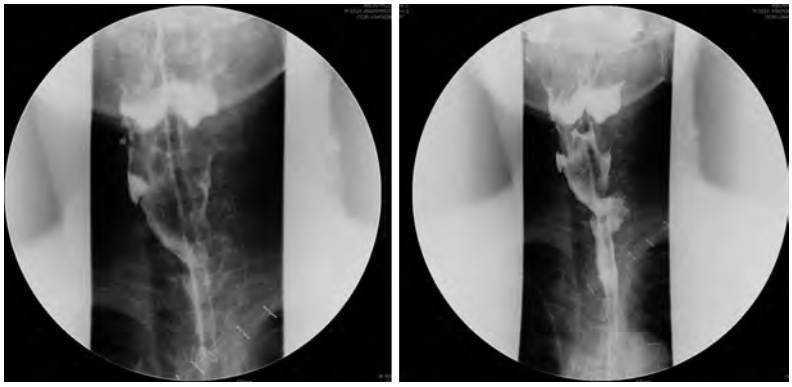

Figure 3 Esophagogram after sternocleidomastoid myocutaneous patch esphagoplasty. The stenotic lesion at the esophago-colonic anastomosis site was widened successfully and the dye passed through the colon conduit without resistance.

thought to be an ideal option for relieving the short, benign, recurrent cervical esophageal stricture.

The choice of tissue to be used as a patch to widen the esophagus varies. Among flaps, a myocutaneous flap has several advantages: its skin provides an adequate patch for the esophageal defect and the well-vascularized muscle forms a seal around the ischemic anastomosis site, obliterates dead space, and conveys antibiotics[7]. The SCM muscle is a logical choice for myocutaneous flap in this case because its anatomic proximity lessens trauma[7]. Because SCM patch esophagoplasty avoids complete transection of the esophagus, coordinated peristalsis is also preserved and vagotomy is avoided[7]. The SCM muscle has a segmental blood supply from branches of three

main vessels: the occipital artery superiorly, the superior thyroid artery in the middle segment, and a branch of the thyrocervical trunk inferiorly. The superior pedicle is more commonly used because it provides greater rotation and allows the SCM to reach the entire length of the ipsilateral cervical esophagus[2]. The SCM myocutaneous flap does, however, have limitations. Safety is a major concern when the SCM flap is used in oncologic patients[8]. In cases of radiation therapy, the SCM myocutaneous flap may be used only if the overlying skin is soft and supple[2]. Furthermore, use of a SCM pedicled skin flap is limited to the cervical esophagus. In conclusion esophagoplasty with SCM myocutaneous flap is thought to be an efficient treatment of recurrent cervical esophageal strictures.

Abstract

A 38-year-old female with a history of alcoholic liver cirrhosis visited our hospital with a massive hematochezia. An esophagogastroduodenoscopy did not demonstrate any bleeding source, and a colonoscopy showed a massive hemorrhage in the ascending colon but without an obvious focus. The source of the bleeding could not be found with a mesenteric artery angiography. We performed an enhanced abdominal computed tomography, which revealed a distal ascending colonic varix, and assumed that the varix was the source of the bleeding. We performed a venous coil embolization and histoacryl injection to obliterate the colon varix. The intervention appeared to be successful because the vital signs and hemoglobin laboratory data remained stable and because the hematochezia was no longer observed. We report here on a rare case of colonic variceal bleeding that was treated with venous coil embolization.

INTRODUCTION

Colonic variceal bleeding is a very rare cause of lower gastrointestinal bleeding. Fewer than 100 cases of colonic variceal bleeding have been reported in English literature and few case reports exist in South Korea. However, most cases in South Korea were caused by different varix locations, etiologies and treatments. A single case in South Korea with ascending colonic variceal bleeding caused by alcoholic liver cirrhosis was treated with a hemicolectomy[1]. We report the first case of an ascending colon variceal bleed caused by alcoholic liver cirrhosis that was treated with venous coil embolization in South Korea.

CASE REPORT

A 38-year-old female was admitted to our hospital with massive hematochezia and hemodynamic instability. She was diagnosed with alcoholic liver cirrhosis (Child-Pugh classification C) 6 years ago and had multiple hospitalizations with complications of esophageal variceal bleeding and hepatic encephalopathy. Upon physical examination, her initial blood pressure was 80/50 mmHg, her heart rate was 110 bpm, her respiration was 28 bpm and her

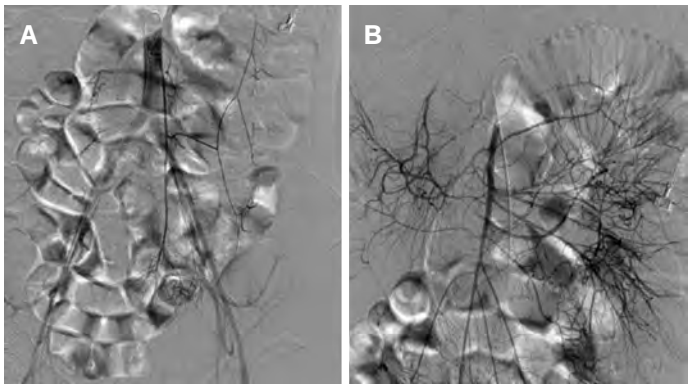

Figure 2 Mesenteric artery angiography. A: The inferior mesenteric artery angiography showing no source of bleeding; B: The superior mesenteric artery angiography showing no source of bleeding.

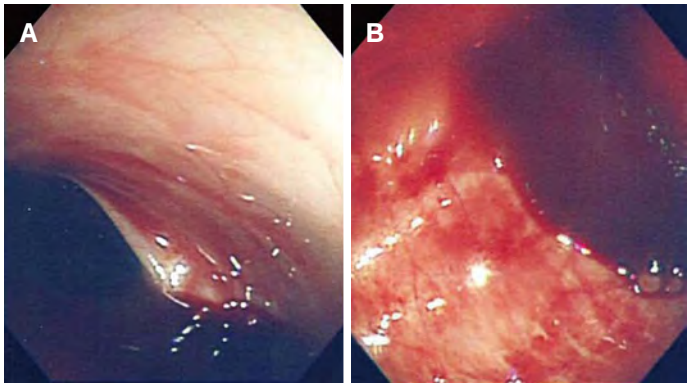

Figure 3 The second colonoscopy. A: Massive hemorrhage within the proximal ascending colon without a definite bleeding focus; B: Fresh blood within the distal ascending colon without a definite bleeding focus.

body temperature was 37 ℃. No evidence of bleeding was detected with nasogastric tube irrigation. Abnormal laboratory data upon admission included the following: hemoglobin 7.0 g/dL, hematocrit 22.3%, platelets 59 000/mm^3, serum creatinine 2.31 mg/dL, international normalized ratio 1.98, and albumin 2.1 g/dL.

An esophagogastroduodenoscopy demonstrated esophageal varices grade Ⅲ but did not show signs of recent bleeding. The colonoscopy showed fresh blood from the ascending colon to the rectum, but there was no evidence of bleeding in the terminal ileum, which demonstrated that the origin of the bleeding could be assumed to be in the ascending colon (Figure 1). Diagnostic angiographies of the superior and inferior mesenteric arteries were performed, but the source of the bleeding could not be found (Figure 2). Even with 2 units of packed RBCs, the hemoglobin level dropped to 5.6 g/dL the next day, and the vital signs remained unstable.

A second colonoscopy was still unable to visualize the bleeding focus and only detected a massive hemorrhage in the ascending colon (Figure 3). We performed an enhanced abdominal computed tomography (CT), which revealed the formation of a varix surrounding and protruding inside the distal ascending colon by the portacaval shunt (Figure 4). The varix was thought to be the source of the gastrointestinal bleeding. We planned an operation, but a right hemicolectomy could not be performed due to poor vital signs and abnormal coagulopathy. Initially, we tried to perform a Balloon-Occluded Retrograde Transvenous Obliteration (BRTO) but failed due to the selection of the portacaval shunt. Because the patient had unstable vital signs that required immediate intervention, we performed a coil embolization and his-

toacryl injection to obliterate the varix (Figure 5). After the coil embolization and 4 units of packed red blood cells, the patient's hemoglobin level rose to 10.0 g/dL, where it stabilized, and the vital signs (blood pressure and heart rate) recovered. There were no further signs of bleeding, such as hematochezia. However, the patient developed complications of pneumonia and renal failure, which led to multiorgan failure. Even with ventilator care and continuous renal replacement therapy, the patient expired 2 wk after the intervention.

DISCUSSION

Colon varices are a very rare cause of lower gastrointestinal bleeding, with a reported incidence of 0.07%[2]. Colon varices can be associated with several conditions, such as portal hypertension, portal venous obstruction, postsurgical changes and idiopathic factors, but the vast majority of colonic varices are related to portal hypertension caused by cirrhosis or portal vein obstruction. Embryologically derived anastomoses between the portal and systemic systems exist in the esophagus, terminal ileum, colon, retroperitoneum, and anterior abdominal wall[3]. The most common sites of colonic varices are the rectum and cecum[4]. Colon varices with portal hypertension are hypothesized to arise in patients in whom the colonic portosystemic venous collateral network is highly developed[5]. The rate of colonic variceal bleeding that causes lower gastrointestinal bleeding with liver cirrhosis is approximately 1%-8%[6,7]. Thus, if a patient has a history of liver cirrhosis and has massive gastrointestinal bleeding, the possibility of colon variceal bleeding should also be considered. Other than portal hypertension, mesenteric venous or splenic vein obstruction, which may be due to thrombosis, tumor invasion, extrinsic compression, acute or chronic pancreatitis, mesenteric adhesions, or congenital anatomic variations, may cause a colon varix. With no etiology, colon varix is classified as idiopathic or primary[5].

A colonoscopy is the principal method for the diagnosis of colon varices, but with massive bleeding, the diagnostic rate of a colonoscopy is 69% (range: 48%-90%) because the varices may be obscured by blood[8]. Thus, in case of massive hematochezia, magnetic resonance imaging, mesenteric angiography and abdominal CT are alternative diagnostic tools[9,10].

Management of colonic variceal bleeding has not been standardized. In a report describing a case of massive lower gastrointestinal bleeding with some hemodynamic instability caused by colonic varix, an operation was the optimal choice[11]. However, most cases with colonic variceal bleeding are associated with cirrhotic liver, which makes many cases inoperable due to coagulopathy. Thus, interventional therapies are tested depending on the underlying etiology and the distribution of the varices. These therapies include transhepatic intravenous portosystemic shunt (TIPS), BRTO, endoscopic variceal ligation, somatostatin infusion, argon plasma coagulation, histoacryl injection, and coil embolization[12-15]. Four other cases of colon variceal bleeding have been

described in South Korea. Theses cases had different varix locations, etiologies and treatments compared to our case. The first case was a 64-year-old female with liver cirrhosis who had descending colon variceal bleeding that was treated with a left hemicolectomy[16]. The second case was a 24-year-old male who had idiopathic rectal variceal bleeding that was treated with low anterior resection[2]. The third case was a 43-year-old male with ascending colon variceal bleeding due to alcoholic liver cirrhosis. This case was very similar to our case but was treated with a right hemicolectomy[1]. The last case was a 33-year-old woman with a history of systemic lupus erythematosus who developed antiphospholipid syndrome and had ascending colon variceal bleeding that was treated with octreotide, a beta-blocker and warfarin[17]. In our case, the patient was inoperable because of the poor vital signs and coagulopathy caused by the abnormal liver function. We initially tried to perform BRTO to obliterate the portacaval shunt, but the angiographic selection of the portacaval shunt failed. Thus, venous coil embolization along with a histoacryl injection was performed on the ascending colon varix. This technique seemed to be successful because the vital signs (blood pressure and heart rate) along with hemoglobin level remained stable, and no further evidence of gastrointestinal bleeding was observed after the intervention. This result is despite the fact that our patient expired due to complications of multiorgan failure because the patient already had terminal liver cirrhosis and had developed unstable vital signs before arriving in the emergency room. Together, these conditions made the patient susceptible to secondary infection and renal failure. Complications of the varix coil embolization procedure could also be considered after the intervention, such as necrosis, vessel perforation, non-targeting embolization and migration of the coil. However, although rate of complications has not been reported, this rate is thought to be very low because the procedure proceeds through a venous approach, and migration of the coil could be corrected during the procedure, and the patient did not complain of post-interventional symptoms such as abdominal pain, fever, or dyspnea. Thus, acute or delayed complications of the venous coil embolization were eliminated. A similar case in Switzerland included a 43-year-old male patient with ascending colon variceal bleeding due to alcoholic liver cirrhosis. The patient had TIPS initially to reduce the portosystemic pressure gradient, but the bleeding did not stop; the patient then underwent histoacryl injection and venous coil embolization. The patient recovered without further incidents[18]. As noted above, there is no standardized management of colon variceal bleeding, but venous coil embolization could be an effective treatment option for patients with massive hematochezia by the colon varix. Even though our patient could not survive due to multiple organ failure and secondary infection, we believe that the successful venous coil embolization had stopped the bleeding, which prevented a more aggressive progression. Our case is thought to be the first case in South Korea that used venous coil embolization to treat ascending colon variceal bleeding caused by alcoholic liver cirrhosis.

In conclusion, the treatment of colon variceal bleeding has not been well established. However, this case has shown that treatment with venous coil embolization on an ascending colon variceal bleeding caused by alcoholic liver cirrhosis is effective. We report here on the first case of ascending colon variceal bleeding caused by alcoholic liver cirrhosis that was treated with venous coil embolization in South Korea.

Abstract

The most frequent cause of pseudomembranous colitis is *Clostridium difficile* (*C. difficile*) infection. This type of colitis is characterized by an endoscopic pattern of numerous small, yellowish or whitish plaques diffusely distributed, which typically compromises the rectum extending to proximal colon. Occasionally, the pseudomembranes compromise only the transverse or right colon, but their exclusive localization over polyps has not been reported. In this case report we have described a patient with symptoms compatible with *C. difficile* infection and positive for *C. difficile* toxigenic culture. Colonoscopy examination showed two small polyps with a whitish surface, and histopathological analysis confirmed them to be pseudomembranes over tubular adenomas. The rest of the colonic mucosa was normal and no other cause was demonstrated. We suggest that this particular distribution might be due to a higher affinity for dysplastic cells such as adenomatous polyps of colon by *C. difficile* and/or its toxins.

INTRODUCTION

The clinical spectrum of *Clostridium difficile* (*C. difficile*) infections may vary from mild diarrhea to life-threatening pseudomembranous colitis (PMC), which may localize from the proximal colon to the rectum[1]. Localized forms of PMC have been reported to compromise the transverse and right colon[2], but to the best of our knowledge, we have not found cases with exclusive localization of PMC over polyps. Below, we report a case with the pseudomembranes only covering the surface of adenomatous polyps.

CASE REPORT

An 86-year-old female receiving anticoagulant therapy due

to an aortic valve prosthesis with auricular fibrillation secondary to aortic stenosis was admitted with an incarcerated umbilical hernia. A hernioplasty was performed without complication, and she was treated with sodium piperacillin-tazobactam (4.5 g *tid*) intravenously for 7 d and discharged 10 d after surgery. Twenty-five days later, she presented hematochezia with hemodynamic compromise. She was admitted to the coronary unit, and an upper endoscopy showed a hiatal hernia with Cameron's ulcers; she was treated with omeprazole. The next day a colonoscopy showed a clean colonic mucosa, absence of blood, and two sessile 6-mm polyps in the transverse colon and in the right colon. The upper surface of both polyps was covered by an adherent and whitish layer and the surrounding mucosa was normal (Figure 1). The polyps were resected with cold biopsy forceps and sent for histopathological study. Strikingly, the day after colonoscopy, the patient developed fever with no apparent cause in the physical exam, while laboratory results showed a hematocrit of 29%, white blood cell count of 8700 cell/μL without band forms and C reactive protein was 10.2 mg/dL. The chest X-ray was normal and the blood and urine cultures were negative. She was empirically treated with sodium piperacillin-tazobactam, but three days later she presented frequent loose stools and diffuse abdominal pain. An enzyme immune assay (EIA) for *C. difficile* toxin was positive. The antibiotic was stopped and she was treated with oral metronidazole with an excellent response. Presence of *C. difficile* was further confirmed by real time-polymerase chain reaction (PCR) and toxigenic culture. PCR-ribotyping indicated that the clinical isolate that caused *C. difficile* infection was not an epidemic strain (non-ribotype 027 strain). A few days later, the histopathological study of the polyps showed two tubular adenomas with a low-grade epithelial dysplasia and pseudomembranes on their surface with a typical volcanic appearance (Figure 2).

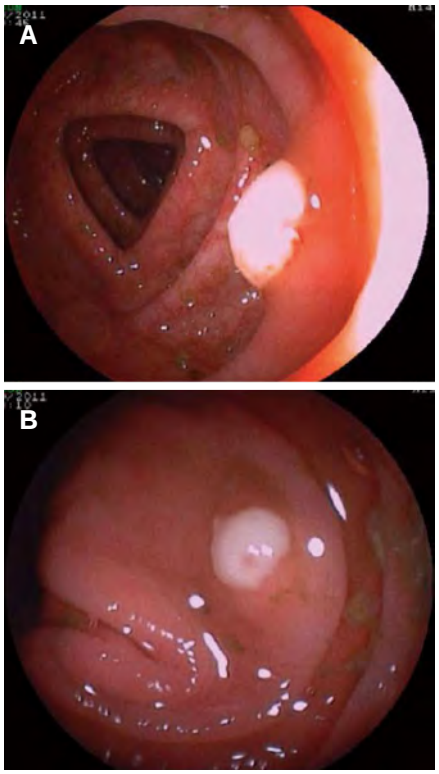

Figure 1 Colonoscopy images showing two polyps, 4 and 6 mm in size, in the right colon with adherent whitish surface. A: Polyp of 6 mm; B: Polyp of 4 mm. The mucosa round the polyps and in the rest of colon is normal.

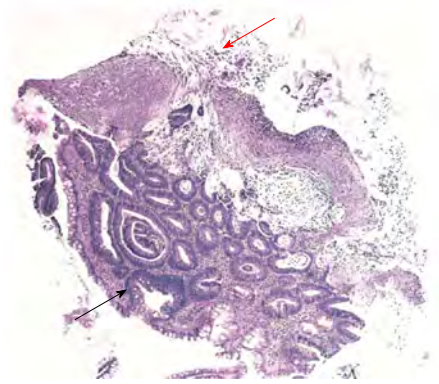

Figure 2 Low power view of a mucosal fragment. Histopathology shows: at the bottom, tubular structures lined by columnar epithelial cells with pseudostratified nuclei, consistent with low grade tubular adenoma (black arrow); at the top, ballooned crypts and intercrypt necrosis, an exudate featuring the classical "volcano" lesion (red arrow) surrounded by a laminated pseudomembrane composed of neutrophils, mucin and fibrin (hematoxylin and eosin, x 100).

DISCUSSION

It is our understanding that this is the first documented case in which the pseudomembranes are exclusively localized over adenomatous polyps with the rest of the colonic mucosa being intact. The term PMC is nonspecific and describes an acute mucosal injury characterized by an endoscopic pattern of numerous, discrete and small (2-5 mm), raised, round and yellowish plaques (pseudomembranes) distributed over an erythematous but unulcerated mucosa[1]. The rectum is frequently involved, but in a few cases the sigmoid and/or right colon is compromised[2]. The histological pattern is characterized by a neutrophil-rich edema fluid in the lamina propria that bursts through tiny breeches to the surface epithelium, like a volcanic eruption, to form a characteristic punctate inflammatory pseudomembrane[1,3]. The PMC is due, in nearly all cases, to *C. difficile*. Other infrequent causes are ischemic or infectious colitis[4]. Piperacillin-tazobactam has been associated at lower rates with *C. difficile* infection than other antibiotics[5]; however, in this case report, the clinical course and the study with EIA, PCR and toxigenic culture confirmed an association with *C. difficile* and the response to treatment with oral metronidazole was concordant.

The specific type of colonic cells where *C. difficile* infections starts is unclear, but it is known that at least enterotoxin A, one of its main virulence factors, has remarkable cytotoxicity for cells derived from human or animal cancer, more than for normal colonic epithelial

cells. One possible explanation, but by no means proven, is that the surface of neoplastic cells possesses a greater density of specific receptors for toxin A and/or toxin B as compared to less sensitive cell lines[6]. Alternatively, it is well known that members of the *Clostridium* genus have a tropism for tumors mainly due to the hypoxic environment as a consequence of poor vascular irrigation[7,8]. Thus, it seems plausible that colonic neoplastic cells might favor *C. difficile* colonization and PMC formation.

In conclusion, we propose that dysplastic changes of the colonic epithelium occurring as adenomatous polyps might represent a site of greater affinity for *C. difficile* toxin and/or tropism of *C. difficile* cells with the consequent formation of pseudomembranes, which were observed by an early colonoscopy in this patient.

Abstract

The SRS™ Endoscopic Stapling System (Medigus, Tel Aviv, Israel) is a new tool capable of creating a totally endoscopic fundoplication, combined with an endoscope, endoscopic ultrasound and a surgical stapler. SRS™ endoscopic stapling for gastro-esophageal reflux disease is a minimally invasive, outpatient procedure, which requires general anesthesia with positive-pressure ventilation. Keeping the patient on positive end-expiratory pressure (PEEP) may minimize the pressure gradient between the esophagus and the mediastinum, as well as help to prevent air from leaking around the screws and causing pneumomediastinum. In addition, in patients with hiatal hernia, higher PEEP levels may be required to increase intra-thoracic pressure and to force the stomach to slide into the abdomen for ease of endoscopy. We advise smoother emergence from anesthesia, taking precautions for retching, postoperative nausea and vomiting (PONV), while coughing and gagging during extubation and PONV may affect the success of the procedure. Total intravenous anesthesia with propofol and remifentanil seems to be a good choice for these reasons.

Topuz U, Umutoglu T, Bakan M, Ozturk E. Anesthetic management of the SRS™ endoscopic stapling system for gastro-esophageal reflux disease. *World J Gastroenterol* 2013; 19(2): 319-320 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i2/319.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i2.319

TO THE EDITOR

Endoscopic ultrasound was developed as a useful diagnostic tool and is being used in the treatment of various gastrointestinal diseases[1,2]. The SRS™ Endoscopic Stapling System (Medigus, Tel Aviv, Israel) is a new tool capable of creating a totally endoscopic fundoplication, combined with an endoscope, endoscopic ultrasound, and a surgical stapler[3]. This modified endoscope fires 3 rows of staples plicating the fundus onto the esophagus. While the anesthesia management of the SRS™ endoscopic fundoplication procedure has not been described, we would like to share our initial experiences with it on 12 patients.

After obtaining written informed consent, patients diagnosed with gastro-esophageal reflux disease, without or with ≤ 3 cm hiatal hernia, were scheduled for this procedure. Following at least 8 h fasting time, patients were premedicated with midazolam, metoclopramide, and a proton pump inhibitor. Total intravenous anesthesia (TIVA) with propofol and remifentanil was used for both induction and maintenance of general anesthesia. After muscle relaxation was achieved with rocuronium, patients were endotracheally intubated. Patients were mechanically ventilated with oxygen/air mixture. During the procedure, the lumen of the stomach was inflated with air for better visualization. To prevent possible air leakage,

positive end-expiratory pressure (PEEP) 4-6 mmHg was applied. If a hiatal hernia was discovered during preliminary gastroscopy, the patient should be tilted 15 degrees head up and the PEEP level must be increased to 7-10 mmHg in order to depress the diaphragm and reduce the gastro-esophageal junction, so that it can be repositioned into the abdomen. Mean interventional time was 75 min; range was between 47-102 min according to the expertise of the operator. Paracetamol 1 g *iv* was administered for postoperative analgesia and ondansetron 4 mg *iv* for postoperative nausea and vomiting (PONV). Recovery was uneventful in all patients.

In conclusion, SRS™ endoscopic fundoplication for gastro-esophageal reflux disease is a minimally invasive, outpatient procedure, which requires general anesthesia with positive-pressure ventilation. Keeping the patient on PEEP may minimize the pressure gradient between the esophagus and the mediastinum and may help to prevent air from leaking around the screws and causing pneumomediastinum. In patients with hiatal hernia, higher PEEP levels may be required to increase intra-thoracic pressure and force the stomach to slide into the abdomen for ease of endoscopy. It must be kept in mind that higher PEEP levels may be associated with arterial hypotension. We advise smoother emergence from anesthesia, taking precautions for retching, PONV, while coughing and gagging during extubation and PONV may affect the success of the procedure. TIVA with propofol and remifentanil seems to be a good choice for these reasons.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

Abstract

Hepatoid adenocarcinoma (HAC) is a rare but important special type of extrahepatic adenocarcinoma with clinicopathological presentation mimicking hepatocellular carcinoma (HCC), and prompt and correct diagnosis can be a challenge, especially in endemic areas with a high incidence of HCC. To date, HAC has only been reported in case series or single case reports, so we aimed to review the clinicopathological characteristics of HAC to obtain a more complete picture of this rare form of extrahepatic adenocarcinoma. All the articles about HAC published from 2001 to 2011 were reviewed, and clinicopathological findings were extracted for analysis. A late middle-aged male with high serum α-fetoprotein and atypical image finding of HCC should raise the suspicion of HAC, and characteristic pathological immunohistochemical stains can help with the differential diagnosis. Novel immunohistochemical markers may be useful to clearly differentiate HAC from HCC. Once metastatic HAC is diagnosed, the primary tumor origin should be identified for adequate treatment. The majority of HAC originates from the stomach, so pan-endoscopy should be arranged first.

INTRODUCTION

Hepatoid adenocarcinoma (HAC) is a rare but important special type of extrahepatic adenocarcinoma with clinicopathological presentation mimicking hepatocellular carcinoma (HCC). HAC was first reported as an α fetoprotein (AFP)-producing tumor in 1970[1], and Ishikura *et al*[2,3], in a report of seven AFP-producing gastric adenocarcinomas (GAC), proposed the term hepatoid adenocarcinoma due to the high AFP levels, ranging from 4730 to 700 000 ng/mL in serum. A serum AFP level higher than 200 ng/mL has been one of the screening criteria for HCC in international guidelines, and HCC may be diagnosed when liver tumors with high serum AFP are found among patients with liver cirrhosis[4,5]. Because of high serum AFP levels among patients with HAC, identification of tumor origin may be difficult, especially when liver tumors aris-

ing from HAC metastasis are initially found. Distinguishing between HAC and HCC is important, especially in areas with a high incidence of chronic hepatitis B, chronic hepatitis C and HCC.

HAC can originate from different organs such as the stomach[6], gallbladder[7], colon[8], lung[9] and urinary bladder[10], and the stomach is the most common origin of tumors in the literature. Finding the primary tumor origin of HAC is crucial, and prompt and adequate treatment may improve outcomes of patients. However, HCC with various extrahepatic metastases such as to the stomach has been reported[11], and determining the tumor origin may become a challenge for physicians, especially when clinicopathological findings of liver tumors are not typical for HCC. Pathological findings in immunohistochemical (IHC) stains may help in the differential diagnosis of HAC, and some specific IHC stains such as cytokeratin (CK)19, AFP, Hep-Par 1 and palate, lung, and nasal epithelium carcinoma-associated protein (PLUNC) have been used in the literature[12]. A systemic literature review regarding differential diagnosis of HAC by IHC stains is lacking, and the IHC presentations of HAC, HCC and common GAC (except HAC) are compared in this review.

The majority of HAC originates from the stomach, and the incidence of gastric HAC among GAC cases was reported to be 0.3%-1% in some recent articles[6,13,14]. The clinical features of gastric HAC are old age, aggressive clinical course, poor survival and frequent metastasis to the liver and lymph nodes, and data have suggested that HAC of the stomach has a poorer prognosis than common GAC[14]. Detection of tumors in the early stage, followed by surgical resection is still considered to be the only way to cure HAC. Because clinical presentations of HAC differ from those of common GAC, studies focusing on gastric HAC may be important in the future, and clinical characteristics may provide useful clues for further research. Moreover, a review of HAC originating from organs other than stomach is still lacking. To date, HAC has only been reported in case series or single case reports, so we aimed to review the clinicopathological characteristics of HAC to obtain a more complete picture of this rare form of extrahepatic adenocarcinoma.

LITERATURE REVIEW

All articles cited in the Medline/PubMed database from January 2001 to December 2011 were searched to identify relevant medical literature, and the search terms included "hepatoid adenocarcinoma", "AFP-producing tumor", "α fetoprotein-producing tumor" and "α fetoprotein-producing gastric cancer". In addition, a manual search of all relevant articles was conducted. All studies with full text were included. The search limits were: (1) type of article: all types; (2) languages: English; (3) species: humans; (4) sexes: both male and female; (5) subsets: all types and fields; (6) ages: all ages; and (7) search field tags: titles. Studies without pathological confirmation of HAC or without clinical data were excluded.

A total of 98 articles were initially identified from the literature search. Among the 98 articles, 32 were excluded because the diagnosis was not confirmed as HAC, and 13 were excluded because the full text was not available. In total, 217 patients with HAC were included in our review. (All 53 reviewed articles are listed in Supplementary References online).

CLINICAL CHARACTERISTICS

The clinical features of HAC cases are summarized in Table 1. Most HAC originated from the stomach (83.9%), and origins other than the stomach, including gallbladder (3.7%), uterus (3.2%), lung (2.3%) and urinary bladder (1.8%), were rare. Moreover, HAC originating from the esophagus and peritoneum was very rare (0.9%), and HACs of the rectum, transverse colon, testis, ovary, jejunum or ureter were only reported in single case report form (< 0.5%). The mean age of HAC patients was 63.0 ± 12.8 years, with a range of 21 to 100 years. Patients with HAC were usually male and the male-to-female ratio was 2.3:1. Most patients had elevated serum AFP (84.8%), with a range from less than 1.0 to 475 000 ng/mL.

When HAC was diagnosed, metastases from original organs were usually found. The most common sites of metastasis were lymph nodes (57.5%), followed by liver (46.3%) and lung (3.4%) metastasis. Liver and gastric tumors were often found simultaneously, and liver tumors could be detected before gastric tumors. As in common gastric cancer, surgical resection was the primary curative treatment in HAC. Most patients received surgical resection (80.2%), even when lymph node or distant metastases were found. In addition, about half of patients (52.1%) received adjuvant chemotherapy following surgical resection. In our literature review, survival data were not reported for all patients, but we were able to analyze data from 125 cases with various tumor origins. The median survival of all HAC patients was 12 mo, and 64 (51.2%) patients died within the first 12 mo.

PATHOLOGICAL CHARACTERISTICS

Hematoxylin and eosin stain

HAC usually showed morphologic similarity to HCC in histology, and polygonal tumor cells were found in hematoxylin and eosin (HE) stains. Polygonal tumor cells proliferating in both trabecular and intestinal-like structures could be found (Figure 1), but definite diagnosis of HAC was difficult only based on findings in histology. Further IHC stains were usually done for differential diagnosis.

Immunohistochemical staining

The major IHC presentations of HAC tumor tissues are depicted in Table 2. Positive AFP stains (Figure 2A) were found in the majority of HAC (91.6%), but positive Hep Par 1 stains were only found in some HAC patients (38.1%) (Figure 2B). In addition, positive carcinoembryonic antigen (CEA) stains were found in most HAC patients (78.7%). Among epithelial markers, all HAC tumors were

positive for both CK18 and CK19 stains (100%), and only a small proportion of HAC patients showed positive stains for CK20 (25%) and CK7 (15.4%). High proportions of HAC tumors were positive for pancytokeratin (AE1/AE3) stain (92.3%) and α1-antitrypsin (α1-AT) stain (91%), and 62.5% of HAC patients were positive for CD10 antigen. In addition, positive glypican 3 (GPC-3) staining (Figure 2C) was found in all HAC patients (100%).

DIFFERENTIAL DIAGNOSIS

Clinical presentation

Although the stomach is the most common origin of HAC, the clinical presentation of HAC may vary greatly depending on the anatomic location of the tumor. Among gastric HAC cases, clinical symptoms were usually non-specific, such as fatigue, weight loss, nausea, poor appetite, emesis, diarrhea, epigastric distress, epigastric mass, abdominal pain or abdominal distension[15-17]. It is difficult to make a differential diagnosis from the clinical symptoms alone.

HAC is usually found in late middle-aged males, and elevated serum AFP is commonly noted among patients with HAC. Due to similar clinicopathological features, HAC may closely resemble and even be indistinguishable from HCC. Serum AFP has long been used for the screening and diagnosis of HCC, and high AFP in HAC may confuse physicians[4,5]. HAC may be incorrectly diagnosed as HCC, especially in endemic areas with a high incidence of HCC. AFP may be elevated in various conditions including HAC, so AFP is not suggested for diagnosis of HCC nowadays[18]. Diagnosis of HCC should be based on dynamic image studies (such as computed tomography or magnetic resonance imaging) and/or liver tumor biopsy, and the typical dynamic image of HCC shows intense arterial uptake followed by "washout" of contrast in the venous and/or delayed phases[18]. Even in liver tumors with elevated AFP, secondary malignancies still should be considered especially when the presentations of imaging studies are atypical, and liver tumor biopsy is recommended for differential diagnosis. In addition, risk factors such as liver cirrhosis, chronic hepatitis B or chronic hepatitis C infection can usually be found among patients with HCC, but those risk factors may not be observed among patients with HAC. Once AFP-producing metastatic liver tumors are found, an intensive search for primary tumor origin should be initiated.

HAC is a very aggressive neoplasm with metastasis in a high proportion of patients at the time of diagnosis. Lymph nodes and the liver are the most common sites of metastasis. Once metastatic HAC is suspected, panendoscopy should be arranged because the stomach is the most common origin of HAC. HCC with metastasis to the stomach has been reported[11], and a clinical challenge of differentiating primary tumor origin arises when liver and gastric tumors are found simultaneously. Pathology markers, especially IHC stains, may provide clues to make a correct diagnosis. In addition, finding the tumor origin may be challenging when no tumor can be detected in the liver and/or stomach, so other organs

Table 3 Comparison of positive rates of commonly-used key immunohistochemical stains in hepatocellular carcinoma, hepatoid adenocarcinoma, and common gastric adenocarcinoma

IHC stains	HCC[1]	HAC[2]	Common GAC[3,4]
AFP	8.2%-37%	92.1%	0%-0.8%
GPC-3	84%	100%	3.4%
Hep Par 1	73%-93%	38.1%	4%-47%
CK19	8.2%-15%	100%	83.6%-89.7%

IHC: Immunohistochemical; HCC: Hepatocellular carcinoma; HAC: Hepatoid adenocarcinoma; GAC: Gastric adenocarcinoma. [1]HCC: AFP stain in 218 cases[16,29,30], GPC-3 stain in 56 cases[30], Hep Par 1 stain in 308 cases[16,29-32] and CK19 stain in 233 cases[16,29,33]; [2]HAC data source: Data based on our review in Table 2; [3]Common GAC data source: AFP stain in 122 cases[34,35], GPC-3 stain in 118 cases[35], Hep Par 1 stain in 108 cases[22,32], CK19 stain in 384 cases[33,36]; [4]Common GAC means GAC except HAC.

such as the gallbladder, urogenital tract, lung and intestine should be carefully checked.

As a result of the high rate of metastasis and a disappointing response to chemotherapy in HAC, poor patient survival can be predicted. Data have suggested that HAC has a poorer prognosis than more common types of tumors[14], and more than half of patients died within the first 12 mo in our literature review. There has been no systemic therapy proven to be effective for HAC until now, but target therapy such as sorafenib is recommended as a standard treatment in HCC with extrahepatic metastasis to prolong patient survival[18].

Pathological presentation

Because HAC bears a striking morphologic similarity to HCC in histology and IHC stains, HCC could be mistakenly diagnosed when liver tumors are the only initial finding, especially in regions with a high incidence of HCC. However, HAC and HCC differ in histologic presentation, and specific findings suggesting HAC may provide important clues. Kodama *et al*[19] described two histologic types of HAC: one was the medullary type, characterized by polygonal cells arranged in a solid nest or sheets, with scattered large pleomorphic or multinucleated giant cells, and the other was well-differentiated papillary or tubular type with clear cytoplasm. However, two types of HAC sometimes coexist in a single tumor. If polygonal tumor cells proliferating in both trabecular and intestinal-like structures are found in HE staining, HAC should be considered (Figure 1).

HAC usually secretes some special chemomediators, so it could be characterized by some IHC stains (Table 2). As an AFP-producing tumor, HAC is commonly > 90% stained for AFP regardless of organ origin (Figure 2A). Although AFP is a characteristic stain for identifying HAC, it can also cause confusion in differentiating HAC from HCC. AFP, a well-known tumor marker of HCC, is usually secreted by HCC and gonadal tumors, and AFP can be positive in tissues of these tumors[20,21]. Hep Par 1, a highly specific marker of HCC, may help in the differential diagnosis between HAC and HCC (Figure 2B), but some HAC tumors can still present with positive staining. In addition, although a low percentage of gastric HAC was stained positive for Hep Par 1 (Table 2), high percentages of non-gastric HAC such as HAC of the gallbladder and urinary bladder were stained positive. However, due to the small case numbers of non-gastric HAC, large cohort studies are needed to confirm this finding. Moreover, other tumors such as adrenal cortical carcinoma, yolk sac tumor, colonic adenocarcinoma, lung carcinoma, ovarian carcinoma and endocervical adenocarcinoma may be occasionally positive for Hep Par 1 stain[22].

The proportion of HAC with a positive CEA stain was high in both gastric (75%) and non-gastric HAC (75%-100%), but it can also be positive in HCC and other metastatic adenocarcinoma of the liver[23] arising from the gastrointestinal tract such as the colon[24,25], stomach[26] and pancreas[27]. Among epithelial markers, AE1/AE3, CK18 and CK19 are usually positive for HAC (92.3%, 100% and 100%, respectively), but the proportions of positive CK20 and CK7 stains are low (25% and 15.4%, respectively). CK7 and CK20 have diagnostic value in differentiating the tumors of unknown primary sites, and epithelial neoplasms with negative staining for CK7 and CK20 include adrenal cortical carcinoma, germ cell tumor, prostate carcinoma, renal cell carcinoma, and HCC[28]. In the differential diagnosis between HAC and HCC for AFP-producing liver tumors, HAC is strongly suggested if AE1/AE3, CK18 and C19 stains show strong positive findings.

Regarding other IHC stains for HAC such as α1-AT, α1-antichemotrypsin, CD10, CDX2, MUC1, PLUNC and GPC-3 have been reported to be promising in the differential diagnosis of HAC[12]. For example, Sentani *et al*[29] reported that positive PLUNC staining was observed in all six gastric HAC, and PLUNC staining was also detected in both liver metastases. Furthermore, PLUNC staining was not observed in 52 cases of HCC, and it was a novel marker that might well distinguish HAC from HCC. However, case numbers in the literature were small (Table 2), and further studies to confirm sensitivity and specificity will be crucial.

In Table 3, we summarize and compare positive rates of commonly-used key IHC stains among HCC, HAC, and common GAC (except HAC) from our literature review[16,29-36] of the most common clinical malignancies needing differential diagnosis. Although the AFP stain can be positive in both HCC and HAC, it is overwhelmingly positive in HAC (91.6%) in our review. In other words, tumors with a negative AFP stain are rare in HAC, and they usually do not indicate HAC. Moreover, AFP staining is almost always negative in common GAC (0%-0.8%) in the literature, and it may be a useful tool to confirm HAC-type GAC. Similar to the AFP stain, the GPC-3 stain can be used in the differential diagnosis because of its low positive rate in common GAC but high positive rate in HAC (Figure 2C). However, although GPC-3 and AFP stains can be positive in both HCC and

HAC, HCC with a negative AFP stain may be confirmed by GPC-3 staining. Hep Par 1 is another important stain with a high positive rate in HCC, but it can also be positive in some HAC (38.1%) in our review. The Hep Par 1 stain is usually negative in common GAC, and liver tumors with a negative Hep Par 1 stain suggest metastasis from other origins such as the stomach. Epithelial marker CK19 stain has an almost 100% positive rate in HAC, and it is also frequently positive in common GAC. However, the positive rate of CK19 in HCC is very low, and HCC is usually not suggested with a positive CK19 stain in liver tumors. In summary, HAC is a special type of extrahepatic adenocarcinoma with pathological presentation mimicking HCC, and HAC should be suspected once polygonal tumor cells proliferating in both trabecular and intestinal-like structures are found in HE staining. There is no single IHC stain that can completely differentiate HAC from HCC, and a panel of IHC stains, such as CK19, PLUNC, Hap-Par 1 and CEA, with detailed clinical history and endoscopic findings are essential for definitive diagnosis.

CONCLUSION

HAC is a rare but important special type of extrahepatic adenocarcinoma with clinicopathological presentation mimicking HCC, and prompt and correct diagnosis can be a challenge, especially in endemic areas with a high incidence of HCC. A late middle-aged male with high serum AFP and atypical image findings of HCC should raise the suspicion of HAC, and characteristic pathological IHC stains can help in differential diagnosis. Novel IHC markers may be useful to clearly differentiate HAC from HCC. Once metastatic HAC is diagnosed, a search for the primary tumor origin should be initiated for adequate treatment. The majority of HAC arise from the stomach, so panendoscopy should be arranged first.

Abstract

The assessment of the prognosis in patients with early hepatocellular carcinoma represents a hot-topic issue that requires further improvements and clarifications. The life expectancy of the patients has been shown to depend on several clinical and histological parameters (such as patient's general conditions, macroscopic tumor morphology and histopathology). Recently, the prognostic role of some biomarkers [i.e., alpha-fetoprotein (AFP)] has been also investigated with controversial findings mainly on the assessment of patient survival. The study by Giannini *et al* failed to show a prognostic value of AFP on survival of patients with well-compensated cirrhosis and small hepatocellular carcinoma. Since the study presents some limitations, a larger clinical trial is needed to clarify the potential prognostic role of serum AFP levels in these patients.

INVITED COMMENTARY ON HOT ARTICLES

The incidence of hepatocellular carcinoma (HCC) has rapidly increased in the last decade to reach the sixth most common cancers worldwide[1]. HCC most often develops in patients with chronic liver disease, usually cirrhosis. Several therapies for HCC have been developed and can be divided into four categories: surgical interventions (tumor resection and liver transplantation), percutaneous interventions (ethanol injection, radiofrequency thermal ablation), transarterial interventions (embolization, chemoperfusion, or chemoembolization) and drugs including gene and immune therapy. However, the diagnosis and treatment of a HCC at an early stage remain the most relevant strategies to improve prognosis[2]. Several pathophysiological biomarkers have been investigated to predict HCC recurrence after liver transplantation[3]. In particular, among different gene, RNA and protein targets, the circulating levels of alpha-fetoprotein (AFP) before the liver transplantation have been recently shown to be independent predictors of HCC recurrence[3]. Firstly described by Abelev *et al*[4], AFP is a large serum glycoprotein, belonging to the class of onco-development protein[5]. It is synthesized by embryonic liver, the fetal intestinal tract and the vitelline sac cells. Similar to albumin, AFP binds and transports a large variety of ligands, such as fatty

acids, retinoids, steroids, heavy metals, dyes, flavonoids, phytoestrogens, dioxin, and various others drugs[6,7]. Previous findings by Toso *et al*[8], showing that a combined score with total tumor volume (TTV) and AFP levels (> 400 ng/mL) was capable of predicting posttransplant survival, further supported the clinical prognostic use of this biomarker in transplanted patients. In this analysis of 6478 adult recipients of an isolated first liver transplant included in the Scientific Registry of Transplant Recipients database, the authors suggested that more traditional Milan criteria might be less efficient especially in patients with large TTV[8]. Despite these promising results, the clinical use of AFP has been also shown to present some important limitations in sensitivity and specificity. In fact, low AFP levels have been described in HCC patients, while high levels might be detected in hepatic cirrhosis without HCC[2]. For instance, Sangiovanni *et al*[9] have found that the level of AFP was increased in only 38% patients developing small HCC nodules. Indeed, AFP might be also useful in detecting other tumors (such as germ cell tumors of the ovary and testis and colorectal cancer)[10,11]. Thus, although currently recommended as a fundamental parameter for HCC screening in patients with cirrhosis[2,12], the prognostic capability of AFP in patients with HCC remains controversial and with important limitations.

The article by Giannini *et al*[13] performed a retrospective analysis from the Italian Liver Cancer group and showed that serum AFP levels did not predict survival in a prospective cohort of 205 patients with well-compensated cirrhosis and small (< 3 cm) hepatocellular carcinoma (Child-Pugh class A and Eastern Cooperative Group Performance Status 0) treated with curative intent. Therefore, accordingly to the Child-Pugh score, which is used to assess the prognostic of the liver disease, and the status that indicates the severity of the disease, the patients for this study exhibit a very early stage of HCC. Interestingly, AFP failed to predict survival also when patients were sub-divided into three groups and analyzed accordingly to their alpha-fetoprotein serum levels (normal: 0-20 ng/mL, n = 116; altered: 21-200 ng/mL, n = 71; diagnostic: > 200 ng/mL, n = 18) at the time of HCC diagnosis. Authors also indicate some potential limitations underlying the study results. AFP levels were within the normal range in a large portion of the cohort, thus confirming the previously discussed limitations in sensitivity of this marker in patients with early HCC and cirrhosis[14]. These low AFP levels also contributed to determine a very low statistical power (22%) to detect differences in survival rates between patient groups. In addition, the stratification from AFP levels revealed a statistically significant difference in male gender between groups. Since AFP levels have been shown to be potentially influenced by the patient gender (increased values in women)[15], this point might represent a critical concern affecting the relevance of the negative results. Finally, potential comorbidities (such as human immunodeficiency virus co-infection previously shown to potentially influence AFP levels) were also not reported[16]. These limitations have been correctly considered by authors, who concluded that the evaluation of more accurate biomarkers (other than AFP) might improve the assessment of prognosis in patients with early HCC. We believe that the study by Giannini *et al*[13] critically confirmed important concerns on strategies targeting a single prognostic biomarker in early HCC. In fact, given several existing confounders and its potential association with HCC nodule size, AFP levels might be more perceptible and relevant in patients with advanced HCC[17]. In particular, the changes from AFP basal levels might be also useful for monitoring the treatment efficacy[18]. In agreement with Giannini *et al*[13], we support a multifactorial approach to improve the prognostic prediction in patients with early HCC. In addition, we would also suggest that larger prospective studies with appropriate statistical power are needed to really evaluate the role of AFP and other biomarkers in these patients.

In conclusion, we believe that the study by Giannini *et al*[13], focused on a hot-topic issue in the hepatological field, importantly contributed to the current debate on the clinical use of serum biomarkers in disease prognosis. Considering the substantial study limitations, larger clinical trials are needed to better evaluate the prognostic role of AFP in early HCC. The matter is opened for future studies and discussion.

Abstract

Heterotopic gastric mucosa of the proximal esophagus (HGMPE), also referred to as "inlet patch" or "cervical inlet patch", is a salmon colored patch that is usually located just distal to the upper esophageal sphincter. HGMPE is uncommon with endoscopic studies reporting a prevalence ranging from less than one percent to 18%. Most HGMPE are asymptomatic and are detected incidentally during endoscopy for evaluations of other gastrointestinal complaints. Most consider HGMPE as clinically irrelevant entity. The clinical significance of HGMPE is mainly acid related or neoplastic transformation. The reported prevalence of laryngopharyngeal reflux symptoms varies from less than 20% to as high as 73.1%. However, most of these symptoms are mild. Clinically significant acid related complications such as bleeding, ulcerations, structure and fistulization have been reported. Although rare, dysplastic changes and malignancies in association with HGMPE have also been reported. Associations with Barrett's esophagus have also been reported but the findings so far have been conflicting. There are still many areas that are unknown or not well understood and these include the natural history of HGMPE, risk factors for complications, role of *Helicobacter pylori* infection and factors associated with malignant transformations. Follow-up may need to be considered for patients with complications of HGMPE and surveillance if biopsies show intestinal metaplasia or dysplastic changes. Despite the overall low incidence of clinically relevant manifestations reported in the literature, HGMPE is a clinically significant entity but further researches are required to better understand its clinical significance.

Chong VH. Clinical significance of heterotopic gastric mucosal patch of the proximal esophagus. *World J Gastroenterol* 2013; 19(3): 331-338 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/331.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.331

INTRODUCTION

Heterotopic gastric mucosa of the esophagus (HGMPE), also commonly referred to as "inlet patch" or "cervical inlet patch", is an island of ectopic gastric mucosa that is found in the proximal esophagus[1,2]. Rarely, they can also been found in the other part of the esophagus[2,3]. HGMPE is widely considered to be congenital in nature. However, it has also been proposed to be an acquired condition[1,4,5].

The reported incidence varies from less than one percent[6] to 13.8% in endoscopic studies[7]. Autopsy study has reported higher incidence of up to 70%[1,2]. Commonly reported symptoms include laryngopharyngeal reflux (LPR) symptoms and the prevalence has been reported to be as high as 73.1%[8]. However, most of these symptoms are mild and the management depends on the severity of symptoms. A clinico-pathologic classification has been proposed which categorized HGMPE into five distinct groups based on their clinical, endoscopic and

histological characteristics (Table 1)[1]. Serious and significant complications of HGMPE have been reported in both adults and the pediatric population[1,2,9]. Interestingly, other common upper aero-digestive disorders have also been linked to HGMPE[2,9]. The clinical significance of HGMPE remains debated due to the limited number of publications. This article reviews the literature and discusses the clinical manifestations and significance of HGMPE in clinical practice.

Table 1 Clinico-pathological classification for heterotopic gastric mucosa of the proximal esophagus

Category	Description	Symptoms/findings
I	Asymptomatic	None
II	Symptomatic	Laryngopharyngeal reflux
III	Symptomatic with benign complications	Strictures/webs/fistula/bleeding
IV	Intra-epithelial dysplasia	None/non-specific
V	Malignant transformation	Asymptomatic/dysphagia

BACKGROUND

Pathogenesis

Currently, there are three proposed theories on the development of HGMPE[1,2,4,5]. The most widely accepted theory is that HGMPE is congenital in origin. During the development of the esophagus and at 24 wk of gestation (equivalent to 90 mm crown rump length during fetal development), squamous lining replaces the columnar lining starting from the mid esophagus moving in both directions. The proximal esophagus is usually the last part to get stratification and this account for the common finding of heterotopic gastric mucosa in the proximal esophagus[1,2]. Although less common, ectopic mucosa can also be found in the other parts including the distal esophagus[2,3]. Another proposed theory involves metaplastic transformation of the squamous lining to columnar from chronic acid injury as seen in Barrett's esophagus[4]. Proliferation of remnant pluripotent cells as result of acid injury has been proposed as the underlying pathogenesis. The third theory involves rupture of proximal esophageal retention cystic glands[5].

The most common histological type is the cardia or oxyntic type mucosa followed by the antral mucosa. Depending on the mucosa type, some HGMPE can produce acid[10-12], and given their close proximity to the laryngopharyngeal complex can easily reflux into this area to cause symptoms. The laryngeal mucosa is also particularly susceptible to acid injury, even with mildly acidic secretion. Non-acidic secretions such as mucus have also been shown to induce laryngopharyngeal symptoms[13].

HGMPE can be colonized by *Helicobacter pylori* (*H. pylori*) and the prevalence have been reported to be as high as 82%[14]. The infection rates probably correlate with the prevalence of *H. pylori* infection in the general population. Although the role of *H. pylori* in HGMPE remains uncertain, one can probably surmise that it can cause changes similar to those seen in the stomach. Inflammatory and histological changes such as atrophy, metaplasia, dysplasia and carcinoma of the HGMPE have also been reported[2,15].

Endoscopic characteristics

HGMPE is often missed during endoscopy as the proximal esophagus is often neglected or briefly examined during routine endoscopic examination. On endoscopy, HGMPE appears as a salmon colored ovoid or round patch that is usually distinct from the surrounding esophageal squamous mucosa (Figure 1A and B). It can be flat, elevated or depressed and the surface can be smooth or nodular. Most HGMPE are located on the lateral walls typically a few centimetres distal to the upper esophageal sphincter (16 and 21 cm from the incisors)[1,2]. The sizes can vary from microscopic to as large as three to five centimeters. Most patients have a single patch while those with multiple patches, the patches tend to be small and are usually found within close proximity of other patches. On specialized imaging such as narrow band imaging, the HGMPE is clearly more visible (Figure 1C).

CLINICAL MANIFESTATIONS

The clinical manifestations of HGMPE can be broadly divided into non-neoplastic and neoplastic. The majority of patients found to have HGMPE are asymptomatic and the HGMPE are detected incidentally during evaluation for other gastrointestinal complaints. These patients are categorized to have type I HGMPE. The non-neoplastic manifestations (type II and III) such as LPR symptoms and strictures and bleeding are probably related to the acid produced by the patch. The least common manifestations are the histological or neoplastic changes (type IV and V)[1,2]. With the exception of malignancy in the pediatric population, all these have been reported both in the adult[1,2] and pediatric population[16-20]. Acid related symptoms are often seen in younger patients whereas neoplastic manifestations have been reported mainly in the elderly population.

Acid-related manifestations

Symptoms associated with HGMPE include LPR symptoms such as regurgitation, dysphagia, hoarseness, globus, throat discomfort and chronic cough[1,2]. Often dysphagia is located in the proximal esophagus or throat level. Associations with chronic ear or sinus problem have also been reported.

Symptoms in adult population

To date, there have only been a few studies that have reported comparisons of symptoms between patients with and without HGMPE. Published studies have so far reported mixed findings, some showing significantly higher LPR symptoms[8,21-24] whilst others reported no significant difference[15,25] (Table 2). The symptoms enquired and reported were not consistent between studies. Some reported the overall prevalence or limited to only

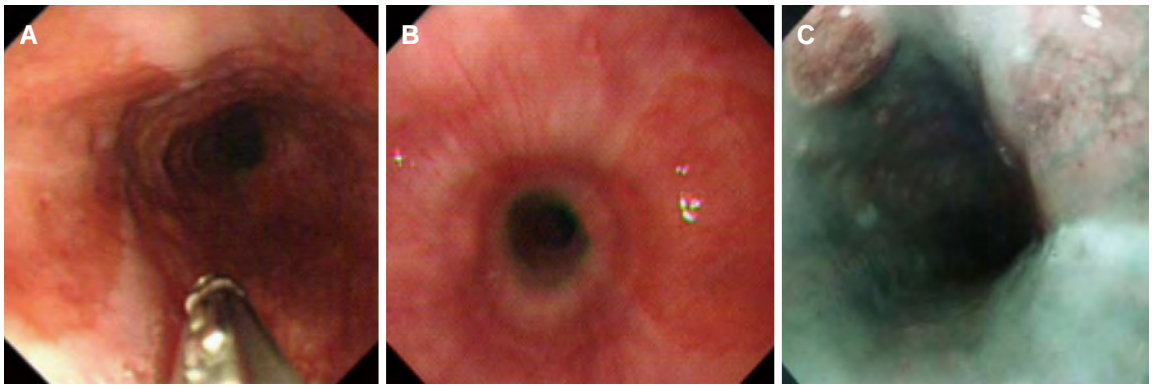

Figure 1 Endoscopic images of heterotopic gastric mucosa of the proximal esophagus. 	Heartburn (any grade upper and lower)	15.2	9.4	NS

[1]In the study by Neumann *et al*, the symptoms presented are symptom recorded as indications for endoscopy. HGMPE: Heterotopic gastric mucosa of the proximal esophagus; LPR: Laryngopharyngeal reflux; NS: Not significant.

one or few symptoms. However, most of the symptoms reported were mild. Prevalence rate of LPR symptoms as high as 73.1% has been reported[8]. The largest study to date based on a database of 487 229 endoscopies carried out in non-referral centers in the United States showed that dysphagia or odynphagia, upper respiration symptoms suggestive of LPR and globus were significantly more common in patients with HGMPE[24]. However, this study was limited by its retrospective nature and the assessment of only referral indications. The other studies were mainly from referral or specialized centers.

Symptoms in pediatric population

Currently, there are only a few studies on HGMPE in the pediatric population and are usually limited by small sample sizes[9,16,18-20]. Most are in the form of case reports[16-20]. To date, there is no endoscopic study that has assessed HGMPE in this population. Clinical manifestations are different from the adult population. Common manifestations include laryngospasm[16], respiratory symptoms[17] and dysphagia from reflux or stricture[9,20]. In one multicentre study that had looked at 15 patients with a median age 9.5 years (range: 3.3-15 years) found that five patients had esophageal atresia, nine with gastroesophageal reflux disease (GERD) and asymptomatic in one. Dysphagia and food impaction were the most common manifestations reported in 14 patients. Six patients had respiratory or ear, nose, and throat symptoms[9]. An autopsy study in the pediatric population showed that HGMPE was more common in younger age and was more significantly associated with unexplained death. Variend *et al*[26] speculated that pulmonary aspiration of esophageal contents may have been the cause of death in some of the children.

Barrett's esophagus

Similarly to clinical symptoms, the association between

Table 3 Endoscopic studies reporting the associations between heterotopic gastric mucosa of the proximal esophagus and other endoscopic findings with special attention to Barrett's esophagus *n* (%)

Ref.	Prevalence of HGMPE	Findings
Positive association		
Avidan *et al*[4]	53 (1.1)	Significantly more reflux esophagitis (77 *vs* 50, $P = 0.023$), Barrett's esophagus (34 *vs* 9, $P < 0.001$), hiatus hernia (49 *vs* 30, $P < 0.05$) and gastric ulcer ($P < 0.05$) On multivariate analysis, hiatus hernia, gastric ulcer and Barrett's esophagus remained significant
Alagozlu *et al*[23]	68 (1)	Significantly more ($P < 0.05$) endoscopic Barrett's esophagus in patients with HGM (13.2 *vs* 2.4) but not with reflux esophagitis (10.3 *vs* 9.5) Hiatus hernia and duodenal ulcer were reported in 13.2% and 10.3% respectively but no comparisons were made
[1]Neumann *et al*[24]	870 (0.18)	Significantly more Barrett's mucosa on biopsy (9.7 *vs* 6.5, $P < 0.001$), adenocarcinoma arising from Barrett's mucosa (3.6 *vs* 0.7, $P < 0.01$) and reflux esophagitis (41.8 *vs* 49.7, $P < 0.001$)
Yuksel *et al*[27]	171 (1.8)	Significantly more reflux esophagitis (25.1 *vs* 5.6, $P < 0.001$) and histologically proven Barrett's esophagus (3.5 *vs* 0.5, $P < 0.000$) No difference in hiatus hernia
No association		
Borhan-Monesh *et al*[3]	64 (10)	No significant difference (all P = NS) between reflux esophagitis (34.3 *vs* 38.1) and Barrett's esophagus
Chong *et al*[8]	26 (5.6)	No significant difference (all P = NS) between esophageal, gastric and duodenal findings including Barrett's esophagus (3.8 *vs* 3.7), hiatus hernia (15.4 *vs* 12.2) and ulcers
Akbayir *et al*[15]	11 (1.67)	No significant difference (all P = NS): Barrett's esophagus (0 *vs* 0.9), hiatus hernia (0 *vs* 10), reflux esophagitis (27 *vs* 16) and duodenal ulcer (9 *vs* 7)
[2]Poyrazoglu *et al*[22]	33 (3.6)	No significant difference (all P = NS): Barrett's esophagus (0 *vs* 0.8), hiatus hernia (3 *vs* 9.1), reflux esophagitis (36.4 *vs* 34.8), gastric ulcer (3 *vs* 3) and duodenal ulcer (6.1 *vs* 6.8)
Weickert *et al*[25]	33 (11)	Overall prevalence: hiatus hernia (n = 92, 30.7%), reflux esophagitis (n = 41, 13.7%), Barrett's esophagus (n = 3, 1%), gastric ulcer (n = 24, 8%) and duodenal ulcer (n = 22, 7%), all P = NS
Jacobs *et al*[28]	33 (4.9)	Significant difference for reflux esophagitis (27.3 *vs* 11.4) but not for hiatus hernia (15.2 *vs* 12.5), Barrett's esophagus (6.1 *vs* 1.1) and any gastric or duodenal ulcer (15.2 *vs* 6.1)

Studies included are those with more than 10 patients with heterotopic gastric mucosa of the proximal esophagus (HGMPE). [1]The study by Neumann *et al* was based on analysis clinic-pathologic records of patients who had undergone upper gastrointestinal endoscopy with biopsies between January 2008 and December 2010 in private outpatient clinics and endoscopy centres in the United States; [2]The study by Poyrazoglu *et al* compared the prevalence of other endoscopic findings between 33 patients with HGMPE with 132 matched controls without HGMPE. NS: Not significant.

HGMPE and Barrett's esophagus remains debated. Studies have reported conflicting results (Table 3). Avidan *et al*[4] showed that patients with HGMPE had up to fivefold higher risk of Barrett's esophagus compared to patients without HGMPE. Three other studies[23,24,27] have reported significant positive correlations while five studies that included more than 20 patients with HGMPE have not found any correlations[3,8,22,25,28]. Two histological studies reported similar mucin staining patterns in Barrett's esophagus and HGMPE suggesting possible shared pathogenesis[29,30]. However, Fuerle *et al*[31] found some differences and postulated that the specialized columnar epithelium of Barrett's esophagus originates from a very immature multipotent gastrointestinal stem cell whereas HGMPE originates from remnant embryonic gastric mucosa located in the proximal esophagus

Non-laryngopharyngeal symptoms

Reports on symptoms associated with HGMPE are mainly on LPR symptoms[2]. There is currently little information to suggest whether HGMPE is associated with non-LPR symptoms. Heartburn has been shown to be common in patients with HGMPE, even in those not found to have any erosive esophagitis[4,8,32]. Explanations offered included symptoms induced by acid secretion flowing downward or increased sensitivity as seen in non-erosive esophagitis. Apart from proximal acid reflux independent of distal acid reflux, Korkut *et al*[11] also showed that some patients with HGMPE have signs of esophageal motor dysfunction based on manometry and 24 h dual probe pH study. They concluded that these abnormalities may be responsible for some of the symptoms experienced by patients with HGMPE. In another study, Rosztoczy *et al*[32] reported several differences between patients with and without HGMPE. Patients with HGMPE had more and prolonged acid exposure in both proximal and distal esophagus, longer bile exposure time in the distal esophagus, reduced lower esophageal sphincter pressure with prolonged relaxation and decreased peristaltic wave amplitude. There was also increased number of simultaneous contractions in the esophageal body of patients with HGMPE. These suggest that patients with HGMPE also have motility disorders contributing to their symptoms.

Other non-neoplastic complications

Complications of HGMPE reported in the literature range from formations of strictures[33-35], web[36-38], ulceration with bleeding[39], fistula formation with or without subcutaneous abscesses[19,40-42], perforation[43,44] and polyps[45-47] (Table 4). HGMPE have been reported to be the possible cause of Plummer Vinson or Paterson Kelly Brown syndrome[1,2,38]. The underlying pathogenesis is probably similar to those seen in acid-related gastric pathologies. In the pediatric population, HGMPE has also been associated with unexplained infant deaths[26], dysphagia from strictures in the

proximal esophagus[9,18,20] or spasm[16] and recurrent neck abscesses secondary to fistula[19].

Histology progressions or neoplastic transformation

Overall, significant histological non-malignant changes or malignancies in HGMPE are extremely rare. Histological changes such as chronic inflammation[3,14], atrophy, intestinal metaplasia[14], and dysplasia[48-50] as seen in the stomach have been reported mainly in the adult population. However intestinal metaplasia has also been reported in children[17]. Macha *et al*[17] reported that 8.3% (n = 2/24) of their pediatric patients with HGMPE had intestinal metaplasia detected on histology. Neoplastic transformations have only been reported in the adult population[2,36-39]. A summary of the reported significant histological or malignancies in association with HGMPE are shown in Table 4.

Since the first case reported by Carrie *et al*[51] in 1950, there have only been 43 cases of adenocarcinoma[52-54] in association with HGMPE reported in the literature to date (Table 4). To date, Neumann *et al*[24] in the largest series of endoscopies done in non-specialised centers did not encounter any cases of HGMPE with malignancy whereas Alagozlu *et al*[23] encountered a case each of adenocarcinoma and low grade dysplasia among 64 patients with HGMPE. Based on these two studies, it can be estimated that the incidence of malignancies among patients with HGMPE ranges between 0 and 1.56%[23,24]. However, the incidence is likely to be much lower than the estimate from the latter study.

Based on a review of 43 cases reported in the literatures by Akanamu *et al*[54], majority of those affected were men (88.4%) with a median age of 60.4 years (range 35 to 85 years). Most of the lesions were advanced at diagnosis especially in the earlier reported. Early lesions (T1 lesion) accounted for 14 cases[54]. The lesions were ulcerated in 31.2%, protruding in 30.2% and polypoidal in 18.6%. Dysphagia was the most common compliant (74.4%) with smaller proportion detected through surveillance. Interestingly, acid-related symptoms were not common. Smoking appeared to be a risk factor.

Associations with extra-esophageal neoplasms

To date, association with extra-esophageal neoplasms have only been reported twice[55,56]. Basseri *et al*[55] reported the case of a 22-year-old lady with asthma and GERD diagnosed with laryngeal adenocarcinoma. She later developed a stricture proximal to a HGMPE (type Ⅲ). In another report, Satoh *et al*[56] reported the case of a 44-year-old lady with hypopharyngeal carcinoma with a HGMPE (2.0 cm × 1.5 cm) bordering the tumor. Chronic irritation from acid was proposed as the contributing cause to the development of the tumors.

OVERVIEW

HGMPE was first reported by Schmidt *et al*[1] as an aberrant gastric fundus-type epithelium located in the proximal esophagus. Despite this, the number of publications on this entity has remained low compared to the other esophageal disorders. Therefore it is not surprising that controversies remain regarding the clinical significance of this entity. Despite the lack of data, HGMPE is clinically significant and the clinical significance is related to acid-related manifestations, mucosal changes and malignant transformations.

The clinical manifestations of HGMPE are best summarized by the classification proposed by von Rahden *et al*[1]. Clinically significant manifestations which have been reported in only a small proportion of patients are categorized as type Ⅱ, Ⅲ, Ⅳ and Ⅴ HGMPE. The most common is the type Ⅱ with clinical symptoms of LPR[1,8]. However, some do not consider type Ⅱ HGMPE as significant as the symptoms experienced are mostly mild[8,13]. On the other hand, these symptoms are chronic and very troublesome for a small minority of patients.

It is currently uncertain if the symptoms are acid-related given that studies have shown that only a small proportion of symptomatic patient have documented acid secretion from the HGMPE[10,31]. However, one can probably surmise that there is a causal association. Similar to the stomach or heterotopic gastric mucosa found in Meckel's diverticulum, excess acid production can lead to acid-related symptoms and complications. Patients with HGMPE have also been shown to have motility disorders and this may contribute to the symptomology of HGMPE[11,32].

Symptomatic patients with HGMPE typically reports LPR symptoms; globus pharyngeus, sore throat, hoarseness, chronic cough, throat clearing and dysphagia[57]. This is not surprising given the close proximity of HGMPE with the laryngopharyngeal complex. The laryngopharyngeal complex is particularly sensitive and even a small amount of weakly acidic secretion can cause symptoms[57,58]. Symptoms can also occur with non-acidic secretions[4]. Presence of gastric enzymes such as pepsin

also contributes to irritations[58].

The prevalence of the various LPR symptoms in association with HGMPE varies from less than 20% to as high as 73.1%[2]. Comparisons of published studies are difficult due to differences in the study methodologies. Symptoms enquired were not always consistent with some studies enquiring on limited number of symptoms or not specifying the symptoms enquired. Furthermore, most studies had small sample sizes.

In clinical practice, we also often encounter patients with LPR symptoms without any heartburn. Such patients are categorized as having extra-esophageal manifestations of GERD. Some of these patients clearly do not have acid exposure in the distal esophagus and as such, LPR symptoms in association with HGMPE should be considered a separate entity separate from GERD.

Associations with neoplastic changes and importantly malignant transformation are reported and these represent the most significant associations of HGMPE. However, the numbers reported is still very low and are considered extremely rare. Interestingly, a large number of the reported cases especially in the non-English literatures have been from Japan[54]. Whether, HGMPE with malignant transformations is more common in the Japanese population is unknown. It may be related to better screening program and increased detection rate. Most of the reported cases were advanced at diagnosis especially in the earlier studies. However, there were more early cancers (T1 lesions) reported in the latter part. Men seem to be more at risk and smoking appears to be a risk factor[54]. Dysphagia was the main complaint leading to detection of tumors.

Association with Barrett's esophagus is another area that remains debated. A widely accepted theory is based on a shared pathogenesis with both Barrett's esophagus and HGMPE being congenital in origin but with differences in pathogenesis in the later part of the development. However, this had been based on western population where the prevalence of Barrett's esophagus is much higher compared to the East. Further large population studies will be required and help shade some lights into this controversy. Associations with other acid related complications such as erosions, ulcerations, bleeding, perforation, fistula and stricture formations have been documented[1,8]. Possible link between HGMPE and unexplained death in children have also been reported[26].

Currently, there are still many issues regarding HGMPE that remain unresolved or unknown. These ranges from the origin of HGMPE, exact correlation with Barrett's esophagus, role of *H. pylori* infection in symptoms manifestations, lack of natural history data and significance of mucosal changes in the HGMPE and its relation to neoplastic transformations.

Given that HGMPE mainly manifests with upper autodigestive symptoms, it is not unexpected that only clinicians from certain specialties such as the gastroenterologists, otorhinolaryngologists and rarely upper gastrointestinal surgeons will encounter such patients. However, it is important that other clinicians from the other specialties to be aware of this entity especially when they come across patients with troublesome LPR symptoms. Establishing a diagnosis is important as it can provide reassurance. This may also lead to symptoms improvement and avoid any further unnecessary investigations or consultations. As the awareness of HGMPE increase, more asymptomatic or symptomatic cases will be diagnosed and with the ageing population, it is very likely the number of cases of neoplastic transformations will also increase, albeit a small increase.

CONCLUSION

The clinical significance of HGMPE lies mainly with its capacity to produce acid and mucosal progressions to dysplasia and frank neoplastic transformation. Currently, there are still many areas of HGMPE that are not well understood and further research are required. Symptomatic patients should to be treated and those found to have metaplasia or dysplasia may need to be considered for surveillance.

Abstract

AIM: To evaluate diagnostic value of α-fetoprotein (AFP)-L3 and prothrombin induced by vitamin K absence-Ⅱ (PIVKA-Ⅱ) in hepatocellular carcinoma (HCC).

METHODS: One hundred and sixty-eight patients during routine HCC surveillance were included in this study. Of the 168 patients, 90 (53.6%) had HCC including newly developed HCC (n = 82) or recurrent HCC after treatment (n = 8). Sera were obtained during their first evaluation for HCC development and at the time of HCC diagnosis before commencing HCC treatment. HCC was diagnosed by histological examination, appropriate imaging characteristics-computed tomography or magnetic resonance imaging. Control sera were collected from 78 patients with benign liver disease (BLD), which were obtained during routine surveillance with a suspicion of HCC. AFP, AFP-L3 and PIVKA-Ⅱ were measured in the same serum by microchip capillary electrophoresis and liquid-phase binding assay on a micro-total analysis system Wako i30 auto analyzer. The performance characteristics of three tests and combined tests for the diagnosis of HCC were obtained using receiver operating characteristic curves in all populations and subgroups with AFP < 20 ng/mL.

RESULTS: Of 90 HCC patients, 38 (42.2%) patients had AFP < 20 ng/mL, 20 (22.2%) patients had AFP 20-200 ng/mL and 32 (35.6%) patients had AFP > 200 ng/mL. Of the 78 BLD patients, 74 (94.9%) patients had AFP < 20 ng/mL. After adjustment for age and HBV infection status, AFP-L3 levels were higher in HCC than in BLD among patients with low AFP levels (< 20 ng/mL) (P < 0.001). In a total of 168 patients, areas under the curve (AUC) for HCC were 0.879, 0.887, 0.801 and 0.939 for AFP, AFP-L3, PIVKA-Ⅱ and the combined markers, respectively. The combined AUC for three markers showed higher value than the AUCs of individual marker (P < 0.05). AFP-L3 had higher AUC value than PIVKA-Ⅱ for HCC detection in entire patients (P = 0.043). With combination of AFP-L3 (cut-off > 5%) and PIVKA-Ⅱ (cut-off > 40 AU/L), the sensitivity were 94.4% and specificity were 75.6% in all patients. In 112 patients with low AFP levels (< 20 ng/mL), AUCs of AFP-L3, PIVKA-Ⅱ and combine AFP-L3 and PIVKA-Ⅱ tests were 0.824, 0.774 and 0.939, respectively. AFP-L3 with a cut-off value of 5% showed sensitivity of 71.1% and specificity of 83.8%, and PIVKA-Ⅱ with a cut-off value of 40 AU/L had sensitivity of 57.9% and specificity of 95.9% in patients with low AFP levels. The combination of AFP-L3 and PIVKA-Ⅱ increased the sensitivity and specificity up to 92.1% and 79.7%, respectively, in low AFP group. Combined markers detected 81.8% of early stage HCC (Union for Inter-

national Cancer Control stage Ⅰ), 86.7% of small sized tumor (< 2 cm) and 91.7% of single tumor of HCC in the low AFP group. In multivariate analysis, AFP-L3 was correlated with AFP and tumor size, and PIVKA-Ⅱ was correlated with laboratory tests including serum aspartate aminotransferase, total bilirubin, platelets and albumin levels. PIVKA-Ⅱ had no correlation with AFP, AFP-L3 or tumor characteristics.

CONCLUSION: Combined determination of AFP-L3 and PIVKA-Ⅱ could improve the diagnostic value for HCC detection in patients with or without increased AFP levels.

Choi JY, Jung SW, Kim HY, Kim M, Kim Y, Kim DG, Oh EJ. Diagnostic value of AFP-L3 and PIVKA-Ⅱ in hepatocellular carcinoma according to total-AFP. *World J Gastroenterol* 2013; 19(3): 339-346 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/339.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.339

INTRODUCTION

Early detection of hepatocellular carcinoma (HCC) is important as the treatment of HCC with surgical resection, liver transplantation or percutaneous ablation can be curative at early stage. Currently, the recommended screening strategy includes measurement of serum α-fetoprotein (AFP) levels and an abdominal ultrasound every 3-6 mo for the detection of HCC at an earlier stage[1-4]. Usually, a serum AFP level of 20 ng/mL is considered as a cut-off value to differentiate HCC from non-HCC[5]. However, serum AFP level has a high false-negative rate for the detection of small or early stage tumors[2,6-9], and it is often markedly elevated in patients with either cirrhosis or those with exacerbated chronic hepatitis without HCC[10,11].

Therefore, additional tumor markers including fucosylated fraction of AFP (AFP-L3) fraction[12,13] and prothrombin induced by vitamin K absence-Ⅱ (PIVKA-Ⅱ) or Des-γ-carboxyprothrombin[14-16] have been suggested, and the surveillance program with these markers have been mostly organized by Japanese study groups[1,17]. The lens culinaris agglutinin-reactive, AFP-L3 has been reported to be highly specific for HCC[5,18-20] and in predicting prognosis[21-24]. Recently, a highly sensitive analytical system using the technically advanced microfluidics-based separation system has been introduced[25]. With this micro-total analysis system (μTAS), AFP-L3 can be measured accurately at very low AFP concentrations under 10 ng/mL with high sensitivity[7,19,25,26]. PIVKA-Ⅱ is an abnormal protein and some reports have indicated the improved specificity of PIVKA-Ⅱ over AFP in the diagnosis of HCC[2,5,27-29]. The combination of AFP-L3 and PIVKA-Ⅱ seems to improve the diagnostic value for HCC patients, and these additive assays are especially recommended for patients with low AFP levels according to previous Japanese studies[19,26,27]. However, diagnostic values of these markers are controversial and different cut-off values have been suggested depending on the study design[5,20,26]. In addition, the clinical values of these markers in combination are not conclusive yet, and the clinical and laboratory factors which possibly effect the measured values of AFP-L3 and PIVKA-Ⅱ have not been sufficiently investigated.

In this study, we compared the levels of AFP, AFP-L3 and PIVKA-Ⅱ in benign liver diseases (BLD) patients and HCC patients, and evaluated the individual and combined diagnostic values of AFP-L3 and PIVKA-Ⅱ for HCC detection according to the total AFP levels and tumor characteristics. The clinical and laboratory factors affecting AFP-L3 and PIVKA-Ⅱ were also analyzed.

MATERIALS AND METHODS

Patients

Serum samples were obtained from 168 patients during routine HCC surveillance at the Seoul St. Mary's Hospital, Seoul, South Korea, during the period between April and November 2011. This study was approved by the Institutional Review Board of Seoul St. Mary's Hospital. Of the 168 patients, 90 (53.6%) had HCC including newly developed HCC (n = 82) or recurrent HCC after treatment (n = 8). Sera were obtained during their first evaluation for HCC development and at the time of HCC diagnosis before commencing HCC treatment. HCC was diagnosed by histological examination, appropriate imaging characteristics-computed tomography or magnetic resonance imaging. Tumor stage was assessed by the Union for International Cancer Control (UICC) staging system, which is based on tumor number, size, vascular invasion and metastasis[4,30]. Control sera were collected from 78 patients with BLD, which were obtained during routine surveillance with a suspicion of HCC. All patients were diagnosed by imaging study and were followed up for 7-16 mo after sampling to confirm non-HCC.

Measurement of AFP, AFP-L3 and PIVKA-Ⅱ

AFP, AFP-L3 and PIVKA-Ⅱ were measured in the same serum by microchip capillary electrophoresis and liquid-phase binding assay on a μTAS Wako i30 auto analyzer (Wako Pure Chemical Industries, Ltd, Osaka, Japan). The measuring range was 0.3-1000 ng/mL for AFP and 5-50 000 AU/L for PIVKA-Ⅱ. AFP-L3 levels were calculated in sera with AFP levels over 0.3 ng/mL. The total imprecision for two levels of the three markers were less than 5% CVs in 20 d of evaluation. Serum samples were stored at -80 ℃ until tested. All processes were preformed automatically and followed the manufacturer's instructions.

Table 1 Demographics and laboratory test values of patients with benign liver disease and with hepatocellular carcinoma *n* (%)

	BLD (*n* = 78)	HCC (*n* = 90)	*P* value
Age (mean ± SD), yr	55.6 ± 12.5	59.7 ± 10.1	0.020

AFP level (mean ± SD, ng/mL)	6.9 ± 13.5	473.9 ± 746.0	< 0.001
AFP-L3 level (mean ± SD, %)	2.3 ± 4.9	40.0 ± 35.7	< 0.001
PIVKA-Ⅱ level (mean ± SD, AU/L)	20.0 ± 31.2	4469 ± 11 553.8	< 0.001

HBV: Hepatitis B virus; HCV: Hepatitis C virus; NANBNC: Non-hepatitis A, non-hepatitis B, non-hepatitis C virus; AFP: α-fetoprotein; PIVKA-Ⅱ: Prothrombin induced by vitamin K absence-Ⅱ; BLD: Benign liver disease; HCC: Hepatocellular carcinoma.

Statistical analysis

Statistical analysis were performed with SPSS version 12.0 (SPSS, Chicago, IL) and Med-Calc version 12. 2. 1. 0 (MedCalc Software, Mariakerke, Belgium). Comparisons were made using *t* test. The performance characteristics of three tests and combined tests for the diagnosis of HCC were obtained using receiver operating characteristic (ROC) curves in all populations and subgroups with AFP < 20 ng/mL. The sensitivity and specificity of these three markers for the diagnosis of HCC were calculated in all the groups and subgroups according to the total AFP levels. A logistic regression model was performed in SPSS on the three markers and ROC curves analysis was performed for area under the curve (AUC) values for the combined markers. All *P* values were 2-tailed with $P < 0.05$ considered statistically significant.

RESULTS

Patient characteristics

Table 1 shows the demographics of the study population. The most common cause of liver disease was hepatitis B virus (HBV) infection in both BLD and HCC patients. HCC patients had a higher frequency of males and HBV infection than that of BLD patients ($P < 0.05$). Of the 90 HCC patients, 38 (42.2%) patients had AFP < 20 ng/mL, 20 (22.2%) patients had AFP 20-200 ng/mL and 32 (35.6%) patients had AFP > 200 ng/mL. Of the 78 BLD patients, 74 (94.9%) patients had AFP < 20 ng/mL. In four patients with non-HCC and increased AFP levels (45.2-72.8 ng/mL), PIVKA-Ⅱ levels were less than 40 AU/L, but AFP-L3 levels were above 10%. The levels of AFP, AFP-L3 and PIVKA-Ⅱ in BLD and HCC patients are plotted with respect to the AFP levels (Figure 1). In patients with AFP < 20 ng/mL, AFP-L3 levels were higher in HCC than that in BLD ($P < 0.001$). Regarding the patients with total AFP levels of 20-200 ng/mL, not AFP-L3 but PIVKA-Ⅱ was able to discriminate HCC from BLD ($P = 0.010$). After adjustment for age (> 50 and < 50 years) and HBV infection status, AFP-L3 levels were still higher in HCC than in BLD among patients with low AFP levels (< 20 ng/mL) ($P < 0.001$).

ROC curve analysis of three markers for the detection of HCC

The ROC curves of AFP, AFP-L3 and PIVKA-Ⅱ for the diagnosis of HCC in all of 168 patients are shown in Figure 2. The maximum AUCs for distinguishing between HCC and BLD were 0.879, 0.887 and 0.801 for AFP, AFP-L3 and PIVKA-Ⅱ, respectively. AFP-L3 had higher AUC than PIVKA-Ⅱ for HCC ($P = 0.043$). Using logistic regression model, the combined AUC for three markers was 0.939 and showed higher AUC values than the individual markers ($P < 0.05$).

In 112 patients with AFP < 20 ng/mL (HCC, $n = 38$; BLD, $n = 74$), the AUC for HCC detection was 0.824 for AFP-L3, 0.774 for PIVKA-Ⅱ and 0.939 for the two combined markers. Combined AUC was significantly higher than each AUC ($P < 0.05$), and the AUC value was not different between AFP-L3 and PIVKA-Ⅱ ($P = 0.516$) (Figure 3).

Sensitivity and specificity of three markers for HCC diagnosis

The sensitivities and specificities of the three markers for all patients and subgroups are shown in Table 2. In all patients, the total AFP showed a sensitivity of 78.9% and a specificity of 84.6% with a cut-off of 10 ng/mL. AFP-L3 with a cut-off value of 5% increased the sensitivity up to 82.2%. When the cut-off value for AFP-L3 and PIVKA-Ⅱ were set at 10% and 40 AU/L, the specificities were improved up to 93.6% and 94.9%, respectively.

In the subgroups according to the total AFP levels (AFP < 20 ng/mL, $n = 112$; AFP < 200 ng/mL, $n = 136$), the sensitivity and specificity of AFP-L3 were close to 70% and 80% respectively with a cut-off of 5%, and there was no significant difference compared to that of the entire group. The sensitivity and specificity of PIVKA-Ⅱ was approximately 60% and 95% respectively with a cut-off of 40 AU/L in all patients and subgroups.

To increase the diagnostic value for HCC detection, we combined the AFP-L3 and PIVKA-Ⅱ results. If either AFP-L3 or PIVKA-Ⅱ level was above the cut-off value, the combined result was defined as positive. With combination of AFP-L3 (cut-off > 5%) and PIVKA-Ⅱ

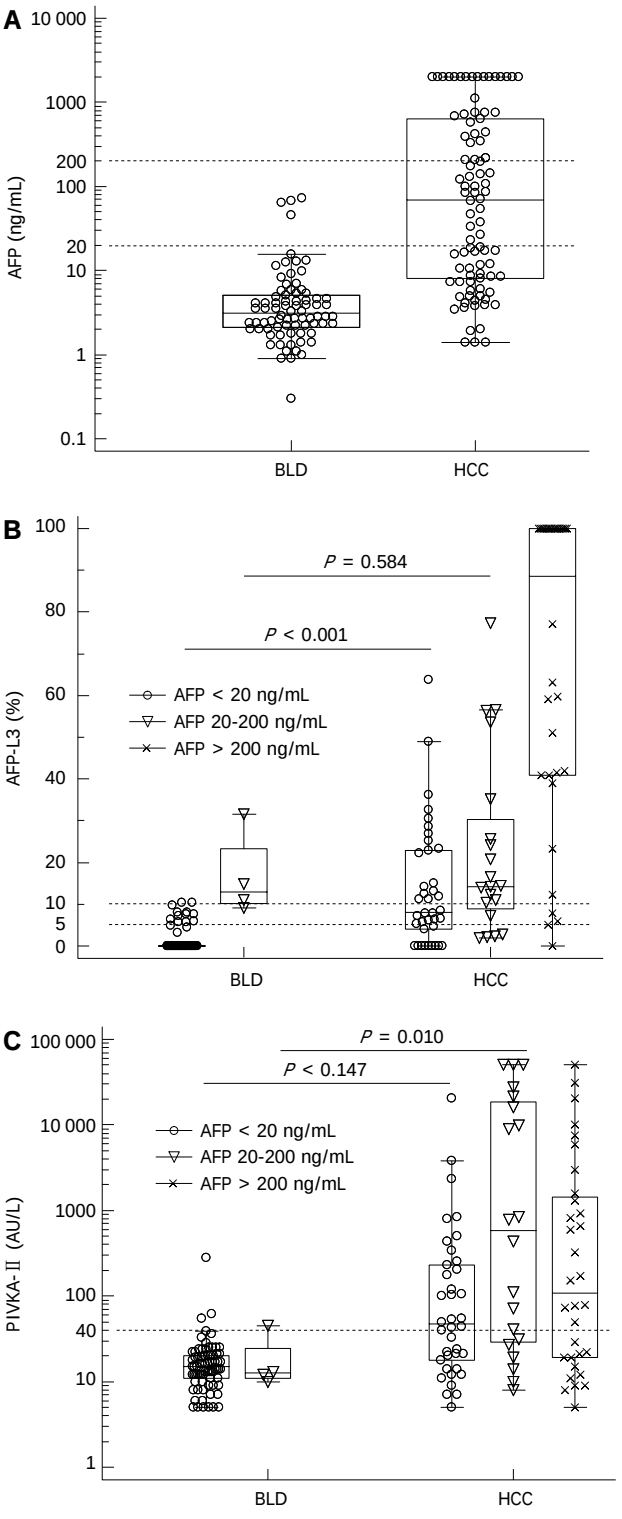

Figure 1 α-fetoprotein (A), α-fetoprotein-L3 (B) and prothrombin induced by vitamin K absence-Ⅱ (C) values in benign liver disease and hepatocellular carcinoma patients. α-fetoprotein (AFP)-L3 and prothrombin induced by vitamin K absence (PIVKA)-Ⅱ levels are plotted by AFP concentrations (AFP < 20 ng/mL, AFP 20-200 ng/mL and AFP > 200 ng/mL). In patients with AFP < 20 ng/mL, AFP-L3 levels were higher in hepatocellular carcinoma (HCC) (P < 0.001) (B). In patients with AFP 20-200 ng/mL, PIVKA-Ⅱ showed higher levels in HCC (P = 0.010) (C). The horizontal dotted lines are cut-off values used for performance analysis in this study. BLD: Benign liver disease.

(cut-off > 40 AU/L), the sensitivities were 92.1%-94.4%

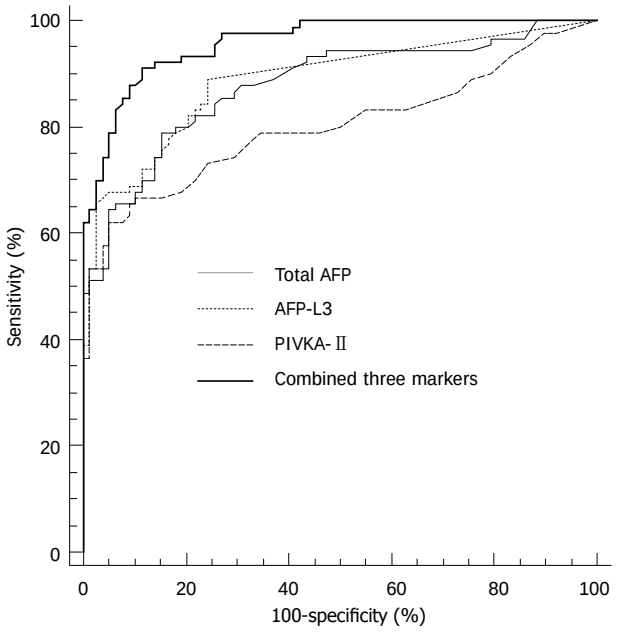

Figure 2 Receiver operating characteristic curves of total α-fetoprotein, α-fetoprotein-L3, prothrombin induced by vitamin K absence-Ⅱ and three combined markers for the diagnosis of hepatocellular carcinoma in all patients. The area under the curve values were 0.879 for total α-fetoprotein (AFP), 0.887 for AFP-L3, 0.801 for prothrombin induced by vitamin K absence (PIVKA)-Ⅱ and 0.959 for the three combined markers.

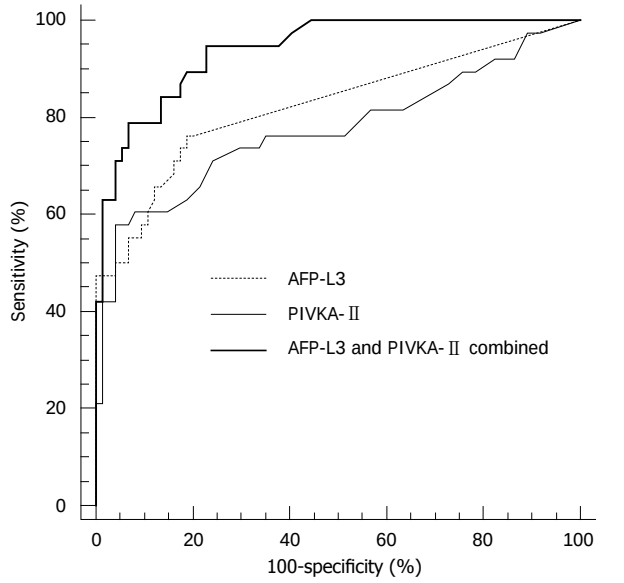

Figure 3 Receiver operating characteristic curves of α-fetoprotein-L3 and prothrombin induced by vitamin K absence-Ⅱ for the diagnosis of hepatocellular carcinoma in patients with total α-fetoprotein < 20 ng/mL. The area under the curve values were 0.824 for α-fetoprotein (AFP)-L3, 0.774 for prothrombin induced by vitamin K absence (PIVKA)-Ⅱ and 0.939 for the two combined markers.

and specificities were 75.6%-79.7% in all patients and subgroups. When a cut-off value was set at 10% for AFP-L3 and combined with PIVKA-Ⅱ, the sensitivities were approximately 80% (78.9%-84.4%) and the specificities were maintained close to 90%.

Table 2 Performance of α-fetoprotein, α-fetoprotein-L3 and prothrombin induced by vitamin K absence-Ⅱ in detecting hepatocellular carcinoma in all patients and in subgroups according to total α-fetoprotein levels: Total α-fetoprotein

		Cut-off value	Sensitivity	Specificity
Entire group	AFP	10 ng/mL	78.9%	84.6%
(*n* = 168, 90 HCC)	AFP-L3	5%	82.2%	79.5%
		10%	67.8%	93.6%

Sensitivity of AFP-L3 and PIVKA-Ⅱ according to the tumor characteristics in patients with AFP < 20 ng/mL

To establish the sensitivity of AFP-L3 (cut-off 5%) and PIVKA-Ⅱ (cut-off 40 AU/L) for the detection of small tumors and early stage HCC especially in 38 HCC patients with AFP < 20 ng/mL, we subgrouped the HCC patients according to the UICC stage (Ⅰ, Ⅱ, Ⅲ, Ⅳa, Ⅳb), tumor size (< 2, 2-5, > 5 cm) and tumor number (single and multiple tumor) (Table 3). The sensitivity of AFP-L3 and PIVKA-Ⅱ in UICC stage Ⅰ-Ⅱ (n = 27) was 63.6%-75.0% and 45.5%-56.3%. The combination of AFP-L3 and PIVKA-Ⅱ increased the sensitivity up to 81.8%-100% (Table 3). In HCC patients with tumor size < 2 (n = 15) and 2-5 cm (n = 17), the sensitivity of AFP-L3 was 46.7% and 47.1%, respectively. The sensitivity of PIVKA-Ⅱ for the detection of HCC with tumor size < 2 and 2-5 cm was 40.0% and 64.7%, and combination of AFP-L3 and PIVKA-Ⅱ resulted in an enhancement of sensitivity up to 86.7% and 94.1%, respectively. With a combined test (AFP-L3 and PIVKA-Ⅱ), 22 (91.7%) of 24 HCCs with a single tumor were detected.

Correlation analysis

To investigate the clinical and laboratory factors which may affect the measured values of AFP-L3 and PIVKA-Ⅱ, we performed univariate and multivariate analyses. In univariate correlation analysis, there was a correlation between AFP-L3 and PIVKA-Ⅱ. AFP-L3 and PIVKA-Ⅱ levels were correlated with tumor stage (UICC), tumor size, aspartate aminotransferase (AST) and albumin. Tumor number and AFP levels were correlated with only AFP-L3 levels.

In multivariate analysis, only AFP and tumor size were significant correlates of AFP-L3 (Table 4). In terms of PIVKA-Ⅱ, laboratory tests including serum AST, total bilirubin, platelets and albumin levels were correlated with the PIVKA-Ⅱ results. However, PIVKA-Ⅱ had no correlation with AFP, AFP-L3 or tumor characteristics.

Table 3 Sensitivity of α-fetoprotein-L3 and prothrombin induced by vitamin K absence-Ⅱ according to the tumor characteristics in 38 hepatocellular carcinoma patients with α-fetoprotein < 20 ng/mL *n* (%)

	n	AFP-L3 (> 5%)	PIVKA-Ⅱ (> 40 AU/L)	AFP-L3 and PIVKA-Ⅱ combined (> 5%, > 40 AU/L)
Tumor stage (UICC)				
Ⅰ	11	7 (63.6)	5 (45.5)	9 (81.8)
Ⅱ	16	12 (75.0)	9 (56.3)	16 (100)
Ⅲ	9	6 (66.7)	6 (66.7)	8 (88.9)
Ⅳa	2	2 (100)	2 (100)	2 (100)
Tumor size				
< 2 cm	15	7 (46.7)	6 (40.0)	13 (86.7)
2-5 cm	17	8 (47.1)	11 (64.7)	16 (94.1)
> 5 cm	6	3 (50.0)	5 (83.3)	6 (100)

DISCUSSION

In patients at risk for developing HCC, systematic screening is required for detection of small tumors at an early stage. Although the diagnostic strategy for early detection of HCC has been changed with the technical development in imaging diagnosis[3], measurement of tumor markers for HCC at regular intervals is still a common practice. AFP is the most widely used tumor marker for HCC. However, recent studies reported that AFP lacks adequate sensitivity and specificity for effective surveillance[6,9-11]. Our data showed that 38 (42.2%) of 90 HCC patients had AFP < 20 ng/mL, and 4 (5.1%) of 78 non-HCC patients had AFP > 20 ng/mL, which support the inadequacy of AFP as a tumor marker shown by previous reports. Therefore, we examined the individual and combined diagnostic values of AFP-L3 and PIVKA-Ⅱ for HCC according to the AFP levels (< 20 ng/mL and

< 200 ng/mL), and investigated the clinical and laboratory factors that influence the measured values of AFP-L3 and PIVKA-Ⅱ.

The AFP-L3 fraction has been reported to be more sensitive than AFP for small sized or early stage HCC[20,31]. AFP-L3 is also known to be highly specific for HCC and reflect tumor characteristics including poor differentiation or malignant invasion[32-35]. The present data of all patients showed that the AUC value of AFP-L3 for HCC detection was 0.887, which was not different with the AUC value of AFP (0.879), but was higher than the AUC of PIVKA-Ⅱ. In focusing on the patients with AFP < 20 ng/mL, AFP-L3 levels were significantly higher in HCC than in non-HCC, and the sensitivity of AFP-L3 for HCC was 71.1% and 47.4% with cut-offs of 5% and 10%, respectively. These values are higher than those reported in previous studies showing sensitivity of 25%-50% with cut-offs between 5% and 10%[19,20]. The high specificity for HCC is an important advantage of AFP-L3 measurement and higher sensitivity without a concomitant reduction in specificity is useful in clinical settings. In the present study, the specificities of AFP-L3 for HCC were 79.5%-97.3% in all patients or in patients with low AFP levels. The values are similar to those in previous reports showing the specificities of AFP-L3 for HCC as over 85% among patients with low total AFP-levels[19,20]. Overall, in patients with low AFP levels, AFP-L3 (cut-off 5%) had reasonable AUC value, sensitivity and specificity (0.824, 71.1% and 83.8%, respectively) which are similar or improved results compare to previously reported data[19,36].

In the present study, PIVKA-Ⅱ alone had sensitivities and specificities close to 60% and 95% in all patients and patients with low AFP levels. PIVKA-Ⅱ was shown to have a higher specificity in previous studies[2,5,27], and all four patients with non-HCC and increased AFP/AFP-L3 levels showed lower values of PIVKA-Ⅱ in the present study. This suggests that the PIVKA-Ⅱ test may be useful in detecting false-positive AFP results.

The levels of AFP-L3 and PIVKA-Ⅱ had no correlation between them and these two may be compensative markers reflecting a different developmental form of HCC[37]. In multivariate analysis, AFP-L3 correlated with total AFP and tumor size. In contrast, PIVKA-Ⅱ had no correlation with AFP or tumor characteristics, but was correlated with some liver function tests including serum AST, tuberculosis, platelet and albumin.

In our study, the combination of PIVKA-Ⅱ and AFP-L3 improved the sensitivity close to 90% and showed significantly increased AUC (0.939) even in patients with low AFP. In addition, the combined tests showed approximately 90% sensitivity for the detection of early stage, small sized or single HCC tumors in patients with low AFP levels. These results suggest that these two biomarkers should be measured simultaneously and in combination with imaging tests to improve the diagnostic accuracy.

Potential limitations of our study include the small number of newly diagnosed HCC patients, lack of randomization and relative short-term follow-up. Our results should be validated with a larger number of patients with age- and sex-matched control subjects. Since AFP-L3 has been suggested as a prognostic marker in patients with HCC[22,23,26], future studies using longitudinal AFP-L3 data analysis or studies regarding the effect of AFP-L3 effect on the survival rate of HCC patients after treatment are needed. Despite these limitations, the present study indicates that AFP-L3 and PIVKA-Ⅱ are useful additive tumor markers for the diagnosis of HCC.

In conclusion, combined determination of AFP-L3 and PIVKA-Ⅱ improved the diagnostic value for HCC detection in patients with or without increased AFP levels. The utility of improved surveillance protocol based on these tumor markers needs to be investigated.

COMMENTS

Background

In patients at risk for developing hepatocellular carcinoma (HCC), systematic screening is required for detection of small tumors at an early stage. Although, α-fetoprotein (AFP) is the most widely used tumor marker for HCC, AFP lacks adequate sensitivity and specificity for effective surveillance. Therefore, additional tumor markers including fucosylated fraction of AFP (AFP-L3) fraction and prothrombin induced by vitamin K absence-Ⅱ (PIVKA-Ⅱ) have been suggested.

Research frontiers

The clinical values of AFP, AFP-L3 and PIVKA-Ⅱ in combination are not conclusive yet, and the clinical and laboratory factors which possibly affect the measured values of AFP-L3 and PIVKA-Ⅱ have not been sufficiently investigated. In this study, the authors evaluated the individual and combined diagnostic values of AFP-L3 and PIVKA-Ⅱ for HCC detection according to the total AFP levels and tumor characteristics. The clinical and laboratory factors affecting AFP-L3 and PIVKA-Ⅱ were also analyzed.

Innovations and breakthroughs

In the study, the combination of PIVKA-Ⅱ and AFP-L3 improved the sensitivity close to 90% and showed significantly increased areas under the curve (0.939) even in patients with low AFP. In addition, the combined tests showed approximately 90% sensitivity for the detection of early stage, small sized or single HCC tumors in patients with low AFP levels. In multivariate analysis, AFP-L3 correlated with total AFP and tumor size. In contrast, PIVKA-Ⅱ had no correlation with AFP or tumor characteristics, but was correlated with some liver function tests including serum aspartate aminotransferase, tuberculosis, platelet and albumin. The present study indicates that AFP-L3 and PIVKA-Ⅱ are useful additive tumor markers for the diagnosis of HCC.

Applications

Combined determination of AFP-L3 and PIVKA-Ⅱ could improve the diagnostic value for HCC detection in patients with or without increased AFP levels. The utility of improved surveillance protocol based on these tumor markers needs to be investigated.

Peer review

This study confirmed that the combined determination of AFP-L3 and PIVKA-Ⅱ improved the diagnostic value for HCC detection in patients with or without increased AFP levels. The authors performed the multivariate analysis and revealed that AFP-L3 and PIVKA-Ⅱ had no correlation between them and might be useful additive and compensate tumor markers for the diagnosis of HCC. The results are interesting and can be used to elucidate the different development form of HCC.

Abstract

AIM: To investigate the epidemiological trends in incidence and mortality of perforated peptic ulcer (PPU) in a well-defined Norwegian population.

METHODS: A retrospective, population-based, single-center, consecutive cohort study of all patients diagnosed with benign perforated peptic ulcer. Included were both gastric and duodenal ulcer patients admitted to Stavanger University Hospital between January 2001 and December 2010. Ulcers with a malignant neoplasia diagnosis, verified by histology after biopsy or resection, were excluded. Patients were identified from the hospitals administrative electronic database using pertinent ICD-9 and ICD-10 codes (K25.1, K25.2, K25.5, K25.6, K26.1, K26.2, K26.5, K26.6). Additional searches using appropriate codes for relevant laparoscopic and open surgical procedures (e.g., JDA 60, JDA 61, JDH 70 and JDH 71) were performed to enable a complete identification of all patients. Patient demographics, presentation patterns and clinical data were retrieved from hospital records and surgical notes. Crude and adjusted incidence and mortality rates were estimated by using national population demographics data.

RESULTS: In the study period, a total of 172 patients with PPU were identified. The adjusted incidence rate for the overall 10-year period was 6.5 per 100 000 per year (95%CI: 5.6-7.6) and the adjusted mortality rate for the overall 10-year period was 1.1 per 100 000 per year (95%CI: 0.7-1.6). A non-significant decline in adjusted incidence rate from 9.7 to 5.6 occurred during the decade. The standardized mortality ratio for the whole study period was 5.7 (95%CI: 3.9-8.2), while the total 30-d mortality was 16.3%. No difference in incidence or mortality was found between genders. However, for patients $\geqslant$ 60 years, the incidence increased over 10-fold, and mortality more than 50-fold, compared to younger ages. The admission rates outside office hours were high with almost two out of three (63%) admissions seen at evening/night time shifts and/or during weekends. The observed seasonal variations in admissions were not statistically significant.

CONCLUSION: The adjusted incidence rate, seasonal distribution and mortality rate was stable. PPU frequently presents outside regular work-hours. Increase in incidence and mortality occurs with older age.

Epidemiology of perforated peptic ulcer: Age- and gender-adjusted analysis of incidence and mortality. *World J Gastroenterol* 2013; 19(3): 347-354 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/347.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.347

INTRODUCTION

Each year peptic ulcer disease (PUD) affects 4 million people around the world[1]. Complications are encountered in 10%-20% of these patients and 2%-14% of the ulcers will perforate[2,3]. Perforated peptic ulcer (PPU) is a quite rare, but life threatening disease and the mortality varies from 10%-40%[2,4-6]. Females account for more than half the cases, they are older and have more comorbidity than their male counterparts[6]. Main etiologic factors include use of non-stereoidal anti-inflammatory drugs (NSAIDs), steroids, smoking, *Helicobacter pylori* (*H. pylori*) and a diet high in salt[3,7]. All these factors have in common that they affect acid secretion in the gastric mucosa. Defining the exact etiological factor in any given patient may often be difficult, as more than one risk factor may be present and they tend to interact[8]. While previous reports have shown a seasonal variation in the incidence of PPU, others have failed to find such a pattern[9-11].

The incidence rate of PPU has, with some fluctuations, been fairly stable in Northern Europe for decades with reported annual incidence rates of about 4-11 per 100 000 per year[12,13]. Several studies have investigated this up to the beginning of the 21st century, however there is hardly any data on incidence reports from this area the last decade. Due to the high mortality and morbidity rates from PPU, it is of importance to understand the epidemiology to, if possible, enable preventive measures.

The aim of this study was to investigate the recent epidemiological incidence trends and presentation of benign perforated gastroduodenal peptic ulcer in a well-defined Norwegian population.

MATERIALS AND METHODS

Study population

In this retrospective study all patients diagnosed with benign perforated peptic ulcer (either gastric ulcer or duodenal ulcer) admitted to Stavanger University Hospital (SUH) between January 2001 and December 2010 were included. Ulcers with a malign neoplasia diagnosis, verified by histology after biopsy or resection, were excluded.

SUH serves as the only hospital in the greater Stavanger area and has a primary mixed urban and rural catchment area of about 330 000 (per January, 2012). The "twin cities" of Stavanger and Sandnes are together the third most populated area in Norway, and Stavanger is the densest populated city in Norway.

Patients were identified from the hospitals administrative electronic database using pertinent ICD-9 and ICD-10 codes (K25.1, K25.2, K25.5, K25.6, K26.1, K26.2, K26.5, K26.6). Additional searches using appropriate codes for various surgical procedures (JDA 60 gastroraphy, JDA 61 laparoscopic gastroraphy, JDH 70 duodenoraphy, JDH 71 laparoscopic duodenoraphy) were done to enable a complete identification of all patients. Patient demographics and clinical data were retrieved from hospital records and surgical notes. Crude and adjusted mortality rates were estimated.

Definitions

Incidence calculations: The crude incidence is the number of new cases of perforated peptic ulcer in our region per 100 000 persons per year. The adjusted incidencerates are the crude rates adjusted for age and gender *vs* the total Norwegian population using Statistics Norway. The crude death rate is the total number of deaths in the study population per 100 000 persons per year. The adjusted mortality rate is the crude death rate adjusted for age and gender *vs* the total Norwegian population using Statistics Norway.

The standardized mortality ratio is the number of observed deaths within 30 d of hospital admission in the study group divided by the number of expected deaths in a general population with the same age and sex distribution.

Ulcer localisation was regarded as gastric when present anywhere in the stomach, including prepyloric and pyloric ulcers. Postpyloric ulcers were classified as duodenal. One ulcer located in an anastomosis after a gastrectomy was regarded as a gastric ulcer. The diagnosis and exact localisation was made at operation in most cases, while some were verified at postoperative endoscopy.

Comorbidity was defined as any concomitant disease at the time of admittance for PPU, including cardiovascular disease, pulmonary disease, autoimmune disorders and known or previous cancer disease in patient history.

NSAIDs included acetylic acid as part of the NSAID group in this study.

Seasons were classified as spring (March, April and May); late spring/summer (May, June, July and August); summer (June, July and August); autumn (September, October and November); and winter (December, January and February).

Evening/night time was defined as the hours between 16:30 and 07:30 all days of the week, including Saturday and Sunday.

Study ethics

The study was approved as a quality control assurance according to general guidelines provided by the Regional Ethics Committee Vest (REK Vest).

Statistical analysis

PASW Statistics 19.0 for Mac (SPSS Inc., Chicago, IL) was used for statistical analysis. Descriptive analyses were performed using χ^2 or Fisher's exact test where appropri-

P values are for trends across groups. Percentages may not add up due to rounding. [1]Data on smoking was missing in 37 (22%) of patients. Percentages are of patients with reported data (*n* = 135). ASA: American Society of Anesthesiology; NSAIDs: Non-steroidal anti-inflammatory drugs.

ate for dichotomous data, and Mann-Whitney *U* test for continuous data, where applicable. Poisson regression analysis was used to test for differences in crude rates between different periods and between different population groups. Time-trends were also tested by a Poisson time series model. Logistic regression was used to test for association with gender and comorbidity. All tests are two sided and *P* values < 0.050 were regarded as statistically significant.

RESULTS

Patient characteristics

A total of 172 patients with a perforated peptic ulcer were identified between 2001 and 2010. Median age was 68 years ranging from 18 to 100 years. There was an equal gender distribution (52% were women), but women were significantly older than men (median age of 73 years *vs* 62 years, respectively, $P < 0.001$). The number of women affected increased significantly with age across age groups, with only one in four patients aged < 50 years of age being female, compared to two-thirds of those > 70 years of age being female (26% *vs* 65% women, respectively, $P = 0.002$). Further patient characteristics are given in Table 1.

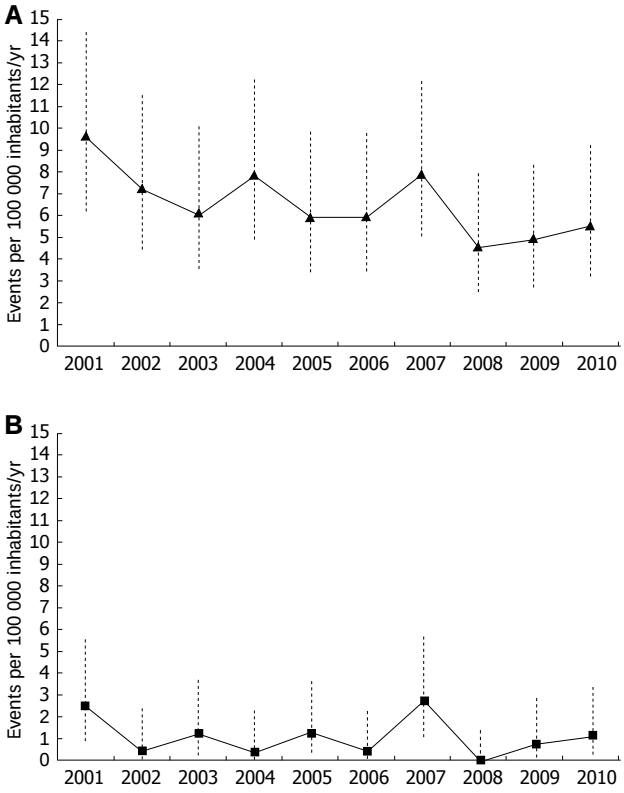

Figure 1 Incidence and mortality of perforated peptic ulcer from 2001-2010. A: The incidence rates of perforated peptic ulcer (PPU) per 100 000 inhabitants per year, adjusted for age and gender; B: The mortality rate from PPU per 100 000 inhabitants per year, adjusted for age and gender.

Crude and adjusted incidence trends

The crude incidence rate of PPU during the study period was 5.6 per 100 000 per year and declined from 8.5 in 2001 to 4.6 in 2010. The adjusted incidence rate for the overall 10-year period was 6.5 per 100 000 per year (95%CI: 5.6-7.6) and declined from 9.7 to 5.6 over the decade, but neither crude nor adjusted incidence rate decline were statistically significant (Figure 1A). Patients ≥ 60 years of age accounted for 117 of 172 (68%), and remained the dominant age group throughout the decade.

When considering the incidence in specific age- and gender-groups, the adjusted incidence rate for men demonstrated considerable differences, with men < 60 years at 2.7 per 100 000 per year (95%CI: 1.9-3.8) compared to 22.1 (95%CI: 16.3-29.4) for men ≥ 60 years of age. A similar pattern was seen in women, with women < 60 years at 1.5 per 100 000 per year (95%CI: 0.9-2.4), while it was 26.1 for those aged ≥ 60 (95%CI: 20.3-32.9) for the whole period. This corresponds to an almost 10-fold increase for men and a corresponding 17-fold increase for women in incidence for those aged ≥ 60 years.

An indicated decline in PPU numbers seen in Figure 1A is evident (but not statistically significant) in those aged > 70 years when the decade was divided in two peri-

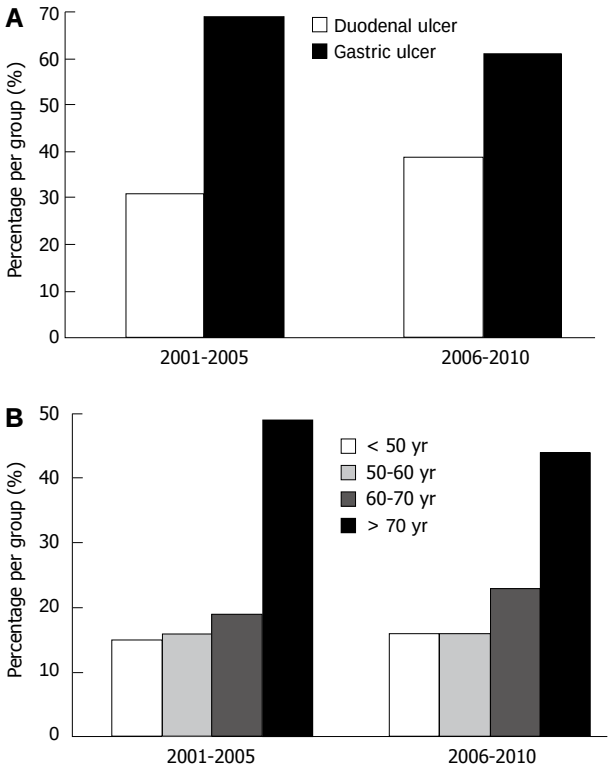

Figure 2 Localisation of ulcers and distribution of age-groups. A: Perforated peptic ulcer (PPU) localisation with admission rates over time. The decade is divided in two periods from 2001-2005 and 2006-2010; B: PPU presentation according to age groups (age in years; < 50, 50-59, 60-69, > 70) divided into the two time periods.

ods, as illustrated in Figure 2.

Crude and adjusted mortality trends

The crude mortality rate for the study period was 0.9 and the adjusted mortality rate for the overall 10-year period was 1.1 per 100 000 per year (95%CI: 0.7-1.6) and was stable during the whole period (Figure 1B). The standardized mortality ratio for the whole study period was 5.7 (95%CI: 3.9-8.2), while the total 30-d mortality was 16.3%.

The adjusted mortality rate for men < 60 years was 0.1 per 100 000 per year (95%CI: 0.0-0.43) and 4.6 (95%CI: 2.21-8.48) for men aged ⩾ 60 years. For women the adjusted mortality rate for the whole decade for those aged < 60 years was 0.1 (95%CI: 0.0-0.45) while it was 5.6 (95%CI: 3.13-9.22) for those aged ⩾ 60 years. This demonstrated negligible differences between genders, but an almost 50 to 60 times increase in mortality among the elderly age group.

Ulcer localisation

Gastric ulcers predominated (Figure 2A) and accounted for 112 of 172 (65%) patients in this study, but declined during the latter years of the period, while the frequency of duodenal ulcers remained stable, but increased somewhat the latter period (Figure 2). Prepyloric ulcers represented 61 of 112 (54%) of gastric ulcers and 21 of 112 (19%) were located in the pylorus. In the corpus/fundus area 12 of 112 (11%) ulcers were observed, while 8 of 112 (7%) were located in the antrum. One ulcer was located in an anastomosis and 9 of 112 (8%) ulcers were missing exact localisation in the stomach, but being classified as gastric ulcers at operation.

Age and comorbidity

Of those aged > 60 years of age 105 of 117 (90%) had comorbidity compared to 37 of 55 (67%) of those aged ⩽ 60 years ($P < 0.001$). Women also had significantly higher rate of comorbidity compared to men (91% *vs* 74%, respectively, $P = 0.002$), also when adjusted for age ($P = 0.036$).

Associated etiologic factors

Data on smoking was obtained in 135 of 172 patients. Of the 135 with confirmed information on smoking habits, 86 (64%) were smokers. Consequently, at least 50% of the total 172 patients were smokers, but likely this is an underestimate. Of those aged < 60 years of age 37 of 44 (84%) were smokers, while 49 of 91 (54%) of those aged ⩾ 60 were smokers ($P = 0.001$). The number of smokers registered was stable during the decade.

The number of NSAID users was stable during the decade studied and were used by 47 of 89 women and 29 of 83 men (53% *vs* 35%, respectively, $P = 0.018$). Also, NSAID-use was more common in those aged ⩾ 60 years (55 of 117; 47%), compared to the younger patients aged < 60 years (20 of 55; 36%), but this was not statistically significant.

Patterns of seasonal and circadian presentation

Patients were admitted at all hours and days during the week. While 70 of 172 patients (41%) were admitted during weekends (Friday, Saturday and Sunday), more than half (91 of 172; 53%) of the patients were admitted during evening/night time shifts and 109 of 172 (63%) patients were admitted either during evening/night time and/or on Saturday/Sunday. Notably, during this time a lower staff: patient ratio than during regular office hours is present.

PPU was more frequent in patients ⩾ 60 years of age (117 of 172; 68%) than < 60 years of age (55 of 172; 32%). This was particularly evident during the four months of late spring/summer. Poisson regression and time series analyses revealed no statistical significant differences regarding monthly variation or seasonal variation for PPU admittance patterns (Figure 3).

DISCUSSION

In this single-institution, population based study we found an adjusted incidence rate of 6.5 (95%CI: 5.5-7.5) per 100 000/year during this period. This is in concordance to several Northern European studies, most of them reporting an incidence between 4-11 per 100 000/year[13-17].

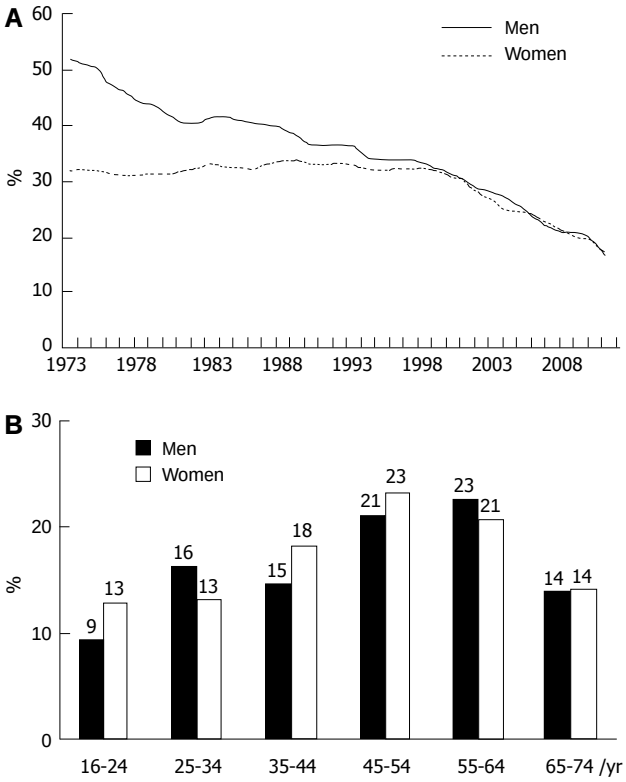

Figure 4 Change in prevalence of daily smokers in Norway. A: The time trend of daily smokers over time in the Norwegian population aged between 16-74 years, showing a decline over time for each gender; B: The distribution of smokers according to age groups and gender for the fiscal year 2011. Data are reproduced and presented from the Norwegian Directorate of Health (http://www.helsedirektoratet.no, accessed October 5, 2012).

Several factors may influence the incidence rates of PPU. For one, epidemiological studies have demonstrated that birth-cohorts born up to the 1930s were at higher risk of acquiring PPU than later birth cohorts[15,18]. The reason for this is not known, but speculation of an overriding influence of *H. pylori* infection on the population, has been postulated as the main cause[18]. However, *H. pylori* infection has been deemed of less importance in perforated peptic ulcer disease compared to that of uncomplicated peptic ulcer disease[1,7]. However, the association between specific birth-cohorts and mortality from PUD has been quite convincing, and a decline in the incidence of PPU may thus be expected when the cohorts at risk disappear with time[4,18]. This may have affected the incidence rates also in this study, which are rates comparable to other epidemiological studies from the turn of the century[19], and which may reflect a stable scenario with a relatively low population at risk for PPU in the current century.

Another etiologic factor for perforated peptic ulcer is smoking[20,21]. Prospective data from SUH between 1987 and 1993 observed that 58 of 104 (56%) of all PPU patients were smokers[22], reflecting the current data. The percentage of smokers in the PPU population may reflect this as a known risk for ulcer disease and perforation. Notably, in 2011 the number of daily smokers in Norway (Figure 4) is reduced to half the number compared to 2001 data[23], and consequently this risk factor has decreased dramatically over just a decade. The decrease in smoking habits is seen in all the age groups from 16-64 years, but most evident in the age group from 16-44 years[23]. As previously stated, PPU is much more common in older than younger people, and the declining number of smokers in the population should influence incidence rates of PPU with time. However, a decade of decline in smoking in the population may not be enough time to reveal this. Also, an increasing age-population and preserved smoking habits in the older may contribute to a stable incidence still.

Medications may influence PPU incidence and occurrence in several ways, both as risk factors and as preventive means. NSAID-use is associated to peptic ulcers and to peptic ulcer complications, however, the majority of PPUs are not related to NSAIDs[24]. In recent years an increase of NSAID-use has been seen and according to numbers from the Norwegian pharmaceutical association: both acetylic acid (14% increase), diclofenac (35% increase) and ibuprofen (26% increase) usage increased from 2006 to 2010 (over the counter sales included), while the usage of the most common PPI (Esomeprazol) was stable[25]. Previous data from Australia has also shown increasing use of NSAIDs in the population without increasing incidence rates of PPU[26]. A study of peptic ulcer complications in the Swedish population over three decades up to 2002, found declining incidence rates after 1988, when PPI were introduced in Sweden. The authors concluded that the reasons for this most likely were multifactorial, but then

including an effect of PPI[14]. However, few studies have found an effect of PPI or H2 blockers on the PPU incidence or mortality rates[13].

The overall mortality at 16.3% is in comparison to other contemporary European studies from Denmark, the United Kingdom and the Netherlands ranging from 12% to 27%[27-29], but differs from a recent South Korean study reporting mortality at 3%[30]. The difference may be explained by methodology to retrieve data, as the European studies are hospital-based cohorts, and the South Korean study is based on a national health insurance claims database. In one Danish national cohort[31], the overall mortality was 27%, and reduced to 17% for patients entered in a pre-specified perioperative protocol to reduce mortality[31]. In the current population under study with an overall mortality of 16%, there was no pre-specified protocol in use, but institutional trend towards an increased use of pre-operative computed tomography for diagnosis and laparoscopy as mode of intervention during the study period[6].

Ulcer site definition may be confusing, since some classify prepyloric and pyloric ulcers as duodenal[10], while others classify those ulcers as part of the stomach and hence gastric ulcers[13]. Further, extensive perioperative and inflammatory tissue changes may make it difficult to distinguish between the duodenum and the pyloric area during the operation, hence clinical misclassification can obviously occur. Nevertheless, gastric ulcers predominated in this study and this is in accordance to similar reports from Norway, The Netherlands and Iceland[32-34]. However, a non-significant decline of perforated gastric ulcers was seen in the latter years of the decade, while the frequency of duodenal ulcers was stable. Decreasing incidence of gastric ulcers in those aged > 70 years have also been shown in a large study from England and Wales[17]. We did not identify any associations according to ulcer site, but a trend towards younger men having more duodenal ulcers and older women having more gastric ulcers were seen. This has been shown in similar studies before and may represent a somewhat different aetiology, with older, female patients more often having NSAIDs exposure prior to PPU episodes[17,35]. The latter was also seen in this study.

The off-hour admission rates were high with almost two of three patients admitted at either evening/night time shifts or during weekends (i.e., Saturday/Sunday). Consequently, a high proportion of potentially very sick patients requiring an acute operation will be seen when senior staff may not be immediately available or in-house, which may potentially delay a correct work-up and timely diagnosis and consequently operative intervention, than if admitted at office hours. However, we do not have data to substantiate this potential association in the current study.

Several studies have addressed seasonal variation of perforated peptic ulcer[9,11,36,37]. In this study a peak of perforated peptic ulcers was observed during the four months of late spring/summer, but this pattern faded when seasons where divided in three months. However a previous study from Western Norway over 5.5 decades found similar seasonal variations and those variations were consistent over time[38]. However, no statistical significance was found for variations over time, and this is in line with previous reports that failed to find such patterns[9,10].

The retrospective nature of this study limits the accuracy of data quality, which would have been obtained by a prospective manner for some variables, such as exposure to risk factors (i.e., smoking status; medications used, *etc.*) which may be subject to bias by underreporting of past history. However, with a population-based catchment area and a well-developed health system of general physicians and a universal health insurance program for all citizens in Norway, patients are usually admitted with admission notes containing past history, although this may obviously be more prone to failure outside office hours and for emergency referrals. Due to restrictions of the number of patients, we are cautious of performing unwarranted subgroup analysis, and may thus not have been able to confirm significant trends found in other studies.

In conclusion, the adjusted incidence rates in the first decade of the 21st century was stable and reflected the decline seen towards the end of the 20th century. Smoking cessation in the general population and a reduction in the population represented by birth cohorts at higher risk are two important factors that may influence the current low incidence of PPU, compared to that in past decades. Perforated peptic ulcer continues to present outside regular work-hours in over half the time and frequently during weekends, with little difference in seasonal distribution. Mortality is unchanged and stable and is most considerable in the aged population. This may be further subject to change with an increasingly elderly population and should be followed by population-based monitoring for this disease over time.

COMMENTS

Background

Perforated peptic ulcer (PPU) is a life threatening disease with historically reported high morbidity and mortality rates. Disease epidemiology has changed during the last century, but current data on epidemiological trends in PPU is lacking. The aim of this study is to investigate epidemiological trends in a well-defined Norwegian population over a decade.

Research frontiers

Central research in perforated peptic ulcer the latter years has focused on safety of laparoscopy as primary operation and regarding short term mortality after operation. Few studies have presented data regarding epidemiology over the last decade. This study demonstrates a stable incidence and mortality rate over a decade.

Innovations and breakthroughs

A change in peptic ulcer disease epidemiology the last decades came with the discovery of *Helicobacter pylori* with the subsequent eradication therapy with antibiotica, and the introduction of proton pump inhibitors. For perforated peptic ulcers little has changed except the use of laparoscopy as a surgical alternative for repair. The mortality remains high and the incidence has been stable.

Applications

The epidemiology of perforated peptic ulcer appears to be stable with few changes compared to the very recent past. A better understanding of the aetiol-

ogy may be warranted for better prevention and reduction of incidence. Understanding factors contributing to mortality will be important to further improve outcomes.

Peer review

The study is an interesting, well designed and well written one. It will help to shed light on the current situation regarding peptic ulcer disease.

Abstract

AIM: To determine the outcome of patients with biliary fistula (BF) after treatment for hydatid disease of the liver.

METHODS: Between January 2000 and December 2010, out of 301 patients with a diagnosis of hydatid cyst of the liver, 282 patients who underwent treatment [either surgery or puncture, aspiration, injection and reaspiration (PAIR) procedure] were analysed. Patients were grouped according to the presence or absence of postoperative biliary fistula (PBF) (PBF *vs* no-PBF groups, respectively). Preoperative clinical, radiological and laboratory characteristics, operative characteristics including type of surgery, peroperative detection of BF, postoperative drain output, morbidity, mortality and length of hospital stays of patients were compared amongst groups. Multivariate analysis was performed to detect factors predictive of PBF. Receiver operative characteristics (ROC) curve analysis were used to determine ideal cutoff values for those variables found to be significant. A comparison was also made between patients whose fistula closed spontaneously (CS) and those with intervention in order to find predictive factors associated with spontaneous closure.

RESULTS: Among 282 patients [median (range) age, 23 (16-78) years; 77.0% male]; 210 (74.5%) were treated with conservative surgery, 33 (11.7%) radical surgery and 39 (13.8%) underwent percutaneous drainage with PAIR procedure A PBF developed in 46 (16.3%) patients, all within 5 d after operation. The maximum cyst diameter and preoperative alkaline phosphatase levels (U/L) were significantly higher in the PBF group than in the no-PBF group [10.5 ± 3.7 U/L *vs* 8.4 ± 3.5 U/L (P < 0.001) and 40.0 ± 235.1 U/L *vs* 190.0 ± 167.3 U/L (P = 0.02), respectively]. Hospitalization time was also significantly longer in the PBF group than in the no-PBF group [37.4 ± 18.0 d *vs* 22.4 ± 17.9 d (P < 0.001)]. A preoperative high alanine aminotransferase level (> 40 U/L) and a peroperative attempt for fistula closure were significant predictors of PBF development (P = 0.02, 95%CI: -0.03-0.5 and P = 0.001, 95%CI: 0.1-0.4), respectively. Comparison of patients whose PBF CS or with biliary intervention (BI) revealed that the mean diameter of the cyst was not significantly different between CS and BI groups however maximum drain output was significantly higher in the BI group (81.6 ± 118.1 cm *vs* 423.9 ± 298.4 cm, P < 0.001). Time for fistula closure was significantly higher in the BI group (10.1 ± 3.7 d *vs* 30.7 ± 15.1 d, P < 0.001). The ROC curve analysis revealed cut-off values of a maximum bilious drainage < 102 mL and a waiting period of 5.5 postoperative days for spontaneous closure with the sensitivity and specificity values of (83.3%-91.1%, AUC: 0.90) and (97%-91%, AUC: 0.95), respectively. The multivariate analysis demonstrated a PBF drainage volume < 102 mL to be the only statistically significant predictor of spontaneous closure (P < 0.001, 95%CI: 0.5-1.0).

CONCLUSION: Patients with PBF after hydatid surgery often have complicated postoperative course with serious morbidity. Patients who develop PBF with an output < 102 mL might be managed expectantly.

Biliary fistula after treatment for hydatid disease of the liver: When to intervene. *World J Gastroenterol* 2013; 19(3): 355-361 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/355.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.355

INTRODUCTION

Hydatid disease, which is caused by the larval form of *Echinococcus granulosus*, is endemic in Mediterranean countries, the Middle East, Australia and South America and has a worldwide distribution[1]. Despite a decreasing incidence, Turkey is an endemic country according to the Ministry of Health database with more than 14 000 cases recorded from 2001-2005[2]. Although this zoonosis is rare in the United States and Europe, it is a gradually increasing cause of morbidity and mortality in these regions, largely due to travel and ongoing immigration[3].

As a definitive treatment, surgery was considered to be relatively safe based on over 4 decades of accumulated experience[4], but a recent meta-analysis of 14 studies analyzing the outcomes of surgery in endemic areas reported minor and major complication rates of 33.0% and 25.1%, respectively, with a mortality rate of 0.7%[5]. Intrabiliary rupture (IBR), which involves a communication ofthe cyst cavity, which is under high pressure,with the biliary system, is the most common and troublesome complication[6]. IBR was reported to occur at a relatively high rate of 5%-30% of the cases, and it has a wide range of complications, such as biliary obstruction, fistula, infection and secondary biliary cirrhosis[7,8]. If not promptly diagnosed and treated, these biliary complications may result in serious postoperative morbidity and mortality[9]. However, most IBRs are occult in nature, and patients may remain clinically silent in most cases, without any specific radiologicalor laboratory findings being observed in the preoperative work-upand with the IBRs only being discovered during or after surgery. The presence of a postoperative biliary fistula (PBF) is believed to determine the prognosis in these patients[10].

In fact, there is limited information regarding the natural course and outcome of those patients who had an IBR that was not treated successfully and developed a PBF. We previously reported our experience with the treatment of liver hydatiddisease[11]. In this study, we aimed to report the clinical significance of PBF after treatment for hydatid disease in a separate cohort of patients and to identify clinical predictors associated with the closure of PBF.

MATERIALS AND METHODS

Between January 2000 and December 2010, 301 patients with a diagnosis of hydatid cyst of the liver were admitted to the Gulhane Military Medical Academy Hospital, Ankara, Turkey. The data were gathered from a prospectively collected database and the electronic medical records of the patients, including age, gender, medical history of hydatid disease, main symptoms and findings, abdominal ultrasonographic cyst characteristics (number of cysts, single, or multiple; presence or absence of other organs involved with the disease), chest radiography, presence of preoperative complications (jaundice, dilation of the biliary tree, intrabiliary, peritoneal or intrathoracic rupture), type of surgical procedure performed, postoperative daily follow-up of complications, duration of stay after the operation and mortality.

All of the patients underwent a complete blood cell count and liver function test determinations. An abdominal ultrasonographic examination (USG) was performed in all of the patients, but computed tomography (CT) was not used routinely. An indirect hemagglutination test was used for the serological confirmation of the diagnosis.

The liver cysts were classified into 5 types according to their ultrasonographic appearance[12]: type Ⅰ, a simple hydatid cyst with pure fluid collection; type Ⅱ, a cyst containing undulated hyperechogenic membranes that float in the cystic fluid (the detached germinative layer of the endocyst); type Ⅲ, a cyst containing secondary vesicles (daughter cysts); type Ⅳ, a cyst with a heterogeneous echopattern and filled with a matrix or amorphous mass; and type Ⅴ, a cyst with a thick and calcified wall. The presence of irregular linear echogenic structures without acoustic shadowing in the bile duct and/or the dilated biliary tract was accepted as a suggestive USG finding of IBR[13]. All of the patients with these USG findings were further evaluated with either abdominal CT or magnetic resonance cholangiopancreatography (MRCP).

In total, 19 patients were excluded from the analysis. This group included patients discharged without treatment (5 patients), patients with a preoperative diagnosis of cholangitis (the presence of 2 out of the following 3 symptoms or findings: fever > 38 ℃, right upper abdominal pain and jaundice) or patients with suggestive findings of IBR on USG (9 patients) who underwent further evaluation with endoscopic retrograde cholangiography (ERCP) preoperatively. Four additional patients with perioperative common bile duct exploration plus T-tube placement and a patient who died of anaphylactic shock after the operation due to free rupture of the hydatid cyst into the peritoneal cavity were excluded.

The technique of the procedure was mainly selected according to the World Health Organization guidelines on the management of the echinococcal disease, with criteria including the size, type and location of the cyst and the general medical condition of the patient[14]. In patients with significant comorbidities who refused surgery and had cysts > 5 cm that were Gharbi Types 1-2 on USG were treated with the puncture, aspiration, injection and reaspiration (PAIR) procedure[15]. Open surgical

Table 1 Preoperative characteristics of patients with hydatid disease of the liver (mean ± SD)

	Bile fistula		*P* value

GGT (U/L)	25.0 ± 71.7	151.0 ± 64.3	0.08
Total bilirubin (mg/dL)	0.9 ± 1.44	1.5 ± 3.0	0.05
White blood cell	8077.3 ± 2945.0	8802.2 ± 3222.7	0.1

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; GGT: Gamma-glutamyltranspeptidase.

procedures were classified as radical for any type of liver resection and en-bloc cystectomy[16]. A partial cystectomy with tube drainage, capitonnage or omentoplasty was considered to be a conservative procedure[17]. In patients with multiple or communicating cysts, the same surgical procedures were used. The intraoperative detection of a biliary fistula (BF) was at the discretion of the attending surgeon. Uniformly, the cyst cavity was opened, explored for a BF or resection surface and carefully evaluated for a bile leak. Further measures included cholecystectomy and saline or methylene blue injection from the cystic duct stump. A PBF was defined as any drain output consistent with a biliary appearance and a bilirubin count higher than the synchronous serum bilirubin count within 5 d postoperatively.

The patients were grouped according to the presence or absence of PBF (PBF *vs* no-PBF groups, respectively). The preoperative clinical, radiological and laboratory characteristics, operative characteristics including the type of surgery, perioperative detection of BF, postoperative drain output, morbidity, mortality, and length of hospital stay of the patients were compared among the groups. A comparison was also performed between the patients whose fistula closed spontaneously and those who received intervention. The postoperative biliary interventions included ERCP with sphincterotomy and stent placement or nasobiliary tube drainage. Percutaneous drainage catheter insertions were performed under USG guidance.

The following variables were analyzed as potential predictors of PBF development: age, sex, findings on physical examination, leukocyte count, preoperative higher-than-normal liver function test results [alanine aminotransferase (ALT), aspartate aminotransferase, alkaline phosphatase (ALP), gamma-glutamyltranspeptidase, and total bilirubin levels], ultrasonographic cyst features (type, diameter, number, and localization), operation type and perioperative attempted fistula closure.

Statistical analysis

The quantitative data were compared using the *t* test, and the categorical data were compared using the Pearson χ^2 test or Fisher's exact test for the presence of a PBF. Receiver operating characteristic (ROC) curve analysis with calculations of the area under the curve (AUC) was used to determine the ideal cutoff values for those variables that were found to be significant. Logistic regression analysis was used for the multivariate analysis, with a $P < 0.20$ being entered into the model, and a $P < 0.05$ was considered to be significant. All of the statistics were performed using the SPSS 18.0 software (SPSS, Inc., Chicago, IL, United States). The study was approved by the local Ethics Committee of the Gulhane Military Medical Academy.

RESULTS

Of the 282 patients, 217 (77%) were male, and 65 (23%) were female. The median age was 23 years (range 16-78 years). A preoperative diagnosis of cholangitis was found in 30 (10.6%) of the patients. The duration of the symptoms ranged from 1 mo to 7 years (median, 3 mo) (Table 1).

Overall, 178 patients (63.1%) had a single cyst, and 104 (36.9%) had multiple cysts. The cysts were localized only in the right lobe of the liver in 150 (53.2%) patients and in the left in 39 (13.8%), and bilobar involvement was observed in 93 (33%). A total of 484 hepatic cysts were treated in the 282 patients. Thirty-two patients (11.3%) had concomitant cysts in the lung, and 17(6%) had cysts elsewhere.

According to the largest cyst diameter in the USG evaluation, 79 (28%) were type Ⅰ, 35 (12.4%) were type Ⅱ, 127 (45%) were type Ⅲ, 35 (12.4%) were type Ⅳ, and 3 (1.1%) were type Ⅴ. The cyst diameter ranged from 2 cm to 20 cm (median, 8.0 cm) (Table 2).

Operations and perioperative interventions

Of the 282 patients, 210 (74.5%) were treated with conservative surgery, 33 (11.7%) were treated with radical surgery, and 39 (13.8%) underwent percutaneous drainage with the PAIR procedure (Table 2). Three patients (9%) treated with radical surgery, 6 (15%) treated with the PAIR procedure and 37 (17.6%) treated with conservative surgery developed a PBF ($P = 0.44$). An infected cyst cavity was found in 13 (4.6%) patients, with 1 developing a PBF. Perioperative suture ligation of the detected cyst-biliary communication was attempted in 39 (13.8%) patients, with 11 (4.2%) developing a PBF.

Outcome of patients with PBF

In total, PBF developed in 46 (16.3%) patients, all of whom were diagnosed within 5 d after the operation. The maximum cyst diameter (cm) and preoperative ALP levels (U/L) were significantly higher in the PBF group than in the no PBF group (10.5 ± 3.7 U/L *vs* 8.4 ± 3.5 U/L, $P < 0.001$; and 40.0 ± 235.1 U/L *vs* 190.0 ± 167.3 U/L, $P = 0.02$, respectively). The hospitalization time was also significantly longer in the PBF group (37.4 ± 18.0 d *vs* 22.4 ± 17.9 d, $P < 0.001$) (Table 3).

The multivariate analysis revealed that high preopera-

Table 2 Characteritics of hydatid cysts in patients with hydatid disease of the liver (mean ± SD)

Cyst	Bile fistula		*P* value
	Absent *n* = 236	Present *n* = 46	
Size localisation (cm)			
Diameter	8.46 ± 3.52	10.59 ± 3.74	0.0001
Right lobe	127 ± 45.9	23 ± 8.2	0.2
Left lobe	36 ± 12.8	3 ± 1.1

PAIR	33 (11.7)	6 (2.1)	

PAIR: Puncture, aspiration, injection and reaspiration.

tive ALT levels (> 40 U/L) and a perioperative attempted fistula closure were significant predictors of PBF development ($P = 0.02$, 95%CI: -0.03-0.5 and $P = 0.001$, 95%CI: 0.1-0.4, respectively).

Factors related to spontaneous fistula closure

The patients with PBF were further divided into 2 groups regarding fistula closure-either spontaneous (CS group, 12 patients, 4.6%) or with biliary intervention (BI group, 34 patients, 12.1%). The mean diameter of the cyst was not significantly different between the CS and BI groups (9.9 ± 4.1 cm *vs* 10.8 ± 3.6 cm). The maximum drain output was significantly higher in the BI group (81.6 ± 118.1 mL *vs* 423.9 ± 298.4 mL, $P < 0.001$). The time for the fistula closure was significantly higher in the BI group (10.1 ± 3.7 d *vs* 30.7 ± 15.1 d, $P < 0.001$).

The ROC curve analysis revealed cut-off values of a maximum bilious drainage < 102 mL and a waiting period of 5.5 postoperative days for spontaneous closure with sensitivity and specificity values of 83.3%-91.1% (AUC: 0.90) and 91%-97% (AUC: 0.95), respectively.

The multivariate analysis demonstrated a postoperative biliary drainage volume < 102 mL to be the only significant predictor of spontaneous closure ($P < 0.001$, 95%CI: 0.5-1.0), and the presence of multiple cysts on preoperative imaging approached significance ($P = 0.06$, 95%CI: 0.2-0.5).

In the BI group, 15 (5.3%) patients had an ERCP with sphincterotomy, and 19 (6.7%) had an ERCP and NBD. Two patients required repeated ERCPs and plastic stent placement. In addition, 5 (10.8%) patients required catheter placement with USG guidance to control the biliary collections that were not adequately drained.

There were 3 (1.1%) deaths in our series: 2 due to spontaneous rupture of the cyst with subsequent anaphylactic shock and 1 who underwent multiple biliary interventions due to PBF and died due to myocardial infarction.

Table 3 Postoperative characteristics of patients with postoperative biliary fistula (mean ± SD)

	Biliary fistula closed		*P* value
	Spontaneous *n* = 12	Intervention *n* = 34	
Maximum output (mL)	81.6 ± 118.1	423.9 ± 298.4	< 0.001
Drain removal (d)	13.0 ± 6.0	27.1 ± 12.8	0.001
Maximum cyst diameter (cm)	9.9 ± 4.1	10.8 ± 3.6	0.4
Time to fistula closure (d)	10.1 ± 3.7	30.7 ± 15.1	< 0.001
Time to intervention (d)	10.1 ± 3.7	11.4 ± 6.7	0.5
Hospitalization (d)	22.4 ± 17.9	11.4 ± 6.7	< 0.001

DISCUSSION

This study investigated the outcome of patients with PBF due to the IBR of a hepatic hydatid cyst. Whether minimally invasive techniques, conservative surgery or radical surgery were used, the goal of treatment was to eliminate the parasite completely and prevent complications, including pressure on adjacent structures, secondary infection or rupture of the cyst into the biliary system that results in PBF. In our series, PBF occurred in 46 (16%) patients, despite preoperative and operative efforts to prevent this complication. The fistula closed spontaneously in only 12 (26%) of the patients with PBF without further intervention, confirming that patients with PBF often have a complicated postoperative course, requiring multiple endoscopic and other interventional procedures with serious morbidity and mortality[18,19].

Although there are several surgical techniques described to control cyst-biliary communications intraoperatively, 10%-32% of cases eventually develop a PBF[20]. A cyst-biliary communication complicates the natural history of the disease and the treatment processes. Aktan *et al*[21] previously reported a median intracystic pressure of 25 mmHg (range 5-55 mmHg) and a positive correlation between cyst size and pressure in viable cysts. Manometric studies indicate that the sphincter of Oddi pressure (basal 10 mmHg, peak 124 mmHg) is higher than the normal common bile duct pressure (10 mmHg). According to the LaPlace Law, the expansion of the cyst due to increased intracystic pressure results in increased cyst diameter, which causes increased tension on the cyst wall that serves as the pericyst containing the neighboring bile ducts. The pressure dynamics arising from higher intracystic pressures than the resting bile duct pressure may explain how the cyst communicates with the biliary system as the pericyst becomes thinner and thinner, eventually eroding into the bile ducts and leading to the development of an IBR[22].

Several studies reported a history of cholangitis, high bilirubin, high ALP levels, a cyst larger than 10 cm and the presence of suggestive USG findings as clinical predictors of IBR, and an ERCP was suggested to delineate the presence of cyst-biliary communication in these cas-

es[8,13]. Our analysis also showed that a high preoperative ALP, history of cholangitis and larger cyst diameter (> 10 cm) were significantly more common in patients that developed PBF. However, the multivariate analysis revealed that a perioperative attempt at suture ligation and a high preoperative ALT level were significant predictors of PBF. Perioperative suture ligation was performed in 39 patients in this cohort, and 11 (28%) patients developed a PBF. We have not encountered any reports on the success rate of perioperative suture ligation attempts in the literature. Our data indicate that there might be a significant failure rate for an attempt to control a detected BF intraoperatively if that was used as the only method to control the cyst-biliary communication.

Our analysis showed no significant difference in the development of PBF based on the type of procedure. During the hydatid surgery in a given patient with a cyst-biliary communication, regardless of whether a conservative or radical approach (total pericystectomy) is taken, the same biliary pedicles will be encountered, and the fistula risk should be the same unless each communicating pedicle is individually detected and effectively controlled. In our experience, PBF developed in 3 patients [3 (9%) out of 33 patients in the radical surgery group) despite at least 1 attempt to control the fistula with suture ligation, suggesting that controlling all of the detected fistulae with suture ligation may not even be possible, especially when the fistula orifices are deeply located in the cyst cavity and liver. Furthermore, our data indicate that certain fistulae may not even be detected intraoperatively. Other than technical failure, such misses may be partially explained by the abovementioned fluctuating pressure dynamics in the biliary system arising from intermittent Oddi sphincter contractions, which may cause a cyst-biliary communication that is not visible at the time of the surgery unless further manipulation is performed. We agree with others that all interventions on liver hydatidosis should be considered to be potentially major operations and that further intraoperative intervention searching for a cyst-biliary communication is warranted in patients with preoperative risk factors[23]. Our results underline the importance of preoperative detection and effective treatment of the cyst-biliary communication. A preoperative MRCP for patients with clinical and laboratory risk factors could detect biliary complications, and an intervention with ERCP and sphincterotomy could decrease the pressure in the biliary tract, with the further benefit of providing useful anatomical information for the surgeon to select the best therapeutic approach[24]. This information may enable the surgeon to safely perform a conservative approach and avoid a possible cholecystectomy and/or biliary exploration procedure that potentially confers further morbidity, especially in patients with previous symptoms or a history of cholangitis. These patients have a cyst that communicates with the biliary system, resulting in an ascendant infection of the cyst contents. Although bacterial superinfection may kill the parasite, this phenomenon causes extensive inflammation with the subsequent adhesion of the duodenum and colon to the cyst, which renders biliary exploration potentially dangerous. There is a growing body of literature suggesting that it is not the type of surgery but rather the preoperative determination of cyst-biliary communication that is more important in avoiding PBF[25,26].

In contrast to post-cholecystectomy fistulae, which close rapidly after ERCP and sphincterotomy, hydatid fistulae were reported to be more resistant and rarely closed spontaneously without decompression of the biliary tract[27]. Endoscopic treatment has been advocated in high-output fistulae with a duration of more than 1 wk and no signs of reduction and in low-output fistulae with a duration of more than 3 wk and no signs of reduction[28]. The ROC curve analysis enabled the detection of a maximum biliary drainage < 102 mL and a waiting period of 5.5 postoperative days for spontaneous closure (sensitivity and specificity values of 83.3%-91.1%, AUC: 0.90 and 91%-97%, AUC: 0.95, respectively) as significant cut-off levels, and multivariate analysis demonstrated a postoperative biliary drainage volume < 102 mL to be the only significant predictor of spontaneous closure (P < 0.001, 95%CI: 0.5-1.0). This information might help with the decision of when to attempt further intervention in a patient with PBF to prevent delays in treatment.

There are several limitations of this study. In addition to the study's retrospective nature and the lack of a uniform treatment protocol, our results may also be influenced by patient selection bias for each type of surgical or PAIR procedure. Furthermore, there was intersurgeon variability in terms of technical experience, which might have an effect on operative outcomes.

This study showed that an aggressive approach to the detection of cyst-biliary communications, both preoperatively and intraoperatively, is warranted to prevent the development of PBF and thus to avoid serious morbidity and mortality in patients with hydatid disease of the liver. Patients who develop PBF with a fistula output < 102 mL may be managed expectantly, but timely endoscopic intervention and aggressive monitoring is necessary to prevent further complications.

COMMENTS

Background

Hydatid disease, which is caused by *Echinococcus granulosus*, has a worldwide distribution, resulting with tissues developing cysts containing the parasite located mainly in the liver in humans. There are several treatment options including, medical, interventional and surgical modalities. Intrabiliary rupture (IBR), which involves a communication of the cyst cavity with the biliary system is the most common and troublesome complication resulting with a biliary fistula (BF) Development of BF complicates the natural history and outcomes of the disease treatment.

Research frontiers

To date, there is limited information regarding to the development of BF after hydatid disease treatment and its outcomes. Several risk factors including the size and location of the cyst in the liver have been documented however, very few groups reported the outcome of the patients with BF. Furthermore, treat-

ment of BF after treatment of hydatid disease is seldom reported. In order to prevent BF complication; developing multimodality approaches for detecting patients with risk factors preoperatively and developing guidelines for selecting the most suitable surgical or conservative management for these patients as well as best postoperative treatment for this complication is an active field of research.

Innovations and breakthroughs

The authors found certain risk factors in preoperative radiology and biochemistry tests of patients for development of a BF. However, this study is different from others in two aspects. The authors' analysis revealed that certain amount of patients undergoing treatment for hydatid disease of the liver would eventually develop a BF regardless of the method chosen to control the disease. Secondly, the authors documented that detecting a BF intraoperatively and attempting to control by the current standard surgical means may not be enough to control the development of BF hence emphasizing the importance of preoperative detection and aggressive intervention. The authors were also able to find a cut-off value for postoperative BF drainage output in order to choose between expectant or interventional treatment.

Applications

The study results suggest that an aggressive approach to the detection of IBR both preoperatively and intraoperatively is warranted to prevent the development of a postoperative BF and thus to avoid serious morbidity and mortality in patients with hydatid disease of the liver. Patients who develop postoperative BF with a fistula output < 102 mL may be managed expectantly.

Peer review

The manuscript is well designed, with clear objective. The manuscript aim to determine the outcome of patients with BF after treatment for hydatid disease of the liver. The authors found certain risk factors in preoperative radiology and biochemistry tests of patients for development of a BF.

Abstract

AIM: To compare the impact of the right recumbent position with the sitting position on gastric emptying of water.

METHODS: In eight healthy male volunteers, the 13C acetate breath test was performed twice to assess gastric emptying of 100 mL tap water. Subjects were seated in one test and lying on their right side in the other. In both positions, pulmonary $^{13}CO_2$ exhalation curves were obtained by plotting breath data against time. Percent gastric retention curves were created by analyzing data using the Wagner-Nelson protocol.

RESULTS: No significant posture effect was found in pulmonary $^{13}CO_2$ output curves (P = 0.2150), whereas a significant effect was seen in gastric retention curves (P = 0.0315). The percent retention values at 10 min and 15 min were significantly smaller when subjects were in the right recumbent position compared with the seated position ($P < 0.05$). Our results verified the accelerating effect of the right recumbent position on gastric emptying of non-nutritive solutions. Concerning clinical implications, this study suggests that placing patients with acute pain on their right side after oral administration of analgesic drugs in solution is justified as an effective practice for rapid pain relief. For patients with gastrointestinal reflux symptoms, sleeping in the right recumbent position may reduce nocturnal symptoms, as delayed gastric emptying can cause reflux symptoms.

CONCLUSION: Gastric emptying of water occurs more quickly when a subject lies on the right side compared with sitting.

Right recumbent position on gastric emptying of water evidenced by ^{13}C breath testing. *World J Gastroenterol* 2013; 19(3): 362-365 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i3/362.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i3.362

INTRODUCTION

Gastric emptying of orally ingested contents is a great concern to clinicians because it is associated with gastrointestinal symptoms and can affect the efficacy of medications. Little absorption takes place in the stomach,

and any oral medication must therefore pass beyond the stomach before being absorbed within the small intestine. The rate of gastric emptying is determined by the balance between the propulsive force (fundic tonic pressure and antral contractions) and the outlet resistance (pyloric and duodenal contractions). For calorie-containing meals, the force-resistance balance is primarily regulated by the nutrient-evoked feedback loop that strictly controls duodenal entry of meals so as to optimize intestinal absorption of nutrients[1]. On the other hand, for non-caloric fluids (e.g., water and normal saline), the feedback system is barely activated and consequently, the stomach behaves like "a motionless bag" in which the fluids passively flow back and forth depending on gravity[2]. Considering this gravity-dependent flow, the idea has been proposed that, among the variety of body positions, the right lateral recumbent position makes emptying of non-nutritive fluids the fastest[3].

Positioning a patient has traditionally been regarded as an effective maneuver to modulate the absorption of orally administered drugs in solution. In the case of oral overdosing, for which drug absorption should be delayed, being recumbent on the left side ("pylorus up" status) is advisable.; In the case of acute pain, for which the rapid onset of analgesic effect is favored, being recumbent on the right side ("pylorus down" status) is recommended. Indeed, the delaying effect of the left recumbent position on gastric emptying of non-caloric liquids has been well documented. However, the evidence that the right recumbent position enhances liquid emptying is much less certain[4]. According to a recent review on the postural effect on gastric emptying[4], only one trial supports the enhanced emptying of non-nutritive liquids in the right recumbent position, showing that emptying is significantly faster than in the left recumbent position[2]. However, this result only suggests that emptying in the left recumbent position is slower than that in the right.

The present study was conducted to elucidate whether gastric emptying of water is faster when lying on the right side than when seated. The sitting position is regarded as "neutral" if the effect of the gravity over intragastric fluids is accounted for, and was thereby set as the reference posture. The ^{13}C-acetate breath test with Wagner-Nelson analysis was used to measure gastric emptying accurately without any invasive procedures.

MATERIALS AND METHODS

Subjects

Eight healthy male volunteers (age: 19-52 years, median 38 years; weight: 48.0-80.2 kg, median 64.0 kg) participated in this study. No subject had a history of, or symptoms referable to, gastrointestinal and pulmonary disease or chronic medical problems. Additionally, no subjects were receiving medication at the time of the study. Written informed consent was obtained from each volunteer. The study protocol was approved by the Ethics Committee of Toho University.

Protocol

The ^{13}C-acetate breath test was used to assess gastric emptying [5]. The assessment was carried out on two randomized occasions, at least 3 d apart, with subjects either seated or lying on their right side. On both occasions, subjects had fasted overnight, and they drank 100 mL tap water labeled with 100 mg ^{13}C-acetate in the sitting position. Breath samples were collected at baseline and, following ingestion of the water, at 5-min intervals for the first 20 min and at 10-min intervals thereafter up to 120 min. On one occasion, the subjects remained seated throughout the 120-min period. On the other occasion, immediately after drinking the test solution, they lay down on their right side and maintained the position until they exhaled the 15-min breath sample; thereafter they remained seated.

Data analysis

Breath $^{13}CO_2$ isotopic enrichment was determined using non-dispersive infrared isotope spectrometry (UbiT-IR 300; Otsuka Electronics, Osaka, Japan). The pulmonary recovery of $^{13}CO_2$ was expressed in %dose/h based on the body surface area and the assumed CO_2 production. The %dose/h recovery values were plotted against time to create the time-breath $^{13}CO_2$ excretion curve, which indirectly reflects gastric emptying. The time to the maximal recovery (Tmax), a semi-quantitative index of gastric emptying, was determined by visual inspection of the $^{13}CO_2$ output curve[6]. The breath data were further analyzed using the Wagner-Nelson method, which enables creation of a percent gastric retention-time curve that is as accurate as the scintigraphic emptying curve[7]. The Wagner-Nelson procedure has been detailed elsewhere[7,8]. In short, estimated fraction of the labeled test meal that has been emptied from the stomach by time t, F(t), is obtained from the conventional equation; F(t) = area under the concentration curve (AUC)(t)/AUC(∞), although the value can differ from those obtained using the scintigraphic method. Wagner-Nelson method allows accurate estimation of F(t) using the revised equation as follows: F(t) = [AUC(t) + C(t)/Kel]/AUC(∞). In the equation, Kel (1/h) is the first-order rate constant for total elimination of $^{13}CO_2$ from the human body, C(t) is the $^{13}CO_2$ excretion rate (%dose/h), AUC(t) is the area under the C(t) curve (%dose) (= the pulmonary recovery of $^{13}CO_2$), and AUC(∞) is the cumulative amount of $^{13}CO_2$ recovered in the breath at the infinite time (% dose).

The time by which half of the water has been emptied ($t_{1/2}$), which is used as the standard index in gastric emptying scintigraphy, was determined by interpolation from the retention-time curve[7].

Statistical analysis

Differences in the pulmonary $^{13}CO_2$ output and the percent gastric retention curves between the two postures were assessed with repeated measures of analysis of variance (ANOVA) using "posture" and "time" as factors. When the ANOVA showed a significant difference, it was

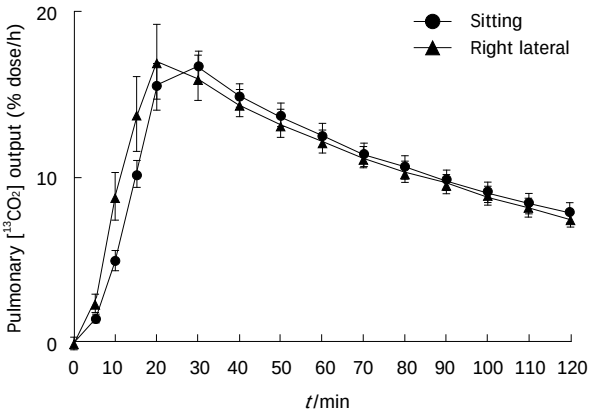

Figure 1 Pulmonary $^{13}CO_2$ recovery-time curves. Error bars indicate SE.

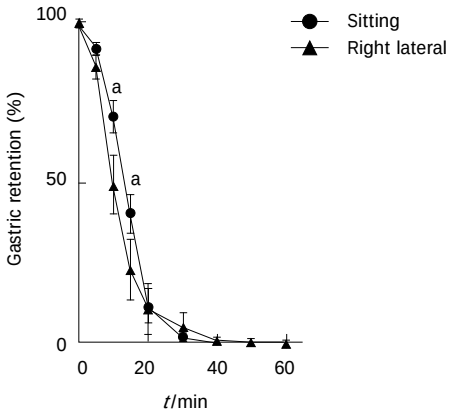

Figure 2 Percent gastric retention-time curves created by Wagner-Nelson analysis. Error bars indicate SE. The asterisk indicates a significant difference ($^aP < 0.05$ *vs* right lateral group).

followed by *post hoc* comparisons at each measurement time with Student's paired *t* test with Bonferroni adjustment. The t_{max} and $t_{1/2}$ values are presented as mean ± SD. Differences in t_{max} and $t_{1/2}$ between the two body positions were also assessed with Student's paired *t* test. The level of significance was set at $P = 0.05$ (two-sided probability).

RESULTS

No significant posture effect was found in pulmonary $^{13}CO_2$ output curves ($P = 0.2150$; Figure 1), whereas a significant effect was found in gastric retention curves ($P = 0.0315$; Figure 2). The *post hoc* comparisons revealed that the percent retention values were significantly smaller in the right recumbent position at 10 min ($P < 0.01$) and at 15 min ($P < 0.05$). On the other hand, neither Tmax nor $t_{1/2}$ was significantly different between the two positions (Tmax: 25.0 ± 5.35 min in the sitting position and 23.1 ± 9.23 min in the right recumbent position; $P = 0.644$, $t_{1/2}$: 13.7 ± 2.79 min in the sitting position and 11.6 ± 5.92 min in the right recumbent position; $P = 0.378$).

DISCUSSION

It seems natural that non-caloric fluids in the stomach should gravitate toward the duodenum in the right recumbent position. It is, therefore, reasonable to assume that the right recumbent position would hasten gastric emptying of fluids compared to a sitting position. However, this assumption has not been verified. The present results provided clear evidence that water is emptied significantly faster when a subject is in the right recumbent position than when seated.

Burn-Murdoch *et al*[2] showed that emptying of saline was significantly faster in the right recumbent position than in the left recumbent position whereas it was not significantly different between the right recumbent position and the seated position. We think that the lack of significant difference between the right recumbent position and the seated position in that study might be due to the suboptimal protocol used to measure gastric emptying: the emptying was quantified as the volume aspirated *via* a nasogastric tube at 10 min after ingestion of 750-mL saline. The aspiration technique appears unreliable to measure residual gastric volume[9].

In the present study, the gastric retention at 10 and 15 min indicated a significant positional effect (Figure 2), whereas the pulmonary $^{13}CO_2$ output curve did not (Figure 1). This is possibly because the Wagner-Nelson modification improved the accuracy of breath testing. In contrast to gastric scintigraphy, which allows direct visualization of duodenal transit of gastric contents[10], the conventional ^{13}C-acetate breath test indirectly reflects gastric emptying and thus is less sensitive[6]. The Wagner-Nelson analytical strategy has been introduced into the breath test system to overcome its indirect nature, making the ^{13}C-breath test as accurate as the "gold standard" of scintigraphy[7]. Gastric emptying of non-nutrient fluids in the sitting position per se is so rapid that conventional breath testing would have overlooked a subtle, albeit real acceleration of emptying in the right recumbent position. This subtle difference would be detected only by the gastric retention curve created by Wagner-Nelson analysis. The $t_{1/2}$ values were not significantly different between the two body positions even though values were derived from the "accurate" Wagner-Nelson analysis. This is probably because the $t_{1/2}$ value itself would be a less accurate parameter than the percent gastric retention at a fixed time point, as shown in the expert recommended guidelines for scintigraphic gastric emptying studies[10].

There are some limitations to the present study. First, we used only a small sample size. Second, only a small volume of tap water was used. A larger volume may influence the results.

In conclusion, our results verified the accelerating effect of the right recumbent position on gastric emptying of non-nutritive solutions. Concerning clinical implications, this study suggests that placing patients with acute pain on their right side after oral administration of analgesic drugs in solution is justified as an effective practice

for rapid pain relief. For patients with gastrointestinal reflux symptoms, sleeping in the right recumbent position may reduce nocturnal symptoms, as delayed gastric emptying can cause reflux symptoms.

COMMENTS

Background

Conventionally, gastric emptying of non-caloric fluids is thought to be accelerated when a person is in the right recumbent position. However, evidence supporting this hypothesis is weak. The present study compared the impact of the right recumbent position with the sitting position on gastric emptying of water.

Research frontiers

For calorie-containing meals, the force-resistance balance is primarily regulated by the nutrient-evoked feedback loop that strictly controls duodenal entry of meals so as to optimize intestinal absorption of nutrients. On the other hand, for non-caloric fluids, the feedback system is barely activated and consequently, the stomach behaves like "a motionless bag" in which the fluids passively flow back and forth depending on gravity.

Innovations and breakthroughs

The present study was conducted to elucidate whether gastric emptying of water is faster when lying on the right side than when seated. The sitting position is regarded as "neutral" if the effect of the gravity over intragastric fluids is accounted for, and was thereby set as the reference posture. The ^{13}C-acetate breath test with Wagner-Nelson analysis was used to measure gastric emptying accurately without any invasive procedures.

Applications

Their results verified the accelerating effect of the right recumbent position on gastric emptying of non-nutritive solutions. Concerning clinical implications, this study suggests that placing patients with acute pain on their right side after oral administration of analgesic drugs in solution is justified as an effective practice for rapid pain relief. For patients with gastrointestinal reflux symptoms, sleeping in the right recumbent position may reduce nocturnal symptoms, as delayed gastric emptying can cause reflux symptoms.

Peer review

This is a prospective study to evaluate the gastric emptying of non-caloric liquids in a seated position versus right lateral recumbence. A total of 8 healthy male volunteers were given 100 mL of tap water labeled with ^{13}C-acetate and evaluated in a seated position on one occasion and, on a separate day, evaluated in a right lateral recumbence position. Breath samples were collected at given intervals and tested for the pulmonary recovery of $^{13}CO_2$. The values were plotted against time to create a time-breath $^{13}CO_2$ excretion curve, which is an indirect measurement of the gastric emptying. The Wagner-Nelson procedure was then used to further analyze the data and extrapolate percent gastric retention-time curve.

Abstract

AIM: To clarify the role of surgical resection for multiple hepatocellular carcinomas (HCCs) compared to transarterial chemoembolization (TACE) and liver transplantation (LT).

METHODS: Among the HCC patients who were managed at Yonsei University Health System between January 2003 and December 2008, 160 patients who met the following criteria were retrospectively enrolled: (1) two or three radiologically diagnosed HCCs; (2) no radiologic vascular invasion; (3) Child-Pugh class A; (4) main tumor smaller than 5 cm in diameter; and (5) platelet count greater than 50 000/mm^3. Long-term outcomes were compared among the following three treatment modalities: surgical resection or combined radiofrequency ablation (RFA) (n = 36), TACE (n = 107), and LT (n = 17). The survival curves were computed using the Kaplan-Meier method and compared with a log-rank test. To identify the patients who gained a survival benefit from surgical resection, we also investigated prognostic factors for survival following surgical resection. Multivariate analyses of the prognostic factors for survival were performed using the Cox proportional hazard model.

RESULTS: The overall survival (OS) rate was significantly higher in the surgical resection group than in the TACE group (48.1% *vs* 28.9% at 5 years, $P < 0.005$). LT had the best OS rate, which was better than that of the surgical resection group, although the difference was not statistically significant (80.2% *vs* 48.1% at 5 years, $P = 0.447$). The disease-free survival rates were also significantly higher in the LT group than in the surgical resection group (88.2% *vs* 11.2% at 5 years, $P < 0.001$). Liver cirrhosis was the only significant prognostic factor for poor OS after surgical resection. Clinical liver cirrhosis rates were 55.6% (20/36) in the resection group and 93.5% (100/107) in the TACE group. There were 19 major and 17 minor resections. *En bloc* resection was performed in 23 patients, multisite resection was performed in 5 patients, and combined resection with RFA was performed in 8 patients. In the TACE group, only 34 patients (31.8%) were recorded as having complete remission after primary TACE. Seventy-two patients (67.3%) were retreated with repeated TACE combined with other therapies. In patients who underwent surgical resection, the 16 patients who did not have cirrhosis had higher 5-year OS and disease-free survival rates than the 20 patients who had cirrhosis (80.8% *vs* 25.5% 5-year OS rate, $P = 0.006$; 22.2% *vs* 0% 5-year disease-free survival rate, $P = 0.048$). Surgical resection in the 20 patients who had cirrhosis did not provide any survival benefit when compared with TACE (25.5% *vs* 24.7% 5-year OS rate, $P = 0.225$). Twenty-nine of the 36 patients who underwent surgical resection experienced recurrence. Of the patients with cirrhosis, 80% (16/20) were within the Milan criteria at the time of recurrence

after resection.

CONCLUSION: Among patients with two or three HCCs, no radiologic vascular invasion, and tumor diameters ≤ 5 cm, surgical resection is recommended only in those without cirrhosis.

INTRODUCTION

Surgical resection is the established treatment modality for hepatocellular carcinoma (HCC) in patients with preserved liver function, and surgical outcomes have been greatly improved with mortality rates of 0%-6.4% and excellent 5-year survival rates of more than 50%[1-3]. However, for patients with multiple HCCs, unfavorable disease-free and overall survival (OS) rates following surgical resection have led to the contraindication of surgical treatment. This contraindication is reflected in the guidelines suggested by the American Association for the Study of Liver Disease[4] and the European Association for the Study of the Liver[5] based on the Barcelona Clinic Liver Cancer (BCLC) staging system. Thus, liver transplantation is recommended as the best option for patients with multiple HCCs, but a worldwide shortage of donor organs greatly limits the application of this recommendation. Therefore, although multidisciplinary strategies are used in the treatment of multiple HCCs, multiple HCCs still pose a therapeutic challenge and are a matter of debate.

Currently, the main treatment modality for multiple HCCs is transarterial chemoembolization (TACE). Although several expert centers have recently reported encouraging durable long-term outcomes of surgical resection for multiple HCCs (50%-60% at 5 years) in patients with well-preserved liver function[6,7], few comparative studies of surgical resection and liver transplantation (LT).

ACE have been reported[8,9]. Therefore, we designed this study to clarify the role of surgery for multiple HCCs by comparing the long-term outcomes following surgical resection, TACE, and LT and investigating prognostic factors in patients who underwent surgical resection.

MATERIALS AND METHODS

Patient evaluation and follow-up

We analyzed a single-institution database of 3928 patients who received their initial treatments for HCCs at Yonsei University Health System, Seoul, South Korea between January 2003 and December 2008. The Institutional Review Board of Yonsei University Health System approved this study. Of the patients who underwent surgical resection (n = 304), TACE (n = 854), and LT (n = 45), the patients who met the following criteria were enrolled in this retrospective, single-cohort study: (1) two or three radiologically diagnosed HCCs; (2) no radiologic vascular invasion; (3) Child-Pugh class A; (4) main tumor smaller than 5 cm in diameter; and (5) a platelet count greater than 50 000/mm^3. Small satellite nodules found in the resected specimen were not included in this study.

The cutoff value of tumor size for therapeutic decision making is a debated issue. The 7th edition of cancer staging of the American Joint Committee on Cancer describes main tumor size greater than 5 cm in multiple tumors as an independent prognostic factor for survival[10]. Additionally, a study comparing the pathologically proven necrosis rate following TACE reported the following frequencies of complete necrosis according to tumor size: 66.7%, 30% and 0% for ≤ 3.0 cm, 3.1-5.0 cm, and > 5.0 cm, respectively[11]. Although TACE has been performed as palliative care for larger HCCs, the OS rates of patients with tumors larger than 5 cm in diameter are very poor[12,13]. In addition to tumor size, the presence of vascular involvement of the tumor is a significant prognostic factor for poor outcome. The 5-year survival rates among patients with tumors with and without macroscopic vascular invasion are significantly different (48% ± 3% *vs* 14% ± 5%, $P < 0.001$)[14]. Therefore, patients with a tumor ≥ 5 cm in diameter or with macroscopic vascular involvement were excluded from this study because those patients were unsuitable for curative therapy.

Ultimately, we included 36 patients who underwent surgical resection or combined resection with radiofrequency ablation (RFA), 107 patients who received TACE, and 17 patients who underwent LT, and we compared long-term outcomes following the respective treatments.

Patients were evaluated preoperatively by abdominal ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and hepatic angiography, if indicated. All patients were assessed using alpha-fetoprotein (AFP), protein induced by vitamin K absence or antagonist Ⅱ (PIVKA Ⅱ), hepatitis B surface antigen, anti-hepatitis C viral antibody, liver biochemistry, coagulation test, and indocyanine green retention rate at 15 min (ICG R15).

The selection of therapeutic options was determined by the anatomical locations of the tumors, liver functional reserve, and patient preference. TACE was generally considered when the tumor was ineligible for complete surgical removal, low remnant liver volume was expected after resection, or the patients declined operative inter-

vention. The patients who had an available liver donor underwent LT.

Eradicating all of the multifocal tumors required a multimodality approach using not only *en-bloc* resection but also separate multi-site resection or resection combined with RFA. All of the patients who underwent surgical resection were routinely assessed by intra-operative US. The effectiveness and safety of combined hepatectomy with RFA for multi-site HCCs were reported by Choi *et al*[15], and our previous work has also shown comparable results between en-bloc resection and multi-site resection or combination hepatectomy with RFA[16]. Separate multi-site resection or resection plus RFA was performed for the multifocal tumors ineligible for en-bloc resection because of bilobar involvement or when there was not enough hepatic function reserve after *en-bloc* resection. Wedge resection was considered for superficial tumors, and RFA was performed for tumors less than 3 cm in diameter that were located deep in the liver.

The median follow-up period for the patients who underwent surgical resection was 38.6 mo (range: 1-94 mo). Surveillance after treatment was conducted with regular monitoring of AFP, PIVKA Ⅱ, and US or CT every three to six months. Suspicious intrahepatic recurrence was confirmed by MRI, hepatic angiography, or image-guided fine-needle biopsy, if needed.

To identify the patients who gained a survival benefit from surgical resection, we also investigated prognostic factors for survival following surgical resection. Twelve clinical variables recorded at the time of diagnosis were analyzed. The variables included age at diagnosis; sex; serum albumin; alanine aminotransferase (ALT) and aspartate aminotransferase levels; ICG R15; serum AFP level; clinical liver cirrhosis; main tumor size and number of tumors on preoperative image studies; lobar distribution of the tumor; and type of operation.

Clinically diagnosed liver cirrhosis was defined as follows: (1) history of overt complications of liver cirrhosis, such as ascites, variceal bleeding, and hepatic encephalopathy; (2) evidence of clinical portal hypertension, including esophageal or gastric varices, or splenomegaly (maximal diameter > 12 cm) with platelet count < 100 000 mm^3; and (3) liver morphology suggesting the presence of cirrhosis on preoperative image studies, including hypertrophy of the left lobe and/or caudate lobe, relative volume reduction of the right lobe, nodularity of the liver surface, presence of regenerative or dysplastic nodules, or the presence of a portosystemic shunt[17-19]. All of the analysis in the current study were performed using a clinical diagnosis of liver cirrhosis to evaluate its clinical usefulness. Minor resection was defined as hepatectomy of two or fewer liver segments.

Statistical analysis

Continuous variables are presented as the mean ± SD and were compared by Student's *t* test. Categorical variables are expressed as frequencies with percentages and were compared by the χ^2 test. Cumulative overall and disease-free survival rates were computed by the Kaplan-Meier method, and differences between the survival curves were compared using a log-rank test. Multivariate analyses of the prognostic factors for survival were performed using the Cox proportional hazard model and included the factors that had *P* values less than 0.1 upon univariate analysis. Statistical analyses were performed using SPSS 15 for Windows (SPSS Inc., Chicago, IL, United States). Statistical significance was set at a *P* value less than 0.05.

RESULTS

Clinical characteristics of the surgical resection group and TACE group

The patients who underwent TACE were older and had lower platelet counts, higher ALT levels, and a higher rate of clinical liver cirrhosis than those in the resection group. Clinical liver cirrhosis rates were 55.6% (20/36) in the resection group and 93.5% (100/107) in the TACE group. Surgical resection was performed more frequently in patients with larger diameter tumors (Table 1).

Operative procedures in the surgical resection group and additional treatments in the TACE group

Table 2 lists the operative procedures and combined treatments with RFA in the resection group. There were 19 and 17 major and minor resections, respectively. *En bloc* resection was performed in 23 patients, multi-site resection was performed in 5 patients, and combined resection with RFA was performed in 8 patients. In the TACE group, only 34 patients (31.8%) were recorded as having complete remission after primary TACE. Seventy-two patients (67.3%) were retreated with repeated TACE, one patient was retreated with repeated TACE and intra-arterial chemotherapy, two patients were retreated with RFA, two patients were retreated with radiation therapy, one patient was retreated with percutaneous ethanol injection, two patients were retreated with intra-arterial chemotherapy and systemic chemotherapy, two patients were retreated with intra-arterial chemotherapy and radiation therapy, and five patients were retreated with holmium therapy.

Long-term outcomes according to treatment modality

The OS rate was significantly higher in the surgical resection group than in the TACE group (48.1% *vs* 28.9% at 5 years, $P < 0.005$) (Figure 1A). LT had the best OS rate, which was better than that of the surgical resection group, although the difference was not statistically significant (80.2% *vs* 48.1% at 5 years, $P = 0.447$) (Figure 1A). The disease-free survival rates were also significantly higher in the LT group than in the surgical resection group (88.2% *vs* 11.2% at 5 years, $P < 0.001$) (Figure 1B).

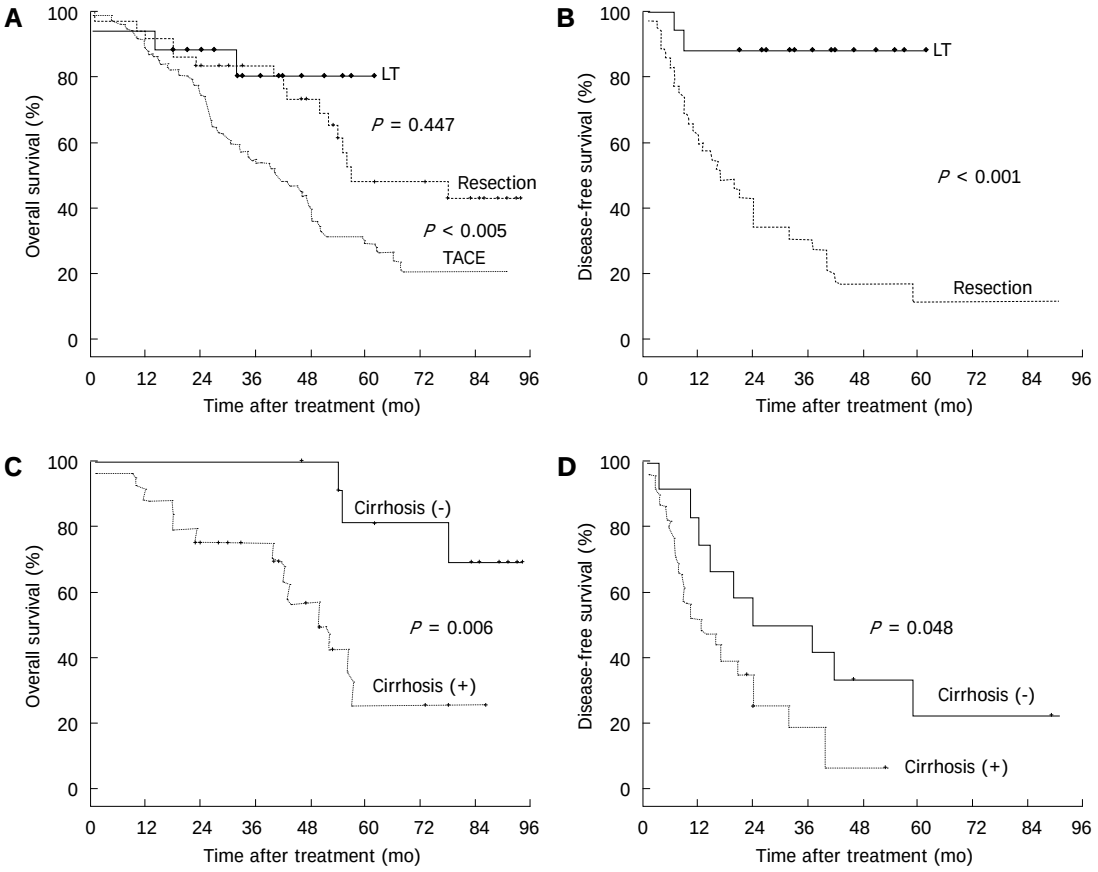

Figure 1 The overall and disease-free survival curves according to treatment modality and presence of liver cirrhosis in surgical resection patients. A: The 1-, 3- and 5-year overall survival (OS) rates were 94.1%, 80.2% and 80.2%, respectively, in the liver transplantation (LT) group; 91.7%, 83.3% and 48.1%, respectively, in the resection group; and 88.7%, 55.6% and 28.9%, respectively, in the transarterial chemoembolization (TACE) group. The OS rate was significantly higher in the surgical resection group than in the TACE group ($P < 0.005$). LT showed the best OS rate (better than the surgical resection group, but not statistically significant, $P = 0.447$); B: The 1-, 3- and 5-year disease-free survival rates were 88.2%, 88.2% and 88.2% in the LT group and 60%, 30.3% and 11.2% in the resection group, respectively. The disease-free survival rates were also significantly higher in the transplantation group than in the surgical resection group ($P < 0.001$); C: The 1-, 3- and 5-year OS rates were 100%, 100% and 80.8% in patients without cirrhosis (-) and 87.5%, 75% and 25.5% in patients with cirrhosis (+), respectively ($P = 0.006$); D: The 1-, 3- and 5-year disease-free survival rates were 75.0%, 50.0% and 22.2% in patients without cirrhosis (-) and 52.3%, 18.7% and 0% in patients with cirrhosis (+), respectively ($P = 0.048$).

Table 1 Clinical characteristics of the surgical resection patients *vs* the transarterial chemoembolization patients

Variable	Surgical resection (n = 36)	TACE (n = 107)	P value
Age (yr)	54.3 ± 8.6	61.2 ± 9.3	< 0.001
Gender (male:female)	34:2	86:21	0.047
Platelet (k/mm^3)	153.4 ± 53.9	121.0 ± 51.8	0.002
Albumin (g/dL)	4.05 ± 0.50	3.93 ± 0.48	0.203
ALT (IU/L)	36.4 ± 15.8	59.0 ± 40.4	0.001
AST (IU/L)	41.2 ± 25.8	53.2 ± 44.7	0.130
HBsAg	28 (77.8)	67 (62.6)	0.099
Clinical liver cirrhosis	20 (55.6)	100 (93.5)	< 0.001
Tumor number			0.549
2	30 (83.3)	90 (84.1)

	+ wedge resection	1
	+ RFA	2
	Segmentectomy only	1
	+ RFA	1
	Wedge resection + RFA	1

En bloc resection (n = 23); multi-site resection (n = 5); resection plus radiofrequency ablation (RFA) (n = 8).

Table 3 Prognostic factors for overall survival in surgical resection patients

Variable	Patients (n = 36)	1-yr OS	3-yr OS	5-yr OS	P value
Age (yr)					0.146
≤ 60	27	88.9%	81.5%	42.3%	
> 60	9	100%	88.9%	66.7%	
Gender					0.245
Male	34	91.2%	82.4%	45.1%	
Female	2	100%	100%	100%	
Serum albumin (g/dL)					0.642
≤ 3.5	10	90.0%	60.0%	48.0%	
> 3.5	26	92.3%	87.7%	46.1%	
ALT (IU/L)					0.593
≤ 50	27	92.6%	81.5%	53.7%	
> 50	9	88.9%	71.1%	23.7%	
AST (IU/L)					0.87
≤ 50	31	90.3%	80.6%	52.4%	
> 50	5	100%	100%	50.0%	
ICG R 15 (%)					0.992
≤ 14	25	92.0%	84.0%	47.1%	
> 14	9	88.9%	77.8%	58.3%	
α-fetoprotein					0.471
≤ 1000 IU/mL	32	90.6%	81.3%	47.3%	
> 1000 IU/mL	4	100%	100%	50.0%	
Cirrhosis					0.023
No	16	100%	93.8%	69.9%	
Yes	20	85.0%	75.0%	26.5%	
Main tumor size (cm)					0.629
< 3.0	17	94.1%	86.3%	43.1%	
≥ 3.0	19	89.5%	73.7%	52.6%	
Number of tumors					0.061
2	31	90.3%	80.6%	40.7%	
3	5	100%	100%	100%	
Lobar distribution of tumors					0.892
One lobes	24	91.7%	83.3%	49.4%	
Two lobe	12	91.7%	83.3%	48.6%	
Operation type					0.568
En bloc resection	23	91.3%	82.6%	43.4%	
Multiple resection or combined with RFA	13	92.3%	84.6%	57.1%	

OS: Overall survival; RFA: Radiofrequency ablation; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ICG R 15: Indocyanine green retention rate at 15.

Prognostic factors for OS in patients who underwent surgical resection

Cirrhosis was the only significant prognostic factor for poor OS after resection in both the univariate (P = 0.023) and multivariate analyses (P = 0.034, odds ratio = 0.552, 95%CI: 0.105-0.915) (Table 3). Clinically diagnosed liver cirrhosis was correlated with pathological cirrhosis with a positive predictive value of 100%, a negative predictive value of 75%, a sensitivity of 83.3%, and a specificity of 100%.

Long-term outcomes of patients who underwent surgical resection according to the presence of cirrhosis

The 1-, 3- and 5-year OS rates were 100%, 100% and 80.8%, respectively, in 16 patients without cirrhosis, and 87.5%, 75% and 25.5%, respectively, in 20 patients with cirrhosis (P = 0.006) (Figure 1C). The disease-free 1-, 3- and 5-year survival rates were 75.0%, 50% and 22.2%, respectively, in patients without cirrhosis and 52.3%, 24.9% and 0%, respectively, in patients with cirrhosis (P = 0.048) (Figure 1D). The OS rates were not different between the surgical resection group and the TACE group among the patients with cirrhosis (87.5%, 75.0% and 25.5% *vs* 91.8%, 61.7% and 24.7% at 1-, 3- and 5-year, respectively, P = 0.225) (Figure 2).

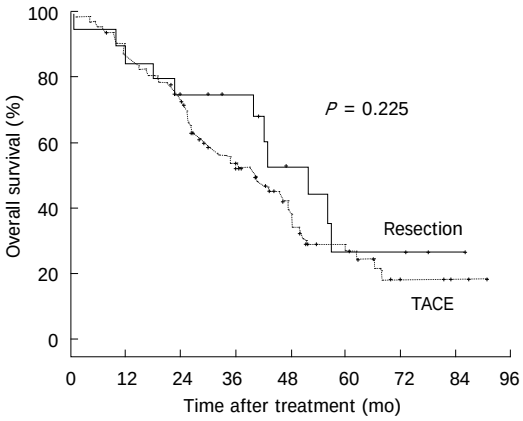

Figure 2 Overall survival curves of surgical resection and transarterial chemoembolization in patients with liver cirrhosis. Among patients with cirrhosis, the overall survival (OS) rates were not different between the surgical resection group and the transarterial chemoembolization (TACE) group (25.5% *vs* 24.7% 5-year OS rate, P = 0.225).

Recurrence pattern after surgical resection

Twenty-nine of the 36 patients who underwent surgical resection experienced recurrence. Of the 29 patients with recurrence, 1 (4%) had a marginal recurrence on the resection margin, 21 (84%) had intra-hepatic recurrences, and 3 (12%) had extra-hepatic recurrences with one in the lung and two in bone. All of the patients with marginal and intra-hepatic recurrence were retreated by TACE. Chemotherapy, radiation therapy, and a clinical trial were used to treat extra-hepatic recurrences. Notably, of the patients with cirrhosis, 80% (16/20) were within the Milan criteria at the time of recurrence after resection.

DISCUSSION

Our study demonstrates that surgery for patients with multiple HCCs is recommended in patients without cirrhosis. Our data revealed that the survival of patients who underwent surgical resection was better than that of patients who received TACE. However, the survival of patients with HCCs was affected not only by HCC itself, but also by underlying liver disease. The majority of patients (93.5%, 100/107) who received TACE had liver cirrhosis. Therefore, when the survival of the patients in the surgical resection group was compared with the TACE group according to the presence of cirrhosis, surgical resection showed no survival benefit in cirrhotic patients.

To confirm the efficacy of surgical resection for mul-

tiple HCCs, its superiority over non-surgical treatment (TACE) should be proven. A recent retrospective cohort study by Ho *et al*[8] reported that hepatectomy yields better survival than TACE even in patients with multiple HCCs in various stages. The authors compared the prognosis of the patients according to stages in different staging systems; however, as the authors note, their study had several weaknesses. Although each staging system represents the prognosis of the patients who have HCC, and in particular, the BCLC system accounts for portal hypertension and the bilirubin level in addition to the Child-Pugh classification in staging, the liver function status in each stage encompasses a wide range and the prognosis in the subgroups of each stage differs significantly[20]. Additionally, the patients in each stage of their study were heterogeneous. Therefore, it is unclear whether the degree of underlying liver disease was evenly distributed between the compared groups. In our study, we limited the inclusion criteria to patients with platelet counts greater than 50 000/mm^3 in addition to a Child-Pugh A classification to exclude patients who had severely advanced liver cirrhosis, for whom surgery is contraindicated due to likely postoperative deterioration of liver function and poor prognosis[17,21].

Liver cirrhosis is a well-known potent predictive factor for OS in patients with HCC[14,22,23], as shown in our patient cohort. According to our analysis, the survival rates of cirrhotic patients with multiple HCCs who underwent surgical resection were extremely disappointing. The 5-year OS rate of the patients with cirrhosis was 25.5%, which was significantly worse than that of the patients without cirrhosis (69.3%, $P = 0.006$) (Figure 1C and D). Furthermore, the outcomes of surgical resection and TACE in the patients with cirrhosis were not different (Figure 2). Therefore, surgical resection for multiple HCCs would be beneficial in patients without cirrhosis, but it remains debatable in patients with cirrhosis.

Despite the fact that surgical resection for multiple HCCs showed acceptable OS rates in our study as well as in several other publications[6-8,22,24], a high recurrence rate is a major drawback of surgical resection as a curative therapy. According to our data, the 5-year disease-free survival rates were 0% in patients with cirrhosis and 22.2% in non-cirrhotic patients. Thus, our single cohort study demonstrated that LT might be the preferred treatment option to offer the chance of a cure for multiple HCCs; the OS and disease-free survival rates were 80.2% and 88.2%, respectively (Figure 1A and B). However, in addition to inevitable immuneesuppressive therapy, which has an adverse oncologic effect, the scarcity of liver donors is another great obstacle to the wide application of LT.

Which loco-regional therapy is superior as a bridge to LT is an issue because of the long waiting time on the transplant list, which results in patients progressing and falling outside the transplant criteria. According to Llovet *et al*[25], approximately 10% of patients are dropped from the transplant list during the waiting period because of tumor progression or liver failure. TACE and RFA have been studied in detail and widely used as a bridge therapy in several transplant centers, but the efficacy of these modalities has not yet been established[26-28].

Recently, Belghiti *et al*[29] proposed three different roles of resection for HCC prior to LT: (1) As a primary therapy, resection can delay or avoid transplantation and can be followed by salvage transplantation for recurrence and deteriorated liver function; (2) As an initial therapy, resection can provide pathologic information about the whole specimen, which enables selection of the best candidates for transplantation; and (3) As a bridge therapy, resection can offer the best control of HCC in patients listed for LT through the possibility of downstaging and providing detailed pathologic information. In addition to these benefits, liver resection can provide superior control and a good survival rate[29,30]. Furthermore, several studies report that 60%-80% of patients who recur after resection for HCC are still amenable to transplantation, and these results are not different between patients with solitary and oligonodular primary HCCs[22,31,32]. Our results also showed that 80% of the recurred patients with cirrhosis following resection were within the Milan criteria. Thus, surgical resection for cirrhotic patients with multiple HCCs might be performed as a bridge to LT. Surgical resection as a bridge is justified by the improved safety of liver surgery and no survival impairment in the event of subsequent LT[31].

Recent studies demonstrated that salvage LT does not compromise the operative morbidity and mortality compared with primary LT[31,33,34]. In contrast, Adam *et al*[35] reported that secondary LT is associated with a higher operative morbidity and mortality; they also argued that patients treated by resection when they were initially transplantable had a higher recurrence rate with more frequent extrahepatic metastasis and vascular invasion, which impair the transplantability and long-term survival of the patients. Therefore, it is too early to conclude whether resection can be performed as bridge therapy. Nevertheless, these efforts to use the limited number of donor organs effectively are necessary, as is further investigation of this issue.

We did not analyze the outcomes according to the types of multiple HCCs in the present study because our data included patients who received resection combined with RFA, which did not allow for pathologic analysis. Discrimination of intrahepatic metastasis (IM) and *de novo* multicentric (MC) HCCs may be important because generally, IMs that have acquired metastatic ability exhibit more aggressive biologic behavior[36,37] and thus influence therapeutic strategy decisions. According to the guidelines of the Liver Cancer Study Group of Japan[38], IM is diagnosed if the tumors definitely originated from portal vein tumor thrombi, if the tumors arose in multiple satellite nodules surrounding a main tumor, or if a satellite tumor near the main tumor shows similar or

poorer histological differentiation than the main tumor. Otherwise, multiple HCCs that do not meet these conditions are deemed *de novo* MC tumors. Although these conventional pathological criteria are convenient, they are relatively subjective. Currently, the most precise method to determine the origin of HCC is DNA clonal analysis[39,40], and clinical differentiation between IM and MC is not possible preoperatively. If a credible diagnosis could be possible for preoperative distinction of the origin of multiple nodules, it might be helpful for the selection of therapy.

In conclusion, surgical resection for HCCs with two or three radiologically identified tumors, no radiologic vascular invasion, and diameters less than 5 cm is recommended for patients without cirrhosis but debatable for patients with cirrhosis. LT might be the best treatment option for patients with multiple HCCs. The retrospective design and the small number of cases are limitations of this-single cohort study. Therefore, further multi-center trials and randomized, controlled, prospective studies are needed, especially to examine the role of surgical resection in cirrhotic patients with multiple HCCs.

COMMENTS

Background

Although surgical resection is the established treatment modality for hepatocellular carcinoma (HCC) in patients with preserved liver function, however, for patients with multiple HCCs, unfavorable disease-free and overall survival (OS) rates following surgical resection have led to the contraindication of surgical treatment. Therefore, although multidisciplinary strategies are used in the treatment of multiple HCCs, multiple HCCs still pose a therapeutic challenge and are a matter of debate. There has been a lack of studies for the efficacy of surgical resection in patients with multiple HCCs.

Research frontiers

The survival of patients with HCCs was affected not only by HCC itself but also by underlying liver disease. Some studies have reported the superiority of surgical resection for multiple HCCs over non-surgical treatment. However, long-term outcomes of the patients according to not only stage but also the degree of underlying liver disease may help to select a proper treatment modality.

Innovations and breakthroughs

Their study demonstrates that surgery for patients with multiple HCCs is recommended in patients without clinical cirrhosis. When the survival of the patients in the surgical resection group was compared with the transarterial chemoembolization group according to the presence of cirrhosis, surgical resection showed no survival benefit in cirrhotic patients. This study is worthy because the surgical outcomes of the patients with multiple HCCs were compared according to the degree of underlying liver disease.

Applications

Liver cirrhosis is a well-known potent predictive factor for OS in patients with HCC. According to the analysis, the survival rates of cirrhotic patients with multiple HCCs who underwent surgical resection were extremely disappointing. Therefore, surgical resection for multiple HCCs is recommended for patients without cirrhosis but still debatable for patients with cirrhosis. Further multi-center trials and randomized, controlled, prospective studies are needed.

Peer review

This study provides clinical outcomes of surgical resection for multiple HCCs compared with the transarterial chemoembolization and liver transplantation. This issue is still debatable in patients with cirrhosis. The retrospective design and the small number of cases are limitations of this study.
