Abstract

Irritable bowel syndrome (IBS) is a chronic gastrointestinal disorder, common in clinic and in the community. It has a significant impact on both society and patients' quality of life. The epidemiology, clinical presentation, and management of IBS may vary in different geographical regions due to differences in diet, gastrointestinal infection, socio-cultural and psychosocial factors, religious and illness beliefs, symptom perception and reporting. Although previous reviews and consensus reports on IBS in Asia have been published, Asia is quite diverse socio-demographically. In this context, India, Bangladesh and Malaysia share some similarities, including: (1) large proportion of the population living in rural areas; (2) rapid development and associated lifestyle changes in urban areas; and (3) dietary, cultural and religious practices. The present review explores the clinical and epidemiological data on IBS from these three major nations in South and South-East Asia. In-depth review of the literature revealed important differences between IBS in the East, as revealed by studies from these three countries, and the West; these include a predominantly rural profile, differences in bowel habit and symptom profile, raising concern with regards to diagnostic criteria and subtyping of IBS, higher dietary fiber consumption, frequent lactose malabsorption, parasitosis, and possible overlap between post-infectious IBS and tropical sprue. Moreover, the current perception on difference in prevalence of the disorder in these countries, as compared to the West, might be related to variation in survey methods.

Epidemiological and clinical perspectives on irritable bowel syndrome in India, Bangladesh and Malaysia: A review. *World J Gastroenterol* 2017; 23(37): 6788-6801 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6788.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6788

INTRODUCTION

Irritable bowel syndrome (IBS) is a bowel disorder in which chronic abdominal pain or discomfort (the latter having been removed in the Rome Ⅳ criteria) is associated with irregularity in stool form and passage in the absence of any organic cause[1]. IBS has a significant impact on patients' quality of life due to physical suffering, psychological co-morbidity, social disability and economic non-productivity[2,3]. Though the global pooled prevalence of IBS has been estimated to be 11.2%[4], this figure has been questioned due to significant heterogeneity in published studies[5]. The prevalence, however, may be lower in the East. As the pathophysiology of IBS is poorly understood, the management generally focuses on the amelioration of symptoms and improvement in the quality of life. At present, the drugs available for the treatment of IBS have only a modest effect on symptom improvement and may not alter the natural history of the condition. The management strategy recommends a positive diagnosis, consideration of the patients' perspective, development of a good doctor patient relationship, identification of contributing factors, critical appraisal of the efficacies of various drugs according to the subtype of IBS and continuing care[6-8].

In view of the recent and growing interest in the gut microbiome and gastrointestinal (GI) diseases, including IBS, data from Asian research (where infection and infestations are common) may be able to offer specific epidemiological insight. Although previous reviews and consensus reports on IBS in Asia have been published[8], Asia remains a geographically and socio-demographically diverse region. Furthermore, a significant portion of the population in Asia live in rural areas, but data from rural epidemiological studies are scant. In this context, India, Bangladesh and Malaysia, three major nations in the South and South East region of Asia, share some similarities: (1) significant proportions of their populations residing in rural areas; (2) rapid development and associated lifestyle changes in urban areas; and (3) dietary, cultural and religious practices that are somewhat similar. Another similarity between these three countries is the language used for medical education and scientific publications. Since the medical education in these three countries are in the English language and the scientific studies are also published in English, local languages were not needed for data extraction from published literature. Hence, the present review aims to explore clinical and epidemiological data on IBS from a South and South-East Asian perspective.

EPIDEMIOLOGY

Prevalence

Several population-based studies have been conducted to explore the epidemiology of IBS in India, Bangladesh, and Malaysia using different diagnostic criteria (Table 1 and Figure 1). In contrast to several studies from the West, most of which are either internet and telephone surveys with their inherent bias, the majority of the eastern studies were house-to-house surveys. Based on these studies, the reported prevalence of IBS varies from 4.2%-7.5%, 7.7%-12.9% and 11%-14% in India[9-12], Bangladesh[13-15] and Malaysia[16,17], respectively.

In addition to the studies summarized in Table 1, a few house-to-house surveys, conducted primarily on chronic constipation, provided data on constipation-predominant IBS (IBS-C) as well. In a house-to-house survey among 505 subjects aged 9-64 years from Chandigarh, India the prevalence of constipation by Rome Ⅱ criteria was 16.8%[18]. In another Indian study among 925 constipated patients presenting to general physicians, 75.6% had functional constipation and 24.4% had IBS-C[19]. It has been reported that the prevalence of IBS in Asian countries is rising, with more developed nations, such as Japan and Singapore, documenting a comparable prevalence to that in western countries[20].

These data suggest that IBS might be related to economic development associated with lifestyle changes, fast living, and psychological stress associated with reduced T regulatory cell response. However, the differences in prevalence across the three countries and within the countries may be a result of variation in the

diagnostic criteria used, socio-demographic differences in the populations studied, survey methods and the study instrument. A previous systematic review and meta-analysis of 260960 subjects from 80 studies across the globe suggested that the pooled prevalence of IBS of all studies was 11.2% (95% confidence interval (CI): 9.8%-12.8%)[4]. However, a more recent systematic review and meta-analysis demonstrated that the estimation of global prevalence of IBS may be inaccurate due to significant heterogeneity between the studies[5].

Urban versus rural prevalence

An urban lifestyle is reported to be associated with greater psychological stress, and thus may be associated with a higher prevalence of IBS compared to rural living. Community-based epidemiological studies on IBS have been published both from the urban and rural population in India, Bangladesh and Malaysia. Rural surveys in India have demonstrated an IBS prevalence of 4.2% (Rome Ⅲ criteria) among 2774 subjects in three villages of Uttar Pradesh, the northern part of India[12], and 4% (Rome Ⅲ criteria) in another northern Indian study[11]. In Bangladesh, an IBS prevalence of 8.5% (Rome Ⅰ criteria) was reported from a rural household survey among 2426 subjects[13]. In the East Coast of Peninsular Malaysia, a 10.9% prevalence of IBS (Rome Ⅲ criteria) was documented among rural subjects of Malay ethnicity[17].

Interestingly, urban surveys in these three countries did not show a significant variation in the prevalence of IBS from the rural communities. A 7.7% prevalence of IBS (using the Manning criteria) was observed among 2549 randomly selected subjects in urban Mumbai, India[9], while an IBS prevalence of 7.7% (Rome Ⅱ criteria) was reported in a survey of 1503 adult subjects in Dhaka city, Bangladesh[14]. In the West Coast of Peninsular Malaysia, investigators reported a relatively high prevalence rate of IBS at 14% (Rome Ⅱ criteria) among 1179 multi-ethnic adult subjects in an urban setting, but not much higher than the previous rural study[17]. In this multi-ethnic study, there were no differences in prevalence among ethnic Malays, ethnic Chinese and ethnic southern Indians, who were of comparable socio-demographic status[17].

The observations from these studies in South Asia appear to contrast with reports, which indicate that IBS is more common in urban as compared to rural populations[21-23]. Population-based studies comparing prevalence of IBS in urban and rural communities have shown differences in Chinese (urban 10.5% *vs* rural 6.14%)[21], Israeli Bedouins (9.4% *vs* 5.8%, $P < 0.01$)[22] and Italians (urban 9.9% *vs* rural 4.4%)[23]. It is uncertain if the lack of difference in IBS prevalence between urban and rural communities highlighted in this review of Indian, Bangladeshi and Malaysian studies is related to lack of head-to-head comparison using uniform diagnostic criteria and study design. Furthermore, previous population studies in Malaysia, using similar methodologies and diagnostic criteria (Rome Ⅱ) have shown significant differences in the prevalence of uninvestigated dyspepsia between urban and rural communities[24].

Sex-related issues

Early institution-based studies from India showed that IBS was 2-4 times more common among male adults compared to female adults[25-27] but subsequent population-based studies revealed mixed findings. The male:female ratios in relation to the prevalence of IBS in India, Bangladesh and Malaysia are highlighted in Table 1. It is important to note that among all these studies that reported female predominance from these three Asian countries, female to male ratios were not as wide as reported from the West. The lack of an obvious female predominance amongst IBS subjects appears to be common in several Asian reports[8,20,28-30]. This is in contrast to the studies from the West, which consistently reported 2-3 times greater prevalence of IBS in women than in men[3].

Although a meta-analysis of community-based studies reported that IBS is 67% higher in females

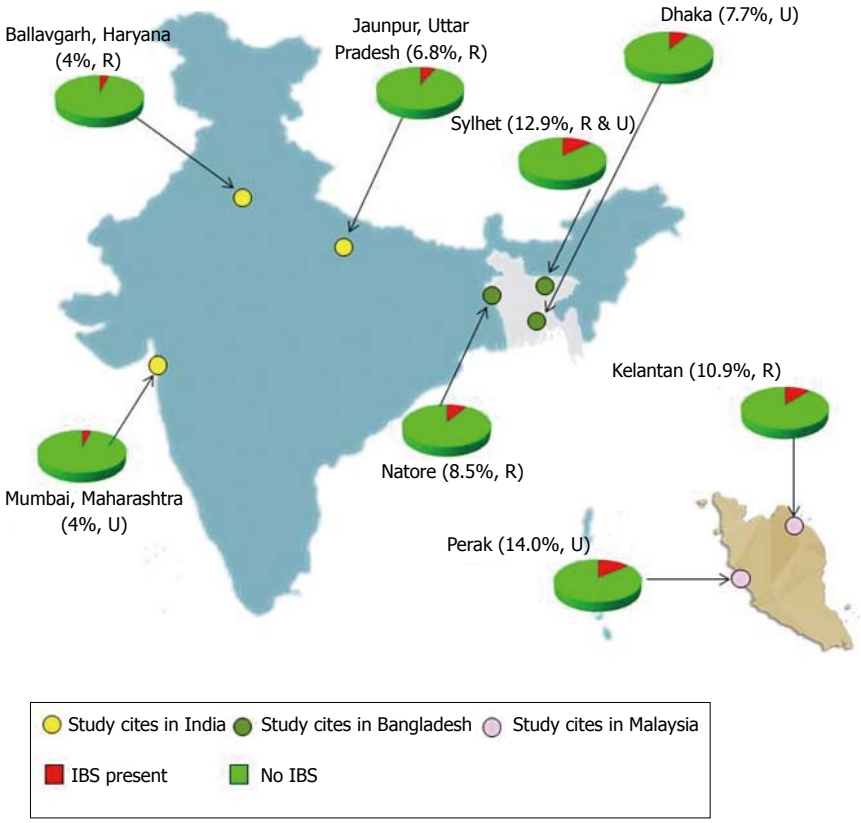

Figure 1 Map of India, Bangladesh and Malaysia showing sites of epidemiological studies on IBS in these countries and its prevalence. IBS: Irritable bowel syndrome; R: Rural; U: Urban.

compared to males (OR = 1.67; 95%CI: 1.53-1.82), no significant sex-related differences were observed in South Asia[4]. A recent meta-analysis on a Global prevalence of IBS found that the pooled prevalence rates were higher among females (10.2%) compared to males (8.8%). The prevalence rates of IBS were higher among females than males in each region of the globe separately[5]. However, as the authors of this meta-analysis acknowledged that due to significant heterogeneity in the number of available studies in different parts of the world and the methods, pooled estimates are expected to be biased.

SYMPTOM PROFILE AND DIAGNOSIS OF IBS

The Rome criteria are currently the most widely accepted for establishing a diagnosis of IBS. However, studies from India and Bangladesh have reported that frequency and/or severity of abdominal pain, a cardinal symptom in the Rome criteria, may not be so common among their population with IBS. A multi-centric study involving 2785 patients visiting physicians at 30 centers across India with chronic lower GI symptoms, no `alarm features' and negative investigations for organic causes has been published; in that study, abdominal pain and discomfort was present in only 70% of subjects[10]. Other institution-based studies on IBS subjects from India have reported abdominal pain in a range from 33%[31] to 70%[32]. As abdominal pain is a pre-requisite for the symptom-based diagnosis of IBS by the Rome criteria, these criteria may have a low sensitivity for diagnosing IBS in India.

In another multi-center, Indian study (MIIBS) using various diagnostic criteria for IBS, the Manning criteria had the highest sensitivity (91%), followed by Asian criteria (74.5%), Rome Ⅰ (68%), Rome Ⅲ (52.5%) and Rome Ⅱ (40%) to diagnose IBS[33]. The higher sensitivity of the Manning and Asian criteria might have been due to the fact that "abdominal pain" was not absolutely necessary for the diagnosis of IBS by both of these criteria. Furthermore, "abdominal bloating" had been included in combination with "abdominal pain or discomfort" by the Asian criteria[8]. When multiple diagnostic criteria were applied in a rural population in Bangladesh, IBS prevalence of 1.8%, 7.3%, 8.8%, and 7.7% was found using Manning ⩾ 3, Manning ⩾ 2, Rome Ⅰ and Rome Ⅱ criteria, respectively. The IBS prevalence varied according to the criteria applied, with rates as high as 27.9% using "Manning ⩾ 2 without pain" and down to 1.8% using "pain with Manning ⩾ 3"[34].

A systematic review previously demonstrated that the Rome Ⅱ criteria had a poor sensitivity for diagnosing IBS in primary care, ranging between 31% to 65%, with the lowest sensitivity rates derived from studies in India[35]. The lack of accuracy of a

symptom-based criterion for diagnosing IBS may be more relevant for patients in India and Bangladesh for at least two reasons. Firstly, IBS patients often do not report abdominal pain as the predominant symptom in this region. Secondly, these criteria were originally developed and validated in Western populations, who are known to differ from Eastern populations with regard to socio-cultural issues, language, symptom perception and epidemiology[36]. Considering the fact that the Rome Ⅳ criteria did not include even abdominal discomfort or bloating as the essential symptom to diagnose IBS (Table 2), the sensitivity of the Rome Ⅳ criteria is expected to be lower in these three countries[37].

A recent study by the Rome Foundation-Asian working team[38] on 1805 consecutive unselected functional gastrointestinal disorder patients presenting to the primary or secondary care centers in 11 Asian centers using a culturally adapted Rome Ⅲ Diagnostic Questionnaire initially translated and validated in 9 Asian languages[39,40] identified 9 symptom clusters by principal component factor analysis with varimax rotation. Authors concluded that though IBS and chronic constipation were the dominant symptom clusters, bowel symptom cluster with meal trigger and a gas cluster were the other prominent groups that were in line with the old Asian concept that identified epigastric localization of pain, and emphasized meal- and gas-related symptoms[41].

Upper abdominal symptoms and overlap with functional dyspepsia in IBS

IBS and functional dyspepsia (FD) have common patho-physiological mechanisms, like visceral hypersensitivity, abnormal central processing of sensory perception, GI dysmotility and psychological factors; these two disorders are, therefore, expected to coexist[42]. Figure 2 shows the prevalence of IBS-FD overlap, IBS and FD in three population-based studies in India and Bangladesh[9,12,15]. These population-based studies from India and Bangladesh demonstrated that 3.5% to 4.5% of the general adult population of India and Bangladesh have dyspepsia-IBS overlap (Figure 2). In a community-based survey conducted among 3000 people in rural and urban populations in a district of Bangladesh, 42% of FD subjects had IBS and 27% IBS subjects had FD. Overall, bowel symptom frequency scores were higher in IBS-FD than IBS alone (10.01 ± 4.17 *vs* 8.16 ± 3.84, $P < 0.000$)[15].

In an urban survey of adults from Malaysia, subjects with IBS were more likely to report symptoms of gastroesophageal reflux disease (GERD) compared to healthy controls [56% *vs* 29%, odds ratio (OR) = 3.06][16]. Environmental factors such as diet may be a contributory factor for upper GI symptoms in IBS sufferers among South Asians. In a study in Mumbai, India, > 99% of the population consumed chili in their diet and 75% of subjects consumed it in a moderate to high quantity[9]. Chili is known to aggravate not only IBS symptoms[43] but has been shown to independently predict dyspepsia in a multi-ethnic population in Malaysia[44]. Furthermore, GERD and *H. pylori* infection are recognized to be more prevalent among ethnic Indians/South Asians compared to other ethnic groups in Asia[45,46]. It is likely that these factors may lead to a greater overlap of IBS-FD and IBS-GERD among South Asians compared to other ethnic groups in Asia.

SUBTYPING OF IBS

IBS sub-classification into diarrhea- and constipation-predominant (IBS-D and IBS-C, respectively) are important for determining appropriate therapeutic strategies. However, studies in India, Bangladesh and Malaysia have reported that the majority of IBS patients could not be easily classified into distinct sub-types. In a multi-centric Indian study, 53% and 47% of 2656 subjects with lower GI symptoms had subjective perceptions of constipation and diarrhea, respectively[10]. However, when stool frequency-based criteria of constipation (stool frequency < 3/wk) and diarrhea (stool frequency > 3/d) were applied to the same subjects, 19% had constipation, 4% had diarrhea and 57% had indeterminate symptoms. In that study, the median stool frequency was similar (2 times/d) in patients who had perceived themselves to have either constipation or diarrhea[10].

In a rural community-based study at Uttar Pradesh, northern India, 83% of the IBS subjects remained unclassified using the Rome Ⅲ criteria. Interestingly, the application of Asian criteria, instead of the Rome Ⅲ criteria, reduced the indeterminate sub-type of IBS subjects in rural India from 83% to 12%[12]. Similarly, the MIIBS study of 1618 subjects with lower GI symptoms found that by stool frequency criteria, 78% subjects remain unclassified, whereas by patient perception and stool form (Bristol stool scale) criteria only 28% and 16% of patients remain unclassified, respectively[33]. In a rural study in Bangladesh, 64% of IBS subjects diagnosed by the Rome Ⅱ criteria could not be sub-typed[13]. In Malaysia, a rural survey of ethnic Malays similarly demonstrated that the majority of IBS subjects fell into a "mixed" category with the Rome Ⅲ criteria as follows: 20.8% IBS-C, 16.7% IBS-D and 58.3% mixed pattern[17].

These studies suggest that several popularly used criteria may be poor at classifying IBS into constipation- and diarrhea-predominant types in Asia. Community-based studies in India and Bangladesh have shown that > 90% of the general population have a bowel motion of at least once per day[10,47,48]. These differences in bowel habit between South Asians and Westerners may be due to differences in dietary pattern, fiber intake, intestinal transit time and frequency of lactose malabsorption as compared to the Western population[49]. In a study from India,

Table 2 Rome III and Rome IV criteria for diagnosis of irritable bowel syndrome[37]

Rome III criteria	Rome IV criteria
At least 3 mo, with onset at least 6 mo previous to recurrent (at least 3 d/mo) abdominal pain or discomfort associated with 2 or more of the following	Recurrent abdominal pain, on average, at least 1 d per week in the last 3 mo, associated with 2 or more of the following
Improvement with defecation	Related to defecation
Onset associated with a change of frequency of stool	Associated with a change in frequency of stool
Onset associated with a change in form of stool	Associated with a change in form (appearance) of stool

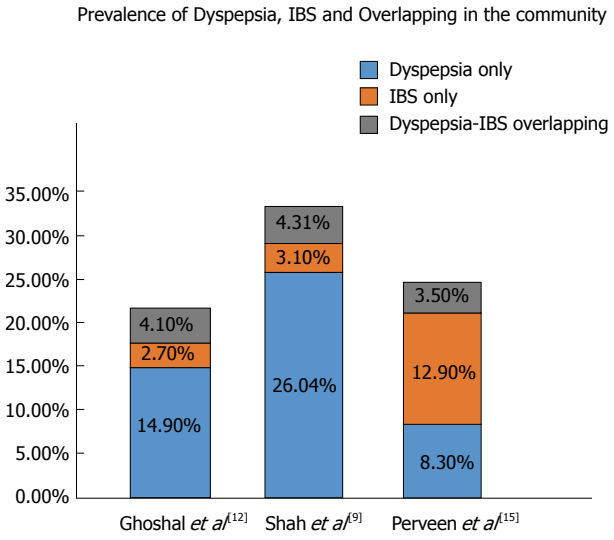

Figure 2 Prevalence of IBS, dyspepsia and overlap syndromes in community studies in India and Bangladesh. IBS: Irritable bowel syndrome.

the mean fiber intake was found to be similar at 52 g in both IBS and healthy controls[50]. This is higher than the recommended daily fiber intake (20-30 g in adults) and actual daily dietary fiber intake (13.3 g) in the West[51-53]. Furthermore, the mean intestinal transit time of 39.85 h among northern Indians contrasts significantly to that of 83.4 h in Caucasian adults[54].

PATHOPHYSIOLOGICAL INSIGHTS

Inflammation and IBS

Current evidence suggests that the pathogenesis of IBS is multi-dimensional consisting of gut microbial dysbiosis, including small intestinal bacterial overgrowth (SIBO), visceral hypersensitivity, intestinal mucosal immune activation, dietary intolerance, increased intestinal permeability, abnormal gut-brain interaction including cognitive dysfunction, psychosocial distress and altered GI motility[55-57]. Low-grade inflammation plays a major role in the pathophysiology in a subset of patients with IBS[57]. This has been explored in several studies in India, Bangladesh and Malaysia. IBS patients in a tertiary care hospital in Bangladesh were found to have a significant increase in chronic inflammatory cells, mast cells and lymphoid follicles compared to control group of healthy subjects ($P < 0.05$). Mast cells but not the number of chronic inflammatory cells, mucosal and submucosal lymphoid follicles, were significantly increased in post-infectious (PI)-IBS compared to non-PI IBS in that study[58]. These findings are in accordance with similar reports of Western IBS patients[56,59]. Mast cell activation is associated with epithelial and neuromuscular dysfunction, visceral hypersensitivity, increased epithelial permeability and altered motility[56,59].

In an Indian case-control study including 221 patients with IBS and 273 age- and sex-matched controls, an interleukin (IL)-1 receptor antagonist under-producer genotype was associated with IBS and its over-producer protective. Moreover, higher levels of IL-1α and IL-1β were found in patients with SIBO, and IL-1α and IL-1β were associated with bloating and loose stools. The findings of that study clearly show the role of inflammation in the pathogenesis of IBS in general and diarrhea-predominant IBS in particular[60]. Several case-control studies, though under-powered, on genetic polymorphisms in candidate pro-/anti-inflammatory and xenobiotic metabolizing genes support the role of inflammation in the pathogenesis of IBS[61-64].

Imbalance in body serotonin (5HT), 95% of which is in the gut, plays a major role in the pathogenesis of IBS, with its deficiency contributing to slow gut transit and constipation, and excess causing diarrhea[65]. In an Indian case-control study, SLC6A4 was found as a potential candidate gene involved in the pathogenesis of IBS[66]. The frequency of SLC6A4 polymorphism and higher levels of 5HT were significantly associated with IBS[66].

The association between microscopic colitis (MC) and IBS has similarly been described. In a recent systematic review and meta-analysis, the pooled prevalence of MC in Western IBS patients was 7.2% (95%CI: 1.5%-17.2%) and the prevalence varied between 2.4% to 11.5% in individual studies[67]. In the only report from Bangladesh, lymphocytic colitis (LC) was found in 37% of 60 patients with diarrhea-predominant IBS, with a complete absence of collagenous colitis. The distribution of LC was restricted in proximal colon in 68.2% patients, in the left colon in 9.1%, and diffuse in 22.7%[68]. A study of 120 subjects in a Malaysian tertiary institution found a very low (1.3% only) prevalence of collagenous colitis among 120 IBS subjects. However, IBS-D patients had a higher prevalence of moderate non-specific, microscopic inflammation compared to controls (14.9% *vs* 2.2%, $P = 0.005$), suggesting that either occult

infection or other causes of inflammation may be contributory towards IBS-D sub-types[69].

In an Indian case series on 29 patients with MC presenting with chronic large bowel diarrhea, of 7, 4, 7 and 11 patients with collagenous colitis, LC, minimal change colitis and microscopic colitis not otherwise specified, 28.6%, 25%, 14.3% and 33.3% had abdominal discomfort, suggesting that they would fulfill the Rome Ⅲ criteria for IBS[70]. In another Indian study among 400 patients with chronic watery diarrhea, 3.7% had microscopic colitis (33% had collagenous colitis and 67% had lymphocytic colitis) and 10/15 of these patients were clinically diagnosed with IBS[71]. Data from the institutional-based studies suggest that MC is rare amongst South and South-East Asian IBS patients, perhaps in keeping with the lower prevalence of inflammatory bowel disease (IBD) in this region[72].

Protozoa and IBS

The presence of amoebic cysts in the stool of a patient with chronic lower GI symptoms creates confusion among physicians, and they often label such patients as suffering from chronic non-dysenteric amebic colitis. A multi-centric study on IBS from India showed that of 1237 patients reporting treatment with metronidazole in the past, 672 (24%) experienced temporary improvement[10]. Two studies in India explored this issue among IBS patients[73,74]. No significant differences were found in the proportion of amoeba in the stool (18% *vs* 18%), serologic evidence of infection (42% *vs* 41%), colonoscopic abnormalities (7% *vs* 3%) or histologic abnormalities among 144 IBS and 100 asymptomatic subjects. Additionally, there was no significant difference in response to therapeutic trial with metronidazole among the symptomatic patients who were cyst-positive or -negative at 6 mo[73]. In a second study of 154 inmates of a leprosy rehabilitation center, detection of amoeba among IBS and controls was found to be 50% and 19%, respectively. All strains of amoeba isolated were found to be non-pathogenic and there was no relationship between detection of amoeba and symptoms of IBS at 12 mo follow-up[74]. These studies suggest that non-pathogenic amoeba is an innocent by-stander in IBS subjects, which are inappropriately termed as "chronic amoebiasis" and often treated with anti-amoebic drugs unnecessarily.

Another common gut parasite found in the intestinal tract of humans and animals, *Blastocystis* sp, has been associated controversially with IBS, possibly as a result of irregular shedding of parasites in stool and variation in fecal detection. A recent study examining parasitic infestations using PCR techniques reported a significantly higher prevalence of *Blastocystis* sp (17% *vs* 5.5%), corroborated by increased cytokines for inflammation (IL-3, IL-5 and IL-10) in IBS patients compared to healthy controls in Malaysia[75]. Furthermore, IBS patients with increased stool frequency were found to have a greater quantity of *Blastocystis* cysts, indicating that the severity of IBS symptoms correlated with the quantity of parasitic infestation[76]. These studies from Malaysia indicate that persistent chronic parasitic infection, which is often undetectable using standard culture or laboratory techniques, may be an additional contributory factor to microscopic gut inflammation in IBS in Asians.

In the light of these observations of protozoal diseases among South and South East Asian patients with IBS, it is not surprising that a multi-centric Indian study showed that 44% of the subjects with chronic lower GI symptoms took metronidazole with temporary symptom improvement among 54%[10]. Additionally, a randomized placebo controlled trial among 45 IBS subjects who were allocated to ispaghula husk (60 d), metronidazole (metronidazole 10 d and placebo 50 d) and placebo (60 d) found that metronidazole provided symptom relief in IBS compared to placebo without affecting recto-sigmoid motility[77].

Helminthiasis and IBS

Helminthic infestation is common in Bangladesh and India. In a report from rural Bangladesh, 70% of 252 children had been found to have soil-transmitted helminthiasis by the age of 2 years[78] . In southern India, a report suggested that 62% of all age groups had hookworm infestations[79]. Intestinal helminthiasis causes a shift in the immune system towards a T-helper 2 cell response[80,81]. This may be associated with a low-grade, protracted inflammation, which is recognized in a subset of IBS patients. Previous reviews have speculated that a high intestinal helminthic/parasitic infestation may be the cause of a low prevalence of IBS in spite of a high incidence of acute infective diarrhea in Asia[82]. Furthermore, the "hygiene hypothesis" speculates that a high childhood infection rate is responsible for the low prevalence of IBS in the developing countries.

PI-IBS and PI-MAS

PI-IBS has been defined as an acute-onset IBS (by Rome criteria) that develops after the individual, who has not previously met the Rome criteria, experiences a GI infection with two or more of the following characteristics: fever, vomiting, diarrhea, and a stool culture positive for an infectious agent[83,84]. The pooled incidence of PI-IBS was found to be 10% in a systematic review and meta-analysis of predominantly Western studies[85]. Data on PI-IBS from Asian countries are scant, whereas acute gastroenteritis is common[86]. Studies from China and Korea have revealed that the incidence of PI-IBS is 8%-15%[87,88]. The incidence rate for acute diarrhea among those aged > 14 years in parts of India and Bangladesh have been reported as 60 per 100 person-years and between 15.2 to 135.7 per 100 person-years, respectively[89-91].

Despite a high incidence rate of acute diarrhea

in the Indian subcontinent, there is no published study on PI-IBS. Furthermore, the relatively low prevalence of IBS in the Indian subcontinent, despite a high burden of acute diarrheal illness, appears enigmatic[83,86]. However, a condition similar to PI-IBS, post-infectious malabsorption (PI-MAS) or tropical sprue has been recognized in the Indian sub-continent for some time. A prevalence rate of 8%-20% of PI-MAS was previously reported in rural southern India following an episode of acute infectious diarrhea[92]. Both PI-IBS and PI-MAS have similar clinical features, etiopathogenesis, and potential response to treatment with antibiotics[93]. Furthermore, both PI-IBS and PI-MAS have been associated with SIBO[94,95] and abnormal small intestinal permeability[96].

It is likely then, as IBS is a symptom-based diagnosis or that patients with mild malabsorption syndrome can be misdiagnosed as IBS, particularly of the diarrhea-predominant type, unless malabsorption is carefully excluded by appropriate investigations. In most studies on PI-IBS, PI-MAS has not been carefully excluded using tests for malabsorption. Considering the fact that PI-MAS or tropical sprue has been described recently following an attack of acute infectious diarrhea in developed countries like the United States, this issue needs consideration in developed and temperate countries as well[97]. Hence, there may be some overlap between PI-IBS and PI-MAS in the Indian sub-continent[83,86,96] and some cases of PI-MAS may be erroneously diagnosed as cases of PI-IBS. In a recent study from Dhaka, Bangladesh, 10% of 23 patients with acute gastroenteritis fulfilling Rome Ⅲ criteria for IBS in the absence of previous IBS were found to have PI-MAS on investigation[98].

SIBO and IBS

SIBO and IBS have similar clinical features. Routine investigations conducted to exclude organic diseases in IBS, such as colonoscopy and blood tests, do not rule out SIBO. Several studies have reported the presence of SIBO in IBS patients in India, as shown in Table 3[95,99-101]. Ghoshal *et al*[99] reported that 19% of 80 IBS patients had SIBO, diagnosed by upper gut aspirate culture with a colony count > 10^5 CFU/mL. In a case-control study among 225 Indian IBS patients, 11% had SIBO by glucose hydrogen breath test (GHBT), whereas 1% of 100 healthy subjects had SIBO[100]. In the third study, 9 (13%) of 69 IBS patients had SIBO by GHBT. There was no significant difference in the frequency of SIBO among subjects with and without lactose intolerance and IBS[101]. In the fourth study, 11 (8.5%) of 129 IBS subjects had SIBO compared to 1 (2%) of 51 healthy subjects[95].

An evidence-based review documented that the prevalence of SIBO in patients with IBS varies widely due to different criteria for defining a positive breath test and the methodology employed. It is 28%-84% with lactose hydrogen breath test (LHBT), 2%-31% with GHBT and 2%-6% based on culture[102]. Most of the studies used GHBT to diagnose SIBO in India. GHBT had a sensitivity and specificity of 44% and 82%, respectively, when the culture of the upper gut aspirate was taken as the gold standard in a study on patients with malabsorption syndrome in India[103]. However, in a recent study on 80 patients with IBS (Rome Ⅲ criteria), GHBT had a sensitivity of 27% and specificity of 100% considering quantitative jejunal aspirate culture as the gold standard[99]. The lower sensitivity of GHBT among patients with IBS as compared to malabsorption syndrome might be related to lower bacterial colony counts in proximal small bowel among the former rather than the latter group of patients.

Further evidence for the association between SIBO and IBS was provided by a randomized, placebo controlled trial from India, of norfloxacin in IBS cases with SIBO compared to those without SIBO. In this study, the response rate (negativity of Rome Ⅲ criteria at 1 mo) of norfloxacin and placebo among IBS patients with and without SIBO was 87.5% (7/8) and 0% (0/7), 25% (8/32) and 0/33 (0%), respectively. Overall, 37.5% of 40 IBS patients responded to norfloxacin[99].

Food intolerance including lactose malabsorption and IBS

In recent years, dietary fermentable oligo, di, monosaccharide, and polyols (FODMAP) have been incriminated in contributing to the symptoms of IBS[104]. However, studies on dietary FODMAP in the pathogenesis of IBS symptoms and their exclusion in its treatment have been scant from India, Bangladesh and Malaysia, except for lactose as an isolated FODMAP. In a multi-centric Indian study, self-reported milk intolerance was present among 32% of 2785 subjects with lower GI symptoms. Patients with IBS-D reported milk intolerance more often than those with IBS-C[10]. In a rural community-based study in Bangladesh, a regular dairy intake was present in 61.7% of 2542 subjects, but 13.8% reported milk intolerance. Among 593 subjects with IBS, 12.6% reported milk intolerance and they showed a higher frequency of frequent bowel motion and loose or watery stool ($P < 0.025$)[13].

However, the diagnostic accuracy of self-reported milk intolerance to diagnose lactose malabsorption was reported as having a sensitivity, specificity, positive predictive value and negative predictive value of 53%, 61%, 26% and 55%, respectively, in a case-control study in India among 112 IBS patients and 53 healthy controls[101]. In the same study, the frequency of lactose malabsorption diagnosed either by LHBT or lactose tolerance test was similar among IBS (82%) and healthy controls (77%). Nevertheless, symptoms of lactose intolerance were more frequent among IBS (55%) compared to healthy subjects (34%).

Table 3 Studies on small intestinal bacterial overgrowth in India

Ref.	Number of IBS patients	Diagnostic criteria of IBS	Number of controls	Method of diagnosis of SIBO	% of SIBO in IBS	% of SIBO in controls
Ghoshal *et al*[99]	80	Rome Ⅲ	-	Culture of upper jejunal aspirate	19	-
Rana *et al*[100]	225	Rome Ⅱ	100	GHBT	11.1	1
Gupta *et al*[101]	69	Rome Ⅱ	-	GHBT	13	-
Ghoshal *et al*[95]	129	Manning	51	GHBT	8.5	2

GHBT: Glucose hydrogen breath test; IBS: Irritable bowel syndrome; SIBO: Small intestinal bacterial overgrowth.

In an Indian study, the researchers demonstrated that lactose malabsorption diagnosed using 25-g lactose dose is clinically more meaningful than that diagnosed using the conventional 50-g lactose dose, which is quite a non-physiological dose; in fact, lactose malabsorption diagnosed using 25-g lactose dose was associated with 10 times higher rate of clinical improvement following milk withdrawal than that diagnosed using 50-g dose[105].

More recently, investigators were able to demonstrate a similar frequency of C/T -13910 and G/A-22018 lactase gene polymorphism between Indian IBS patients and healthy controls[106]. These studies indicate that the prevalence of lactose malabsorption is high in South Asians, with no difference between IBS and non-IBS adults. However, the clinical consequences of lactose malabsorption are likely to be exaggerated in patients with IBS who often have underlying abnormalities in motility and visceral sensation and a reduced pain threshold.

Of the other FODMAP agents, a northern Indian study showed that 14.4% patients with IBS, particularly IBS-D, as compared to 2.4% of healthy controls had fructose malabsorption as demonstrated by fructose hydrogen breath test[107]. Importance of dietary factors in occurrence of IBS in the third world countries has been shown in a Brazilian study as well[108]. More studies on FODMAP diet and IBS, and their elimination in its treatment are needed from South Asia.

Psychological comorbidity and IBS

With rapid development and urbanization in many of the South Asian countries, including India, Malaysia and Bangladesh, it is anticipated that an increase in urban-related psychopathology may contribute to IBS symptoms, severity and clinic visit in these nations. In a cross-sectional study of 248 adult patients in a referral center in Malaysia, a higher prevalence of anxiety and depression was observed in FD, non-erosive reflux disease and IBS patients compared to a healthy control group (43.5%, 45.2% and 67.7% *vs* 14.5%, $P < 0.001$; and 22.6%, 33.9% and 38.7% *vs* 6.5%, $P < 0.0001$). IBS patients had a higher rate of anxiety than FD patients ($P = 0.01$) and non-erosive reflux disease patients ($P = 0.02$), while no significant differences in depression rates were observed among all three groups of functional GI disorders[109].

In a similar study from India, a greater prevalence of major depressive (47.3% *vs* 5.1%, $P < 0.001$), somatoform (50% *vs* 14.6%, $P < 0.001$) and panic disorder (44% *vs* 11.6%, $P < 0.001$) were identified in IBS patients compared to healthy controls[110]. Whilst these studies in Malaysia and India have indicated an association between psychological disorders and IBS, a causal relationship could not be considered from these studies as patients with any chronic disorder are expected to have more psychological issues than healthy subjects. Furthermore, data on the efficacy of psychopharmacological therapy among Indian subjects with IBS have not been convincing. A prospective double-blind randomized controlled study among 90 IBS patients showed that oxyphenonium bromide and imipramine was not superior to placebo in improving symptoms nor the health-related quality of life ($P > 0.05$)[111]. Nevertheless, about one-third of patients with lower GI symptoms in India were reported to be on tricyclic antidepressants in a previous survey[10].

Healthcare seeking/consultation behavior

Several community-based studies in India and Bangladesh have investigated healthcare seeking behavior among IBS subjects in both rural and urban areas. Table 4 shows the consultation rates of IBS patients in India and Bangladesh. Physician consultation rates were 34.9%[13] and 65.5%[14] of IBS subjects in rural and urban Bangladesh, respectively, with no significant sex differences (68.6% *vs* 61.2%, $P > 0.05$). The main predictor of consultation was the presence of multiple dyspeptic symptoms. The studies from India have alluded to a similarly high consultation rate (Table 4), with higher consultation rates for male IBS subjects (70% *vs* 44%, $P = 0.00001$)[9]. The types of healthcare practitioners consulted were explored in one study and found to include physician of modern medicine (MBBS and above) 3.1%, homeopathic physicians 5%, ayurvedic physicians 8.3% and Unani practitioners 0.8%[12]. These studies from India and Bangladesh suggest that availability, accessibility, and cost of the consulting physician may be important determinants of the consultation behavior of the IBS patients.

CONCLUSION

This review has highlighted several unique aspects

Table 4 Consultation rate of IBS patients in different population-based studies in India and Bangladesh

Ref.	Study areas/ country	Number of IBS patients	Diagnostic criteria of IBS	Consultation Rate	Reason of consultation	Nature of consulting doctors
Shah *et al*[9]	Urban/India	190	Manning	28.94%	-	-
Ghoshal *et al*[12]	Rural/India	FGIDs	Rome Ⅲ	17.20%	-	MBBS and above (3.1%) Homeopathic (5%) Ayuervadic (8.3%) Unani (0.8%)
Masud *et al*[13]	Rural/Bangladesh	593	Manning	39.0%	Altered stool passage Sense of incomplete evacuation Mucus in stool	
Perveen *et al*[14]	Urban/Bangladesh	116	Rome Ⅱ	65.50%	Multiple dyspeptic symptoms	

IBS: Irritable bowel syndrome; FGIDs: Functional gastrointestinal disorders.

of IBS in the populations of India, Bangladesh and Malaysia. The prevalence of IBS is comparable in urban and rural areas of these three countries. A male predominance has been reported in institution-based studies in India, but a sex-based disparity has not been observed in community studies. Upper abdominal symptoms and FD are common among IBS subjects in the community. The sensitivity of the Rome criteria to diagnose IBS is lower in India. Many patients with IBS cannot be subtyped into constipation- and diarrhea-predominant sub-types based on popularly used criteria developed in the West, and a stool subtype and the Asian criteria appear to be more sensitive.

From a pathophysiological perspective, chronic gut infections, gut microbial dysbiosis, and SIBO appear to have important roles in IBS in South Asia. In spite of the high incidence of acute infective gastroenteritis, the low prevalence of IBS in India and Bangladesh remains somewhat enigmatic. PI-IBS, PI-MAS and SIBO may have a great degree of overlap in adults and may need specific investigations to differentiate them. Therefore, a role of the gut-specific antibiotics, such as rifaximin, cannot be over-estimated. Healthcare consultation by IBS subjects in India and Bangladesh are high in both rural and urban areas.

Future direction

Further epidemiological studies using the same instruments and survey method are needed for valid comparison of the prevalence of IBS in the East and the West, as well as a head-to-head comparison in the rural and urban areas in Asian countries. Further studies are also needed on the symptom profile and subtyping of IBS in Asian countries using clinical, Rome and Asian-based criteria. Considering the high burden of acute infectious diarrhea in the Indian Subcontinent and frequently reported cases of tropical sprue, more studies are needed on the pathophysiology of PI-IBS and PI-MAS.

Abstract

AIM

To investigate gender-specific liver estrogen receptor (ER) expression in normal subjects and patients with hepatitis C virus (HCV)-related cirrhosis and hepatocellular carcinoma (HCC).

METHODS

Liver tissues from normal donors and patients diagnosed with HCV-related cirrhosis and HCV-related HCC were obtained from the NIH Liver Tissue and Cell Distribution System. The expression of ER subtypes, ERα and ERβ, were evaluated by Western blotting and real-time RT-PCR. The subcellular distribution of ERα and ERβ was further determined in nuclear and cytoplasmic tissue lysates along with the expression of

inflammatory [activated NF-κB and IκB-kinase (IKK)] and oncogenic (cyclin D1) markers by Western blotting and immunohistochemistry. The expression of ERα and ERβ was correlated with the expression of activated NF-κB, activated IKK and cyclin D1 by Spearman's correlation.

RESULTS

Both ER subtypes were expressed in normal livers but male livers showed significantly higher expression of ERα than females ($P < 0.05$). We observed significantly higher mRNA expression of ERα in HCV-related HCC liver tissues as compared to normals ($P < 0.05$) and ERβ in livers of HCV-related cirrhosis and HCV-related HCC subjects ($P < 0.05$). At the protein level, there was a significantly higher expression of nuclear ERα in livers of HCV-related HCC patients and nuclear ERβ in HCV-related cirrhosis patients as compared to normals ($P < 0.05$). Furthermore, we observed a significantly higher expression of phosphorylated NF-κB and cyclin D1 in diseased livers ($P < 0.05$). There was a positive correlation between the expression of nuclear ER subtypes and nuclear cyclin D1 and a negative correlation between cytoplasmic ER subtypes and cytoplasmic phosphorylated IKK in HCV-related HCC livers. These findings suggest that dysregulated expression of ER subtypes following chronic HCV-infection may contribute to the progression of HCV-related cirrhosis to HCV-related HCC.

CONCLUSION

Gender differences were observed in ERα expression in normal livers. Alterations in ER subtype expression observed in diseased livers may influence gender-related disparity in HCV-related pathogenesis.

Key words: Estrogen receptor α; Estrogen receptor β; Hepatitis C virus-related cirrhosis; Hepatitis C virus-related hepatocellular carcinoma; Sex and gender; Normal liver

Core tip: Our study, for the first time, demonstrates gender-based differences in basal expression of estrogen receptor α (ERα) in the liver of normal males and females. Altered nuclear and cytoplasm liver ER subtype protein expression was also observed in hepatitis C virus (HCV)-cirrhosis and HCV-related hepatocellular carcinoma (HCC) that correlate with the inflammatory and oncogenic markers, activated NF-κB and cyclin D1, implicating their role in chronic cirrhosis and malignant transformation. These findings may have an impact on future planning strategies for the development of novel treatments or prognostic markers by targeting ERs or their signaling pathways during chronic HCV-related cirrhosis and HCC development.

Iyer JK, Kalra M, Kaul A, Payton ME, Kaul R. Estrogen receptor expression in chronic hepatitis C and hepatocellular carcinoma pathogenesis. *World J Gastroenterol* 2017; 23(37): 6802-6816 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6802.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6802

INTRODUCTION

Hepatitis C virus (HCV) infection is a major health problem in the United States[1]. HCV-infection tends to be asymptomatic for long periods of time during which fibrosis and cirrhosis can develop, resulting in end-stage liver disease[2,3]. No viable vaccine is currently available for HCV prevention and, while newer and expensive direct acting antivirals are available for treating early HCV-infection, transplantation is the only effective treatment for patients with advanced or end stage liver disease[4,5]. HCV-infection related fibrosis and cirrhosis are associated with the development of chronic liver disease that eventually leads to hepatocellular carcinoma (HCC), the most common type of liver cancer[6-8]. The latest epidemiological data shows that HCC has the fastest growing death rate in the United States[9]. Thus, there is an urgent need to develop novel, effective and affordable therapeutics to treat chronic HCV-infections.

Understanding the contribution of host factors that directly or indirectly interact with HCV is central to finding new treatment modalities[10]. Striking gender disparity in HCV and HCC pathogenesis has led to the investigation of estrogen as one of the key host players in modulating the course of HCV-pathogenesis. Epidemiological and clinical studies have shown that chronic HCV-infections are more prevalent in males and progress more rapidly to cancer development as compared to females[11,12]. Similar to males, postmenopausal females lacking circulating estrogen show accelerated progression of HCV-infection to fibrosis and HCC development[12,13]. In contrast, physiological estrogen levels seen in premenopausal females, have been associated with less severity and slow progression through all stages of HCV infection[11,14]. Direct evidence of the therapeutic potential of estrogen has come from experimental studies demonstrating that administration of 17β-estradiol inhibits HCC development in *in vitro* and *in vivo* animal models[15,16]. However, clinical trials evaluating hormonal therapy using selective estrogen receptor modulators (SERMs) have shown inconsistent outcomes in HCC patients[17-19]. These inconsistencies may be attributed to the differences in the expression of estrogen receptors (ERs) in the liver[20].

Liver is a sexually dimorphic organ and expresses the ERs, ERα and ERβ, making it responsive to the

actions of estrogen[21,22]. These receptors classically function as transcription factors, shuttling between the cytoplasm and nucleus for regulating the expression of various genes involved in cell cycle, proliferation, apoptosis and inflammation[23]. More recently, the non-classical role of ERs in cell signaling has become increasingly evident[24,25]. The two subtypes, ERα and ERβ share significant structural homology and ligand binding properties and yet function very differently, often antagonizing each other's actions[26]. Thus, the relative expression of the two subtypes can have a significant impact on net cellular responses to estrogen.

In breast cancer, ERα:ERβ expression ratio is thought to play a key role in estrogen-dependent tumor development[27,28]. Like breast cancer, aberrant increase in ER gene expression has been reported in liver tumors when compared to normal or non-tumor parts of the liver in HCC patients[29,30]. However, there is very limited information available on the relative expression of ERα and ERβ subtypes and ERα:ERβ expression ratio in livers of normals, HCV-related cirrhosis and HCV-related HCC.

We hypothesized that basal liver ERα and ERβ expression differs in males *vs* females and this differential expression dictates host susceptibility to chronic HCV or its progression to hepatocellular carcinoma. In the present study, we evaluated the expression of ERα and ERβ in the livers of normals, HCV-cirrhosis and HCV-related HCC at the mRNA and protein levels using different techniques. We further determined the correlation of ER subtype expression with the levels of inflammatory and oncogenic markers like NF-κB and cyclin D1. Our findings show that the basal expression of ER subtypes is different between normal males and females. Furthermore, sub-cellular expression of both ER subtypes is altered in HCV cirrhosis and HCV-related HCC livers as compared to normals and correlates with the expression of inflammatory and oncogenic markers. This altered expression of ER subtypes in the liver may contribute to the progression of cirrhosis and cancer development during HCV-pathogenesis.

MATERIALS AND METHODS

Patients

Explant liver tissues from normal donors and HCV-related cirrhosis and HCV-related HCC patients (Tables 1-3) were obtained from the NIH Liver Tissue and Cell Distribution System (LTCDS) at the University of Minnesota. Liver explants were aseptically collected under the institutional review board (IRB) guidelines of University of Minnesota. The study was conducted at Oklahoma State University-Center for Health Sciences under IRB guidelines. In order to avoid interference of other co-factors, patients co-infected with human immunodeficiency virus (HIV) or hepatitis B virus (HBV) or with a history of alcohol consumption or drug use were excluded from the study. Liver explants were snap frozen in liquid nitrogen and stored at -80 ℃ until further use.

Western blot analysis

Whole tissue lysates were prepared by homogenizing approximately 200 to 300 mg of liver tissues in liquid nitrogen followed by lysis in buffer comprising of 50 mmol/L Tris-HCl (pH 8.0), 400 mmol/L KCl, 10 mmol/L EDTA, 2 mmol/L phenylmethylsulfonyl fluoride, 1 μg/mL aprotinin and 1 μg/mL leupeptin. The homogenates were centrifuged at 30000 × *g* for 1 h at 4 ℃. The supernatants were collected and stored at -80 ℃ until further use. Cytoplasmic and nuclear fractions were prepared from liver tissues using the NE-PER kit (Pierce Chemical Co., Rockland, IL, United States) as per the manufacturer's instructions. Protein concentrations were determined by Bicinchoninic acid assay (Pierce Chemical Co., Rockland, IL, United States). Thirty micrograms of protein from each lysate (whole tissue lysate, cytoplasmic or nuclear tissue lysates) was resolved on 4%-12% Bis-Tris Gel (Invitrogen, Carlsbad, CA, United States). The separated proteins were electrophoretically transblotted on to a 0.2 μm nitrocellulose membrane. Purified recombinant ERα and ERβ proteins were included as positive controls. The membrane was blocked in 5% non-fat dry milk made in TBS (20 mmol/L Tris-HCl, pH 7.6 and 136 mmol/L NaCl) containing 0.1% Tween-20 for 2 h and probed with antibodies specific for human ERα (rat monoclonal against human ERα, H222, Fitzgerald Industries International Inc., Concord, MA, United States), human ERβ (mouse monoclonal against amino acids 1-153 of human ERβ, 14C8, Affinity Bioreagents, Golden, CO, United States), phosphorylated IκB-kinase (IKK) αβ (rabbit polyclonal against a phosphopeptide corresponding to amino acids surrounding Ser176/180 of human IKKα, Cell signaling Technology, Danvers, MA, United States), IKKα (rabbit polyclonal against a peptide corresponding to 20 amino-terminal amino acids of human IKKα, Cell signaling Technology, Danvers, MA, United States), Cyclin D1 (rabbit polyclonal against amino acids 1-295 of human cyclin D1, H-295, Santa Cruz Biotechnology, Dallas, TX, United States), phosphorylated NF-κB (mouse monoclonal against a phosphopeptide corresponding to amino acids surrounding Ser536 of human NF-κB p65 subunit, Cell signaling Technology, Danvers, MA, United States), NF-κB (rabbit monoclonal against a peptide corresponding to amino acids near the amino-terminus of human NF-κB p65 subunit, Cell signaling Technology, Danvers, MA, United States) and β-actin (rabbit polyclonal against a peptide corresponding to amino acid 20-33 of actin, Sigma-Aldrich, St. Louis, MO, United States). After incubation with alkaline phosphatase conjugated secondary antibodies (Sigma-Aldrich, St. Louis, MO, United States), the protein

bands were detected by enhanced chemiluminescence (Pierce Chemical Co., Rockland, IL, United States). To ensure the purity of cytoplasmic and nuclear fractions, the blots were also probed with anti-GAPDH (rabbit monoclonal against a peptide corresponding to a part of the carboxyl terminus of human GAPDH, Cell signaling Technology, Danvers, MA, United States) and anti-histone H1 (mouse monoclonal against nuclei from biopsies of myeloid leukemia cells, EMD Millipore, Billerica, MA, United States) antibodies respectively. Images of the protein bands were digitally captured with Alpha Innotech instrumentation (Alpha Innotech Corp, San Leandro, CA, United States) and quantified with Image analysis program, ImageJ (NIH, Bethesda, MD, United States). The phosphorylated forms were expressed as a ratio of the phosphorylated protein to total protein.

Immunohistochemistry

Immunohistochemistry was performed on normal and diseased explant liver tissue sections to confirm the protein expression of ERα, ERβ and cyclin D1. Formalin-fixed liver tissues were embedded in paraffin and sectioned into 4-μm thick sections. Non-enzymatic antigen retrieval was performed in citrate buffer (pH 6.0) using a microwave procedure. Slides were allowed to cool down for 20 min at room temperature and endogenous peroxidase was quenched with Dako EnVision system kit according to manufacturer's instructions (Dako, Carpintaria, CA, United States). The sections were washed and incubated for 30 min with 0.5% Triton X-100 in PBS followed by 5% rabbit serum. The tissue sections were incubated overnight with primary antibodies against ERα (rabbit polyclonal against a peptide corresponding to the carboxyl terminus of mouse ERα, MC-20, 1:50 dilution, Santa Cruz Biotechnology, Dallas, TX, United States), or ERβ (mouse monoclonal against peptide corresponding to the carboxyl terminus of ERβ, PPG5/10, 1:20 dilution, Dako, Carpinteria, CA, United States) at 4℃. Slides were washed with PBS containing 0.05% Tween and treated for one hour at room temperature with corresponding HRP labeled secondary antibodies (Dako, Carpinteria, CA, United States). The tissue sections were stained with 3,3'-diaminobenzidine and the nuclei were counterstained with Mayer's hematoxylin. A similar immunostaining procedure was used for cyclin D1 (rabbit polyclonal antibody against amino acids 1-295 of human cyclin D1, H-295, 1:150 dilution, Santa Cruz Biotechnology, Dallas, TX, United States). For negative controls, sections were incubated with PBS instead of the primary antibody. The stained sections were visualized using Nikon microscope (Nikon H600 L) and sections with staining of ⩾ 10% of the cells were defined as positive.

Real-time RT-PCR

Total RNA was isolated from liver tissues with Trizol (Thermo Fisher Scientific, Waltham, MA, United States) followed by purification on RNeasy columns (Qiagen, Valencia, CA, United States) as per the manufacturer's instructions. Total RNA from each sample was treated with DNase (Thermo Fisher Scientific, Waltham, MA, United States) and then reverse-transcribed to synthesize cDNA using the High capacity cDNA synthesis kit (Applied Biosystems, Foster City, CA, United States). The expression of target genes was evaluated by quantitative real-time PCR using commercially available ERα and ERβ specific Taqman primers and probe assay mixes (Applied Biosystems, Foster City, CA, United States) on an ABI StepOne Real-Time PCR System (Applied Biosystems Foster City, CA, United States). Hypoxanthine-guanine phosphoribosyl transferase (HPRT) was included as the endogenous control. Relative differences in gene expression between groups were determined using the $2^{-\Delta\Delta CT}$ method using the normal group for normalization[31].

Statistical analysis

The statistical methods of this study were performed and reviewed by Dr. Mark E. Payton from Department of Statistics, Oklahoma State University, Stillwater, United States. Data obtained from Western blotting and real time RT-PCR experiments were analyzed statistically using SAS software v9.4 (SAS Institute Inc., Cary, NC, United States). Statistical significance between appropriate groups was determined by non-parametric analyses that included the Kruskall-Wallis test and Mann Whitney *U* test. Post-hoc analyses were performed using Fisher's Protected Least Significant Difference comparisons using rank data test. Correlations of ER subtypes with other proteins were analyzed by using the Spearman's rank correlation test. $P \leqslant 0.05$ was considered statistically significant. All graphs were made and depicted using the GraphPad Prism v6 software (GraphPad Software Inc, La Jolla, CA, United States).

RESULTS

Basal expression of ERα is significantly higher in liver of normal males than females

Due to the well-established gender disparity in HCC prevalence, we initiated this study by investigating the expression of ERα and ERβ in normal males and females. Whole tissue lysates of liver explants obtained from normal females and normal males (Table 1) were evaluated by Western blotting using validated ERα and ERβ directed antibodies (Figure 1A). Densitometric analysis of protein bands showed comparable ER subtype expression in normal male and female tissues when the gender data was pooled (Figure 1B). However, when ER subtype expression data was segregated based on gender, we found that there was a significantly higher expression of ERα in males as

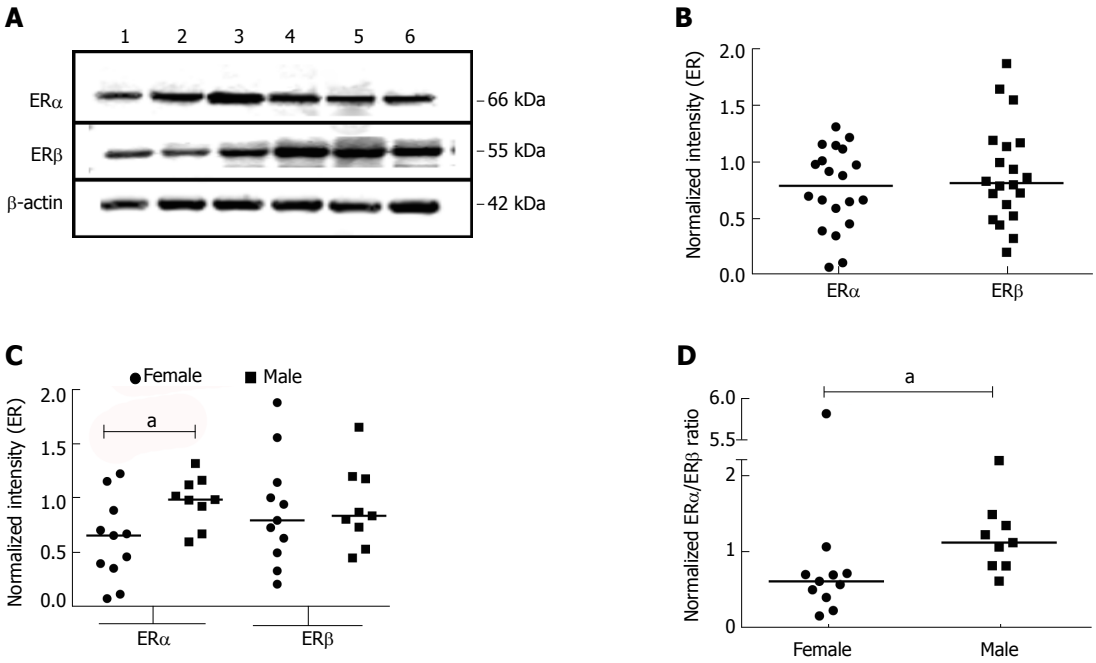

Figure 1 Expression of estrogen receptor subtypes in whole tissue lysates from normal male and female subjects. A: Whole tissue lysates from liver tissues of normal donors were subjected to Western blotting and probed with antibodies against ERα, ERβ and β-actin. A representative blot is shown. B-D: The bands corresponding to ERα, ERβ and β-actin were quantified by densitometric analyses using ImageJ. Each symbol represents one individual. Expression of the ER subtypes was normalized to the expression of β-actin and plotted (B). Gender-based ER subtype expression was evaluated by segregating the gender and plotted (C). The ERα:ERβ expression ratio was also plotted for each gender group (D). $^{a}P < 0.05$ was considered significant. ER: Estrogen receptor.

Table 1 Age ranges of normal and diseased subjects in whole tissue lysates

Group	No. of subjects	No. of females	Age range (yr)	No. of males	Age range (yr)
Normal	20	11	42-67	9	34-64
HCV	14	4	53-60	10	43-55
HCC	14	1	56	13	44-66

HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

Table 2 Age ranges of normal and diseased subjects in mRNA analysis

Group	No. of subjects	No. of females	Age range (yrs)	No. of males	Age range (yrs)
Normal	9	8	42-67	1	64
HCV	10	3	43-60	7	43-53
HCC	10	0	N/A	10	44-59

HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

Table 3 Age ranges of normal and diseased subjects in nuclear and cytoplasmic tissue lysates

Group	No. of subjects	No. of females	Age range (yr)	No. of males	Age range (yr)
Normal	10	5	43-67	5	50-64
HCV	12	3	51-60	9	46-53
HCC	16	0	NA	16	44-66

HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

compared to females (Figure 1C). No difference was found in the expression of ERβ between males and females. Since physiological outcomes are determined by the expression of both, ERα and ERβ, we compared the ERα:ERβ expression ratio between male and females and found that males showed a significantly higher ERα:ERβ expression ratio compared to females (Figure 1D).

Altered expression of ERα is observed in males with HCV-related cirrhosis and HCV-related HCC

The expression of ER subtypes was compared in liver explants of normals, HCV-related cirrhosis and HCV-related HCC (Tables 1 and 2) by real time RT-PCR and Western blotting (Figure 2). At the transcriptional level, there was an increase in the liver mRNA expression of ERα (ESR1) and ERβ (ESR2) subtypes in chronic HCV and HCV-related HCC as compared to normals (Figure 2A and B). This change in expression significantly decreased the ER subtype ratio in the HCV-related cirrhosis group compared to normal (Figure 2C), suggesting that HCV infection may result in altering the expression of ER subtypes.

When we measured ER subtype protein levels by Western blotting, we could not detect any significant differences among the three groups when the data was evaluated without gender segregation (Figure 2 D-G). However, upon separating males and females,

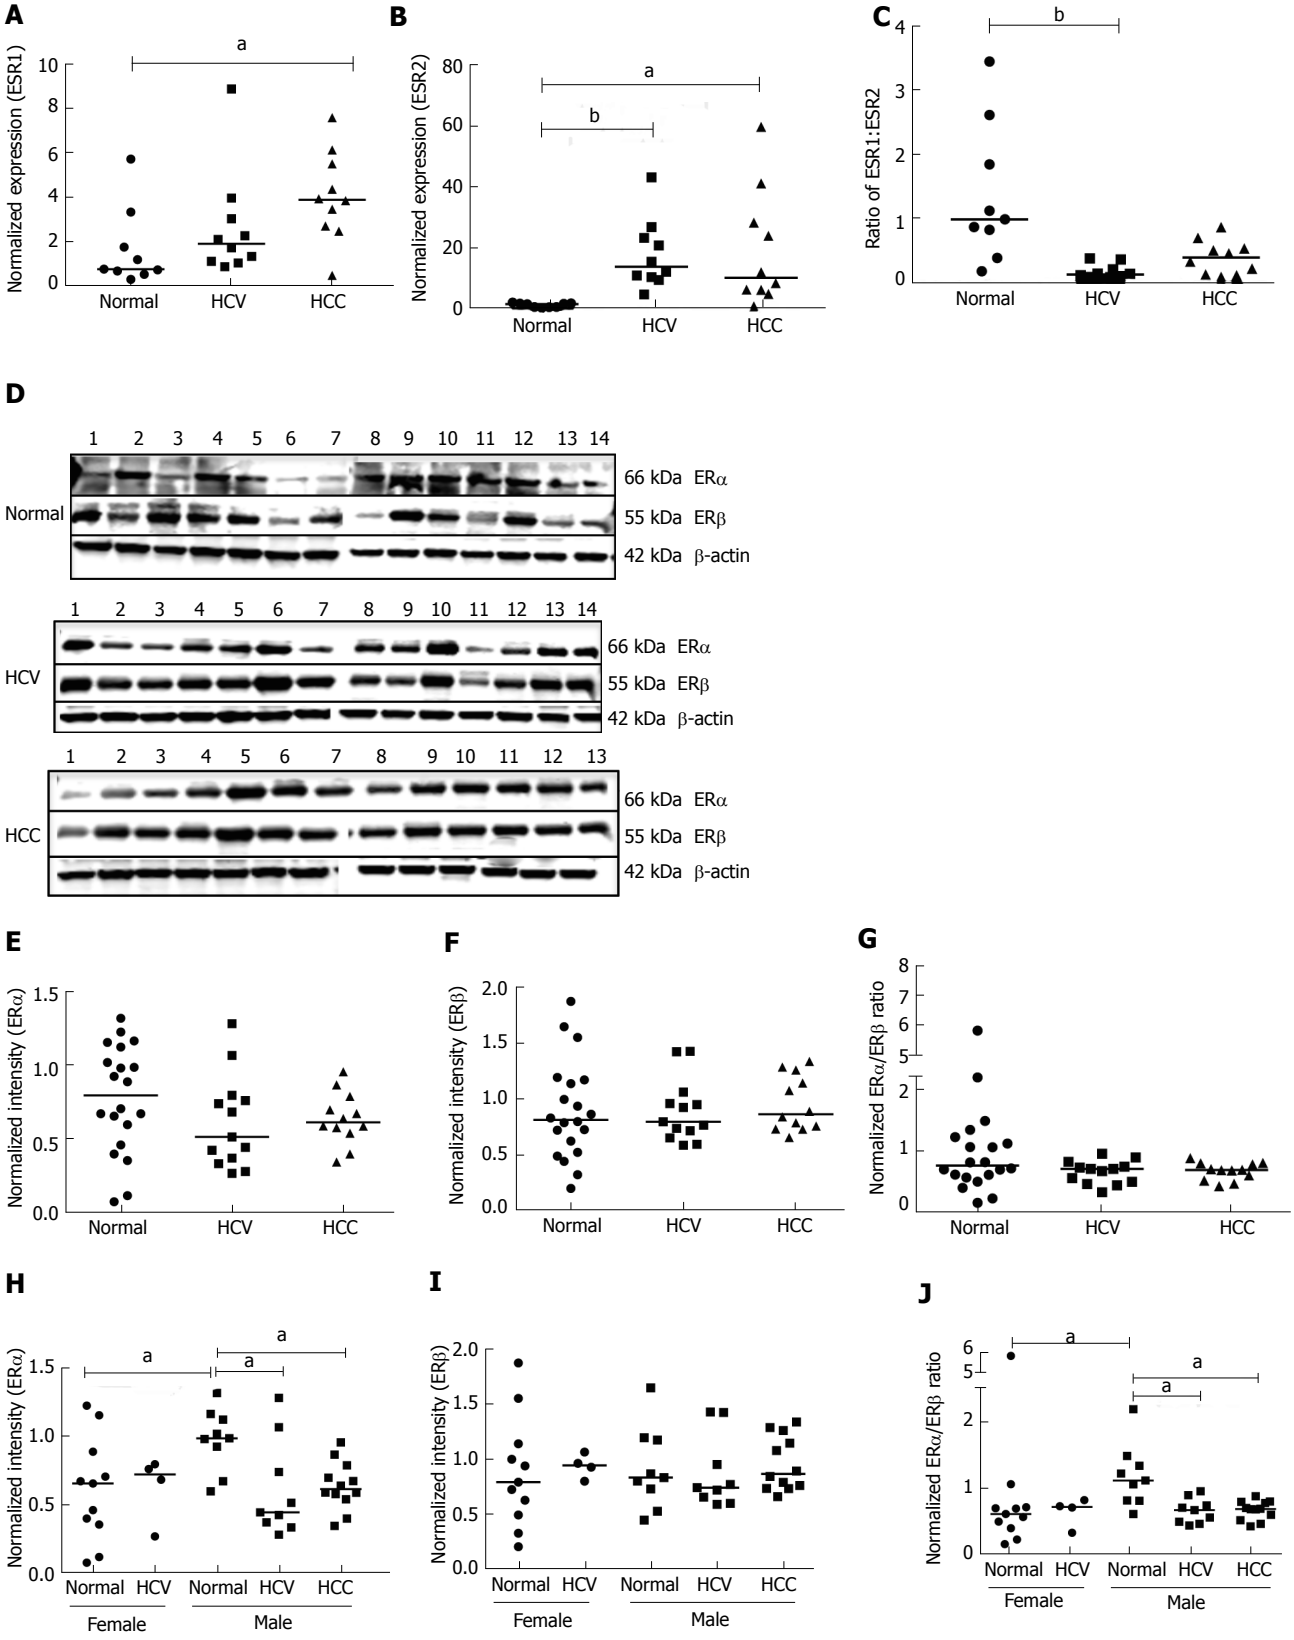

Figure 2 Expression of estrogen receptor subtypes from normal and diseased subjects. A-C: Total RNA extracted from normal, HCV-related cirrhosis and HCV-related HCC livers was subjected to RT-PCR. The abundance of ESR1 (A) and ESR2 (B) transcripts was determined by real time PCR and normalized to the expression of HPRT. ESR1:ESR2 expression ratio was also plotted for the three groups (C). [a]$P < 0.05$ or [b]$P < 0.001$ was considered significant. D: Whole tissue lysates from liver tissues of normal, HCV and HCC subjects were subjected to Western blotting and probed with antibodies against ERα, ERβ and β-actin. Representative blots for each group are depicted. E-J: The bands corresponding to ERα, ERβ and β-actin were quantified by densitometric analyses using ImageJ. Expression of the ERα and ERβ was normalized to the expression of β-actin and plotted (E and F). The ERα:ERβ expression ratio was also plotted for normal, HCV and HCC group (G). Expression of ER subtypes and ERα:ERβ expression ratio in the male population of normal, HCV and HCC groups was plotted separately (H-J). [a]$P < 0.05$ was considered significant. HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma; ER: Estrogen receptor.

we observed a significant decrease in the expression of ERα in diseased livers (HCV as well as HCC) compared to normal livers (Figure 2H) but no difference in the expression of ERβ (Figure 2I) in males. This resulted in a significant decrease in ERα:ERβ expression ratio in male diseased livers (HCV as well as HCC) compared to normal male livers (Figure 2J). Among the females, we could compare the expression of ER subtypes between normals and HCV-related cirrhosis only as there were no females in the HCV-related HCC category. We found that there were no significant differences in protein levels of ERα and ERβ between normal livers and HCV-related cirrhotic livers in females (Figure 2H and I). We further observed a positive-correlation between the expression of ERα and ERβ in HCV-related cirrhosis and HCV-related HCC group based on gender-pooled data (Table 4).

Thus the results from the mRNA and protein analyses performed in whole tissue extracts showed different trends. Since classical ERs shuttle between the nuclear and cytoplasmic compartments of the cells and mediate their regulatory functions by binding to estrogen response elements on DNA, we evaluated the expression of ER subtypes in nuclear and cytoplasmic extracts of liver tissues.

Increased nuclear translocation of ER subtypes is observed in HCV-related cirrhosis and HCV-related HCC

The distribution and expression of ERα and ERβ in nuclear and cytoplasmic extracts of normal, HCV-related cirrhosis and HCV-related HCC group is depicted in Figure 3. We observed a higher expression

of ERα in the nuclear extracts of normal males as compared to normal females but the increase was not statistically significant, probably due to the small sample size (Supplementary Figure 1). There was no change in the expression of nuclear ERβ. These observations in normals for the expression of nuclear ERα and ERβ were similar to the results observed in whole tissue extracts.

When we compared the expression of ER subtypes in nuclear and cytoplasmic extracts of normal and diseased livers, we could not perform statistically relevant gender analyses due to the small sample size and scarcity of female subjects in the diseased groups. Hence we have reported our results without gender segregation. We observed a significant increase in the expression of nuclear ERα and ERβ in HCV-related HCC and HCV-related cirrhosis (Figure 3A, B and D) respectively when compared to normals. However, there was no significant difference in the expression of cytoplasmic ERα, while HCV-related HCC group showed a significantly higher expression of cytoplasmic ERβ compared to HCV-related cirrhosis group (Figure 3C and E). An increase in the nuclear:

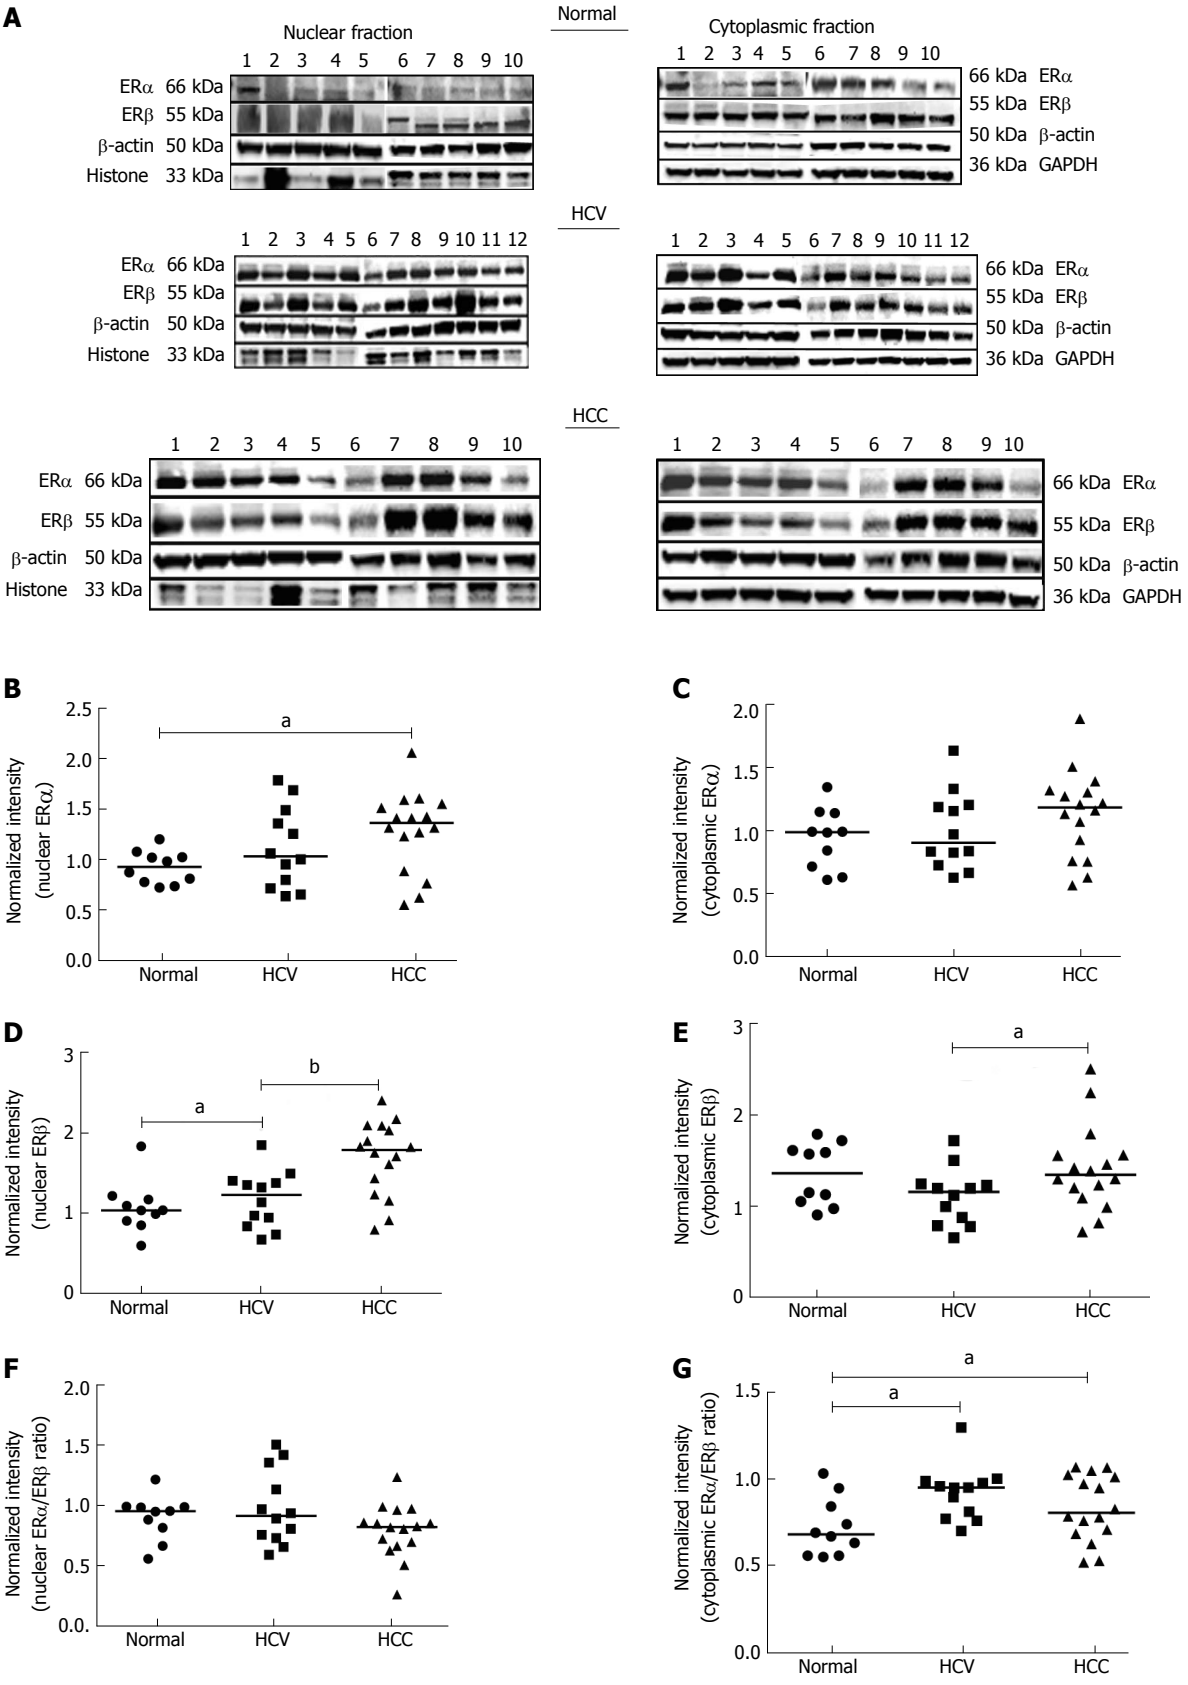

Figure 3 Expression of estrogen receptor subtypes in nuclear and cytoplasmic tissue lysates from normal and diseased subjects. A: Lysates prepared from nuclear and cytoplasmic fractions of liver tissues from normal, HCV and HCC subjects were subjected to Western blotting and probed with antibodies against ERα, ERβ, β-actin, histone (nuclear lysates only) and GAPDH (cytoplasmic lysates only). Representative blots for each group are depicted. B-G: The bands corresponding to ERα, ERβ and β-actin were quantified by densitometric analyses using ImageJ. Expression of the ERα and ERβ was normalized to the expression of β-actin and plotted with (B and C). The ERα:ERβ expression ratio was also plotted for normal, HCV and HCC group (D). Expression of ER subtypes and ERα:ERβ expression ratio in the male population of normal, HCV and HCC groups was plotted separately (E-G). $^{a}P < 0.05$ or $^{b}P < 0.001$ was considered significant. HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma; ER: Estrogen receptor.

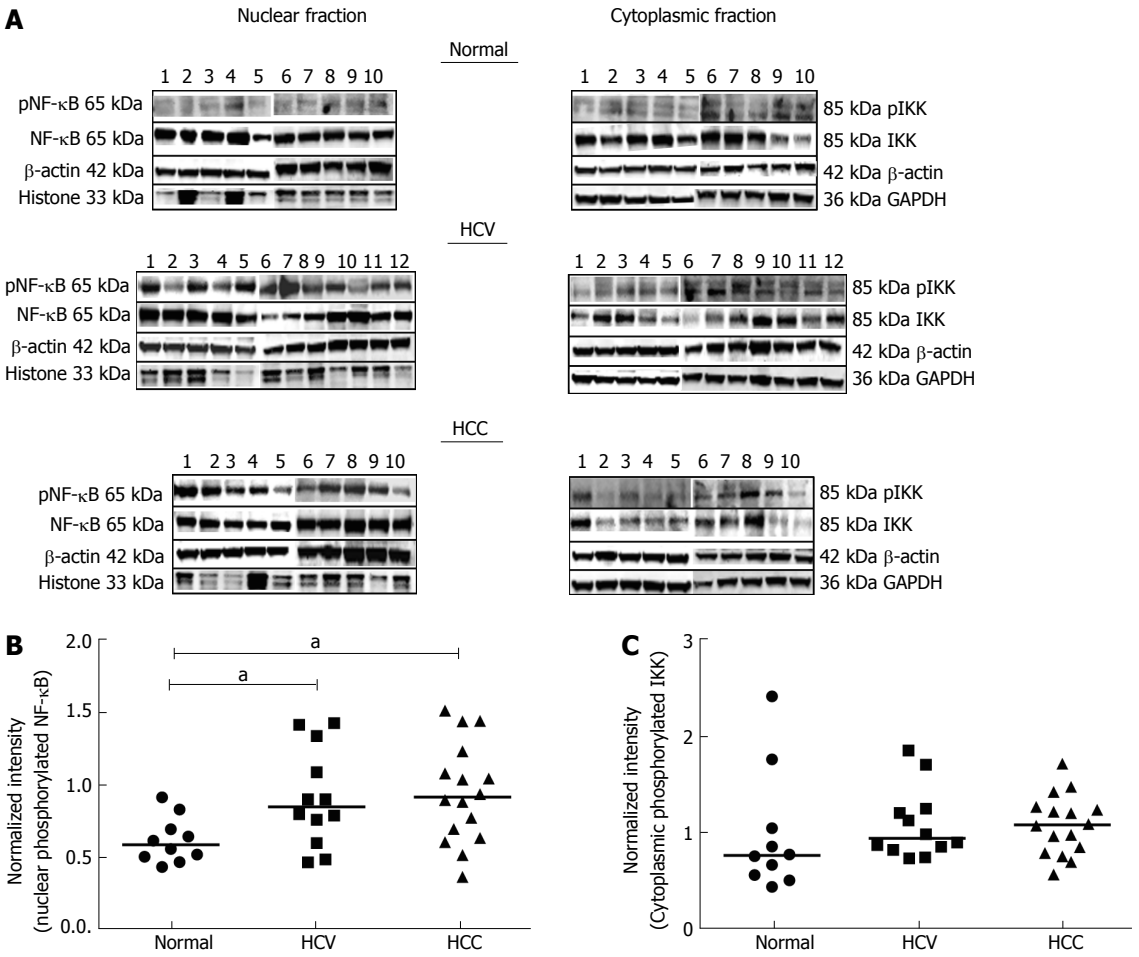

Figure 4 Expression of pNF-κB and pIKK in nuclear and cytoplasmic tissue lysates from normal and diseased subjects. A: Lysates prepared from nuclear and cytoplasmic fractions of liver tissues from normal, HCV and HCC subjects were subjected to Western blotting. Nuclear tissue lysates were probed with antibodies against pNF-κB, NF-κB, β-actin, and histones while cytoplasmic tissue lysates were probed with antibodies against pIKK, IKK, β-actin and GAPDH. Representative blots for each group are depicted. B and C: The bands corresponding to pNF-κB, NF-κB, pIKK, IKK and β-actin were quantified by densitometric analyses using ImageJ. The ratio of pNF-κB:NF-κB was normalized to the expression of β-actin and plotted (B). The ratio of pIKK:IKK was normalized to the expression of β-actin and plotted with gender pooled (C) subjects. $^{a}P < 0.05$ was considered significant. HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma; ER: Estrogen receptor.

cytoplasmic ratio of both, ERα and ERβ, in the diseased groups were observed compared to the normals (Supplementary Figure 1) suggesting that there is increased transcriptional activation of ER subtypes in the progression to HCV-related cirrhosis to HCV-related HCC. Furthermore, there was a significant increase in the ratio ERα:ERβ in the cytoplasmic compartment of the HCV-related cirrhosis and HCV-related HCC groups compared to normals (Figure 3G) but there was no significant difference in the ratio of the nuclear ER subtypes (Figure 3F).

HCV-related cirrhosis and HCV-related HCC group show higher activation of NF-κB

HCV infection is known to trigger inflammatory pathways and livers displaying chronic inflammation are more at risk of developing hepatocellular carcinoma[32,33]. Most inflammatory pathways involve NF-κB, hence we evaluated the activation of the NF-κB signaling pathway by detecting the phosphorylation of the p65 subunit and IKK; the kinase that phosphorylates IκB, resulting in its dissociation from NF-κB and degradation by the proteasome. Livers chronically infected with HCV and HCV-related HCC tissues showed significantly higher expression of phosphorylated NF-κB (Figure 4A and B) compared to normals. There was an increase in the expression of pIKK from normal livers to HCV cirrhosis and HCV-related HCC, but the increase was not statistically significant (Figure 4C). We also observed a weak negative correlation between nuclear ERα and pNF-κB in normal liver tissues (r = -0.62968, P = 0.0511; Table 5). On the contrary, HCV-related HCC group demonstrated a weak positive correlation between nuclear ERα and pNF-κB (r = 0.4793, P = 0.0516; Table 5). In addition, expression levels of pIKK and the cytoplasmic ER subtypes showed a strong negative correlation in the HCC group (ERα: r = -0.56014, P = 0.0194; ERβ: r = -0.60848, P = 0.0095; Table 6).

ERα levels correlate with expression of cyclin D1 in both HCV cirrhosis and HCV-related HCC

In order to study the correlation of ERs with oncogenic markers in diseased livers, we determined the

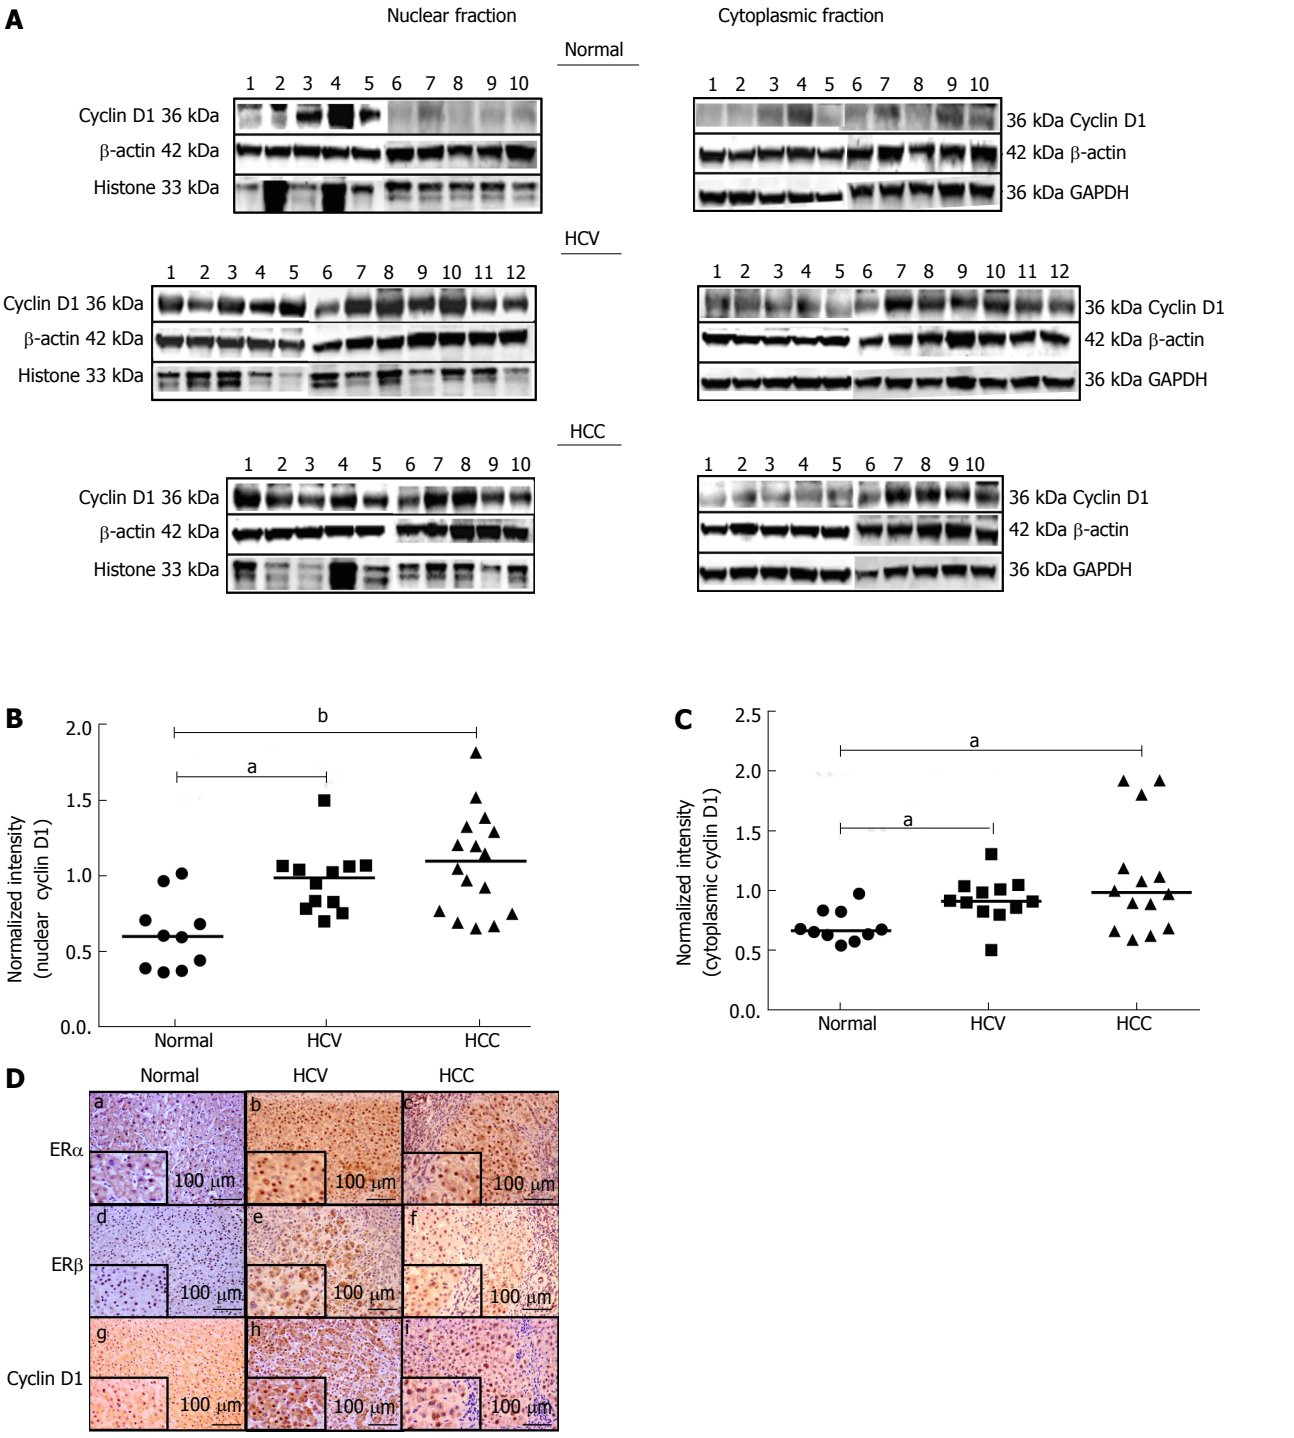

Figure 5 Expression of cyclin D1 in nuclear and cytoplasmic tissue lysates from normal and diseased subjects. A: Lysates prepared from nuclear and cytoplasmic fractions of liver tissues from normal, HCV and HCC subjects were subjected to Western blotting and probed with antibodies against cyclin D1, β-actin, histones (nuclear lysates only) and GAPDH (cytoplasmic lysates only). Representative blots for each group are depicted. B and C: The bands corresponding to cyclin D1 and β-actin were quantified by densitometric analyses using ImageJ. Expression of cyclin D1 was normalized to the expression of β-actin in nuclear (B) and cytoplasmic (C) lysates and plotted. $^{a}P < 0.05$ or $^{b}P < 0.001$ was considered significant. D: Immunohistochemical staining of ERα, ERβ and cyclin D1 in normal (a, d, g), HCV-related cirrhosis (b, e, h) and HCV-related HCC (c, f, i) is depicted. A magnified region of the stained tissue section is depicted as an inset in each corresponding image. Scale bar = 100 μm. HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

expression of cyclin D1 in the nuclear and cytoplasmic liver tissue extracts of normals, HCV-related cirrhosis and HCV-related HCC group by Western blotting (Table 3). As shown in Figure 5, there was a significant increase in the expression of cyclin D1 in both, the nuclear and cytoplasmic fractions of diseased livers, suggesting that chronic HCV infection primes hepatocytes to proliferate. A positive-correlation between the expression of nuclear ERα and ERβ with nuclear cyclin D1 was observed in both HCV-related cirrhosis (ERα: $r = 0.75728$, $P = 0.0043$; ERβ: $r = 0.64445$, $P = 0.0237$; Table 5) and HCV-related HCC

(ERα: $r = 0.55714$, $P = 0.0202$; ERβ: $r = 0.51223$, $P = 0.0355$; Table 5) groups but not in normals, signifying the importance of ER subtypes in cyclin D1 activation (Table 5). We further determined the expression of ER subtypes and cyclin D1 by immunohistochemistry (IHC). As observed with Western blotting, IHC showed over-expression of ERα and cyclin D1 in HCV-related cirrhosis and HCV-related HCC groups (Figure 5D, Supplementary Tables 1-3).

DISCUSSION

Various epidemiological studies around the globe have recognized the role of gender bias in the progression of HCV infection to chronic liver disease and cirrhosis due to poor therapeutic responses or further development of HCV-related HCC in these patients[34]. Remarkable differences have been observed in the incidence, progression of HCV-related chronic liver disease and outcome of interferon therapy in males, postmenopausal females and premenopausal females[13,35]. This has generated a significant interest in the scientific community to investigate the role of estrogen as the key host factor in HCV-related pathogenesis. Recent studies in postmenopausal women with HCV-related fibrosis clearly show clinical benefits from estrogen replacement therapy in conjunction with standard HCV treatment[12]. One of the most compelling evidence is the inhibition of HCV life cycle by 17β-estradiol in an ERα dependent manner in human liver cell lines[36,37]. Raloxifene, a SERM, treatment has been shown to improve the efficacy of antiviral treatment in HCV-infected postmenopausal women[38]. These findings suggest a protective role of estrogen affecting not only viral replication but also HCV pathogenesis in the host.

Despite the recognition of estrogen as a potentially significant host factor in HCV pathogenesis, little progress has been made to understand the underlying mechanisms on how ER subtypes may be involved in progression to HCV chronic disease in some patients and rapid clearance of HCV in others. Perhaps this gap in understanding is one of the major factors contributing to the current debatable potential of estrogen therapy[17,19]. In addition, most of the clinical studies did not monitor ERα and ERβ expression in the liver of the enrolled patients or the hormonal status of females at the time of recruitment or during treatment[20]. Some studies evaluated ER subtype expression by measuring mRNA levels in the liver or performing less specific ligand binding assays[39, 40].

One of the most important premises of the current study was to evaluate the gender-based (males *vs* females) ER subtype protein expression in the liver of normals (basal expression) and further evaluate the changes in expression of these subtypes in HCV-related cirrhosis or HCV-related HCC patients. Further, we employed subcellular fractionation (nuclear verses cytoplasmic) protein studies to examine the relative expression of ER subtypes and correlate their presence with activation of NF-κB or cyclin D1 in these fractions. Our findings in whole tissue extracts of normal livers indicated that males express significantly higher levels of ERα protein compared to females but comparable levels of ERβ. We also found a significant increase in the ERα:ERβ expression ratio in males as compared to females. To our knowledge, this is the first report demonstrating gender-based differences in ERα at the basal level thereby affecting the ratio of ER subtypes in the liver. Whether these differences in ER subtype expression at basal levels predispose males to severe and fast disease progression of HCV infection needs further investigation.

We were able to detect ERα and ERβ transcripts in normal, HCV-related cirrhosis and HCV-related HCC groups. Similar observations were made in a Korean population study where they observed ERα and ERβ mRNA transcripts in more than 95% of HCV-related HCC liver tissues[40]. There was an increase of ERα and ERβ transcripts in diseased livers compared to normals but there were no changes in the protein levels of ERs among the groups in whole tissue lysates. However, gender analyses of ER expression in whole tissue lysates revealed that there was a significant decrease in ERα but not ERβ expression only in diseased male patients suggesting its disease specific role in these patients. These findings are in agreement with Villa *et al* who showed that there was reduction or even loss of wild-type ERα in male HCV-related HCC livers but an increase in the expression of variant ERα, which we have not evaluated[41,42].

Further, ER expression in the nuclear and cytoplasmic fractions from gender-pooled diseased livers differed when compared to normals. In the nuclear fraction, we found a higher expression of ERα and ERβ subtypes in HCV-mediated HCC and HCV-mediated cirrhosis tissues respectively compared to normal liver tissues, which is in contrast to the findings in the whole tissue extracts. HCV-mediated HCC tissues also showed significantly higher expression of cytoplasmic ERβ only when compared to HCV-cirrhosis tissues. We found a significant increase in the ERα to ERβ ratio in the cytoplasmic fraction than in the nuclear fraction of both HCV-related cirrhosis and HCV-related HCC livers as compared to normal livers. The clinical relevance of these changes in ER subtype expression in the subcellular compartments needs to be further investigated. ER protein levels have been shown to vary under physiological states during breast tumor progression and hormonal therapy[43]. A recent study in the MCF7 cell-line has shown that estrogen stimulation involves dynamic changes in protein subcellular spatial distribution rather than changes in total protein abundance and propose that cells may be transformed by perturbations in nucleocytoplasmic shuttling of nuclear hormone receptors and other proteins[44,45]. In addition to breast cancer, ERs have also been implicated to play important roles

in gastrointestinal cancers like gastric, colon and colorectal cancers[46-48]. Since ERs primarily function as nuclear receptors and act as transcription factors for gene regulation, we propose that evaluating the expression of these proteins in cellular fractions as opposed to the whole tissue lysates would be a more accurate representation of their biological activity. Furthermore, our immunohistochemistry analysis also supported the increase in nuclear and cytoplasmic expression of ERα in both groups of diseased livers compared to normal livers (Supplementary Table 1). The expression of cytoplasmic ERβ was comparable among all the three groups by immunostaining. However, we observed a loss of nuclear ERβ in some HCC tissues (Supplementary Table 2). Loss of ERβ was also reported by Iavarone *et al*[39], who evaluated the expression of ER subtype mRNA in liver cancer tissues. Additionally, in breast, colon and prostate cancers, there are reports that indicate that presence of ERβ leads to better prognosis[49-52]. These findings about differential expression of nuclear or cytoplasmic ERβ expression in HCV cirrhosis or HCC can be substantiated only by increasing the sample size in the study.

Inflammation has been associated with the initiation and progression of hepatocarcinogenesis[53]. Since HCV infection triggers inflammation, and chronic inflammation promotes carcinogenesis, NF-κB has been viewed as an important player in inflammation-induced cancer[54,55]. In the current study, we found a significant increase in activated NF-κB in HCV-related cirrhosis and in HCV-related HCC liver tissues. Significant increase in ERs in the cytoplasmic fraction of diseased livers may modulate the activity of pIKK thereby influencing the activation of NF-κB and inflammation outcome. ERα and NF-κB have been shown to directly interact in the nuclei of U2-OS cells treated with 17β-estradiol and aberrant ERα and NF-κB expression correlated with invasion and metastasis in HCC[56,57]. 17β-estradiol, *via* ERα, can also inhibit the transport of p65 to the nucleus and downregulate inflammation[58]. Detailed mechanistic studies are warranted to explore the cross talk between ERα and NF-κB to unfold the nature of their interaction in a HCV infection setting.

Unlike mammary carcinoma, the target genes and mechanism for ER regulation in liver are not well studied. There is a correlation between dysregulation in ER subtype with the overexpression of cyclin D1[59]. In our study, we observed increased expression of cyclin D1 in HCV-related cirrhosis and HCV-related HCC compared to normal livers and the expression of nuclear cyclin D1 correlated with the expression of nuclear ER subtypes in diseased livers. These findings along with other studies suggest that ERs may play a role in dysregulation of cellular proliferation by participating in increased transcription of cyclin D1 that aids in the progression of HCV infection to cirrhosis and eventually to hepatocellular carcinoma[60]. Cyclin D1 expression can also be regulated by ERα *via* non-genomic signaling. Treatment of HepG2 cells with 17β-estradiol activates the MAPK/ERK pathway by membrane-localized ERs resulting in increased expression of the cyclin D1 gene[61]. Apart from its role in cell cycle progression, cyclin D1 has recently been recognized to play a role in influencing sex steroid metabolism by increasing estrogen levels and decreasing androgen levels[62]. This is the first study that correlates the expression of ER subtypes with cyclin D1 in HCV-related cirrhosis and HCV-related HCC.

Increased expression of different isoforms or variants of ERα in diseased livers has been reported by mRNA studies and their involvement to activate oncogenic signaling pathways in cell lines has been reported[63,64]. The variants, ERα36 and ERα46 have been shown to modulate signaling pathways linked to proliferation and apoptosis[65, 66]. Differential expression of ERα36 has been observed in various cancers like breast, gastric, and endometrial cancer[67] and its expression correlates with a worse prognosis in breast cancer[68] but its role in HCV-mediated HCC has not been thoroughly investigated. Various ERβ variants have also been detected in different tissues but their role in carcinogenesis has not been evaluated as extensively as the ERα variants[69]. The present study focused to fill the gap in knowledge for the expression of wild type ERα and ERβ in normal and diseased livers. However, the expression of variant ER receptors also needs to be investigated to understand their role, if any, in HCV-related carcinogenesis. In addition to ER subtypes, the expression of androgen receptors should also be evaluated as HCV infection enhances androgen receptor-mediated signaling in an *in vitro* model[70] but it is not clear if androgen receptors play a role in carcinogenesis due to existing conflicting reports[71,72].

Finally, in the current study, we have demonstrated for the first time that the basal expression of wild-type ERα in the liver is higher in males than females. Furthermore, the increased sub-cellular expression of ER subtypes observed in diseased livers correlates with the expression of inflammatory and oncogenic markers. This altered expression of ER subtypes in the liver may contribute to the progression of cirrhosis and cancer development during HCV-pathogenesis. These observations have been made in end stage HCV-related cirrhosis and HCC. In future, early disease or stage specific prospective longitudinal studies that include a larger sample size (in both males and females category) can be conducted to further clarify the role of nuclear or cytoplasmic ER expression at early stages of HCV-related cirrhosis or HCV-related HCC. Impact of gender associated ER subtype ratio distribution in the liver can also be studied relative to oncogenic markers and that may help us to monitor host therapeutic responses, viral clearance or improved prognosis during the carcinogenesis process. In conclusion, we expect that by evaluating the expression of sex

hormone receptors and understanding the signaling pathways they affect, gender and stage-related personalized therapies can be designed to treat and manage chronic HCV infections and HCV-related HCC.

ACKNOWLEDGMENTS

We thank Dr. Senait Assefa and Zachary Lovato for their technical assistance and Ayantika Sen for reviewing this manuscript. Liver tissues were obtained from the NIH Liver Tissue and Cell Distribution System (LTCDS; Contract No. HHSN276201200017C).

COMMENTS

Background

Hepatitis C virus (HCV) infection-related fibrosis and cirrhosis lead to the development of chronic liver disease that can ultimately result in hepatocellular carcinoma (HCC). According to epidemiological and clinical studies, chronic HCV infection mediated cirrhosis is more prevalent in males and progresses to cancer development faster as compared to premenopausal females who show better therapeutic responses and clear the infection. However, females with menopausal estrogen deficiency may have reactivation of the HCV infection resulting in accelerated progression to fibrosis and HCC development, confirming estrogen related etiology. Previous hormonal therapies in HCC have been inconclusive perhaps due to them poor understanding of estrogen receptor (ER) subtype expression in the normal livers from both males and females and also how changes in the expression of ERs may contribute to HCV-related disease progression. In the current study, they evaluated the basal liver ERα and ERβ expression in males versus females and have studied the changes in liver ER subtype expression and their correlation with inflammatory and proliferative markers in HCV-related cirrhosis and HCV-related HCC

Research frontiers

Gender disparity in immunity to chronic infectious disease, autoimmunity and cancer development is increasingly being recognized in various clinical and experimental studies. Systemic estrogens in females play an important role in host innate immunity, however, the contributions of estrogen receptors are poorly recognized. In addition to hormonal cancers like breast, prostate and uterus, ER subtypes are being increasingly implicated in non-hormonal tissue cancers as well that include liver, colon, pancreas and stomach.

Innovations and breakthroughs

This is the first report demonstrating gender-based differences in the basal expression of ERα in the liver that also results in change in ER subtype ratio. In addition to ER subtype expression in the whole liver tissue extracts, subcellular fractionation of liver extracts for expression of ER subtypes, inflammatory and proliferative markers in nucleus and cytoplasm of both, normal and diseased livers, were also evaluated. To our knowledge, this is the first study that correlates the expression of ER subtypes with cyclin D1 in livers of HCV-related cirrhosis and HCV-related HCC.

Applications

Investigating gender associated changes in ER subtype ratio in the liver during the course of HCV-related disease progression along with oncogenic marker expression may help us to monitor gender specific host therapeutic responses, viral clearance and cancer development more effectively. Furthermore, these ER subtype expression studies will further complement existing treatments and pave the way to develop gender and stage-related personalized therapies that are highly needed to treat and manage chronic HCV infections and HCV-related HCC.

Terminology

Cirrhosis of the liver is damage caused by chronic Hepatitis C viral infection. Cirrhosis involves replacement of normal liver tissue with scar tissue that affects liver function and leads to end-stage disease.

Peer-review

Authors investigated ER expression in liver hepatocytes from normal subjects and patients with hepatitis C virus-related cirrhosis and Hepatocellular Carcinoma. The expression of ER subtypes, ERα and ERβ, were evaluated for the first time in relation to gender.

Abstract

AIM

To identify glycosylation-related genes in the HT29 derivative cell line, HT29-MTX-E12, showing differential expression on infection with *Helicobacter pylori* (*H. pylori*).

METHODS

Polarised HT29-MTX-E12 cells were infected for 24 h with *H. pylori* strain 26695. After infection RNA was isolated from both infected and non-infected host cells. Sufficient infections were carried out to provide triplicate samples for microarray analysis and for qRT-PCR analysis. RNA was isolated and hybridised to Affymetrix arrays. Analysis of microarray data identified genes significantly differentially expressed upon infection. Genes were grouped into gene ontology functional categories. Selected genes associated with host glycan structure (glycosyltransferases, hydrolases, lectins, mucins) were validated by real-time qRT-PCR analysis.

RESULTS

Infection of host cells was confirmed by the isolation of live bacteria after 24 h incubation and by PCR amplification of bacteria-specific genes from the host cell RNA. *H. pylori* do not survive incubation under the adopted culture conditions unless they associate with the adherent mucus layer of the host cell. Microarray analysis identified a total of 276 genes that were significantly differentially expressed ($P < 0.05$) upon *H. pylori* infection and where the fold change in expression was greater than 2. Six of these genes are involved in glycosylation-related processes. Real-time qRT-PCR demonstrated significant downregulation (1.8-fold, $P < 0.05$) of the mucin MUC20. REG4 was heavily expressed and significantly downregulated (3.1-fold, $P < 0.05$) upon infection. Gene ontology analysis was consistent with previous studies on *H. pylori* infection.

CONCLUSION

Gene expression data suggest that infection with *H. pylori* causes a decrease in glycan synthesis, resulting in shorter and simpler glycan structures.

Core tip: Few studies on *Helicobacter pylori* (*H. pylori*) infection focus on glycosylation-related genes in the host cells yet key cell-cell interactions are likely mediated through surface glycoconjugates. We use HT29-MTX-E12 cells, a promising and novel model of the stomach epithelium, to investigate the transcriptomic effects of *H. pylori* infection. HT29-MTX-E12 cells produce a thick adherent mucus layer and show a level of pluripotency that gastric cells naturally present and which some other model cell lines do not. Furthermore both *H. pylori* strain 26695 (lacks BabA adhesin) and HT29-MTX-E12 host cells (TLR2-negative) have some features atypical of more common models of *H. pylori* infection.

Glycosylation-related gene expression in HT29-MTX-E12 cells upon infection by *Helicobacter pylori*. *World J Gastroenterol* 2017; 23(37): 6817-6832 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6817.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6817

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a major cause of peptic ulcer disease and chronic gastritis, and is a causative agent for both gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma[1-3]. Gastric cancer is the second most common cause of cancer-related deaths and is the fifth greatest killer worldwide after tuberculosis. Eradication of *H. pylori* infection with antibiotics may cause as much as a 40 % decrease in the cases of gastric cancer[4]. Despite its occurrence in approximately two-thirds of the world's population, infection with *H. pylori* is asymptomatic in the majority of cases. How *H. pylori* manages to establish chronic infection in the hostile environment of the human stomach and to evade a vigorous immune response is not known.

An acute response to *H. pylori* infection is characteristically marked by the induction of interleukin (IL)-8. This is evident in both human biopsies and cell line studies. An acute response is followed by a chronic response which is marked in humans by the production of IgA autoantibodies to IL-8[5]. A rhesus macaque model of *H. pylori* infection showed a dramatic change in gastric epithelial morphology over the first few hours of infection but a restoration of normal morphology within 24 h despite the continued presence of the pathogen[6]. These morphological changes were associated with modified O-glycan structures. It has been shown previously that transcript levels of *B3GNT5* were upregulated upon *H. pylori* infection of gastric cell lines MKN45 and AGS and that overexpression of this gene, associated with glycosylation of glycolipids, led to increased sialyl Lewis x presentation and adhesion of *H. pylori*[7]. Furthermore, host cells in asymptomatic infected human patients appear to modify O-glycans in order to counter the effects of the invading *H. pylori*[8].

H. pylori resides in the stomach where there is a thick adherent layer of mucus. While most invading pathogens are excluded from epithelial surfaces by the mucous layer, *H. pylori* survives in the mucous layer and can penetrate it to attach to the underlying cells. The main mucin components of mucus in the stomach are MUC5AC, MUC6, MUC1 and MUC16[9-11] with *H. pylori* displaying a distinct tropism for MUC5AC[12,13]. Although *H. pylori* may reside in the mucous layer it is through adhesion to the underlying epithelial cells that the bacteria exert their harmful/inflammatory effects. *H. pylori* binds to cells through adhesins, such as BabA that binds Lewis b and H-type 1 antigens on epithelial cell glycoproteins or glycolipids. They can also use the SabA adhesin to bind to sialyl Lewis x and sialyl Lewis a antigens, though this is expected to play a greater part in chronic infection. More recently LabA has been identified which binds to LacdiNAc structures present on MUC5AC[14]. Only a small fraction of *H. pylori* associated with infected cells is found internally[15], instead the bacteria inject the effector protein CagA and subvert host cell signalling[16,17].

Transcriptomic studies, through the use of high density DNA microarrays, have been applied to various aspects of *H. pylori* infection including analysis of human biopsies[18-23], analysis of human tissue after eradication treatments[24,25], the analysis of animal models[6,26,27] and the analysis of various cell

lines[7,28-30]. High variability in the data sets has been attributed to different model systems, different host cells and the diverse nature of the different *H. pylori* strains used.

Human cell lines, isolated from the gastrointestinal tract (GIT), have been commonly used to study *H. pylori* infection. The responses of different gastric cell lines to *H. pylori* infection have been detailed in a recent paper[31]. The HT29 colon cell line and its derivatives have been used frequently as a model of the gastrointestinal tract because the cells are multipotent and can be directed along different paths of selection and differentiation. Some HT29 derivatives have an absorptive (enterocyte-like) phenotype while others have a mucus-secreting (goblet-like) phenotype. This makes HT29 cells particularly suited to the study of glycan structures in the gastrointestinal tract and mucus-associated effects on bacterial infection. The HT29-MTX-E12 (E12) cell line is a HT29 derivative selected on the basis of tight junction formation and adherent mucus production, which has many of the characteristics of a gastric cell[32-36]. In particular, differentiated E12 cells express MUC5AC, MUC1, MUC 6 and only trace amounts of MUC2[35], a composition which more closely resembles the stomach mucin makeup than the intestine.

The aim of this study was to determine the transcriptomic response of the mucus-secreting E12 cells to *H. pylori* infection with special focus on the glycomic response. Because known *H. pylori* adhesins bind glycosylated structures on the cell surface and in the mucous layer and glycosylation is known to play a major role in general host-pathogen and cell-cell interactions, it is of interest to know how glycosylated structures may change in response to infection.

MATERIALS AND METHODS

E12 culture

E12 cells, a kind gift from Per Artursson of the University of Uppsala, were maintained in flasks in complete Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% foetal calf serum (Life Technologies), 2 mmol/L L-glutamine (Life Technologies), 1% nonessential amino acids and antibiotics (penicillin (50 U/mL) and streptomycin (50 μg/mL). Cells (2×10^6) were seeded on transwell filters (0.4 μm pore polycarbonate membrane insert) in 6-well plates. Cells were incubated at 37 ℃ in a humidified 5 % CO_2 atmosphere and media was added every second day. Transepithelial electrical resistance (TEER) measurements were taken at 20 d. Antibiotics were removed from the cells at least 24 h before infection assays.

H. pylori culture

Bacteria (*H. pylori* strain 26695) were plated on Columbia blood agar (Oxoid) and grown for 48 h in a microaerophilic environment using gas packs (Oxoid, BR0038). Bacteria were harvested from plates into Brucella broth, the OD_{600} adjusted to 0.1 and grown in T25 tissue culture flasks at 37 ℃ under microaerophilic conditions with shaking at 70-80 rpm until the OD_{600} reached 0.6. Gram staining of bacterial cultures was used to check coccoid levels were less than 5%. Washed bacteria were resuspended to an OD_{600} of 1.8 with antibiotic-free RPMI.

Infection protocol

On day 20 E12 cells in transwells were washed with HBSS and 2 mL antibiotic-free complete DMEM media was added to the base of each well and 1 mL of RPMI to the apical surface of each well. *H. pylori* do not survive in DMEM[37] but will in RPMI. On day 21200 μL bacteria (6×10^8) were added to each well at a multiplicity of infection (MOI) of 300. Plates were incubated at 37 ℃ for 24 h. Cells were harvested for RNA isolation. Replicate transwells were washed gently with sterile PBS and harvested using trypsin EDTA as described previously[35,38]. Serial dilutions of the trypsinised cells were plated in triplicate on Columbia blood agar plates and incubated under microaerophillic conditions. Colonies were counted after 4-5 d incubation to determine the number of bacteria (CFU/mL) that were associated with the cells. Though some infections resulted in low IL8 transcript levels this did not appear to correlate with low CFU values.

RNA isolation and microarray hybridisation

RNA for microarray hybridisations and qPCR analysis was isolated by TRIzol extraction followed by standard RNA purification protocols (Qiagen). RNA (100 ng) was labelled with biotin using the Affymetrix 3' IVT Express Protocol. All hybridisations were carried out using the hybridisation and wash solutions as recommended in the Affymetrix 3' IVT Express Protocol and were carried out by DNA Vision, Charleroi, BE.

Microarray analysis

Spot intensities provided (DNA Vision) were normalised and analysed in GeneSpring (Ver 12.3). Data were log transformed and quantile normalised. Subsequently all normalised data was baseline transformed to the median of all samples. Intensity values for all entities (54675) were initially filtered to exclude values which were less than 50 in all three samples of both conditions (uninfected, infected). Significantly differentially expressed genes were identified based on log values using an unpaired *t*-test (variance assumed equal)[39], with a FDR cut-off value of 0.05. Multiple test correction was carried using the Benjamini and Hochberg correction. The data discussed in this publication have been deposited in NCBI's Gene Expression Omnibus[40] and are accessible through GEO Series accession number GSE74492 (https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE74492). Where microarray data is

graphed, the raw signals for uninfected samples were the actual spot intensities and for the infected samples the signals were corrected using the fold change determined from normalised data for each gene. Standard deviations are shown for the three samples in each condition using raw spot intensities (uninfected) and raw spot intensities corrected for fold change (infected). Where the microarray data is shown as a log fold change, standard deviations were generated using propagation of errors rules.

For Gene Ontology analysis, DAVID (Database for Annotation, Visualization and Integrated Discovery, v6.7) was used[41] (http://www.david.ncifcrf.gov/). The number of significant genes (6034) was reduced further using more stringent parameters (FDR < 0.01, fold change > 1.2). Where directional analysis was carried out, only the top 500 upregulated genes (FDR < 0.005, fold change > 1.2) were included in the GO analysis and this was compared with whatever number of downregulated genes (714) had *P*-values below the *P*-value of the 500th upregulated gene (FDR = 0.0046) in order to maintain a balanced comparison. GO analysis also excluded GO terms where the number of genes in the GO term was more than 10% of all the genes on the array; this therefore removed broader gene ontology terms which were not generally informative. These restrictions were not imposed for GO analysis of the glycosylation-related genes because of the lower number of genes involved.

qRT-PCR

qRT-PCR validation was carried out on RNAs from samples collected independently of the microarray samples. The RNA samples for qRT-PCR validation were also from several different infections: this adds some of the variability seen in the data and is an issue that is discussed further in the manuscript. For real time qRT-PCR RNA (1 μg) was reverse transcribed using the VILO cDNA Synthesis Kit (Invitrogen) according to the manufacturer's instructions. PCR was carried out using diluted template (2 μL) and GoTaq® qPCR Master Mix (18 μL) on a Mx3000P qPCR System (Stratagene). Cycling conditions for all primer pairs was 95 ℃ for 5 min followed by 40 cycles of 95 ℃ 10 s and 60 ℃ 10 s. Dissociation curves were determined using a temperature gradient from 95 ℃ to 56 ℃. Primer sequences were either retrieved from primer repositories (PrimerBank, https://pga.mgh.harvard.edu/primerbank/ and qPrimerDepot, https://primerdepot.nci.nih.gov/), designed using Primer3 (http://primer3plus.com/web_3.0.0/primer3web_input.htm) or taken from relevant papers (Supplementary Table 1 and references therein). Several primer pairs were tested for their potential as housekeeping genes and geNorm analysis[42] was used to select an optimal set of three genes for subsequent normalisation (*GAPDH*, *RPLP0*, *UAP1*). All fold change values were calculated within geNorm which also generated standard deviations based on the rules for the propagation of errors. Standard two-tailed *t*-tests were used to determine where fold changes were significant. As an approximate measure of gene expression level, cycle threshold (Ct) values determined by qRT-PCR for each gene (uninfected cells) were compared to a Ctmax, in this case *IL32* the lowest expressed of our selected genes

RESULTS

This study investigated the effects of *H. pylori* (strain 26695) colonisation on the transcriptome of E12 cells, a specialised derivative of the HT29 cell line. The cell line forms a functional layer of polarised cells and produces an adherent mucous layer when grown on transwells for 21 d.

Microarray analysis

E12 cells were grown on transwells for 21 d and infected with *H. pylori* strain 26695 at a MOI of 300. Cells were harvested for RNA isolation after incubation at 37 ℃ for 24 h. *H. pylori* maintains viability during infection despite its normal requirement for a microaerophilic environment, possibly as a consequence of close association with the mucous layer surrounding the E12 cells. Microarray analysis of all samples showed separate clustering of infected E12 (n = 3) and uninfected E12 samples (n = 3) (Supplementary Figure 1). The infected samples, originating from triplicate wells in a single infection experiment, clustered very tightly. Although greater variability was seen in the uninfected E12 samples, this is probably because these samples originate from two separate infection experiments.

Confirmation of a global modulation of E12 genes in response to H. pylori *infection*

Statistical analysis of the microarray data suggested significant differential expression of 6034 genes (FDR < 0.05) upon infection. Of these, 276 unique genes (< 5 %) showed fold changes greater than two (see Table 1 for the top 15 upregulated and downregulated genes; Supplementary Table 2 for all 276 genes). GO analysis of a reduced list (2639 genes) of regulated genes (FDR < 0.01, fold change> 1.2) is presented in Figure 1A. This analysis was sensitive to the selected fold change cut-off therefore we considered it appropriate to choose quite a low value (1.2-fold). To provide some additional perspective, GO analysis was repeated separately on the most significantly upregulated and downregulated genes (data not shown). This analysis gave an idea of the direction in which each significant process (as shown in Figure 1A) was regulated. GO analysis of the top 500 upregulated genes (FDR < 0.005, fold change > 1.2) revealed

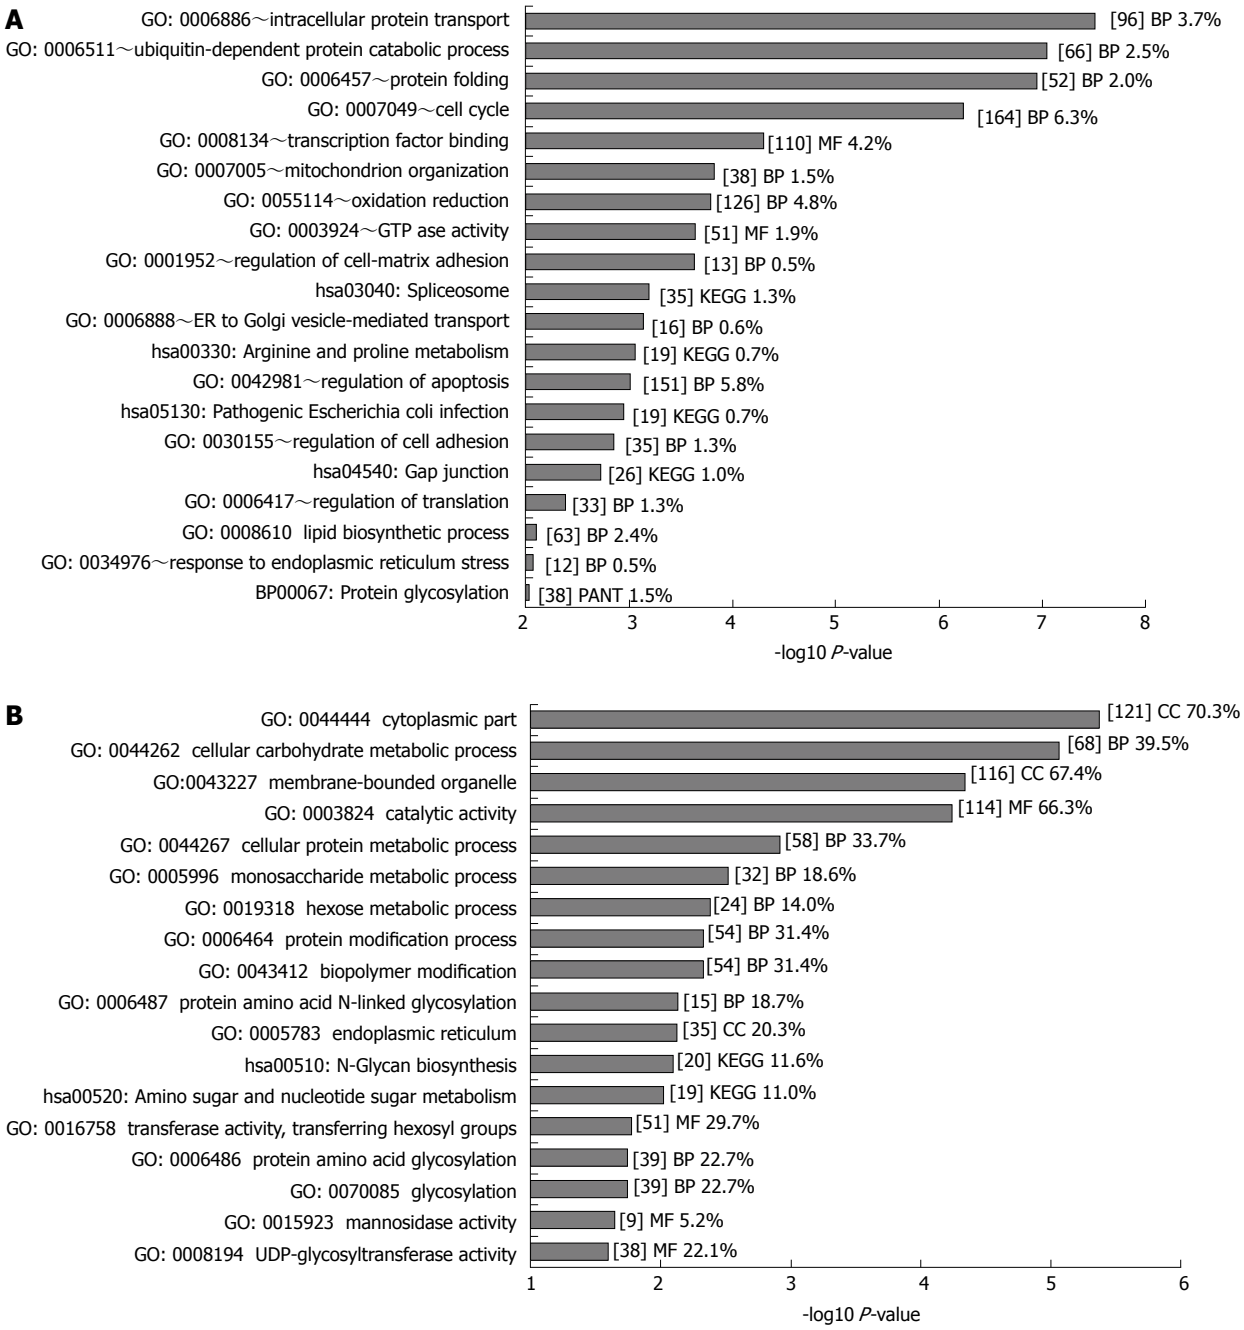

Figure 1 GO analysis of significant differentially expressed genes. A: GO analysis of 2639 genes deemed significantly differentially expressed ($P < 0.01$, fold change > 1.2) was carried out in DAVID. Only GO terms with a *P*-value below 0.01 are shown (-log10 *P*-value > 2). GO terms were excluded where the number of genes belonging to that GO term exceeded 10% of all genes. B: GO analysis of 374 significantly differentially expressed glycosylation-related genes ($P < 0.001$) was carried out in DAVID. Only GO terms with a *P*-value below 0.1 are shown (-log10 *P*-value > 1). Some Panther (PANT) gene ontology and KEGG pathway terms were included from the DAVID analysis. The number of genes included in each term is given within square brackets [ ] together with the percentage of significant genes relative to the total number of genes of that term on the array. BP: Biochemical process; MF: Molecular function; CC: Cellular component.

significant processes related to protein ubiquitination, protein folding, cell redox homeostasis, oxidative phosphorylation and the mitochondrial membrane. GO analysis of the top downregulated genes (FDR = 0.005, fold change > 1.2, 714 genes) revealed significant processes associated with ECM-receptor interaction, focal and cell adhesion, phosphorylation and modulation of the cytoskeleton. Some GO processes included genes with approximately equal numbers of up and downregulated genes: these additional GO terms included Golgi vesicle mediated transport, dolichol-linked oligosaccharide biosynthetic processes, phosphorylation-related signalling, apoptosis, cell junction function, molecular adaptor activity, cell cycle, transcription, antigen presentation and apical junction complex. These terms are consistent with the reported effects of *H. pylori* on cells and therefore support our supposition that the observed effects on glycosylation,

[1]qRT-PCR analysis showed *CLIP1* was downregulated.

the focus of this study, relate to infection by *H. pylori*.

Modulation of glycosylation-related genes in response to H. pylori infection

In order to study changes in the glycome of E12 cells upon *H. pylori* infection we examined those gene probes on the Affymetrix U133 Plus 2 Array that were associated with a glycosylation role, selected with reference to the Consortium for Functional Glycomics (CFGv3) array. We identified 170 significantly differentially expressed genes upon *H. pylori* infection that were glycosylation related (see Table 2 for the top 20 upregulated and downregulated genes; Supplementary Table 3 for all 170 genes). Only 6 (< 4 %) of these genes showed fold changes greater than 2-fold. The most upregulated gene from the microarray analysis was *LGALS7/7B*, (lectin, galactoside-binding, soluble, 7/7B, 2.3-fold) and the most downregulated gene was *REG4* (regenerating islet-derived family, member 4, 2.5-fold) followed by *OGT* (O-linked N-acetylglucosamine (GlcNAc) transferase, 2.2-fold) and *AMIGO2* (adhesion molecule with Ig-like domain 2, 2.2-fold). These small changes in glycosylation-related genes are not uncommon in significant processes that involve glycosylation[7,43].

GO analysis of differentially regulated glycosylation-related genes was referenced against this Affymetrix array-derived glycome to determine which GO terms, relevant to glycosylation, were significant in the *H. pylori* infected E12 cells (Figure 1B). The most relevant terms were nucleotide sugar metabolism, N-glycan biosynthesis, cell death and galactose metabolic process, all of which generally related to upregulated genes, and hexose metabolic process, mannosidase activity and UDP-glycosyltransferase activity, which related to downregulated genes (Figure 1B).

Changes in terminal sugars of E12 glycoconjugates upon H. pylori infection

Microarray signal strength is not a robust measure of gene expression because probes bind with different affinities to the array. However, fold change measurements are robust because the same probe is used to compare two conditions. In this and the following sections the fold change differences between infected and uninfected gene levels are therefore quantitative. However, this data alone omits useful information about the expression level of one gene relative to another, always bearing in mind that two probes could have very different binding efficiencies for

the array. In Figure 2, where three selected groups of glycosylation related genes are presented, a gene has only been included if microarray analysis showed that it was either significantly differentially expressed or that it was represented on the array by more than one probe. In addition a signal strength cut-off was set to 20 to exclude weak genes which were less likely to be relevant (though technically significant in the original analysis). For sialylation (Figure 2A) *ST6GALNAC1*, *NEU1*, *SLC35A1*, *ST3GAL5* and *NANP* were significant but because they were each represented by only one probe their absolute expression levels relative to the other genes shown may be less representative. Where a gene was not significant but represented by multiple probes (*e.g.*, *ST3GAL2*), the data was considered sufficiently reliable to warrant presenting expression levels relative to the other genes.

Terminal glycosylation of cell surface glycoconjugates directly determines the interaction of bacteria with the host cell. Therefore, sialylation and fucosylation were expected to be key processes affected by *H. pylori* infection. Terminal sialylation of glycoconjugates is a consequence of sialyltransferase expression and therefore can be predicted based on the transcript expression levels of the sialyltransferase enzymes from the microarray data. *ST3GAL4*, which can sialylate most glycoconjugate types and is believed to be involved in sialyl Lewis x and sialyl T antigen formation, was significantly downregulated (1.7-fold) whereas *ST3GAL5*, which is involved in ganglioside GM3 synthesis in glycolipids, was significantly upregulated (1.9-fold) on *H. pylori* infection (Figure 2A). *ST6GALNAC1* (down, 1.3-fold) and *ST6GALNAC4* (up, 1.8-fold) were also significantly differentially

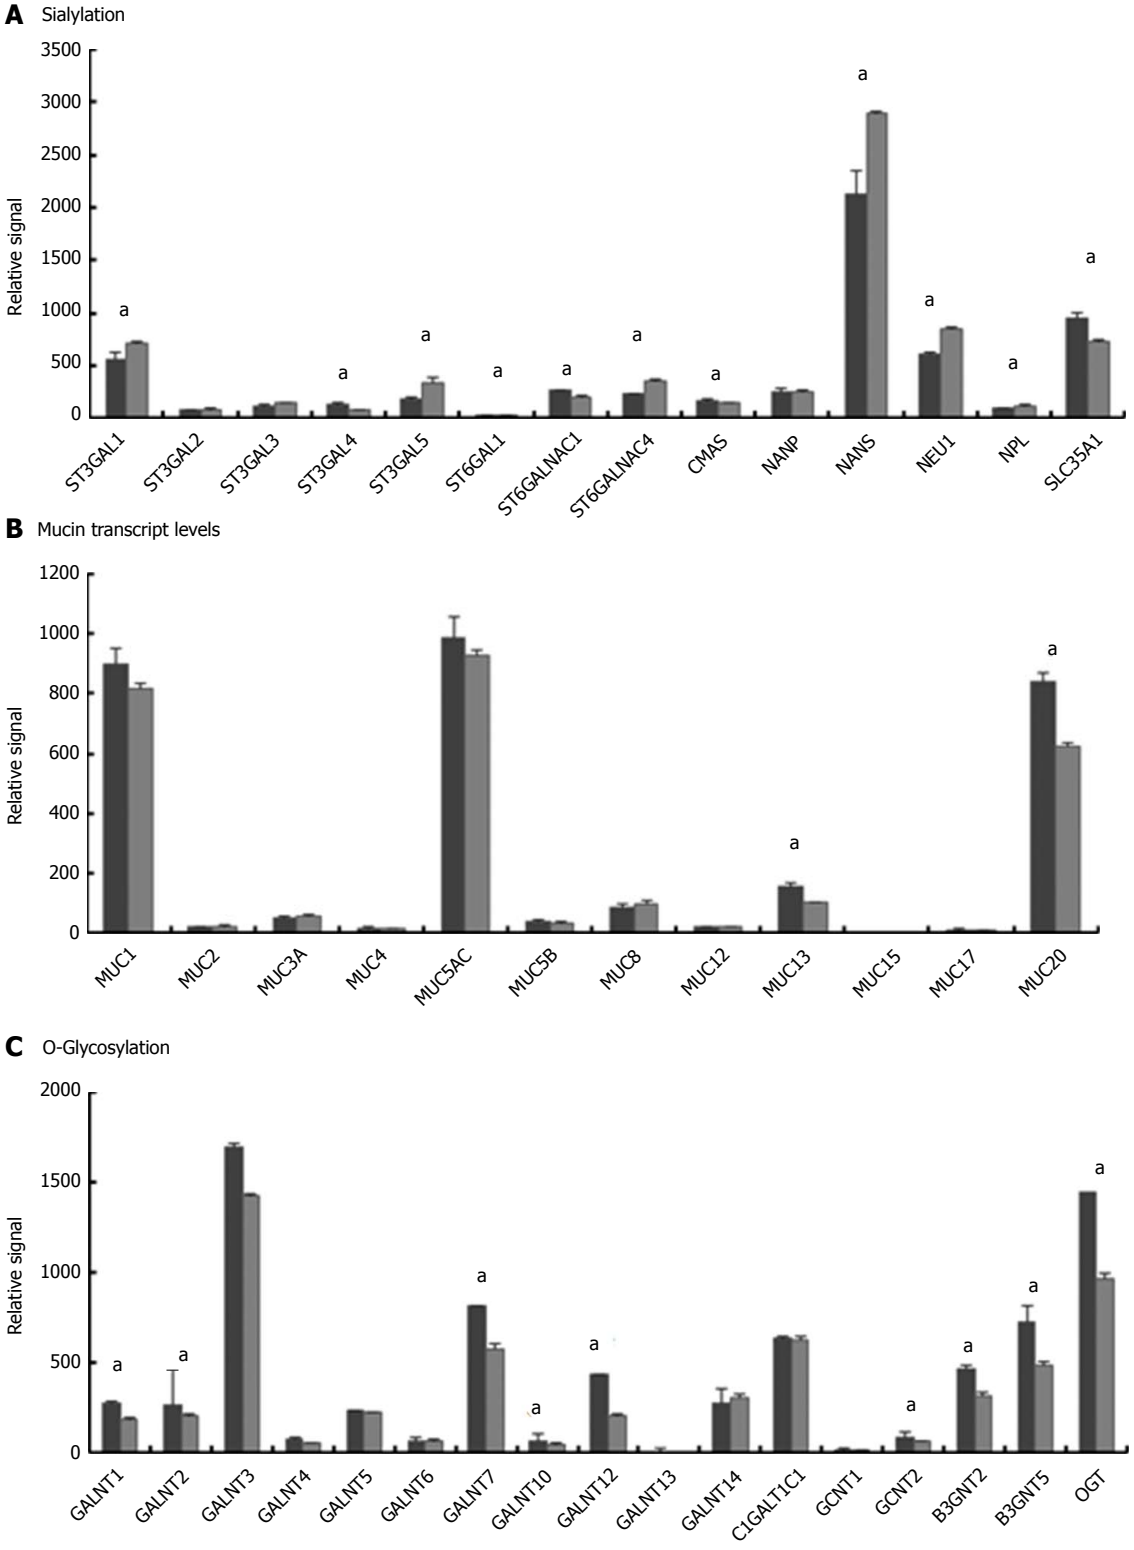

Figure 2 Transcript levels determined by microarray analysis of selected glycosylation related processes. A: Sialylation-related genes; B: Mucin genes; C: O-glycosylation genes. Raw signals reported for each gene were the strongest signals where multiple probes were available (except for MUC2 where the negligible signal from the single probe, indicating very weak expression, was confirmed by qRT-PCR). All signals for uninfected samples were raw values whereas all infected samples were extracted using fold change values of normalised data as detailed in Materials and Methods. Uninfected (dark grey) or Infected (light grey). Error bars show standard deviations (n = 3). ([a]FDR < 0.05).

expressed upon *H. pylori* infection. *ST6GALNAC4* is involved in the biosynthesis of ganglioside (GD1A from GM1B) and the transfer of NeuAc to GalNAc residues of O-glycans to form the stunted sialyl Tn antigen. Based on signal intensities, ST3GALs 2-5 were all moderately expressed (raw control intensity < 500), *ST3GAL1* was highly expressed (> 500) and *ST3GAL6* was negligibly expressed (< 10). ST6GALs were lowly

(< 50) (*ST6GAL1*) to negligibly expressed (*ST6GAL2*) and all ST8SIAs (1-5) were also negligibly expressed. This is in line with the predominance of NeuAcα2-3Gal linkages over NeuAcα2-6Gal in HT29 cells[44] and the predominance of O-glycans over N-glycans. The overall effect to be expected is therefore one of increased sialyl Tn antigen, decreased sialyl Lewis x/a determinants on glycoproteins with potential effects on glycolipids. This may result in shorter glycan chains and may affect packing density because some GALNTs require recognition of neighbouring GalNAc residues, now increasingly masked by sialylation, to initiate new glycan chains.

Although a number of fucosyltransferases (*FUT1, FUT3, FUT4, FUT5, FUT6* and *FUT11)* were moderately expressed, only *FUT1* was upregulated significantly (1.2-fold) upon *H. pylori* infection (data not shown). This would suggest no major role for fucosylation in the E12 response to *H. pylori* infection. *FUCA1* is a lysosomal fucose hydrolase. Its strong expression and upregulation on infection (1.2-fold) might suggest net removal of surface expressed fucose residues.

Changes in O-glycosylation upon H. pylori infection

As stated above, E12 cells produce a copious adherent mucous layer of which the main components are O-glycans. The data presented here show expression of *MUC5AC, MUC1, MUC20* and *MUC13*. Only *MUC13* and *MUC20* were significantly downregulated (Figure 2B). *MUC5AC* was represented by two high signal probes on the array but neither showed any change upon *H. pylori* infection. (It is noted that *MUC5AC* appears as a significantly upregulated gene (1.2-fold) in Supplementary Table 3, however, this probe produced only a weak signal).

Mucin O-glycosylation initiates with the transfer of N-acetylgalactosamine (GalNAc) to a Ser/Thr residue on the protein catalysed by the polypeptide N-acetylgalactosamine transferases (GALNTs). Of 14 GALNTs represented on the array all 5 that were significant were downregulated upon *H. pylori* infection - *GALNT1* (1.5-fold), *GALNT2* (1.3-fold), *GALNT7* (1.4-fold), *GALNT10* (1.4-fold) and *GALNT12* (2.1-fold) (Figure 2C). *GALNT12* is believed to be involved in the initial glycosylation of MUC5AC and MUC1 but not of some other mucins[45]. It has different activities towards already glycosylated MUC5AC and MUC1 peptides suggesting that its activity may determine packing density of multiple O-linked glycans and that specifically glycan density may be reduced on *H. pylori* infection where *GALNT12* appears downregulated. Sialylation of the polypeptide-linked GalNAc by ST6GALNACs may also change the recognition of initiation sites by specific polypeptide GalNAc transferases. Changes in O-glycan initiation have been reported previously in serum proteins of patients with gastric carcinoma[46]. Differential expression of GalNAc transferases in gastric cancer cell lines and gastric carcinoma may be associated with occupancy of potential O-glycosylation sites in mucins[47,48]. GalNAc transferase expression has been reported to be variable among gastric cell lines with GALNTs 1, 2 and 3 showing ubiquitous expression while other GalNAc transferases show more restricted expression[49].

No genes coding enzymes that have the potential to produce core 1 to core 8 O-linked glycan structures were significantly regulated upon *H. pylori* infection. *C1GALT1* and *C1GALT1C1 (COSMC)* were expressed at moderate and high levels respectively based on signal intensities suggesting the likely presence of core 1 structures on E12 O-glycans. Extension of the core structures by B4GALTs and B3GNTs seemed likely with moderate expression of several B4GALTs and B3GNTs. The galactose transferases and N-acetylglucosamine transferases that were significantly downregulated were those more often associated with N-glycan (*B4GALT5,* 1.5-fold; *B4GALT1*, 1.2-fold) or glycosphingolipid synthesis (*B4GALT5*, *B4GALT1* and the strongly expressed *B3GNT5*, 1.5-fold). We detected downregulation of *B3GNT5* and *B3GALT5* whereas a gastric biopsy study showed upregulation of the same genes[50]. The downregulated *B3GNT2* (1.4-fold) is commonly involved in polylactosamine

synthesis so may be involved in N-glycans, O-glycans and/or glycosphingolipids. The other common form of non-mucin O-glycosylation in E12 cell glycoconjugates initiated by O-GlcNAc protein glycosyltransferase was significantly downregulated on *H. pylori* infection (*OGT*, 2.3-fold) according to microarray data (Supplementary Table 3).

Changes in N-glycosylation upon H. pylori infection

N-glycosylation can be split into the lipid-linked oligosaccharide (LLO) precursor synthesis process generating $Glc_3Man_9GlcNAc_2$ and the processes of trimming and extension. There was a general upregulation of the genes involved in the LLO step except for *ALG13* which instead showed downregulation. *ALG13* showed the largest fold change (1.8-fold, Table 2) of all the genes involved in LLO precursor synthesis. There was a general downregulation of the genes involved in trimming and extension. All mannosidases, most moderately expressed, were downregulated (Supplementary Table 3) and one, MAN2A2, was consequently confirmed by qPCR (below).

The significance of changes in N-glycosylation in an O-glycan-dominated environment is unclear. Also, whether the altered N-glycans are on mucins, other transmembrane glycoproteins, or both, cannot be determined from the available data. It has been suggested previously that LLO-precursor synthesis could be a constitutive process where precursors are available in excess and control is elsewhere[51]. *ALG13* may, however, play a key role because it showed the largest fold change of all the genes in the precursor synthesis pathway, it was *down*regulated unlike other genes in the LLO-precursor synthesis pathway and interestingly it adds on the first GlcNAc of the LLO-precursor. Downregulated mannosidases (*MAN2A1*, 1.9-fold; *MAN1A1*, 1.5-fold; *MAN2B2*, 1.3-fold) are suggestive of an overall reduction of trimming and an increased level of the $Man_9GlcNAc_2$ glycan. Overall the effects suggest shorter and less complex N-glycan chains following *H. pylori* infection.

Changes in availability of activated sugars upon H. pylori infection

Glycan synthesis could be limited by changes in the abundance and availability of activated sugars. The UDP-galactose (*SLC35A2*, 1.3-fold; *SLC35B1*, 1.5-fold) and GDP-fucose (*SLC35C2*, 1.3-fold) transporters were significantly upregulated while the CMP-sialic acid (*SLC35A1*, 1.3-fold) and UDP-GlcNAc (*SLC35A3*, 2.1-fold) transporters were downregulated upon infection (Supplementary Table 3). The UDP-Gal, UDP-GlcNAc and CMP-sialic acid transporters were all strongly expressed while the GDP-fucose transporter was moderately expressed. N-Acetylneuraminic acid synthase (*NANS*) was very strongly expressed and significantly upregulated on infection (Figure 2A). This suggests the availability of Neu5Ac, however, the downregulation of both *SLC35A1* and *CMAS* expression (though marginal) (Figure 2A) would possibly make a subsequent rise in activated Neu5Ac (CMP-Neu5Ac) levels seem less likely. Increased levels of sialidase (*NEU1*) may lead to cell shedding of sialylated epitopes with a compensatory switch on of Neu5Ac biosynthesis (Figure 2A). GO analysis had indicated the significance of hexose and, more specifically, galactose metabolism. All significant galactose metabolism enzymes were upregulated as were all significant mannose metabolism enzymes. All significant fucose metabolism enzymes were downregulated as were all sialic acid metabolic enzymes.

Modulation of lectin levels upon H. pylori infection

The two LMAN lectins *LMAN1* (1.5-fold down) and *LMAN2* (1.6-fold up) were expressed strongly and differentially (Supplementary Table 3). Both lectins are expressed in the endoplasmic reticulum and Golgi body and are believed to be involved in N-glycan sorting and recycling. Of the Gal binding lectins, *LGALS1* (1.4-fold) and *LGALS7* (2.3-fold) were both upregulated significantly, and *LGALS2* (1.6-fold) and *LGALS8* (1.4-fold) were both downregulated significantly, all being expressed at moderate levels (Supplementary Table 3). *LGALS7* is a myoepithelial cell marker, associated positively with cancer progression and metastasis, while *LGALS8* is involved in integrin-like cell interactions and is negatively associated with malignancy. The opposite regulation of *LGALS7* and *LGALS8*, therefore, is consistent with an altered cell phenotype. *LGALS3* and *LGALS4* were expressed very strongly (raw signal >5000) but not differentially upon infection according to microarray data. Where oligosaccharide chains are not terminated with sialic acid, the major exposed sugar is galactose. It might therefore be relevant that two Gal binding lectins (LGALs) were expressed very strongly (*LGALS3* and *LGALS4*) and four others were significantly regulated upon infection. Most other lectins (CLECs, collectins, selectins, siglecs) were either weakly or negligibly, but not differentially, expressed.

qRT-PCR validation of prediction changes in gene expression level

qRT-PCR validation was carried out on RNA from samples collected independently of the microarray samples and from several different infection experiments in an effort to identify variability between infections. qRT-PCR analysis was carried out on a selected set of genes. Initially two non-glycogenes (*PDK4*, *CLIP1*) were selected based on the maximum fold changes observed on the microarray. *PDK4* expression was confirmed as downregulated though with a smaller fold change. It was shown subsequently that *CLIP1* was not upregulated though initial microarray analysis had suggested upregulation. Only one (1558924_s_at) of six *CLIP1* probes on the array

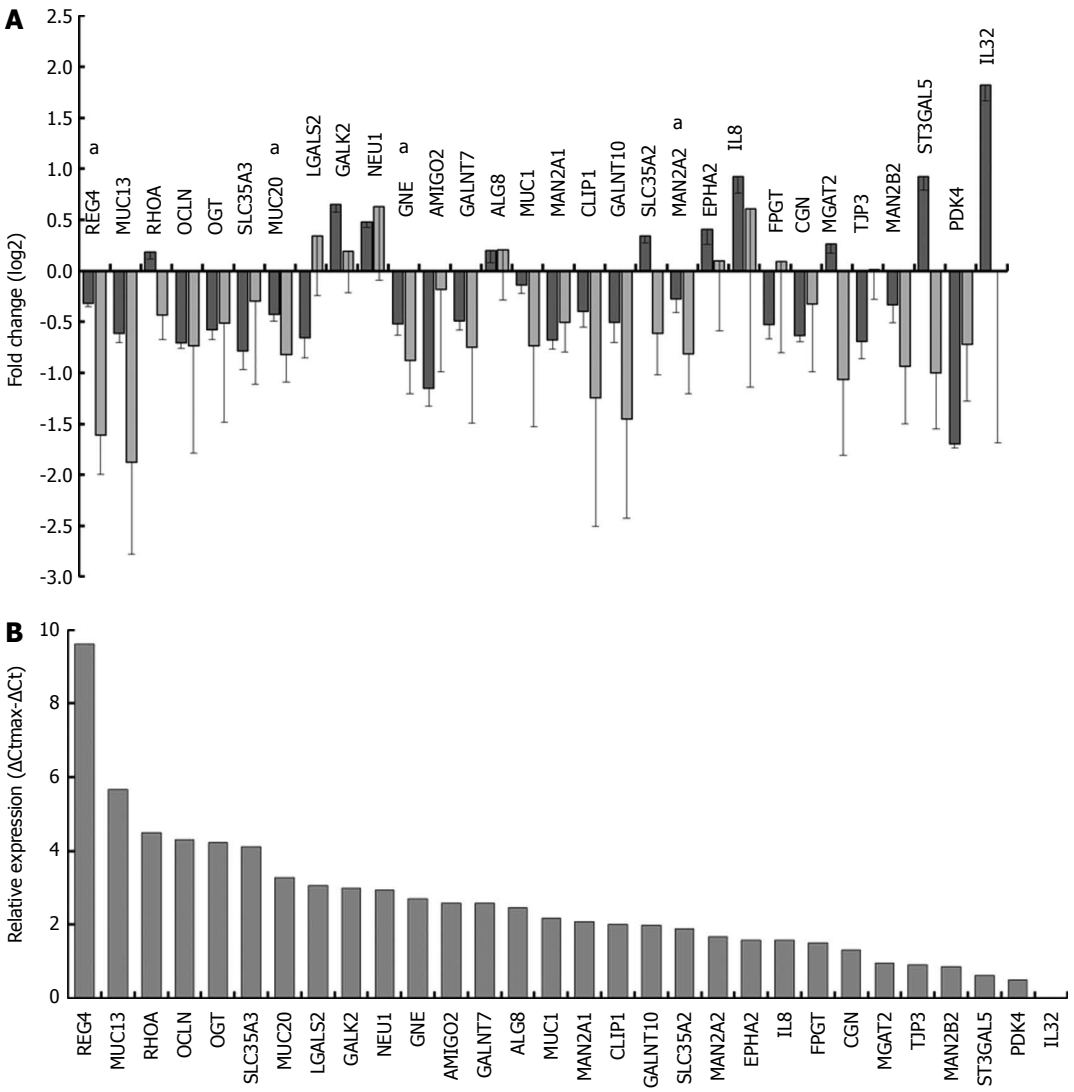

Figure 3 qRT-PCR validation of selected genes. Differential expression of selected genes upon *Helicobacter pylori* (*H. pylori*) infection of E12 cells was compared between microarray (dark grey) and qRT-PCR (light grey) analyses. qRT-PCR validation was carried out on RNAs from samples collected independently of the microarray samples. A: Microarray data (n = 3) was normalised across samples with GeneSpring. qRT-PCR data (n = 3) were normalised using geNorm and a panel of three housekeeping genes. Error bars show standard deviations determined using propagation of error rules; B: Relative expression of each gene in uninfected E12 cells was estimated by qRT-PCR using ΔCt determinations. ΔCtmax was the ΔCt for the lowest expressing gene (IL32) after correcting Ct values across samples with the housekeeping gene GAPDH. Further details are given in Materials and Methods. All genes were significantly differentially expressed in microarray analysis and genes marked with asterisks (a) were confirmed significant by qRT-PCR.

suggested upregulation: a probe producing a much higher intensity signal (201975_at) instead suggested 1.3-fold significant downregulation and it is this probe that correlated with the qRT-PCR analysis (Figure 3). In general *H. pylori*-infected samples showed qRT-PCR-corroborated upregulation of *IL8* and downregulation of *REG4* (Figure 3A), though the upregulation of *IL8* (and *IL32*) was highly variable across samples (see Supplementary Figure 2) resulting in an absence of significance. The stomach mucin *MUC1* showed no significant change in expression by either microarray analysis or qRT-PCR. This was true also for *MUC13*, a gene found at low levels in normal gastric mucosa but often expressed in metaplasia[52,53]. These two genes did however show consistent (not significant) downregulation in both microarray analysis and qRT-PCR. A third mucin gene, *MUC20*, was shown to be significantly downregulated (1.4-fold). *MUC5AC* showed no significant expression change based on microarray data (Figure 2B) or in a preliminary screen by qRT-PCR (data not shown). qRT-PCR did not corroborate regulation of a number of genes where the expected fold changes by microarray analysis were less than 2 (*LGALS2*, *ST3GAL5*, *MGAT2, FPGT* and *SLC35A2*).

Four genes (*REG4*, *MUC20*, *GNE* and *MAN2A2*) showed significant differential regulation by qRT-PCR (P < 0.05), and others approached significance (P < 0.1 - *MAN2B2, SLC35A2*, *RHOA*; P < 0.2 - *TFF1*, *ST3GAL5* and *PDK4*) (Table 3). The absence of significance in some cases was partly due to the small fold changes detected both by microarray and qRT-PCR analyses,

but it was also due to variability in the samples used for qRT-PCR. In several cases one of the three uninfected samples behaved differently from the other two. This was very striking for the interleukins *IL8* and *IL32*, and for *TFF1* which showed high downregulation (10.4-fold) on infection, but was not significant because one uninfected sample (3 in Supplementary Figure 2) showed much lower levels than the other two uninfected samples (1 and 2, Supplementary Figure 2). Hierarchical clustering (Pearson correlation with average linkage clustering) clearly shows the inconsistency across the qRT-PCR samples (Supplementary Figure 2) and how inconsistent genes cluster with other inconsistent genes suggesting a biological rather than a technical reason for this variability. This anomalous behaviour in the uninfected samples had also been seen in the microarray analysis. A small cluster of seven genes including all of the MUC genes assayed and *GALNT10*, suggests some common regulatory feature. *REG4*, *TFF1* and *ST3GAL5* also formed a tight cluster (Supplementary Figure 2).

DISCUSSION

A recent study of gastric cell lines has shown a wide range of responses to *H. pylori*[31]. Commonly used cell lines differ in their ability to polarise, to maintain a stomach-like epithelial morphology and differ in their pattern recognition receptors. *H. pylori* is, for the most part, a non-invasive bacterium that colonises the mucous layer surrounding the stomach and does not survive without this mucous layer. We have chosen for our study the HT29 derivative E12 cells because they produce an adherent mucous layer and the cells support *H. pylori* infection while the parent HT29 cells do not support *H. pylori* infection[36]. The main mucin components of the stomach mucous layer *in vivo* are the secreted gel-forming mucin, MUC5AC, and the cell surface mucin, MUC1. Other mucins include MUC4, MUC12, MUC13 and MUC6[54]. E12 cells have been shown by immunofluorescent methods to express high levels of MUC5AC and MUC1, and to a lesser extent MUC2[35]. The transcriptomic data presented here show expression of *MUC5AC*, *MUC13*, *MUC1* and *MUC20* with little or no expression of either *MUC2* or *MUC6*. E12 cells have therefore a mucin profile approximating that of the stomach and provide a good model for *H. pylori* infection studies.

The cellular response to pathogenic organisms is orchestrated by Toll-like receptors (TLRs). Strong evidence suggests that *H. pylori* infection is TLR2-mediated[55-57] yet there is some evidence that TLR4 is involved[58,59]. E12 cells however produce the hallmark response of IL-8 production upon *H. pylori* infection despite being TLR2 negative. The cellular response will also be determined by the receptor/adhesin characteristics of the host-pathogen interaction. Some *H. pylori* strains can bind to cells through the BabA adhesin which binds to the fucosylated Lewis b antigens on epithelial cell surface glycoconjugates[60,61]. Strain 26695, used throughout this study, possess an active *cag* pathogenicity island (PAI) associated with virulence[62] yet it has an inactive BabA adhesin[36]. Furthermore, fucosylated structures are relatively scarce on mucins secreted by E12 cells[36]. Therefore in this infection system the BabA adhesin interaction with Lewis antigens is not a factor in the IL-8 response to *H. pylori* and other *H. pylori* adhesin-host cell receptor combinations[63] are likely to play a role in mediating these responses.

Expression patterns of *H. pylori*-infected and uninfected E12 cells indicated variability especially in the uninfected E12 cells. The reasons for this are unclear. It might suggest that some E12 cells did not fully differentiate to form a fully polarised cell layer. However, TEER measurements were consistently high (about 600 Ω/cm^2) across all uninfected samples and could not differentiate E12 subpopulations. E12 cells, like the parent HT29 cells, are not a clonal population[64,65]. It has been shown that E12 cells show the occasional MUC2-expressing cell and that these cells can be expanded under the appropriate conditions[34]. It may therefore be that random samples contain differing proportions of cell types and so produce different expression profiles. It is likely that clonal cell lines would give more consistent results, however, we would argue that *in vivo* cells lining the stomach are not clonal, and therefore that non-clonal E12 cells may better reflect variation that is present *in vivo*.

Infection of the E12 cells was confirmed in this work by the presence of *cagA* RNA in exposed cells (data not shown). All significant expression changes on *H. pylori* infection were small with only 4%-5% being greater than 2-fold. This has been noted previously in similar experiments with *H. pylori* infection. The altered expression of glycosyltransferases and other glycosylation-related genes identified in this study is different in some specifics to that seen in related studies. This could be because E12 cells are derived from the colon where similar studies of *H. pylori* infection have used gastric cell lines[7,28,29]. But variability in gene expression response is also seen across gastric cell lines possibly as a result of differences in mucin presentation. We would therefore argue that E12 cells, with their gastric-like mucin composition, constitute a valid model of *H. pylori* infection. Although the expression of specific genes did not correspond with that seen in similar studies, gene ontology terms were in general agreement suggesting that, in the broader functional picture, there are strong similarities across the different *H. pylori* infection studies. Variability in gene response could equally be due to the choice of *H. pylori* strain.

One consistently downregulated gene was *REG4*, a 17 kD secreted C-type lectin, expressed in selected

enteroendocrine cells throughout the GIT and some goblet cells[66]. The functional role of REG4 is still unclear though it appears to be coexpressed with various enteroendocrine hormones. Although it is reportedly not expressed in normal stomach tissue, it is expressed, and has potential as a biomarker, in gastric carcinoma[67]. qPCR confirmed microarray data that expression of the *REG4* transcript was very high. Why this should be in E12 cells is unclear. It could be a manifestation of the colonic origins of HT29/E12 cells, or of the selection process for generating the E12 derivative, or it may be related to the high mucin production of this cell line. Another member of the REG family, REG3γ, has been shown to be intimately involved in the mucous layer protecting the underlying epithelial cells from bacterial colonisation[68] but there is no evidence yet that REG4 has any anti-bacterial activity.

The overall shortening of O-glycans and the decreased complexity of both N- and O-glycans that this study suggests follow *H. pylori* infection may be driven by the infecting bacteria in their efforts to ease access through the mucus to the underlying enterocytes. It could equally be a host cell response to reduce potential bacterial adhesion sites or a way to facilitate shedding of the mucous layer and the attached bacteria. The results presented from the E12 model will require confirmation by detailed oligosaccharide analysis. Alternative approaches, such as lectin histochemistry or direct biophysical analysis of released glycans from glycoproteins and glycolipids, may not be able to detect the responses seen at the transcriptomic level because of overlapping specificities of lectins. However, it is of interest that the results presented are consistent with the Rhesus Macaque *in vivo* model of *H. pylori* infection[6] and with the analysis of adherent mucins isolated from asymptomatic *H. pylori* infected patients[8].

In conclusion, E12 cells are a promising model of the stomach epithelium; the cells form tight junctions, they polarise, they produce a thick adherent layer of mainly MUC5AC and have a mucin composition similar to that of the stomach. The glycosyl transferase gene expression profiles suggested core 1 and core 2 extended structures on O-glycans, with little or no core 3-8 structures, which is consistent with mass spectroscopy studies of isolated E12 glycoproteins. This study has shown that *H. pylori* infection increased expression of some sialyltransferases which may lead to shortened O-glycan chains. Furthermore, differential changes to various ppGalNAc transferase transcripts (mainly downregulation) suggested effects on O-glycan packing density and O-glycan site occupancy. The enzyme profiles would also suggest a change in N-glycan structures upon infection to more high-mannose and less complex oligosaccharides. Such changes may not affect the overall glycocalyx since it is so O-glycan dominated but could affect specific N-glycoproteins. Many of the transferase enzyme transcripts that are regulated upon *H. pylori* infection have a noticeable preference for glycolipids which is consistent with the presence of Lewis b ligands on glycolipids rather than glycoproteins in E12 cells[36]. While the overall changes to glycosyltransferase transcripts upon infection were small, small changes in enzyme activities that determine physicochemical properties of the mucus and the range of exposed epitopes could lead to profound effects on the phenotype of these infected cells.

ACKNOWLEDGMENTS

We would like to thank Aislinn Slater for technical assistance and also acknowledge the late Prof Anthony Moran for his early input into this project.

COMMENTS

Background

Key pathogen-host cell interactions are likely mediated through the glycan components of surface glycoproteins and glycolipids. *Helicobacter pylori* (*H. pylori*) is protected in the harsh environment of the stomach by the mucus layer of the gastric epithelium. Here we have used a HT29-derivative cell line that secretes a thick adherent mucus layer. This study explores changes in host cell gene transcription, specifically the genes that code mucins, glycosyltransferases, glycosyl hydrolases and lectins that may be associated with *H. pylori* infection.

Research frontiers

H. pylori infections are currently effectively cleared by antibiotics, however, the occurrence of antibiotic resistant strains is increasing and it is inevitable that new treatments will need to be developed. Understanding the key interactions between host and pathogen will drive the development of new drugs possibly analogues of surface sugars such as sialic acid and fucose.

Innovations and breakthroughs

Different strains of *H. pylori* display different levels of virulence. Some strains of *H. pylori* bind *via* BabA adhesins to Lewis antigens on the host cells and the host response is mediated through the TLR2 receptor. Here they use a common virulent strain (26695) that does not present one of the typical adhesins (BabA) commonly involved in *H. pylori* adhesion.

Applications

Changes in glycan structure on host cells in response to *H. pylori* infection will be changes initiated by the host to fight off infection and changes in the host induced by the infecting bacteria. By understanding which enzymes are involved in these host and pathogen modified glycan structure changes, it may be possible to design specific inhibitors of these enzymes.

Terminology

Transepithelial electrical resistance is a measure of the integrity of a cell layer and indicates that tight junctions have formed between cells.

Peer-review

This is a well written manuscript that attempts to identify genes significantly differentially expressed upon *H. pylori* infected in the HT29 derivative cell line by using microarray analysis and qRT-PCR analysis.

Abstract

AIM

To elucidate the role of STAT3 in hepatocarcinogenesis and biliary ductular proliferation following chronic liver injury.

METHODS

We investigated thioacetamide (TAA)-induced liver injury, compensatory hepatocyte proliferation, and hepatocellular carcinoma (HCC) development in hepatic STAT3-deficient mice. In addition, we evaluated TAA-induced biliary ductular proliferation and analyzed the activation of sex determining region Y-box9 (SOX9) and Yes-associated protein (YAP), which regulate the transdifferentiation of hepatocytes to cholangiocytes.

RESULTS

Both compensatory hepatocyte proliferation and HCC formation were significantly decreased in hepatic STAT3-deficient mice as compared with control mice. STAT3 deficiency resulted in augmentation of hepatic necrosis and fibrosis. On the other hand, biliary ductular proliferation increased in hepatic STAT3-deficient livers as compared with control livers. SOX9 and YAP were upregulated in hepatic STAT3-deficient hepatocytes.

CONCLUSION

STAT3 may regulate hepatocyte proliferation as well as transdifferentiation into cholangiocytes and serve as a therapeutic target for HCC inhibition and biliary regeneration.

Core tip: Cell transdifferentiation has been identified as one of the crucial sources of organ regeneration. In liver regeneration, both mature hepatocytes and cholangiocytes have been shown to transdifferentiate to each other to maintain hepatic homeostasis. Although STAT3 has been also shown to be implicated in cellular differentiation, the differentiative role of STAT3 in liver regeneration remains unknown. In this study, we found that hepatic-STAT3 deficiency promoted biliary ductular proliferation with upregulation of Yes-associated protein (YAP)/sex determining region Y-box9 (SOX9), crucial regulators of transdifferentiation, in liver injury of mice. This work suggests that STAT3 determines liver cell fate regulating YAP/SOX9 in liver regeneration.

INTRODUCTION

Interleukin (IL)-6 family cytokines are indispensable to liver regeneration. The Janus kinase/signal transducers and activators of transcription (JAK/STAT3) pathway is thought to play the central role in signal transduction mediated by IL-6 family. Several target genes of STAT3 have been identified; these genes include *cyclin D, c-myc, bcl-xL*, and *mcl-1*, which are essential for cell proliferation and survival. In murine models of liver injury, ablation of STAT3 in liver results in enhanced liver injury and reduced liver regeneration[1]. These findings suggest the protective and proliferative roles of STAT3 in liver regeneration. In addition, STAT3 has been implicated in cellular differentiation, and its activation is associated with differentiation of T cells and macrophages[2]. Studies have demonstrated that STAT3 is essential for the maintenance of pluripotency of embryonic stem (ES) cells[3,4] and self-renewal of tumor-initiating cells in the liver[5]. However, the differentiative role of STAT3 in liver regeneration is questionable.

Both cholangiocytes and hepatocytes are derived from hepatoblasts generated in the foregut endoderm during liver development. The bipotential hepatobiliary stem/progenitor cells, such as small hepatocytes and oval cells, have been shown to exist in adult liver and are thought to contribute to liver regeneration[6]. On the other hand, previous reports have revealed direct transdifferentiation between hepatocytes and cholangiocytes in chronic liver damage[7,8]. Cholangiocytes transdifferentiate into hepatocytes and replenish massive hepatocyte loss[9]. In reverse, cholangiocytes were shown to be generated from transdifferentiating hepatocytes during biliary injury[10]. These evidences suggest that both mature cholangiocytes and hepatocytes play complimentary roles to promote liver regeneration through transdifferentiation. Sex determining region Y-box9 (SOX9), required for the normal differentiation of the biliary tract, is primarily expressed in mature cholangiocytes. However, weak expression of SOX9 was also observed in a small population of hepatocytes, which may display the potential to transdifferentiate into cholangiocytes[11]. Otherwise, cellular fate in the liver is regulated by Yes-associated protein (YAP), an important effector of Hippo pathway[12,13]. YAP depletion in the liver is characterized by cholangiocytes proliferation after biliary obstruction[14]. In contrast, YAP activation in hepatocytes results in their transdifferentiation into cholangiocytes, leading to over-

growth of atypical ductal cells - a process termed as atypical ductular reaction[12]. By interacting with TEAD transcription factor, YAP induces the expression of target genes, including *Notch2*[15]. NOTCH2 signaling, in turn, induces the expression of its target genes *SOX9*[12]. Therefore, YAP/SOX9 axis promotes transdifferentiation of hepatocytes into cholangiocytes. However, the mechanism underlying the regulation of YAP/SOX9 axis activation in hepatocytes needs to be elucidated.

To investigate if STAT3 is implicated in hepatocyte proliferation and differentiation in liver injury, we evaluated thioacetamide (TAA)-induced hepatocarcinogenesis and hepatocyte transdifferentiation in mouse with STAT3-deficient liver. STAT3-deficient liver showed profound ductular proliferation with upregulated YAP/SOX9 expression in hepatocytes. Our study indicates that STAT3 regulates transdifferentiation of hepatocytes into biliary cells.

MATERIALS AND METHODS

Mice

Mice were hosted in the cage whose dimension is 218 mm × 320 mm × 133 mm, in which recycled paper bedding and enrichment that stimulates natural instincts were put, and had free access to water and a standard rodent diet during the experimental period. All mice were maintained under specific pathogen-free conditions, and were monitored every other day. We observed any signs of abnormalities (*i.e.* marked weight loss or behavior change), but no mice became ill or died prior to the experimental end point. All mice experiments were conducted in strict accordance with the NIH Guidelines for the Care and Use of Laboratory Animals and were approved by the University of Kurume Institutional Animal Care and Use Committee. Albumin-Cre (Alb-Cre) mice on a C57/BL6 background expressing Cre recombinase under the control of the mouse albumin gene regulatory region and STAT3$^{flox/flox}$ mice on a C57/BL6 background were prepared previously described[16]. To generate hepatic-STAT3 deficient (*STAT3*$^{\Delta hep}$) mice, Alb-Cre mice were crossed with STAT3 $^{flox/flox}$ mice. 4-6 wk male mice weighing 15-20 g were used in this study. For modelling medium- and long-term Thioacetamide (TAA) responses such as inflammation, cirrhosis, and hepatocellular carcinoma (HCC), individual mice received drinking water with TAA (300 mg/L; Wako) for 16 wk (n = 3 for *STAT3*$^{\Delta hep}$ mice, n = 4 for control mice (wild-type mice or STAT3 $^{flox/flox}$ mice) and 30 wk (n = 6 for both *STAT3*$^{\Delta hep}$ and control mice) respectively. Mice were sacrificed by an overdose of diethyl ether.

Histological and immunohistochemical staining

Liver specimens were fixed in 10% buffered formalin and embedded in paraffin. Then, consecutive 4-μm sections were cut and stained with hematoxylin and eosin. Histopathological diagnosis was made according to the General Rules for the Clinical and Pathological Study of Primary Liver Cancer edited by the Liver Cancer Study Group of Japan. For evaluation of fibrosis, Azan staining was performed on paraffin-embedded tissue sections using standard methods. The area of fibrosis was quantified using WinRoof image software (version 6.1, Mitani Corporation, Fukui, Japan) and the results were presented as the ratio of the fibrotic area to the total area of the image. We performed immunohistochemical staining of the paraffin-embedded tissue slices using antibodies against; PCNA (PA5-27214; Thermo Fisher Scientific; dilution 1:100), Keratin19 (KRT19; a gift of Atsushi Miyajima; dilution 1:500), SOX9 (ab71762; Abcam, Cambridge, United Kingdom; dilution 1:500) and YAP (ab39361; Abcam, Cambridge, United Kingdom; dilution 1:100). The slices were soaked with 10mM citrate buffer (pH 6.0) and autoclaved at 121℃ for 5 min for antigen retrieval. Nonspecific protein staining was blocked by preincubation with Protein Block Serum-Free (DAKO). The slices were then exposed to each primary antibody or rabbit IgG as a negative control at 4℃ overnight. After washing, the sections were incubated with Envision secondary antibody labeled with horseradish peroxidase-polymer complexes (DAKO) and stained with DAB. The cellular nuclei were counterstained with hematoxylin.

Immunoblotting analysis

Isolated hepatocytes and liver tissues were homogenized with RIPA buffer (25 mmol/L Tris-HCl pH 7.6, 150 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS) containing 1 mmol/L EDTA (pH 8.0), 0.1 mmol/L NaF, 0.1 mmol/L Na_3VO_4, 100 mmol/L PMSF, 1 mmol/L DTT, 2 × Protease Inhibitor Cocktail (Nacalai Tesque), and 2 × Halt phosphatase inhibitor cocktail (Pierce). Equal proteins (35 μg) were subjected to SDS-PAGE and subsequently transferred onto equilibrated polyvinylidene difluoride (PVDF) membranes (Bio-Rad, Hercules, CA, United States). Immunoblotting analysis was performed using antibodies against; SOX9 (ab71762; Abcam, Cambridge, United Kingdom) and YAP (ab39361; Abcam, Cambridge, United Kingdom), phospho (Y357)-YAP (ab62751; Abcam, Cambridge, United Kingdom), Alpha-1-Fetoprotein (AFP) (DAKO, Glostrup, Denmark), phospho(Y416)-Src family (#2101; Cell Signaling Technologies, Beverly, MA, United States), STAT3 (sc 482; Santa Cruz Biotechnology, CA, United States) and GAPDH (sc25779; Santa Cruz Biotechnology, CA, United States).

Quantitative real-time PCR

Total RNA was isolated using the TRIZOL Reagent I (Invitrogen, Carlsbad, CA, United States) and reverse transcription was performed using Superscript Ⅲ (Invitrogen). Real time PCR was carried out using SYBR

Green (Life Technologies) and TaqMan Assays (Life Technologies) with the following primers. *GAPDH* control forward: 5′-TGACGTGCCGCCTGGAGAAA-3′, *GAPDH* control reverse: 5′-AGTGTAGCCCAAGATGCCCTTCAG-3′; *SOX-9* forward: 5′-TGCAGCACAAGAAAGACCAC-3′, *SOX-9* reverse: 5′-TCTCAATGTTGGAGATGACG-3′; *KRT19* forward: 5′-GACTTCCTATAGCTATCGCC-3′, *KRT19* reverse: 5′-AGTAGGAGGCGAGACGATCA-3′; *AFP* forward: 5′-GGCCGACATTTTCATTGGACATT-3′, *AFP* reverse: 5′-TGGGGGAGGGGCATAGGTTTT-3′; *MMP2* forward: 5′-GATAACCTGGATGCCGTCGTG-3′, *MMP2* reverse: 5′-CTTCACGCTCTTGAGACTTTGGTTC-3′; *MMP9* forward: 5′-GCTGACTACGATAAGGACGGC-3′, *MMP9* reverse:5′-AGGAAGACGAAGTGAAGGGGAAGA-3′. TaqMan probes/primers for YAP (Mm01143263_m1), IL-6 (Mm00436767_m1), IL-33 (Mm00505403_m1) and Osteopontin (Mm00436767_m1) were purchased from Life Technologies. Expression of mRNA was calculated using the $2^{-\Delta\Delta Ct}$ method. The relative amount of specific mRNA was normalized to GAPDH.

Statistical analysis

Statistical significance was assessed using the Mann-Whitney *U*-test. $P < 0.05$ was considered statistically significant. The data were presented as mean ± SE.

RESULTS

Hepatic STAT3 deficiency enhanced necroinflammatory change

To examine the protective role of STAT3 in hepatocytes, we first examined whether hepatic-STAT3 deficiency promoted TAA-induced liver injury. $STAT3^{flox/flox}$ mice were crossed with Alb-Cre mice to generate hepatic-STAT3 deficient ($STAT3^{\Delta hep}$) mice (Figure 1A). $STAT3^{\Delta hep}$ and control mice were given water with TAA. Metabolites of TAA, which are covalently bound to proteins and lipids, caused hepatocytes necrosis and periportal infiltration of inflammatory cells. As shown Figure 1B, TAA-induced inflammatory infiltrates were augmented in $STAT3^{\Delta hep}$ mice compared to control mice. Moreover, TAA-induced necrotic changes of hepatocytes were also enhanced in $STAT3^{\Delta hep}$ mice (Figure 1B and C), indicating that hepatic-STAT3 deficiency promoted TAA-induced hepatocytes injury. As a consequence of enhanced inflammatory change, $STAT3^{\Delta hep}$ mice exhibited significantly severe liver fibrosis compared to control mice (Figure 1D and E).

Hepatic STAT3 deficiency suppressed hepatocyte proliferation and HCC development

To elucidate the proliferative role of STAT3, we next examined whether TAA-induced hepatocytes regeneration was attenuated in $STAT3^{\Delta hep}$ mice. Immunohistochemical staining for proliferating cell nuclear antigen (PCNA) showed compensatory proliferation of hepatocytes in TAA-induced liver injury (Figure 2A). PCNA positive hepatocytes were significantly decreased in $STAT3^{\Delta hep}$ mice (Figure 2A and B), indicative of the proliferative role of hepatic STAT3 in TAA-induced liver injury. Compensatory proliferation triggered by hepatocyte loss leads to not only liver regeneration but also development of HCC. Therefore, we next examined whether TAA-induced HCC development was inhibited in $STAT3^{\Delta hep}$ mice. TAA treatment for thirty-week developed liver tumors which were histologically consistent with well-differentiated HCC with no evident cholangiocellular carcinoma (Figure 2C). The liver tumor formations of $STAT3^{\Delta hep}$ mice were significantly lesser than those of control mice (Figure 2D). These findings suggested that STAT3 was required, at least in part, for compensatory hepatocyte proliferation leading to HCC development.

Hepatic STAT3 deficiency accelerated TAA-induced biliary ducts and ductular structure formation

Hepatic necroinflammatory change induces atypical ductular reaction, which is characterized by proliferation of ductular cells. TAA treatment caused the biliary duct/ductular structure formation especially around periportal area (Figure 3A). To confirm the characteristics of bile duct/ductular cells, we performed immunohistochemical staining for KRT19, a marker of mature cholangiocytes. Most of ducts/ductular cells were immunoreactive for KRT19 (Figure 3B). The number of bile duct/ductular structures around periportal area of $STAT3^{\Delta hep}$ mice was higher than that of control mice (Figure 3C left). The bile duct/ductular formations in centrilobular area were rarely observed in control mice, but those of $STAT3^{\Delta hep}$ mice were significantly increased (Figure 3C right). KRT19-positive bile ducts/ductular structures were significantly expanded at both periportal and centrilobular area in $STAT3^{\Delta hep}$ mice (Figure 3C and D).

STAT3 deficient hepatocytes showed upregulated SOX9 expression following TAA-induced liver injury

The formation of ducts/ductular structures has been thought to be attributable to both proliferation of mature cholangiocytes and biliary transdifferention of hepatocytes. To examine the origin of bile ducts/ductular structures, we next performed immunohistochemical staining for SOX9, because SOX9 is expressed in cholangiocytes and bipotential hepatobiliary cells[11]. As shown Figure 4A, the bile ducts/ductular structures were frequently composed of SOX9-positive cells. The number of SOX9-positive bile ducts/ductules of $STAT3^{\Delta hep}$ mice was higher than that of control mice (Figure 4B). Furthermore, immunoreactive intensity for SOX9 was increased in the bile ducts/ductular cells of $STAT3^{\Delta hep}$ mice compared to control mice. TAA treatment upregulated SOX9 expression in periportal hepatocytes. Interestingly, SOX9 expression was also

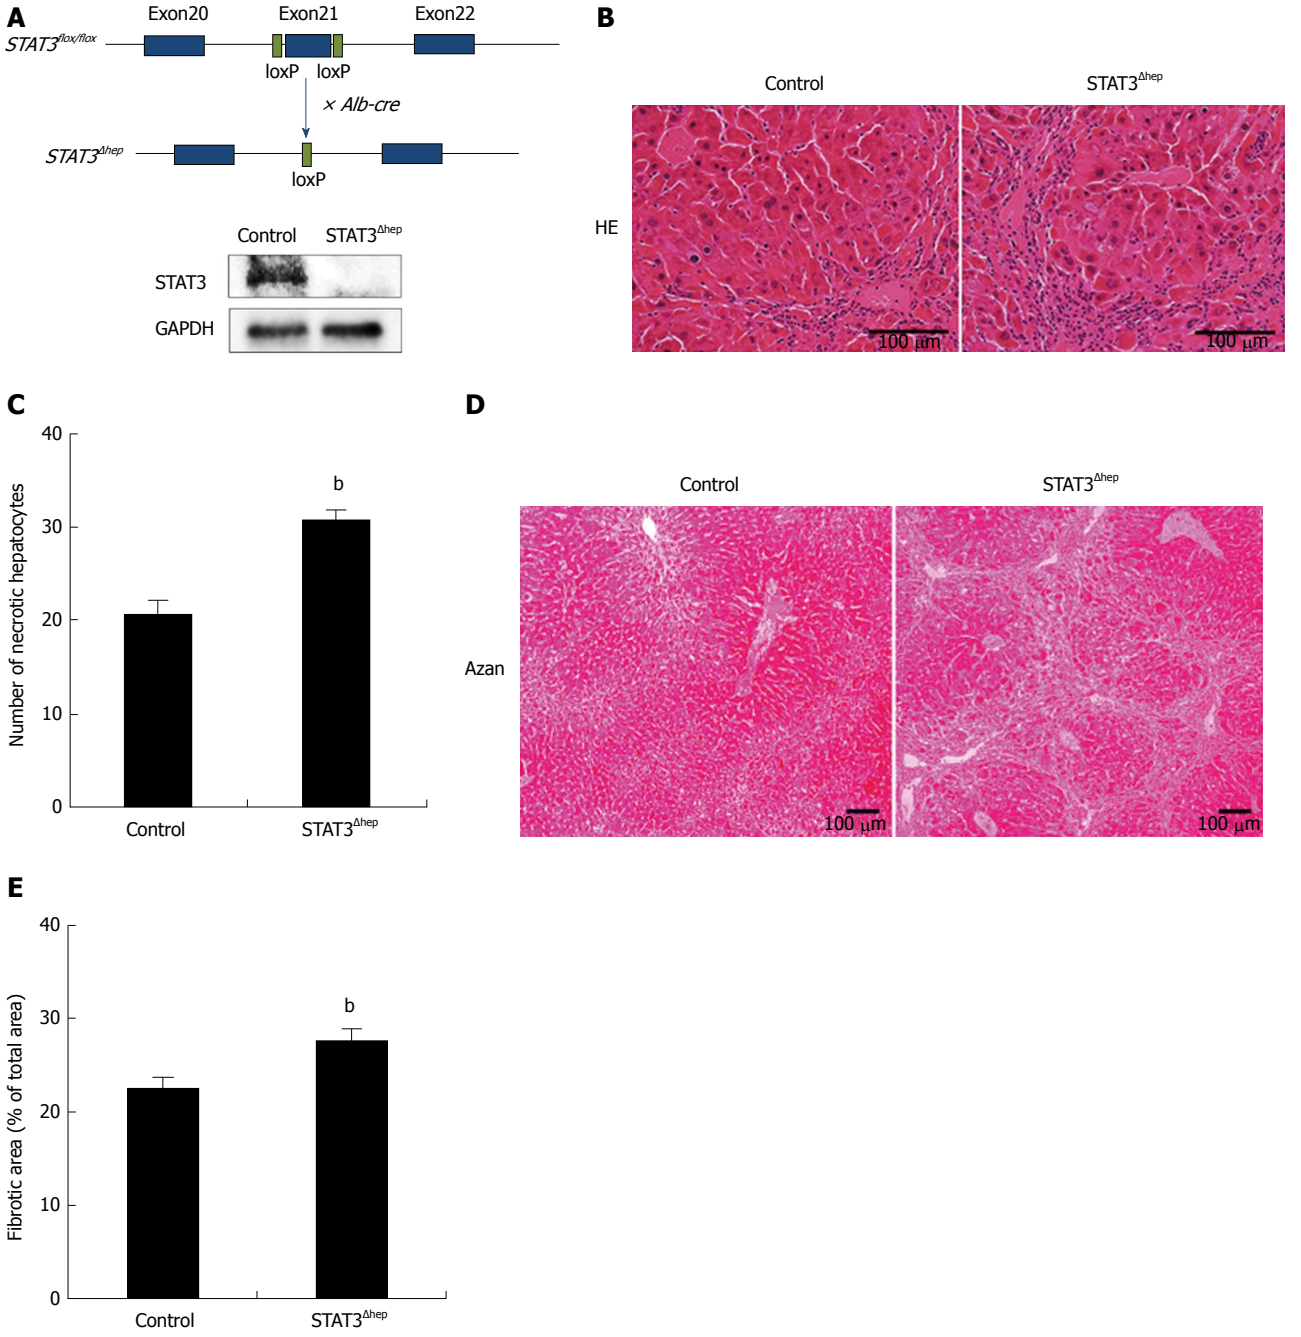

Figure 1 Establishment of hepatic-STAT3 deficient (*STAT3$^{\Delta hep}$*) mice. Hepatic-STAT3 deficiency enhanced thioacetamide-induced liver injury. A: The exon 21 of STAT3 was flanked by two identically oriented loxP sites (STAT3$^{flox/flox}$). To disrupt hepatic-STAT3 gene, STAT3$^{flox/flox}$ mice were crossed with mice carrying albumin promoter-driven Cre transgene (Alb-Cre). Deficiency of hepatic-STAT3 protein was confirmed by immunoblotting analysis. B: Representative hematoxylin and eosin (H&E) staining images of control and STAT3$^{\Delta hep}$ livers with TAA treatment for 16 wk. Hepatic-STAT3 deficiency accelerated inflammation cells infiltration and hepatocytes necrosis. C: Quantification of necrotic hepatocytes. Necrotic hepatocyte was identified with the eosinophilic/vacuolated cytoplasm and nuclear destruction such as karyolysis or Pyknosis. Values represent means ± SE of the mean. $^{b}P < 0.01$ ($P = 0.000269$) *vs* control. D: Representative Azan staining of control and STAT3Δhep livers with TAA treatment for 16 wk. E: Quantification of the ratio of fibrosis area to the total area in control and STAT3$^{\Delta hep}$ livers. Values represent means ± SE of the mean. $^{b}P < 0.01$ ($P = 0.00235$) *vs* control. TAA: Thioacetamide.

augmented in STAT3-deficient hepatocytes (Figure 4C).

YAP was activated in STAT3-deficient hepatocytes following TAA-induced liver injury

We next performed quantitative RT-PCR analysis to determine whether SOX9 expression was regulated at transcriptional level. TAA treatment upregulated the level of *SOX9* mRNA expression, which was significantly increased in the liver of *STAT3$^{\Delta hep}$* mice compared to that of control (TAA 16 wk) (Figure 5A). Immunoblot analysis confirmed higher levels of SOX9 expression in the liver of *STAT3$^{\Delta hep}$* mice (Figure 5B). In accordance with the marked bile duct/ductular cell proliferation, the liver of *STAT3$^{\Delta hep}$* mice showed robust up-regulation of KRT19 expression at transcriptional and protein level. Although IL-33 is a

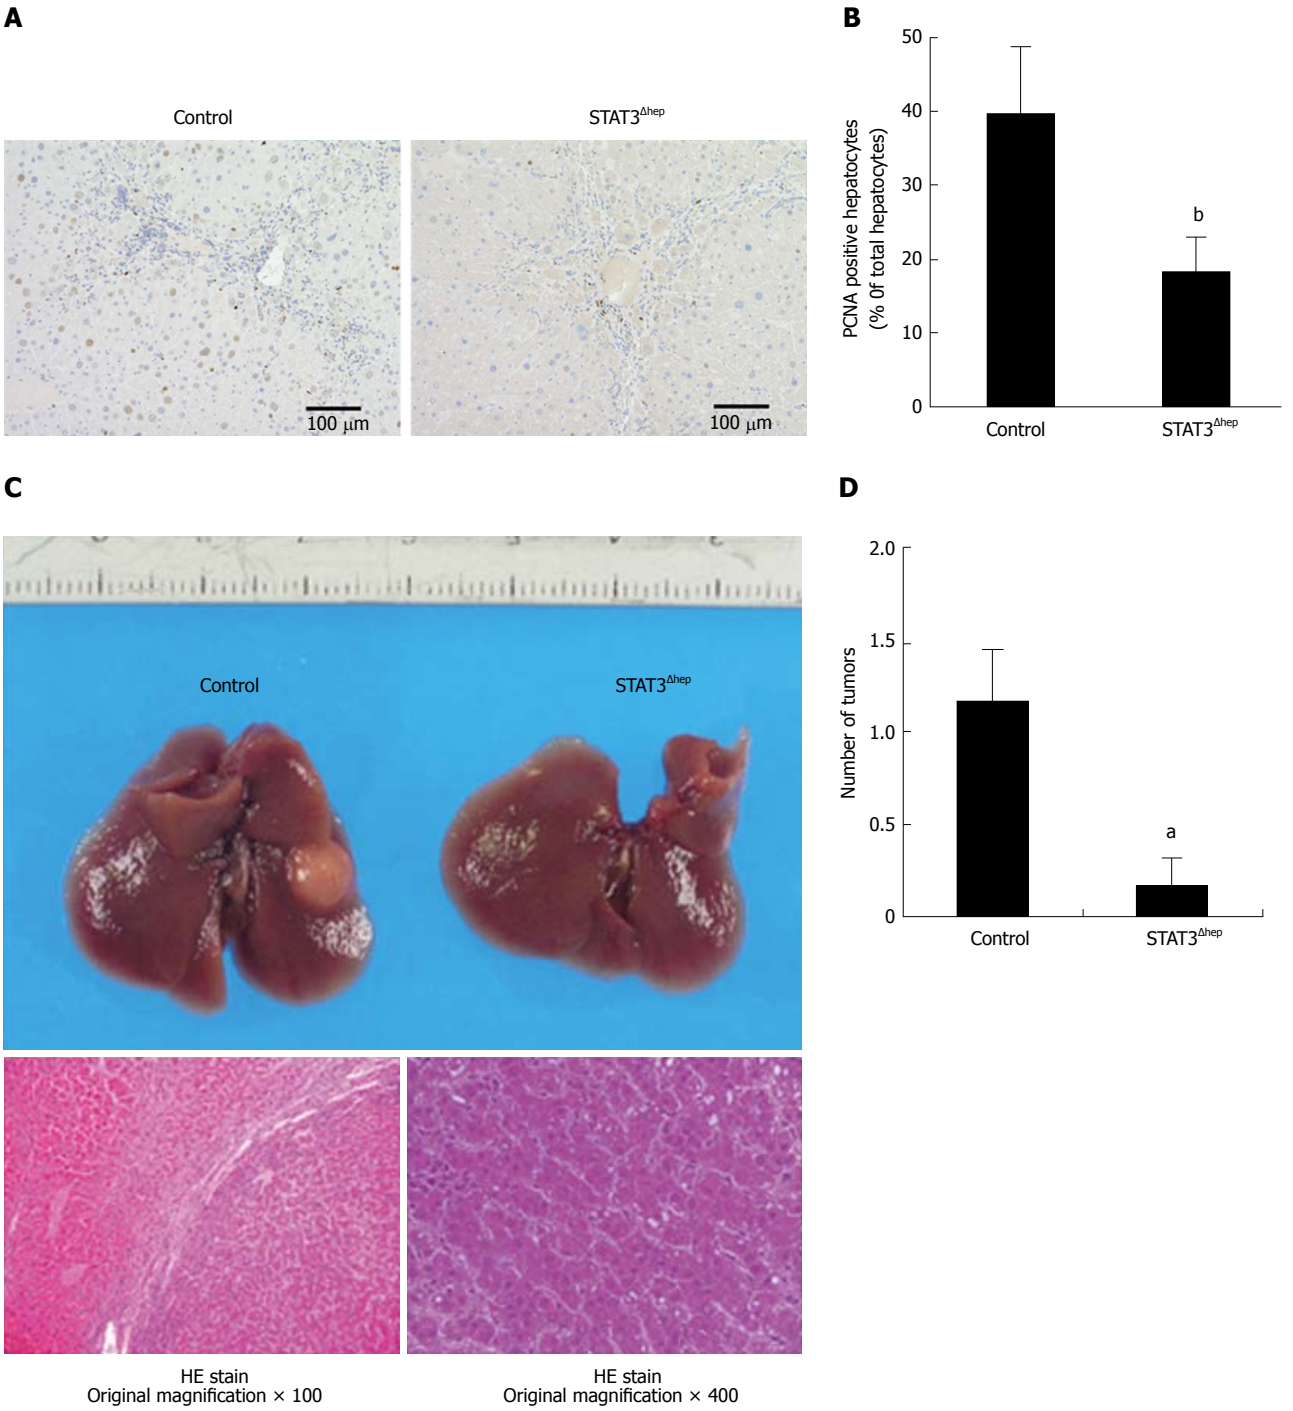

Figure 2 Hepatic STAT3 deficiency reduced hepatocyte proliferation and inhibited the development of hepatocellular carcinoma. Original magnification × 100 (lower left panel) and × 400 (lower right panel). D: The number of HCC in control and STAT3$^{\Delta hep}$ mice. Values represent means ± SE of the mean ($n = 6$). $^{a}P < 0.05$ ($P = 0.0219$) *vs* control. TAA: Thioacetamide.

pivotal growth factor for cholangiocytes, *IL-33* mRNA was not upregulated in the liver of *STAT3*$^{\Delta hep}$ mice (Figure 5A). On the other hand, AFP expression of the liver of *STAT3*$^{\Delta hep}$ mice was decreased as compared to that of control mice (Figure 5A and B). Whereas YAP expression was restricted in normal liver, TAA treatment resulted in upregulation of YAP expression. *YAP* mRNA expression in the liver of *STAT3*$^{\Delta hep}$ mice was slightly higher than that of control mice. However, YAP protein expression was markedly increased in the liver of *STAT3*$^{\Delta hep}$ mice. Previously, it was shown that src-family kinase induced-YAP tyrosine (Y357) phosphorylation leads to its stabilization and nuclear localization, activating its transcriptional property[17].

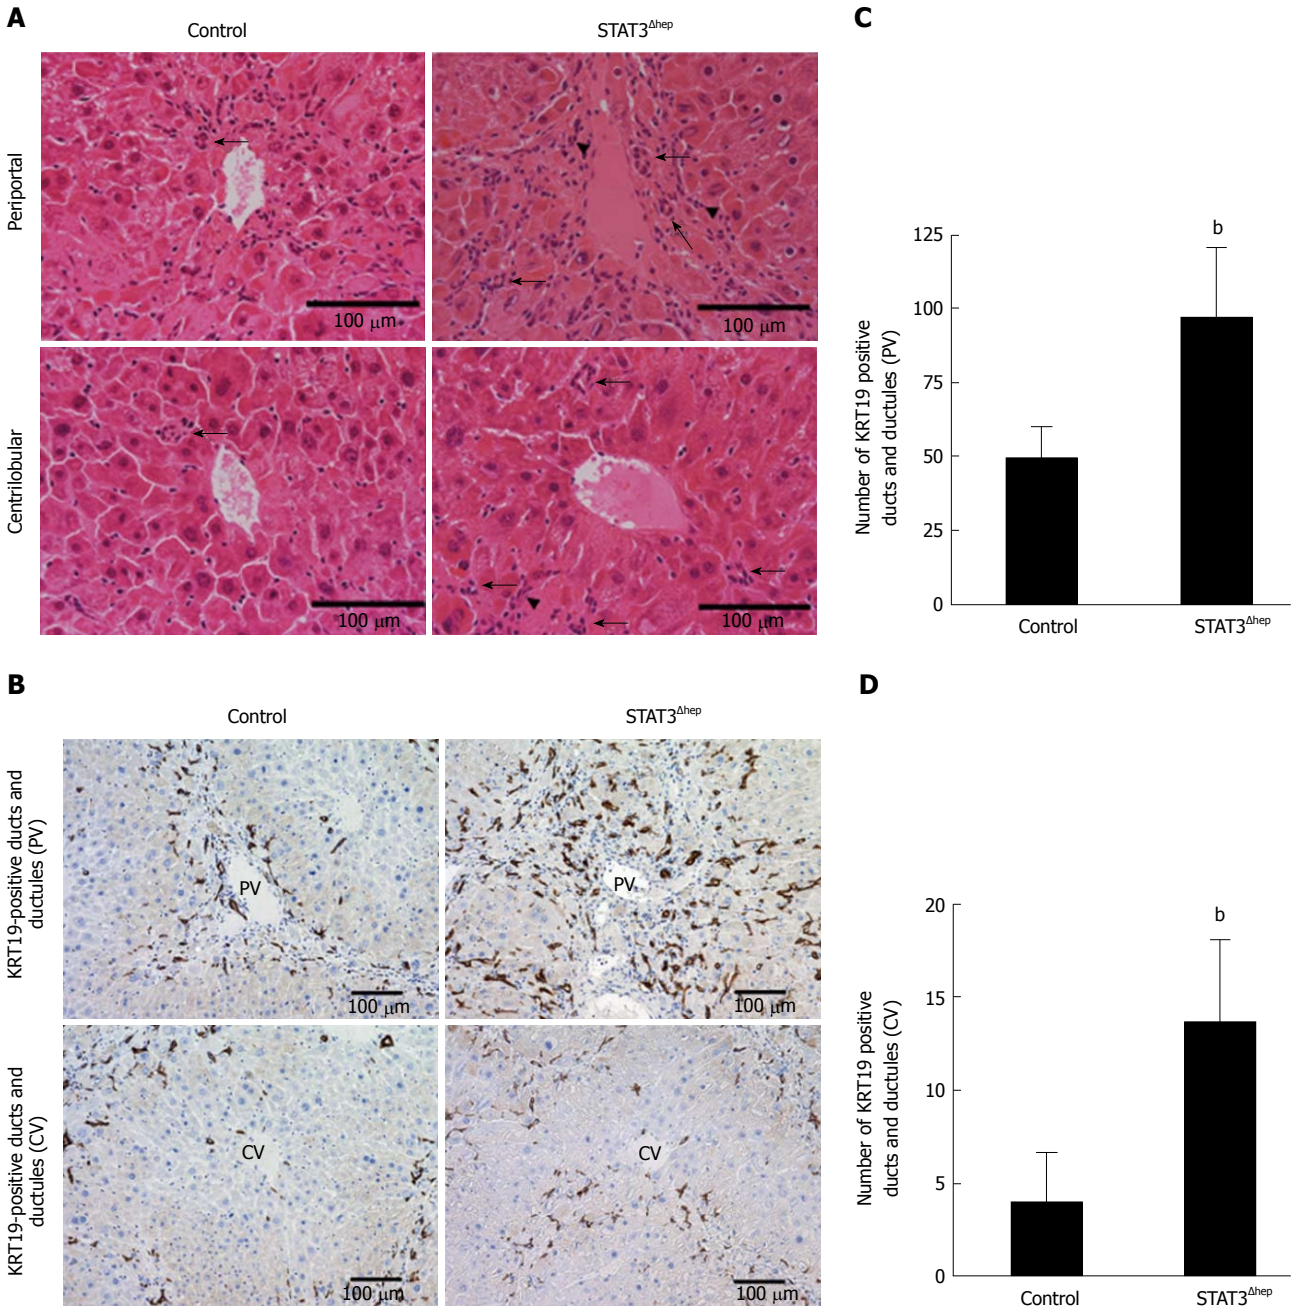

Figure 3 Increase in the formation of bile ducts and ductular structure in hepatic STAT3 deficient liver. A: Hematoxylin and eosin staining images of representative areas around portal vein (PV) and central vein (CV) of control and *STAT3*$^{\Delta hep}$ livers following treatment with TAA for 16 wk. TAA treatment caused bile ducts/ductular formation (arrow). B: Immunohistochemistry staining for keratin 19 (KRT19) in control and *STAT3*$^{\Delta hep}$ livers following TAA treatment for 16 wk. Original magnification × 200. C and D: The number of KRT19-positive bile ducts/ductules around PV and CV. To quantify the number of bile ducts/ductules around PV and CV, we observed three different samples per group using 20 × objective lens, imaged five randomly selected cross-sectional veins in the center of field, and calculated the average value after counting the bile duct/ductule number in the total area of the image. Values represent means ± SE of the mean. $^{b}P < 0.01$ [(C) $P = 0.00272$, (D) $P = 0.00187$] *vs* control. TAA: Thioacetamide.

YAP tyrosine (Y357) phosphorylation and src-kinase phosphorylation were enhanced in the liver of *STAT3*$^{\Delta hep}$ mice. Furthermore, immunohistochemical staining showed robust YAP expression in the nucleus of STAT3-deficient hepatocytes, indicating hepatocytes-transdifferentiation (Figure 5C and D). Taken together, profound proliferation of bile duct/ductular cells in the liver of STAT3$^{\Delta hep}$ mice may not be due to the proliferation of mature cholangiocytes but may be associated with transdifferentiation of hepatocytes into cholangiocytes.

DISCUSSION

In this study, we show that STAT3-deficient liver displayed reduced HCC development and promoted biliary ductular proliferation during TAA-induced liver injury. STAT3-deficient hepatocytes exhibited YAP activation and upregulation of SOX9 expression, indicating transdifferentiation of hepatocytes into

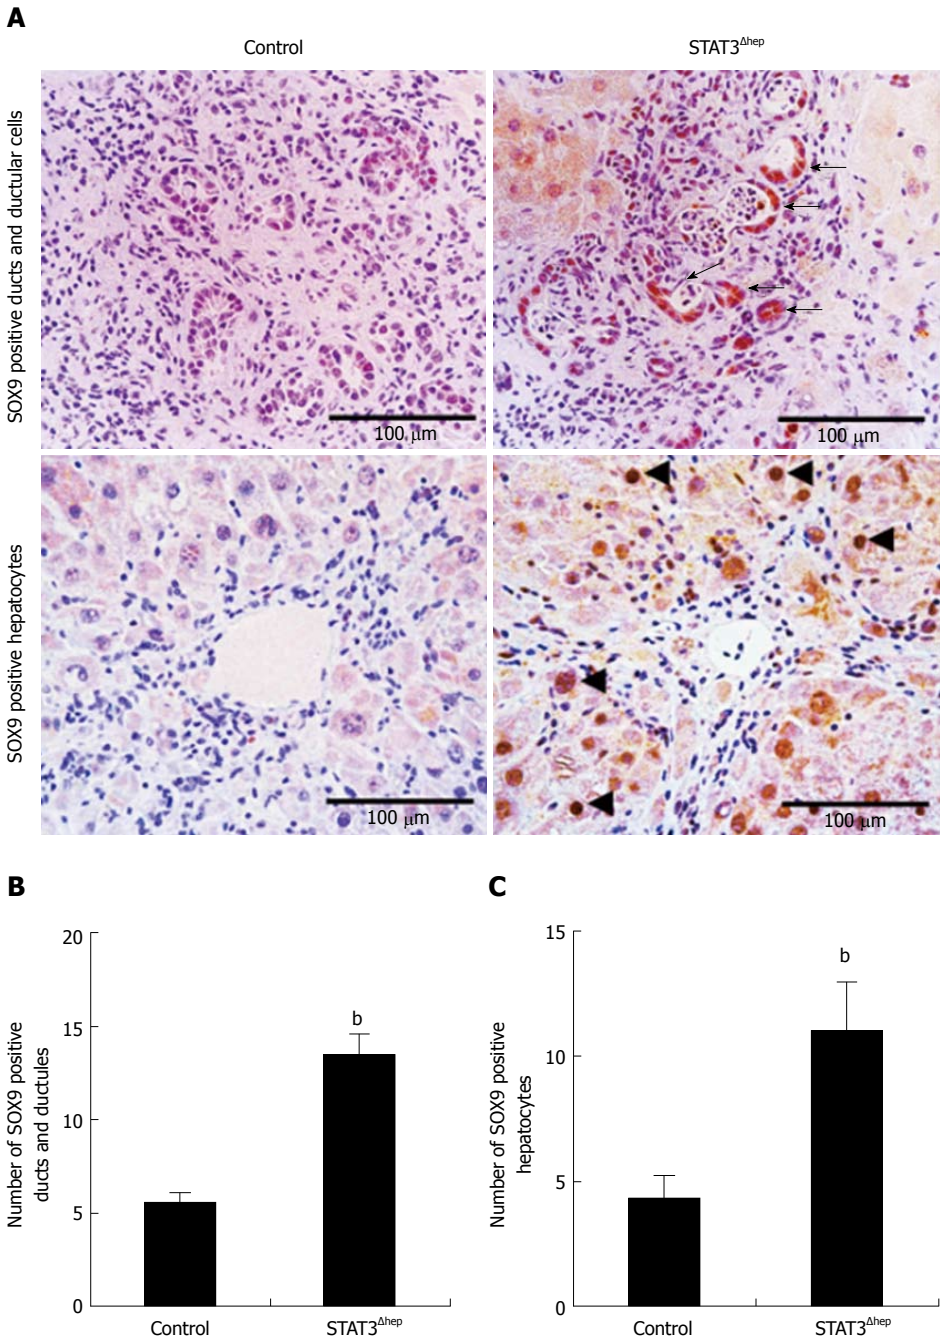

Figure 4 Hepatic STAT3 deficiency upregulated SOX9 expression in thioacetamide-induced liver injury. A: Immunohistochemistry staining for SOX9 in control and STAT3$^{\Delta hep}$ livers with TAA treatment for 16 wk. SOX9 expression was markedly enhanced in bile ducts/ductular structure (upper panel) and hepatocytes (lower panel) of STAT3Δhep livers. Original magnification × 200 (upper panel) and × 400 (lower panel). B and C: The number of SOX9 positive bile ducts/ductular structure and hepatocytes. For quantification of SOX9 positive bile ducts/ductular structure, three different samples per a group were observed using a 20 × objective lens and SOX9 positive ducts/ductular structure was counted at five PV areas. For quantification of SOX9 positive hepatocytes, three different samples per a group were observed using a 40 × objective lens and SOX9 positive hepatocytes was counted at five PV areas. Values represent means ± standard error of the mean. $^{b}P < 0.01$ [(B) $P = 0.0000103$, (C) $P = 0.00834$] *vs* control. TAA: Thioacetamide.

cholangiocytes. This study is the first report that STAT3 is implicated in both proliferation and differentiation of hepatocytes after liver injury.

IL-6 family cytokines are obviously essential for liver repair. IL-6-deficiency impairs liver regeneration and causes liver failure characterized with blunted DNA synthesis in hepatocytes but not in nonparenchymal cells[18]. The role of JAK/STAT3 pathway has been extensively evaluated and thought to be essential for IL-6-mediated liver repair, because STAT3 regulates many of genes associated with cell survival and proliferation. During liver regeneration after partial hepatectomy, hepatocytes-STAT3 activation was observed in periportal area[19], which might harbor putative stem cell nische[20]. Recently, periportal hepatocytes were shown to have extensive proliferative property for liver repair[11]. These reports suggested that STAT3 activation in periportal area was crucial for

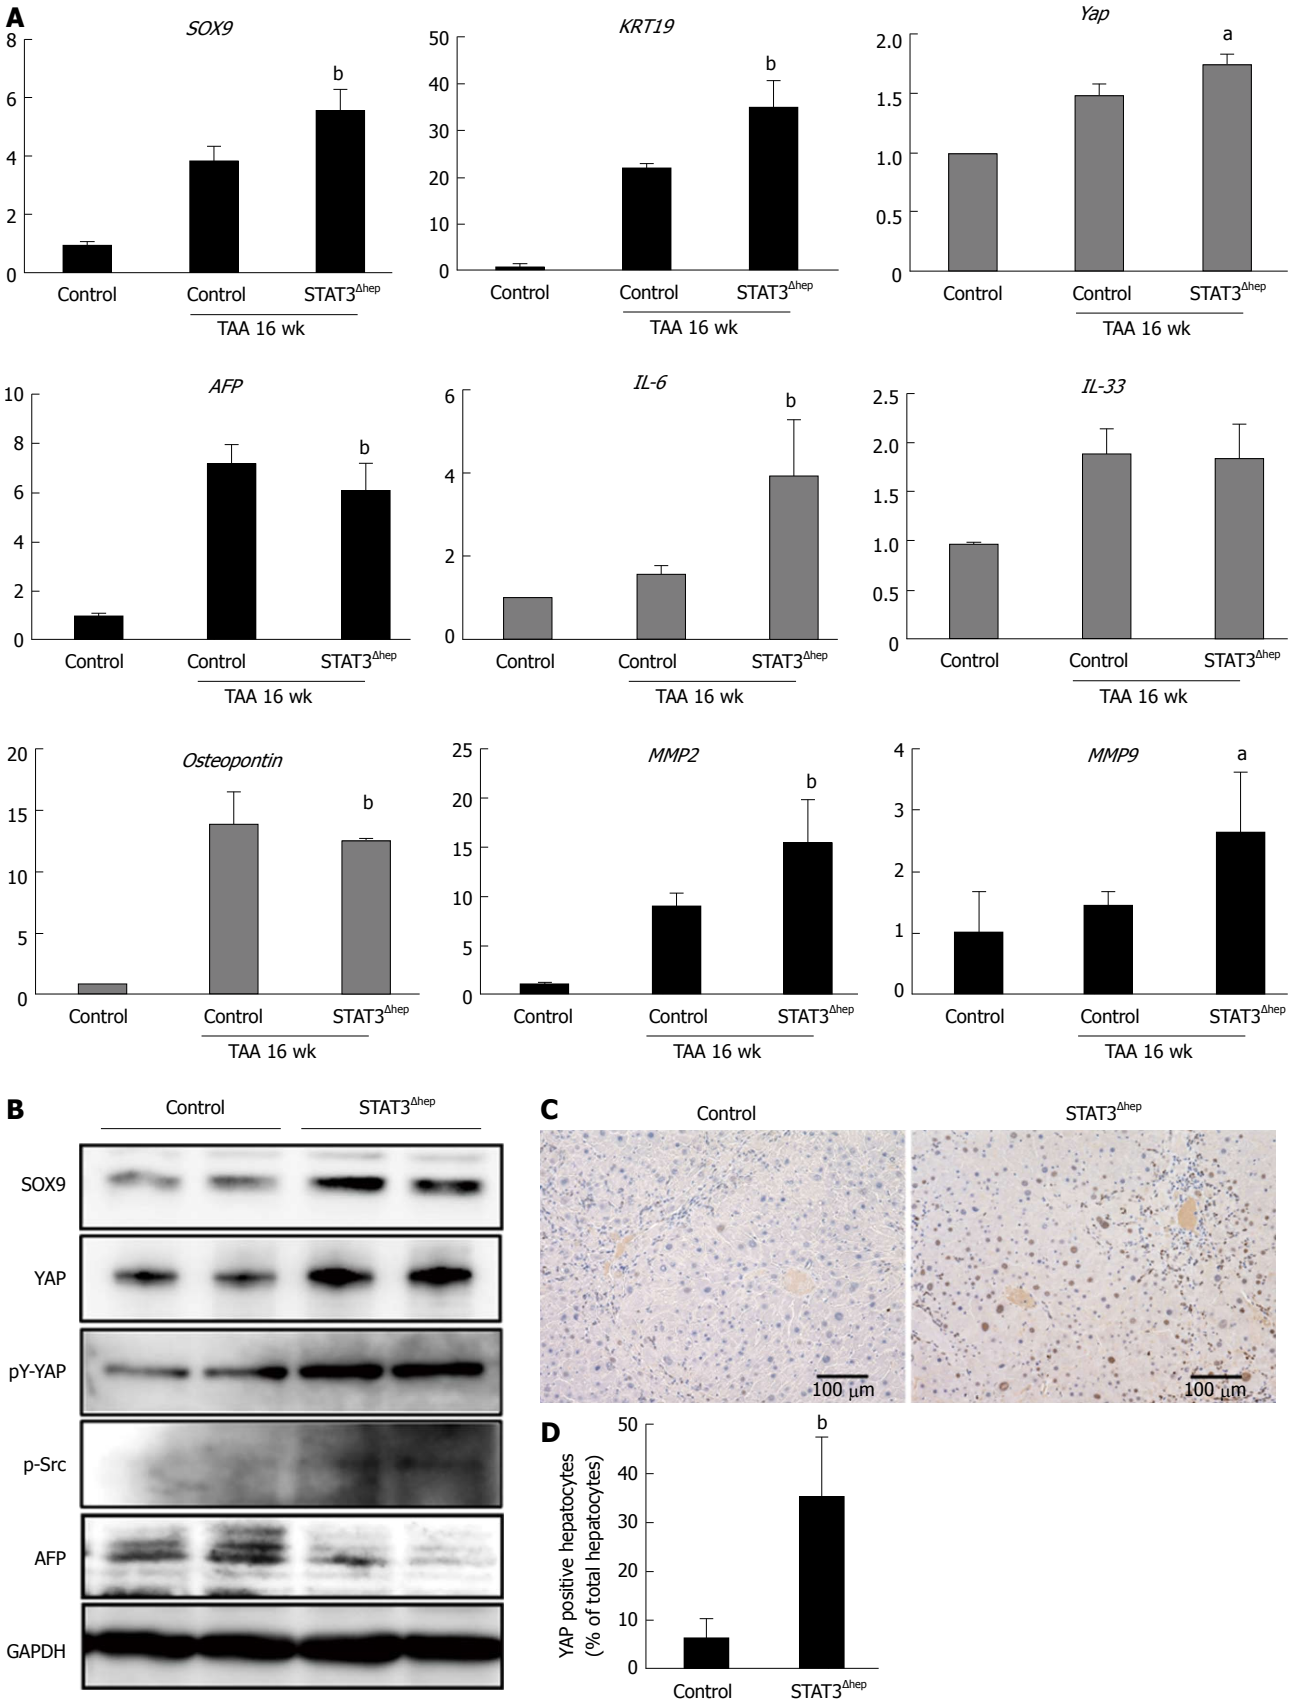

Figure 5 YAP activation in STAT3-deficient hepatocyte with thioacetamide treatment. A: Quantitative real-time RT-PCR analysis for *SOX-9*, *KRT 19*, *YAP*, *AFP*, *IL-6*, *IL-33*, *Osteopontin*, *MMP2*, and *MMP9* mRNA expression levels. The relative expression of each gene mRNA was normalized to GAPDH mRNA (n = 6). ^{a}P < 0.05 (*YAP*; P = 0.0134, *AFP*; P = 0.00347, *MMP9*; P = 0.00271) and ^{b}P < 0.01 (*SOX9*; P = 0.00274, *KRT19*; P = 0.00402, *IL-6*; P = 0.00147, *MMP2*; P = 0.00404) *vs* control (TAA treatment for 16 wk). B: Immunoblotting analysis for SOX-9, YAP, pY-YAP, p-Src and AFP protein expression levels. GAPDH served as loading control. C: Representative immunohistochemical staining for YAP in livers of control and STAT3$^{\Delta hep}$ mice with TAA treatment for 16 wk. Nuclear YAP was augmented in STAT3$^{\Delta hep}$ hepatocytes with TAA treatment for 16 wk. Original magnification × 200. D: The number of nuclear YAP positive hepatocytes. Ratio of nuclear YAP positive hepatocytes to all hepatocytes was quantified in three different samples per a group. Values represent means ± SE of the mean. ^{b}P < 0.01 (P = 0.00312) *vs* control. TAA: Thioacetamide.

liver regeneration. Indeed, TAA-induced liver damage was augmented in liver specific STAT3-deficient mice compared to control mice. However, hepatic STAT3 deficiency did not cause lethal liver injury after TAA treatment. Consistently, previous reports showed that hepatic STAT3 deficiency, unlike IL-6 deficiency, caused modest reduction of liver regeneration with no liver failure after partial hepatectomy[1]. These findings suggest that hepatic STAT3 plays a part of IL-6-mediated liver repair property. Because IL-6 family cytokines activate ERK/MAPK and PI3K/Akt pathways as well as JAK/STAT3 pathway through its receptor gp130, these pathways may lead to compensation of proliferation in STAT3-deficient hepatocytes.

Until recently, YAP has been shown to regulate cell proliferation in some organs including liver[21]. By binding to TEAD transcription factor in nucleus, YAP activates expression of multiple genes including *CTGF, CCND1* and *BCL2L1* responsible for cell proliferation, antiapoptosis and survival. In Hippo/Lats pathway, YAP serine (S127) phosphorylation results in cytoplasmic sequestration and inhibition of its transcriptional coactivator activity[22,23]. In contrast, src-family kinase induced-YAP tyrosine (Y357) phosphorylation leads to its stabilization and nuclear localization, activating its transcriptional property[17]. Recent report revealed that IL-6-mediated YAP tyrosine (Y357) phosphorylation via a gp130-src family kinase module promotes intestinal epithelial proliferation *in vivo*[24]. Therefore, YAP and STAT3 cooperatively might promote hepatocytes proliferation and survival for IL-6-mediated liver regeneration. Compensatory YAP activation probably due to IL-6 upregulation might restore the property of STAT3-deficient hepatocytes proliferation and survival. Recently IL-22 has also been shown to be critical for liver regeneration[25]. Although IL-22 does not interact gp130, IL-22 receptor bind SHP2 leading to activation of both src family kinase and STAT3[26]. YAP and STAT3 might be involved in not only IL-6-mediated but IL-22-mediated liver regeneration.

In addition to the role of cell proliferation and survival, YAP sustains undifferentiated state and pluripotency through regulating expression of stemness-associated genes such as *Oct4*, *Sox2* and *Nanog*[13]. YAP is overexpressed in cultured ES cells and may be required for self-renewal and suppression of differentiation[27]. YAP activation was shown to dedifferentiate mature hepatocytes into hepatobiliary progenitor cells[12]. SOX9-positive periportal hepatocytes display high regenerative property and were shown to self-renew and transdifferentiate into cholangiocytes[11]. It is interesting that SOX9 expression is upregulated by YAP activation through NOTCH pathway[12]. Therefore, activation of YAP/SOX9 axis is critical for hepatocyte dedifferentiation to accomplish liver repair. However, the regulation of YAP/SOX9 axis activation in hepatocytes is still unknown. In this study, we found that STAT3 deficiency enhanced YAP tyrosine (Y357) phosphorylation and SOX9 expression through Src activation during TAA-induced liver injury. These findings suggest that STAT3 may inhibit dedifferentiation and transdifferentiation of hepatocytes by preventing the activation of YAP/SOX9 axis.

Demetris *et al*[28] previously reported that KRT19 positive/AFP negative hepatocytes, called ductular hepatocytes, appeared to exhibit ductular reaction in submassive liver necrosis. The ductular hepatocytes were thought to contribute to biliary repair through transdifferentiation into cholangiocytes. As AFP synthesis and secretion were derived from differentiated hepatocytes in liver injury, TAA treatment upregulated AFP expression reflecting hepatocytes repopulation. The TAA treatment-induced AFP upregulation was significantly inhibited in hepatic-STAT3 deficient mice, whereas the expression of KRT19 was upregulated compared to control mice. Interestingly, AFP expression is suppressed by YAP in undifferentiated ES cells, and YAP inhibition results in AFP expression with differentiation of ES cell[27]. These findings suggest that YAP activation in STAT3-deficient hepatocytes might direct their transdifferentiation into cholangiocytes instead of their dedifferentiation into progenitor cells. An important question is whether YAP activation in STAT3-deficient hepatocytes contribute to development of liver cancer, as YAP has been found to be involved in cholangiocarcinoma[29]. However, hepatic-STAT3 deficient mice did not cause cholangiocarcinoma, suggesting that STAT3 deficiency-induced YAP activation is insufficient for oncogenic transformation at least in the model of TAA-induced liver injury. Otherwise, hepatic STAT3 depletion promoted fibrotic regeneration in TAA-induced liver injury model. Recent report showed that YAP expression was positively correlated with liver fibrosis in non-alcoholic steatohepatitis[30]. Because YAP has also been found to promote epithelial-mesenchymal transition[31], the possibility is not excluded that YAP activation might promote transdifferentiation of hepatocytes into myofibroblast leading to liver fibrosis.

In conclusion, STAT3 is not only involved in HCC development but also prevents biliary ductular formation in TAA-induced liver injury. Our study highlights hepatic STAT3 as a plausible target for biliary repair during liver injury.

COMMENTS

Background

JAK/STAT3 pathway plays the central role in signal transduction mediated by

IL-6 family, indispensable cytokines for liver regeneration. Several target genes of STAT3 are essential for cell proliferation and survival. In murine models of liver injury, ablation of STAT3 in liver results in enhanced liver injury and reduced liver regeneration.

Research frontiers

Cholangiocytes transdifferentiate into hepatocytes and replenish massive hepatocyte loss. In addition, cholangiocytes are generated from transdifferentiating hepatocytes during biliary injury. STAT3 is implicated in cellular differentiation of some immune cells, although the role of STAT3 in transdifferentiation between hepatocytes and cholangiocytes has not been elucidated.

Innovations and breakthroughs

This study indicates that STAT3 regulates transdifferentiation of hepatocytes into biliary cells through Yes-associated protein (YAP)/Sex determining region Y-box9 (SOX9) axis activation.

Applications

Hepatic STAT3 is a plausible target for biliary repair during liver injury.

Terminology

YAP, an important effector of Hippo pathway which controls organ size in animals through the regulation of cell proliferation and apoptosis. A recent report revealed that YAP activation in hepatocytes results in their transdifferentiation into cholangiocytes. SOX9, one of transcription factors which is required for the normal differentiation of the biliary tract. It was recently reported that SOX9-positive periportal hepatocytes transdifferentiate into cholangiocytes and that SOX9 expression is upregulated by YAP activation. Transdifferentiation, a process in which one mature somatic cell converts into another mature somatic cell without going through an intermediate pluripotent or progenitor cell type.

Peer-review

The authors provided evidence showing that STAT3 may mediate carcinogen-induced hepatocellular carcinoma in mouse model. Hepatocyte-specific deletion of STAT3 reduced compensatory proliferation and cancer formation in response to TAA. Additional test indicated that deficiency of STAT3 enhanced YAP activation and SOX9 expression, which may contribute to the enhanced formation of biliary ductular structures. The manuscript was well-written and the results are straightforward.

Abstract

AIM

To investigate and compare the analytical and clinical performance of TianLong automatic hypersensitive hepatitis B virus (HBV) DNA quantification system and Roche CAP/CTM system.

METHODS

Two hundred blood samples for HBV DNA testing, HBV-DNA negative samples and high-titer HBV-DNA mixture samples were collected and prepared. National standard materials for serum HBV and a worldwide HBV DNA panel were employed for performance verification. The analytical performance, such as limit of detection, limit of quantification, accuracy, precision, reproducibility, linearity, genotype coverage and cross-

contamination, was determined using the TianLong automatic hypersensitive HBV DNA quantification system (TL system). Correlation and Bland-Altman plot analyses were carried out to compare the clinical performance of the TL system assay and the CAP/CTM system.

RESULTS

The detection limit of the TL system was 10 IU/mL, and its limit of quantification was 30 IU/mL. The differences between the expected and tested concentrations of the national standards were less than ± 0.4 Log_{10} IU/mL, which showed high accuracy of the system. Results of the precision, reproducibility and linearity tests showed that the multiple test coefficient of variation (CV) of the same sample was less than 5% for 10^2-10^6 IU/mL; and for 30-10^8 IU/mL, the linear correlation coefficient r^2 = 0.99. The TL system detected HBV DNA (A-H) genotypes and there was no cross-contamination during the "checkerboard" test. When compared with the CAP/CTM assay, the two assays showed 100% consistency in both negative and positive sample results (15 negative samples and 185 positive samples). No statistical differences between the two assays in the HBV DNA quantification values were observed (P > 0.05). Correlation analysis indicated a significant correlation between the two assays, r^2 = 0.9774. The Bland-Altman plot analysis showed that 98.9% of the positive data were within the 95% acceptable range, and the maximum difference was -0.49.

CONCLUSION

The TL system has good analytical performance, and exhibits good agreement with the CAP/CTM system in clinical performance.

Core tip: The TianLong automatic hypersensitive hepatitis B virus DNA quantification system achieved a limit of detection of 10 IU/mL, limit of quantification of 30 IU/mL and good analytical performance in terms of accuracy, precision, reproducibility, linearity, genotype coverage and cross-contamination. In clinical performance, the TL system showed good correlation and agreement with the Roche CAP/CTM system.

Performance verification and comparison of TianLong automatic hypersensitive hepatitis B virus DNA quantification system with Roche CAP/CTM system. *World J Gastroenterol* 2017; 23(37): 6845-6853 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6845.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6845

INTRODUCTION

Hepatitis B virus (HBV) infection is a worldwide disease, and over 2 billion people once have been infected with HBV and of these, 240 million have chronic hepatitis B[1,2]. Although there are effective vaccines and anti-viral medicine, HBV infection is still a major condition threatening the human health[3-5]. Globally, 30% of patients with liver cirrhosis and 45% with liver cancer are caused by HBV infection, respectively. Nationally, 500-600 million people in China have been infected with HBV, accounting for nearly 40% of the total national population[6-8]. Currently, China has approximately 93 million chronic HBV infected individuals, and 20 million of these patients have chronic hepatitis B[9,10]. An even higher percentage of patients with liver cirrhosis (60%) and hepatocellular cancer (HCC) (80%) were caused by HBV infection [11,12].

During the last decade, with the advent of new type interferon and antiviral drugs with a high genetic barrier to resistance, the antiviral treatment of chronic HBV infection has achieved significant progress[13-16]. HBV DNA quantification is one of the most important indicators used in HBV antiviral therapy, and can be used to determine whether the patient is suitable for antiviral therapy, monitor antiviral treatment response and virus resistance[17-19]. Use of hypersensitive HBV DNA quantification system to accurately detect HBV DNA in serum is the key factor in determining the curative effect and endpoints of hepatitis B antiviral therapy.

International associations for the study of liver diseases have required HBV DNA quantification detection, with hypersensitivity (a HBV detection kit should reach the sensitivity criterion of 10-15 IU/mL), wide linearity range (1-9 log_{10} IU/mL), and high specificity and good repeatability[20].

Many automatic HBV DNA detection systems are currently available in the Chinese market, including COBAS TaqMan HBV assay used in combination with COBAS AmpliPrep, abbreviated to CAP/CTM (Roche Molecular Diagnostics, Pleasonton, CA, United States), and Abbott Real Time HBV assay used in combination with Abbott m2000sp (Abbott Molecular, Des Plaines, IL, United States). However, due to their high cost and slow detection speed, these assays are not widely applied.

Most of the real-time HBV DNA qPCR detection kits in China have common shortcomings, such as poor specificity, low detection sensitivity, poor quantitative accuracy, narrow quantitative linear range and difficulty in detecting low or high viral load. To address these problems, the Chinese Food and Drug Administration (CFDA) released "The guideline principles for the technical review of hepatitis B virus DNA quantitative detection reagents registration" in

Table 1 Detail information of national standard materials

Art. No.	Standard Material No.	Batch No.	Standard material name	Reference Conc.
HS-0001	GBW (E) 090137	201511003	HBV DNA serum standard material	1.41×10^3 IU/mL
HS-0002	GBW (E) 090138	201512004	HBV DNA serum standard material	5.9×10^4 IU/mL
HS-0003	GBW (E) 090139	201511003	HBV DNA serum standard material	4.6×10^5 IU/mL

2013, which clearly put forward the requirements for HBV DNA detection. These principles will also guide the development direction of hypersensitive HBV DNA detection kits and prompt the rapid development of automatic hypersensitive HBV DNA quantitative detection systems.

The TianLong automatic hypersensitive HBV DNA quantification system (TL system) owns proprietary intellectual property rights, and has been approved by the CFDA. This study evaluates the analytical performance of the TL system and its clinical performance compared with the CAP/CTM system.

MATERIALS AND METHODS

Clinical samples

HBV-DNA positive samples: 200 residual blood samples were obtained from HBV infected patients in the clinical laboratory at 302 Military Hospital of China. These samples included HBV A genotype (4 cases), HBV B genotype (70 cases), HBV C genotype (66 cases), HBV D genotype (28 cases) and unknown genotype (32 cases).

HBV-DNA negative samples: These serum samples were obtained after immunology testing in the clinical laboratory at 302 Military Hospital of China, and were retested using the CAP/CTM system and confirmed to be negative.

High-titer HBV-DNA mixture samples: High-titer HBV-DNA samples were collected from the clinical laboratory at 302 Military Hospital of China. The high-titer HBV-DNA mixture samples were diluted 100 times and measured three times with the CAP/CTM system. The original concentration of the high-titer HBV-DNA mixture samples was calculated to be 2.5×10^8 IU/mL.

The clinical serum samples were tested for co-infections with HIV, HCV and HDV. All results were negative.

Standards samples (reference serum)

The worldwide HBV DNA performance panel (WWHD301, SeraCare, Milford, Massachusetts, United States) which contains HBV DNA (A-H) genotypes was used in this study. National standard materials for HBV serum were used to verify the assay performance including accuracy, limit of detection and limit of quantification. Details of the national standard materials are shown in Table 1.

TianLong automatic hypersensitive HBV DNA quantification system assay

The TL system consists of a PANA 9600E automatic nucleic acid workstation, Gentier 96E real-time quantitative PCR system (Xi'an TianLong Science and Technology, Xi'an, Shaanxi, China), nucleic acid extraction kit (magnetic bead method) and a HBV DNA quantitative detection kit (fluorescence qPCR method).

The experimental method for the TL system assay followed the manufacturer's instructions. Serum of 200 μL was used for HBV DNA extraction, and for PCR reaction assessment, 40 μL for each sample was prepared on the PANA 9600E automatic nucleic acid workstation. The Gentier 96E real-time quantitative PCR system was used for quantitative detection as follows: 50 ℃ for 2 min, 95 ℃ for 3 min, [94 ℃ for 15 s, 60 ℃ for 30 s (read fluorescence)] × 45 cycles. The data were automatically analyzed by software and the results were expressed in international units per milliliter (IU/mL). The TL system detected 96 samples (89 samples, 4 quantitative standards, a negative control, a weak positive control and a strong positive control) within 140 min (80 min for nucleic acid extraction and 60 min for real-time PCR detection).

Roche COBAS HBV v2.0 assay (CAP/CTM)

HBV DNA was extracted from 650 μL of serum by the Cobas AmpliPrep instrument according to the manufacturer's instructions. The Cobas TaqMan 48 analyzer was used for automated real-time PCR amplification and detection of PCR products according to the manufacturer's instructions. The data thus generated were analyzed with Amplilink software. HBV DNA levels were expressed in international units per milliliter (IU/mL).

Limit of detection

National standard materials for HBV serum [GBW (E) 090137, Batch No. 201511003] at a concentration of 1.41×10^3 IU/mL were diluted with HBV DNA negative serum to nominal concentrations of 30 IU/mL, 15 IU/mL, 10 IU/mL, 5 IU/mL, and 2.5 IU/mL. 25 replicates per run were tested with three different batches of reagents in three runs, and the test results were log transformed to verify whether the limit of detection of the TL system met the standard (10-15 IU/mL) recommended by the European Association for the

Table 2 Limit of detection test results

Sample Conc. (IU/ml)	1st Batch of reagent			2nd Batch of reagent			3rd Batch of reagent			Average detection rate
	NO. detected	NO. not detected	Detection rate	NO. detected	NO. not detected	Detection Rate	NO. detected	NO. not detected	Detection rate

Study of Liver (EASL) [21].

Limit of quantification

National standard materials for HBV serum [GBW (E) 090137, Batch No. 201511003], at a concentration of 1.41×10^3 IU/mL were diluted with HBV DNA negative serum to nominal concentrations of 30 IU/mL, 20 IU/mL, and 10 IU/mL. 25 replicates per run were tested with three different batches of reagents in three runs, and the test results were log transformed to verify whether the limit of detection of the TL system met the standard (30 IU/mL) required in "The guideline principles for the technical review of hepatitis B virus DNA quantitative detection reagents registration".

Accuracy

National standard materials for HBV serum were used as samples and three replicates were tested at each concentration in three runs with three different batches of reagents. The sample results were log transformed to evaluate the accuracy of the TL system assay.

Comparison of clinical samples with CAP/CTM assay

A total of 200 clinical HBV positive samples with a uniform distribution of concentrations were tested with the TL system and the CAP/CTM system. The quantitative results from the two assays were counted and the Statistical Program for Social Sciences (SPSS 13.0 for Windows; SPSS, Chicago, IL, United States) was used to assess the agreement between the positive results obtained with the two assays.

Precision and reproducibility

High-titer HBV-DNA mixture samples were diluted with HBV DNA negative serum to nominal concentrations of 1×10^7 IU/mL, 1×10^4 IU/mL and 1×10^2 IU/mL. Twenty replicates were tested at each concentration with the same batch of reagent to assess the intra-assay precision. The inter-assay precision was evaluated by three tests with different batches of reagents, and five replicates at each concentration were tested per run. The inter-assay precision test was repeated over 4 d, in order to validate the reproducibility of the TL system assay. The results were log transformed for analysis.

Linearity

High-titer HBV-DNA mixture samples were diluted to nominal concentrations of 1×10^8 IU/mL, 1×10^7 IU/mL, 1×10^6 IU/mL, 1×10^5 IU/mL, 1×10^4 IU/mL, 1×10^3 IU/mL, 1×10^2 IU/mL, 60 IU/mL and 30 IU/mL. Triplicate measurements were made at each concentration level, the sample results were log transformed and then analyzed by Pearson's correlation analysis and linear regression analysis to assess the quantitative linear range of the TL system.

HBV genotypes coverage

The HBV DNA performance panel (WWHD301, Sera-Care, Milford, Massachusetts, United States) which contains all the genotypes of the HBV DNA (A-H) was used, triplicate measurements were continuously carried out for each HBV genotype for 3 days with the TL system to validate its capability of detecting all HBV DNA (A-H) genotypes.

Cross-contamination test

To assess the anti-cross contamination performance of the PANA 9600E automatic nucleic acid workstation, the "checkerboard" test was performed twice, using high-titer mixture samples interspersed with aliquots of HBV negative serum samples during DNA extraction. Each high-titer sample was included with HBV DNA negative plasma samples in the batch of 96 tests (48 positive samples and 48 negative samples) and the positions of positive samples and negative samples in the second round of testing were interchanged.

RESULTS

Limit of detection

The test results of the limit of detection are shown in Table 2, and a detection rate $\geqslant$ 95% was taken as an acceptable detection limit criterion. According to the test results, the average detection rates of the samples at five concentration levels were 44.0%, 84.0%, 98.7%, 100%, and 100%, respectively. Of these results, the detection rates for the 10 IU/mL samples were above 95% in all three tests. Therefore, the concentration of 10 IU/mL was determined as the detection limit of the TL system, which meets the

Table 3 Limit of quantification test results

Sample Conc. (IU/mL)	Test batch	Test result (Log_{10}IU/mL)			Accurate rate	
		Avg. value	CV	No. ≤ ± 0.4	per batch	Average

	2	1.40	8.51%	25	100.00%	
	3	1.46	5.55%	25	100.00%	

Table 4 Accuracy test results

National standard materials for Hepatitis B virus serum		Expected	mean ± SD,	Absolute value of Log_{10} IU/mL difference
Standard material No.	Reference Conc.	Log_{10} IU/mL	Log_{10} IU/mL	
GBW (E) 090137	1.41×10^3 IU/mL	3.15	3.11 ± 0.02	0.04
GBW (E) 090138	5.9×10^4 IU/mL	4.77	4.80 ± 0.07	0.07
GBW (E) 090139	4.6×10^5 IU/mL	5.66	5.70 ± 0.05	0.05

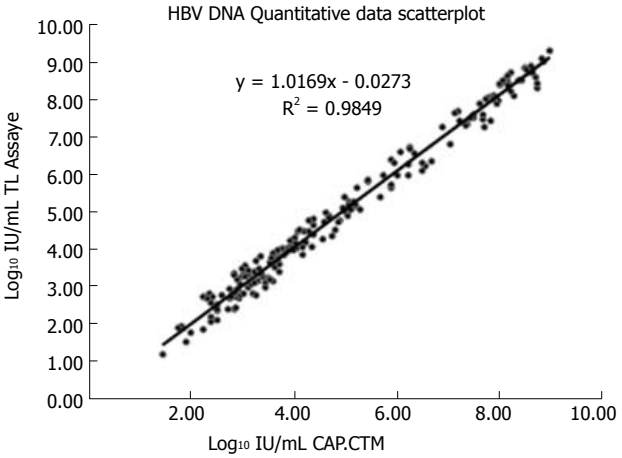

Figure 1 The correlation of measured hepatitis B virus DNA concentrations between the TL system assay and the CAP/CTM assay. HBV: Hepatitis B virus.

standard (10-15 IU/mL) recommended by the EASL.

Limit of quantification

The test results of the limit of quantification are shown in Table 3. Log_{10} IU/mL difference represents the log value difference between the detected and the expected concentrations. Taking ± 0.4 Log_{10} IU/mL as an acceptable value range in the detection results, this was converted using detected values of traceable national standard materials according to the National Center for Clinical Laboratories (NCCL) in China. When the detection accuracy rate of certain concentration was ⩾ 95%, this was considered the system quantification limit. According to the test results, all three test results for the 30 IU/mL samples showed 100% accuracy rate and the Log_{10} IU/mL difference values were between -0.22 Log_{10} IU/mL and 0.19 Log_{10} IU/mL. Therefore, the concentration of 30 IU/mL was determined as the quantification limit of the TL system, which meets the standard (30 IU/mL) required in "The guideline principles for the technical review of hepatitis B virus DNA quantitative detection reagents registration".

Accuracy

The accuracy test results are shown in Table 4. The Log_{10} IU/mL difference represents the log value difference between the detected and the expected concentrations, and when the Log_{10} IU/mL difference was less than ± 0.4, the test result was considered accurate. According to the test results, for three concentration levels of HBV national standard serum, the absolute values of Log_{10} IU/mL differences were 0.04, 0.07, and 0.05, respectively; therefore, the test results meet the accuracy requirement.

Comparison of clinical samples with CAP/CTM assay

In December 2015, 200 HBV samples were collected and used to compare the results of the TL system assay with the CAP/CTM assay. The results of the two assays showed 100% consistency for both negative and positive results (15 negative samples, 185 positive samples), and the concentrations of positive samples were uniformly distributed between 60 IU/mL and 8.7×10^9 IU/mL. The Statistical Program for Social Sciences (SPSS 13.0 for Windows; SPSS, Chicago, IL, United States) was used to assess the agreement between the positive results obtained with the two assays. The normality test results indicated that the concentration distribution did not conform to the normal distribution (P = 0.00, P < 0.05). The hypothesis test summary indicated that there were no statistical differences between the TL system and CAP/CTM assays (P = 0.817, P > 0.05). The scatter plot for the two assays is shown in Figure 1, with the linear equation y = 1.0286x - 0.0829 and correlation

Table 5 Precision and reproducibility test results

Sample Conc. (IU/mL)		1.0×10^7		1.0×10^4		1.0×10^2	
Tested Results Log_{10} (IU/mL)		Mean Value	CV	Mean Value	CV	Mean Value	CV
Intra assay precision[1]		6.97	0.23%	4.06	1.10%	2.29	3.10%
Inter assay precision	1st Day[2]	6.94	0.91%	4.19	1.82%	2.26	3.79%
	2nd Day[2]	6.95	1.04%	4.31	1.49%	2.41	3.25%
	3rd Day[2]	7.08	0.64%	4.31	1.67%	2.39	3.72%
	4th Day[2]	7.10	0.81%	4.32	1.63%	2.42	3.47%
Reproducibility[3]		7.02	1.36%	4.28	2.08%	2.37	4.41%

[1]n = 20; [2]n = 15; [3]n = 60 (15 tests/d × 4 d).

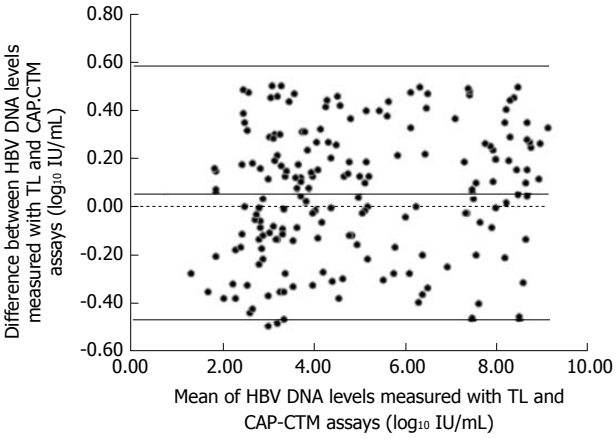

Figure 2 The difference of measured hepatitis B virus DNA concentrations between the TL system assay and the CAP/CTM assay. HBV: Hepatitis B virus.

coefficient r^2 = 0.9774, which indicated a significant correlation between the two assays. The Bland-Altman plot analysis was used to assess the difference between the positive results obtained with the two assays (Figure 2). The results showed that 98.9% (183/185) of the positive data were within the 95% acceptable range, the average difference value was 0.06, the maximum difference was -0.49, and 82.3% (153/185) of the difference values were between ± 0.4 Log_{10} IU/mL.

Precision and reproducibility

The precision and reproducibility test results are shown in Table 5. As shown in this Table, in the sample concentration range of 1.0×10^2 IU/mL to 1.0×10^7 IU/mL, the CV of intra-assay precision, inter-assay precision and reproducibility was all less than 5%.

Linearity

The linearity test results are shown in Figure 3. The linear regression analysis of eight concentration levels of HBV-DNA samples showed good linearity (the linear equation y=0.9848x - 0.0775 and correlation coefficient r^2 = 0.99).

HBV genotypes coverage

The HBV genotype coverage test results indicated that the TL system was capable of detecting all eight HBV DNA (A, B, C, D, E, F, G, H) genotypes as shown in Table 6. This almost covers all common genotypes worldwide, and meets the clinical requirements.

Cross-contamination

Following two rounds of "checkerboard" tests with the TL system assay, the detection rate of positive samples was 100%, and the detection rate of negative samples was 0. Therefore, throughout the entire test process, the negative samples were not contaminated.

DISCUSSION

HBV includes ten genotypes (A-I)[22-24]. According to its distribution in China, genotype B is the most frequent genotype in northern areas, genotype C is commonly seen in southern areas, mixed C/D genotypes are frequent in the Tibetan population in west China and genotype D is prevalent among Uighurs in Xinjiang, where genotype C is rare[25]. Infection with other HBV genotypes has not been reported in China. The 200 clinical HBV positive samples tested in this study were mainly composed of genotype B (70 cases), genotype C (66 cases) and genotype D (28 cases), genotype A (4 cases) and unknown genotypes. In order to verify the HBV genotype coverage using the TL system assay, the worldwide HBV DNA performance panel was used. The test results showed a 100% detection rate, which indicated that the TL system assay was capable of detecting not only the four genotypes in clinical samples, but also the eight HBV DNA (A, B, C, D, E, F, G, H) genotypes included in the worldwide HBV DNA performance panel.

In this study, the quantification limit test criterion adopted the analytical standard, which refers to the acceptable range ⩽ ± 0.4 Log_{10} IU/mL of external quality assessment used by the NCCL of China. The results of three rounds of 30 IU/mL quantification limit tests in this study complied with this criterion. However, there is another international frequently-used criterion that considers CV ⩽ 5% as the acceptable quantification limit test criterion. In this study, the CV in three rounds of 30 IU/mL quantification limit tests was 6.09%, 8.51%, and 5.55%, which failed to

Table 6 Hepatitis B virus genotypes coverage test Ct value

Hepatitis B virus DNA genotypes	Average tested Ct value			
	1st day	2nd day	3rd day	Negative
A	25.62	25.89	25.71	Undetected
B	25.58	25.78	25.78	Undetected
C	25.94	25.86	25.99	Undetected
D	22.61	22.78	22.78	Undetected
E	22.67	22.70	22.68	Undetected
F	22.68	22.72	22.71	Undetected
G	24.50	24.78	24.76	Undetected
H	24.81	24.80	24.85	Undetected

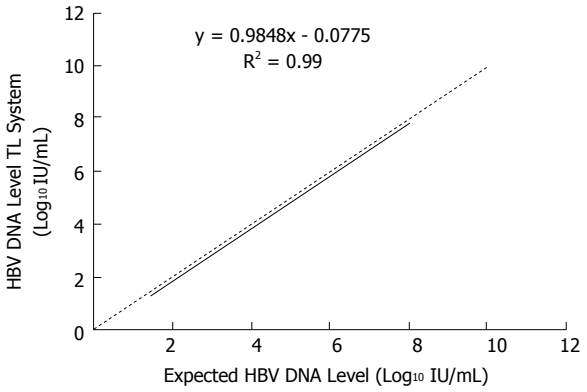

Figure 3 Linear correlation test standard curve. HBV: Hepatitis B virus.

meet this criterion. However, during the precision and reproducibility tests, the CV values for intra-assay and inter-assay tests of 1.0 × 10^2 IU/mL samples were both less than 5%. These findings indicate that the TL system assay still requires further optimization for the 30 IU/mL concentration test.

In this study, during the comparison test of 200 clinical samples, the upper limit of linearity range of both the TL assay and CAP/CTM assay was 1 × 10^8 IU/mL. Of 185 positive clinical samples, the test results of 23 samples obtained using both the TL and CAP/CTM assays exceeded the upper limit of linearity range. Four samples had the test results by the TL assay exceeded the upper limit of linearity range (8.08, 8.03, 8.08, 8.40), while the corresponding test results for the CAP/CTM assay were close to the upper limit of the linearity range (7.88, 7.80, 7.88, 8.00), but the Log_{10} IU/mL differences between the two assays were all less than ± 0.4. Following elimination of these 27 samples, the correlation analysis results (P = 0.575) showed no significant statistical differences between the two methods and good consistency. However, there were differences between the two assays in the detection of samples at a concentration over or close to the linearity range upper limit. In order to obtain more effective quantitative results, it is recommended that clinical samples are diluted and tested again.

In addition, this study also performed a cross-reaction test to analyze the effect of interfering substances on the TL system performance. However, we were unable to obtain the corresponding drug pharmacokinetic samples; thus, the HBV positive serum samples were adopted as the control group in the cross-reaction test, and these HBV positive serum samples were added to the interfering substances as the test group. The cross-reaction test results showed that the TL system was capable of detecting HBV positive serum samples containing four typical endogenous interfering substances (free hemoglobin, triglyceride, bilirubin and IgG) and four typical exogenous interfering substances (IFNα, lamivudine, adefovir dipivoxil, telbivudine) and the Log_{10} IU/mL differences between the corresponding samples from the test group and the control group were all less than ± 0.4. Therefore, it can be concluded that the TL system has anti-interference capability for both endogenous and exogenous interfering substances. For more precise evaluation of the anti-interference performance of the TL system, more tests should be carried out with drug pharmacokinetic samples and clinical samples containing interfering substances.

Qiu *et al*[26] reported a comparison of the Abbott and Da-an real-time PCR for the quantitation of serum HBV DNA. The Abbott assay had a higher sensitivity, shorter assay time, and wider dynamic range compared with the Da-an assay. However, the costs of the Abbott assay limited its routine use in clinical molecular laboratories in China. The clinical performance of the TL system was comparable to the CAP/CTM system, with reasonable costs.

There are some deficiencies in the TL system found by performance verification. First, although no negative samples were detected in the cross-contamination test, two amplification curves for negative samples showed an increased tendency at 43-45 cycles, but did not reach the threshold line. Thus, cleaning and maintenance processes are particularly important in the case of a long run time, and the possibility of accumulated contamination should be validated over this period. Second, the TL system assay adopts pre-packaged nucleic acid extraction kits (24T×4); thus, when the amount of test sample is not a multiple of 24, some nucleic acid extraction reagent is wasted and can increase costs, and this is one of the main deficiencies of the TL system which needs to be improved.

Only 200 μL of sample were required by the TL system, its limit of detection (10 IU/mL) meets the standard (10-15 IU/mL) recommended by the EASL, and its limit of quantification (30 IU/mL) also meets the standard required in "The guideline principles for the technical review of hepatitis B virus DNA quantitative detection reagents registration" issued by the CFDA. The differences between the expected and tested concentration values of national standards were less than ± 0.4 Log_{10} IU/mL, which demonstrated the high accuracy of the system. In addition, there were no statistically significant differences between the TL system assay and the CAP/CTM assay. This

study also assessed the precision, reproducibility, and linearity of the TL system, and the results showed that between 10^2 IU/mL and 10^6 IU/mL, the multiple test CV of the same sample was less than 5%; and between 30 IU/mL and 10^8 IU/mL, the linear correlation coefficient r^2 = 0.99. Furthermore, the worldwide HBV DNA performance panel, which contains HBV DNA genotypes (A-H), was used to validate the capability of the TL system to detect all eight genotypes. Finally, two rounds of "checkerboard" tests with 96 samples (48 strongly positive and 48 negative) were tested to validate the anti-cross-contamination performance of the TL system, and the results showed a 100% coincidence rate. In summary, the TL system has good analytical performance, clinical performance and stability.

COMMENTS

Background

Use of the hypersensitive hepatitis B virus (HBV) DNA quantification system to accurately detect HBV DNA in serum is important in hepatitis B antiviral therapy. International associations for the study of liver diseases have required HBV DNA quantification detection with hypersensitivity (limit of detection: 10-15 IU/mL), a wide linearity range (1-9 $\log_{10}$ IU/mL), high specificity and good repeatability. The CAP/CTM system is regarded as a worldwide standard for HBV DNA quantification. This study was conducted to validate and compare the automatic hypersensitive HBV DNA quantification system produced in China with the internationally accepted CAP/CTM system.

Research frontiers

The sensitivity, reproducibility and system automaticity for HBV DNA quantification have improved in recent years, and are important factors in determining the curative effect and endpoints of hepatitis B antiviral therapy.

Innovations and breakthroughs

This is the first study to evaluate the analytical performance of the TianLong automatic hypersensitive HBV DNA quantification system, which is the first CFDA approved system produced in China, and to compare its clinical performance with the CAP/CTM system. The TL system showed good analytical performance, and good correlation and quantitative agreement with the CAP/CTM system.

Applications

This study will be helpful in improving the performance of this system and its clinical applications.

Peer-review

The authors have evaluated the performance characteristics of the domestic TianLong HBV DNA Quantification System by testing 200 clinical HBV samples and compared the results with the international automatic HBV DNA detection systems including Roche CAP/CTM System. There was no statistically significant difference between TianLong and CAP/CTM systems. This study reports valuable results to validate the detection performance of TianLong HBV DNA Quantification System, which can pave the way to reduce cost of HBV DNA quantitative detection in the Chinese market.

Abstract

AIM

To investigate the association between 16 insertion-deletions (INDEL) polymorphisms, colorectal cancer (CRC) risk and clinical features in an admixed population.

METHODS

One hundred and forty patients with CRC and 140 cancer-free subjects were examined. Genomic DNA was extracted from peripheral blood samples. Polymorphisms and genomic ancestry distribution were assayed by Multiplex-PCR reaction, separated by capillary electrophoresis on the ABI 3130 Genetic Analyzer instrument and analyzed on GeneMapper ID v3.2. Clinicopathological data were obtained by consulting the patients' clinical charts, intra-operative documentation, and pathology scoring.

RESULTS

Logistic regression analysis showed that polymorphism variations in *IL4* gene was associated with increased CRC risk, while *TYMS* and *UCP2* genes were associated with decreased risk. Reference to anatomical localization of tumor Del allele of *NFKB1* and *CASP8* were associated with more colon related incidents than rectosigmoid. In relation to the INDEL association with tumor node metastasis (TNM) stage risk, the Ins alleles of *ACE*, *HLAG* and *TP53* (6 bp INDEL) were associated with higher TNM stage. Furthermore, regarding INDEL association with relapse risk, the Ins alleles of *ACE*, *HLAG*, and *UGT1A1* were associated with early relapse risk, as well as the Del allele of *TYMS*. Regarding INDEL association with death risk before 10 years, the Ins allele of *SGSM3* and *UGT1A1* were associated with death risk.

CONCLUSION

The INDEL variations in *ACE*, *UCP2*, *TYMS*, *IL4*, *NFKB1*, *CASP8*, *TP53*, *HLAG*, *UGT1A1*, and *SGSM3* were associated with CRC risk and clinical features in an admixed population. These data suggest that this cancer panel might be useful as a complementary tool for better clinical management, and more studies need to be conducted to confirm these findings.

Core tip: The insertion-deletions (INDEL) variations in *IL4* gene was associated with increased colorectal cancer (CRC) risk, while *TYMS* and *UP2* genes were associated with decreased risk. The Del-alleles of *NFKB1* and *CASP8* were associated with more colon related incidents than rectosigmoid. The Ins-alleles of *ACE*, *HLAG* and *TP53* were associated with higher TNM stage. The Ins-allele of *ACE*, *HLAG*, and *UGT1A1* were associated with early relapse risk, as well as the Del-allele of *TYMS*. The Ins-alleles of *SGSM3* and *UGT1A1* were associated with death risk. These data suggest that these INDEL might be useful as a complementary tool for better CRC clinical management.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer type in men and the second in women, considering 1477402 new cases in both sexes in 2015[1]. In that same year, Brazil was the tenth country with the highest CRC incidence, with 37167 new cases in both sexes[1], and making matters worse, its incidence and mortality continue to increase in the country.

Both genetic and environmental factors cause CRC[2], especially when combined[3,4]. Interestingly, these factors are ample and they vary pursuant to the cancer geographical regions[5]. However, inherited susceptibility is a major component of CRC predisposition, with an estimated 12%-35% risk attributed to genetic factors[6-8].

In relation to genetic factors, there are several mutations that might occur in human DNA, such as substitution, insertion, and deletion[9]. The second most abundant form of genetic variation in humans, after single nucleotide polymorphisms (SNPs), are the insertion-deletions (INDEL)[10]. INDELs are important because they are common genetic variations within genomes and among different ethnic groups[11,12], that may alter human traits and cause diseases[10,13], including CRC[14], by modifying the coding region[10,13] or mRNA stability[15]. The polymorphisms investigated in this study exhibit common features, given they are

all functional polymorphisms that alter the expression of genes participating in metabolic pathways associated with carcinogenesis. Also, these genes are associated with different types of cancer with high incidence in the Brazilian population, such as stomach and CRC.

Furthermore, allele frequency varies among different populations[16], and genomic ancestry distribution may influence cancer development[17,18] by affecting polymorphisms distribution[19,20]. Few studies have been evaluated INDEL association in CRC in admixed population, mainly in Brazil. Thus, the aim of this study was to determine the association between CRC risk and prognostic follow-up with 16 INDELs in genes involved in apoptosis signaling (*CASP8*), GTPase-activating (SGSM3), steroids metabolism (*CYP2E1*, *CYP19A1*, and *UGT1A1*), immune system (*HLAG*, *IL1A*, *IL4*, and *NFKB1*), MDM2-P53 pathway (*MDM2* and *TP53*), DNA replication and repair (*TYMS* and *XRCC1*) and angiogenesis (*UCP2* and *ACE*) in an admixed population from Rio Grande do Norte state (in the Northeast Region of Brazil).

MATERIALS AND METHODS

A statement of ethics

The protocol used in this study was approved by the Research Ethics Committee of Liga Norte Riograndense Contra o Câncer (Rio Grande do Norte, Brazil) by number 211/211/2011. Moreover, all participants signed a consent form prior to providing a blood sample.

Casuistic distinctions

The patients in the case group (n = 140) were diagnosed with CRC as primary cancer and treated in the Proctologist Clinic and Colorectal Surgery Department of Liga Norte Riograndense Contra o Câncer (Rio Grande do Norte, Brazil). The control subjects were cancer-free blood donors (n = 140) from the hemotherapy service (Hemovida, Rio Grande do Norte, Brazil) and were recruited in 2014.

Both Peripheral blood samples and questionnaire answers were collected from all subjects. The clinicopathological data were obtained by consulting the patients' clinical charts, intra-operative documentation, and pathology scoring. Furthermore, the CRC patients were followed up to 20 years by medical records.

Definitions

Alcohol consumption was classified as having the habit of alcohol consumption (Yes) or not having the habit of alcohol consumption (No). The subjects who have the habit of consuming alcohol were subcategorized according to consumption frequency (Eventually: $\leqslant$ 3 d per month; Frequently: > 3 d per month). The tobacco consumption was classified as have already smoked (Already) or not (Never). The subjects who have already smoked were subcategorized in Former (Stopped smoking for at least 1 year) and Current.

Tumor location was classified as rectosigmoid (sigmoid colon and rectum) and colon (ascending, transverse and descending colon) based on colonoscopy or on radiographic exam. The relapse records were obtained from histological or radiographic exams with subsequent clinical/radiological progression.

Overall survival was defined as the time from the date of surgery to the date of death or the date of the last follow-up of patients who were still alive. The relapse time was defined as the time from the date of surgery to the date of the first local. Patients with no local or distant relapse evidence at the date of death or the date of the last follow-up were censored.

DNA extraction and quantification

Genomic DNA was extracted by using a DNA extraction commercial kit, QIAamp DNA Blood Mini Kit (Qiagen, Hilden, Germany), and quantified with Qubit® 2.0 Fluorometer (Invitrogen, Carlsbad, CA, United States).

Polymorphism selection

Recently, INDELs have been the focus of multiple investigations[21-25]. This type of polymorphism presents interesting features as genetic markers: (1) INDELs are spread throughout the human genome; (2) INDELs derive from a single event (they do not present homoplasy); (3) since the allele frequencies of many INDELs are significantly different in separated populations; (4) small INDELs can be analyzed using short amplicons, which improves the amplification of degraded DNA and facilitates multiplexing; and (5) INDELs can be easily genotyped with a simple dye-labeling electrophoretic approach. Furthermore, all these genes evaluated in the present study show potential activity in pathway and may contribute to the carcinogenesis process (Table 1). Their genetic variations could contribute to: (1) risk of developing CRC; (2) impact on treatment response; or (3) in prognosis.

Genotyping of polymorphism

Multiplex PCR was used to simultaneously amplify the 16 investigated markers, as shown in Supplementary Table 1. The amplification was performed on ABI Verity thermocycler (Life Technologies, Foster City, CA, United States). A single multiplex reaction used Master Mix QIAGEN Multiplex PCR kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. The samples were incubated at 95 ℃ for 15 min, followed by 35 cycles at 94 ℃ for 45 s, 60 ℃ for 90 s, and 72 ℃ for 1 min, with a final extension at 70 ℃ for 30 min.

For fragment analysis, we used capillary electrophoresis on the ABI 3130 Genetic Analyzer instrument (Life Technologies). 1.0 μL of PCR product was added to 8.5 μL of HI-DI deionized formamide (Life Technologies) and 0.5 μL of GeneScan 500 LIZ pattern size standard (Life Technologies). After data collection,

Table 1 Potential biological effects of insertion-deletions polymorphism selected in this study

[1]According to the single nucleotide polymorphism database (dbSNP); UTR: Untranslated region; INDEL: Insertion-deletions.

samples were analyzed on the GeneMapper ID v.3.7 software (Life Technologies).

Analysis of genetic ancestry

Genomic ancestry analysis was performed based on the method described by Santos *et al*[25] using 62 autosomal ancestry informative markers (AIMs). Two multiplex PCR reactions of 20 and 22 markers were performed and amplicons were analyzed by electrophoresis using the ABI Prism 3130 sequencer and GeneMapper ID v.3.2 software. The individual proportions of European, African, and Amerindian genetic ancestries were estimated using STRUCTURE v.2.3.3 software, assuming three parental populations (European, African, and Amerindian).

Statistical analysis

The categorical variables case and control participants were tested by the Chi-squared test. For ancestry index and age at diagnosis variables we used the Mann-Whitney test. Logistic regression analyses between the genotype model and CRC risk were performed by the SNPassoc package v.1.9-2, along with clinical features variables. The association between genotype and free-relapse survival time was evaluated by Kaplan-Meier plots, performed by the survival package v.2.41-3. Log-rank and Wilcoxon tests were used to examine the genetic effect on survival outcomes. The statistical power was estimated by 10000 simulations. All statistical analyses and plotting were performed with R package v.3.1.2[26]. Differences between groups were considered significant at $P < 0.05$.

RESULTS

Demographic characteristics

We analyzed 140 subjects with CRC and 140 cancer-free individuals. The demographic characteristics of participants were summarized in Table 2, which shows demographic features of the groups. Regarding genomic ancestry, significance was observed with the distribution of African ancestry ($P = 0.049$), Table 3. However, there was no difference between groups when an analysis of multinomial logistic regression was performed.

Distribution of genotypes associated with susceptibility to CRC

All INDEL polymorphisms are in Hardy-Weinberg equilibrium ($P > 0.05$). The genotypic and allelic frequencies of the subjects are presented in the Table 4. Genotypic frequency ($P = 0.01$) of *IL4* gene polymorphism was significantly different between case-controls, and higher frequency of Del allele were observed in cases than in controls.

The significant logistic regression analyses between case-controls are summarized in Table 5. Del allele polymorphism in *IL4* gene ($P = 0.0110$) was associated with an increased risk of CRC development, while Ins allele in *UCP2* ($P = 0.0210$) was decreased

CRC risk. Furthermore, the Del allele in the *TYMS* (P = 0.0120) gene was associated with decreased CRC risk.

Distribution of genotypes associated with prognostic follow-up in CRC

The baseline characteristics of CRC patients are summarized in Table 6. The follow-up time median was 5.28 years among 78 patients who had complete genotype and follow-up information. The 5-year free-relapse rate was 70% and the 10-year free-relapse rate was 66.4%. The 5-year survival rate was 91.4% and the 10-year survival rate was 87.9%.

We also evaluated the genetic impact in the clinical features. The Del allele in *NFKB1* and *CASP8* were associated with more incidents to colon than rectosigmoid (Table 7). In relation to the INDEL association with TNM stage risk, the Ins alleles of *ACE*, *HLAG* and *TP53* (6 bp INDEL) were associated with a higher TNM stage (Table 8). Regarding the INDEL association with relapse risk, the Ins alleles of *ACE*, *HLAG*, and *UGT1A1* were associated with relapse risk, as well as the Del allele of *TYMS* (Table 9). Moreover, these findings corroborate those observed in the free-relapse survival curve (Figure 1). Regarding INDEL association with death risk, the Ins alleles of *SGSM3* and *UGT1A1* were associated with death risk (Table 10).

DISCUSSION

Despite the effective strategies for prevention, early detection, and treatment[27-32], there are ethnic differences in the CRC incidence and survival[33,34], specifically in individuals with African American ancestry, who have higher CRC incidence and lower 5-years survival rates than other ethnic groups[33-38].

In this work, we evaluated the association between 16 INDEL [*ACE, CASP8, SGSM3, CYP19A1, CYP2E1, HLAG, IL1A, MDM2, NFKB1, TP53* (16 and 6 bp), *TYMS, UCP2, XRCC1*, *IL4* and *UGT1A1*] and the risk of developing CRC in a Brazilian population, as well as their clinical features. We found significant association between three investigated INDEL polymorphisms and CRC risk, two associated with anatomical localization, three associated with TNM stage, four associated with early relapse risk, and two associated with death risk before 10 years.

Variations in the IL-4 activity or in the IL-4 receptor due to mutations have been associated with cell proliferation and might affect signal transduction pathways in cancer[39]. We evaluated INDEL of 70 bp in intron 3 of the *IL4* gene (rs79071878), a variation which may influence the production of this cytokine. The higher IL-4 production may result in diminished cell-mediated immune response, and escape from immune surveillance in the tumor cells. The cell-mediated immune response may be inhibited by downregulating the expression of Th1 cytokines, decreasing the CD8+ T-cell response in the tumor microenvironment[39-41]. Furthermore, this INDEL has been associated with gastric cancer[39] and other immune diseases[42,43]. However, this is the first study indicating an association between this *IL4* polymorphism and the risk of developing CRC. Our results indicate that the Del allele in *IL4* was associated with the risk of developing CRC.

The *TYMS* gene plays an essential role in the biosynthesis of the DNA-component thymidylate (dTTP) and is required for DNA replication and repair[44]. The insertion of 6 bp in the 3'-UTR of *TYMS* primary transcript (rs151264360) may significantly influence gene expression as shown by using a luciferase assay[15]. Mandola *et al*[15] observed that a Del allele might decrease the TYMS mRNA stability, and the TYMS protein expression. Moreover, Rahman *et al*[45] showed in vitro that TYMS overexpression might induce the transformation of mammalian cells into a malignant phenotype. Studies indicate that this INDEL is associated with many cancers[46-49], especially colorectal[48]. These results suggested that this INDEL variation might decrease CRC risk, as showed in the present work. However, this finding diverges from data from Mexico[50], in which association was not observed. On the other hand, our results showed that this Del allele was associated with an increase relapse risk.

Uncoupling proteins (UCPs) are a family of mitochondrial proteins, which were originally reported to play essential roles in reducing the reactive oxygen species[51,52]. *UCP2* plays a role in carcinogenesis in various tissues, including colon cancer, and regulates the responsiveness of carcinomas to chemotherapy[53-56]. Adaptive mechanisms of cancer cells include resistance to tumor growth inhibition and evasion of apoptosis, and cellular events that are appreciably affected by oxidative stress[57,58]. The UCP2 expression level is significantly higher in colon cancer tissue than in its adjacent tissue and *UCP2* may play a role in intestinal epithelial cells from benign to malignant transformation[59]. However, the role of *UCP2* in development of colon cancer is unclear. INDEL polymorphism may regulate *UCP2* mRNA stability via post-transcriptional modification of UCP2 protein expression[60,61]. Indeed, in the present study was observed that INDEL polymorphism might be associated with colorectal cancer. However, this is the first study indicating an association between this *UCP2* polymorphism and the risk of developing CRC.

The renin-angiotensin system (RAS), which regulates systemic blood pressure, also exerts local effects on cell proliferation, apoptosis, inflammation and angiogenesis in different tissues[62]. In addition, there is evidence linking the RAS with tumorigenesis and tumor angiogenesis[63]. The polymorphisms in the various components of the RAS that may possess clinical relevance[62], and the most common polymorphism in the gene encoding angiotensin converting enzyme (*ACE*) is INDEL of a 287-bp fragment in intron 16 and is responsible for the inter-individual variation in the

ACE levels in blood and tissues[64]. The insertion allele in this gene was associated with ACE levels, the rate of disease progression, shorter TTF, and lower circulating levels of ACE[62,65]. This INDEL has been associated with cancer risk susceptibility[66-68], including CRC[65,68], and with response to bevacizumab[62]. Our results indicate that Ins allele was not associated with CRC risk development, as showed by Yang *et al*'s meta-analysis[69] and Liu *et al*[70] case-control study (241 cases and 299 control, China). On the other hand, our results also showed that this INDEL was also associated with TNM stage risk and relapse risk.

The *HLAG* is an important immunomodulatory molecule related to several mechanisms of tolerance[71]. Since the discovery of the HLA-G protein expression in cancer[72], several pieces of evidence have supported a considerable role for HLA-G in tumor cell escape from immuno-surveillance and antitumor immune responses[73]. The 14 bp INDEL (rs371194629) has been suggested to have functional significance. The Ins allele has been shown to be associated with alternative splicing, resulting in deletion of 92 bp in

exon 5 from mature mRNA, which then leads to low levels of soluble HLA-G (sHLA-G)[74]. Furthermore, our results indicated that the Ins allele was associated with a higher TNM stage and relapse up to 5 years. These findings suggest that low levels of sHLA-G might influence in poor prognostics.

UGT1 is a family of membrane-bound enzymes involved in the inactivation and elimination of lipophilic molecules through glucorination. Moreover, variants

in this gene have been shown to be useful tools to identifying patients more likely to experience severe toxicity related to irinotecan-containg regimens[75]. In particular, INDEL variants in *UGT1A1* (rs8175347) were associated with significantly decreased glucuronidation activity, which results in reduced SN-38 clearance[76] and an increased risk of these toxicities in patients homozygous for the Ins allele[75,77-80]. Our results showed that the Ins allele in UGT1A1 was associated with early relapse risk, as well as with death risk prior to 8 years. This genetic variation may identify patients who might benefit from increased irinotecan dosing, as observed by Chen *et al*[75].

The *SGSM3* belongs to a novel protein family consisting of three members and appears to be associated with small G-protein coupled receptor signal transduction pathways, and could control cellular functions by a Ras-mediated signaling pathway[81]. Studies have linked Rab dysfunction to various human diseases including cancer[82,83], and our results have shown that the Ins allele might also be associated with death risk prior to 8 years.

The aims of this study were to determine the association between CRC risk and the clinical features with 16 INDEL in genes involved with carcinogenesis pathways in an admixed population from Brazil. Although we have achieved our goal, there are limitations regarding sample number. We suggest, therefore, that an extensive study should be conducted in the Brazilian population to confirm the findings, as well as in other admixed populations.

In summary, the present work indicates that polymorphisms in *ACE* (rs4646994), *TYMS* (rs151264360), *UCP2* (45 bp), *IL4* (rs79071878), *NFKB1* (rs28362491), *CASP8* (rs3834129), *TP53* (rs17880560), *HLAG* (rs371194629), *UGT1A1* (rs3213239), and *SGSM3* (rs56228771) genes were associated with CRC risk and clinical features in an admixed population. These data suggest that this cancer panel might be useful as a complementary tool for better clinical management, and more studies need to be conducted to confirm these findings.

ACKNOWLEDGMENTS

We thank all participants who allowed us to carry out this study. We are also grateful to the students and technicians from LGHM/UFPA/PA, LBBM-LABMULT/UFRN/RN, Laboratory of Pathology and Cytopathology/Liga Norte Riograndense Contra o Câncer/RN and Hemovida/RN. We are also grateful to Philip Barsanti for the invaluable and constructive English review of the manuscript. Furthermore, we are grateful to André Ribeiro-dos-Santos and Ana Paula Schaan for help with statistical revision.

COMMENTS

Background

Colorectal cancer (CRC) is the third most common cancer type in men and the second in women. Despite the effective strategies for prevention, early detection, and treatment, there are ethnic differences in CRC incidence and survival. These variances occur specifically in African Americans, who have higher CRC incidence and lower survival rates than other ethnic groups. Thus, the present study evaluated the association between 16 insertion-deletions (INDEL) polymorphisms with colorectal cancer risk in an admixture population, as well with clinical features.

Research frontiers

The second most abundant form of genetic variation in humans, after single nucleotide polymorphisms (SNPs), are the INDEL. The INDEL understanding is important because they are common genetic variations within genomes, and they may alter human traits and cause diseases, including colorectal cancer, by modifying the coding region or mRNA stability. One of the challenges for genetic polymorphism association studies is the lack of knowledge regarding the frequency of the polymorphism in the targeted population, mainly in admixed populations (*e.g.* Brazil).

Innovations and breakthroughs

This is the first case-control study to evaluate the association between these 16 INDEL polymorphisms with colorectal risk, clinical features and prognostic follow-up in an admixture population, adopting the methodology that can be easily used to perform multiplexing assays.

Applications

This pilot study is design and findings could be used to determine sample size for a larger randomized controlled study aiming to test the impact of these INDEL polymorphism panel in colorectal risk, clinical features and prognostic follow-up.

Terminology

Ancestry informative marker - In population genetics, an ancestry informative marker (AIM) is a polymorphism that exhibits substantially different frequencies between populations from different geographical regions. A set of many AIMs can be used to estimate the proportion of ancestry of an individual derived from each geographical region.

Peer-review

This is an interesting study aiming to determine the association between CRC risk, and the clinical features with 16 INDEL in genes involved with carcinogenesis pathways in an admixed population from Brazil. The overall structure of the manuscript is complete and conforms to the academic rules.

Abstract

AIM

To reduce readmissions and improve patient outcomes in cirrhotic patients through better understanding of readmission predictors.

METHODS

We performed a single-center retrospective study of patients admitted with decompensated cirrhosis from January 1, 2011 to December 31, 2013 (n = 222). Primary outcomes were time to first readmission and 30-d readmission rate due to complications of cirrhosis. Clinical and demographic data were collected to help describe predictors of readmission, along with care coordination measures such as post-discharge status and outpatient follow-up. Univariate and multivariate

analyses were performed to describe variables associated with readmission.

RESULTS

One hundred thirty-two patients (59.4%) were readmitted at least once during the study period. Median time to first and second readmissions were 54 and 93 d, respectively. Thirty and 90-d readmission rates were 20.7 and 30.1 percent, respectively. Predictors of 30-d readmission included education level, hepatic encephalopathy at index, ALT more than upper normal limit and Medicare coverage. There were no statistically significant differences in readmission rates when stratified by discharge disposition, outpatient follow-up provider or time to first outpatient visit.

CONCLUSION

Readmissions are challenging aspect of care for cirrhotic patients and risk continues beyond 30 d. More initiatives are needed to develop enhanced, longitudinal post-discharge systems.

Core tip: To reduce readmissions and improve patient outcomes, we conducted a retrospective cohort study of 222 decompensated cirrhotics admitted to a single institution and followed longitudinally for readmission. Nearly 60% were readmitted during the study, with hepatic encephalopathy as the most common cause of readmission, with social factors, education level and insurance, also affecting readmission rates. We also found that readmission risk in this population continues well beyond 30 d, with 30% of patients being readmitted at 90 d, calling for continued, coordinated care after hospitalization.

INTRODUCTION

Cirrhosis is the second most common digestive disease cause of death and 12th overall cause of death in the United States[1]. Cirrhosis and complications of cirrhosis account for around 40000 deaths in the United States annually, similar to diabetes and slightly more than kidney diseases, with a mortality rate of 25.7 deaths per 100000 people[2,3]. In addition to high mortality, cirrhosis and its complications are the cause of many high-cost hospitalizations. One study in 2002 showed that cirrhosis accounts for 150000 hospitalizations in the US, with an estimated single hospital admission cost of $15000 and a total estimated cost of $4 billion annually[2]. A more recent study found that 37% of patients with decompensated cirrhosis were readmitted within one month of discharge at a cost of roughly $20000 per admission[4]. The additional burdens of disease, including lost days of work, diminished quality of life, and health care costs are difficult to measure.

In the current value-based healthcare landscape, hospitals will be increasingly held financially accountable for readmissions under value-based care programs. Moreover, no evidence-based systems have been developed to reduce readmission rates in most chronic disease conditions. Providers and health systems face challenges, as the current body of literature lacks data on effective chronic disease care management for cirrhosis, and our current episodic system of health care delivery is insufficient to tackle this issue. Factors associated with readmissions in decompensated cirrhosis in previous works include Model for End-Stage Liver Disease (MELD), diabetes, nosocomial infections, BMI and hepatic encephalopathy[5-7].

Our institution has sought to improve the continuity of care for high-risk patients through post-discharge phone calls, as well as through care management programs for chronic conditions such as heart disease and diabetes. We hope to extend such programs to patients with cirrhosis to improve clinical outcomes and reduce readmissions[8]. We performed this study to better understand and define the predictors of readmission, as well as time to first readmission, in a cohort of patients with decompensated cirrhosis, to better target future programs aimed at reducing readmissions and improving patient outcomes.

MATERIALS AND METHODS

Selection of cohort

We utilized an internal research patient data registry (RPDR), which is a database consisting of 1 billion records encompassing 4.5 million patients from 1988 to the present, to identify our cohort. Data come from multiple sources within 5 major Boston area hospitals, including billing registries and electronic medical records, and contain patient encounters, laboratory test results, imaging, and other clinical data. We searched this database to identify potential subjects by any of the International Classification of Diseases 9 (ICD-9) diagnosis groups or common procedure terminology codes associated with cirrhosis and complications of cirrhosis (Table 1).

Patients over the age of 18 who were hospitalized

Table 1 ICD-9 codes used to identify patients

Bleeding from esophageal varices	456
Esophageal varices in diseases classified elsewhere	456.2
Spontaneous bacterial peritonitis	567.23
Alcoholic fatty liver	571
Alcoholic cirrhosis of liver	571.2
Laennec's cirrhosis	571.2
Cirrhosis of liver nos	571.5
Cirrhosis of liver without mention of alcohol	571.5
Macro nodular cirrhosis	571.5
Micro nodular cirrhosis	571.5
Portal cirrhosis NOS	571.5
Posthepatitic cirrhosis	571.5
Post necrotic cirrhosis	571.5
Cholangitic cirrhosis	571.6
Cholestatic cirrhosis	571.6
Hepatic encephalopathy	572.2
Portal hypertension	572.3
Hepatorenal syndrome	572.4
Other sequelae of chronic liver disease	572.8
Hepatopulmonary syndrome	573.5
Ascites	789.5

due to one of the complications of cirrhosis between January 1, 2011 - December 31, 2013 were included in the initial study cohort. Complications of cirrhosis from Table 1 were grouped into the following categories for analysis: (1) Hepatic encephalopathy (HE), defined as altered mental status due to chronic liver disease and improved after treatment with lactulose; (2) Gastrointestinal bleeding (GIB), defined as a clinically significant bleeding and varices, gastric antral vascular ectasia and portal hypertensive gastropathy seen on endoscopy; (3) Spontaneous bacterial peritonitis (SBP), defined as infection of preexisting ascitic fluid and more than 250 polymorphonuclear cells per high power field and/or monomicrobial culture in the ascitic fluid without evidence for an intra-abdominal secondary source such as a perforated viscus; (4) Volume related, defined as ascites or hepatic hydrothorax requiring paracentesis during the hospitalization. Acute renal failure or hyponatremia was also included in this category; and (5) Other complications defined as hepatorenal syndrome, hepatopulmonary syndrome, hepatocellular carcinoma (HCC) and portal vein thrombosis.

Emergency Department (ED) visits or hospitalizations due to any diagnosis other than complications of cirrhosis were not considered as a readmission. We did not include alcohol-related admissions, such as alcohol withdrawal, as admissions due to complications of cirrhosis. Also, in our institution many patients receive regular large volume paracentesis for ascites in ED visits. These brief encounters were not considered an elective readmission due to decompensation.

Exclusion criteria were advanced extrahepatic malignancy, end stage renal failure, end stage heart failure, patients with prior liver transplant, patients who had no further encounters within our health care system, and patients who died or were placed on hospice within one month from the index hospitalization.

Institutional structure

This study was conducted at a single academic transplant center. Our outpatient liver program includes 7 hepatologists, 31 gastroenterologists not specifically trained in hepatology, and 2 nurse practitioners, as well as an advanced liver fellow. Inpatients patients with liver disease can be admitted to our dedicated liver service but are most often admitted to a general medicine hospitalist service with hepatology or gastroenterology consultation. A majority of our patients are local and live within an hour's drive or less from the hospital, though patients on the transplant list may come from other parts of New England, such as Maine and New Hampshire, and are seen more regularly as outpatients by local primary care physicians (PCPs) and gastroenterologists.

Collection of baseline data

Medical records for patients meeting the above inclusion criteria were individually reviewed. Baseline variables collected from chart review and RPDR data included age, gender, race, education, health insurance, marital status, MELD scores, laboratory test results, co-morbidities, medications, date of index and subsequent admissions, date of follow-up visits by a PCP or a gastroenterologist, post-discharge setting, smoking history and alcohol use. Admission and discharge MELD scores were calculated based on Mayo Clinic MELD calculator, using creatinine, total bilirubin, and international normalized ratio (INR) extracted closest to the admission and discharge time, respectively[9]. The Charlson Co-morbidity Index (CCI) was also calculated for each patient at index admission[10].

Follow-up time and study outcomes

Patients were followed from the index admission until readmission, death, discharge with hospice care, liver transplantation, loss to follow-up or December 31, 2013, whichever came first. All patients were followed post-discharge for a minimum of 90 d and all readmissions were reviewed. The primary outcomes were time to first readmission and 30-d readmission rate for cirrhosis or a complication of cirrhosis. The secondary outcome was the 90-d readmission rate.

Statistical analysis

Univariate analyses were performed using chi-square or proportional hazard ratio to find predictors of 30-d readmission and time to first readmission. Clinically relevant candidate variables with $P < 0.15$ were used

in Cox proportional hazards regression (for time to first readmission) and logistic regression (for 30 and 90 d readmission rates) models. Due to co-linearity between reason for index admission and medications at discharge, medications at discharge was excluded from the final models. Two-sided P values ≤ 0.05 were considered significant. All statistical analyses were performed using SAS v.9.3. The statistical methods and results of this study were reviewed by biostatistician Han Lee, PhD of Massachusetts General Hospital and Harvard Medical School.

RESULTS

From January 1, 2011 to December 31, 2013, 222 patients were admitted to our center due to one of the complications of cirrhosis and did not meet any of the exclusion criteria. The median time from hospital discharge to end of the study period was 273 d. Baseline characteristics of the study population are presented in Table 2.

One hundred thirty-two of these 222 patients (59.4%) were readmitted at least once during the study period. The median time to first readmission, our primary outcome, was 54 d. Thirty and 90-d readmission rates were 20.7 and 30.1 percent, respectively. The most common cause of index admission was one of the volume related conditions (28.8%) while the most common cause of readmission was hepatic encephalopathy (35.5%) (Table 3). The average length of stay for the index hospitalization was 7.2 d, and 88 patients (49.4%) were readmitted with the same complication of cirrhosis.

Post-discharge conditions are summarized in Table 4 based on the post-discharge care setting. Patients discharged to a skilled nursing facility, those who left the hospital against medical advice, and homeless patients who were discharged to shelters had more 30-d readmissions but the results were not statistically significant (P < 0.12).

One hundred sixty five patients out of the 222 index patients (74.3 %) had a follow-up outpatient visit in our institution at some point after index admission (Table 4). The rest of the patients were not seen at our center after discharge and may have had local follow-up. Of those 165 patients seen at our institution, 83 (37.4%) were seen only by a gastroenterologist, 22 (9.9%) only by a PCP and 31 (14%) both by a gastroenterologist and a PCP. The remaining 29 patients had an outpatient visit scheduled post-discharge but were readmitted before the scheduled visit. Among the patients who had a post-discharge follow-up visit at our institution, there was no significant difference in 30-d readmission rates based on the visit by a PCP versus a gastroenterologist

History of HCC	1.85 (1.10-3.08)	0.01	1.67 (0.95-2.93)	0.07
HE	1.51 (1.04-2.16)	0.01	1.61 (1.11-2.40)	0.01

[1]Education variable was adjusted for unknown status. HCC: Hepatocellular carcinoma; MELD: Model for End-Stage Liver Disease; HCV: Hepatitis C virus.

or both ($P = 0.9$).

We further analyzed 30 d readmission rates stratified by time until first post-discharge follow-up visit: < 2 d, 2-14 d, and > 14 d. Thirty five patients (21%) were seen in an office visit within two days after index discharge, 66 (40%) between 2 and 14 d, and 64 (38.8%) after 14 d, but there was no statistically significant difference in the rate of readmission amongst these groups ($P = 0.1$). The average time between discharge and the first outpatient follow-up appointment was also calculated at 22.6 d for patients seen by a GI specialist, 31.9 d for those who saw a PCP and 24.7 d for those who saw both.

In the univariate time-to-event analysis, the following covariates were associated with time to readmission ($P < 0.05$): education level, etiology of cirrhosis, MELD score, diagnosis of HE at index admission, history of HCC, and history of depression or bipolar disorder (Table 5). In the multivariate analysis, lower education level, any cirrhosis etiology other than alcohol, higher MELD score, HE at index admission and history of HCC were associated with shorter time to readmission (Table 5). Kaplan-Meier curves for time to readmission stratified by MELD score and etiology of cirrhosis are shown in Figures 1 and 2, respectively. In both the univariate and multivariate analysis of predictors for 30-d readmissions, patients with lower education, HE at index, ALT more than upper limit of normal (ULN) and Medicare patients had higher 30-d readmission rates ($P < 0.05$) (Table 6). The c-statistic for this test was 0.75.

DISCUSSION

Hospital readmissions are costly and represent opportunities for improvements in quality of care,

Table 6 Predictors of 30-d readmission

Variable	Univariate analysis		Multivariate analysis	
	OR (95%CI)	*P* value	OR (95%CI)	*P* value
Insurance (ref =Medicaid/No insurance)	1		1

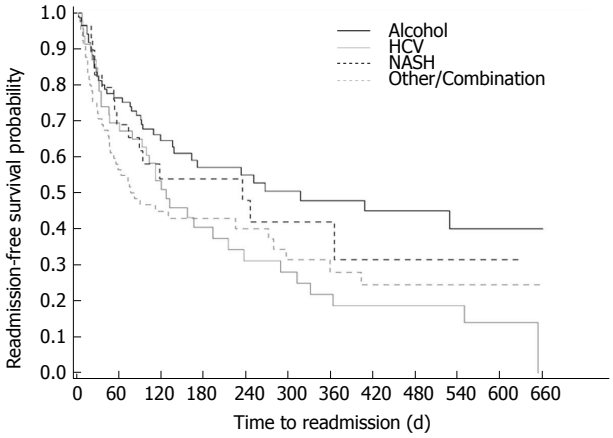

Figure 2 Kaplan-Meier curve for time to readmission stratified by etiology of cirrhosis.

communication, and coordination. Readmissions are viewed as potentially avoidable and the large payers, such as the United States Department of Health and Human Services Center for Medicare and Medicaid Services Readmission Prevention Program penalizes hospitals for higher than expected readmissions for heart failure, myocardial infarction and pneumonia. As healthcare moves towards value-based payment methods, primary care and specialists alike must prepare to better organize care for the highest risk and highest cost patients. Understanding the attributes of patients and causes for readmission is the foundation for designing strategies to mitigate the economic losses and prevent clinical morbidity. Additionally, while the current 30-d readmission threshold is appropriate for discrete admission events, such as surgery, applying this model to a chronic disease population may not capture true readmission risk or opportunity for improvement. By studying our patients longitudinally, we showed that about 20% of our patients were readmitted within 30 d, but that rate rose to 30% at 90 d. We also found that lower education level, MELD score ⩾ 15, chronic liver disease due to more than one etiology, HE at index admission, and history of HCC are associated with shorter time to readmission with the median time to first readmission of 54 d.

Our data is consistent with previous studies which have shown similar 30-d and 90-d readmission results[4,7,11-13]. We also found that Medicare patients, patients with lower education levels, higher ALT levels at discharge, and HE at the time of presentation are associated with higher 30-d admission rates. We also found that MELD score, which is a measure of hepatic and renal function combined, is associated with more 30-d readmission and shorter time to first readmission rates. Prior studies have also demonstrated that patients with higher MELD score are more prone to 30-d readmission[4,11] or more first hospital admission in patients who had not been admitted the previous year[14].

As seen in other recent studies, hepatic encephalopathy was a predictor for readmission, based on both 30-d and time to readmission analyses[7,15,16]. The one-year mortality for cirrhotic patients with hepatic encephalopathy is very high, approaching 60%-80% in recent studies[17,18]. HE is an expensive disease, costing approximately $63000 per case and is responsible for approximately 7.2 billion dollars

in direct costs annually[19,20]. Thirty-four out of 62 (54.9%) of our patients who presented first with hepatic encephalopathy were readmitted at least once with the same diagnosis in one year. HE is not simply a marker of disease severity; forty four (71%) of our index patients who presented with HE had MELD score below 15. This is an opportunity for focused management, as we hypothesize that HE patients are more prone to readmission due to the functional impact of encephalopathy.

Careful discharge planning and expedited outpatient follow-up may help prevent readmissions, though further study is needed for cirrhosis patients. In our study, patients discharged to skilled nursing facility, those who left the hospital against medical advice and homeless patients who were discharged to shelters had higher 30-d readmission rates, but the results were not statistically significant. While not statistically significant, it is worth noting that the majority of our patients (54.3%) were discharged home without any support services, and only 27.2% of our patient cohort had VNA services after their index admission, pointing to an opportunity for further outreach once the patient leaves the hospital. As many cirrhotic patients have HE, compromising their decision making, coordinating medications and returning to their outpatient clinics for follow-up more challenging. As health systems design interventions for these complex patients, the role of home health care should be considered, with home visits for patients in our catchment area from nurses and/or allied health professionals who help patients organize their care once they've left the hospital.

Early outpatient follow-up by primary care and/or specialists may be another opportunity to improve outcomes but not necessarily reduce readmissions. A recent study conducted by the VA found that early (within 7 d of discharge) outpatient follow-up in patients with cirrhosis slightly increased the rate of 30-d readmissions, but significantly lowered the risk of mortality[21]. A study in Denmark showed that one-hour rehabilitation clinic within 1-3 wk after discharge from HE, reduced alcohol consumption and improved survival, but did not diminish the subsequent hospital admissions[22]. While our own numbers on outpatient follow-up were small, we did not show that relatively early medical follow-up (14 d or less) prevented readmissions. Follow up in two or three weeks for cirrhotics may not be sufficient. As the average time to a post-discharge visit ranged from 22.6-31.9 d, and 29 patients were readmitted before they had an outpatient visit, there is clearly room to improve access to post-discharge care, potentially harnessing alternate care models such as home health services, RN-led clinics and virtual visits.

Due to our use of clinical records, rather than insurance claims data, we were not able to directly gather data about hospitalizations outside our health care system. Also, our inclusion criteria only searched for admissions due to complications of cirrhosis, although (many) patients were hospitalized electively or non-electively for existing co-morbidities other than complications of cirrhosis. Our study is subject to selection bias given that patients followed at tertiary care centers tend to be more medically complex.

In summary, we showed that readmission risk for patients with cirrhosis continues well beyond 30 d and may be attributable to serious chronic disease and compromised coping skills. We found that lower education level, MELD score $\geqslant$ 15, chronic liver disease due to more than one etiology, HE at index admission, and history of HCC are associated with shorter time to readmission with the median time to first readmission of 54 d. As health systems and insurers increasingly support the adoption of value-based payment methods and patient-centered care, providers and health systems leaders must work proactively to identify high-cost and high-risk patient populations that may benefit from integrated care systems to help proactively manage chronically ill patients[23,24]. We believe that patients with cirrhosis are a population that will benefit by a systematic multidisciplinary outreach program which has the potential for preventing readmissions, improving care and saving money. Future studies should explore systems of care to define post-discharge best practices for continued care once the patient leaves the hospital environment.

COMMENTS

Background

Hospital readmissions are gaining increasing scrutiny as a measure of value-based health care as they directly impact both quality and cost of care. Cirrhosis and complications of cirrhosis account for around 40000 deaths in the United States annually and also account for 150000 hospitalizations in the US, with an estimated total estimated cost of $4 billion annually. A recent study found that 37% of patients with decompensated cirrhosis were readmitted within one month of discharge at a cost of roughly $20000 per admission.

Research frontiers

In the current value-based healthcare landscape, hospitals will be increasingly held financially accountable for readmissions under value-based care programs. Moreover, no evidence-based systems have been developed to reduce readmission rates in most chronic disease conditions, such as cirrhosis.

Innovations and breakthroughs

Factors associated with readmissions in decompensated cirrhosis in previous works include MELD, diabetes, nosocomial infections, BMI and hepatic encephalopathy. Early outpatient follow-up by primary care and/or specialists may be another opportunity to improve outcomes but not necessarily reduce readmissions. A recent study found that early (within 7 d of discharge) outpatient follow-up in patients with cirrhosis slightly increased the rate of 30-d

readmissions, but significantly lowered the risk of mortality. While our own numbers on outpatient follow-up were small, we did not show that relatively early medical follow-up (14 d or less) prevented readmissions. Follow up in two or three weeks for cirrhotics may not be sufficient, as the average time to a post-discharge visit ranged from 22.6-31.9 d, and 29 patients were readmitted before they had an outpatient visit; there is clearly room to improve access to post-discharge care, potentially harnessing alternate care models such as home health services, RN-led clinics and virtual visits.

Applications

Authors' institution has sought to improve the continuity of care for high-risk patients through post-discharge phone calls, as well as through care management programs for chronic conditions such as heart disease and diabetes, and they hope to extend such programs to patients with cirrhosis to improve clinical outcomes and reduce readmissions. Authors performed this study to better understand and define the predictors of readmission, as well as time to first readmission, in a cohort of patients with decompensated cirrhosis, to better target future programs aimed at reducing readmissions and improving patient outcomes.

Terminology

Value-based payments are a strategy increasingly adopted by payers with the goal of shifting from volume-based payment, *e.g.*, "fee-for service" payments, to those based on improved clinical outcomes.

Peer-review

For chronic disease populations, current 30-d readmission thresholds may not capture true readmission risk or opportunities for improvement. This paper found that lower education level, MELD score ≥ 15, chronic liver disease due to more than one etiology, HE at index admission and history of HCC are associated with shorter time to readmission with the median time to first readmission of 54 d. Designing post-admission continuity of care interventions with these factors in mind would improve clinical practice and patient outcomes.

Abstract

AIM

To investigate the clinical utility of biological age (BA) measurement in screening colonoscopy for the detection of colorectal adenomas in the average-risk population.

METHODS

A consecutive series of asymptomatic subjects aged ⩾ 30 years who underwent colonoscopy in routine check-ups were enrolled. Colorectal adenoma was classified according to size, number, and location. BAs were calculated using the MEDIAGE™ Biological Age Measurement System.

RESULTS

A total of 2696 subjects were investigated (1876 men and 820 women). The mean chronological age (CA) was 46.0 years and the mean BA was 44.7 years. Metabolic syndrome (MS) was diagnosed in 218 subjects (8.1%). The prevalence of overall colorectal adenoma was 23.1% (622/2,696). When the subjects were divided into four groups based on BA (⩽ 39 years; 40-49 years; 50-59 years; ⩾ 60 years), the prevalence of colorectal adenoma was increased as BA increased (P < 0.001). Colorectal adenoma located in the proximal colon was more prevalent in the BA-dominant group (BA-CA ⩾ 5

years) than the CA-dominant group (CA-BA ⩾ 5 years) (P = 0.034). When the subjects were categorized into four groups according to MS and age gap between BA and CA, the incidence of colorectal adenoma increased with MS and BA-dominance (P < 0.05).

CONCLUSION

Measurement of BA may help to assess the risk of colorectal adenoma in screening colonoscopy.

Key words: Chronological age; Biological age; Colorectal adenoma; Age gap

Core tip: The present study was conducted on the basis of the hypothesis that colorectal adenoma recognized as a premalignant lesion of colorectal cancer is associated with the biological aging process, suggesting that biological age (BA) represents a biological activity in human. Thus, we intended to assess the risk of colorectal adenomas in the average-risk population from the biological perspective. As a result, the present study demonstrated that the prevalence of colorectal adenoma correlated well with BA, and was more common in the distal colon in BA -dominance.

Measurement of biological age may help to assess the risk of colorectal adenoma in screening colonoscopy. *World J Gastroenterol* 2017; 23(37): 6877-6883 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6877.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6877

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies and a leading cause of cancer mortality in the world[1,2]. Colonoscopy is effective for detecting adenomatous polyps, and colonoscopy with polypectomy has been shown to significantly reduce the expected incidence of CRC by 76%–90% in multiple cohort studies[3,4].

The guidelines of the American Society of Gastrointestinal Endoscopy for colorectal cancer screening and surveillance recommend that screening colonoscopy should begin at the age of 50 for average-risk individuals[5,6]. The current cutoff age is based mainly on the fact that the incidence of CRC begins to rise during the 6th decade of life[7]. However, given the long lead time associated with adenoma-to-carcinoma progression, the increased number of CRCs diagnosed in this age group may reflect the end result of adenomas present in individuals under 50 years old[6]. In fact, nearly 1 in 15 of CRCs develops in adults under 50 years of age[8]. Therefore, reasonable guidelines for performing screening colonoscopy for colorectal cancer should be proposed for the average-risk population.

Aging is a highly individual process, and has a high degree of inter-individual and between-individual difference[9]. Chronological age (CA) is the age as determined by the passage of time since birth. However, biological age (BA) is determined by physiology rather than chronology[10]. As CA does not accurately reflect the functional state of the body, it does not provide an accurate indication of the aging process[11,12]. CA and BA may differ significantly, since both genetics and the environment contribute to BA[10]. Individuals might be healthier, more vital, and biologically younger than might be expected from their CA, and vice versa[13].

If subjects with an average risk of colon cancer undergo colonoscopy according to BA, colon cancers may be prevented by colonoscopy with polypectomy for colorectal adenomas and premalignant lesions at the optimal age of life. Thus, it is necessary to stratify the risks and identify high-risk groups in a specialized manner. In addition, there might be a rationale by which to recommend screening colonoscopy for early cancer detection and prevention besides CA determination.

To date, no worldwide studies have been conducted to estimate the clinical application of BA as a new indicator in CRC screening. Hence, we intended to assess the risk for colorectal adenomas in the average-risk population from the biological perspective. Therefore, the aim of the present study was to investigate the clinical utility of BA measurement in screening colonoscopy for the detection of colorectal adenomas in the average-risk population.

MATERIALS AND METHODS

Subjects

We conducted this study on a consecutive series of asymptomatic subjects ⩾ 30 years of age who underwent colonoscopy during a routine check-up at the Health Promotion Center of Bundang Jesaeng Hospital in Gyungki-do, South Korea between August 2011 and August 2012. The exclusion criteria were a history of colonic disease, such as CRC, polyps, and inflammatory bowel disease, and a history of colorectal surgery or colonoscopy within the previous 10 years. Information regarding age, sex, medical history of diabetes mellitus and hypertension, and family history of colon cancer was collected from a standardized questionnaire. The study was approved by the Institutional Review Board of the Bundang Jesaeng Hospital in Korea (IMG 15-04).

Measurement of BA

BAs were calculated as described previously using models for predicting BA (MEDIAGE™ Biological Age Measurement System, MEDIAGE Research Center, Gyeonggi-do, South Korea)[14,15]. This measurement

system has been used as an adjunctive measure for easily predicting individual differences in health and aging status with the use of clinical parameters that are commonly used at many health check-up centers in South Korea.

Test battery parameter

We collected clinical profiles such as physical, biochemical, and hormonal parameters for the calculation of BA. A profile of physical parameters included height, weight, waist circumference, lean body mass, body fat measurement, body mass index, blood pressure, forced expiratory volume 1, and forced vital capacity. Waist circumference was measured at the high point of the iliac crest during minimal respiration. Blood samples were drawn from the antecubital space in the morning. Biochemical parameters included complete blood count with differential count, erythrocyte sedimentation rate, fasting blood glucose, liver function test, lipid profile, blood urea nitrogen, creatinine, bone turnover markers such as osteocalcin and deoxypyridinoline, and tumor markers such as prostate specific antigen, and total antioxidant status were measured using Randox TAS assay kits (Randox, United States) based on the reaction between metmyoglobin and hydrogen peroxide. Lastly, the hormonal parameters included thyroid-stimulating hormone, temporary threshold shift, sex hormone-binding globulin, follicle-stimulating hormone, insulin-like growth factor-1, and dehydroepiandrosterone sulphate.

Metabolic syndrome

Based on the ATP Ⅲ-WPRO (Regional Office for the Western Pacific Region of WHO) definition according to the WPRO criteria, metabolic syndrome (MS) was defined as the presence of three or more of the following[16]: (1) abdominal obesity, waist circumference > 90 cm in men and > 80 cm in women; (2) hypertriglyceridemia, ≥ 150 mg/dL; (3) low high-density lipoprotein cholesterol level, < 40 mg/dL in men and < 50 mg/dL in women; (4) high blood pressure, ≥ 130 mm Hg systolic or ≥ 85 mm Hg diastolic; and (5) high serum fasting glucose level, ≥ 110 mg/dL.

Colonoscopy

We performed colonoscopies that reached the cecum after bowel preparation with 4 L of Colyte powder (TAEJOON PHARM Co., Ltd., South Korea). The Colyte powder was composed of polyethylene glycol (3350.29 g), anhydrous sodium sulfate (2.85 g), sodium hydrogen carbonate (0.84 g), sodium chloride (0.73 g), and potassium chloride (0.37 g). We examined colonoscopic features, including the size, location, number, and histologic findings of polyps. Polyp size was assessed using open colonoscope biopsy forceps (MTW-Endoskopie Manufaktur, Wesel, Germany). Adenoma size was classified into < 10 and ≥ 10 mm (the largest size was used for multiple adenomas). The location of colorectal adenomas was divided into three categories: the proximal colon, including the cecum, ascending colon, and transverse colon; the distal colon, including the splenic flexure, descending colon, sigmoid colon, and rectum; and both sides of the colon. The number of adenomas was classified as either single or multiple (≥ 2). Histological findings were classified according to their premalignant potential: colorectal adenomas included tubular, villous, or serrated adenomas; and controls had normal colonoscopic findings and non-polypoid benign lesions such as non-specific colitis or histologically confirmed hyperplastic polyps. In addition, advanced adenomas were defined as ≥ 1 cm in estimated diameter, containing ≥ 25% villous features, and/or high-grade dysplasia.

Statistical analysis

For continuous variables, data distribution was first evaluated for normality using the Shapiro-Wilk test. As all the variables did not pass not pass normality test, data were analyzed using Mann-Whitney's *U* tests and presented as medians (P_{25}–P_{75}). Descriptive variables were analyzed using χ^2 analyses or Fisher's exact tests, as appropriate, and $P < 0.05$ were considered statistically significant. Statistical analyses were conducted using SPSS 21.0 (IBM Corp., Armonk, NY, United States).

RESULTS

We identified a total of 2699 subjects in the study period. Among them, three with colorectal carcinoma were excluded. Thus, the study population consisted of 2696 subjects. The demographic and clinical characteristics of the enrolled subjects are summarized in Table 1.

The subjects comprised 1876 men (69.6%) and 820 women (30.4%). The median age of the subjects in CA was 46.0 years, whereas the median age og the subjects in BA was 44.7 years old.

MS was diagnosed in 218 subjects (8.1%). When the subjects were divided into four groups based on BA (≤ 39 years; 40-49 years; 50-59 years; ≥ 60 years), the prevalence of MS was increased with increasing BA ($P < 0.001$). Interestingly, the gradient of prevalence of MS in BA was higher than that of CA.

The prevalence of overall colorectal adenoma was 23.1% (622/2696). The colonoscopic findings of the subjects according to location, size, and number are summarized in Table 2.

When the subjects were divided into four groups based on BA or CA (≤ 39 years; 40-49 years; 50-59 years; ≥ 60 years), the prevalence of colorectal adenoma was increased as BA and CA increased ($P < 0.001$) (Figure 1).

Clinical and colonoscopic characteristics were evaluated in accordance with the age gap between CA and BA. The prevalence of colorectal adenoma in

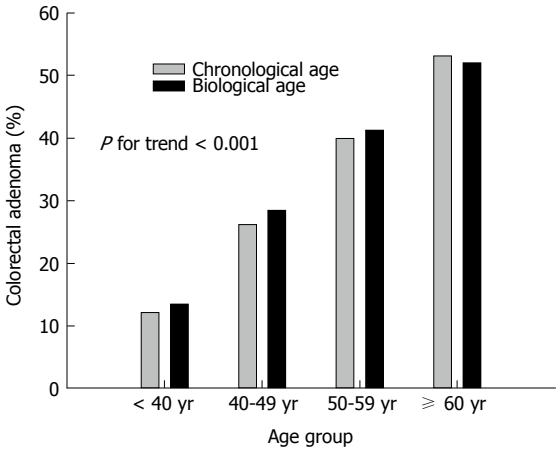

Figure 1 Prevalence of colorectal adenoma according to chronological age and biological age. When the subjects were divided into four groups (≤39 yr; 40-49 yr; 50-59 yr; ≥ 60 yr), the prevalence of colorectal adenoma increased with increasing biological age ($P < 0.001$).

Table 2 Characteristics of colorectal adenoma in subjects *n* (%)

	All subjects (*n* = 2696)
Colorectal adenoma	
Yes	622 (23.1)

dominant age groups was assessed. The subjects were divided into two groups based on an age gap between CA and BA of more than 5 years: BA-dominant group (BA-CA ≥ 5 years) and CA-dominant group (CA-BA ≥ 5 years). The incidences of MS as well as high blood pressure, fasting glucose level, and HbA1c in the BA-dominant group were significantly higher than those in the CA-dominant group (Table 3). As shown in Table 4, colorectal adenoma located in the distal colon was more prevalent in the BA-dominant group than the CA-dominant group ($P = 0.034$).

The prevalence of colorectal adenoma according to MS and age gap was evaluated. We categorized subjects into four groups according to MS and age gap between BA and CA. As a result, the incidence of colorectal adenoma increased with MS and BA-dominance: The incidence of colorectal adenoma was 21.5%, 22.8%, 34.5%, and 39.2% for the first group (MS^- and BA < CA, $n = 368/1711$), the second group (MS^- and BA ≥ CA, $n = 175/767$), third group (MS^+ and BA ≥ CA, $n = 31/79$), and the fourth group (MS^+ and BA < CA, $n = 48/139$) ($P < 0.05$) (Figure 2).

DISCUSSION

The present study was conducted on the basis of the hypothesis that colorectal adenoma recognized as a premalignant lesion of colorectal cancer is associated with the biological aging process, suggesting that BA represents a biological activity in human. Thus, we intended to assess the risk of colorectal adenomas in the average-risk population from the biological perspective. As a result, the present study demonstrated that the prevalence of colorectal adenoma correlated well with BA, and was more common in the distal colon in BA-dominance. Furthermore, the incidence of MS correlated more precisely with BA compared with CA.

Aging in humans refers to a multidimensional process of physical, psychological, and social changes that occur from birth[14]. Aging is usually assessed in terms of the CA, which is defined as the time elapsed since birth. However, CA fails as an accurate indicator of the aging process[17]. BA estimates the functional status of an individual with respect to their chronological peers on the basis of how well they function in comparison with others of the same CA[18]. Different individual rates of aging lead to differences between CA and BA, and individual values of BA can therefore vary widely at any given CA and are ultimately expected to correspond to the inter-individual variations in longevity and timing and/or magnitude of sequelae of the aging process[19,20]. It has been proposed that BA may serve as an indicator of an individual's general health status, remaining healthy life span, and active life expectancy[21]. Considering that BA corresponds well with the aging process, BA may be a good indicator for starting screening colonoscopy at the most biologically

BA: Biological age; CA: Chronological age.

Figure 2 The prevalence of colorectal adenoma according to metabolic syndrome and age gap. The incidence of colorectal adenoma increased for the first group (MS- and BA < CA), the second group (MS- and BA ⩾ CA), the third group (MS+ and BA ⩾ CA), and the fourth group (MS+ and BA < CA) (P < 0.05). MS: Metabolic syndrome; BA: Biological age; CA: Chronological age.

optimal time in an individual's life. If so, CRC may eventually be preventable using colonoscopy with polypectomy for premalignant lesions.

Many previous studies have revealed that colorectal adenoma is associated with MS. The clinical characteristics of MS, such as obesity, dyslipidemia, and insulin resistance, have been linked to an increased risk of CRC in several studies[16,22]. In this study, the subjects with MS had more colorectal adenomas compared to those without MS (44.9% *vs* 27.8%, P < 0.001). In particular, the prevalence of colorectal adenoma was increased along with MS and BA-dominance (P < 0.001) (Figure 2).

In this study, the prevalence of MS increased proportionally with BA compared with CA. This suggests that MS is related to BA more than to CA because the metabolic change is associated with aging. Soprano *et al*[23]. reported that MS can be considered an age-related disease by identifying a correlation between MS and aging. In addition, they highlighted aging-related dysfunctions that contribute to the onset of several metabolic diseases[23]. Therefore, physiological disorders such as MS should be measured based on BA rather than CA.

In this study, a CA-dominant subject was defined as an individual younger than their CA, showing that they are healthier than expected. On the other hand, a BA-dominant subject was defined as an individual older than their CA, showing that they are less healthy than expected. The prevalence of MS was higher in the BA-dominant group than in the CA-dominant group in this study. Therefore, this result also suggests the clinical application of BA to various metabolic diseases related with age.

In this study, the prevalence of colorectal adenoma increased with BA. As shown in Figure 1, the prevalence of colorectal adenoma rose sharply along with BA distribution rather than CA distribution with increasing age. The prevalence of colorectal adenoma was higher in the BA-dominant group than in the CA-

dominant group, although the difference between the two groups was not statistically significant. Interestingly, colorectal adenomas in the distal colon were more common in the BA-dominant group compared with the CA-dominant group ($P = 0.034$).

Based on these results, BA deserves attention as an alternative indicator for screening for various cancers including CRC. Interestingly, the prevalence of colorectal adenoma in subjects aged < 50 years was as high as 19.9% (329/2696) in this study. Hence, the commencement of screening colonoscopy should be determined based on BA and physiological criteria rather than indiscriminately at 50 years of CA. This strategy will help in identifying those at risks of CRC at an early stage (before the age of 50 years).

This study was limited because the study population, who voluntarily attended health screening, may have been individuals more concerned about their health than average and trying harder to maintain their health than members of the general population. As a result, the age gap between BA and CA was not as large as expected. Therefore, further studies targeting members of the general population are needed in the future.

The present study highlights the important implications for the future planning of CRC screening in that the higher prevalence of BA-dominance was observed in subjects with colorectal adenoma. It should be emphasized that long-term prevention of both colorectal adenoma along with the biological aging process is of clinical importance.

In conclusion, measurement of BA may help to assess the risk of colorectal adenoma in screening colonoscopy. In particular, careful colonoscopic examination in the distal colon should be performed in BA-dominant individuals.

COMMENTS

Background

Current guidelines for colorectal cancer screening are based on chronological age (CA) of 50 years. However, a significant number of colorectal cancers have been found even under 50 years of age. Therefore, screening colonoscopy at a more reasonable age may be necessary from the biological perspective.

Research frontiers

The authors investigated the clinical utility of biological age (BA) measurement in screening colonoscopy for the detection of colorectal adenomas in the average-risk population.

Innovations and breakthroughs

The present study demonstrated that the prevalence of colorectal adenoma correlated well with BA, and was more common in the distal colon in BA-dominance. Furthermore, the incidence of metabolic syndrome correlated more precisely with BA compared with CA.

Applications

Measurement of BA may help to assess the risk of colorectal adenoma in screening colonoscopy. In particular, careful colonoscopic examination in the distal colon should be performed in BA-dominant individuals.

Terminology

BA is determined by physiology rather than chronology. BA estimates the functional status of an individual with respect to their chronological peers on the basis of how well they function in comparison with others of the same CA.

Peer-review

The author aimed to investigate the clinical utility of BA measurement in screening colonoscopy for the detection of colorectal adenomas in the average-risk population. The present paper is indeed interesting.

Abstract

AIM

To evaluate the endoscopic treatment efficacy and

prognostic factors of long-term response to treatment for painful chronic pancreatitis.

METHODS

This retrospective analysis identified 168 patients with painful chronic pancreatitis hospitalized during January 2010-January 2015 in a Romanian tertiary referral center. Data on demographics, medical history, alcohol consumption, smoking habit, clinical parameters, type and number of endoscopic procedures and hospital admissions number were collected from the medical charts and analyzed. The absence or substantial reduction of pain (mild pain) at the end of the follow-up associated with the technical success of endotherapy was considered as clinical success.

RESULTS

Among the 168 patients with painful chronic pancreatitis admitted to our department during the study period, 39 (23.21%) had optimal response to the medical therapy. One hundred and twenty-nine patients required endoscopic treatment. The median follow-up period was 15 mo (range, 0-60 mo). Overall, technical success of endotherapy was achieved in 105 patients (81.39%). More than two-thirds of patients (82.78%) had substantial improvement of pain after the endoscopic treatment, including frequency and severity of the pain attacks. Patients younger than 40 years had significantly more successful endoscopic procedures (P = 0.041). Clinical success was higher in non-smoking patients (P = 0.003). The hospital admission rate was higher in patients with recognized alcohol consumption (P = 0.03) and in smokers (P = 0.027). The number and location of pancreatic stones and locations of strictures did not significantly influence the technical success (P > 0.05) or the clinical success (P > 0.05).

CONCLUSION

Younger age than 40 years can be considered an important factor positively influencing endoscopic treatment outcome in patients with painful chronic pancreatitis.

Key words: Pain; Chronic pancreatitis; Endoscopic procedures; Alcohol; Smoking; Hospital admission; Technical success; Clinical success

Core tip: We evaluated the endoscopic treatment efficacy and prognostic factors of long-term response in painful chronic pancreatitis. Technical and clinical success was achieved in more than two-thirds of patients. Patients younger than 40 years had significantly more successful endoscopic procedures. Non-smoking patients had greater clinical success. Also, the hospital admission rate was higher in patients with recognized alcohol consumption and in smokers. Number and location of pancreatic stones and locations of strictures did not significantly influence the technical or clinical success. Younger age can be considered an important factor that positively influences the endoscopic treatment outcome in these patients.

Prognostic factors of response to endoscopic treatment in painful chronic pancreatitis. *World J Gastroenterol* 2017; 23(37): 6884-6893 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i37/6884.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i37.6884

INTRODUCTION

Patients with chronic pancreatitis (CP) often present with severe abdominal pain, resistant to common analgesics. The exact pathophysiology of CP is still unknown, being a debated subject[1]. Increased intrapancreatic pressure within the parenchyma and/or pancreatic duct causing tissue ischemia (due to pancreatic duct strictures and stones), inflammation of the pancreas, and pancreatic and extrapancreatic complications[1] (*i.e.,* pseudocysts, bile duct/duodenal strictures and peptic ulcers) are factors suggested as causing pain in CP.

The endoscopic treatment of painful CP remains a clinical challenge. The goals of endotherapy are to drain the pancreatic duct[2], to reduce the frequency and the severity of the pain, and to resolve the local complications of the disease. Unfortunately, few data are available on the long-term efficacy of this endoscopic treatment. Most of the authors of the related literature consider that endoscopic retrograde cholangiopancreatography (ERCP) should be used as a first-line treatment in patients unresponsive to medical therapy. The efficacy of ERCP is comparable to that surgery, with a higher success rate in properly selected patients and a low morbidity rate. Moreover, it can be performed repeatedly and independently of patient age. In some cases it may be considered as a "bridge" to subsequent surgery[3-5].

Several studies have identified the factors associated with a good long-term outcome of endoscopic treatment in painful CP, including cephalic intraductal stones, complete pancreatic clearance, absence of ductal stricture, and recent onset of disease[6-9]. Also, cessation of alcohol consumption and of smoking is associated with a good outcome[7,10]. Higher rates of clinical success have been associated with a short interval between the CP onset and endoscopic therapy and older age at the onset of disease[7]. Different literature data have evidenced better results of surgery *vs* endoscopic treatment in terms of pain control[11,12]. Regarding the short-term outcome, no significant differences have been found between endoscopic treatment and surgery in terms of hospitalization rate and medical costs. Instead, the hospitalization rate

and its duration were found to be significantly higher in patients with endoscopic treatment, regarding the long-term outcome compared to surgery[13].

In this study, we considered our case experience from a referral tertiary center in Romania to evaluate the endoscopic treatment efficacy and prognostic factors of long-term response to treatment in patients with painful CP. Our intention was to determine whether ERCP maintains merits in the management of pain in CP and if there are some new clinical or endoscopical factors which might help to achieve long-term results.

MATERIALS AND METHODS

Patients

We retrospectively searched the medical database of our hospital (a tertiary referral center; Regional Institute of Gastroenterology and Hepatology, Cluj-Napoca, Romania) to identify all patients with painful CP hospitalized for treatment in our Gastroenterology Department during January 2010-January 2015 (n = 168). Patients with good response to medical therapy and without required endotherapy were excluded from the study (n = 39). All patients who underwent endotherapy with treatment intention were included in the study (n = 129).

Data on demographics, medical history, clinical data (*i.e.,* abdominal pain pattern and severity, diarrhea, diabetes, jaundice), hospital admissions number, type and number of endoscopic procedures and complications of treatment were collected from the medical charts and analyzed. Alcohol consumption was defined as a daily intake of > 20 g of ethanol for both women and men. Cigarette smoking was defined as smoking at least 5 pack-years[7].

The first parameter taken into account was abdominal pain relief in patients with pancreatic drainage. The pain character and intensity was quantified based on patients' medical records at study enrollment and at end of follow-up. No standardized instruments for pain quantifying, quality of life or psychosocial impact evaluation were used. In the medical records, the severity of pain was qualified as severe, moderate and/or mild with continuous or intermittent pattern.

Endoscopic treatment

All ERCPs and endoscopic procedures were performed by the same experienced endoscopist physician (> 600 ERCPs/year). According to the initial pancreatography findings, the patients with pancreatic drainage were divided into three different groups: patients with pancreatic strictures; patients with pancreatic intraductal stones; and patients with pancreatic strictures and intraductal stones. An efficient pancreatic sphincterotomy and/or successful stent placement across the strictures and/or intraductal stones removal was considered a technical success. Otherwise, the endoscopic treatment was considered as a failure. Also, we considered any form of surgical drainage performed during the follow-up period as indicating failure of the endoscopic treatment. All instances of early complications (in first 24 h post-ERCP) were also noted.

In patients with intention to treat, the endoscopic treatment was considered as complete if no further ERCP session was required and if no pancreatic stents were *in situ* at the cut-off date (January 2015). Otherwise, endotherapy was considered as ongoing. The absence of significant reduction of pain (absent or mild pain) at the end of follow-up associated with the technical success of endotherapy was considered a clinical success. Treatment of concomitant bile duct strictures (n = 35) and pseudocysts (n = 28) were also noted. Considering biliary drainage, clinical success was noted in the case of jaundice improvement with the bile duct stricture waist disappearing.

According to the European Society of Gastrointestinal Endoscopy guidelines, in patients with pseudocysts, technical success was considered where at least one stent from a pancreatic pseudocyst to the digestive lumen was able to be inserted[6] or by resolution of the fluid collection. Short-term clinical success was considered in the case of complete relief of the initial symptoms with a decrease in pseudocyst diameter of at least 30%-50% at 1 mo[6]. For large ductal stones in the pancreatic head or body, one or multiple sessions of extracorporeal shock wave lithotripsy (ESWL) were performed. A third-generation electromagnetic lithotripter (Dornier MedTech, Weissling, Germany) was used, with the patient under general anesthesia.

Statistical analysis

Qualitative data is presented as counts and percentages. Quantitative data is presented as means and standard deviations for normally distributed data, and as medians and standard deviations and interquartile ranges or ranges for skewed distributions. Associations between qualitative variables were assessed with the chi-square test or Fisher's exact test. Comparisons between two groups of quantitative skewed data were performed with the Wilcoxon rank sum test, and comparisons between three groups with the Kruskal-Wallis test, followed by nonparametric post hoc tests.

For all statistical tests performed, we used the two-tailed P-value and an 0.05 level of significance. All analyses were computed with R environment for statistical computing and graphics version 3.2.3 (http://www.R-project.org/).

RESULTS

Clinical characteristics of patients

From January 2010 to January 2015, 168 patients with painful CP were admitted to our department.

Table 1 Demographic, etiological and clinical characteristics of patients at study entry, [*n* = 129, *n* (%)]

Sex as male/female	106 (82.17)/23 (17.83)
Age (mean ± SD, yr)	51.55 ± 11.34)
Etiology	
Alcoholic	102 (79.07)
Autoimmune	2 (1.55)
Genetic	2 (1.55)
Idiopathic	13 (10.08)
Metabolic	3 (2.33)
Pancreas divisum	7 (5.43)
Pain pattern: continuous/intermittent	22 (17.05)/107 (82.95)
Pain intensity: severe/moderate	57 (44.19)/72 (55.81)
Diabetes	41 (31.78)
Diarrhea	63 (48.84)

Thirty-nine patients (23.21%) had optimal response to the medical therapy (*i.e.,* paracetamol, non-steroidal anti-inflammatory drugs, tramadol, co-medication for neuropathic pain, and pancreatic enzyme substitution) and they were excluded from the study. Thus, 129 patients were enrolled in the study. The mean age was 51.55 years (range, 15-82 years). One hundred and six were men (82.17%) and 23 were women (17.83%). Demographical, etiological and clinical data are shown in Table 1. Seventy-five patients (58.14%) were alcohol drinkers and 47 patients (36.43%) were smokers at study enrollment. The median follow-up period was 15 mo (range, 0-60 mo).

Endoscopic pancreatic drainage

During the study period a total of 265 ERCPs were performed, with a median of 2.8 procedures/patient. At the initial pancreatography, 89 patients (68.99%) had only pancreatic duct strictures, 17 patients had only intraductal pancreatic stones (13.18%) and 23 patients (17.83%) had both intraductal stones and strictures. Seven patients (5.43%) had pancreas divisum and were treated *via* the minor papilla.

Overall, technical success was achieved in 105 patients (81.39%). At the end of study, endoscopic treatment was completed in 103 patients and ongoing in 2 patients. Endotherapy failure was noted in 24 patients (18.6%). In 7 of these patients (29.16%) the endoscopic procedures could not be performed due to severe stenosis of the pancreatic duct and/or giant intraductal stones. The number and size of the intraductal pancreatic stones and the location of ductal stenosis did not significantly influence the clinical and technical success (Tables 2 and 3).

Early complications post-ERCP appeared in 7 patients (6.67%) who had technical success and in 2 patients (8.33%) who had failure of the endoscopic treatment. Acute pancreatitis post-ERCP was noted in 8 patients (6.2%) and post-sphincterotomy bleeding in 1 patient (0.77%). All complications were successfully managed conservatively.

Patients with at least one session of endoscopic treatment (*n* = 122): There were no statistically significant differences regarding the number of hospital admissions, the number of ERCP/patients and the number of endoscopic procedures between patients with technical success (86.06%) *vs* failure of endotherapy (13.93%) (Table 4). More than two-thirds of the patients with at least one session of endoscopic treatment (*n* = 101, 82.78%) had clinical success after the endoscopic treatment, including improvements in frequency and severity of pain attacks (Table 5).

Patients with pancreatic strictures alone at initial pancreatography (*n* = 85): In 23 patients (27.05%), a pancreatic sphincterotomy was the only sufficient procedure. Sixty-two patients (72.94%) required multiple procedures. Multiple pancreatic restenting sessions were performed in 6 patients (7.05%). The clinical success rate was 81.17% (*n* = 69) (Table 6).

Patients with pancreatic intraductal stones alone at initial pancreatography (*n* = 17): Two patients (11.76%) required initial ESWL followed by endoscopic stone extraction. To achieve stone clearance, multiple sessions of stone extraction were performed in all patients. The clinical success rate was 76.47% (*n* = 13) (Table 6).

Patients with pancreatic strictures and intraductal stones at initial pancreatography (*n* = 20): Multiple procedures were performed in all patients. Six patients (30%) required pancreatic restenting, five of who (25%) required multiple stone extraction sessions. Two patients still had pancreatic plastic stents in place at the end of the study period. The clinical success rate was 95% (*n* = 19) (Table 6). There were significant differences regarding the number of ERCP/patient between the group of patients with pancreatic strictures and those with strictures and stones ($P < 0.001$) and in terms of procedures/patient in all three groups ($P < 0.001$) (Table 6). No statistically significant differences were found regarding the mean age and severity of initial pain, technical success ($P = 0.995$) or clinical success ($P = 0.899$). However, the technical success was significantly higher in patients younger than 40-years-old ($P = 0.041$).

No statistically significant association was found between the continuation of alcohol drinking and clinical success ($P = 0.066$). In contrast, non-smoking patients had a higher rate of clinical success than their smoking counterparts ($P = 0.003$). Considered separately, patients without any alcohol consumption or smoking had a better prognosis than patients who had one or both addictions ($P = 0.007$) (Table 7). Alcohol drinkers (*n* = 75) had a higher hospital admission rate (4 *vs* 3, $P = 0.03$) than patients who were not alcohol drinkers (*n* = 54). The number of

Table 2 Technical and clinical success according to the initial pancreatography *n* (%)

	n	Technical success	Clinical success

	Technical success		
	Yes, *n* = 105	No, *n* = 17	*P* value
Hospital admissions	3 (3-5)	3 (3-5)	0.728
ERCP/patient	2 (1-3)	2 (1-2)	0.605
Procedures/patient	3 (1-4)	2 (0-3)	0.055

Data are presented as median (IQR). IQR: Interquartile range; ERCP: Endoscopic retrograde cholangiopancreatography.

endoscopic procedures/patients was higher (3 *vs* 2) in alcohol drinkers, but not significantly (P = 0.249). In smokers (n = 47), the hospital admission rate was higher (4 *vs* 3, P = 0.027) than for patients who were non-smokers (n = 82) and the endoscopic procedures required was also greater (3 *vs* 2, P = 0.622). Newly diagnosed diabetes appeared in 14 patients (13.46%) with clinical success during follow-up.

Biliary drainage

During the follow-up period, 35 patients (28.68%) developed biliary stricture with jaundice. Biliary drainage was achieved using a single plastic biliary stent in 21 patients (60%) and simultaneous biliary plastic stents in 2 patients (5.71%). Multiple biliary stent sessions were performed in 12 patients (34.29%). Covered self-expending metallic stents (SEMS) were used in 2 patients (5.71%) who were deemed at high surgical risk. Biliary drainage was successful in 26 patients (74.29%) and failed in 9 patients (25.71%).

Pancreatic pseudocysts

Pancreatic pseudocysts were identified in 28 patients (22.95%). Transpapillary drainage was performed in 17 cases (60.71%) and transmural drainage in 9 cases (32.14%). In 1 patient (3.57%) the endoscopic approach could not be achieved due to the severe stenosis of the pancreatic duct and surgical drainage was indicated. Technical success was achieved in 96.43% cases (n = 27). Short-term clinical success was achieved in 26 patients (96.3%). Endoscopic ultrasound drainage was indicated in 1 patient because of an increase in the size of the pseudocyst and remarkable collateral circulation in the portal hypertension context.

Surgery

In 24 patients (18.6%) the endoscopic treatment failed and some form of surgery was performed during follow-up. In 7 patients, no endoscopic procedures were performed. The endoscopic treatment was converted to surgery in 17 patients (13.93%).

DISCUSSION

Through this retrospective study, we obtained results of the endoscopic approach of painful CP patients in a tertiary referral center. Technical success was achieved in 81.39% of patients with significant improvement of pain experienced by more than two-thirds of the patients, including frequency and severity of pain attacks. About 50% of the patients were pain-free at the end of follow-up. We found that age under 40 years, no smoking, no alcohol consumption and multiple ERCP sessions are independent factors associated with a good response to the endoscopic treatment.

Few data are available on the long-term efficacy of endoscopic treatment in painful CP[4,6-8,14,15]. Endoscopy societies recommend endoscopic drainage as first-line therapy in painful obstructive CP[6,16]. Our study was conducted on a large group of patients with a median long-term follow-up and describes the new approach to the position of endotherapy in treatment of patients suffering from CP.

The aim of endotherapy is to decompress the main pancreatic duct by complete stone clearance and ductal drainage[17]. The cause of pain in CP is multifactorial, explaining why symptom relief can be unsatisfying even if technical success is achieved[16]. Surgery is indicated in patients with persistent pain that does not respond to medical and/or endoscopic treatment[16], in patients with a heavy stone burden (especially in the body/tail of the pancreas with pancreatic ductal dilatation and/or strictures[11,17,18]) or in the case of a suspected pancreatic inflammatory mass[16]. Endotherapy should also be considered in patients at high surgical risk[19].

There are several studies with good results regarding the long-term outcome after endoscopic treatment in painful CP[4,7-8,14-15] with a median rate of endotherapy success of 83%[6]. In our series, most patients required multiple procedures to obtain the goal of endoscopic therapy. In these patients, the pancreatography changes were more severe than those in patients with only a pancreatic sphincterotomy. There is one small series with a median of three stents for refractory pancreatic strictures showing good results after a mean follow-up of 38 mo[20], and three prospective series of the use of SEMS[21,22]. The use of multiple large plastic stents and expandable metal mesh stents in the pancreatic duct is not yet considered standard of care[16]. In a selected center with experience, ESWL of large pancreatic stones can lead to ductal clearance, as effective and more cost effective than the ERCP combination[9,23]. Our center does not dispose of equipment for ESWL, and 2 patients with large intraductal stones with diameter > 15 mm, impacted upstream of a tight ductal stenosis benefited from this procedure in another center prior to endoscopic ductal clearance.

We found that the numbers of procedures and sessions of ERCP was statistically higher in patients with stones and strictures than in patients with stones or strictures alone. But, we did not find any correlation between the size and number of stones or the number and location of stenosis with technical or clinical success. Data showed that the cephalic stones[9], complete pancreatic stone clearance and absence of main pancreatic duct stricture are the factors independently associated with long-term (⩾ 2 years) pain relief following endoscopic therapy[6,24,25]. A single stricture located in the pancreatic head is the ideal situation for endoscopic treatment compared to an isolated stricture in the tail or multiple strictures in the pancreas body[24].

There are few data regarding the correlation between age of patient and technical or clinical success of endotherapy[25]. Using a cut-off of 40 years for age, we noticed that younger patients had a better response to endoscopic treatment (*P* = 0.041). As far as we know, our study is the first described in the literature to evaluate the association of younger age and endoscopic technical success in patients with painful CP. We must emphasize that endoscopic treatment should be initiated earlier in young patients with painful CP in order to achieve better results.

Alcohol and smoking are independent risk factors of CP. Alcohol abuse causes pancreatic fibrosis by stellate cell activation[26] and is an important factor for mortality in CP. Alcohol abstinence may help in providing pain relief[16]. Smoking is an independent

Table 7 Smoking and alcohol drinking influence on clinical success and technical success [*n* = 122, *n* (%)]

	Technical success					Clinical success				
	Yes	No	OR (95%CI) *vs* none	*P* value	*P* value overall	Yes	No	OR (95%CI) *vs* none	*P* value	*P* value over all
Smoker only, *n* = 11	8 (66.67)	3 (33.3)	0.16 (0.02-1.15)	0.036		7 (63.64)	4 (36.36)	0.05 (0.001-0.59)	0.006	
Alcohol only, *n* = 36	31 (77.5)	5 (22.5)	0.27 (0.04-1.20)	0.064		30 (83.33)	6 (16.67)	0.13 (0.003-1.17)	0.048	
					0.103					0.007
Non-smoker and non-alcohol, *n* = 40	39 (92.8)	1 (7.14)	-	-		39 (97.5)	1 (2.5)	-	-	
Smoker and alcohol, *n* = 35	27 (77.1)	8 (22.8)	0.26 (0.04-1.23)	0.099		25 (71.43)	10 (28.5)	0.066 (0.001-0.52)	0.002	

risk factor for the development and progression of pancreatitis[10,27] and carcinogenesis[28]. It has been shown that abstinence not only slows the disease progression but also prevents complications such as pancreatic cancer[29-31]. Cessation of alcohol has beneficial effects on clinical outcome and progression of painful CP[30,31]. An association between smoking and CP pain has yet to be determined.

We found that patients without any alcohol consumption or smoking had better prognosis than patients who had one or both addictions, regarding clinical success (P = 0.007). Cigarette smoking was associated with a poor clinical outcome in our group. Furthermore, hospital admission rates were significantly higher in patients who continued alcohol drinking and smoking. Our results add new and important data regarding the association of smoking and CP pain and emphasized the importance of smoking and alcohol cessation in those patients.

Endoscopic drainage is also recommended as a first-line treatment in uncomplicated pancreatic pseudocysts[32], with similar outcomes to surgery regarding the recurrence rate during long-term follow-up and better results in terms of mortality[33,34], medical cost and quality of life[35]. In our series, endoscopic drainage was feasible in almost all patients, and technical success was 96.43% with a short-term clinical success of 96.3%; similar results are in the literature[36-39].

The success of endotherapy in biliary drainage in CP is poor in most of the published series, with a 10%-33% rate of stricture resolution[40-47]. The choice between endoscopic and surgery drainage should be made according to the medical center's expertise, patient co-morbidities and compliance to repeat endoscopic procedures[6]. Multiple simultaneous plastic stents reportedly have better results[48-50] than single biliary plastic stenting. Recent data demonstrate good results using covered expandable metal stents[51-54]. In our series, biliary drainage was successful in 74.29% of patients during follow-up. Multiple single biliary stent sessions were performed in 12 patients (34.29%) and simultaneous biliary plastic stents in 2 patients (5.71%). Covered SEMS were used in 2 patients with multiple comorbidities and high surgical risk.

CP is a progressive inflammatory disease. Patients with long-term CP or extensive pancreatic resection can develop type 3 diabetes mellitus, characterized by a lack of insulin and other counter-regulatory islet hormones, such as glucagon[55-57]. In our series, diabetes was present initially in one-third of patients. Newly diagnosed diabetes appeared in a quarter of patients with clinical success during follow-up. We speculate that endoscopic and clinical success do not stop the progression of exocrine and endocrine pancreatic deterioration.

Our study has several weaknesses that should be considered when interpreting our results. This is a retrospective study in a single tertiary academic center and can overestimate clinical success. We did not do use any objective assessment of pain control, standardized instruments for pain quantification, quality of life and psychosocial impact evaluation in patients with CP. Also, the continuing use of concomitant medical therapy was not followed. We consider that large, multicenter randomized studies are required to evaluate ERCP efficacy *vs* surgery in patients with painful CP without response to medical therapy.

In conclusion, endoscopic therapy in painful CP is effective and safe. Technical success was achieved in 81.39% of cases. Clinical success was achieved in 82.78% of the patients, with multiple endoscopic procedures being required in the majority of cases. Positive prognostic factors of response to endoscopic treatment are age under 40 years, no smoking, no alcohol consumption, and multiple ERCP sessions. Number and size of the intraductal pancreatic stones and the location of ductal stenosis did not significantly influence the clinical and technical success. Alcohol drinking and smoking should be recognized early and aggressively advised against to improve the quality of life and to reduce hospital admission. Endoscopic treatment should be considered as the first choice of

pain treatment, especially in younger patients.

COMMENTS

Background

The endoscopic management of patients with chronic pancreatitis (CP) pain is very challenging. The intraductal stone location, complete pancreatic clearance, absence of ductal stricture, recent onset of the disease and alcohol cessation are proven factors associated with a good long-term outcome of endoscopic treatment in painful CP. Other prognostic factors, such as young age and smoking cessation, are under investigation. In this retrospective study, we evaluated new clinical or endoscopical factors which might help to achieve long-term results.

Research frontiers

Few studies have evaluated the association of smoking with CP pain. No study to date has evaluated the prognostic role of younger age in patients with painful CP who undergo endoscopic treatment.

Innovations and breakthroughs

The results of this study underline the efficacy of endoscopic treatment in patients without response to medical therapy regarding pain relief, especially in younger patients. The authors have found that younger age, no smoking, no alcohol consumption, and multiple endoscopic retrograde cholangiopancreatography (ERCP) sessions are independent factors associated with a good response to endoscopic treatment.

Applications

Most patients with painful CP undergo endoscopic treatment as first step strategy. In the present study, the endoscopic treatment in young patients with painful CP might affect long-term clinical outcome.

Terminology

ERCP is an endoscopic procedure that combines the use of endoscopy and fluoroscopy to diagnose and treat certain problems of the biliary or pancreatic ductal systems (stones, strictures, pseudocysts, tumors).

Peer-review

This is a retrospective study discussing the efficacy of endoscopic therapy in chronic pancreatitis. Overall the study is well written. Results are clear and to the point.

Abstract

AIM

To examine usefulness of virtual biopsy using endocytoscopy by comparing the *in vivo* endocytoscopic and histopathological images of gastric cancers.

METHODS

Endocytoscopy was performed in 30 patients with early gastric cancer. Of these, 26 patients showed well differentiated adenocarcinomas, while 4 patients showed poorly differentiated adenocarcinomas (including one signet ring cell carcinoma). Cancerous and non-cancerous areas were observed after double staining with 0.05% crystal violet and 0.1% methylene blue. The endocytoscopic images obtained were evaluated by an expert endoscopist and an expert pathologist without knowledge of patient clinical data, and endocytoscopic and histopathological diagnoses were compared.

RESULTS

The endocytoscopic images of the cancerous area were assessed as evaluable in 25 (83.3%) and 27 (90%) patients by endoscopist A and pathologist B, respectively, and those of the non-cancerous area as evaluable in 28 (93.3%) and 23 (76.7%) patients by the endoscopist and pathologist, respectively. The sensitivity, specificity, and diagnostic accuracy of gastric cancer diagnosis using evaluable endocytoscopic images were 88.0% and 92.9%, and 90.6% by endoscopist A, and 88.9% and 91.3%, and 90.0% by pathologist B, respectively. Evaluation of the diagnostic concordance rate between the endoscopist and the pathologist by inter-observer agreement calculation revealed no significant difference between the two observers. The inter-observer agreement (κ-value) for endocytoscopic diagnosis was 0.745.

CONCLUSION

Endocytoscopy is useful for the differentiation of cancerous from non-cancerous gastric mucosa, making it a promising tool for virtual biopsy.

Core tip: Endocytoscopy, which allows for ultra-high-magnifying observation of the gastrointestinal mucosa, has recently been developed, enabling the visualization of the gastrointestinal mucosa at resolutions approaching those of histology. Although the usefulness of virtual biopsy using endocytoscopy in the diagnosis of esophageal cancer, colorectal cancer, lung cancer and ulcerative colitis has been reported, few studies are available on the diagnosis of gastric cancer. This study showed the usefulness of virtual biopsy using endocytoscopy by comparing the *in vivo* endocytoscopic and histopathological images of gastric cancers.

INTRODUCTION

The incidence of gastric cancer has been decreasing worldwide, but gastric cancer still remains a major cause of cancer-related death. The annual number of deaths from this disease is second only to that from lung cancer in Japan. A global analysis of gastric cancer-related mortality reveals higher mortality rates in East Asia (Japan, China, and South Korea) compared to those in Europeans and Caucasian populations of the United States.

Early detection, accurate staging, and appropriate treatment administration are important to improve survival outcomes and reduce mortality rates in gastric cancer. Recent advances in endoscopic technology have been remarkable, and high-resolution endoscopy has made it possible to detect endoscopically-treatable early gastric cancer more frequently. Magnifying endoscopy and image-enhanced endoscopy have been developed, and NBI-magnifying endoscopy has facilitated the differential diagnosis and histological typing of gastric cancer[1-3]. However, the gold standard for the diagnosis of malignant gastrointestinal tumors is histopathological examination, and definitive diagnosis requires endoscopic biopsy. However, diagnostic biopsy is time-consuming, increasing the risk of bleeding in patients taking antithrombotic agents, in addition to causing submucosal fibrosis, which potentially hampers endoscopic treatment.

Two endoscopic technologies (confocal endomicroscopy and endocytoscopy) have recently been developed, making it possible to observe living cells *in vivo*. To date, we have reported that confocal endomicroscopy can distinguish gastric cancer from normal gastric mucosa[4], and determine the mucin phenotype of gastric cancer by visualizing brush borders and goblet cells[5]. Fluorescent dyes used for confocal laser endomicroscopy stain cells, enabling the evaluation of structural atypia, but not that of nuclear atypia, because they do not stain nuclei. However, dye spraying during endocytoscopy results in the staining of cells and nuclei, thereby producing *in vivo* images similar to those on the histological study of biopsies (the current gold standard for pathological diagnosis).

As endocytoscopy provides real-time microscopic images *in vivo*, its application to histological diagnosis by virtual biopsy (without the need to take biopsies) is promising. Although the usefulness of virtual biopsy using endocytoscopy in the diagnosis of esophageal cancer, colorectal cancer, lung cancer, and ulcerative colitis has been reported[6-9], few studies to date have evaluated its usefulness in the *in vivo* diagnosis of gastric cancer[10-12].

In this study, we retrospectively examined the usefulness of virtual biopsy using endocytoscopy, by comparing *in vivo* endocytoscopic and histopathological images of gastric cancers.

MATERIALS AND METHODS

Subjects

This pilot study was performed at the Nagoya University Hospital between January 2011 and October 2012. Thirty patients with early gastric cancer were enrolled (Table 1). Of these, 26 patients showed well differentiated, and 4 patients showed poorly differentiated adenocarcinomas (including one signet ring cell carcinoma). This study was approved by the Ethics Committee of Nagoya University Hospital (approval no. 911), and informed consent was obtained from all patients.

Endocytoscopy system

An integrated-type endocytoscope (GIF-Y0002, Olympus Co., Tokyo, Japan) was used in the present study. As with a conventional magnification endoscope, the magnification was adjustable by pulling a lever to perform continuous observation, from conventional to ultra-high magnification. The maximum magnification was × 380, the microscopic field area 700 μm × 600 μm, and the depth of observation was 50 μm. The image quality of the endocytoscope was comparable to that of GIF-Q260 (Olympus, Japan), and was sufficient to make an accurate diagnosis.

Methods of observation

Patients were pretreated with an oral dose of 20000 units of pronase and 1 g of sodium bicarbonate, followed by an intramuscular injection of 20 mg of butylscopolamine or 1 mg of glucagon. Under intravenous conscious sedation, the patients underwent endocytoscopy. Conventional observation was performed. Then, the lesion was washed sufficiently using saline water, and sprayed with approximately 5 mL of 0.05% crystal violet and 0.1% methylene blue. One minute later, the excess dye solution was washed away, and ultra-high-magnifying observation was performed. If cells and nuclei were poorly stained, the lesion was sprayed again with the dyes. Both the lesion and the surrounding non-cancerous mucosa were observed. All examinations were performed by a single expert endoscopist (Tsurudome I), qualified as Board certified fellow of the Japan Gastroenterological Endoscopy Society.

Histopathological examination

Lesions observed by endocytoscopy underwent endoscopic biopsy or endoscopic resection. Biopsies and resected specimens were fixed, embedded in paraffin, and cut into thin sections horizontal to the mucosal surface. They were stained with hematoxylin and eosin (H&E), and examined and classified by expert pathologists according to the revised Vienna classification[13]. Lesions classified as category 4 in the Vienna classification were defined as gastric cancer, but those classified as category 3 were defined as gastric adenoma, and excluded from the category of gastric cancer.

Definitions of endocytoscopic findings compared to histopathological images

Normal mucosa (without intestinal metaplasia). In the fundic gland mucosa, the foveolar epithelium was arranged in a circle, and the glandular lumens were round (Figure 1A).

In the pyloric gland mucosa, the foveolar epithelium was arranged in ridges, and the glandular lumens were slit-like (Figure 2A). The arrangement of the epithelial cells was regular, closely resembling that seen in H&E-stained horizontal tissue sections (Figures 1B and 2B). The nuclei were faintly stained, showing no atypia.

Intestinal metaplastic mucosa

In the intestinal metaplastic mucosa, the epithelium exhibited a villous architecture (varying in size). The gland lumens were widened due to epithelial atrophy (Figure 3A). Some epithelial cells had vacuoles, suggestive of goblet cells. These findings were very similar to those in H&E-stained horizontal sections (Figure 3B). Nuclei were stained more intensely than in the normal mucosa, but demonstrated no atypia.

Gastric cancer

In well differentiated adenocarcinoma, the glands were branched irregularly and the width of the lumen varied. The epithelium was arranged in a disorderly fashion (Figure 4A). The nuclei were deeply stained and pseudostratified, and showed an increased nuclear density and nuclear atypia. In poorly differentiated adenocarcinoma, the tubular architecture was completely lost, and the nuclei were hyper-chromatic and anisokaryotic (Figure 5A). These findings closely resembled those in H&E-stained horizontal sections (Figures 4B and 5B).

Evaluation of endocytoscopic images

The endocytoscopic images obtained were analyzed separately by an endoscopist A (Ryoji M) and a pathologist B (Satou A), who were blinded to clinical information. The diagnosing physicians interpreted three photographs chosen by the examining physician,

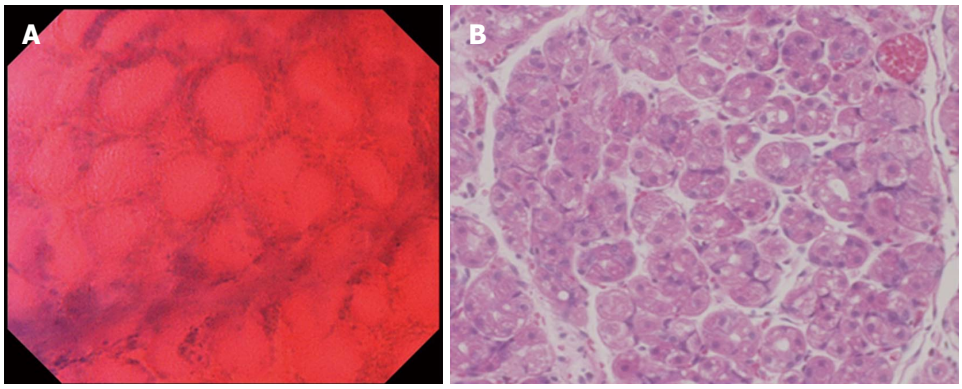

Figure 1 Normal mucosa (fundic gland mucosa). A: Endocytoscopic appearance of fundic gland mucosa. The foveolar epithelium was arranged in a circle, and the glandular lumens were round. The nuclei were weakly stained; B: Histological appearance of the corresponding normal mucosa (H&E-stained horizontal section, × 200).

Table 1 Patient clinicopathological characteristics

Variable	
Patients	30
Sex (male/female)	24/16
Mean age, yr (range)	72.2 (48-87)

and classified the image quality as evaluable (nuclei and glandular structures evaluable) or unevaluable (neither nuclei nor gland structures evaluable), and determined whether the tissue was cancerous or non-cancerous if the image was of evaluable quality. The results were then compared with the actual pathology.

Outcome measures

Primary endpoint: Diagnostic accuracy: The endocytoscopic diagnosis performed independently by the endoscopist and the pathologist were compared with the pathological diagnosis, and sensitivity, specificity, and accuracy were evaluated.

Secondary endpoint: Diagnostic concordance rate between endoscopist and pathologist. To evaluate the diagnostic concordance rate between the endoscopist and the pathologist in the diagnosis of gastric cancer using endocytoscopy, inter-observer agreement was calculated.

Statistical analysis

The statistical software package SPSS 19.0 was used for data analysis. The endoscopic diagnoses by the endoscopist and the pathologist were compared using the χ^2 test, and a *P*-value of less than 0.05 was considered as significant. For evaluable images, the unweighted κ-statistic was calculated to evaluate inter-observer agreement.

RESULTS

Evaluation of endocytoscopy images

The endocytoscopy images of the cancerous areas were assessed as evaluable in 25 (83.3%) and 27 (90%) of the 30 patients by endoscopist A and pathologist B, respectively, and those of the non-cancerous areas as evaluable in 28 (93.3%) and 23 (76.7%) patients, by the endoscopist and the pathologist, respectively. The images that were assessed as unevaluable were excluded from the analysis. Endocytoscopic images of lesions in the lesser curvature of the gastric body are prone to artifacts due to cardiac pulsation, and it was difficult to place the endocytoscope in the desired position to visualize lesions in the fornix or greater curvature of the gastric body, thus complicating observation in these areas.

Table 2 shows the interpretation of endocytoscopic images by the endoscopist and the pathologist. Calculated from these findings, the sensitivity, specificity, and diagnostic accuracy of endocytoscopy in the diagnosis of gastric cancer using evaluable images were 88.0%, 92.9%, and 90.6% as performed by endoscopist A, and 88.9%, 91.3%, and 90.0% as performed by pathologist B, respectively (Table 3). Using the χ^2 test, no significant difference was found

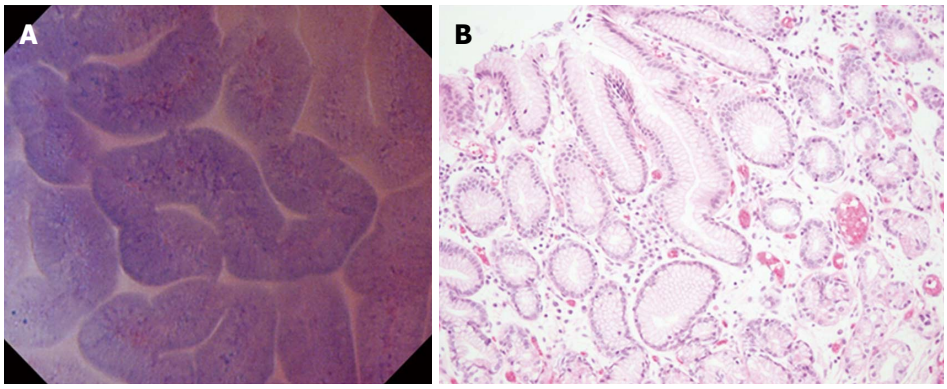

Figure 2 Normal mucosa (pyloric gland mucosa). A: Endocytoscopic appearance of pyloric gland mucosa. The foveolar epithelium was regularly arranged in ridges, and the glandular lumens were slit-like. The nuclei were weakly stained; B: Histological appearance of the corresponding pyloric gland mucosa (H&E-stained horizontal section, × 200).

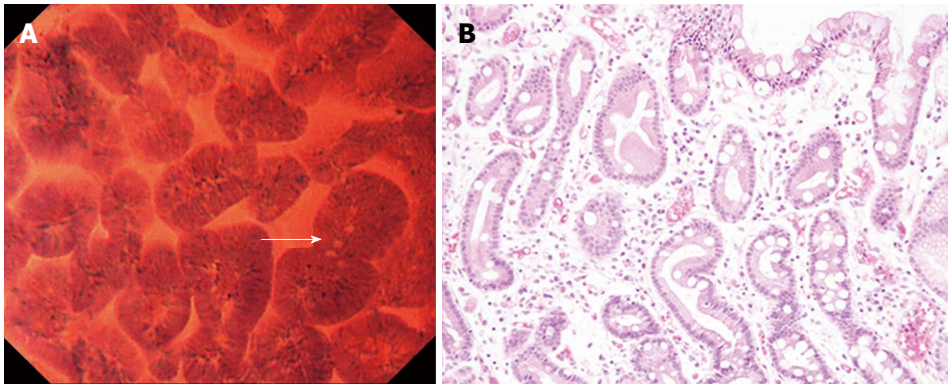

Figure 3 Intestinal metaplastic mucosa. A: Endocytoscopic appearance of intestinal metaplastic mucosa. The foveolar epithelium exhibited a villous architecture and the gland lumens were widened. Goblet cells (arrow) were observed among the epithelial cells. The nuclei were stained more intensely than in the normal mucosa; B: Histological appearance of the corresponding intestinal metaplastic mucosa (H&E-stained horizontal section, × 200).

Table 2 Comparison of endocytoscopic and histological diagnoses as performed by an endoscopist and a pathologist

	Endoscopist A		Pathologist B	
Histological diagnosis	Cancer	Non-cancer	Cancer	Non-cancer
Cancer	22	3	24	3
Non-cancer	2	26	2	21

between the two observers, and the κ-value was 0.745.

Complications

No complications were observed in this study, and none of the patients required temporary discontinuation of endocytoscopy.

DISCUSSION

At present, magnifying endoscopy facilitates observation of the mucosal surface structure as indicated by its surface patterns and the vascular structure as revealed by microvessels, thus mainly allowing evaluation of structural atypia. On the other hand, the resolution that endocytoscopy offers, allows visualization of individual cell nuclei and enables *in vivo* tissue observation, yielding results comparable to those obtained from histopathological images. Using an integrated endocytoscopy system, it is now possible to perform continuous observation of tissues with conventional to ultra-high magnification, creating the possibility of performing real-time virtual biopsies without obtaining physical lesion biopsies.

Endocytoscopy requires vital staining in order to evaluate the cellular and nuclear morphology, and methylene blue is generally used for this purpose. However, the diversity and poor staining of the gastric mucosa due to the presence of mucus[14] make observation and evaluation difficult. Therefore, to date, few studies have reported *in vivo* experiments in humans with gastric cancer[10-12].

Kodashima *et al*[15] attempted to optimize the staining conditions (staining time and dye concentration) for endocytoscopy in porcine experiments using different dyes, and reported that the ability of crystal violet to stain esophageal, gastric, and colonic tissues was inferior, and the optimal staining conditions were as follows: staining of esophageal tissue with 1% methylene blue solution for 60 s; staining of gastric

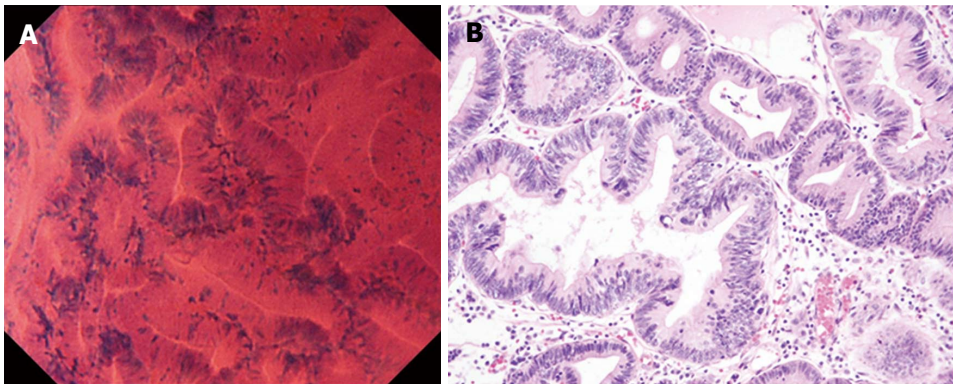

Figure 4 Well differentiated adenocarcinoma. A: Endocytoscopic appearance of a well differentiated adenocarcinoma. The glands were branched irregularly and the width of the lumen varied. The epithelium was arranged in a disorderly fashion. The nuclei were deeply stained and pseudostratified; B: Histological appearance of the corresponding well-differentiated adenocarcinoma (H&E-stained horizontal section, × 200).

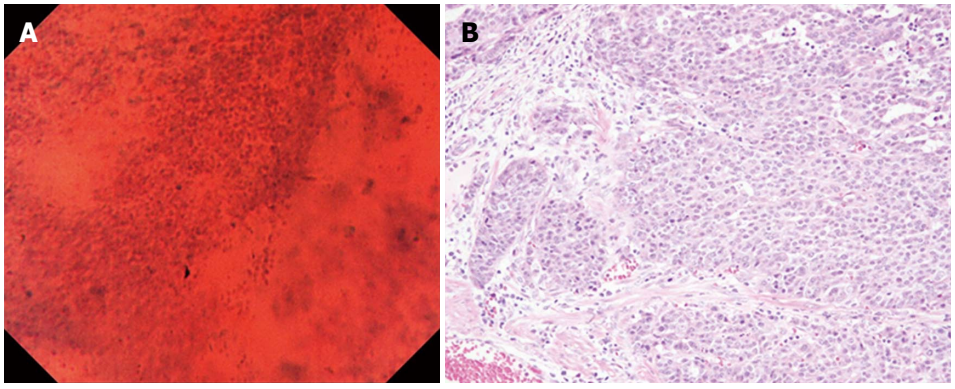

Figure 5 Poorly differentiated adenocarcinoma. A: Endocytoscopic appearance of a poorly differentiated adenocarcinoma. The tubular architecture was lost, and the nuclei were hyper-chromatic and anisokaryotic; B: Histological appearance of the corresponding poorly differentiated adenocarcinoma (H&E-stained horizontal section, × 200).

Table 3 Performance of endocytoscopy in the diagnosis of early gastric cancer, as scored by an endoscopist and a pathologist

	Sensitivity (95%CI)	Specificity (95%CI)	PPV (95%CI)	NPV (95%CI)	Accuracy (95%CI)
Endoscopist A	88.00% (76.6-93.3)	92.90% (82.7-97.6)	91.70% (79.8-97.2)	89.70% (79.8-94.2)	90.60% (79.8-95.6)
Pathologist B	88.90% (78.4-93.8)	91.30% (79.0-97.1)	92.30% (81.4-97.4)	87.50% (75.7-93.0)	90.00% (78.7-95.3)

PPV: Positive predictive value; NPV: Negative predictive value.

and colonic tissues with 0.25% toluidine blue solution for 60 s. A double-staining method using crystal violet and methylene blue has recently been developed. In this method, methylene blue stains cellular nuclei purple, and crystal violet stains cells pink, thereby enabling the visualization of images resembling those of H&E staining. Kudo *et al*[6] and Minami *et al*[16] have demonstrated usefulness of the methylene blue and crystal violet double-staining method in the evaluation of neoplastic lesions in the colon and the esophagus, respectively. This same double-staining method has been used in the present study. Further studies are needed to compare this double-staining method with others such as the crystal violet and toluidine blue double-staining method.

The use of endocytoscopy in this study enabled us to evaluate the morphology of glandular lumens, arrangement of gastric foveolar cells, degree of nuclear stainability, and presence or absence of nuclear pseudostratification.

To determine the diagnostic performance of endocytoscopy to differentiate benign from malignant lesions, structural atypia were evaluated based on the morphology of glandular lumens and arrangement of foveolar cells; nuclear atypia were assessed based on the degree of nuclear chromasia and presence or absence of nuclear pseudostratification. Lesions with or without structural or nuclear atypia were diagnosed as cancerous or non-cancerous, respectively. Endocytoscopic images obtained from the normal gastric mucosa, gastric mucosa with intestinal metaplasia, and gastric cancers, were similar to those obtained from H&E-stained horizontal tissue sections. Thus, using endocytoscopic images, we were able to differentiate cancerous from non-cancerous lesions

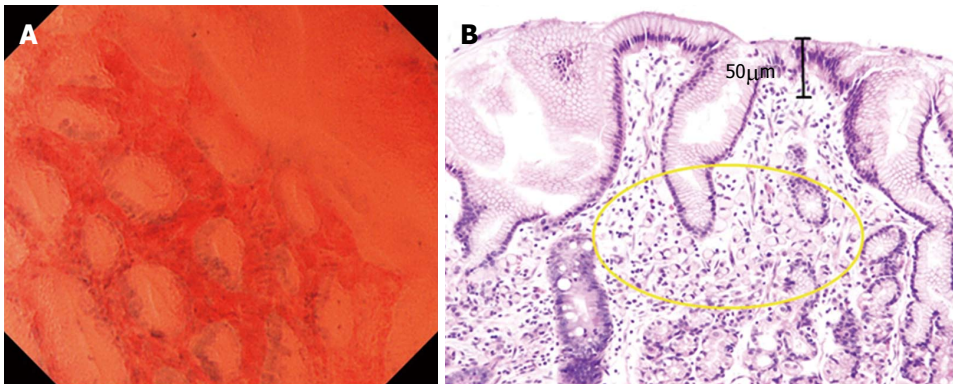

Figure 6 Signet ring cell carcinoma. A: Endocytoscopic appearance of a signet ring cell carcinoma. Slit-like glandular lumens surrounded by regularly arranged foveolar cells were observed, a finding consistent with normal mucosa in endocytoscopy; B: Histological appearance of the corresponding signet ring cell carcinoma (H&E-stained horizontal section, × 200). Signet-ring cells were observed in the lamina propria (circle), but not exposed on the mucosal surface.

with high sensitivity, specificity, and accuracy. In addition, the findings that goblet cells were observed in the intestinal metaplastic mucosa were similar to those reported by Chiu *et al*[17].

Although endocytoscopy enables *in vivo* observation of the mucosal tissue at the microscopic level, it only provides information about cells and nuclei of the superficial layer of the mucosa. In this study, both the pathologist and the endoscopist classified a signet ring cell carcinoma as a false-negative by endocytoscopy (Figures 6A and B). Although Fasoli *et al*[18]. reported that signet ring cells can be observed in resected gastric cancer specimens with endocytoscopy[18], the visualization by endocytoscopy is limited to the superficial mucosal layer (up to 50 μm in depth). In some poorly differentiated adenocarcinomas, carcinoma cells may spread in the lamina propria without any distortion to gland structure (Figure 6B). In these cases, the diagnosis of carcinoma with endocytoscopy alone is difficult.

This study has several limitations. First, only the best images that were chosen by the examining physician were evaluated. That is, the diagnostic capability of endocytoscopy was not evaluated in real-time. Second, the stomach moves actively due to peristalsis, aortic pulsation, and respiration, making focusing and fiber manipulation during endocytoscopic observation difficult for beginners. Third, the endoscopist requires knowledge of pathology when evaluating endocytoscopic findings. Fourth, this study did not include patients with adenoma. Finally, the sample size was small, implying that additional studies with a larger number of patients is indicated to confirm our findings.

In conclusion, we were able to obtain high quality endocytoscopic images, which were adequate for the differentiation of benign lesions from malignant ones. As this was a retrospective pilot study involving a small number of patients, a large-scale prospective study is indicated.

COMMENTS

Background

Endocytoscopy, which allows for ultra-high-magnifying observation of the gastrointestinal mucosa, has recently been developed, enabling the visualization of the gastrointestinal mucosa at resolutions approaching those of histology. Although the usefulness of virtual biopsy using endocytoscopy in the diagnosis of esophageal cancer, colorectal cancer, lung cancer, and ulcerative colitis has been reported, few studies are available on the diagnosis of gastric cancer.

Research frontiers

The gold standard for the diagnosis of malignant gastrointestinal tumors is histopathological examination, and definitive diagnosis requires endoscopic biopsy. As endocytoscopy provides real-time microscopic images *in vivo*, its application to histological diagnosis by virtual biopsy (without the need to take biopsies) is promising.

Innovations and breakthroughs

Endocytoscopy allows recognition of nuclei and cells, thereby producing *in vivo* images similar to those produced by histological study of biopsies. This study suggested the usefulness of virtual biopsy for gastric cancer.

Applications

Using endocytoscopy, it is expected that we will be able to diagnose gastric cancer with virtual biopsies, eliminating the need for physical biopsies. The need for tissue biopsies, and associated limitations like bleeding and fibrosis at biopsy site may be pre-empted for gastric cancer diagnosis, improving patient outcomes.

Terminology

Endocytoscopy involves an ultra-high magnification endoscope that allows observation of nuclei and cells *in vivo*. Virtual biopsy denotes a procedure to obtain a tissue image of high resolution with nuclear and cellular visualization, without performing and analyzing a physical tissue biopsy.

Peer-review

This manuscript addresses the usefulness of endocytoscopy for distinguishing gastric cancer. Although this pilot study involved a small number of patients, the content of this manuscript is interesting.

Abstract

Achalasia is a rare esophageal motility disorder that is characterized by a loss of peristalsis in the distal esophagus and failure of lower esophageal sphincter relaxation. The risk of developing esophageal motility disorders, including achalasia, following bariatric surgery is controversial and differs based on the type of surgery. Most of the reported cases occurred with laparoscopic adjustable gastric banding. To our knowledge, there are only three reported cases of achalasia after Roux-en-Y gastric bypass and no reported cases after revision of the surgery. We present a case of a 70-year-old female who had a previous history of Roux-en-Y gastric bypass with revision. She presented with persistent nausea and regurgitation for one month. Esophagogastroduodenoscopy showed a dilated esophagus without strictures or stenosis. A barium study was performed after the endoscopy and was suggestive of achalasia. Those findings were confirmed by a manometry. The patient was referred for laparoscopic Heller's myotomy.

Core tip: Achalasia is a rare esophageal motility disorder. It is uncommonly reported after bariatric surgeries. Achalasia is a very rare complication after Roux-en-Y gastric bypass. We report a case of a 70-year-old female who she presented with persistent nausea and regurgitation for one month. She had a previous history of Roux-en-Y gastric bypass with revision. As part of her inpatient evaluation, a computed tomography of the chest, a barium study and an upper endoscopy were suggestive of achalasia. Those findings were confirmed by a manometry. The patient was referred for laparoscopic Heller's myotomy.

INTRODUCTION

Achalasia is a rare esophageal motility disorder characterized by loss of peristalsis in the distal esophagus and failure of lower esophageal sphincter (LES) relaxation[1,2]. It usually presents with dysphagia for solids and liquids as well as regurgitation[3]. Primary achalasia is an idiopathic disease with unknown etiology, whereas secondary achalasia or pseudoachalasia is associated with infections, paraneoplastic syndromes and extrinsic compression by benign or malignant processes[4-6]. Interestingly, relationships have previously been reported between abnormalities in esophageal manometry, including achalasia, and both morbid obesity and bariatric surgery[7-18]. Most of the reported cases of achalasia after bariatric surgery occurred after laparoscopic adjustable gastric banding (LAGB)[11-14]. Achalasia after Roux-en-Y gastric bypass (RYGB) is rare[15-18] and could be related to surgical trauma in the area[15]. In these cases, it is important to rule out stenosis of the gastrojejunostomy.

CASE REPORT

A 70-year-old female with a past medical history of coronary artery disease and morbid obesity (previous body mass index (BMI) of 52 kg/m^2) presented to our institution with persistent nausea and regurgitation for one month.

Her surgical history was significant for laparoscopic cholecystectomy and laparoscopic RYGB approximately two years prior to presentation. Her post-operative course was complicated by a gastro-gastric fistula and gastro-jejunal anastomosis ulcer with gastrointestinal bleeding requiring admission to the hospital, blood transfusion and endoscopic hemostasis. Her surgery was revised approximately 2 mo prior to her presentation.

Her symptoms were mostly post-prandial. She also described mild dysphasia to both solids and liquids, so she started to drink in small sips. She denied any change in her weight or appetite, abdominal pain or change in bowel habits. Her vital signs were unremarkable. Her abdomen was soft, without tenderness to palpation and with bowel sounds present. The wound from her recent surgery was clean, with no evidence of discharge or poor healing.

Initial laboratory workup showed alanine aminotransferase (ALT) 33 unit/L (normal 13-69 unit/L), aspartate aminotransferase (AST) 35 unit/L (normal 15-46 unit/L) and alkaline phosphatase (ALP) 123 unit/L (normal 42-140 unit/L). A CT scan of the abdomen and pelvis with contrast (Figure 1) showed enteric contrast within the dilated distal esophagus and was suspicious for a mild stricture at gastroesophageal sphincter (GES). There was no evidence of peri-gastric inflammatory changes. Her stool workup was negative for *Clostridium difficile* toxin, ova and parasites. She was started on IV hydration, given IV ondansetron 4 mg every 6 h as needed for nausea and admitted for further evaluation.

The next day, esophagogastroduodenoscopy (EGD) showed large amounts of thick secretions in the esophagus. The esophagus was tortuous, dilated and had a "sigmoid esophagus" appearance, but no strictures, stenosis or evidence of malignancy were noted. A Barium study (Figure 2) was performed after the EGD and showed persistent narrowing of the gastroesophageal junction with a moderately dilated, debris-filled esophagus proximally and some tertiary esophageal contractions. These findings were suggestive of achalasia.

The patient was discharged with outpatient follow-up with a manometry study. The manometry was performed 2 wk later and revealed high pressure in the LES with abnormal relaxation and high resting pressure, in addition to aperistalsis. These results were consistent with type Ⅱ achalasia (Figure 3). She was referred to surgery for evaluation and laparoscopic Heller's myotomy.

DISCUSSION

Achalasia is a rare esophageal motility disorder that is characterized by neurodegeneration, preferentially involving the inhibitory nitric oxide-producing neurons. It leads to a loss of peristalsis in the distal esophagus and failure of LES relaxation[1,2]. It is derived from the

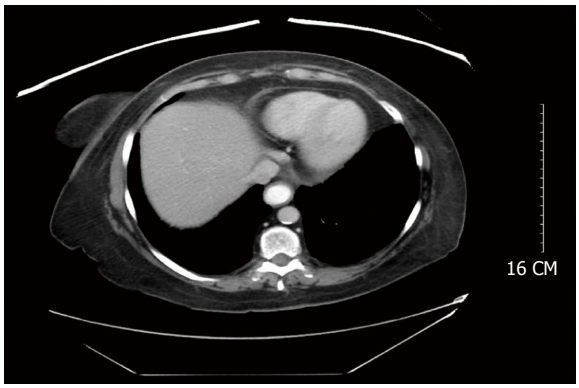

Figure 1 Computed tomography scan of the abdomen and pelvis with contrast showing enteric contrast within the dilated distal esophagus, and was suspicious for mild stricture at the gastroesophageal junction.

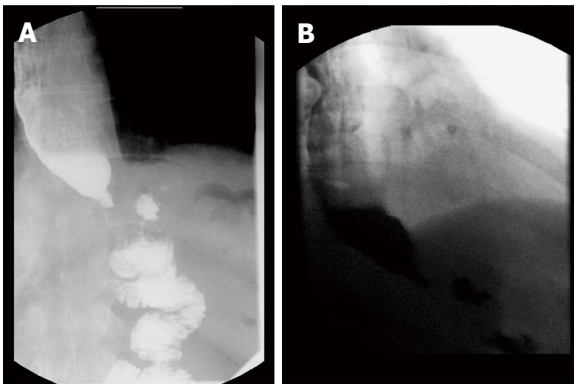

Figure 2 Barium study showing persistent narrowing of the gastroesophageal junction with a moderately dilated, debris filled esophagus proximally and some tertiary esophageal contractions.

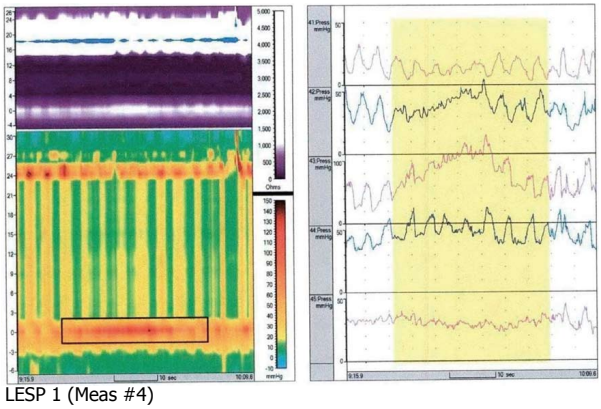

Figure 3 Esophageal manometry showing high lower esophageal sphincter pressure with abnormal relaxation and high resting pressure in addition to aperistalsis. These findings were consistent with type Ⅱ achalasia.

Greek term meaning "does not relax". Achalasia occurs equally in males and females, with an annual incidence of approximately 1.6 cases per 100000 individuals[2].

Dysphagia for solids and liquids and regurgitation of undigested food or saliva are the most common symptoms in patients with achalasia[3]. The etiology of primary achalasia is unknown, though autoimmune and viral infectious etiologies have been proposed[4,5]. In its secondary form or pseudoachalasia, there are many potential causes of esophageal motor abnormalities that are similar or identical to those of primary achalasia. Examples include infections such as Chagas disease, paraneoplastic syndromes and extrinsic compression of gastroesophageal junction by either benign or malignant processes[6].

Bariatric surgeries are among the fastest growing operative procedures worldwide[19-21]. They are recommended for adults who have a BMI of at least 40 kg/m^2 or 35 kg/m^2 with other comorbidities[21]. RYGP remains the most commonly performed bariatric procedure in the United States[19-21]. The risk of developing esophageal motility disorders, including achalasia, following bariatric surgery is still controversial and differs with the type of surgery[11-14,16-18]. Pseudoachalasia after LAGB placement has been described, though there is evidence that the pseudoachalasia may be reversible after the band is removed[11-14]. It has been postulated that malpositioning of the band near the gastroesophageal junction creates a high-pressure area, causing clinical symptoms of pseudoachalasia[11-14].

In contrast, the development esophageal motility disorders after RYGB is rare and has only been reported a few times in the literature (Table 1)[15-18]. To the best of our knowledge, there are only 3 reported cases of achalasia after RYGB[16-18], and this is the first case described after revision of RYGB. Interestingly, several case reports have been published on the simultaneous treatment of achalasia and morbid obesity with laparoscopic esophageal myotomy and gastric bypass[22-23]. The exact pathophysiology of motility disorders that develop after RYGB in general, and achalasia specifically, is unknown. Surgical trauma is one potential explanation. Shah *et al*[15] described a retrospective study of 64 patients with achalasia compared with a control group of 73 patients without achalasia evaluated by manometry and endoscopy. A significant association was found between achalasia and trauma to the upper gastrointestinal tract. Of the patients with operative trauma and achalasia, 2 had undergone gastric bypass. Finally, it is worth mentioning that another important consideration in similar cases is to rule out stenosis of the gastrojejunostomy, which we did in our patient.

Achalasia is a rare esophageal motility disorder that is characterized by neurodegeneration, of the inhibitory nitric oxide-producing neurons. It usually manifests with dysphagia to both solid and liquids and regurgitation. Obesity is a global epidemic and

Table 1 Reported cases of achalasia after Roux-en-Y gastric bypass

Case	Age and gender	Pre-operative BMI (kg/m^2)	Procedure	Presentation	Onset of symptoms postoperative	Upper GI series/ Barium swallow	EGD	Esophageal manometry	Treatment
Ramos *et al*[16] 2009	44-yr-old female	47	Laparoscopic RYGB	Dysphagia to solids, and regurgitation	4 yr	Dilated esophagus, poor esophageal emptying, and tapering of the LES	Normal gastroesophageal junction, a 4-cm gastric pouch without lesions, and a wide gastrojejunostomy	Elevated resting LES pressure, aperistalsis, and hypo contractility of the esophagus.	Laparoscopic Heller myotomy
Torghabeh *et al*[17] 2015	48-yr-old female	44.75	Laparoscopic RYGB	Dysphagia to solid, regurgitation, and chest pain	5 yr	Dilated esophagus and stricture at the LES	Tortuous esophagus with retained food products and *Candida* plaques. Stricture was balloon dilated	Elevated resting LES pressure, aperistalsis, and failure of LES relaxation	Laparoscopic Heller myotomy
Chapman *et al*[18] 2013	53-yr-old female	NA	Open PYGB	Epigastric and LUQ pain and reflux symptoms	2 yr	Dilated thoracic esophagus with reduced primary peristalsis. Contrast was slow to pass through the gastro-esophageal junction	Dilated esophagus, esophagitis and ulceration above the gastro-esophageal junction	Absence of LES relaxation and aperistalsis	Laparoscopic Heller myotomy
Our case 2016	70-yr-old female	52	Laparoscopic RYGB	Regurgitation, mild dysphagia, nausea and occasional vomiting	2 yr	Persistent narrowing of the gastroesophageal junction with a dilated, debris filled esophagus. Some tertiary contractions	Dilated, tortuous esophagus that appeared as a "sigmoid esophagus" but no strictures or stenosis was noted.	Elevated LES pressure with abnormal relaxation in addition to aperistalsis and	Scheduled for laparoscopic Heller myotomy

LES: Lower esophageal sphincter.

can be associated with esophageal motility disorders. Esophageal motility disorders, including achalasia, occur as a consequence of bariatric surgeries.

COMMENTS

Case characteristics

Persistent nausea, regurgitation and mild dysphagia to solids and liquids for one month. History of RYGB 2 yr ago with reversal 2 mo prior to presentation.

Clinical diagnosis

Hemodynamically stable with normal vital signs. Abdomen was soft, without tenderness to palpation and with bowel sounds present. The wound from her recent surgery was clean, with no evidence of discharge or poor healing.

Differential diagnosis

Distal esophageal stricture, Stenosis of the gastrojejunostomy, achalasia, tumor of the gastric cardia or distal esophagus, infectious gastroenteritis.

Laboratory diagnosis

Initial complete blood count, basic metabolic panel (kidney function and electrolytes) and liver panel were unremarkable. Stool workup was negative for infection.

Imaging diagnosis

A computed tomography scan of the chest with contrast showed enteric contrast within the dilated distal esophagus and was suspicious for a mild stricture at gastroesophageal sphincter . A Barium study was showed persistent narrowing of the gastroesophageal junction with a moderately dilated, debris-filled esophagus proximally and some tertiary esophageal contractions. Manometry was performed 2 wk after discharge and revealed high pressure in the lower esophageal sphincter (LES) with abnormal relaxation and high resting pressure, in addition to aperistalsis. These results were consistent with type Ⅱ achalasia.

Endoscopic diagnosis

Esophagogastroduodenoscopy showed a tortuous and dilated esophagus with large amounts of thick secretions in the esophagus. No strictures, stenosis or evidence of malignancy were noted.

Treatment

Supportive treatment while inpatient with intravenous fluids and anti-emetics. She was referred for evaluation and laparoscopic Heller's myotomy after her

diagnosis.

Related reports
Table 1 summarize previous reported cases of achalasia in association with RYGB.

Term explanation
Achalasia is a rare esophageal motility disorder characterized by loss of peristalsis in the distal esophagus and failure of LES.

Experiences and lessons
Achalasia and other esophageal motility disorders may occur as a consequence of bariatric surgeries including RYGB.

Peer-review
A rare case report that achalasia after bariatric Roux-en-Y gastric bypass surgery was well described by the authors. Only 3 reported cases of achalasia after RYGB had been reported in the world, and this was the first case described after revision of RYGB. It's a worth case to be reported.

Abstract

Magnesium deficiency can cause a variety of symptoms, including potentially life-threatening complications such as seizures, cardiac arrhythmias and secondary electrolyte disturbances. Hypomagnesemia can be a serious adverse effect to proton pump inhibitor (PPI) therapy, which is worrying due to the widespread use of PPIs. Current evidence suggest that the mechanism of PPI induced hypomagnesemia is impaired intestinal magnesium absorption. In this report, we present the case of a long-term PPI user with persistent hypomagnesemia with severe symptoms at presentation. He was unable to stop PPI treatment because of severe reflux symptoms, and was dependent on weekly intravenous magnesium infusions, until his magnesium levels finally normalized without the need for supplementation after a successful laparoscopic fundoplication.

INTRODUCTION

Magnesium plays an essential role in several physiological and biochemical bodily processes. Consequently, magnesium deficiency can cause a variety of symptoms, ranging from nonspecific complaints of weakness, fatigue and nausea to potentially life threatening complications such as seizures, cardiac arrhythmias and secondary electrolyte disturbances. Hypomagnesemia can develop due to gastrointestinal and/or renal disease, as well as an adverse effect to several medications. Several reports of severe hypomagnesemia associated with long term proton pump inhibitor (PPI) therapy[1,2] is causing concern due to the widespread use of PPIs[3]. Current evidence suggest that PPI impair the intestinal magnesium absorption through a molecular effect on magnesium transporters in genetically predisposed individuals[4].

We present the first case of a long-term PPI user with severe and symptomatic persistent hypomagnesemia treated with surgery. Due to severe reflux, the patient was PPI dependent, and needed weekly intravenous magnesium infusions. After a successful laparoscopic fundoplication, the PPI treatment could be discontinued, and the magnesium levels normalized without the need for supplementation.

CASE REPORT

A 67-year-old male with a history of gastroesophageal reflux disease (GERD) and hypertension, first presented with severe hypomagnesemia during a hospital admission in 2012. At that time, he was taking 10 mg amlodipine and 20-40 mg omeprazole daily. Prior to admission, he had suffered from severe dizziness, double sight and vomiting for several weeks, and was initially dehydrated with electrolyte derangement (hypokalemia). A few days after admission he developed general seizures, and additional laboratory tests revealed severe hypomagnesemia [0.23 mmol/L (0.71-0.94 mmol/L)], considered a result of excessive vomiting prior to admission. His serum electrolyte levels normalized upon intravenous treatment. An extensive work-up resulted in a possible diagnosis of viral encephalitis, and after discharge, he underwent a prolonged rehabilitation course. A year later, he was re-admitted because of dizziness, balance problems and paresthesia. Laboratory results again showed severe hypomagnesemia (0.08 mmol/L). He received intravenous magnesium infusions and his symptoms disappeared. During ambulatory follow-up, he was found to have persistent hypomagnesemia, and oral magnesium was prescribed. He underwent endocrinological and gastrointestinal investigations including colonoscopy, which did not reveal any other cause of his hypomagnesemia. His urinary magnesium level was low (< 0.080 mmol/L). Despite oral magnesium supplementation, magnesium levels continued to stay low, and in 2015, he was started on weekly magnesium infusions to maintain normal magnesium levels. The only medication he was on during these years was omeprazol 20-40 mg daily. He had been advised several times during the years to stop PPI treatment, but was unable to cope with the resulting reflux symptoms. In April 2016, he did, however, agree to stop taking PPI and consequently maintained normal magnesium levels without infusions. 24-h pH testing confirmed reflux disease, and he was offered anti-reflux surgery (laparoscopic fundoplication). While awaiting the operation, he started taking daily PPI again, which resulted in a prompt drop in his serum magnesium levels demanding a resumption of weekly magnesium infusions. The patient underwent a laparoscopic fundoplication and was discharged after an uncomplicated peri-and postoperative course. After the operation, the reflux symptoms as well as the need for PPI disappeared, and his magnesium level maintained normal without supplementation at the follow-up visit. The course of the patient's magnesium levels is illustrated in Figure 1.

DISCUSSION

This rare case illustrates a long-term PPI user with persistent hypomagnesemia causing severe symptoms at presentation. For years, he was dependent on oral and later weekly intravenous magnesium supplementation, until his hypomagnesemia rapidly improved upon PPI discontinuation. Re-challenge of PPI treatment resulted in a prompt drop in serum magnesium within days, and his magnesium levels again normalized rapidly following PPI withdrawal after laparoscopic fundoplication.

PPI-induced hypomagnesemia (PPIH) was first described by Epstein *et al*[5] in 2006, and subsequently several other case reports have demonstrated the association. In 2011, the United States Food and Drug Administration issued a safety announcement regarding the association between long term PPI use and hypomagnesemia, and PPIH is now well-established as a rare, but potentially serious, adverse effect of long term PPI treatment. However, PPIH is still not widely acknowledged, and the frequency and risk

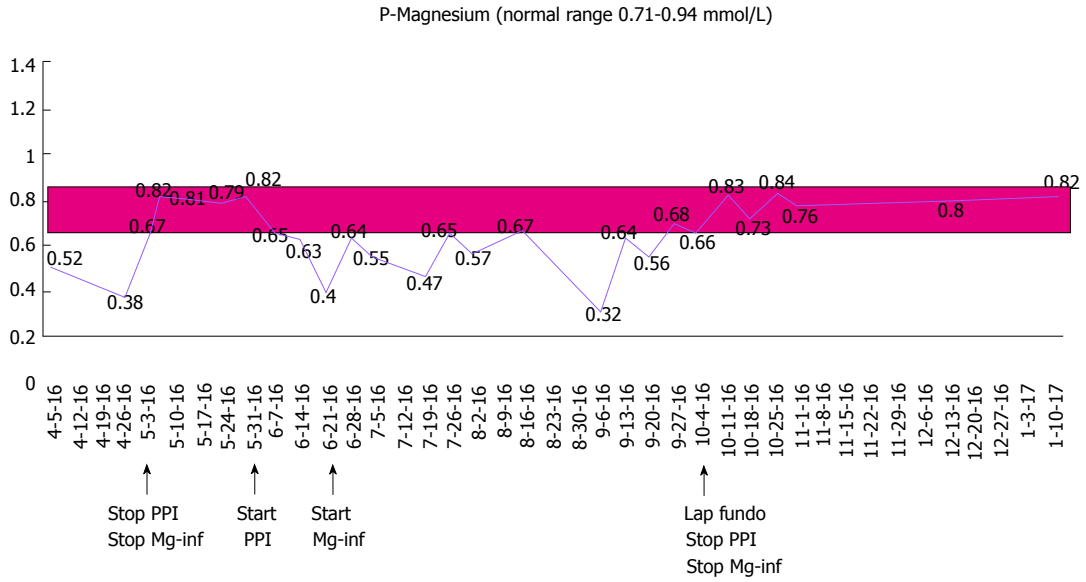

Figure 1 Course of the patient's magnesium levels. The figure illustrates how the patient´s S-Mg level stays persistently below the normal range while he is on PPI therapy despite receiving magnesium infusions. S-Mg normalizes promptly after cessation of PPI therapy. PPI: Proton pump inhibitor.

factors of PPIH are not well recognized.

PPIH has been observed with all different formulations of PPIs and is thus considered a class drug effect. Similar to our case, previous reports have documented only partial effect of oral magnesium supplements in correcting the hypomagnesemia during ongoing PPI-therapy[2], and only short term relief with intravenous magnesium infusions. In contrast, hypomagnesemia is typically improved promptly after the PPI is discontinued, and PPI re-challenge results in rapid recurrence of hypomagnesemia[1,2]. The same phenomenon has not been observed with histamine 2 receptor antagonists (H2RAs), although a recent population-based study suggested a similar but weaker association with the use of these drugs[6]. Previous reports have suggested that PPIH occurs after long term PPI use[1]; however, duration of exposure to PPI therapy is often difficult to quantify retrospectively and the duration of PPI use necessary to cause PPIH remains uncertain.

Magnesium homeostasis is mainly determined by absorption in the small intestine, and renal excretion. Intestinal magnesium absorption is complex, and occurs via both passive and active transport mechanisms. Firstly, magnesium is passively absorbed through a paracellular pathway between the enterocytes of the intestine across a concentration gradient. Secondly, a transcellular active transport mechanism occur by means of a combined action of magnesium channels in the apical membrane of enterocytes on the luminal surface, particularly transient receptor potential melastin (TRPM) 6 and 7. It has been proposed that increased luminal pH in the intestine caused by PPIs may alter the affinity of the TRPM6/7 channel for magnesium, resulting in reduced active transport of magnesium, and that individual genetic variations in the TRPM could explain why PPIH does not develop in all PPI users[4]. Several other drugs can cause hypomagnesemia, where the underlying mechanism is tubular magnesium wasting[1]. In contrast, previous case reports of PPIH have documented consistently low urinary excretion coherent with efficient tubular magnesium retention[1,2], which is thought to support the theory of impaired gastrointestinal absorption as the mechanism leading to PPIH.

Some patients might be more susceptible to PPIH due to other coexisting risk factors such as concomitant medication (diuretics) or other medical conditions associated with hypomagnesemia such as diabetes mellitus, inflammatory bowel disease, short-bowel disease, chronic pancreatitis, diarrhea and/or alcoholism. It remains controversial whether serum magnesium should be monitored in all long-term PPI users, or perhaps in specific subsets of patients with additional risk factors. Nonetheless, PPIH should be remembered as a differential diagnosis in patients with PPI use and unexplained hypomagnesemia. Patients with PPIH and persistent troublesome reflux symptoms after PPI discontinuation could be considered for anti-reflux surgery. It should be remembered, however, that a majority of patients treated with anti-reflux surgery have resumed PPI therapy 10-15 years after the operation[7], and it is mandatory to control for hypomagnesemia if patients with previous PPIH resume PPI treatment.

COMMENTS

Case characteristics

A 67-year old male with gastroesophageal reflux disease and persistent severe hypomagnesemia demanding weekly intravenous magnesium infusions.

Clinical diagnosis

Extensive work-up did not reveal any other cause of hypomagnesaemia.

Serum magnesium levels rapidly normalized upon pump inhibitor (PPI) discontinuation, and re-challenge of PPI treatment resulted in a prompt drop in serum magnesium within days. Magnesium levels again normalized following PPI withdrawal after laparoscopic fundoplication.

Differential diagnosis

Gastrointestinal or renal disease causing either impaired absorption or increased excretion of magnesium.

Laboratory diagnosis

Initially the patient had severe hypomagnesemia (0.23 mmol/L) with associated hypokalemia, which both resolved with intravenous magnesium infusions. However, the patient had continuously low S-Mg levels during the disease course despite both oral and intravenous magnesium supplementation, where other laboratory tests were normal.

Imaging diagnosis

Neither colonoscopy nor CT scans revealed any other explanation for the patient´s persistent hypomagnesaemia.

Pathological diagnosis

Biopsies taken from terminal ileum and colon during colonoscopy were normal.

Treatment

The patient underwent a successful laparoscopic fundoplication, and his serum magnesium levels again normalized following PPI withdrawal after the surgery.

Related reports

PPI-induced hypomagnesemia (PPIH) was first described in 2006, and subsequently several other case reports have demonstrated the association. In 2011, the US Food and Drug Administration issued a safety announcement regarding the association between long term PPI use and hypomagnesemia, and PPIH is now well-established as a rare, but potentially serious, adverse effect of long term PPI treatment.

Term explanation

PPIH is a rare, but potentially serious adverse effect where persistent severe hypomagnesemia is associated with of long-term PPI treatment. PPIH is probably caused by impaired intestinal magnesium absorption through a molecular effect on magnesium transporters in genetically predisposed individuals.

Experiences and lessons

PPIH should be remembered as a differential diagnosis in patients with PPI use and unexplained hypomagnesemia. Patients with PPIH and persistent troublesome reflux symptoms after PPI discontinuation could be considered for anti-reflux surgery

Peer-review

The manuscript describes surgical option in the management of hypomagnesemia induced by PPIs. The condition has been described earlier but fundoplication as an option has not been discussed in earlier reports. The manuscript is well written and may be accepted with few clarifications.

Abstract

Pancreatic neuroendocrine tumors (pNETs) are particularly rare. The various forms of PNETs, such as cystic degeneration, make differentiation from other similar pancreatic lesions difficult. We can detect small lesions by endoscopic ultrasound (EUS) and obtain preoperative pathological diagnosis by EUS-guided fine needle aspiration (FNA). We describe, here, an interesting case of pNET in a 42-year-old woman with no family history. Computed tomography and magnetic resonance imaging revealed an 18 mm × 17 mm cystic lesion with a nodule in the pancreatic tail. Two microtumors about 7 mm in diameter in the pancreatic body detected only by EUS, cystic rim and nodules all showed similar enhancement on contrast-harmonic EUS. Preoperative EUS-FNA of the microtumor was performed, diagnosing multiple pNETs. Macroscopic examination of the resected pancreatic body and tail showed that the cystic lesion had morphologically changed to a 13-mm main nodule, and 11 new microtumors (diameter 1-3 mm). Microscopically, all microtumors represented pNETs. From the findings of a broken peripheral rim on the main lesion with fibrosis, rupture of the cystic pNET was suspected. Postoperatively, pituitary adenoma and parathyroid adenoma were detected. The final diagnosis was

multiple grade 1 pNETs with multiple endocrine neoplasia type 1. To the best of our knowledge, no case of spontaneous rupture of a cystic pNET has previously been reported in the English literature. Therefore, this case of very rare pNET with various morphological changes is reported.

Core tip: Cystic or multiple pancreatic neuroendocrine tumors (pNETs) are very rare. This report describes a case of cystic pNET with multiple small tumors diagnosed from endoscopic ultrasonography (EUS) alone. Preoperative diagnosis was able to be obtained by EUS-guided fine needle aspiration biopsy. Postoperatively, 11 other micro-pNETs with multiple endocrine neoplasia type 1 were detected and cystic pNET morphologically changed to a small nodule because of suspected spontaneous rupture. Spontaneous rupture of cystic pNET has not been reported previously in the English literature.

INTRODUCTION

Neuroendocrine tumors can arise in endocrine organs throughout the whole body and cause various clinical symptoms. Pancreatic neuroendocrine tumors (pNETs) are particularly rare, representing only 1%-2% of all pancreatic neoplasms[1]. PNETs sometimes show various forms, such as cystic degeneration[2] or multiple microtumors[3], but such variations appear to be rare.

Most pNETs are solid and show strong enhancement during the arterial phases on contrast-enhanced computed tomography (CT)[4-6]. Diagnosis is therefore relatively easy. However, morphologically changed pNETs, such as cystic pNETs, are difficult to differentiate from other pancreatic cystic tumors[7]. Multiple PNETs are often diagnosed in multiple endocrine neoplasia type 1 (MEN1)[8], but diagnosis of microtumors in the pancreas on CT is difficult. In such cases, endoscopic ultrasonography (EUS) is superior to CT for detecting pNETs, particularly small lesions[9]. Furthermore, contrast-enhanced harmonic EUS (CH-EUS) allows the diagnosis as pNETs with hypervascular enhanced tumors with high sensitivity and specificity, and EUS-guided fine needle aspiration (FNA) enables preoperative pathological diagnosis[10].

This paper presents a case of pNETs with microtumors detected only by EUS in a 42-year-old woman with MEN1. In addition, a rare event of spontaneous rupture of the cystic pNET was strongly suspected from the postoperative pathological findings.

CASE REPORT

A 42-year-old woman was referred to our hospital because of a pancreatic cystic lesion incidentally detected on unenhanced CT performed for inspection of painless enlargement of a cervical lymph node 1 mo earlier. No physical findings involving the abdomen were evident. No contributory family history was elicited. The patient had a history of urinary stones at 30-years-old. The only abnormality from laboratory tests was a mild elevation of liver enzymes.

Unenhanced CT revealed a 16 mm × 15 mm, somewhat obscure cystic lesion in the pancreatic tail (Figure 1A). Contrast-enhanced CT revealed an 18 mm × 17 mm cystic lesion with a well-defined, hyperenhanced thin peripheral rim and a nodule about 6 mm in diameter inside the rim (Figure 1B). The outer rim was enhanced to a greater degree than normal pancreatic parenchyma during the arterial phases of bolus contrast administration, and iso-enhanced during the portal venous phase (Figure 1B and C).

On magnetic resonance imaging (MRI), the lesion in the pancreatic tail appeared hypointense and some areas appeared relatively hyperintense compared to inside the cyst on T1-weighted images (Figure 2A), and mainly hyperintense with a hypointense peripheral rim and nodule on T2-weighted images (Figure 2B). On diffusion-weighted images, the lesion appeared relatively hyperintense (Figure 2C). The lesion was not continuous with the main pancreatic duct on magnetic resonance cholangiopancreatography (Figure 2D).

We also performed EUS, showing the cyst with a low echoic peripheral rim and nodule. Inside the cyst, no echoic fluid or solid structure was detected, and internal bleeding or necrosis was expected (Figure 3A). Apart from the main lesion, we detected two microtumors (7 mm and 6 mm in diameter) in the pancreatic body only on EUS (Figure 3B). On CH-EUS, the relatively thick rim of the cystic lesion, nodule and two microtumors showed similar enhancement from immediately after the injection of contrast medium (Figure 3C and D). We performed EUS-FNA of a 7-mm microtumor (Figure 3E).

Histopathologically, the EUS-FNA specimen comprised cells with round nuclei (hematoxylin and eosin stain, ×100; Figure 4A). Tumor cells were negative

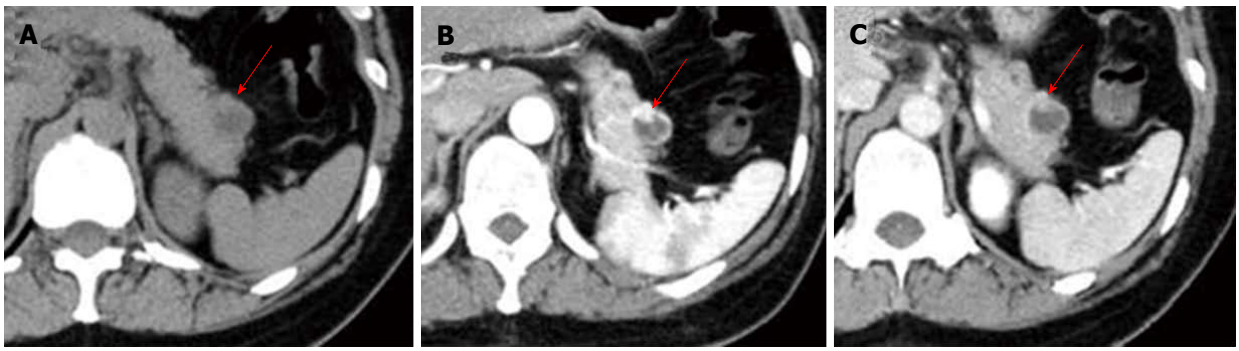

Figure 1 Findings from computed tomography. A: Unenhanced computed tomography (CT) shows a 16 mm × 15 mm, somewhat obscure cystic lesion (red arrow) in the pancreatic tail; B: Contrast-enhanced CT shows an 18 mm × 17 mm cystic lesion (red arrow) with a well-defined, hyper-enhanced, thin peripheral rim and a 6-mm nodule during the arterial phase; C: The outer rim appears iso-enhanced compared to normal pancreatic parenchyma during the portal venous phases (red arrow).

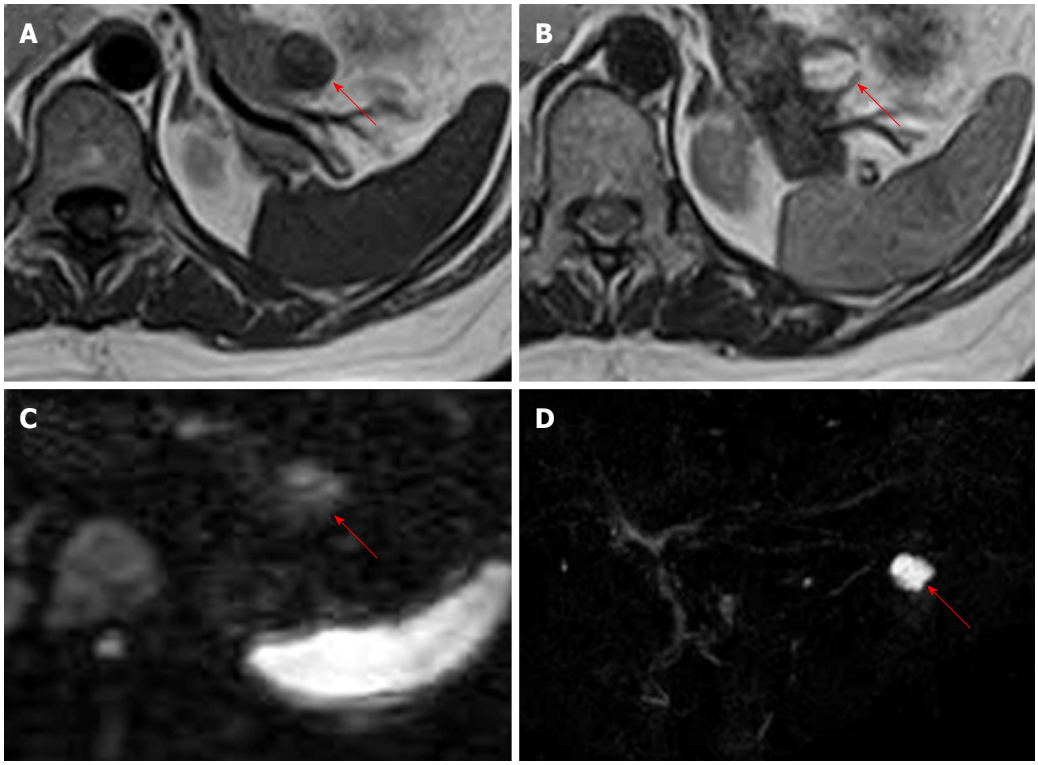

Figure 2 Findings from magnetic resonance imaging. A: The cystic lesion in the pancreatic tail (red arrow) appears hypointense and some areas appear relatively hyperintense compared to inside the cyst on T1-weighted images; B: The lesion (red arrow) appears mainly hyperintense, while the peripheral rim and nodule appear hypointense on T2-weighted images; C: The lesion (red arrow) appears relatively hyperintense on diffusion-weighted images; D: The lesion (red arrow) is not continuous with the main pancreatic duct on magnetic resonance cholangiopancreatography.

for CD10 and CD56 (Figure 4B and C), but positive for chromogranin A and synaptophysin (Figure 4D and E) by immunohistochemical staining (×100). Based on these findings, multiple grade 1 endocrine neoplasms of the pancreas were diagnosed[11].

Preoperatively, endocrine examination was performed. Abnormal laboratory results included elevated parathyroid hormone at 136 pg/mL (normal, 15-65 pg/mL) and cortisol at 25.1 μg/dL (normal, 4.5-21.1 μg/dL), while other values were within normal ranges. The tumor was non-functional pNET, because levels of pancreatic endocrine hormones such as insulin were not elevated. After sufficient preparation and obtaining consent from the patient and her family members, we performed laparoscopic spleen-preserving pancreatic body and tail resection 50 d after EUS-FNA.

Macroscopically, the main cystic lesion morphologically changed to a nodule 13 mm in diameter with internal scarring (Figure 5A and C), considered to represent traces of cystic degeneration. The microtumor in the pancreatic body on which EUS-FNA was performed was separate from the main lesion (Figure 5A and B). A scar from EUS-FNA was identified in the microtumor (Figure 5B). Besides the main lesion and

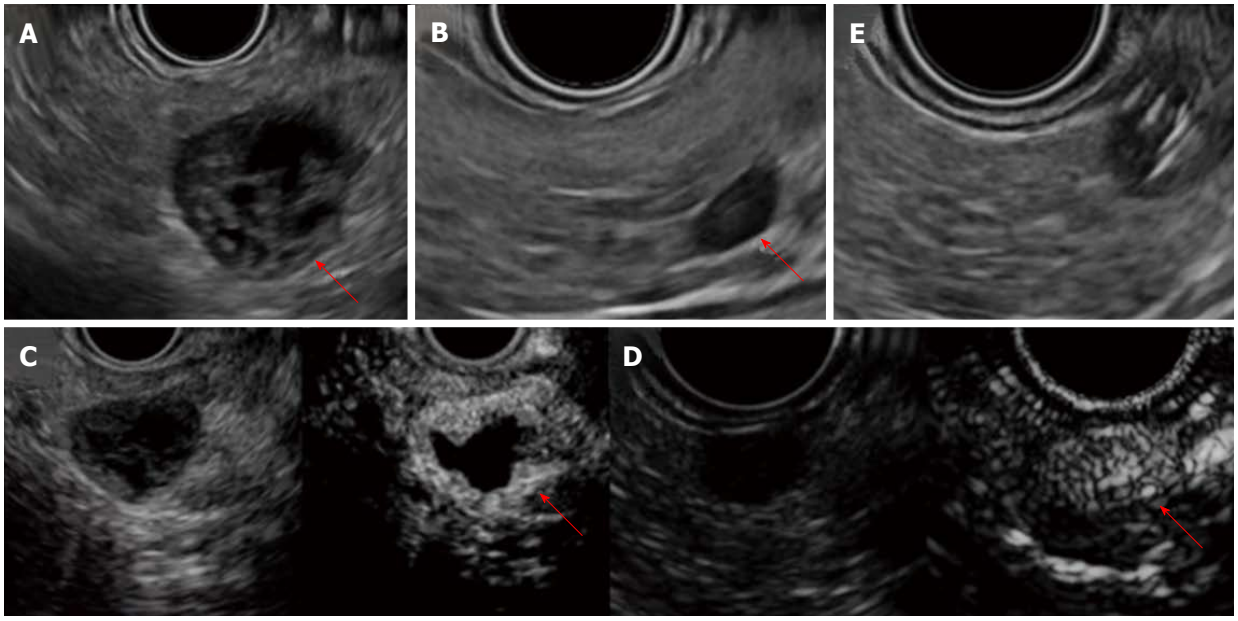

Figure 3 Findings from EUS and CH-EUS. A: The lesion in the pancreatic tail shows a hypoechoic peripheral rim and nodule. Inside the cyst, no echoic fluid or solid structure is detected; B: A new, 7-mm microtumor in the pancreatic body, apparent only on EUS; C: The rim of the cystic lesion and nodule appear enhanced immediately after injection of contrast medium on CH-EUS; D: The 7-mm microtumor is similarly enhanced on CH-EUS; E: Endoscopic ultrasound-fine needle aspiration to biopsy the 7-mm microtumor. CH-EUS: Contrast-enhanced harmonic-endoscopic ultrasound; EUS: Endoscopic ultrasound.

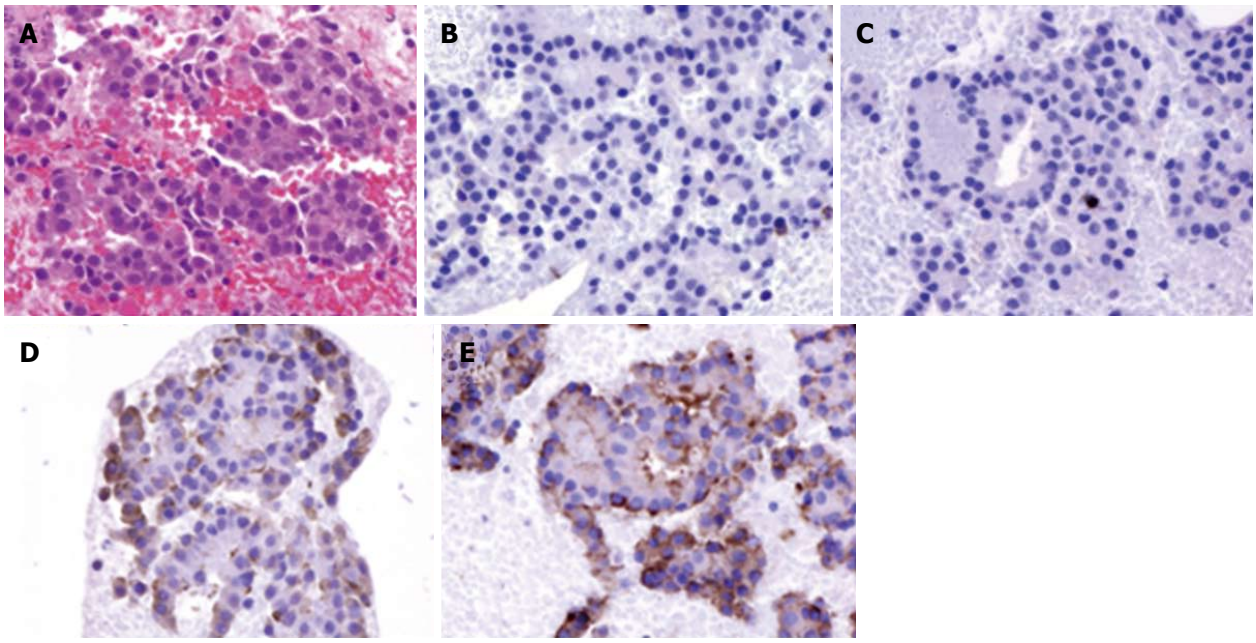

Figure 4 Histopathological findings for the specimen obtained by endoscopic ultrasound-fine needle aspiration. A: The specimen comprises cells with round nuclei arranged in sheets or rosettes (hematoxylin and eosin, ×100); B and C: Tumor cells show negative results for CD10 (B) and CD56 (C) immunohistochemical staining (×100); D and E: Tumor cells show positive results for chromogranin A (D) and synaptophysin (E) on immunohistochemical staining (×100).

two microtumors detected previously on EUS, 11 microtumors (1-3 mm diameters) were newly detected (Figure 5D).

Microscopically, the main lesion comprised cells with round nuclei arranged in sheets or rosettes (Figure 6A), with < 2 mitoses per 50 high-power fields (Figure 6B). The Ki-67 index in the main lesion was 1.01%. All other microtumors showed similar findings (Figure 6C and D). After evaluating the potential causes of morphological changes to the main cystic lesion, the peripheral rim was considered most likely to have broken in one place, followed by fibrosis after

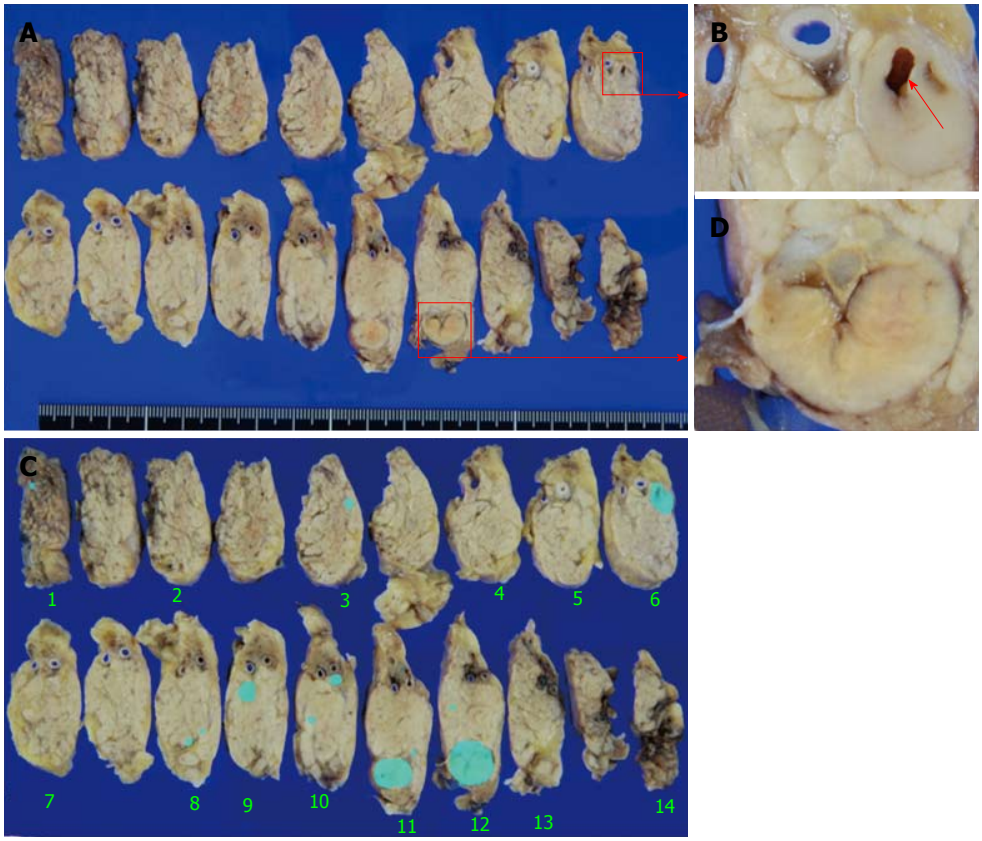

Figure 5 Macroscopic findings for the resected pancreas. A: The main cystic lesion has morphologically changed to a 13-mm nodule (red square C). The microtumor in the pancreatic body on which EUS-FNA was performed was separate from the main lesion; B: A scar from EUS-FNA is evident in the microtumor (red arrow); C: The main nodule shows internal scarring; D: The main lesion and two microtumors detected on EUS, and another 11 new microtumors (1-3 mm) (blue areas). EUS-FNA: Endoscopic ultrasound-fine needle aspiration.

inflammation (Figure 6E).

After surgery, whole-body examination detected asymptomatic pituitary adenoma and parathyroid adenoma on MRI and ultrasound. The final diagnosis was multiple pNET grade 1, stage 1 T1N0M0 with MEN1 and a strong suspicion of spontaneous rupture of the cystic pNET. As of the time of writing, the patient remains alive without recurrence for more than 2 years postoperatively. Asymptomatic pituitary adenoma and parathyroid adenoma are being followed-up by an endocrine physician, and no clinical symptoms or abnormal results from blood testing have been encountered.

DISCUSSION

Image features of pNETs and various morphological changes

PNETs are rare and represent only 1%-2% of all pancreatic neoplasms[1]. However, due to the development of increasingly sophisticated imaging modalities, more pNETs are being reported[12].

The clinical symptoms of pNET primarily depend on whether the tumor is functional or non-functional, and the type of hormone produced by a functional tumor[1]. Most pNETs are solid lesions, but some are detected as tumor with cystic degeneration[2]. Cystic pNETs were classically considered very rare, but recent studies have suggested that cystic pNETs may be more common than previously reported[13]. Some studies have reported that 9.3%-21% of pNETs are detected as cystic degeneration on imaging modalities including CT, ultrasound, MRI, and EUS or by pathological examination of a resected specimen[14-19].

Solid pNETs are typically enhanced to a greater degree than normal pancreatic parenchyma during the arterial and portal venous phases of bolus contrast administration[4-6], because of the rich vascularity[20]. On the other hand, the radiological features of cystic pNETs have been suggested to represent an enhanced outer rim with blood flow-rich tissue[21]. As another specific finding of pNETs, multiple and microtumors in the pancreas are rarely detected. Multiple PNETs are often diagnosed in cases of MEN1[8], but diagnosis of microtumors in the pancreas on contrast-enhanced CT is difficult[9].

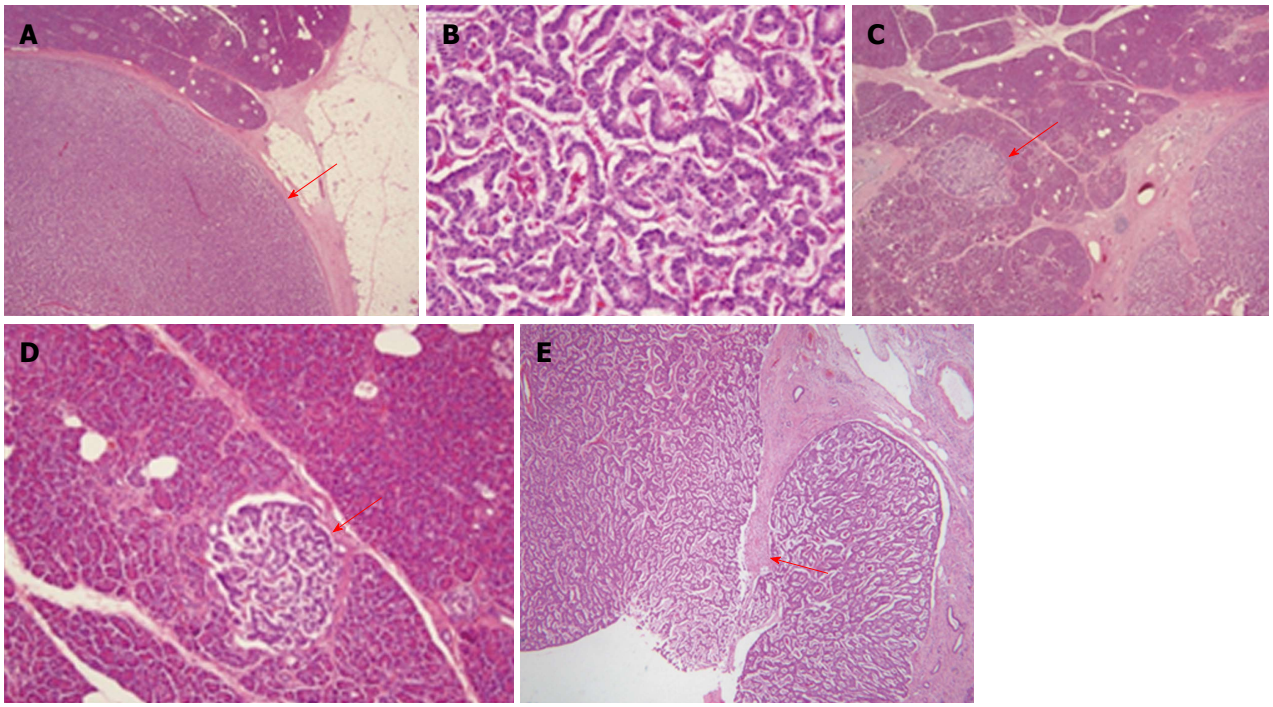

Figure 6 Microscopic findings for the resected pancreas. A: The main lesion (red arrow) comprises cells with round nuclei arranged in sheets or rosettes (hematoxylin and eosin, × 4); B: Less than 2 mitoses per 50 high-power fields are evident (hematoxylin and eosin, × 40); C and D: The other microtumors (red arrow) show similar findings (hematoxylin and eosin; C, × 4; D, × 10); E: The peripheral rim appears broken at one site, and fibrosis (red arrow) is evident with inflammation (hematoxylin and eosin, × 10). A trace of a cystic lumen is apparent below the red arrow.

EUS as one of the best imaging modalities for small pNETs

EUS is superior to CT for detecting small pNETs. In a study of 231 pNETs, CT detected 84% of tumors but was more likely to miss lesions < 2 cm in diameter (P = 0.005), while the sensitivity of EUS for detecting 56 pNETs (91.7%) was greater than that of CT (63.3%; P = 0.0002), and EUS detected 20 of 22 CT-negative tumors (91%)[10]. Furthermore, CH-EUS allowed the diagnosis of hypervascularly enhanced tumors as pNETs with 78.9% sensitivity (95%CI: 61.4%-89.7%) and 98.7% specificity (95%CI: 96.7-98.8%) respectively[11].

In this manner, EUS appears useful for the diagnosis of pNETs, but we often encounter challenges, particularly in diagnosing cystic pNET. This is because we need to differentiate the pathology from other pancreatic cystic tumors, such as intraductal papillary mucinous neoplasm, mucinous cystic neoplasm, mucinous cystadenocarcinoma, serous cystic neoplasm, solid and cystic papillary tumors, or even non-neoplastic pseudocyst[7].

In such cases, we should consider EUS-FNA for preoperative histological diagnosis. EUS-FNA correctly diagnosed PNETs, offering 90.1% diagnostic accuracy[22]. When CH-EUS was combined with EUS-FNA, the sensitivity of EUS-FNA increased from 92.2% to 100%[11]. EUS-FNA accuracies for the malignancy of cystic and solid PNETs were 89.3% and 90% respectively[23], but EUS-FNA for cystic lesions of the pancreas is not recommended in Japan.

In our case, the cystic lesion in the pancreas tail was initially detected on CT. MRI was additionally performed, but we could not obtain a confirmed diagnosis from the imaging findings. The cystic lesion was evaluated in more detail and 2 new microtumors were detected in the pancreatic body only on EUS. In addition, the rim of the cyst and microtumors were hyperenhanced on CH-EUS, and we became confident the lesions represented pNETs. In addition, we performed EUS-FNS of a microtumor, and obtained pathological confirmation of the preoperative diagnosis.

Features of pNETs in MEN1

MEN is an autosomal-dominant inherited disease presenting with tumorous lesions, mainly in various endocrine organs[3], and 15% of MEN1 patients have no family history[24]. MEN1 is diagnosed when at least 2 of the main tumorous diseases (parathyroid tumor, pNET or pituitary tumor) are found, and hyperparathyroidism is the most frequent initial disease in MEN1 (85%)[25]. According to a Japanese nationwide survey, MEN1 was found in 10% of pNET patients. The type of pNET in MEN1 was gastrinoma in 25%, insulinoma in 14% and non-functioning in 6.1%[12]. In addition, PNETs in MEN1 often have

multiple tumors in the pancreas, and 74% of pNET with MEN1 had multiple tumors[8].

Rupture of cystic neoplasms

This was a typical case of pNETs with MEN1, but spontaneous rupture of the cystic pNET was a remarkable feature. The rupture of a pancreatic neoplasm is very rare. Ruptures of intraductal papillary mucinous neoplasm[26-28], mucinous cystic neoplasm[29], acinar cell carcinoma[30,31] and anaplastic cell carcinoma[32] have been reported, but rupture of cystic pNET does not appear to have been described. Involvement of either infarction and liquefactive necrosis of a large tumor or internal hemorrhage have been considered as causes of cystic degeneration in pNETs[21,33]. The cause of cyst formation of cystic pancreatic NET, thus, remains controversial[15,34,35].

Spontaneous rupture of cystic lesions of the pancreas has been suggested due to high pressure inside the cyst or inflammatory stimulation by others factors, such as acute pancreatitis[27], but only a small number of cases have been reported, and the exact cause remains thusly unknown. In our case, internal bleeding, rather than necrosis, might have been involved in cystic degeneration. We performed EUS-FNA of the microtumor in the pancreatic body separate from the cystic pNET in the pancreatic tail, so EUS-FNA might not have been related to rupture.

We could not rule out the possibility that rupture was associated with instrumental pressure from EUS examinations, but such high pressure on the cystic lesion was considered unlikely to arise in normal EUS examination or EUS-FNA. The scar from EUS-FNA is shown in Figure 5B. The thin part of the rim was not intact, and thinning of the tumor part and high pressure inside the cyst were considered as causes, but more detailed causes of the rupture could not be clarified.

In conclusion, pNETs are rare and show various forms of tumor, such as cystic degeneration. PNETs with MEN1 often show multiple tumors, and detecting microtumors on CT or MRI is sometimes difficult so that EUS and CH-EUS should be performed. In addition, we should search for endocrine tumors in other organs affected by MEN1. To the best of our knowledge, spontaneous rupture has not been reported previously, so this case was reported.

ACKNOWLEDGMENTS

We wish to thank endoscopic engineers Ohata T, Yamasaki K. Sakata N, Tauchi M, Tasaki M, Matou M and Kudou C of Oita San-ai Medical Center, for their helpful technical assistance in EUS.

COMMENTS

Case characteristics

A 42-year-old woman was referred to our hospital with a pancreatic cystic lesion found incidentally on computed tomography (CT). She had no relevant family history.

Clinical diagnosis

Cystic pancreatic neuroendocrine tumor (pNET) with many microtumors.

Differential diagnosis

Differential diagnoses included intraductal papillary mucinous neoplasm, mucinous cystic neoplasm, solid pseudopapillary tumor and pancreatic neuroendocrine tumor.

Laboratory diagnosis

Abnormal laboratory results included mild liver enzyme, cortisol and intact parathyroid hormone elevation in blood serum

Imaging diagnosis

Contrast-enhanced CT showed an 18 mm × 17 mm cystic lesion with a well-defined hyperenhanced thin peripheral rim. On magnetic resonance imaging, the lesion appeared mainly hypointense on T1-weighted images and hyperintense on T2-weighted images. On EUS, apart from the main lesion, two microtumors were detected (7 mm and 6 mm) in the pancreatic body.

Pathological diagnosis

The final pathological diagnosis was multiple grade 1 pNETs. The main cystic lesion changed to a 13-mm nodule, and spontaneous rupture of the cystic pNET was strongly suspected.

Treatment

The patient was treated with pancreatic body tail resection.

Related reports

Recent studies suggest that cystic pNETs may be more common than previously reported, but rupture of a cystic pNET has not been reported.

Term explanation

There are no non-standard terms used in this manuscript.

Experience and lessons

The authors present this case to share important knowledge for pNET diagnosis.

Peer-review

The authors reported an interesting case, which they believed to be a spontaneous rupture of cystic pNET with many microtumors.

Abstract

In their review, Arslan *et al*[1] did not describe the status of *Helicobacter pylori* (*H. pylori*) treatment with furazolidone and the resistance to this antibiotic. We have presented different surveys showing the resistance of *H. pylori* to furazolidone from Asia and South America. The resistance rates varied but were mostly low (< 5%). There are not enough data on its efficacy and resistance in the United States and Europe. *H. pylori* mutations occurring in the *oorD* gene, including A041G, A122G, C349A(G), A78G, A112G, A335G, C156T and C165T, and in the *porD* gene, including G353A, A356G, C357T, C347T, C347G and C346A, have been indicated to be possibly related to the observed resistance. Additionally, to complete Arslan *et al*'s statement regarding levofloxacin resistance, it should be noted that compound mutations of N87A, A88N and V65I at codon Asn-87 were recently observed in the *gyrA* gene for the first time. However, the results on these topics are not sufficient, and more worldwide studies are suggested.

TO THE EDITOR

We have read with great interest the valuable article by Arslan *et al*[1], titled "Importance of antimicrobial susceptibility testing for the management of eradication in *Helicobacter pylori* infection". One of the main subjects of the review was the description of the resistance rates of different antibiotics and the potential mechanisms leading to decreased in *Helicobacter pylori* (*H. pylori*) antimicrobial susceptibility. However, the authors should consider clarifying two important issues.

The authors did not allude to the status of *H. pylori* treatment with furazolidone and the resistance to this antibiotic. We have provided existing surveys reporting the resistance of *H. pylori* to furazolidone in Table 1. The resistance rates have been mostly reported to be lower than 5%; however, these rates can vary geographically. Furazolidone is not used widely in the United States and Europe; therefore, there are not enough data on its efficacy and resistance in these regions.

One of the main reasons for the emergence of resistance is related to the extensive use of furazolidone. In addition, regarding the molecular mechanisms, some genetic mutations have been identified. Mutations occurring in the *2-oxoglutarate:acceptor oxidoreductase* (*oorD*) gene, including *A041G*, *A122G*, *C349A(G)*, *A78G*, *A112G*, *A335G*, *C156T* and *C165T*, and in the *pyruvate oxidoreductase* (*porD*) gene, including *G353A*, *A356G*, *C357T*, *C347T*, *C347G* and *C346A*, are possibly related to the resistance[2,3]. *The oor and por* genes are involved in the generation of acetyl coenzyme A (acetyl-CoA) and succinyl-CoA[4]. Despite these findings, additional molecular methods are proposed to reach a better understanding of the mechanisms that were mentioned.

Arslan *et al*[1] accurately documented the mechanism of levofloxacin resistance; *i.e.*, point mutations in the *gyrA* (DNA *gyrase*) gene were stated to be potentially linked to the resistance. However, to complete their statement, it should be noted that compound mutations of N87A, A88N and V65I at codon Asn-87 were recently observed in the *gyrA* gene for the first time. L45F, A55S, A97V, D91N, R130K and G60S are other possible mutations that need to be assessed in studies with broader sample bases[5].

ABOUT COVER

Editorial board member of *World Journal of Gastroenterology*, Jorg Kleeff, MD, Professor, Department of Visceral, Vascular and Endocrine Surgery, University Hospital Halle (Saale), Halle (Saale) 06120, Germany

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1375 experts in gastroenterology and hepatology from 68 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology (*WJG*) is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central and Directory of Open Access Journals. The 2017 edition of Journal Citation Reports® cites the 2016 impact factor for *WJG* as 3.365 (5-year impact factor: 3.176), ranking *WJG* as 29th among 79 journals in gastroenterology and hepatology (quartile in category Q2).

Abstract

Gastric cancer (GC) remains a leading cause of cancer death worldwide. Radical gastrectomy is the only potentially curative treatment, and perioperative adjuvant therapies may improve the prognosis after curative resection. Prognosis largely depends on the tumour stage and histology, but the host systemic inflammatory response (SIR) to GC may contribute as well, as has been determined for other malignancies. In GC patients, the potential utility of positron emission tomography/computed tomography (PET/CT) with the imaging radiopharmaceutical ^{18}F-fluorodeoxyglucose (FDG) is still debated, due to its lower sensitivity in diagnosing and staging GC compared to other imaging modalities. There is, however, growing evidence that FDG uptake in the primary tumour and regional lymph nodes may be efficient for predicting prognosis of resected patients and for monitoring tumour response to perioperative treatments, having prognostic value in that it can change therapeutic strategies. Moreover, FDG uptake in bone marrow seems to be significantly associated with SIR to GC and to represent an efficient prognostic factor after curative surgery. In conclusion, PET/CT technology is efficient in GC patients, since it is useful to integrate other imaging modalities in staging tumours and may have prognostic value that can change therapeutic strategies. With ongoing improvements, PET/CT imaging may gain further importance in the management of GC patients.

Key words: Gastric cancer; Prognosis; ^{18}F-fluorodeoxyglucose; Positron emission tomography-computed tomography; Bone marrow

Core tip: Gastric cancer (GC) is still a leading cause of cancer death worldwide. Prognosis depends on surgical curability, response to adjuvant therapies, tumour stage and histology, but also on the systemic inflammatory response to malignancy. While the diagnostic role of positron emission tomography with ^{18}F-fluorodeoxyglucose (FDG) in GC is still debated, due to unsatisfactory sensitivity, there is growing evidence that FDG uptake, either at the tumour sites or in the bone marrow, may represent an efficient tool for predicting prognosis of resected patients and for monitoring tumour response to adjuvant treatments, and may have prognostic value in directing therapeutic strategies.

De Raffele E, Mirarchi M, Cuicchi D, Lecce F, Cola B. Evolving role of FDG-PET/CT in prognostic evaluation of resectable gastric cancer. *World J Gastroenterol* 2017; 23(38): 6923-6926 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/6923.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.6923

INTRODUCTION

Gastric cancer (GC) remains a leading cause of cancer death worldwide, with poor prognosis despite significant advances in diagnosis and treatment. Survival rates are progressively increasing in western countries[1-3], and are highest in Japan, due to focused management of preventive and prognosis-related factors (*i.e.* infection and smoking, respectively)[2]. Prognostic factors related to GC are quite well established, such as local extension, lymph node involvement and presence of distant metastases, and can be adequately defined by the conventional imaging modalities, including endoscopic ultrasound (EUS), computed tomography (CT) and magnetic resonance imaging (MRI). However, some emerging prognostic factors related to the metabolism of tumour cells, such as the glucose avidity, or to the systemic inflammatory response (SIR) to the tumour can be better evaluated through the metabolic information that are provided by positron emission tomography (PET) integrated with CT, even though the role of PET/CT imaging in the evaluation of GC is still controversial.

CLASSIFICATION, THERAPEUTIC STRATEGIES AND PROGNOSIS

GC can be categorized according to anatomical location, as either true GC (non-cardia) or gastro-oesophageal-junction (cardia) cancer (GEJ)[1,2]. In general, GC are predominantly adenocarcinomas, classified according to the World Health Organization (WHO) classification into tubular, papillary, mucinous (MAC), poorly cohesive and rare variants[1-3]. The Lauren classification distinguishes GC according to intestinal type, diffuse type (including signet ring cell carcinoma (SRC)), mixed type and indeterminate type[1-3]. Classification of GC based on molecular subtyping has been proposed recently[1] and is promising for helping to improve the accuracy of prediction of individual prognosis and for providing individually-tailored therapies.

Radical surgical resection is the only potentially curative therapeutic option for resectable GC presently. Adequate surgery includes complete resection of the primary tumour and appropriate lymphadenectomy. Tumours of the lower two-thirds of the stomach can be selectively treated with distal subtotal gastrectomy; otherwise, total gastrectomy is recommended[2-4]. This approach has contributed in part to the amelioration of cure rates from 30% to over 50% in selected series over the past decade[1]. Early GC (EGC) is defined as limited to the mucosa or submucosa (T1 stage or lower), regardless of nodal status. Endoscopic resection is considered appropriate for small ($\leqslant$ 20 mm), non-ulcerated, superficial GC that are well differentiated and limited to the mucosa (T1a), because the incidence of regional lymph node metastases is very low[3]. If, however, the tumour has invaded the submucosa (T1b), radical gastrectomy with lymphadenectomy is required, since lymph node involvement is observed in up to 20% of cases[1,2].

Locally advanced GC (AGC; invading the muscularis propria and beyond (T2 stage or higher)) presents in most cases with metastases to lymph nodes, distant organs, or both. Patients without distant metastases are candidates for potentially radical surgery, either conventional or minimally invasive by laparoscopy[1-4]. Perioperative therapies for resectable GC include chemotherapy (CHT), radiotherapy and chemoradiotherapy, performed before and/or after surgery. Even though adjuvant and neoadjuvant therapies have been demonstrated to improve prognosis after potentially curative resection of locally AGC, the optimal strategy is still debated[1-3].

Despite substantial advances in the staging procedures, imaging techniques and treatment options, prognosis of GC remains poor, with postoperative 5-year survival rates of 25%-30% in western countries, because of the high incidence of advanced tumours[3]. Cardia GC and diffuse-type non-cardia GC have the worst prognosis. For resectable locally AGC, outcome depends on the surgical disease stage. Resection of EGC provides excellent 5-year survival rates, up to 90%. However, at the time of diagnosis GC is usually advanced, with reported involvement of the regional lymph nodes in 70% to 80% of cases. If the tumour invades the subserosa (T3 stage), 5-year survival decreases to less than 50%. Moreover, the presence of nodal involvement in T3 lesions further decreases 5-year overall survival to less than 30%[2].

Besides tumour-related factors, the survival of GC patients, as for other malignancies, is also dependent on the host's reaction to the cancer. SIR plays a critical role in carcinogenesis and tumour diffusion[5]. Several host SIR markers (SIRMs) have been identified as prognostic factors. Neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), albumin and C-reactive protein (CRP) have been indicated, alone or in combination, as significant factors for predicting postoperative prognosis of GC patients[6,7].

ROLE OF PET/CT IN DIAGNOSIS AND PROGNOSTIC EVALUATION

Clinical evaluation of GC has greatly improved with the availability of EUS, CT, MRI, PET/CT and laparoscopic staging. PET/CT using ^{18}F-fluorodeoxyglucose (FDG) has proven useful for staging, detecting recurrence, evaluating treatment response and predicting prognosis[1-4,8,9]. However, the overall sensitivity of FDG-PET/CT for detecting GC is lower than for most other malignancies, so that its effective role in GC patients is still controversial[8,9]. FDG-PET may have different sensitivities for different histotypes, with better sensitivity for GEJ tumours, but significantly lower sensitivities for diffuse type adenocarcinoma, including SRC, or for MAC[8,9]. Since tumour size and depth of invasion are significant factors influencing FDG-PET detection of GC, sensitivity is low for EGC and far higher for AGC. Altogether, the role of PET/CT is limited in T staging due to its low spatial resolution[9]. For N staging in GC, the sensitivity and specificity of FDG-PET/CT range between 33.3%-64.6% and 85.7%-97.0%, respectively[8]. The low sensitivity in detecting lymph node metastases may be related to the histotype of the primary tumour, or even to the size of the metastatic lymph nodes; some small lymph nodes may be difficult to visualize because of the radioactive volume effect generated by the nearby primary cancer[8,9]. Nonetheless, FDG-PET/CT is considered to have higher specificity than CT and MRI in the N staging of GC, especially for the N2 and N3 groups[9]. FDG-PET/CT has lower sensitivity than CT for the diagnosis of peritoneal seeding, while being more efficient in the detection of solid organ metastases, including those involving the lung, liver, bone or adrenal gland, with near 100% sensitivity and specificity[8,9].

Despite these limitations, FDG-PET/CT is emerging as an effective tool for therapeutic and prognostic evaluation of AGC. Preoperative FDG uptake has been demonstrated as an independent, significant prognostic factor following curative gastrectomy[8,9]; although, the collective data are not in full agreement. Patients with lower preoperative FDG uptake in the GC have shown significantly lower incidence of recurrence and better recurrence-free survival after surgery[8,9]. Lower preoperative FDG uptake has been reported as a predictor of tumour curability at the time of surgery, since higher FDG uptake in the primary tumour and positive FDG uptake in local lymph nodes have been significantly associated with non-curative resection, suggesting that these patients should be candidates for neoadjuvant CHT[9].

Neoadjuvant treatments have been increasingly used for AGC to reduce tumour stage, plan the optimal surgical timing and strategies, and improve the overall prognosis[9]. About 30% to 60% of histologically partial or even total responders have been reported with different therapeutic regimens[8]. Since patients with clinical and pathological response to neoadjuvant therapies are considered to gain significant survival benefit, the prompt identification of responders seems to be essential. FDG uptake in PET/CT scans is actually considered an early and sensitive indicator of response to treatment[2,3,8,9], concordant with histopathological analysis for tumour response. Changes in FDG uptake soon after the initiation of treatment have been related to final outcome also. In some studies, metabolic responders have shown better prognosis than non-responders, while FDG non-avid tumours seem to have poor response rates to CHT and unfavourable prognosis, indicating that neoadjuvant therapies may be ineffective in metabolic non-responders and in patients with low FDG uptake at baseline PET imaging[8].

In neoplastic patients, FDG uptake in bone marrow (BM) on PET/CT has been shown to be significantly associated with SIRMs, suggesting that this imaging finding has a significant relationship with SIR to malignancy[7]. In non-small cell lung cancer patients with curative surgical resection, Lee *et al*[7] have recently shown that the FDG uptake in BM and the BM to liver uptake ratio (BLR) were significantly correlated with albumin and CRP levels, white blood cell count, NLR and PLR; moreover, the BLR was identified as an independent prognostic factor of recurrence-free survival. The authors concluded that the FDG uptake in BM for non-small cell lung cancer patients reflects the degree of SIR and can be used as a prognostic factor after curative surgery[7].

In a recent retrospective series of 309 GC patients undergoing curative surgical resection, Lee *et al*[10] demonstrated that the preoperative BM FDG uptake, and BLR especially, are correlated with SIRMs of GC. In addition, patients with AGC, recurrence and positive FDG uptake of primary cancer were shown to have higher BM FDG uptake than those with EGC, no recurrence and negative FDG uptake, respectively; thus, GC patients with advanced stage and aggressive features might have higher degrees of SIR. BLR was identified as an independent prognostic factor for predicting survival, along with T4 stage, lymph node metastasis and positive resection margin. The authors conclude that for GC, both tumour factors and SIR could play important roles in long-term prognosis of resectable patients, and that BM FDG uptake could

reflect the degree of SIR to cancer and provide information on prognosis after curative surgery.

CONCLUSION

In conclusion, PET/CT technology represents an efficient tool for use in GC patients, since it is useful to integrate other imaging modalities in staging tumours. Moreover, it can be effective in monitoring tumour response to treatments and may have prognostic value with the potential to change therapeutic strategies. Although some problems still persist, PET/CT imaging remains promising, and with ongoing improvements may gain further importance in the evaluation and treatment of GC patients.

Abstract

Chronic pancreatitis (CP) is an inflammatory disease of the pancreas evolving in progressive fibrotic disruption of the gland with exocrine and endocrine pancreatic insufficiency. Although imaging features of CP are well known, their correlation with exocrine pancreatic function tests are not obvious, particularly in the early stage of the disease. There are many clinical classification of CP, all suggested for better distinguish and manage different forms based on etiological and clinical factors, and severity of the disease. Recently, a new classification of CP has been suggested: the M-ANNHEIM multiple risk factor classification that includes etiology, stage classification and degree of clinical severity. However, more accurate determination of clinical severity of CP requires a correct determination of exocrine function of the pancreas and fecal fat excretion. Recently, Kamath *et al* demonstrated that the evaluation of exocrine pancreatic function by acid steatocrit and fecal elastase-1 (EF-1) was helpful, but EF-1 was able to detect exocrine pancreatic insufficiency in more patients, upgrading some patients in higher stage of disease according to M-ANNHEIM classification. So, EF-1 is a more accurate test to determine exocrine pancreatic insufficiency and to stage chronic pancreatitis in the M-ANNHEIM classification. On the contrary, EF-1 determination shows low sensitivity in detecting exocrine pancreatic insufficiency in early stage of the disease.

Key words: Chronic pancreatitis; Exocrine pancreatic insufficiency; Fecal elastase-1; Pancreatic function tests; Steathorrea

Core tip: Classification of chronic pancreatitis is useful for planning adequate diagnosis and management of the disease, particularly in the early detection and prevention of related-complications. Recognition of pancreatic exocrine insufficiency is useful for graduating severity of chronic pancreatitis in modern classification systems, and fecal elastase determination appears the better method in term of simplicity and sensitivity to stage exocrine function of the pancreas. However, sensitivity of elastase-1 is low in early stage of chronic pancreatitis, and new diagnostic tools or combination of different procedures are needed to better stage pancreatic function.

INTRODUCTION

Chronic pancreatitis (CP) is the most commonly known cause of pancreatic exocrine insufficiency (PEI)[1]. Every patient with a new diagnosis of CP should be screened for PEI and in order to detect maldigestion prior to the occurrence of overt clinical symptoms, the presence of PEI should be evaluated annually in patients with CP. PEI can lead to poor quality of life, steathorrea, abdominal pain and malabsorption, and early diagnosis of PEI is important to prevent malnutrition-related complications. Many tests are nowadays available for the diagnosis of PEI, but each one has some diagnostic limitations. As a consequence, PEI is still underdiagnosed and undertreated. In addition to its clinical relevance, PEI represents an helpful method for staging CP in different classification systems. The M-ANNHEIM classification is a new system for staging and grading the severity of CP[2]. The M-ANNHEIM classification system is based on the categorization determined by etiological factors, clinical stage and severity of CP. This system constitutes a simple, objective, accurate and non-invasive method for clinicians which combines the influence and interaction of several risk factos on the course of the disease. These multiple (M) risk factors included the subsets of alcohol consumption (A), nicotin consumption (N), nutritional factors (N), hereditary factors (H), efferent pancreatic duct factors (E), immunological factors (I), and various rare miscellaneous and metabolic (M) factors[2]. The M-ANNHEIM staging of CP is divided into an asymptomatic phase (stage 0) and a symptomatic phase (stages I, II, III, IV) of the disease[2]. The latter phase represents the period of clinically evident chronic inflammation of he pancreas. The evaluation of the symptomatic phases of CP is based on pain and on the presence and degree of PEI[2]. An accurate evaluation of PEI is therefore necessary to validate the diagnosis and allow the proper treatment of the disease. In fact, a correct diagnosis of PEI suggests the pancreatic enzyme replacement therapy (PERT) and it is essential to monitor the efficacy of treatment in order to avoid complications of CP. Only few studies in the literature have compared the different diagnostic power of the tests available to evaluate PEI, and only few data are available for determining their role in the present staging system of CP.

STUDY ANALYSIS

In the recent issue of the *World Journal of Gastroenterology*, Kamath *et al*[3] reported a prospective analysis comparing two tests for PEI to use in M-ANNHEIM staging for pancreatitis. In this study, 116 patients with CP were included. PEI was analyzed by faecal elastase-1 (FE-1) value and fecal fat excretion by the acid steatocrit method. Based on the results of the two tests, the patients were separately categorized as per M-ANNHEIM stages. Among the 116 patients with CP, the presence of PEI was evident in 61 (52.5%) and 79 (68.1%) by the acid steatocrit method and FE-1, respectively. A statistically significant difference was seen between the M-ANNHEIM stages as classified separately by acid steatocrit and the FE-1. The Authors concluded that FE-1 estimation permits better staging of pancreatitis by the M-ANNHEIM classification, since it diagnosed a higher number of patients with exocrine pancreatic insufficiency. They recommend the use of FE-1 test for staging CP by the M-ANNHEIM classification. The study of Kamath *et al*[3] is interesting because it deals with the assessment of PEI, which still remains a diagnostic challenge in patients affected by CP.

The ideal test for the diagnosis of PEI should be accurate, non-invasive, widely available and easy to perform. In our Center, in twenty years of experience, we observed 325 patients with a diagnosis of CP, and among them 253 received surgery[4,5]. In this period, different tests were used to diagnose PEI (fecal fat excretion, p-aminobenzoic acid test, coefficient of fat absorption, fecal chymotrypsin)[4-6], and in more recent years they have been replaced by FE-1 test. Nowadays, two different groups of tests (direct and indirect tests) are available for the diagnosis of PEI[1] (Table 1). Among direct tests, the most sensitive method is derived from the aspiration of the pancreatic secretions during secretin-cholecystokinin/cerulein administration[7]. However, this test is invasive and it is available only in few specialized centers[7]. Among indirect test, the coefficient of fat absorption (CFA), the fecal-elastase-1 determination and the acid steatocrit test are the most frequently used[7]. FDA have approved treatments for PEI based on randomized

Table 1 Advantages and pitfalls of function tests for pancreatic exocrine insufficiency

Test	Advantages	Pitfalls
Aspiration of pancreatic contents (during secretin-cholecystokinin/cerulein administration)	High sensitivity	Invasive; only available in specialized centers
CFA	Gold standard; useful in monitoring PERT	Need of a strict diet; unpleasant and long stool collection; no simultaneous PERT
FE-1	Easy test; widely available; no need to stop PERT	Low sensitivity in mild PEI; not clear cut-off
Acid steatocrit	Good correlation with CFA	Lack of standardization; Influenced by dietary fat intake
^{13}C-mixed Triglyceride Breath Test	Good sensitivity in detecting mild to moderate PEI; useful in monitoring PERT	Only available in specialized center; false positive results in non pancreatic fat malabsorpion

CFA: Coefficient off at absorption; PERT: Pancreatic enzyme supplementation therapy; FE-1: Fecal elastase-1; PEI: Pancreatic exocrine insufficiency.

controlled trials that used CFA to define PEI[8]. The CFA is also useful to monitor pancreatic enzyme replacement therapy (PERT). The CFA requires patients to maintain a strict diet containing 100 g of fat per day over five days, and to collect the total amount of stools excreted over the last three days[9]. A CFA < 93% is considered pathological[9]. However, this test is not easy to perform, it is difficult to control the amount of fat consumed, especially in alcoholic patients, and collection of faeces is unpleasant and cumbersome for patients. Fecal Elastase-1 (FE-1) is an indirect assessment of the pancreatic secretion. This test is easy to perform, widely available and only requires a small stool sample for analysis[10]. However, FE-1 test is not able to exclude mild to moderate PEI, and there is no consensus concerning the ideal cut-off for PEI in patients with CP: figures of < 15, 50, 100 and 200 mg/g have been proposed, and a threshold of 200 mg/g has been used most frequently in accordance with the intended use label of the test[11]. The acid steatocrit method is a quantitative measurement of fat expressed as a proportion of an entire centrifugated homogenized stool sample; it correlates well with the 72 h quantitative faecal fat estimation[12]. However, the acid steatocrit method has some disadvantages which include a lack of standardization of the test and the possible effect of dietary fat intake during the sample collection[12].

Other tests are currently available. The 13 C-Mixed Triglyceride Breath test (TGBT) is a valid alternative to the CFA, both for the diagnosis of PEI and for evaluating the efficacy of PERT in clinical practice[13]. Modifications of the test may allow the detection of mild to moderate PEI[13]. However, the test also has limitations in terms of specificity (false positive results in non-pancreatic fat malabsorption), it is not easily available since it is commercialized only in few European countries. Pancreatic secretion volume can be evaluated semiquantitatively by secretin enhanced-MRCP (s-MRCP)[14]. Pancreatic secretion evaluated by this technique correlates with FE-1 test results; however, its sensitivity for PEI is as low as 69%[14]. In addition, there is very limited evidence supporting this technique for the diagnosis of PEI in clinical practice.

In conclusion, many tests are available for the diagnosis and evaluation of PEI in CP, but every test has some limits and pitfalls. In particular, a diagnostic, non-invasive method to differentiate mild and moderate PEI is still required. Further studies are needed to identify the ideal method in the diagnostic setting of PEI.

PERSPECTIVE

Accurate staging of pancreatitis is crucial to study both the natural history of the disease and the effect of treatment. In the study by Kalmath *et al*[3], acid steatocrit and FE1 were compared, while other standard tests like CFA or the 13 C-Mixed Triglyceride Breath test were not considered. It would be interesting in future studies to investigate the comparative usefulness of these tests comprehensively. Moreover, it is reasonable to believe that the additional use of biomarkers could improve the staging systems and this aspect should be explored in future studies. Recently, it has been reported that serum monocyte chemoattractant protein-1 levels were lower in patients with CP and PEI as compared to patients with CP without PEI[15]. A panel of 6 serum miRNA has been recently suggested as potential useful investigation for diagnosis of CP, especially for the early diagnosis of CP[16]. Future studies concerning the association of tests, such as pancreatic function tests, biomarkers or radiological-endoscopic imaging, could be helpful for the early detection of CP.

Abstract

Gastrointestinal ultrasound is a practical, safe, cheap and reproducible diagnostic tool in inflammatory

bowel disease gaining global prominence amongst clinicians. Understanding the embryological processes of the intestinal tract assists in the interpretation of abnormal sonographic findings. In general terms, the examination principally comprises interrogation of the colon, mesentery and small intestine using both low-frequency and high-frequency probes. Interpretation of findings on GIUS includes assessment of bowel wall thickness, symmetry of this thickness, evidence of transmural changes, assessment of vascularity using Doppler imaging and assessment of other specific features including lymph nodes, mesentery and luminal motility. In addition to B-mode imaging, transperineal ultrasonography, elastography and contrast-enhanced ultrasonography are useful adjuncts. This supplement expands upon these features in more depth.

Core tip: In general terms, gastrointestinal ultrasound examination principally comprises interrogation of the colon, mesentery and small intestine using both low-frequency and high-frequency probes. In addition to B-mode imaging, transperineal ultrasonography, elastography and contrast-enhanced ultrasonography are useful adjuncts.

How to perform gastrointestinal ultrasound: Anatomy and normal findings. *World J Gastroenterol* 2017; 23(38): 6931-6941 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/6931.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.6931

INTRODUCTION

Gastrointestinal ultrasound (GIUS) is an accurate diagnostic imaging tool for inflammatory bowel disease[1-3]. Utilisation has steadily increased in different global regions including Asia-Pacific[4]. To correctly interpret GIUS findings, it is necessary to have a firm grounding in intestinal anatomy, the fundamentals of ultrasonography, as well as the examination techniques and approach. The indications for intestinal ultrasound are wide-ranging including inflammatory bowel disease, assessment of functional aspects and general gastroenterological conditions such as diverticular disease. Various educational theories are relevant in the process of learning intestinal ultrasonography including the learning process itself, using formative assessments such as DOPS (direct observation of procedural skills), adopting the apprenticeship or core competencies model and formulation of a GIUS curriculum. These principles and a process of learning GIUS have been recently proposed[1].

The purpose of this paper is to review our knowledge of intestinal embryology relevant to GIUS. Understanding the origins and evolution of abdominal structures during the embryological process can assist in highlighting the reasoning behind abnormalities found on GIUS. We then expand upon examination techniques relevant to different segments of and structures around the intestine, including an overview of transperineal ultrasonography. We describe specific intestinal luminal parameters to be assessed in GIUS including special techniques such as contrast-enhanced ultrasound.

REVIEW OF INTESTINAL EMBRYOLOGY

In the 6th and 8th week of intrauterine life, the primitive mid-gut intestinal tube elongates on the mesentery around the superior mesenteric artery (SMA), herniating into the umbilical cord. As the gut grows and returns into the peritoneal cavity, it eventually rotates 270 degrees counter-clockwise, such that the duodenum rests behind the SMA[1]. The caecum, initially in the upper abdomen, descends to the right lower quadrant. Thus the mesentery attachment of the small bowel takes an oblique course from the duodeno-jejunal junction at the level of the left L2 process, over the 3rd part of the duodenum, down to the level of the right sacroiliac joint[5]. Though the mesentery attachment is only 15-20 cm long, it supplies a length of small intestine approximately 40 times its length, a feat achieved through progressive fan-like ruffles. Seen with traditional barium enterography, each curve of the intestine has a concave and convex aspect, the concave generally pointing towards the mesentery whilst the convex aspect representing the anti-mesenteric border[6]. These can be viewed in real time with GIUS.

Towards the end of the first trimester, the peritoneum of the newly forming ascending colon and the hind-gut derived left colonic segments, begin to fuse with the posterior abdominal wall. Although traditionally described as retroperitoneal structures, modern post-mortem studies have found that two thirds of the ascending and a third of the descending colonic segments have mobile portions of elongated mesentery[7]. Nonetheless, peritoneal attachments have significance for the flow of free fluid within the abdomen as fluid tends to flow caudally, medial to the ascending colon towards the ileocaecal junction and thus metastatic deposits may become lodged in the mesenteric ruffles en route.

Relative thickenings of the mesocolon provide ligamental support to the colonic flexures; the nephrocolic ligament runs from the inferior aspect of the right kidney to the hepatic flexure which then becomes intimately related to the descending duodenum before the transverse mesocolon begins; the splenic flexure is suspended by (1) the phrenicocolic ligament which runs from the diaphragm and also supports the spleen; (2) the splenocolic; and (3) the pancreaticocolic ligaments which are essentially extensions of the transverse

mesocolon[5,7]. These attachments provide fixed points for ultrasound evaluation of the colon, which can at times, be highly mobile within the abdomen.

The taenia coli, thickenings of the longitudinal muscle layer grow from diffuse sheets at the caudal end of the bowel, become more defined in the proximal colon until they encase the caecum[6]. The taeniae are one sixth shorter than the colon[5], forming the haustrae. The muscle fibres in the longitudinal layer end by turning at right angles to merge with the circular fibres and thereby acting as fixed linkage points for contraction. Contractions can occur asymmetrically obliterating some haustrae, giving the false impression of small-bowel-like semi-circular folds and bowel wall thickening.

Vascular supply of the colon flows from the mesenteric border, vessels spreading around the colon. The vasa recta penetrate through oblique connective tissue clefts in the bowel wall, the site of diverticular protrusion, but importantly enter these clefts on the anti-mesenteric aspect. In practice, diverticula are rare on the anti-mesenteric border between the taenia omonetalis and taenia libera. A vasa recta vessel runs over the long aspect of each diverticulum before entering the submucosa at the antimesenteric border[6].

EXAMINATION TECHNIQUE

General considerations and examination technique

An optimal environment for United States is within a dedicated space or consulting room, offering indirect low light sources and facilitating patient comfort. Prior cross-sectional imaging and endoscopy reports should be available to inform of post-surgical and anatomical variants.

In most scenarios patient preparation is not required but specific measures can be used. Fasting for 4-6 h decreases bowel motility whilst two cups of water can be used to improve visualisation of the duodenum[8]. Negative oral contrast may improve detection of jejunal and proximal ileal stenosis, particularly where examination findings are negative; 250-800 mL of polyethylene glycol solution generally reaches the terminal ileum after an average duration of 30 min[9]. Once contrast is seen to flow into the caecum, retrograde examination of the small bowel can be performed.

Examination of the intestinal tract begins with a comfortable patient, relaxed in a supine position so as not to tense the abdominal wall. The transducer is held maintaining contact with the patient's skin to gauge pressure, whilst the left hand is free to optimize image characteristics on the machine. A systematic approach in examining the whole intestine is encouraged (Figure 1). Firstly, the low frequency 3-8 MHz (multifrequency) curvilinear probe initially allows orientation to the anatomy and detection of gross changes, whilst high frequency linear probes (7-17 MHz) are preferable for interrogating specific regions of interest in depth.

Colonic examination

Beginning at the right anterior superior iliac crest and moving medially to the edge of the rectus muscles in a sagittal plane, the common iliac (iliacal) vessels are identified. Rotating anticlockwise to a transverse plane and moving cranially, the first bowel loop crossing from medial to lateral is identified as the terminal ileum. This is followed to the ileocaecal (Bauhin's) valve and caecum. The base of the appendix can be identified at the deep margin of the caecum where the colonic taenia meet before the ascending colon is followed up towards the hepatic flexure. The rest of the colon can be followed *via* the transverse segment distally towards the rectum. Alternatively, the same technique can be used on the left side identifying the sigmoid colon as the first loop of bowel crossing the left iliac vessels, which can be followed to the descending colon and towards the spleen as far as the rib margin allows. The iliopsoas muscle can be used as an alternative landmark for identification of the terminal ileum and sigmoid colonic segments in the right and left iliac fossae respectively. Intercostal imaging may be required to visualise the left or splenic flexure where it has attachment to the spleen; elevating the left arm and rotating to a partial right decubitus position with a straight left leg can spread the ribs and improve image acquisition (Figure 1C). Placing the probe in the epigastric region in sagittal orientation demonstrates the liver and stomach; one can then follow the gastrocolic ligament to the transverse colon. Although the transverse colon can be followed on ultrasound, it may not be reliably viewed in its entirety. Be aware that the rectum and distal parts of the colon cannot always be displayed satisfactorily by transabdominal United States. Transperineal imaging, in such cases, can be useful to evaluate the distal rectum and perianal tissues.

Mesentery and small intestine examination

Mesenteric fat is evident sonographically and is considered to be abnormal if it extends over more than half the circumference of the bowel loop, if it is thickened beyond 5-6 mm or consistently greater than the normal bowel wall thickness[10].

Examination of the mesentery begins in the epigastrium at the duodenojejunal flexure which then runs obliquely towards the right iliac fossa. To aid visualization, the patient is asked to breath in deeply and as they exhale, pressure is applied to the transducer following which excellent views of the small bowel mesentery sheets and abnormalities can be achieved. A systematic scanning of the small bowel may start in the right iliac fossa by defining the terminal ileum and following its course in a proximal direction as far as possible. Finally, a systematic overlapping "Lawn Mowing" strategy is used, sweeping up and down the abdomen to provide an overview of the small bowel. This is performed with the probe in horizontal,

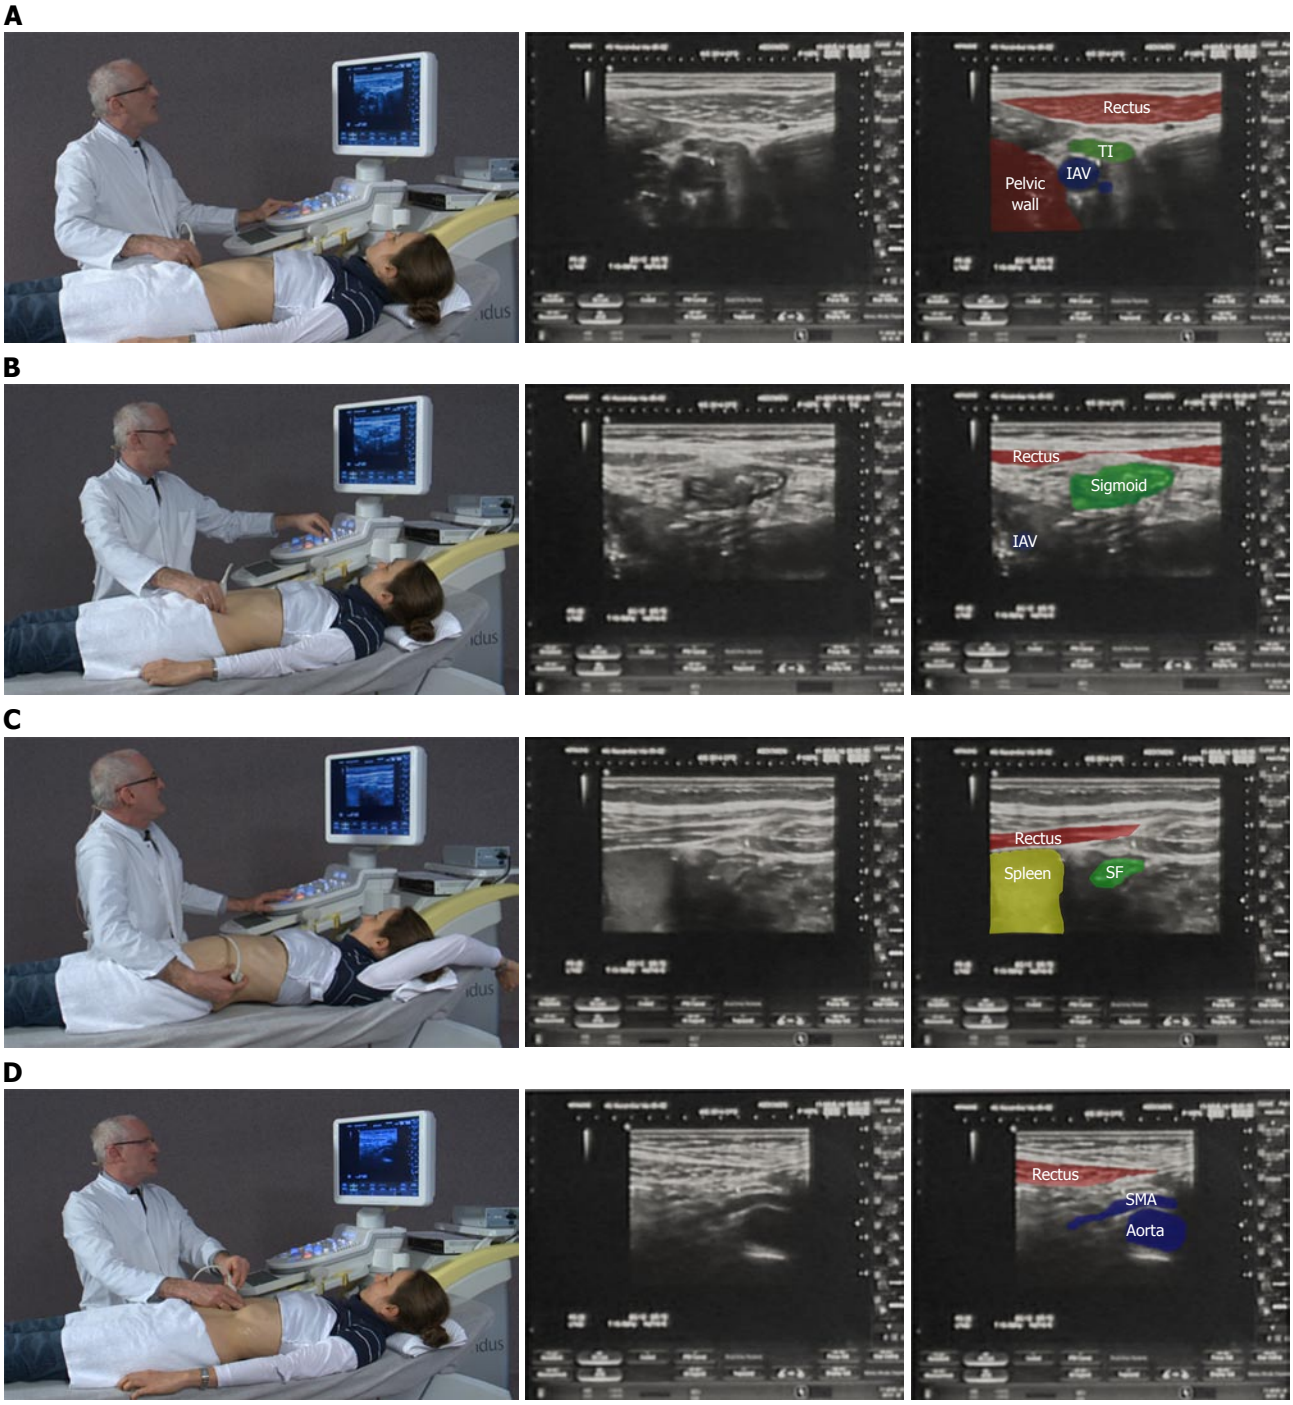

Figure 1 A systematic approach in examining the whole intestine. A: Examination begins in a relaxed ventral position; B: Beginning medial to the right anterior superior iliac spine, the iliacal vessels (IAV) are identified and the first bowel loop crossing medial-to-lateral is the terminal ileum (TI). The same technique on the right identifies the sigmoid colon; C: Elevating the arm spreads the rib spaces to improve visualisation of the splenic flexure (SF); D: Gentle pressure as the patient breaths out improves visualization of the mesentery and superior mesenteric artery (SMA) to exclude lymphadenopathy. The videos can be accessed *via* the efsumb website [www.efsumb.org/education/cfd-videos001.asp].

sagittal and oblique (parallel to the mesenteric attachment) orientations in order to allow one's eye to follow structures and detect abnormalities. A full video explanation of abdominal and intestinal ultrasound examination technique is freely available on the EFSUMB website[11] (www.efsumb.org/education/cfd-videos001.asp).

Perineal ultrasound

TPUS allows visualisation of the perianal tissues, anal canal, sphincters, the distal 5-7 cm section of the rectum, vagina and a part of urinary bladder. A point for orientation is the symphysis. Knowledge of the pelvic anatomy is essential[12,13] (EFSUMB Case of the Month). No specific patient preparation is required.

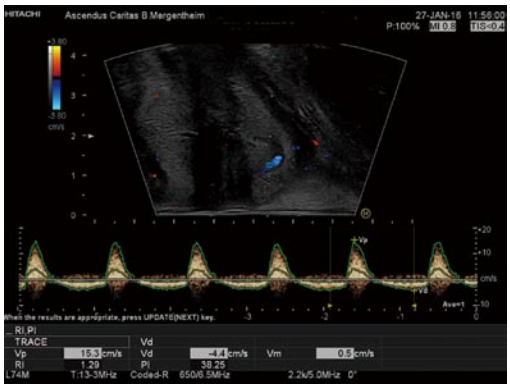

Figure 2 Example on the use of color doppler imaging and continous duplex scanning. Perineal ultrasound showing the hemorrhoidal pleaxus using color doppler imaging and continous duplex scanning with the typical spectrum of the hemorrhoids.

The patient is placed in the left lateral position as for a digital rectal examination. The probe is covered in either a sterile cover or an examination glove with ultrasound gel between the layers.

Examination begins in the midline just above the anus with the probe in a sagittal plane. The ultrasound probe can be moved laterally, however angulated views have reduced sensitivity for identification of pathology. Fistulous tracts can be followed by first placing the probe over the external opening. If necessary, the probe can be placed in a coronal angle, although this is usually less comfortable for the patient. It is useful to start with an abdominal convex probe (lower frequency) for the deeper structures and then continue with a higher frequency probe (7-15 MHz). Examination is also possible after rectal amputation (*e.g.*, Quénu-Operation).

The anal canal, sphincter complexes, hemorrhoidal plexus (Figure 2), recto-vaginal plus ano-vaginal septums, the walls of the vagina and distal rectum can be defined. Fistulae should be classified as per Parks' classification[14] although TPUS has reduced sensitivities for sphincteric relationships and therefore the American Gastroenterological Association (AGA)[15] distinction of "simple" from "complex" is of more clinical utility; the former including low fistulae (superficial, intersphincteric or intrasphincteric) below the dentate line, with a single external opening and without perianal complications or active proctitis[16]. Fistula and abscesses visibility can be improved with ultrasound contrast agents (UCA) using contrast enhanced ultrasound techniques[17,18]. Colour Doppler improves the differentiation of inflammatory reactions.

INTESTINAL LUMINAL FEATURES

Bowel wall thickness

Bowel wall thickness (BWT) is the measure most consistently reported in diagnostic and activity trials. Wall thickness of the alimentary tract differs by region and depends on the degree of distension and contraction[19,20]. The overall thickness should be measured under mild compression from just above an air-mucosal interface to the outside of the outer muscularis propria layer border, including the whole bowel wall[21]. Under these standardised conditions, the stomach wall thickness measures 3-6 mm; terminal ileum 1-3 mm; and colon 0.5-2 mm. In fact, the normal range is likely to be even lower than this[22]. Values in children can be reliably obtained without the need for sedation[22] but bear in mind that values do increase over childhood[23] whilst still remaining < 2 mm. The optimal threshold for abnormal thickness is debatable, as specificity improves with increasing wall thickness at the cost of sensitivity (Figures 3 and 4).

Bowel wall layers

The GI wall has five layers that usually can be visualized with ultrasound. The sonographic layers are a combination of interface echoes and the echo characteristics of the histological layers[24-26]. When imaged in the anterior wall of a bowel loop starting from the lumen the hyperechoic layer 1 corresponds to the interface between the mucosa and the lumen and is not a part of the actual GI wall. The hypoechoic layer 2 corresponds to the mucosa without the interface between the submucosa and mucosa, the hyperechoic layer 3 to the submucosa including this interface echo, the hypoechoic layer 4 to most of the proper muscle and layer 5 to the hyperechoic interface echo between the proper muscle and the serosa.

Interface echoes are always hyperechoic and located distally to the actual tissue interface. Therefore, the correspondence between histology and sonographic layers differ slightly in the dorsal wall. Specifically, the interface between lumen and mucosa (layer 1) is a part of the actual mucosa and layer 2 represents the rest of the mucosa without muscularis mucosae, which normally is covered by an interface echo and add thickness to layer 3. Moreover, the interface between submucosa and the proper muscle adds thickness to layer 3 and reduces the thickness of layer 4. Finally, the interface between the proper muscle and serosa (layer 5) extends beyond the actual serosa[27,28].

The interface from the serosa is hard to delineate. Accordingly, the measurement should be made from the start of the hypoechoic layer of the proper muscle to the end of the hypoechoic layer of the mucosa. Transducer-compression of the bowel wall will reduce thickness and can make it challenging to distinguish wall layers[29,30]. However, some operators practice mild compression suggesting that this improves reproducibility of measurements[21,22,31-33]. The examiner should also be aware of interpretation difficulties due to mucosal folds and haustrations and to keep the probe angle perpendicular to the bowel wall to avoid tangential measurements. In conclusion, dosed compression is a prerequisite for a reproducible examination for some authors whereas others use it with caution.

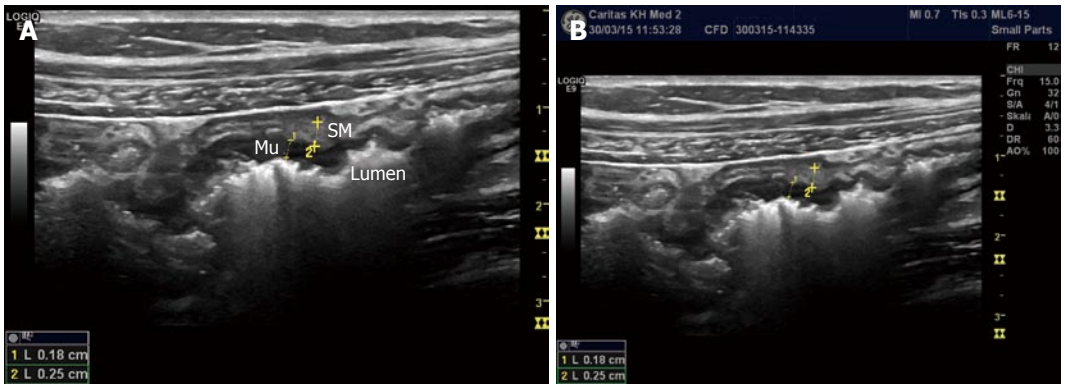

Figure 3 Measurement of the bowel wall. The measurements are best taken ventrally since posterior artefacts occur (A) and the measurements (B) are not reliable. Mu: Mucosa; SM: Submucosa.

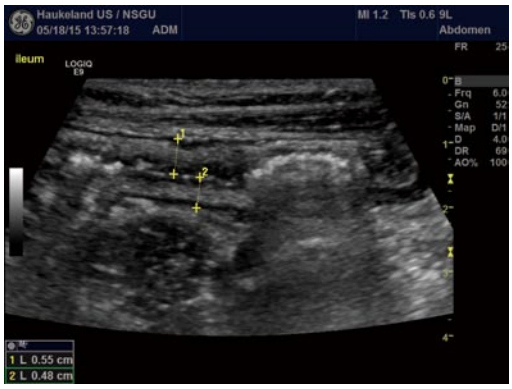

Figure 4 Measurement of the bowel wall. In a patient with Crohn's disease of the small intestine, ultrasound was applied to evaluate disease extension and wall thickness. B-mode image shows moderate wall thickening in the ileum with well-preserved layer structure. Be aware the marked thickening of the submucosal layer in white, often seen in IBD. The crosses mark the wall thickness in the anterior and posterior wall denoting a slight difference in thickening.

Sarcoidosis
Diverticulitis
Neoplasia
Lymphoma
Ischemia

The layered wall structure changes with disease[34]. In severe disease the stratification may disappear due to deep mural ulcers, increasing inflammatory infiltrate and neovascularisation. In chronic inactive disease, accentuated wall layers are more common. The distinctions are less apparent with milder disease phenotypes.

Symmetry

The symmetrical nature of changes is relevant. Asymmetry has been assumed to correspond to endoscopic signs of focal ulceration or polypoid mucosal changes, whilst diffuse thickening is evident with ulcerative colitis (UC) or infectious colitis. The differential diagnoses for chronic inflammatory bowel findings, with or without asymmetry are listed in Tables 1 and 2.

Luminal diameter and motility

The small and large bowel can usually be distinguished by scanning the haustrae of the colon and/or the circular folds of Kerckring in the small intestine. In unclear cases, scanning of the intestine during various stages of filling may be helpful. Changes in Kerckring's folds and luminal fluid quantity can be associated with disease[35]. The small bowel diameter varies widely depending on recent meals and activity, but dilatation beyond 25 mm should be regarded as abnormal, particularly when motility is reduced[36]. Assessment of peristaltic activity and lumen compressibility are two advantages of ultrasound over other imaging modalities. Strictures may be identified by the co-existence of thickened and stiffened bowel wall with narrowing of the intestinal lumen, particularly if less than 10 mm[9]. The presence of proximal loop dilatation with fluid or echogenic content is not required for the diagnosis[36] but may carry clinical significance.

Dilatation of the proximal small bowel loops with hypo- or hyperperistalsis can be caused not only by chronic fibrotic strictures but also by acute inflammatory stenosis or passenger invagination. Functional ultrasonography is helpful in differentiation[37-40].

Extent of disease

Evaluating the length and extent of involved bowel segments is performed by estimated longitudinal

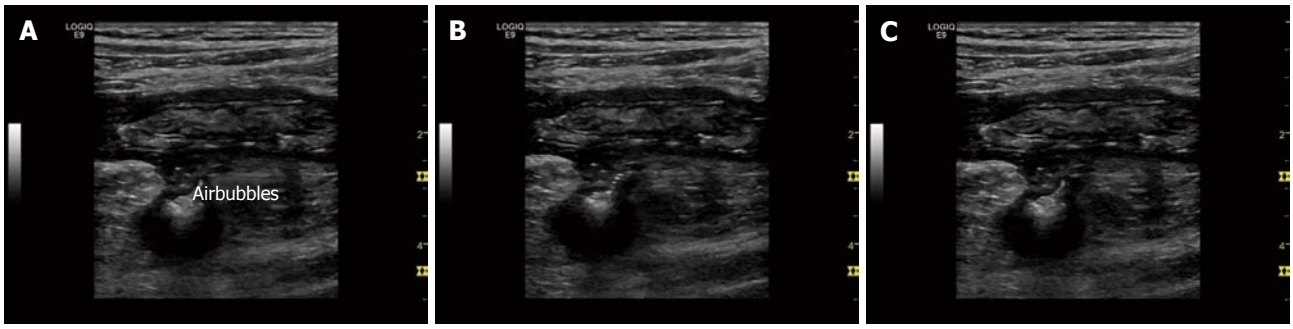

Figure 5 Typical complications in Crohn's disease, fistula. Typical ultrasound findings in Crohn's disease include transmural inflammation, fistula and abscess formation. A-C: The typical sign of fistula is hypoechoic transmural inflammation with (moving) air bubbles outside of the bowel lumen. The air bubbles are best visualised using a real-time examination or video. Here we demonstrate single images of a video to demonstrate the changes within one second.

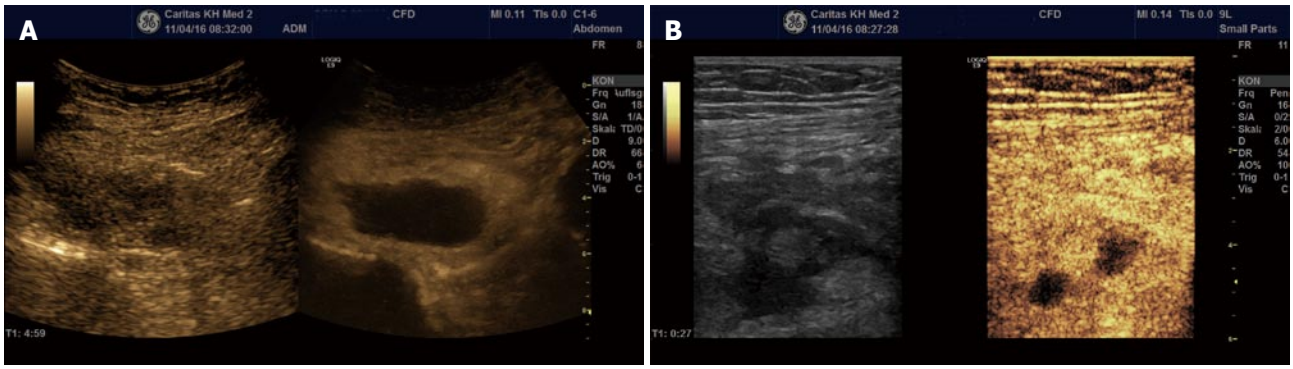

Figure 6 Typical complications in Crohn's disease, abscess. Typical ultrasound findings in Crohn's disease include transmural inflammation, fistula and abscess formation. Contrast enhanced ultrasound allows to better delineate larger (A) and smaller abscess formation (B) not clearly suspected using B mode ultrasound.

measurement and taking note of skip lesions. Bowel wall thickening, luminal diameter for stenosis or dilatation > 25 mm, and motility should be noted in each region. Chronic inflammation tends to produce an isolated, fixed segment without peristalsis and abnormal angulation due to the fibrofatty proliferation of the mesentery[41,42].

Transmural reactions

Transmural inflammation and fibrosis may result in an asymmetrically thickened, stratified bowel wall, which are the typical findings of Crohn's disease (CD). A hypoechoic extension through the normal bowel wall stratification correlates with cellular and oedematous tissue infiltration. Even though the extent of the fibro-fatty proliferate correlates with the degree of intestinal inflammation in CD, there is no standardized method to date to quantify the mesenteric fat by using GIUS. Note should be made if the reaction extends beyond the muscularis propria layer, and whether it does so into the mesenteric or anti-mesenteric border. Fistulae are identified as hypoechoic tracts extending through the bowel wall, often with reverberations (circumscribed bright air echoes) within them (Figure 5). Rounded hypoechoic areas (non-contrast imaging) within the mesentry are suspicious for abscesses or inflammatory phlegmons often with an irregular wall or internal echoes (Figure 6). The occurrence of free peritoneal fluid is important to note, though clinical data corroborating its significance are scant[21].

Fistulae and abscesses

Two prospective studies suggest a sensitivity and specificity for the GIUS detection of fistulae of 72%-87% and 90%-96%, respectively[43]. This performance is equivalent to CT/MR studies in meta-analysis[44], whilst small intestine contrast ultrasound (SICUS) may have a sensitivity as high as 96%. Estimates of the sensitivity and specificity for detecting abscesses have been reported in a somewhat higher range; 71%-100% and 77%-94% respectively[21,45-49]. The direct application of contrast agents into the orifice of the fistula may be helpful in determining the route and connection(s)[12,13,50].

SECONDARY MESENTERIC FEATURES

Mesenteric lymph nodes

Lymph node enlargement is a frequent sonographic finding in CD[10], however their interpretation and clinical implications remain to be further clarified in the literature. It has been suggested that they may represent a very early manifestation of CD in children for example[22]. They are correlated with duration of disease and the presence of fistulae but more importantly, for the ultrasound learner, they provide a

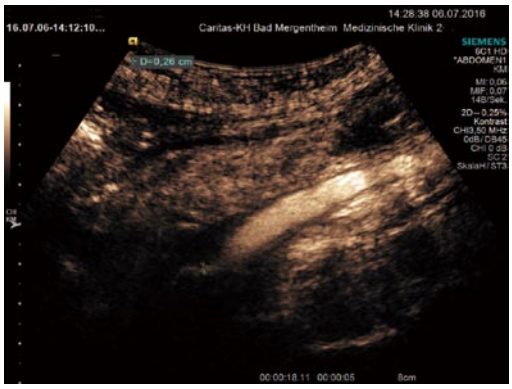

Figure 7 Complications of inflammatory bowel disease. Thrombosis of the superior mesenteric vein. Partial recanalisation is shown by the markers.

marker of procedural competence and interpretation. B mode characteristics of lymph nodes to consider include their length and particularly for those < 15 mm; their short axis dimension should be less than half their longitudinal diameter. Furthermore, the normal lymph node architecture and hilum should be preserved in normal or inflammatory nodes[51].

Mesenteric inflammation, oedema and vascularity

The supporting structures of the intestine run within the sheets of mesentery, seen as layers of mixed echogenicity with hyperechoic serosal layers on either side, which does not have peristaltic movement and appears similar in both transverse and sagittal planes. Fat wrapping has long been recognised by surgeons as a common and specific feature of CD. So-called (creeping) fat, extending from the mesenteric attachment to partially cover the small or large intestine resulting in loss of bowel mesentery angle, is seen as an early event in the disease course and plausibly plays a role in the inflammatory milieu[52]. In practical terms the serosal planes on either side of the mesentery may be detected and should cover less than half of the bowel circumference. It is also the most common cause of bowel loop separation[41]. A subjective impression of increased thickening and echogenicity has been applied in the literature[10], correlating with clinical severity and primary luminal findings; although in long standing disease it can become more heterogeneous and hypoechoic[41].

TECHNIQUES FOR INTERROGATION OF FEATURES OF INTEREST

Doppler imaging of tissue and SMA parameters

Colour Doppler imaging of the bowel wall is part of standard assessment of the intestine and mesenterial vessels (Figure 7). Hyperaemia is associated with inflammation, usually seen in the submucosal layer and the penetrating vessels of the muscularis propria. Use of Doppler evaluation increases the sensitivity of US for evaluating disease activity[33,39,53-59]. The degree of vascularity can be graded by the Limberg scale, a semi-quantitative assessment[60] that lacks routine practical relevance. Other more complex quantitative measurements of Doppler parameters have been proposed, however a standardised protocol to compensate for confounders has not yet become widely used. Power Doppler assessment of the arterial inflow, in particular the inferior mesenteric artery (IMA) for left sided colonic disease and SMA for proximal colon and small bowel activity, can be assessed in the majority of patients and correlates with other ultrasound markers of disease activity. It should therefore be interpreted in the overall context of ultrasound findings[61]. A prognostic role for Doppler parameters was previously proposed[62] but awaits further study and validation.

Contrast-enhanced US

Second generation contrast agents such as SonoVue®, produce harmonic frequencies from micro-bubbles approximately the size of a single red blood cell, and are stable within the circulation[17,63]. Imaging systems thereafter allow visualisation of individual blood vessels through a tissue and thereby improve the accuracy of Doppler US in evaluating bowel wall vascularity. This technique has been shown to be useful in the assessment of disease activity in CD, in particular differentiating inflammatory masses from abscesses and may help to distinguish inflammatory from fibrotic strictures in certain situations[64-66]. Use of Contrast-Enhanced US (CEUS) during GIUS has been standardized, does not requires specific expertise, and its use in IBD presently is increasing[67].

Elastography

Similar to palpation, the elastic properties of a tissue can be evaluated by assessing the speed of a sheer wave through tissue or the amount of deformity created by the sheer stress (strain imaging). Various sonographic approaches to generating and measuring these parameters are available[68], which may compliment standard B-mode assessment of a lesion. Fibrotic lesions may appear stiff and inflammatory lesions soft using elastography, which can help to characterise intestinal lesions and has been correlated with endoscopic findings (Figure 8)[69,70].

CONCLUSION

Understanding the anatomy and embryology of the intestinal tract is highly relevant in identifying sonographic abnormalities relevant to GIUS. The general principles of examination involve specific interrogation of the colon, small intestine and mesentery. Further work is required to validate and understand the significance of certain sonographic parameters where understanding is limited; this includes further evaluation of abnormal wall thicknesses and quantifying this to a higher degree of accuracy, understanding the significance of peritoneal fluid present as a reflection of transmural reactions,

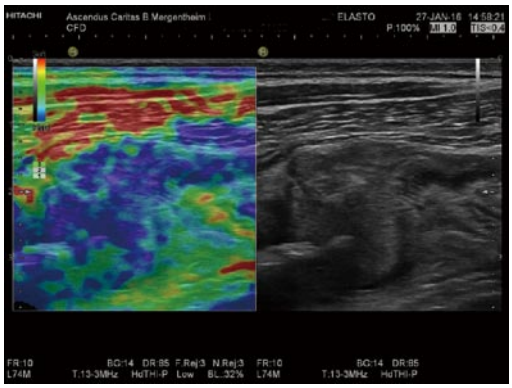

Figure 8 The evaluation of bowel wall stiffness. Elastography is helpful to determine stiff tissue as shown in this patient with colorectal carcinoma and infiltration of the abdominal wall.

and the accurate interpretation and implications of lymph nodes. Despite the presence of semi-quantitative measures, such as the Limberg score, they lack practical relevance and so there is a need for further multi-centre prospective studies.

Various sonographic abnormalities can be detected and interpreted currently but a standardized scoring system for GIUS in inflammatory bowel disease, akin to validated endoscopic scores (such as the Ulcerative Colitis Endoscopic Index of Severity) is lacking. Ultimately, formulating a reproducible and validated scoring system integrating different sonographic parameters to reflect severity will be highly relevant; this will require agreement amongst GIUS experts and validation in multi-centre prospective studies. Finally, a standardized method of documentation, including how to capture images, needs to be developed.

Abstract

Dysphagia is a common symptom that is important to recognise and appropriately manage, given that causes include life threatening oesophageal neoplasia, oropharyngeal dysfunction, the risk of aspiration, as well as chronic disabling gastroesophageal reflux (GORD). The predominant causes of dysphagia varies between cohorts depending on the interplay between genetic predisposition and environmental risk factors, and is changing with time. Currently in white Caucasian societies adopting a western lifestyle, obesity is common and thus associated gastroesophageal reflux disease is increasingly diagnosed. Similarly, food allergies are increasing in the west, and eosinophilic oesophagitis is increasingly found as a cause. Other regions where cigarette smoking is still prevalent, or where access to medical care and antisecretory agents such as proton pump inhibitors are less available, benign oesophageal peptic strictures, Barrett's oesophagus, adeno- as well as squamous cell carcinoma are endemic. The evaluation should consider the severity of symptoms, as well as the pre-test probability of a given condition. In young white Caucasian males who are atopic or describe heartburn, eosinophilic esophagitis and gastroesophageal reflux disease will predominate and a proton pump inhibitor could be commenced prior to further investigation. Upper gastrointestinal endoscopy remains a valid first line investigation for patients with suspected oesophageal dysphagia. Barium swallow is particularly useful for oropharyngeal dysphagia, and oesophageal manometry mandatory to diagnose motility disorders.

Key words: Dysphagia; Oesophagus; Eosinophilic; Manometry; Gastroesophageal reflux; Aspiration; Food bolus impaction

Core tip: Dysphagia may represent serious and life-threatening pathology such as oesophageal neoplasia or oropharyngeal dysfunction capable of causing aspiration. In young white Caucasian males, eosinophilic esophagitis and gastroesophageal reflux

disease are predominant causes, and a trial of proton pump inhibitor is suggested whilst awaiting endoscopy.

INTRODUCTION

Dysphagia is a common symptom in patients presenting to both generalist and specialist medical practitioners[1,2]. The key initial consideration for clinicians is to rule out life-threatening pathology such as neoplasia, and to identify patients who are at risk of aspiration such that immediate intervention can occur[3]. Dysphagia is most commonly due to chronic benign disorders, although it can be associated with appreciable morbidity and impaired quality of life (QOL)[4]. Gastroesophageal reflux disease (GORD) is the major cause in younger individuals, whilst oropharyngeal dysphagia (OD) secondary to cerebrovascular disease is more frequent in the elderly[1,4]. Dysphagia as a symptom attributable to GORD in younger adults does not automatically mandate investigation, rather a trial of a proton pump inhibitor (PPI) and strict follow-up to ensure symptomatic resolution might be sufficient[5]. OD and oesophageal dysphagia can often be reliably differentiated symptomatically and might help reduce the risk of aspiration in OD[6]. A comprehensive awareness of the multitude of potential causes of dysphagia, including common medications and rheumatological conditions, is necessary to allow for efficient and thorough evaluation. Judicious investigation with the appropriate choice of tests in order to consider both common and unusual aetiologies is required; high quality endoscopy with care to take sufficient oesophageal biopsies even if mucosa looks normal [*e.g.*, eosinophilic oesophagitis (EoE)], high resolution oesophageal manometry (HRM) in suspected motility disturbance, barium swallow and where appropriate, cross-sectional imaging [*e.g.*, computed tomography (CT) scan]. The escalating frequency of GORD and EoE, and the increase in mean age (and associated conditions such as CVA) will ensure that dysphagia remains a common presentation in the future[7,8]. This review attempts to present a contemporary understanding and approach to patients with dysphagia.

EPIDEMIOLOGY

Dysphagia is the subjective awareness of an impairment in swallowing of saliva, liquid or solid food. The prevalence varies by age of cohort, method of data collection, and if the dysphagia is classified as acute or chronic[1,4,9]. A community survey of 1000 individuals in Sydney Australia, demonstrated a prevalence of dysphagia of 16% (defined as ever having the symptom), although few (1%) reported dysphagia as chronic or severe[4]. GORD, hypertension and psychological symptoms (anxiety and depression) were independently associated with dysphagia[4]. Subjectivity in symptom reporting and the contribution of GORD have emerged as important themes in contemporary studies of dysphagia[1]. A study of patients with GORD reported resolution of dysphagia with PPI[10]. General practice cohorts have found a frequency of dysphagia of up to 23%, thus reflecting the significant health care burden taken up by this patient group[2]. Self-reported dysphagia is often variably defined[11]; an isolated globus sensation can erroneously be considered a form of dysphagia.

In a large survey of an adult United States population (n = 7640, 3669 respondents), 17% of respondents reported "infrequent" (< 1 episode per week) and 3% "frequent" (> 1 episode per week) dysphagia[1]. On interrogation of these respondents' medical files, symptoms of heartburn and endoscopic diagnosis of GORD were significantly associated with both the "frequent" and "infrequent" cohorts[1]. Perhaps due to the limited sample size and old age of the respondents (mean 62 years), other typical conditions were not statistically associated with dysphagia. Primary oesophageal conditions (EoE, achalasia, cancer) and systemic conditions (scleroderma, rheumatoid arthritis) were only reported amongst the "frequent" dysphagia group[1]. Therefore, clinically significant (or frequent) dysphagia should alert the clinician to serious underlying pathology, whilst infrequent dysphagia is most likely to represent GORD and a trial of acid suppression may be worthwhile in the first instance provided there are no alarm symptoms. This view is supported by several experts in the field (see below).

AETIOLOGY AND PATHOGENESIS

Dysphagia is the subjective awareness of impairment in the passage of food from the oropharynx to the stomach, and therefore may signify an actual delay in bolus transit, or merely the sensation thereof[12]. It is useful to consider the anatomical structures implicated in swallowing (including innervation), and the location of pathology within (Figure 1)[10]. The process of swallowing, whereby food or liquid travels from the mouth to the stomach, involves a complex sequence of muscular contraction and relaxation, involving striated (oropharynx and upper 1/3rd of the oesophagus) and smooth muscle (lower 2/3rd of the oesophagus) that is controlled by motor neurons of the brainstem, and autonomic innervation (of the myenteric plexus) respectively[10,11]. The oropharyngeal component is

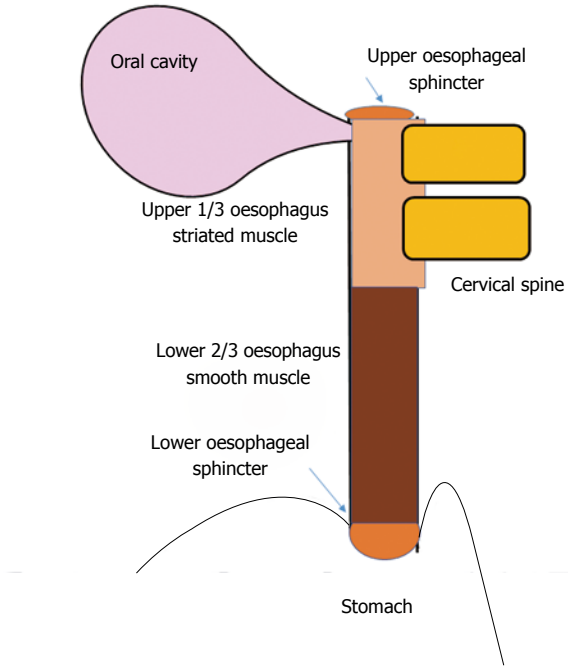

Figure 1 Anatomy of the oesophagus. Disease of the upper 1/3 of the oesophagus causing dysphagia may include extrinsic compression (*e.g.*, cervical osteophytes), or dysfunction secondary to rheumatological conditions (*e.g.*, Sjogrens's syndrome) or in eosinophilic oesophagitis (along with the lower oesophagus). The lower oesophagus can be afflicted in scleroderma, gastroesophageal reflux disease and in eosinophilic oesophagitis.

initially voluntary (including chewing). This is followed by an involuntary phase initiated by food entering the pharynx, whereby the swallowing reflex causes simultaneous relaxation and contraction of the soft palate, upper oesophageal sphincter, oesophagus and lower oesophageal sphincter[6].

Causes of dysphagia vary across the world, and there is evidence of a change in the relative proportion of the various disease states in the last few decades[8]. In the United States, benign oesophageal stricture has become less common, whilst EoE is increasing, along with oesophageal adenocarcinoma[8]. This pattern is mirrored in other Western nations[18]. Oesophageal squamous cell cancer remains a common condition in Asia, whilst Chagas disease still is prevalent is some regions of South America[18].

The oesophageal lumen can become narrowed by inflammation (*e.g.*, erosive reflux disease or EoE), neoplasia or fibrous stricture, or can be compressed externally by lymph nodes or degenerative disease of the cervical spine[8,12-15].

Luminal stenosis

Narrowing of the oesophageal lumen by inflammation, stricture, web or tumour can result in dysphagia[16]. Distal oesophageal inflammation from GORD can result in dysphagia due to transient decrement in peristaltic vigour, and if sustained can lead to fibrous stricture formation[8,15]. Barrett's oesophagus and/or sliding hiatus hernia (HH) are present in > 80% of those with chronic severe GORD and there is some evidence that both may independently influence oesophageal peristalsis[17,18]. Treatment of Barrett's oesophagus with endoscopic mucosal resection (EMR) and radiofrequency ablation can lead to fibrosis[19]. The Schatzki ring (a mucosal ring of the distal oesophagus), occurs just proximal to the gastroesophageal sphincter, often within a hiatus hernia, and is relatively common[20,21]. Barium swallow reveals Schatzki ring in 5%-15% of patients with HH[8]. The association with dysphagia and and its cause (congenital, secondary to GERD or even EoE) are debated[22]. Proximal oesophageal webs have been described in individuals with dysphagia. An association with iron deficiency anaemia (the Plummer-Vinson syndrome) was apparently common in the first half of last century, although is rarely reported today[23,24]. EoE is perhaps the most important, benign cause of dysphagia behind GORD. It is increasingly common and may be responsible for some cases previously diagnosed as fibrous strictures or webs[7]. This is an important consideration amongst Caucasian patients in western countries, and is readily treatable (see below)[8,25]. The prevalence of EoE is estimated at between 1 in 500 and 1 in 1000 adult Caucasian males[26]. The importance of EoE is redoubled by the frequent occurrence of food bolus obstruction, a complication that is associated with significant morbidity including the need for hospitalisation, upper gastrointestinal endoscopy (UGE) and (rarely but catastrophically) oesophageal perforation[27].

Non-obstructive gastro-oesophageal reflux disease

Many patients that describe dysphagia will have normal investigations including UGE and high-resolution manometry (HRM), suggesting that a dysfunction of the somatosensory as opposed to neuromuscular apparatus might be present[28,29]. A unifying hypothesis to explain this apparent dichotomy is that a minor disturbance in peristalsis (caused for example by GORD, or non-erosive reflux disease - NERD) may be below the threshold of detection even by sensitive HRM, yet be experienced by the patient as dysphagia. Indeed, many people will describe a resolution of symptoms with proton pump inhibition (PPI). Interventions aimed at modulating the somatosensory system have hence been advocated[28,29].

Primary motility disturbance

Achalasia is the prototypical condition classified as a primary (isolated to the oesophagus) disorder of oesophageal motility, yet is quite rare, with an estimated prevalence of 0.17% in individuals undergoing endoscopy[30]. Patients typically present with a chronic history of dysphagia for liquids and/or solids, and often with retrosternal discomfort, heartburn and weight loss[31]. The underlying pathophysiology is of an imbalance between excitatory

and inhibitory neurons of the myenteric plexus at the distal oesophageal sphincter, with a decrement in inhibitory innervation (nitrous oxide, or vasoactive intestinal peptide) leading to aperistalsis and failure of relaxation of the lower oesophageal sphincter during primary swallowing in classical (Type I) achalasia, pan-oesophageal pressurisation in early (Type II) achalasia or spasm of the oesophageal body (Type III achalasia), but manometry is required to accurately define subtype[32]. Current literature suggests that achalasia is an autoimmune condition associated with antibodies directed at the myenteric plexus and linked to HLA class II DR and DQ alleles[33]. Distal oesophageal spasm and "jackhammer" oesophagus (formerly, nutcracker oesophagus) are disorders of distal oesophageal hypercontractility which can present as dysphagia and/or chest pain and are defined with high resolution manometry as per the recent Chicago classification update (see below)[34-37]. These primary, major disorders of oesophageal motility, may be part of a disease spectrum with shared pathogenesis[38-40]. It is important to always consider secondary achalasia (pseudo-achalasia) that can result from neoplastic infiltration of the distal oesophagus, or be secondary to infection (Chagas disease, primarily occurring in South America)[41,42].

The advent of HRM and subsequent diagnostic algorithms has led to a reconsideration of minor disorders of peristalsis as a cause of dysphagia (defined by the Chicago Classification)[35]. Many patients presenting with dysphagia will have ineffective oesophageal motility in the distal oesophagus or fragmented peristalsis (defined by HRM and the Chicago Classification)[35]. Previously, it had been demonstrated that these abnormalities are frequently found in patients with GORD[43]. The symptom of dysphagia did not correlate with minor disorders or peristalsis on HRM[28,44]. An evolving consensus is arguably emerging that these "abnormalities" may lack clinical application and relevance[44].

Rheumatological conditions

To ensure a systematic evaluation occurs and that relevant pathology is not overlooked, an awareness of rheumatological and neurological conditions, medications that may cause oesophageal dysmotility, and causes of extrinsic anatomical compression is required[3,45-48]. Dysphagia is frequently reported by patients with Sjogren's syndrome, systemic lupus erythematosus (SLE), mixed connective tissue disease (MCTD) and rheumatoid arthritis, not to mention the more commonly recognised association with systemic sclerosis (as part of the CREST syndrome)[45] (Table 1). More than 1/3 of patients with Sjogren's syndrome report dysphagia, caused both by xerostomia and thus deficient lubrication of the food bolus, and by abnormal peristalsis demonstrable by oesophageal manometry (particularly in the upper 1/3 of the oesophagus)[45,49].

Table 1 Medications implicated in causing dysphagia

Medication	Putative mechanism
Antipsychotic, *e.g.*, olanzapine[63], clozapine[62]	Block dopamine receptors
Tricyclic antidepressant, *e.g.*, amitriptyline[56]	Anticholinergic, decreased saliva and impairment secondary peristalsis
Opioids[90]	Increase lower oesophageal contractility, oesophageal spasm
Iron supplements	Localised oesophagitis[58,59]
Potassium supplements	
NSAIDs	
Tetracyclines	
Macrolides	
bisphosphonates	
Calcium channel blockers	Smooth muscle relaxation (including lower oesophageal sphincter)[56]
Nitrates	
Alcohol	
Theophylline	

Similarly, patients with SLE and MCTD frequently describe dysphagia, and proximal oesophageal peristalsis is often weak or fragmented[45]. The cause of the abnormal motility in these conditions is unknown, although an inflammatory myopathy or neuropathy has been postulated[45]. Manometry was unable to correlate these symptoms with dysmotility[45]. In patients with rheumatoid arthritis, distal oesophageal peristalsis can be weak or fragmented; although life-threatening subluxation of the cervical spine needs to be considered[50]. Oesophageal dysmotility as a feature of the CREST syndrome is the best known and most studied of the rheumatological conditions, although dysphagia is often overshadowed by heartburn[51,52]. The pathophysiological process of fibrous replacement of the smooth muscle of the mid and lower oesophagus leads to incompetence of the lower oesophageal sphincter (LOS) and the clinical sequalae of GORD and dysphagia[53].

Extrinsic compression of the oesophagus can be a feature of osteoarthritis of the cervical spine, with (particularly) anterior osteophyte formation[13]. This is also occurs in a more florid fashion with diffuse idiopathic skeletal hyperostosis (DISH)[54]. Ironically, neurosurgical interventions for degenerative cervical spine disease (such as anterior discectomy) can result in dysphagia both in the short term (with post-operative swelling, or rarely because of damage to the cranial nerves) or long term (compression secondary to a cage implant, if placed)[48]. Other causes of extrinsic compression include mediastinal or hilar lymphadenopathy (*e.g.* due to haematological or disseminated solid organ neoplasia) and goitre[14,55].

Medications

Medications cause or contribute to dysphagia by influencing oesophageal peristalsis, xerostomia, as a secondary consequence of esophagitis ("pill oesophagitis"), or by causing GORD (Table

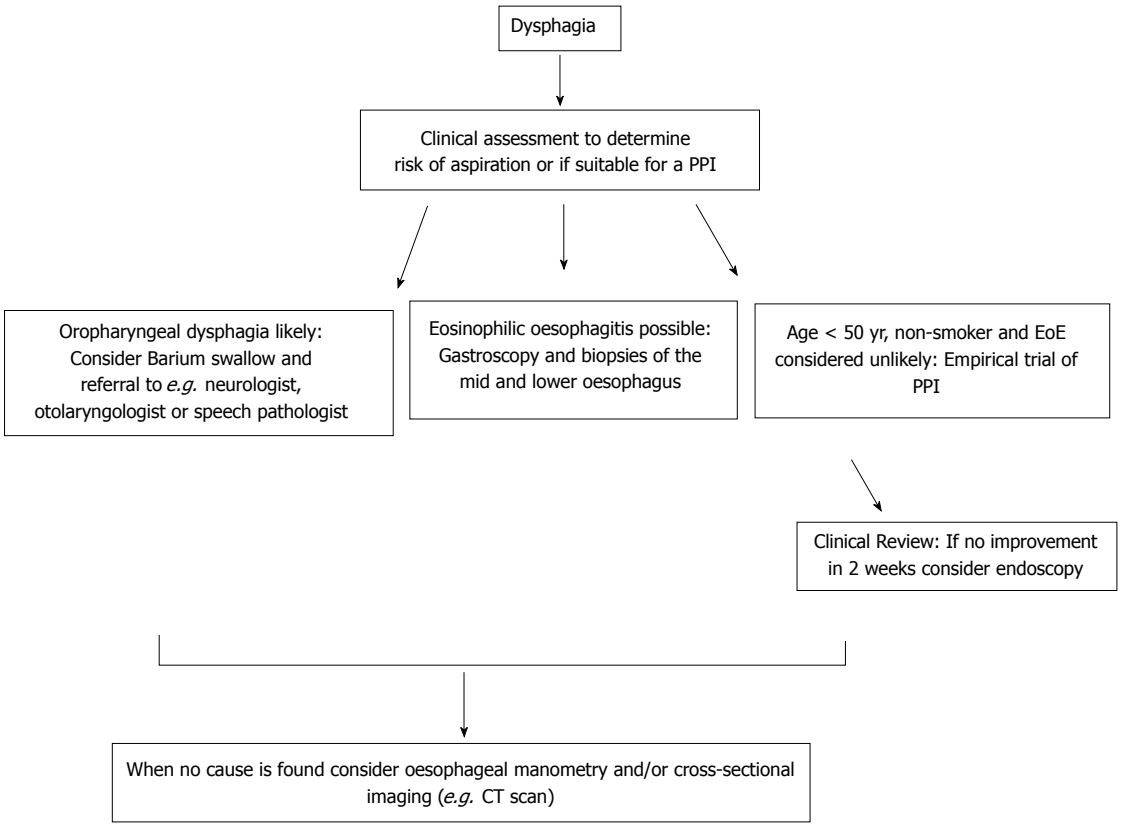

Figure 2 Proposed management algorithm for patients presenting with dysphagia.

Table 2 Neurogenic dysphagia - Common causes

Condition	Description
Parkinson's disease[68]	Oropharyngeal and oesophageal dysphagia is possible
Multiple sclerosis[64]	Oropharyngeal and oesophageal dysphagia is possible
Cerebrovascular disease[3,67]	Oropharyngeal dysphagia typical
Motor neuron disease[11,64]	Features of bulbar and pseudobulbar palsy possible
Myasthenia gravis[64,91]	
Myopathy (various, including inflammatory)[45,64]	Oropharyngeal and proximal oesophageal
Cerebellar pathology (various)[64]	

2)[47,56-59]. Sedative agents can lead to compromise of airway maintenance and thus aspiration is a risk. Finally, medications that have a local or systemic immunosuppressant effect can predispose to infective oesophagitis[60]. Among individuals with a psychiatric diagnosis, dysphagia may relate, at least in part, to the use of psychotropic medication[61]. The anticholinergic and antidopaminergic effects of antipsychotics and tricyclic antidepressants have been implicated, not only in causing a dry mouth (anticholinergic) thus limiting lubrication of the food bolus, but also in decreasing the coordination and strength of peristalsis and the timing of lower oesophageal sphincter relaxation[62,63]. It is also possible that serotonergic pathways may be responsible for the dysphagia caused by clozapine, although this hypothesis is perhaps refuted by the absence of case reports relating SSRIs to dysphagia[63]. Individuals with psychiatric diagnoses may also have an increased rate of neurological disorders (such as Parkinson's disease), particularly among older individuals in residential care, that can cause dysphagia[3,61]. The use of opiates, even if low dose and over the counter, can lead to hypercontractile or hypertensive sequelae of the oesophagus and/or LOS, sometimes even mimicking Type III achalasia.

Neurological disorders

Neurogenic dysphagia, a term loosely applied to cases where the pathology involves the central, autonomic or peripheral nervous system (and not isolated to the oesophagus such as achalasia) is more often characterised by an oropharyngeal component, with neurologists and speech pathologists primarily involved in management[64,65]. Dysphagia is common after cerebrovascular accidents (CVA) involving the cortex often causing hemiplegia[66]. Rapid improvement in swallowing function occurs in the majority[67]. Brainstem infarcts with cranial nerve involvement is another (albeit less common) lesion, but can be severe and sustained[3]. The basal ganglia are the major site of pathology in Parkinson's disease, and oropharyngeal involvement (with difficulty initiating swallowing and impairment in bolus transit between the pharynx and proximal oesophagus) demonstrable at video fluoroscopy[68].

Table 3 Rheumatological causes of dysphagia

Condition	Description
Scleroderma[52]	Distal oesophageal dysmotility, part of the CREST syndrome
Sjogren's syndrome[49]	Xerostomia limits bolus lubrication and food passage, proximal oesophageal dysmotility
Rheumatoid arthritis[45]	Proximal oesophageal dysmotility. Always consider and rule out associated cervical spine disease
Systemic lupus erythematosus (SLE)[45]	Proximal oesophageal dysmotility
Degenerative cervical spine disease, surgery on the cervical spine and diffuse idiopathic skeletal hyperostosis (DISH)[48,54]	Anterior cervical osteophytes cause extrinsic compression of the oropharynx and proximal oesophagus

Awareness of Parkinson's disease as a cause of dysphagia is of importance to gastroenterologists given the recent finding of neurological pathology beyond the brainstem. Furthermore other gastrointestinal symptoms such as constipation may precede the characteristic clinical syndrome of tremor, rigidity and bradykinesia[68-70]. Other neurogenic causes of dysphagia are outlined in Table 3.

CLINICAL ASSESSMENT

The aetiology of dysphagia can be variably classified, but traditionally oropharyngeal dysphagia (OD) and oesophageal dysphagia are defined as distinct groups because the immediate treatment approach to the former is to consider aspiration risk and dietary modification (Figure 2)[6]. It has been estimated that the presence of one or more of a 4-symptom cluster can predict OD accurately: delay in oropharyngeal initiation of swallowing, deglutitive cough, deglutitive nasal aspiration and the need to repetitively swallow to clear nasal secretions[71]. OD is principally managed by neurologists, ENT surgeons and speech pathologists, and is therefore beyond the focus of this review. Further useful sub-classifications of oesophageal disease include dysphagia to solids only (implying an anatomical distortion) or to liquids and solids (implying a physiological or motility disturbance), although the precision of any such clinical "rule of thumb" is not absolute. Longstanding symptoms of mixed dysphagia would normally suggest a motility disturbance[31].

INVESTIGATIONS

UGE remains a central tool in the investigational algorithm, being essential for the diagnosis of oesophageal malignancy, refractory GORD and EoE[72]. At least middle and lower biopsies of the oesophagus should be taken in patients with dysphagia, even when the macroscopic appearance is normal, primarily with the intention of excluding EoE. The role of UGE as a mandatory primary investigation is debated. Whilst dysphagia can signify life-threatening pathology such as oesophageal or gastric neoplasia, in the majority UGE will be normal or demonstrates only mild erosive disease , leading several experts to advocate a trial of PPI first in otherwise healthy subjects[5]. This is a departure from orthodox teaching where dysphagia is considered an alarm symptom mandating gastroscopy[11]. Thus, a trial of PPI can be considered both diagnostic and therapeutic. The significance of dysphagia however should not be minimised, as the condition is common, and the morbidity in terms of utilisation of healthcare and impairment in quality of life considerable[1,4].

Barium oesophogram (barium swallow) is the next investigation to consider after UGE, particularly when upper oesophageal anatomical or structural pathology is suspected (*e.g*, a pharyngeal pouch), or to exclude a major motility disorder (*e.g*, achalasia, spasm) when HRM availability is limited[73,74]. Indeed, experts disagree when it comes to the sequence of the investigations, with some advocating barium swallow as the initial test in all, citing the ability to pre-plan endoscopic inventions such as dilatation, to avoid unnecessary repeated testing and to avoid potential risks including pharyngeal pouch perforation and aspiration in patients with suspected oropharyngeal dysphagia[75]. Barium esophagography can also be considered when extrinsic compression is being considered, or when there is a strong suspicion of para-oesophageal (previously known is "rolling") HH. Cross-sectional imaging may assist in some cases, with communication between reporting radiologists being imperative in this setting[76,77].

HRM is most useful when a motility disorder is suspected, or if a HH is thought to be contributing to refractory GORD and dysphagia. HRM is more accurate in the diagnosis of sliding HH, and is the gold standard for major disorders of peristalsis (achalasia, distal oesophageal spasm, jackhammer oesophagus and aperistalsis), demonstrating superiority over conventional manometry and barium studies[78-80].

The last decade has seen not only the advent of HRM, but also of intraluminal oesophageal impedance, and intraluminal oesophageal impedance planimetry (commercially known as Endoflip)[81,82]. As well as being a measure of gastric reflux (alkaline and acid), IOI can detect bolus transit abnormalities[83]. Many would argue that whilst this technology has proved of value to researchers, the clinical value is limited or yet unrealised[84]. This assertion is based on data showing that impairment in bolus clearance defined by IOI correlates poorly with both the symptom of dysphagia

and with manometric findings[28]. Endoflip has only recently become available and can measure the hitherto unknown parameter of resistance to distension (distensability)[85] .This technology has shown promise in assessing reduced distensiblity in EoE and in post-operative measurement of achalasia response. On the other hand, inclusion of Impedance sensors with HRM has helped provide a visual impression of bolus transport or interruption, which is akin to radiology.

TREATMENT

Once a malignant process is excluded, the aims of treatment are to avoid aspiration or food bolus impaction, and minimise the morbidity associated with ongoing symptoms. Effective management of dysphagia obviously starts with early identification of the cause with judicious use of investigations. Requests for endoscopy for patients with oropharyngeal dysphagia where the risk of periprocedural aspiration is considerable and the utility questionable should ideally be preceded by an assessment of crico-pharyngeal function and speech pathologist evaluation of oral intake.

Proton pump inhibitors should be used when GORD is suspected as well as in cases of EoE to determine if this might be proton pump Inhibitor responsive oesophageal eosinophilia (PPI-REE)[25]. Patients with persistent eosinophilia will require swallowed topical corticosteroids (*e.g.*, budesonide 1mg orally twice daily administered as an oral viscous solution) or an elimination diet[25]. Specific treatment for oesophageal neoplasia is beyond the scope of this review and will depend on the extent of local invasion or occurrence of metastasis. The treatment of hypercontractile disorders of peristalsis may entail botulinum toxin injection of the distal oesophagus, and of achalasia might include pneumatic dilatation, or myotomy (surgical or per-oral endoscopic myotomy (POEM)][32,38]. Botulinum toxin injection will last only for a few months, and commonly requires repeated therapy[86,87]. Surgical myotomy can result in durable improvement, whilst POEM may offer a less invasive approach, although long-term data is currently unavailable[88,89]. Medications such as oral nitrates or calcium channel blockers lack efficacy but can be used as a holding measure while definitive therapy is being considered[87].

CONCLUSION

Dysphagia is a common symptom with a diverse range of aetiologies. In young healthy patients that do not describe additional red flag symptoms, a trial of PPI is reasonable and will result in symptomatic resolution in many cases. GORD can cause not only a decrement in peristaltic vigour, but may contribute to hyperalgesia, such that whilst food passes freely into the stomach, the patient experiences dysphagia indicating a somatosensory dysfunction. When further investigation is required, reconsideration of the site and the nature of symptoms (*e.g.*, oropharyngeal *vs* oesophageal), and early recourse to upper gastrointestinal endoscopy is suggested, particularly given the increasing frequency of EoE and thus the need for oesophageal biopsies. HRM is required to exclude major disorders of peristalsis (achalasia, jackhammer oesophagus, distal oesophageal spasm and aperistalsis), although the finding of minor disorders of peristalsis is of unclear significance. Finally, gastroenterologists require a comprehensive knowledge of conditions that may cause or worsen dysphagia so that timely and efficient management occurs.

Abstract

Recurrent acute pancreatitis (RAP) is defined based on the occurrence of two or more episodes of acute pancreatitis. The initial evaluation fails to detect the cause of RAP in 10%-30% of patients, whose condition is classified as idiopathic RAP (IRAP). Idiopathic acute pancreatitis (IAP) is a diagnostic challenge for gastroenterologists. In view of associated morbidity and mortality, it is important to determine the aetiology of pancreatitis to provide early treatment and prevent recurrence. Endoscopic ultrasound (EUS) is an investigation of choice for imaging of pancreas and biliary tract. In view of high diagnostic accuracy and safety of EUS, a EUS based management strategy appears to be a reasonable approach for evaluation of patients with a single/recurrent idiopathic pancreatitis. The most common diagnoses by EUS in IAP is biliary tract disease. The present review aims to discuss the role of EUS in the clinical management and diagnosis of patients with IAP. It elaborates the diagnostic approach to IAP in relation to EUS and other different modalities. Controversial issues in IAP like when to perform EUS, whether to perform after first episode or recurrent episodes, comparison among different investigations and the latest evidence significance are detailed.

Key words: Endoscopic ultrasound; Pancreatitis; ERCP; MRCP; USG; CT; Idiopathic recurrent pancreatitis; Ascariasis; Pancreatic cancer; Biliary sludge; Gallstones; Microlithiasis; Common bile duct stones

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory process of the pancreas affecting peripancreatic tissues and distant sites. In most patients after an attack of AP, aetiology can be found with gallstones and alcohol use being most often implicated. Approximately 20% of patients will develop subsequent attacks, defined as recurrent acute pancreatitis (RAP). Most aetiologies of AP can lead to recurrent attacks, if the underlying etiology persists[1,2,3]. RAP is a challenging condition, because it leads to significant patient morbidity, can progress to chronic pancreatitis (CP), and has limited treatment options[3]. In up to 10% of patients with a single episode of AP and in up to 30% of patients with RAP, the aetiology is not identified after the initial evaluation. This condition is known as idiopathic pancreatitis[4]. Evaluation and treatment is important as 50% of untreated patients with IRAP experience current episodes that may lead to CP[2]. Endoscopic ultrasound (EUS) is minimally invasive, highly accurate imaging modality for studying the pancreas and the biliary tree[5]. The goal of this review is to discuss the role of EUS in idiopathic pancreatitis, focusing on the methodology, findings, and limitations of the available literature.

WHAT IS IDIOPATHIC PANCREATITIS?

RAP has various definitions. RAP is defined as the occurrence of two or more episodes of AP without concurrent clinical or imaging evidence suggestive of CP[3]. Another definition is two or more episodes of AP with or without complete or near complete resolution of symptoms between episodes[6]. AP or RAP can be from an identifiable etiology or idiopathic (unidentifiable etiology). Initial evaluation of a patient with AP/RAP can identify the aetiology in 70%-90% of cases. When the etiology could not be identified on initial evaluation as it happens in 10%-30% of the patients, AP/RAP can be defined as IAP (idiopathic acute pancreatitis)/IRAP[2,3,7]. The initial evaluation includes a thorough history (including medication review and family history of pancreatitis), physical examination, laboratory studies (serum liver tests, calcium and triglyceride levels), transabdominal right upper quadrant ultrasound, contrast-enhanced abdominal computerized tomography (CT), or magnetic resonance cholangiopancreatography (MRCP). Various explanations for non-detection of aetiology of AP includes microlithiasis as the cause being difficult to diagnose using standard imaging analysis; pancreatic inflammation/necrosis, preventing visualization of pancreatic solid or cystic tumours; and biological abnormalities occurring during the initial days of AP, making difficult to diagnose lipid- or calcium metabolism abnormalities[8]. There are limited studies regarding the natural history following a single attack of IAP. These studies suggest relapse rates varying from 14% to 24%[9-11]. According to the latest prospective study by Wilcox *et al*[12], the relapse rate is 24. Various diagnostic studies to investigate the remaining 10%-30% cases includes microscopic bile examination (MBE), pancreatic function testing, genetic testing for mutations associated with pancreatitis, secretin-enhanced MRCP (MRCP-S), EUS, EUS elastography, and endoscopic retrograde cholangiopancreatography (ERCP) with sphincter of oddi manometry (SOM). This additional workup usually leads to the diagnosis of microlithiasis or biliary sludge, sphincter of oddi dysfunction (SOD), pancreas divisum (PD), hereditary pancreatitis, cystic fibrosis, a choledochocele, annular pancreas, an anomalous pancreatobiliary junction, pancreatobiliary tumours, duodenal duplication cyst, periampullary diverticulum or pancreatic-biliary ascariasis (Figures 1 and 2)[2,4,13-16]. After a complete additional advanced work-up, the aetiology remains unknown in no more than 10% of RAP, which can then be defined as true IRAP[2,3]. However, which test(s) to perform is not standardized. EUS is emerging as a diagnostic tool of choice for the patients with idiopathic pancreatitis[12].

Diagnostic yield of endoscopic ultrasound in idiopathic acute pancreatitis and its advantages

Since the early 1980s, EUS has been in use and is a safe, minimally invasive diagnostic procedure in patients with RAP. Various advantages includes close proximity of EUS probe to the pancreas and availability of high frequency EUS probes leading to high resolution images, and non-interference of the intestinal gases with image acquisition. EUS has few complications[17,18]. The diagnostic yield of EUS in various studies varies from 29%-80%. In a recent systemic review of 13 studies evaluating the role of EUS in IAP, the most frequent aetiology was

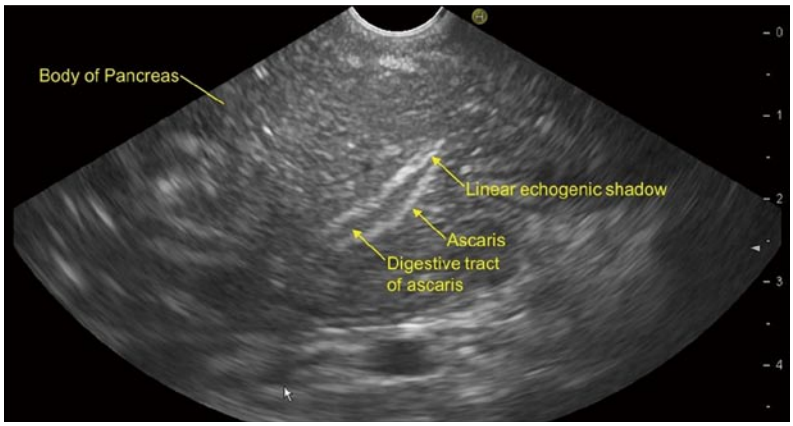

Figure 1 Linear endoscopic ultrasound from the stomach showing *Ascaris lumbricoides* in the body of the pancreas.

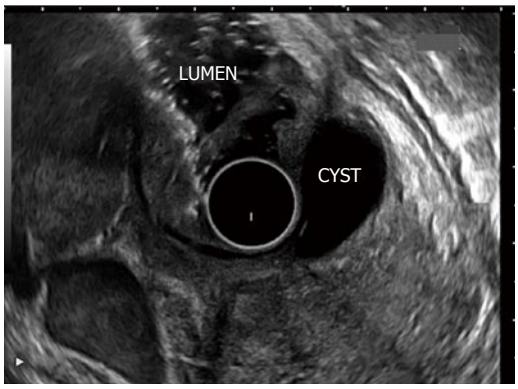

Figure 2 Radial endoscopic ultrasound from the duodenum shows duodenal duplication cyst as etiology of idiopathic pancreatitis.

biliary tract disease (biliary stones, microlithiasis and sludge). In the above mentioned 13 studies, different diagnostic modalities (1 or combination of 2 or more) were mentioned for diagnostic accuracy. They were ultrasonography, CT, MRCP, ERCP, SOM. Reference standard varied depending on the study. EUS identified pancreatic disease like CP, PD, periampullary tumours or pancreatic parenchymal change and/or pancreatic ductal change in 22.1% ± 26.6% of patients with IAP. Overall, EUS identified additional diagnostic information in 61% of patients with IAP, with 41% having biliary tract disease[19]. Various studies on the sensitivity of EUS to detect biliary tract disease suggests that EUS has superior sensitivity to other commonly used tests like ultrasonography (USG), CT, MRCP or MBE[12,17,18-22]. EUS is a reliable diagnostic method to detect PD[23,24]. EUS is quite useful to diagnose biliary and pancreatic tumours with a diagnostic accuracy higher than CT particularly in tumours smaller than 2.5 cm in diameter[25]. EUS is highly specific in the diagnosis of pancreatic cancer with a negative predictive value of 100%[26]. EUS can detect pancreatic solid tumours and cystic tumours at an early stage before they are identified by USG or CT. Detecting them earlier can lead to early operative management and better prognosis[27]. EUS is a useful diagnostic technique to detect the presence of CP in patients initially diagnosed with IRAP[28]. EUS is the least expensive initial investigation for the diagnostic evaluation of patients with IAP with gallbladder *in situ*[29].

Endoscopic ultrasound vs endoscopic retrograde cholangiopancreatography in idiopathic pancreatitis

Before the advent of EUS, ERCP was a primary diagnostic and therapeutic tool with a diagnostic yield of about 80%; however the contribution of EUS and MRCP has changed the diagnostic algorithm of IAP[3]. Established (microlithiasis, neoplasms) and controversial (PD, SOD) aetiologies of IAP may now be identified with EUS, limiting the role of ERCP to its therapeutic arm[3]. EUS has a diagnostic yield of about 80% which is about the same as the diagnostic yield of ERCP but with much less complication rates compared to ERCP which is 10%-15%[4].

Along with the lesser complication rates compared to ERCP, the added advantage of EUS is, EUS can diagnose biliary and pancreatic tumors especially tumors communicating with the pancreatic duct which can cause IAP[4]. In the past, ERCP was advised only after the second episode of IAP or after the first in severe IAP[30,31]. ERCP and EUS are considered the "gold standards" in clinical practice; however, MRCP has been proposed as a non-invasive alternative imaging technique to ERCP[32].

Endoscopic ultrasound vs magnetic resonance cholangiopancreatography in idiopathic pancreatitis

MRCP is a non-invasive investigation revealing detailed images of the hepatobiliary and pancreatic systems[32]. MRCP is indicated to diagnose PD, choledochocele, anomalous pancreatobiliary junction, or annular pancreas in patients with IARP[2,33]. Advantages includes no administration of intravenous contrast or ionizing radiation, can be used in all patients

including infants or those with allergies to iodine-based contrast materials[33,34]. It is less operator-dependent than USG or ERCP[35]. Disadvantages includes no therapeutic manoeuvres possible as it is primarily diagnostic investigation. MRCP is less sensitive than EUS for microlithiasis, small ampullary lesions, and ductal strictures[36-38].There are various studies showing better diagnostic yield of MRCP after secretin stimulation(MRCP-S) in CP,PD, SOD and pancreaticobiliary malformation as compared to simple MRCP[32,39-43]. In view of the available literature, MRCP-S may be more beneficial in IAP instead of MRCP if available.

There are three studies which has directly compared EUS and MRCP in IAP[18,43,44]. All have found higher diagnostic yield of EUS particularly to exclude biliary causes. In a prospective study of 49 patients with IAP, diagnoses were compared between EUS and MRCP. The diagnostic yield of EUS was more than that of MRCP (51% *vs* 20%, $P = 0.001$). It was concluded that EUS should be performed for establishing a possible biliary aetiology in patients with intact gall bladder (GB)[44]**.** In a study of 40 patients with MRCP negative IAP by Rana *et al*[18], the diagnostic yield of EUS was 55%. The most common aetiology was occult biliary tract disease in 50 percent[18].

Endoscopic ultrasound in pancreas divisum

PD is controversial aetiology of IAP[3]. Various studies have assessed the role of EUS as a reliable substitute for ERCP in patients of PD. Some believe that the sensitivity and specificity of EUS need further evaluation[5,45]. However, various studies considers EUS as an accurate, minimally invasive diagnostic method for PD[23,24,46-48]. In a study by Rana *et al*[46], the sensitivity, specificity, positive predictive value, negative predictive value of EUS for diagnosis of PD was 100%, 96%, 80%, 100% and 96%, respectively. In a recent retrospective cohort study of 45 consecutive patients diagnosed with PD on ERCP, diagnostic accuracy of EUS was compared to CT and MRCP. The sensitivity of EUS was 86.7%, significantly higher than CT (15.5%) or MRCP (60%).It was concluded that EUS is a sensitive test for diagnosing PD and is superior to MDCT and MRCP[48]. As per recent systemic review comparing diagnostic accuracy of MRCP with MRCP-S, MRCP-S has significant higher diagnostic accuracy and should be preferred for diagnosis of PD[42]. However, MRCP-S is not easily available. We believe that EUS is excellent diagnostic investigation for PD instead of MRCP[24].

Endoscopic ultrasound in biliary tract disease (biliary stones, microlithiasis and sludge)

USG (abdomen) has high accuracy in detecting gallstones, with reported sensitivities ranging from 92% to 96%[49]. However, when stones are less than 3 mm in diameter or are located in the GB infundibulum, the sensitivity is only 65%[50]. EUS is superior than USG for GB imaging due to its high-image resolution and close proximity to the biliary system. In a prospective study of 100 consecutive patients with AP, EUS was more sensitive than USG in detecting gallstones (100% *vs* 84%). The sensitivities of ERCP and EUS for choledocholithiasis were both 97%. It was concluded that EUS can be useful in selecting patients with AP who require therapeutic ERCP, thereby avoiding complications associated with diagnostic ERCP[49].

In a recent systemic review of 13 studies evaluating the role of EUS in IAP, the most frequent aetiology was biliary tract disease (41%)[19]. Various studies have found biliary microlithiasis/sludge (Figures 3, 4 and 5) as a cause of IAP in up to 75% of these patients[7,51,52]. However, there are few studies where biliary aetiology is not the most common cause of IAP[27,53].

In patients with intact GB, the most common cause of IAP is biliary microlithiasis/sludge which is detected in up to 80% of patients[7,51]. In the past, MBE was considered the gold standard for microlithiasis[54]. However, the disadvantages include high false negative rate, time consuming and high failure rate[4]. EUS has now replaced ERCP and bile sampling to diagnose microlithiasis in IRAP[8]. There are various reasons due to which EUS is highly accurate in detecting biliary microlithiasis. These includes GB being closely related to the stomach/duodenal wall; the median distance between the EUS transducer and the gallbladder is small (0.5 mm); the whole gallbladder is examined, even under acute pancreatitis; and use of high frequency probe[18].

The prevalence of the various aetiologies of RAP depends on whether the gallbladder is present or absent. If GB is present insitu, then the prevalence of microlithiasis would be about 50%, SOD-20%, CP-15%, PD-10% and choledocholithiasis 5%[29]. In patients who underwent cholecystectomy the prevalence of microlithiasis falls to 10%-15% whereas the prevalence of SOD, PD and CP rises[45].

Endoscopic ultrasound in chronic pancreatitis

RAP is a diagnostic and therapeutic challenge in clinical practice. It is sometimes impossible to differentiate clearly between recurrent attacks of AP and the early stages of CP[55]. Recurrent attacks of AP may complicate the course of chronic subclinical pancreatitis[13] (Figure 6). Although one of the limitations of EUS is being operator dependent, EUS has high diagnostic accuracy for the pancreatic parenchyma. EUS can detect early signs of CP, although the diagnostic significance of some changes is still debated[43]. In a study by Yusoff *et al*[27], EUS findings consistent with CP were reported

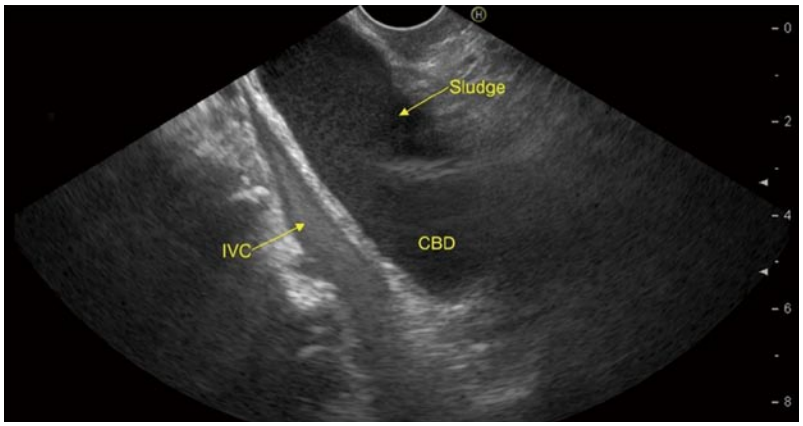

Figure 3 Linear endoscopic ultrasound from the duodenal bulb shows echogenic biliary sludge in the common bile duct.

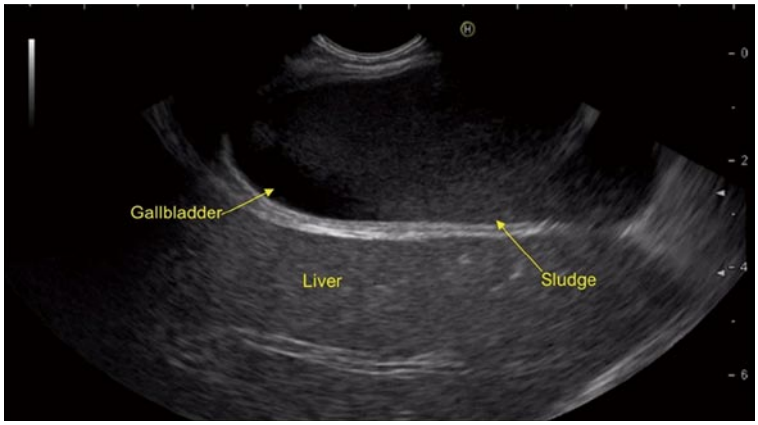

Figure 4 Linear endoscopic ultrasound from the duodenal bulb shows echogenic sludge in the gallbladder.

as the most common finding in patients with IAP.

When to perform endoscopic ultrasound, after first episode or recurrent episodes of idiopathic acute pancreatitis?

There is controversy in the literature about the timing of EUS in IAP whether to perform after first episode or recurrent episodes[21,27,56]. In a study by Yusoff *et al*[27], the diagnostic yield of EUS was not significantly different after a single attack or recurrent attacks of IAP. Therefore, the authors concluded that it is reasonable to perform EUS after the first episode, especially in older patients. Many authors have supported this opinion[12,18,21,57]. On the other hand there are few studies where the diagnostic yield is more in recurrent episodes than a single episode[51,58].

IAP is a common condition but the natural history is not well studied and the best diagnostic approach to both single and multiple attacks remains undefined. The suggested diagnostic approach in various studies and guidelines to IAP is highly variable[12]. As per the American Gastroenterological Association, EUS is not recommended after first episode of IAP in patients less than 40 years of age. It recommends EUS as investigation of choice in IRAP and after first episode in patients with more than 40 years of age[59]. As per American College of Gastroenterology, extensive evaluation using EUS or MRCP is recommended following recurrent attacks of IAP[60]. As per the International Association of pancreatology, patients with IAP should undergo EUS as the investigation of choice irrespective of first or recurrent episodes and, if negative, then, a MRCP-S as the next step[61].

In a recent landmark prospective study of patients with IAP over a 10-year period, 201 patients were enrolled. 80 were with single attack and 121 with multiple attacks of IAP. After EUS, 54% of patients with a single attack were categorized as idiopathic, while for multiple attacks 14 % were idiopathic. Long-term follow-up documented recurrence of pancreatitis in 24% of the patients with a single attack and in 49% of the patients with multiple attacks. On multivariate analysis, number of previous attacks was found to significant predictor of recurrence. It was concluded that following a single idiopathic attack of pancreatitis and a negative EUS examination, relapse was infr-

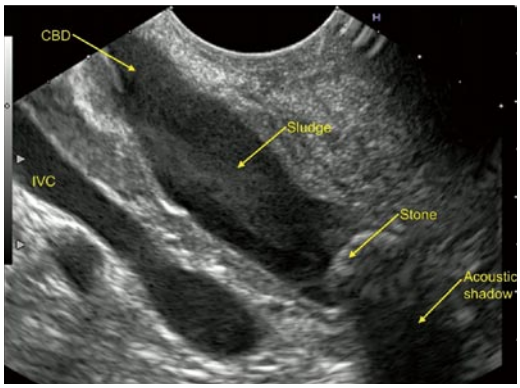

Figure 5 Common bile duct stone with sludge seen on linear endoscopic ultrasound from the duodenal bulb in a 36-year-old male presenting with 3 episodes of idiopathic acute pancreatitis in last 7 mo.

equent. A negative EUS after a single attack had significant prognostic value as it identified low rate of recurrence. This study suggest that EUS may be an useful test following a single attack given its yield and potential prognostic value. This study had prospective EUS based approach to idiopathic pancreatitis[12]. In a recent systemic review of 13 studies by Smith *et al*[19], the diagnostic yield of EUS was not influenced by recurrent disease. Considering the available literature, we recommend EUS after first episode of idiopathic pancreatitis.

Endoscopic ultrasound vs secretin enhanced endoscopic ultrasonography

Intravenous secretin when used with MRCP (MRCP-S) or EUS (EUS-S) may help the visualization of the pancreatic ductal system and can recognise some undetected ductal abnormalities that are of diagnostic importance in IRAP patients. In a study by Mariani *et al*[43], the diagnostic yield of EUS-S in IRAP was 13.6% and 16.7% higher than MRCP-S and ERCP respectively. ERCP alone did not find a diagnosis in any case missed by the other two investigations. It was concluded that both MRCP-S and EUS-S should be used as complementary, first-line, imaging techniques, rather than ERCP in the diagnostic work-up of IAP[43]. However, there are limited studies on the EUS-S and further data are required regarding its efficacy in IAP as compared to EUS without IV secretin.

When to perform endoscopic ultrasound after idiopathic pancreatitis?

The timing of performing EUS examination after an episode of IAP remains controversial and unclear. Different studies have used different timings[4]. In a recent prospective study of patients with IAP, EUS was performed 1 mo or more after hospital discharge[12]. Rana *et al*[18] performed EUS at least 1 mo after the episode of AP when the patients were asymptomatic for abdominal pain. In a study by Norton *et al*[62], EUS

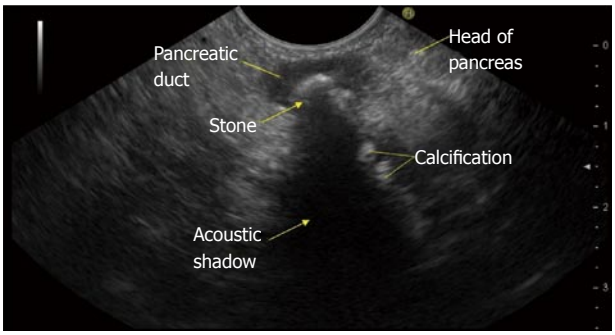

Figure 6 Features of chronic pancreatitis seen on linear endoscopic ultrasound from descending duodenum.

was performed when patients resume food intake while Liu *et al*[20] perform EUS after resolution of AP during admission. Yusoff *et al*[27] performed EUS atleast 4 wk after episode of AP to make sure that acute pancreatic parenchymal changes have resolved when EUS is performed.

Thevenot *et al*[8] suggested to perform MRCP/EUS at a longer interval after the initial AP as inflammation and/or necrosis can prevent visualization of pancreatic lesions during the acute phase. In two recent studies investigating the role of EUS/MRCP in IAP, these examinations were performed1 mo after initial AP when patients were eating normally. The explanation for delayed examination is that fasting is usually advised as initial treatment of AP which can induce GB sludge and, consequently, can result in a false-positive diagnosis of biliary AP if the examination is made early although this is not proven by studies[43,44].

Disadvantages of late EUS after 4 wk of AP includes papillary/ampullary stones (Figure 7) not being diagnosed early with the risk of relapse of AP, early/small periampullary tumours (Figure 8) might be missed as patient may lost to follow up after hospital discharge[4] and possible low diagnostic accuracy as microlithiasis may be missed[21]. Further studies exploring the role of early EUS in IAP are required to come to final conclusion regarding the ideal timing.

Which should be the first investigation after idiopathic acute pancreatitis: Magnetic resonance cholangiopancreatography vs endoscopic ultrasound

There is slight controversy regarding the first investigation after an episode of IAP. Different studies/authors/guidelines have variable opinions on this topic. Although MRCP is less invasive, cheaper and widely available than EUS, and has recently benefited using IV secretin, performance of EUS remains higher than that of MRCP[8]. However, few studies[43,44] have demonstrated that MRCP can detect few aetiologies undiagnosed by EUS. Further prospective studies are required regarding the cost benefit analysis for EUS/MRCP but at present they

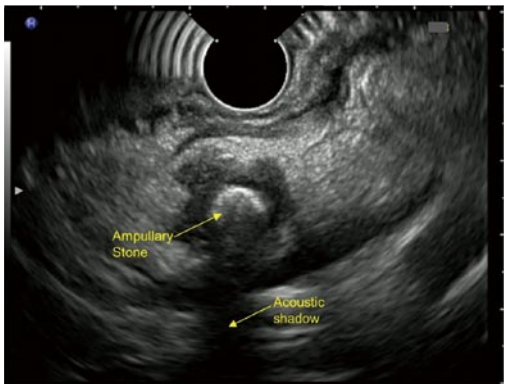

Figure 7 Ampullary stone with acoustic shadow seen on radial endoscopic ultrasound from descending duodenum.

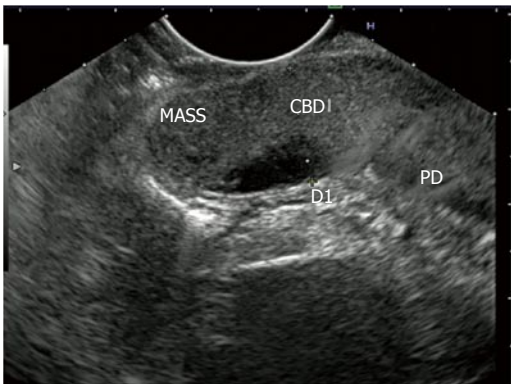

Figure 8 Hypoechoic ampullary mass extending into common bile duct.

should be considered complimentary rather than competitive.

After reviewing the extensive literature on IAP, our opinion which is shared by many authors/guidelines [12,19,21,22,52,57,59,61] and not agreed by few authors/guidelines[32,59], is performing EUS as the first investigation after IAP with intact GB. There is some debate regarding the choice of investigation in post cholecystectomy patients where CP, SOD and PD are the most common diagnoses in which MRCP has demonstrated good diagnostic accuracy[21,52]. As per the latest systemic review in 2015 comparing the diagnostic accuracy of EUS and MRCP in diagnosis of choledocholithiasis, both tests were found to be similar and the choice of test will be decided by availability and contra-indications to each test[63]. However, EUS is superior to MRCP in detecting choledocholithiasis smaller than 5 mm[64]. Various authors and studies believe that the decision to perform EUS or MRCP as the first diagnostic investigation in post cholecystectomy patients must take into account various factors like local expertise, availability and patient details such as claustrophobia, gastric surgery etc. ERCP should always be considered a therapeutic intervention when required[61,63-65].

The role of PD and SOD as causes of IAP remains highly controversial. In a study by Coté *et al*[66] and Wilcox *et al*[12], inspite of endoscopic therapy, RAP occurred in almost 50% patients with SOD. In addition, despite repeat endoscopic interventions, further relapse was also very common. These studies questions the role of endoscopic therapy in PD and SOD. These studies shows that diagnosing SOD and PD may not alter the natural history/prognosis of these patients presenting with IAP. Hence, MRCP and ERCP with SOM may not be that useful in diagnostic workup of IRAP. This also supports EUS as first investigation of choice after IAP irrespective of gallbladder status and is agreed by many studies[12,19, 21,22,54,59].

CONCLUSION

As per the recent prospective study done by Wilcox *et al*[12] on EUS based approach to the evaluation of Idiopathic Pancreatitis and after reviewing the literature, EUS as a first strategy towards the etiological evaluation of IAP appears to be useful not only as a diagnostic but as an important prognostic yield irrespective of gallbladder status. In view of high incidence of biliary tract disease as a cause of IAP in most of the studies and given the high diagnostic accuracy of EUS in identifying them, EUS should be considered as an initial diagnostic step for IAP after conventional radiography fails to identify the aetiology.

Considering all the prior studies, the diagnostic yield of EUS is not influenced by whether the episode is first or recurrent. Hence, EUS should be performed after the first episode of IAP if possible. MRCP preferably MRCP-S can be performed if EUS expertise is not available. MRCP can be complimentary to EUS in identifying controversial aetiologies like PD and SOD. ERCP can be then be performed to treat biliary stones and PD. However, in view of high risk of post ERCP pancreatitis, ERCP with SOM should be reserved in those patients in whom MRCP and EUS has found to be negative for diagnostic and therapeutic evaluation especially with post cholecystectomy cases. We recommend an EUS as the first-line examination in the evaluation of patients with idiopathic pancreatitis, because it is minimally invasive, low risk and accurately identifies most occult causes of pancreatitis.

Abstract

AIM

To test whether a delayed and short course of rapamycin would induce immunosuppressive effects following allogeneic orthotopic liver transplantation (OLT) in rats.

METHODS

Allogeneic OLTs were performed using Dark Agouti

livers transplanted into Lewis recipients, and syngeneic OLTs were performed using the Lewis rat strain. Rapamycin (1 mg/kg per day) was administered by gavage from day 4 to day 11 post-transplantation. Lymphocyte cellular compartments were analyzed by flow cytometry in draining lymph nodes, non-draining lymph nodes and the spleen at days 11 and 42 in rapamycin-treated rats, untreated control rats and syngeneic grafted rats. Skin grafts from Dark agouti or from F344 RT were performed at day 30 on liver grafted rats treated with rapamycin.

RESULTS

An 8-d course of rapamycin treatment initiated 4 d following transplantation resulted in the survival of grafted rats for more than 100 d. In contrast, untreated rats died of liver failure within 13 to 21 d. The analysis of the cellular compartment revealed an increase in two cellular subpopulations, specifically myeloid-derived suppressor cells (MDSCs) and $CD8^{+}CD45RC^{low}$ T cells, without major modifications in the regulatory T cell (Treg) compartment in treated rats in the early stages after grafting. We evaluated the ability of treated rats to reject third-party allogeneic skin grafts to confirm their immune competence. In contrast, when skin was collected from rats syngeneic to the grafted liver, it was not rejected.

CONCLUSION

Our results demonstrate that short and delayed rapamycin treatment allows for tolerance in allogeneic OLT. The results also allowed for the identification of the mechanisms of tolerance induced by rapamycin by identifying MDSCs and $CD8^{+}CD45RC^{low}$ T cells as associated with the state of tolerance.

Key words: Myeloid-derived suppressor cells; Liver transplantation; Rapamycin; Regulatory T cells

Core tip: Rapamycin is an immunosuppressive drug that is rarely used for liver transplantation treatment due to its side effects. Here, we show that a delayed and short course of rapamycin initiated on day 4 following allogeneic orthotopic liver transplantation in rats resulted in the survival of grafted rats for more than 100 d. The analysis of the cellular compartment revealed an increase in two cellular subpopulations, specifically myeloid-derived suppressor cells and $CD8+CD45RC^{low}$ T cells. The treated liver grafted-rats rejected third-party allogeneic skin grafts, but tolerated skin from syngeneic liver donor rats. Our results identify one of the mechanisms by which the state of tolerance is established.

Delayed and short course of rapamycin prevents organ rejection after allogeneic liver transplantation in rats. *World J Gastroenterol* 2017; 23(38): 6962-6972 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/6962.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.6962

INTRODUCTION

Current immunosuppression treatments following solid organ transplantation are based on calcineurin inhibitors (CNIs). However, prolonged CNI exposure leads to nephrotoxicity[1], neurotoxicity[2], an increased risk of cancer[3], and hypertension[4], all of which are associated with long-term morbidity and mortality. Reducing the use of CNIs by combining or replacing them with immunosuppressive drugs that exert different mechanisms of action remains the primary strategy to lower the incidence of these adverse events. The drug rapamycin, a mammalian target of the rapamycin (mTOR) inhibitor, is a potential alternative due to its strong immunosuppressive properties in humans.

Rapamycin mediates immunosuppressive effects by preventing T cell cycle progression from the G1 to the S phase, thereby blocking T cell proliferation[5]. Rapamycin also acts on dendritic cells (DCs) by inhibiting their capacity to differentiate from immature into mature DCs, thus reducing their ability to activate T cells. In turn, immature DCs promote the expansion of $CD4^{+}CD25^{+}Foxp3^{+}$ regulatory T cells (Tregs) while concomitantly inducing T cell anergy and apoptosis and promoting graft tolerance[6]. In a model of experimental graft-*vs*-host disease facilitating the detection of donor-derived luciferase-labeled conventional T cells *in vivo*, the combination of Tregs and CNIs, but not rapamycin, suppresses Treg function[7]. In an allogeneic transplantation model, myeloid-derived suppressor cells (MDSCs) can also be recruited during mTOR inhibitor treatment[8]. Furthermore, following the activation of nitric oxide synthase (iNOS) and arginase (Arg1), MDSCs inhibit T cell proliferation and induce their apoptosis[9].

Currently, rapamycin is widely used to prevent rejection following renal[10], liver[11], and heart[12] transplantation. However, its use is primarily restricted to renal transplantation and is not recommended as a first-line treatment for liver transplantation due to deleterious side effects such as delayed wound-healing processes[13], thrombosis of the hepatic artery inducing graft loss, and increased mortality[14,15]. In liver transplantation, previous clinical trials have successfully demonstrated the possibility to introduce mTor inhibitors at day 30 in combination with reduced CNI treatments[16]. Here, we evaluated the possibility of using the mTor inhibitor alone in order to avoid CNI side effects in patients. Therefore, we tested a novel delayed and shortened rapamycin administration protocol in a model of orthotopic liver transplantation rejection in rats.

MATERIALS AND METHODS

Animals

Inbred Lewis RT1^{l} male (LEW) and Dark Agouti RT1^{av1} male (DA) rats weighing 220 to 280 g were purchased from Janvier Labs (Le Genest-Saint-Isle, France) and F344 *RT1^{1v}* male rats weighing 220 to 280 g were purchased from Charles River Labs (L'Arbresle, France). The rats were maintained in animal facilities for at least one week prior to surgery under standard conditions. All experimental protocols were performed according to European Union guidelines and with the approval of the Regional Ethics Committee in Animal Experimentation no. 16, Ile-de-France, France (authorization no.11/12/12-11B).

Orthotopic liver transplantation

Non-arterialized OLT was performed according to Kamada's technique[17]. The allografts were transplanted orthotopically. Vena porta clamping ranged from 19-23 min. Allogeneic OLTs were performed by grafting a DA liver (donor) into a LEW rat (recipient). Syngeneic OLTs were performed with LEW rats (donor and recipient).

Treatment

Rapamycin[18] was administered by oral gavage (1 mg/kg body weight per day) every day starting on day 4 after transplantation until day 11. Non-draining lymph node (non-dLN; axillary), dLN (periportal), spleen, and liver samples were collected for analysis on day 11 and day 42 after sacrifice. The residual concentration of rapamycin was analyzed in naive and liver-grafted rats after the administration of rapamycin for 8 d. Whole blood samples were collected in ethylenediaminetetraacetic acid (EDTA) tubes for chromatographic analysis on days 0, 4, 9 and 11.

Flow cytometry

Cell suspensions obtained by mechanical shredding (draining lymph nodes, not draining lymph nodes and the spleen) were used for phenotypic analysis. Anti-CD3, anti-CD4, anti-CD8, anti-CD25, anti-CTLA-4, anti-CD62L, anti-CD278 (ICOS), anti-CD11b/c, anti CD161, and anti-MHC-Ⅱ, anti-Foxp3, anti-IFNγ, anti-TNFα labelled with phycoerythrin (PE), phycoerythrin cyanine 7 (PE-Cy7) fluorescein isothiocyanate (FITC), peridinin chlorophyll protein complex eFluor 710 (perCP eFluor 710), allophycocyanin (APC), and eFluor 450 were purchased from ebioscience (Paris, France). Anti-CD45RC-PE was purchased from BD Biosciences and Anti-CD3-Vioblue and Helios-APC were purchased from Miltenyi Biotec (Paris, France). Events were acquired on a FACS Canto Ⅱ flow cytometer (BD Biosciences) and analyzed using FlowJo (Tree Star, Ashland, OR, United States) software.

Skin grafting

Skin grafting was performed according to the method of Billingham and Medawar[19]. Full-thickness tail skin (1 cm^2) from two donors (DA and F344) was grafted onto the right and left dorsal thorax, respectively, of liver-grafted recipients after 30 d of tolerance (DA skin and F344 skin onto LEW rats). Rejection was defined as more than 80% graft necrosis upon daily inspection.

Histologic analysis

Grafted livers were excised, fixed in 10% formaldehyde buffer, paraffin-embedded, sectioned (5 μm) and stained with hematoxylin and eosin (H and E) according to a standard protocol. The histological grading of rejection was performed based on the BANFF classification[20].

Serum biochemical testing

Serum samples were stored at -20 ℃ until the analysis was performed. Transaminase enzyme and total bilirubin levels were measured to evaluate hepatocellular injury.

Statistical analysis

Differences between the groups were evaluated using an unpaired-t-test performed with Prism software 5.0 (Graph Pad Software, Inc., La Jolla, CA, United States). The results were considered statistically significant when $P < 0.05$.

RESULTS

Short and delayed rapamycin treatment prevents the rejection of allogeneic orthotopic liver transplantation

In this study, we used a model of DA liver transplantation in LEW recipient rats. These two rat strains differ in their major histocompatibility antigens. Allogeneic transplantation resulted in the death of all untreated rats within 13 to 21 d due to allogeneic liver rejection (Figure 1A). Four grafted rats were sacrificed for histological examination of their transplanted livers on day 11 and exhibited the characteristic signs of acute rejection according to the BANFF classification (mean score = 8.75 ± 0.25, Figure 1B and C). Next, we evaluated whether delayed rapamycin treatment exerts immunosuppressive effects. Four rats received rapamycin at a dose of 1 mg/kg per day beginning on day 4 post-transplantation and continuing until day 30. Under these conditions, 3 out of 4 grafted animals survived over 100 d without any additional treatment, suggesting that delayed and long-term rapamycin treatment is effective (Figure 1A).

We then tested whether a shorter course of rapamycin also leads to transplant liver maintenance. Eleven grafted rats received 1 mg/kg per day of rapamycin from day 4 to day 11 (8 d) and only 2 out of 11 rats died on days 19 and 49 (Figure 1A). To evaluate immunosuppression levels in transplanted livers, 4 rats were sacrificed on day 11 at the end of the treatment period. Compared to untreated control transplanted rats, the treated rats demonstrated a dramatic reduction in their histological rejection grade (Figure 1B and C). Four additional transplanted rapamycin-treated

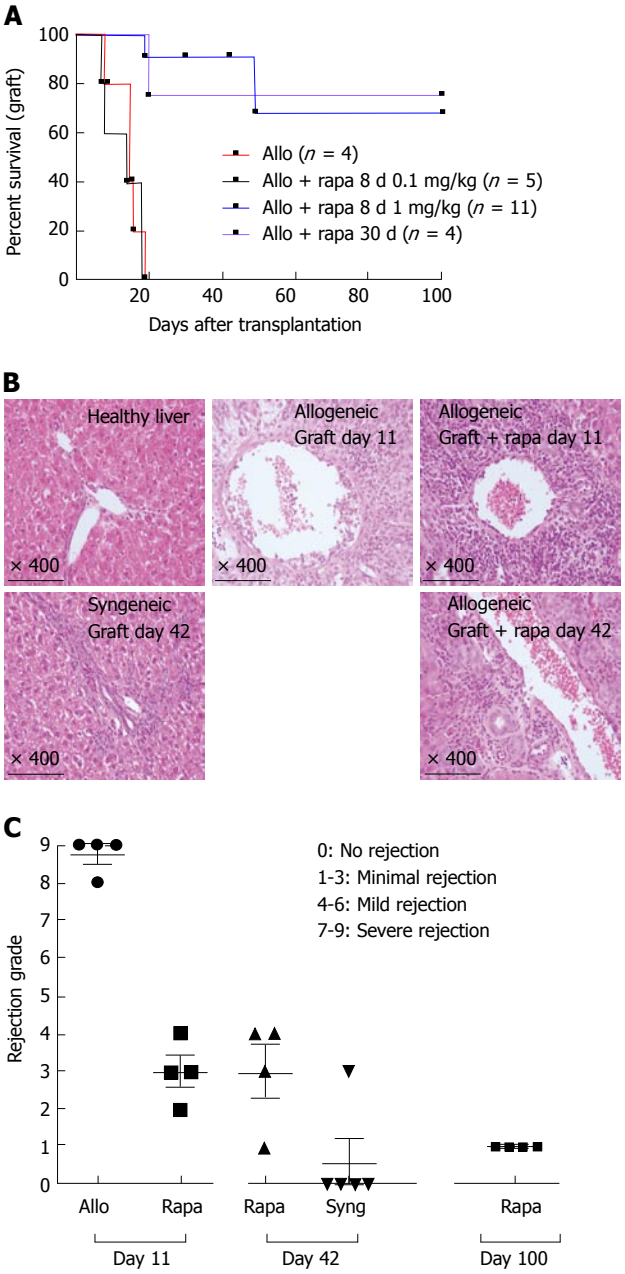

Figure 1 A short course of rapamycin prolongs liver transplantation in rats. A: Fully allogeneic liver transplantation (DA donor to LEW recipient) was performed, and the rats were given no treatment or were treated with rapamycin as follows: a short course at a dose of 1 mg/kg (oral gavage for 8 d from day 4 to day 11, *n* = 11), a short course at a dose of 0.1 mg/kg (8-d treatment from day 4 to day 11, *n* = 5) or a long course at a dose of 1 mg/kg (30-d treatment from day 4 to day 34, *n* = 4). Survival curves based on cumulative data are shown; B: H and E-stained histological sections from biopsy samples of a healthy liver and a grafted liver at the time of sacrifice on day 11 after liver transplantation (no treatment *vs* short course of rapamycin at 1 mg/kg) and on day 42 (short course of rapamycin at 1 mg/kg *vs* syngeneic); C: Histological grading of liver grafts using Banff scoring on day 11 and day 42 after transplantation, *n* = 4-5 rats/group.

rats were sacrificed on day 42 (1 mo after the end of rapamycin treatment) to compare their histological scores to those observed in syngeneic liver-transplanted animals. Although significantly higher than the scores observed in rats that did not reject their syngeneic liver transplants, the histological scores of the rapamycin-protected animals remained constant between day 11 and day 42 and were dramatically reduced compared to those of the untreated, transplanted rats (Figure 1B and C). Importantly, 4 protected animals sacrificed at day 100 did not display any histological signs of liver rejection. In addition, the blood analysis of residual rapamycin levels after 48 h of treatment administered in non-grafted control rats was under the threshold of detection of our platform, but rapamycin persisted in livers on day 21 (10 d after the end of rapamycin treatment, 6.66 ± 0.44 ng/g liver). Notably, none of the treated rats demonstrated dehiscence of either the abdominal wall or the vascular anastomosis, therefore circumventing a major side effect of the treatment on wound-healing processes. We also tested a reduced dose of rapamycin, 0.1 mg/kg, administered from day 4 to day 11. Under these experimental conditions, all animals rejected their transplanted livers with the same kinetics observed in the non-treated animals (Figure 1A). Therefore, graft acceptance following delayed, short-term treatment is dose-dependent.

We next assessed hepatocellular injury by quantifying total bilirubin, ALAT and ASAT in the blood of transplanted animals administered a short course of rapamycin on days 11 and 42. On day 11, we observed a dramatic decrease in total bilirubin in the treated rats compared to the untreated control rats (15.50 ± 4.51 μmol/L *vs* 109.5 ± 11.43 μmol/L, respectively) and decreasing trends for ALT (147.66 ± 66.02 UI/L *vs* 263.25 ± 45.88 UI/L, respectively) and AST (1257 ± 240.62 UI/L *vs* 558.25 ± 364.01 UI/L, respectively). On day 42, transaminase levels continued to decrease in rapamycin-treated rats compared to day 11, but remained higher than in rats with syngeneic liver transplants (ALAT = 609.8 ± 133.7 UI/L *vs* 152 ± 61.50 UI/L, respectively; ALAT = 130 ± 22.84 UI/L *vs* 35.50 ± 4.36 UI/L, respectively) (Figure 2). Therefore, the relationship between these biological abnormalities and the time from treatment appears to correlate with BANFF scores.

Based on our results, a delayed and short course of rapamycin effectively prevents allogeneic OLT rejection and correlates with low histological scores and long-term preserved liver function.

Allogeneic orthotopic liver tolerance under rapamycin treatment is associated with activated CD4$^+$ and CD8$^+$ regulatory T cell phenotypes and MDSC expansion

Given the *in vivo* effects of a delayed and short course of rapamycin in the allogeneic liver transplant model, we next sought to evaluate the involvement of different cell populations in these tolerance effects at the end of treatment and one month later.

We performed a flow cytometry analysis of the CD4$^+$Foxp3$^-$ (CD4conv) and CD8$^+$Foxp3$^-$ (CD8conv) T cell populations in non-dLNs and dLNs and in the spleens of grafted animals at two important time points: day 11 post-transplantation (the timing of liver

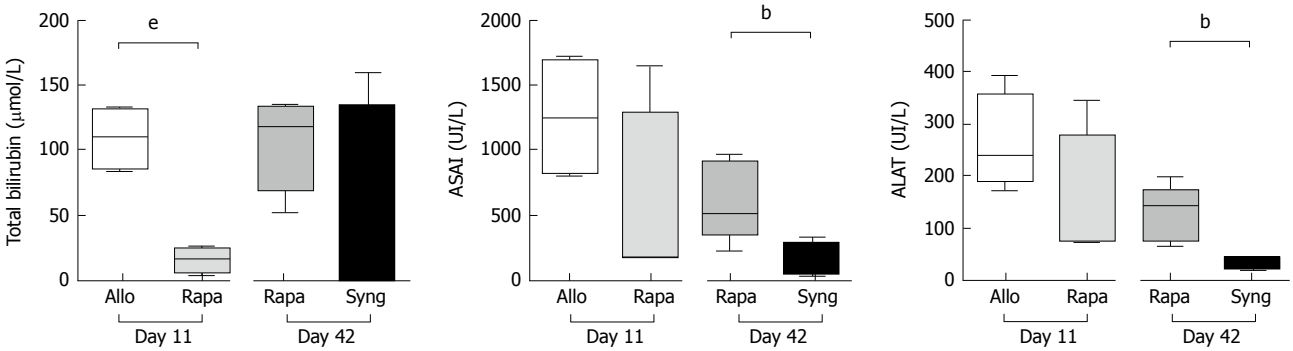

Figure 2 The protective effects of a short course of rapamycin on liver function. Fully allogeneic liver transplantation (DA donor to LEW recipient) was performed, and the rats were given no treatment or were treated with 1 mg/kg rapamycin (8-d treatment from day 4 to day 11). Total bilirubin, ALAT, and ASAT expression levels were measured in rat sera on postoperative days 11 (control *vs* rapamycin) and 42 (rapamycin *vs* syngeneic graft). The graph shows the cumulative data from 4-5 rats/group. *P*-values are indicated when the differences between the two groups of rats are significant ($^{b}P \leqslant 0.01$, $^{e}P \leqslant 0.001$). ALAT: Alanine aminotransferase; ASAT: Aspartate aminotransferase.

rejection and the end of treatment) and day 42 (when tolerance appears to be strong in the rapamycin-treated group). We did not observe any differences in the percentage or the number of CD4conv and CD8conv T cells at day 11 or day 42 (data not shown). Although we did not observe any changes in the naïve compartment on day 11, on day 42, the percentage of naïve CD4conv ($CD4^+Foxp3^-CD62L^+CD45RC^+$) T cells in dLNs and non-dLNs increased in the rapamycin-treated group compared to day 11 and was statistically significantly higher compared to the rats that received syngeneic liver transplants (Figure 3A).

We then quantified IFNγ and TNFα production by $CD4^+$ and $CD8^+$ T cells in the dLNs of grafted animals. Compared to untreated rats, rapamycin reduced the expression of IFNγ in both $CD4^+$ and $CD8^+$ T cells on day 11 post-transplantation ($CD4^+$ = 5.59% ± 1.15% *vs* 2.6% ± 0.54%, $CD8^+$ = 5.07% ± 1.58% *vs* 3.13% ± 0.35%, Figure 3B), but with weak modification of the expression of TNFα. One month after the end of the treatment, IFNγ expression in $CD4^+$ and $CD8^+$ T cells was higher in the rapamycin-treated rats compared to the rats with syngeneic grafts, but the percentage of secreting cells remained weak. Therefore, a short course of rapamycin appears to transiently inhibit the T cell inflammatory cytokine production capacity.

To identify the cellular mechanisms associated with liver acceptance, we then analyzed both $CD4^+$ and $CD8^+$ Tregs in grafted animals on day 11 and day 42. No major changes in the frequency of $CD4^+CD25^+Foxp3^+$ Tregs were observed in the treated rats (Figure 4A). However, rapamycin treatment induced CD25 overexpression based on the mean intensity of fluorescence (MFI) on day 11. Additionally, ICOS (MFI) overexpression in $CD4^+CD25^+Foxp3^+$ Tregs observed on day 42 in rapamycin-treated rats compared to untreated rats grafted with syngeneic livers suggested the activation of $CD4^+$ Tregs 1 mo after the end of rapamycin treatment (Figure 4A). According to previous studies, the transcription factor Helios is required to maintain regulatory T cell identity[21,22]. In our model, Helios frequency in $CD4^+Foxp3^+$ cells was higher in rapamycin-treated rats one month after the end of treatment on day 42 than in syngeneic-grafted rats, suggesting a stable regulatory profile for this transcription factor.

$CD8^+Foxp3^+CD25^+$ regulatory cells are central mediators of tolerance during allogeneic heart transplantation in rats[23]. In our model, compared to untreated rats, rapamycin-treated rats demonstrated a slight increase in $CD8^+Foxp3^+CD25^+$ cells in the dLNs on day 11 and increased MFI CD25, ICOS and CTLA-4 expression in these cells on day 42, suggestive of their activated status compared to rats transplanted with syngeneic livers (Figure 4B). Additionally, $CD8^+CD45RC^{low}$ Tregs in transplanted livers are associated with organ transplant tolerance[24]. We observed a significant increase in $CD8^+CD45RC^{low}$ Tregs in the dLNs of rapamycin-treated rats on day 11.

Several recent studies have shown the beneficial effects of MDSCs during solid organ allograft rejection in humans and mice[25]. In our OLT model, we phenotypically characterized these myeloid cells in the spleens of grafted rats based on their expression of CD11b/c, their intermediate expression of CD161, and the lack of MCH class Ⅱ protein expression. Compared to untreated control rats, rapamycin treatment increased the frequency of MDSCs in the spleen on day 11 (1.603 ± 0.302% *vs* 4.085 ± 0.4596%) (Figure 5). The MDSC proportion remained relatively stable on day 42 and comparable to that of MDSCs observed in the syngeneic group on day 42. Therefore, these two subpopulations ($CD8^+CD45RC^{low}$ Tregs and MDSC) appear to be involved in tolerance during the early phase of rejection.

A short course of rapamycin induces antigen-specific tolerance

To test whether a short course of rapamycin treatment induces donor-specific tolerance, skin allografts were performed one month after liver transplantation (20 d after the end of rapamycin treatment). We grafted donor skin collected from syngeneic liver donor rats (DA) or skin collected from third-party donor rats

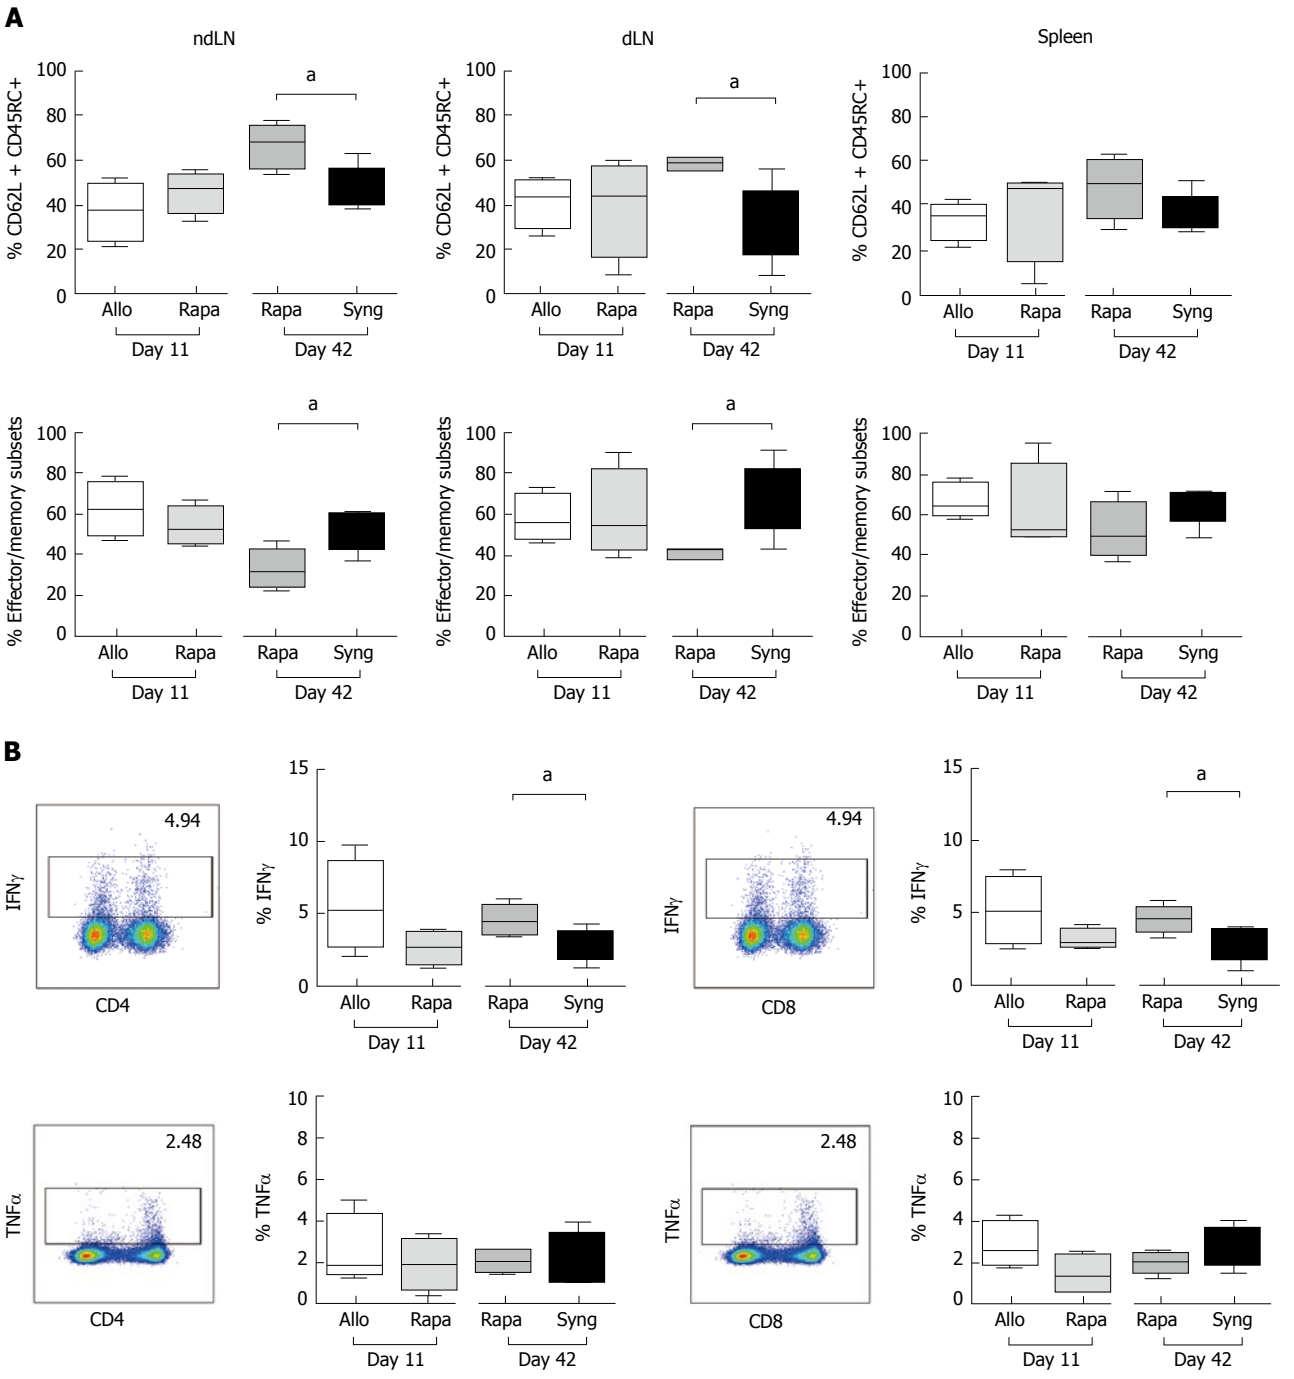

Figure 3 The effects of a short course of rapamycin treatment on naïve and effector memory cells (A) seems to transiently inhibit the T cell function (B). A: The ndLNs, dLNs and spleens of grafted animals were collected on day 11 and day 42 and conventional T cells were analyzed by flow cytometry. Naïve T cells, defined as $CD62L^{+}CD45RC^{+}$, and effector/memory cells, defined as ($CD62L^{-}CD45RC^{-}$) + ($CD62L^{+}CD45RC^{-}$) + ($CD62L^{-}CD45RC^{+}$), were analyzed in $CD4^{+}Foxp3^{-}$ and $CD8^{+}Foxp3^{-}$ T cell populations. The results are expressed as the mean +/- SEM of the percentages of effector/memory and naïve T cells, respectively. P-values are indicated when the differences between the two groups of rats are significant ($^{a}P \leqslant 0.05$). The graph shows the cumulative data from 4-5 rats/group; B: Quantification of IFNγ and TNFα expression by $CD4^{+}$ and $CD8^{+}$ T cells in the dLNs of grafted animals after PMA/ionomycin stimulation for 4 h. The graph shows the cumulative data from 4-5 rats/group. The results are expressed as the mean +/- SEM. *P*-values are indicated when the differences between the two groups of rats are significant ($^{a}P \leqslant 0.05$).

(neither donor nor recipient, F344) onto rapamycin-treated rats. In control LEW rats grafted with both DA and F334 skin, we observed no signs of rejection on day 7. On day 18, all skin transplants were rejected. In rapamycin-treated rats that did not reject their DA liver transplants, we observed the first signs of F344 skin rejection starting on day 7 and all skin grafts were fully rejected on day 10. Conversely, no signs of rejection were observed for DA-grafted skin on day 7 and black hairs from DA donor skin were detectable on protected animals until day 60 (Figure 6A and B).

DISCUSSION

Since the establishment of a small-animal liver transplant model[26], different preclinical studies have

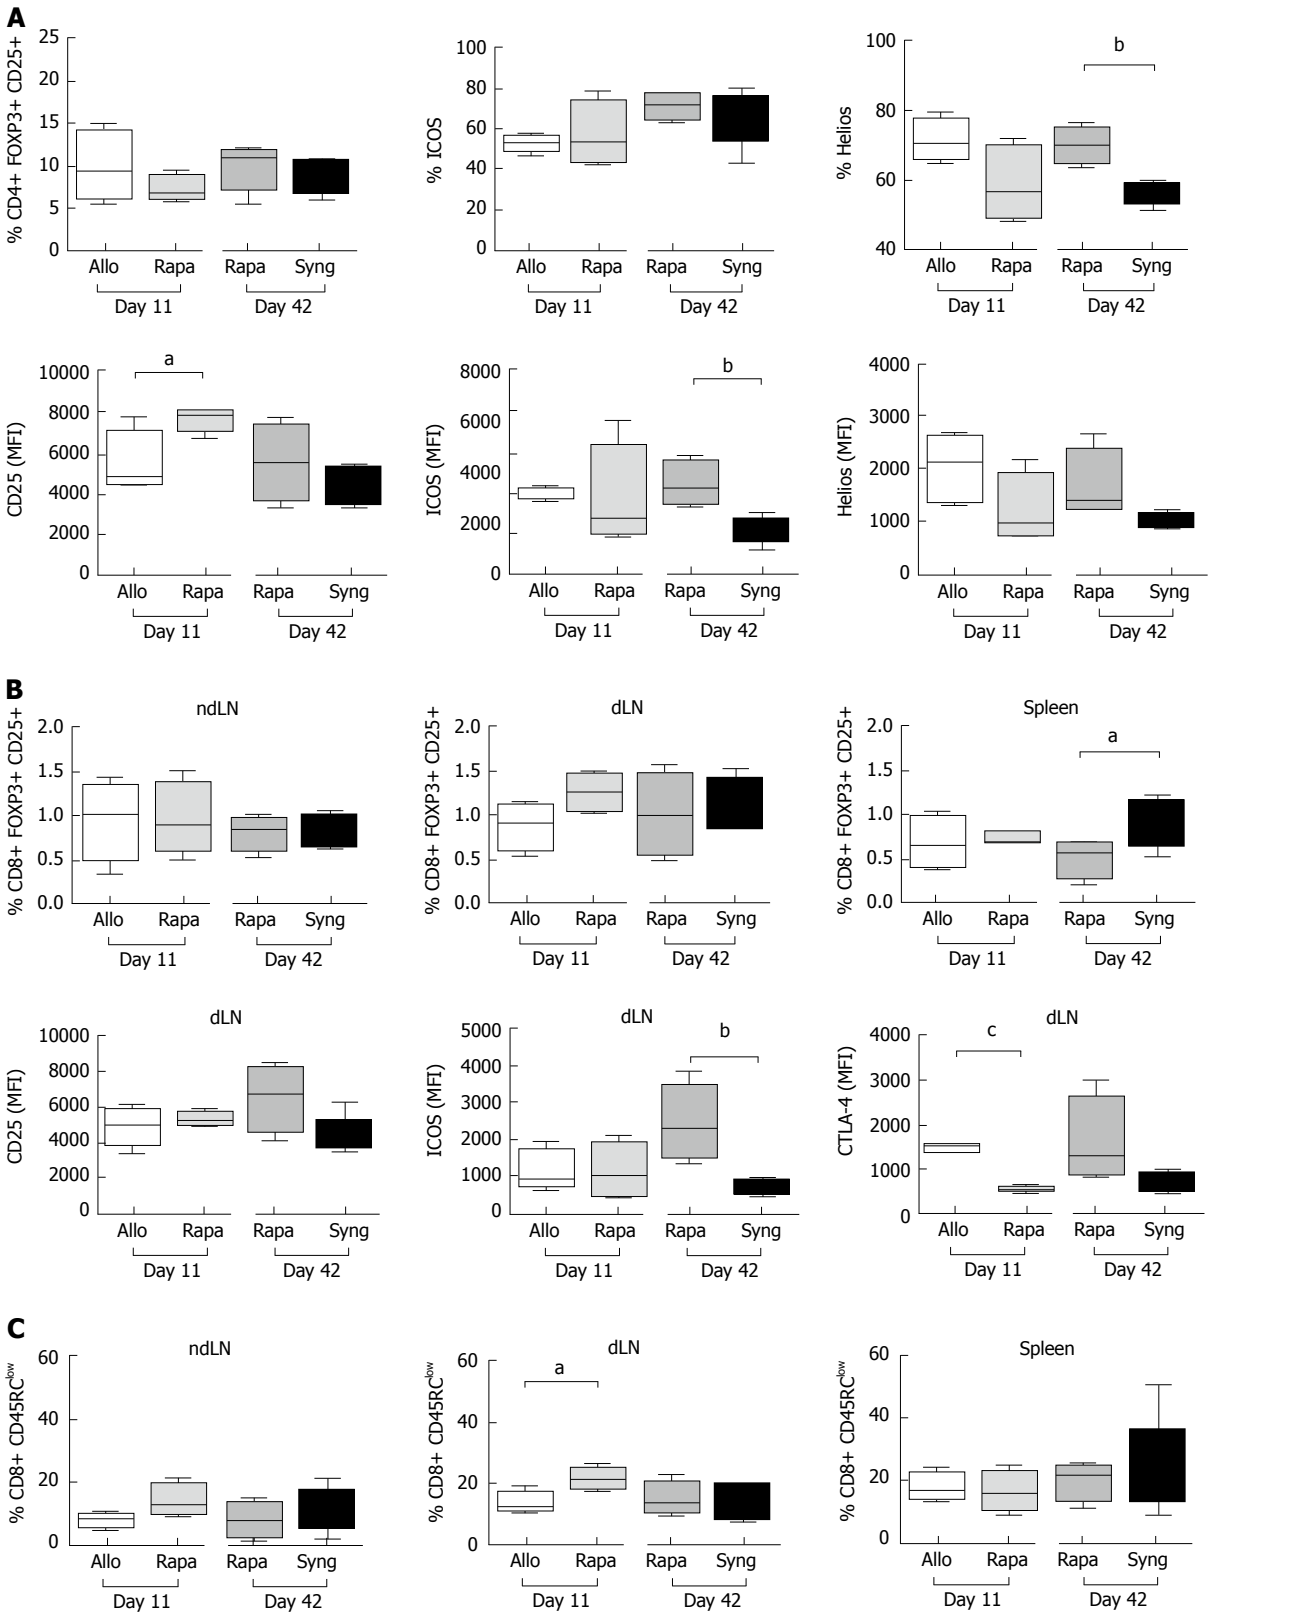

Figure 4 The effects of a short course of rapamycin treatment on CD4$^+$ and CD8$^+$ regulatory T cell phenotypes. A: The dLNs of grafted animals were collected on day 11 and day 42 and regulatory CD4$^+$ T cells were analyzed by flow cytometry. Different activation markers were studied (CD25$^+$, ICOS$^+$, Helios$^+$) after gating on CD25$^+$FOXP3$^+$ among CD4$^+$ cells. The results are expressed as the mean +/- SEM of the percentages of CD25$^+$, ICOS$^+$, and Helios$^+$ or the MFI values for CD25, ICOS, and Helios; *n* = 4-5 rats/group. *P*-values are indicated when the differences between the two groups of rats are significant ($^aP \leqslant 0.05$, $^bP \leqslant 0.01$). MFI, mean fluorescence intensity; B: The ndLNs, dLNs and spleens of grafted animals were collected on day 11 and day 42 and the percentages of CD25$^+$Foxp3$^+$ regulatory CD8$^+$ T cells were analyzed by flow cytometry. The MFI values of the activation markers (CD25, ICOS, and CTLA-4) are shown for the dLNs. The results are expressed as the mean +/- SEM. *P*-values are indicated when the differences between the two groups of rats are significant ($^aP \leqslant 0.05$, $^bP \leqslant 0.01$, $^cP \leqslant 0.0001$); C: The percentages of CD45RC^{low} cells among CD8$^+$ cells in the dLNs, ndLNs and spleens of grafted rats are shown. The results are expressed as the mean +/- SEM. *P*-values are indicated when the differences between the two groups of rats are significant ($^aP \leqslant 0.05$).

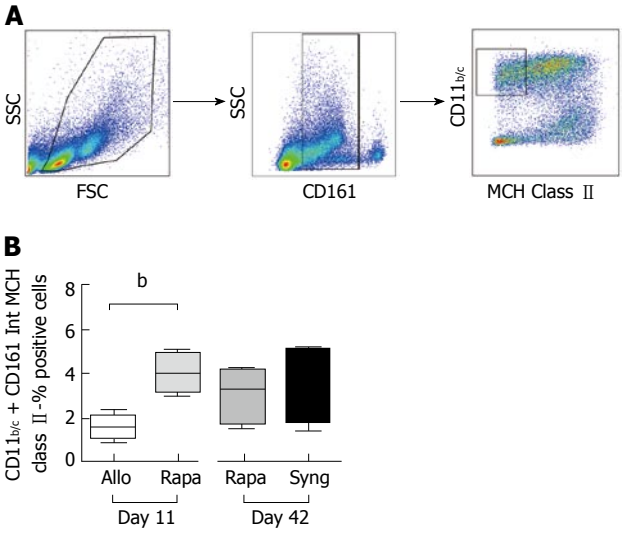

Figure 5 A short course of rapamycin increases myeloid-derived suppressor cells numbers on postoperative day 11 in allogeneic liver-grafted rats. The spleens of grafted animals were collected on day 11 and day 42, and myeloid-derived suppressor cells (MDSCs) were analyzed by flow cytometry. A: Gating strategy for MDSC analysis: CD11b/c^{+}CD161^{int}MCH class Ⅱ$^{-}$; B: Cumulative data indicating MDSC percentages. The results are expressed as the mean +/- SEM of the MDSC percentages. *P*-values are indicated when the differences between the two groups of rats are significant ($^{b}P \leqslant 0.01$).

demonstrated the feasibility of reducing or even substituting immunosuppressive drugs in favor of alternative therapies[27-29] to overcome the side effects responsible for significant morbidity and mortality[15]. In this context, we were strongly invested in the development of new pharmacological strategies to induce tolerance in transplantation. Notably, we have studied different approaches based on low-dose IL-2 administration in different pathophysiological settings. In allogeneic stem cell transplantation, we observed that low dose IL-2 +/- rapamycin treatment had no effect on GVHD, particularly in a model of xeno-GVHD using human cells[30]. In contrast, a similar protocol significantly delayed allogeneic skin graft rejection in mice. At the beginning of this work, we tried to transfer this therapeutic protocol in a model of allogeneic liver transplantation to rats considered as a less immunogenic setting. Fortuitously, in a group of control rats, we were surprised to observe that a 30-d rapamycin administration initiated at day 4 was sufficient to allow for allogeneic liver acceptance. We initially decided to delay rapamycin administration to day 4 to avoid the known side effects of the molecule when used at the time of transplantation. Additionally, the elevated grade of histopathological rejection observed as soon as day 11 led us to treat the rats at day 4 to avoid the potentially irreversible rejection process if administered too late. Due to the impressive results obtained with 30 d of treatment, we tested the potential of a reduced treatment duration. In summary, we investigated a novel rapamycin administration protocol to prevent acute liver rejection. A short (8 d) and delayed (starting on day 4 after transplantation) course of rapamycin was sufficient to control acute OLT rejection in rats and induce a state of operational tolerance. Indeed, more than 75% of grafted animals treated with 1 mg/kg rapamycin *via* oral administration survived more than 100 d without any additional immunosuppressive treatment. This is in marked contrast to previous results and represents a dramatic improvement over a previously described protocol using the same rat strains. Indeed, the authors tested the administration of rapamycin between days 0 and 7, resulting in an MST of OLT of 24 d[31]. Our results are of significant importance because they demonstrate that delayed rapamycin treatment does not jeopardize the safety of the transplanted organ. Rapamycin can also be stopped without impairing the developed graft tolerance. These results are consistent with a previous study that tested a delayed and short-course treatment with an anti-CD3 mAb[32] to obtain strong and long-term tolerance of allogeneic cardiac allografts. Therefore, in the context of transplantation, establishing a strong but time-limited allogeneic immune response prior to the initiation of a therapeutic approach may be favorable in the establishment of sustainable and specific tolerance.

We also sought to identify the immunological mechanisms underlying this long-term tolerance obtained with rapamycin. CD4^{+} Tregs have been regarded as a potential therapeutic modality for the prevention and treatment of allogeneic immune responses for a long time[33]. They also demonstrate potential for the specific targeting of cells involved in the allogeneic immune response without inducing general immunosuppression. We observed the preservation of immune potential as indicated by the capacity of tolerant rats to reject allogeneic skin grafts and accept skin grafts that originated from rats with the same background as the accepted livers. We quantified Tregs contents in the dLNs of grafted animals on day 11 (at the end of the rapamycin treatment) and one month later. In contrast to the results of a previous report[34], we did not observe a major change in the percentage of Tregs. However, CD25 overexpression on day 11 and the overexpression of ICOS in CD4^{+} Tregs on day 42 suggested the activation of these cells in rapamycin-treated rats. We also observed an increase in CD8^{+}Foxp3^{+}CD25^{+} regulatory cells, but this increase was only present on day 11 and only in the spleen. At the same time point, CD8^{+}Foxp3^{+}CD25^{+} Tregs overexpressed CD25, ICOS and CTLA4 in the dLNs of rapamycin-treated animals compared to syngeneic grafted rats, again suggesting an activated CD8^{+}Foxp3^{+}CD25^{+} Tregs phenotype[35]. CD8^{+}CD45RC^{low} Tregs[36] have also been associated with organ transplant tolerance[24,37]. We observed a significant increase in CD8^{+}CD45RC^{low} Tregs in the dLNs of rapamycin-treated rats on day 11. In murine cardiac allograft models, a short course of rapamycin leads to the recruitment of MDSCs and increases their expression of iNOS. According to Nakamura *et al*[8], even if the T cell activity is suppressed in a dose-dependent manner in vitro, monocytic MDSCs treated

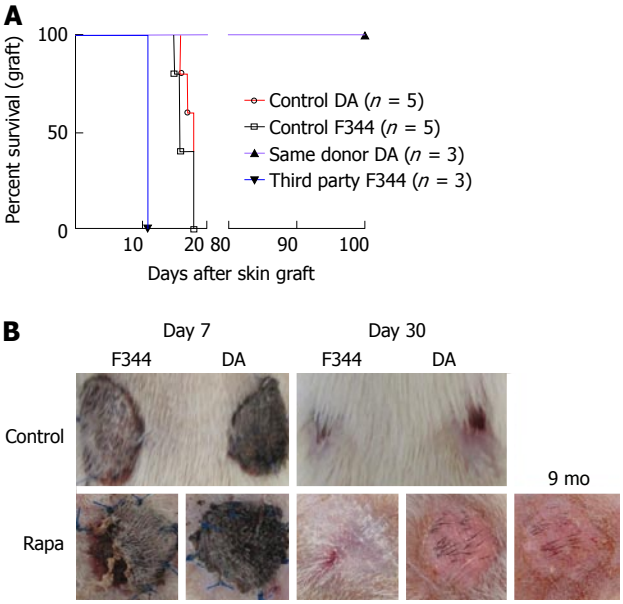

Figure 6 A short course of rapamycin induces antigen-specific tolerance. Allogeneic liver transplantations were performed (DA donor to LEW recipients), and the rats were treated with a short course of rapamycin (1 mg/kg, days 4 to 11). On day 30 after liver transplantation, skin grafts were performed with skin from the same DA donor or from third-party F344 rats. The control groups received allogeneic skin grafts from DA or F344 donors with rats (LEW) that did not undergo liver transplantation. A: Cumulative survival curves; days indicate the days post-skin graft, *n* = 3-5 rats/group; B: Representative images are shown on day 7 and day 30 after skin grafts.

with rapamycin suppress $CD4^+$ T cell proliferation more efficiently than granulocytic MDSCs treated with rapamycin. Therefore, mTOR down-regulation promotes monocytic MDSC migration in vitro and *in vivo*[38]. Altogether, our results suggest that MDSCs and $CD8^+CD45RC^{low}$ Tregs are involved in the early stages of tolerance initiation followed by sustained tolerance that involves both $CD4^+$ and $CD8^+Foxp3^+CD25^+$ Tregs.

In summary, our results provide new perspectives on research regarding the use of rapamycin in OLT. Notably, the precise mechanisms of tolerance remain to be identified by sequential depletion of the different regulatory cell subtypes to confirm their potential roles in graft acceptance. Additionally, if rapamycin should be reintroduced early in the therapeutic arsenal for the prevention of liver transplant rejection in humans, several steps must be taken. First, the main concern in using early rapamycin involves hepatic artery thrombosis. Consequently, the efficacy of our protocol remains to be tested in an additional model of OLT with consideration of this central parameter in a large animal model for example. Finally, the compatibility of early rapamycin administration should be evaluated with the gold standard of liver rejection prevention that relies on FK506 or CNI administration. Such a comparative study deserves specific experiments that would allow for a direct comparison of the clinical effects of these two type of molecules and also for the identification of the mechanisms of tolerance that take place depending on the molecule used. This information would even support therapeutic decisions consistent with the mechanisms of tolerance identified.

COMMENTS

Background

Solid organ transplantation remains the last option for vital organ failure. Even though the control of the immune response in the recipient is now better controlled, the side effects of the immunosuppressive approach are still present and the therapeutic approach needs perpetual improvement. Current immunosuppression treatments following solid organ transplantation are based on calcineurin inhibitors (CNIs). However, reducing the use of CNIs by combining or replacing them with immunosuppressive drugs that exert different mechanisms of action remains the primary strategy to lower the incidence of adverse events.

Research frontiers

The main challenge in transplantation is to identify therapeutic protocols that allow for organ specific tolerance with reduced or absent side effects.

Innovations and breakthroughs

Our data revealed that (1) rapamycin as mono-therapy allows for long-term allogeneic liver protection in rats; (2) this treatment was slightly delayed as opposed to rats treated at day 0; and (3) an 8-d treatment was as efficient as a 3-wk treatment to induce long-term tolerance. We also identified two populations of immune cells (MDSC and CD8+CD45low) that were increased in tolerant rats. These results reveal notable new perspectives by identifying the precise mechanisms at the origin of this state of tolerance.

Applications

These results support the development of similar therapeutic approaches in large animal models.

Terminology

Allogeneic orthotopic liver transplantation (OLT) is performed with a liver from a donor with a different genetic background from the recipient. A syngeneic graft is performed within the same genetic background.

Peer-review

An interesting and readable manuscript to explore a delayed and short course of rapamycin initiated on day 4 following allogeneic OLT in rats resulted in the survival of grafted rats for more than 100 d. This study is very clear, and the manuscript is well written. The main flaws of the study are its limited translational components.

ACKNOWLEDGMENTS

We want to acknowledge the staff of our animal facility platform (EFPA) for their excellent animal care. We are also indebted to France Noizat-Pirenne and Etablissement Français du Sang for access to their cytometry platform.

Abstract

AIM

To investigate whether mesenchymal stem cells (MSCs) from adipose-derived stromal cells (ADSCs) and bone marrow stromal cells (BMSCs) have similar hepatic differentiation potential.

METHODS

Mouse ADSCs and BMSCs were isolated and cultured. Their morphological and phenotypic characteristics, as well as their multiple differentiation capacity were compared. A new culture system was established to induce ADSCs and BMSCs into functional hepatocytes. Reverse transcription polymerase chain reaction, Western blot, and immunofluorescence analyses were performed to identify the induced hepatocyte-like cells. CM-Dil-labeled ADSCs and BMSCs were then transplanted into a mouse model of CCl_4-induced acute liver failure. Fluorescence microscopy was used to track the transplanted MSCs. Liver function was tested by an automatic biochemistry analyzer, and liver tissue histology was observed by hematoxylin and eosin (HE) staining.

RESULTS

ADSCs and BMSCs shared a similar morphology and multiple differentiation capacity, as well as a similar phenotype (with expression of CD29 and CD90 and no expression of CD11b or CD45). Morphologically, ADSCs and BMSCs became round and epithelioid following hepatic induction. These two cell types differentiated into hepatocyte-like cells with similar expression of albumin, cytokeratin 18, cytokeratin 19, alpha fetoprotein, and cytochrome P450. Fluorescence microscopy revealed that both ADSCs and BMSCs were observed in the mouse liver at different time points. Compared to the control group, both the function of the injured livers and HE staining showed significant improvement in the ADSC- and BMSC-transplanted mice. There was no significant difference between the two MSC groups.

CONCLUSION

ADSCs share a similar hepatic differentiation capacity and therapeutic effect with BMSCs in an acute liver failure model. ADSCs may represent an ideal seed cell type for cell transplantation or a bio-artificial liver support system.

Core tip: We investigated whether mesenchymal stem cells from adipose-derived stromal cells (ADSCs) and bone marrow stromal cells (BMSCs), have similar hepatic differentiation potential. We found that adipose-derived stromal cells resemble bone marrow stromal cells in their hepatocyte differentiation potential *in vitro* and *in vivo*. Because ADSCs are obtained more easily and less invasive than BMSCs, ADSCs might be more suitable seed cells for cell transplant or liver tissue engineering. We also developed a new protocol of preparing mouse BMSCs and established a new hepatic induction system.

Adipose-derived stromal cells resemble bone marrow stromal cells in hepatocyte differentiation potential *in vitro* and *in vivo*. *World J Gastroenterol* 2017; 23(38): 6973-6982 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/6973.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.6973

INTRODUCTION

Liver transplantation remains the only effective treatment for liver failure. However, its clinical application is limited by donor organs and immune rejection. To this end, hepatocyte transplantation and a bio-artificial liver support system are two potential surrogate complementary therapies for patients with liver failure. Hepatocyte-like cells can be induced from mesenchymal stem cells (MSCs) for xenotransplantation and have been demonstrated to perform hepatocyte functions in preclinical animal studies[1,2]. However, the best type of MSC has not yet been investigated, and therefore it is important to screen for an ideal seed cell type for cell transplantation or a bio-artificial liver support system.

MSCs are non-hematopoietic multipotent stem cells that can be isolated from multiple tissues, such as bone marrow, adipose tissue, cord blood, and amniotic fluid[3-5]. Bone marrow stromal cells (BMSCs) are the most extensively studied and fertile stem cell source used in regenerative medicine and liver tissue engineering[6,7]. More recently, adipose-derived stromal cells (ADSCs) were identified as another promising and extensively studied stem cells for use, especially in liver tissue engineering[8]. Although both ADSCs and BMSCs can be induced into hepatocyte-like cells[9-12], there is no uniform culture system to evaluate their hepatic differentiation potential. Therefore, it is necessary to establish an ideal system to improve the efficiency of hepatic induction.

In this study, we developed a novel culture protocol for mouse BMSCs and optimized the hepatic differentiation system. We compared the morphological and phenotypic characteristics, as well as the multi-differentiation capacity of BMSCs and ADSCs *in vitro*. We also compared therapeutic effect of BMSCs and ADSCs following transplantation into a mouse model of acute liver failure.

MATERIALS AND METHODS

Experimental animals

Male BALB/c mice (3 d old and 6 wk old; Charles River, Beijing, China) were purchased from the Laboratory Animal Center of the Academy of Military Medical Sciences of China (Beijing). All studies were conducted after approved by the Ethics Committee of the Animal Facility of Chinese PLA General Hospital and complied with the guidelines for the care of laboratory animals. Mice were housed in cages in a controlled environment (25 ℃ and a 12 h light/dark cycle) and fed standard mouse chow and tap water, and were observed every day in our animal facility.

Isolation and purification of adipose-derived stromal cells and bone marrow stromal cells

The isolation and purification of ADSCs were performed as previously described[13]. Fibrous tissue was excluded and adipose tissue was minced into pieces of < 1 mm^3 and digested in 1 mg/mL collagenase I for 1 h at 37 ℃. The cell suspension was filtered through a 100 μmol/L cell strainer and centrifuged at 300 × *g* for 5 min. ADSCs were plated at a density of 5 × 10^5/cm^2 with alpha minimal essential medium (α-MEM) supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin, and cultured in a humidified incubator at 37 ℃ and 5% CO_2. Cells were harvested after reaching a 90% confluence with 0.25% trypsin-EDTA (Gibco, American). Cells in passages 2-4 were used for subsequent experiments.

A new method was established to isolate mouse BMSCs as follows: 3-d-old male BALB/c mice were sacrificed by cervical dislocation and soaked in 75% alcohol for 5 min. The tibia and fibula were isolated under sterile conditions and washed twice with phosphate-buffered saline (PBS) containing 5% penicillin/streptomycin. Muscle and fibrous tissue were excluded. Tibias and fibulas were minced into pieces of < 1 mm^3 and washed once with α-MEM, cultured directly by incubation with α-MEM supplemented with 10% FBS and 1% penicillin/streptomycin in a humidified incubator at 37 ℃ and 5% CO_2. After 72 h, half of the medium was changed and the bone chips were kept. After reaching a 50% confluence, cells were harvested with 0.25% trypsin-EDTA and seeded as the first passage. At each passage, cells were diluted 1:3-4 every two days. BMSCs at passages 2-4 were used for subsequent experiments.

Measurement of adipose-derived stromal cells and bone marrow stromal cells proliferation

For the cell proliferation assay, 2 × 10^3 viable ADSCs and BMSCs were seeded in triplicate onto a 96-well plate. Cell proliferation was measured using a Cell Counting Kit-8 (CCK-8; Beyotime, China). Plates were placed in a humidified incubator at 37 ℃ until the cells adhered to the plate. Next, 10 μL of the CCK-8 solution was added to each well and plates were incubated for another 2 h at 37 ℃ prior to reading the absorbance at 450 nm on a microplate reader. The assay was repeated every day at the same time for 10 d.

Flow cytometry

Passage 2 and 3 ADSCs and BMSCs were trypsinized and incubated with fluorescein isothiocyanate-conjugated CD45 and CD90, and phycoerythrin-conjugated CD11b and CD29 antibodies for 30 min at 4 ℃, followed by two washes with PBS. Fluorescent-labeled cells were analyzed on a flow cytometer.

Differentiation assays

For adipogenic differentiation, cells were seeded at 1 × 10^4/cm^2 on 12-well plates. When cells adhered to the plate, the expansion medium (α-MEM supplemented with 10% FBS and 1% penicillin/streptomycin) was replaced with adipogenic induction medium containing 10^{-6} mmol/L dexamethasone (Dex), 0.5 μmol/L isobutylmethylxanthine, 200 μmol/L indomethacin, and 5 μg/mL (wt/v) insulin, and the cells were incubated for 8 d. Cells cultured in a base medium of α-MEM supplemented with 10% (v/v) FBS served as a negative control. Adipogenic differentiation was assessed by Oil-Red-O staining.

For osteogenic differentiation, cells were seeded at 5 × 10^3/cm^2 on 12-well plates. When cells adhered to the plate, the expansion medium was replaced with osteogenic induction medium containing 10^{-7} mmol/L Dex, 10 mmol/L β-glycerol phosphate, and 50 μmol/L ascorbate-2-phosphate. Cells cultured in a base medium of α-MEM supplemented with 10% FBS were used as a negative control. Cells were incubated for 3 wk and osteogenic differentiation was assessed by Alizarin Red staining.

Hepatic differentiation was achieved following a one-step procedure using mouse ADSCs and BMSCs. ADSCs and BMSCs (passage 3) were seeded at 5 × 10^3/cm^2 onto 24-well culture dishes in expansion medium. When cells adhered to the plate, the expansion medium was replaced with hepatocyte culture medium (HCM; DMEM containing 10% FBS) supplemented with 50 ng/mL hepatocyte growth factor (HGF), 25 ng/mL fibroblast growth factor 4 (FGF4), 30 ng/mL oncostatin M (OSM), 20 ng/mL epidermal growth factor (EGF), 25 ng/mL acidic fibroblast growth factor (aFGF), 10 ng/mL basic fibroblast growth factor (bFGF), 10^{-6} mmol/L Dex, 1 × insulin-transferrin-selenium (ITS), 2 mmol/L ascorbic acid (Vc), and 50 μmmol/L nicotinamide (Vpp). Differentiation medium (1 mL) was added to each 24-well culture dish and changed every 3 d. Afterwards, cells were cultured for 10 d in HCM. Undifferentiated cells served as negative controls and the HepG2 cell line served as a positive control.

Reverse transcription polymerase chain reaction

On day 10 of hepatic differentiation, total RNA was isolated from ADSCs and BMSCs with Trizol reagent

(Sigma-Aldrich, St. Louis, MO, United States), reverse-transcribed into first-strand cDNA using oligo (dT) primer, and amplified with 35 cycles (95 ℃, 10 min; 58 ℃, 1 min; and 72 ℃, 5 min) of PCR using 10 pmmol/L of specific primers. Upon completion of the PCR, products were examined by 2% agarose gel electrophoresis. Actin was used as an internal standard (30 cycles of amplification were performed). To compare the differences in expression levels of albumin (ALB), alpha fetoprotein (AFP), cytokeratin 18 (CK-18), CK-19, and glucose-6-phosphate (G-6-P) between undifferentiated and differentiated ADSCs and BMSCs, the products were quantified on an image analyzer (Uvitec, Warwickshire, United Kingdom). The primer sequences used are listed in Supplement Table 1.

Western blot analysis

Western blot analysis was performed as previously described[6]. In brief, total cellular proteins were prepared and quantified by the Bradford method. A total of 80 μg of lysates was electrophoresed by 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and blotted onto a nitrocellulose membrane (Immoblin-P, Millipore, Bedford, MA, United States). Membranes were blocked with 5% fat free milk powder at room temperature for 2 h and incubated overnight with polyclonal rabbit anti-mouse CYP1A1 or CK-19, goat anti-mouse ALB, AFP, or CK-18 (1:1000; Santa Cruz Biotechnology, Dallas, TX, United States), or anti-β-actin antibody (Santa Cruz Biotechnology) at 4 ℃ overnight. After three washes of 15 min in Tris-buffered saline containing Tween 20 (TBST), the membranes were incubated with horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG antibody, HRP-conjugated rabbit anti-goat IgG antibody (Zhongshan Jinqiao, Beijing, China), or goat anti-mouse IgG antibody for 2 h at room temperature. The membranes were washed again in TBST. Enhanced chemiluminescence reagent was added and monitored for color development.

Immunofluorescence

Cultured cells were fixed with 4% paraformaldehyde (Sigma-Aldrich) for 30 min at room temperature, washed twice with PBS, and permeabilized with 1% Triton X-100 (Sigma-Aldrich) for 20 min at room temperature. Cells were then incubated with blocking solution consisting of PBS and 10% normal goat serum NGS at room temperature for 2 h. For immunofluorescence staining, primary antibodies (1:200; Santa Cruz Biotechnology) against ALB, AFP, CK-18, CK-19, or CYP1A1 were used. Following incubation with the primary antibodies overnight at 4 ℃, cells were incubated with secondary antibodies for 2 h at 37 ℃. Subsequently, cells were stained with 4′,6-diamidino-2-phenylindole (DAPI) for 5 min at room temperature and photographed with a structured illumination fluorescence microscope.

Transplantation

Six-week-old BALB/c mice were used for the transplantation experiment. An acute liver failure model was established by administering one dose of CCl_4. Mice received intraperitoneal injection of 100 μL/20 g body weight of olive oil containing 10 μL CCl_4 24 h before MSC transplantation. On day 0, mice underwent MSC transplantation at a concentration of 1×10^6 cells per mouse (0.2 mL cell suspension was injected *via* the tail vein). As a control, PBS-transplanted CCl_4-treated mice and non-transplanted olive oil-treated mice were used. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were measured on days 1, 2, 3, and 7 after transplantation. Liver tissue samples were harvested at the indicated time points after cell transplantation, fixed with 4% paraformaldehyde, embedded in paraffin, and stained with hematoxylin and eosin (HE). Frozen sections (8 μm thick) were used for fluorescence observations.

Statistical analysis

Data are presented as the mean ± SD. ALT and AST levels were analyzed by Student's *t* test using SPSS software version 19.0 (SPSS Inc., Chicago, IL, United States). Significance for all statistical analyses was defined as $P < 0.05$.

RESULTS

Cellular morphology of adipose-derived stromal cells and bone marrow stromal cells

Cells were observed under an inverted microscope. On the second day of primary culture, few ADSCs were observed. On the third day, the number of cells increased (the cell density was approximately 60%) and, on the fourth day, the cells exhibited a spiral-shaped structure and reached a 90% confluence. Cells were passaged at 1:3 (Supplement Figure 1A). On the second day of primary culture (BMSCs), few fibroblast-like cells had "climbed out" around the bone fragments. The number of cells increased over time and, on the fourth day, BMSCs reached a 50% confluence and were passaged at 1:1 (Supplement Figure 1A).

From passages 1-4, the two types of MSCs were long and spindle-shaped and showed no difference in morphology (Supplement Figure 1B).

Cell proliferation ability

The cell number of the second and third generations of the two cell types was determined over time and a growth curve was drawn. The two cell types showed active proliferative capacity, with an S-shaped growth curve. During the first three days, cells grew slowly. Between days 4 and 7, the two cell types grew rapidly and entered a logarithmic growth period. Cells

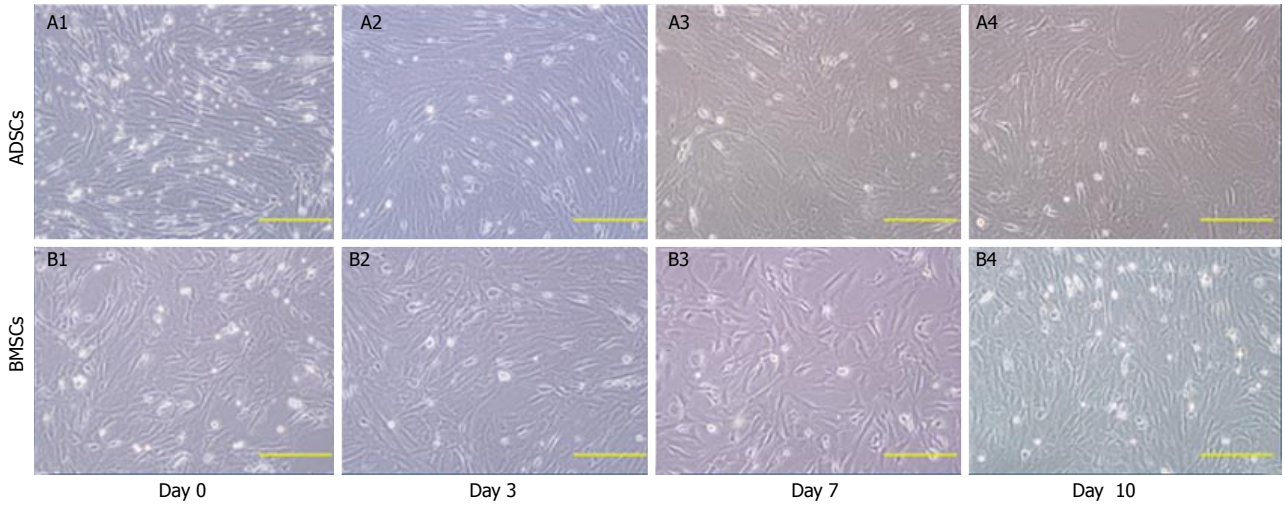

Figure 1 Morphological changes of adipose-derived stromal cells and bone marrow stromal cells following hepatic differentiation. After hepatic differentiation, the cellular morphology changed gradually and, on day 10 after differentiation, the induced cells were polygonal in shape. ADSCs: Adipose-derived stromal cells; BMSCs: Bone marrow stromal cells.

stopped growing at day 8 and entered the growth plateau phase (Supplement Figure 1C). There was no significant difference between the two types of adult stem cells in the same generation, and there was no significant difference between the same kinds of adult stem cells in the different generation (Supplement Table 1).

Phenotypic characterization of adipose-derived stromal cells and bone marrow stromal cells

ADSC and BMSC cell surface markers were analyzed by flow cytometry. Both ADSCs and BMSCs expressed the stem cell-associated surface markers CD90 and CD29, but did not express CD11b or CD45 (Supplement Table 2). The two cell types had a similar proliferative ability and stem cell capacity, consistent with our previous study.

Multiple differentiation ability of adipose-derived stromal cells and bone marrow stromal cells

The adipogenic and osteogenic differentiation of ADSCs and BMSCs was evaluated at passages 2 and 3. Small and round vacuoles began to appear in the cytoplasm on the third day of induction. On the 8th day, a large number of lipid droplets appeared in the majority of the induced cells and the cells became round, oval, or polygonal. Adipogenic differentiation was identified by Oil-Red-O staining, which stained the lipid vacuoles bright red.

After three weeks of induction, cells aggregated in some areas and formed a multilayered, nodular structure known as a bone nodule. Osteogenic differentiation was identified by Alizarin Red staining, which stained the bone nodules red. Oil-Red-O and Alizarin Red images of such cells were shown in our previous study.

Hepatic differentiation of adipose-derived stromal cells and bone marrow stromal cells

Before differentiation, both ADSCs and BMSCs exhibited fibroblast morphology with spindle cell bodies. After differentiation, the cell morphology changed dramatically. On day 4 after hepatic differentiation, cells became round in shape. On day 7, the number of oval and polygonal cells increased, and on day 10, the induced cells exhibited a clear polygonal shape (Figure 1). The expression of several hepatic genes was examined after hepatic differentiation by RT-PCR. Uninduced cells served as a negative control. On day 10 after hepatic differentiation, the expression of ALB, AFP, CK-18, CK-19, and G-6-P was significantly enhanced (Figure 2A).

The expression of ALB, AFP, CYP1A1, and CK-18 in hepatocyte-like cells was confirmed by Western blot analysis (Figure 2B). The expression of ALB, AFP, CYP1A1, and CK-18 increased continuously in the two types of hepatocyte-like cells compared with undifferentiated ADSCs and BMSCs, suggesting that these two types of MSCs were successfully induced into hepatocyte-like cells *in vitro*.

On day 10 after differentiation, immunofluorescence staining showed that the differentiated hepatocyte-like cells expressed the hepatocyte markers ALB, CK-19, CK-18, AFP, and CYP1A1 (Figure 2C), whereas the undifferentiated ADSCs and BMSCs (Figure 2C) did not express the hepatocyte-related markers.

Transplanted cells were found in damaged livers

To investigate whether the CM-Dil-labeled MSCs localized to the injured liver, animals were sacrificed on days 1, 2, 3 and 7 following treatment. In the ADSC and BMSC groups, red fluorescent cells were detected in the injured livers. In addition, the largest number of cells was detected on day 3 after transplantation and

On day 10 after differentiation, immunofluorescence staining revealed that the differentiated hepatocyte-like cells expressed the hepatocyte markers ALB, CK-19, CK-18, AFP and CYP1A1. Scale bar: 200 μm.

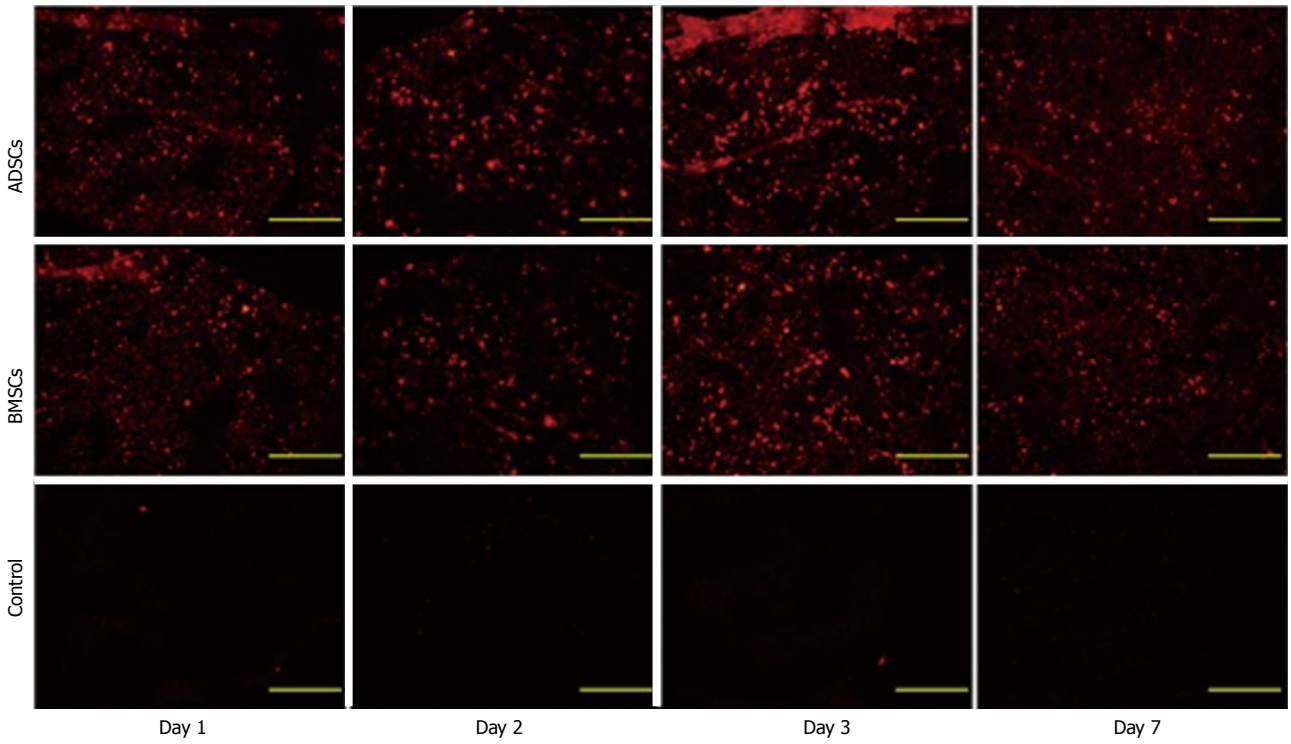

Figure 3 Tracing transplanted cells in a mouse model of acute liver failure. Red fluorescent cells were detected in the injured livers under fluorescence microscopy on days 1, 2, 3 and 7 following the transplantation. ADSCs: Adipose-derived stromal cells; BMSCs: Bone marrow stromal cells.

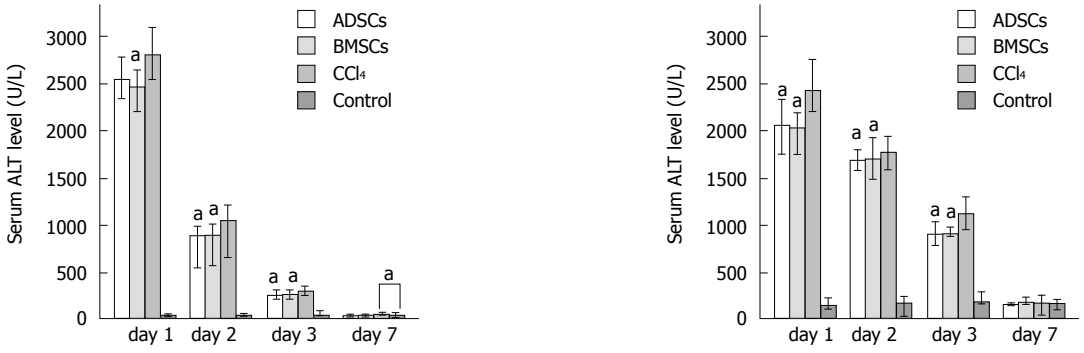

Figure 4 Analysis of liver function in CCl_4-treated mice following mesenchymal stem cell transplantation. Comparison of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels in the experimental and CCl_4 groups. Hepatic function nearly recovered on day 7 ($^aP < 0.05$ compared to the CCl_4 group). ADSCs: Adipose-derived stromal cells; BMSCs: Bone marrow stromal cells.

gradually decreased on day 7 (Figure 3). These results suggest that cells transplanted *via* the intravenous route can be integrated in the liver parenchyma during the early stage of transplantation.

Both adipose-derived stromal cells and bone marrow stromal cells improved liver function

To address whether ADSCs and BMSCs can regenerate the injured mouse liver, these cell types were transplanted into liver-injured mice. Twenty-four hours after CCl_4 injection, mice exhibited serious liver injury. Biochemical parameters, including ALT and AST, were measured and stem cells were transplanted. The therapeutic abilities of the two experimental groups were compared at different time points. Following transplantation, the ALT and AST levels of the

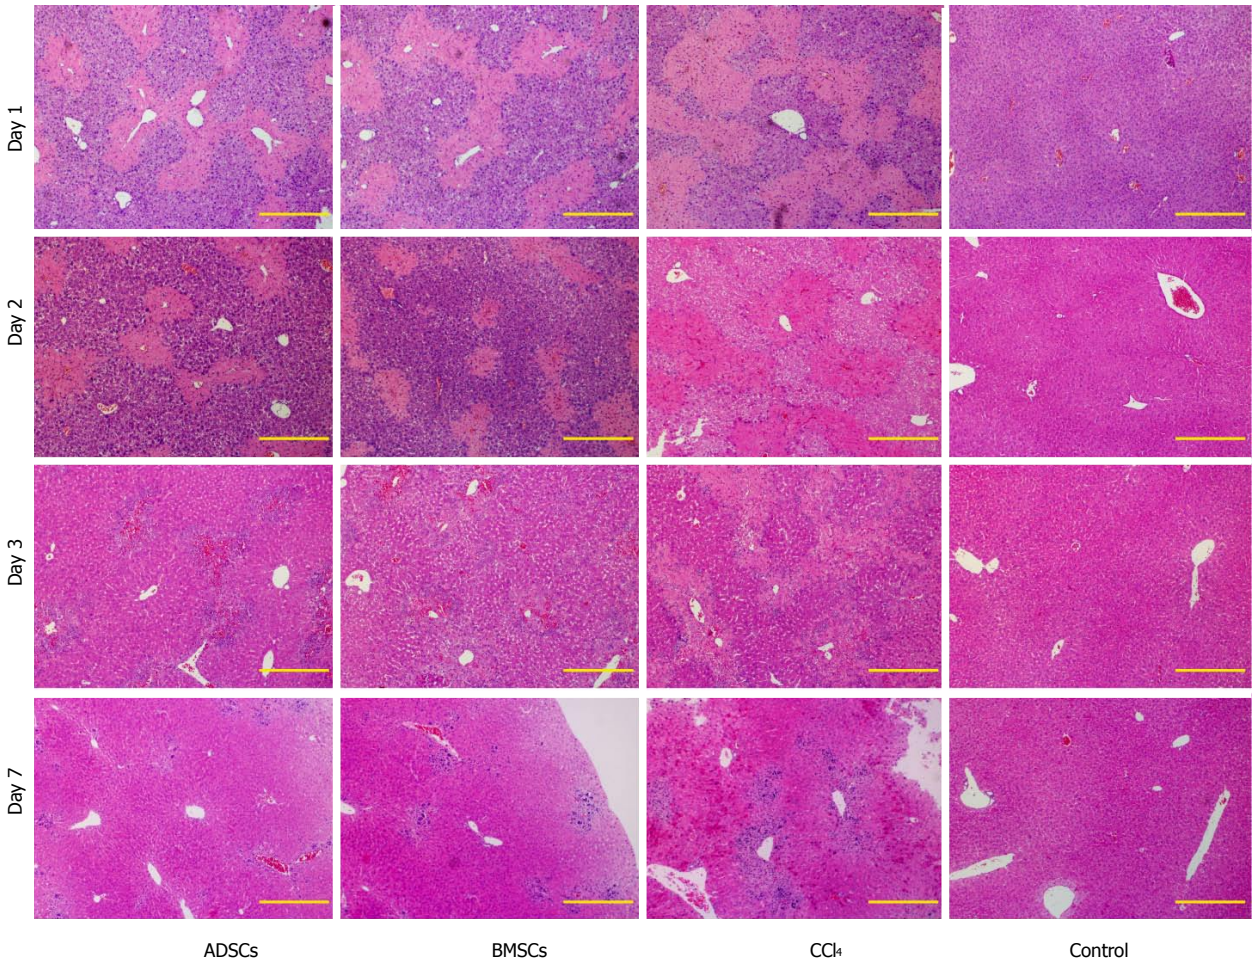

Figure 5 Hematoxylin and eosin staining in CCl_4-treated mice following mesenchymal stem cells transplantation. HE staining of liver tissue on different days following MSC transplantation (100 × magnification). The MSC groups showed smaller congested areas than the CCl_4 group. ADSCs: Adipose-derived stromal cells; BMSCs: Bone marrow stromal cells; HE: Hematoxylin and eosin; MSC: Mesenchymal stem cells; Scale bar: 200 μm.

experimental groups decreased significantly compared with the control group (Figure 4). HE staining revealed that the degree of injury was much weaker in the injured transplanted mice than in the injured, non-transplanted mice (Figure 5). On day 7, all of the experimental groups recovered histologically. However, damaged areas were still observed in the CCl_4 group. These observations indicated that ADSCs and BMSCs possessed similar repairing abilities against CCl_4-induced liver injury.

DISCUSSION

MSC transplantation is a promising alternative therapy for some liver diseases.

Availability of a large number of functional hepatocytes is essential for cytotherapy. However, primary hepatocyte cultures have been hindered by their short life span and the rapid loss of hepatic function *in vitro*[14]. MSCs have become a promising type of seed cell for liver transplantation for their multiple differentiation potential, high proliferation capacity, and plastic adherence properties. However, it is difficult to determine the ideal seed cells from different types of MSCs. In the present study, we established a novel isolation and culture protocol for mouse BMSCs that could provide a large number of BMSCs in a short period of time and share a similar multiple differentiation ability with ADSCs. We also established a new HCM that not only shortens the induction time but also produces a large number of hepatocyte-like cells. With the same induction system, ADSCs resembled BMSCs in term of hepatocyte differentiation potential both *in vitro* and *in vivo*.

A large quantity of ADSCs can be easily obtained by digesting adipose tissue derived from mice, rats, and humans with collagenase I[15]. However, it is difficult to obtain a large quantity of pure mouse BMSCs. We analyzed the conditioned medium method of Sun *et al*[16] and the compact bone method of Zhu *et al*[17], and developed a novel and reliable isolation and culture method that provides a large number of BMSCs in a short period of time. Compared to the method of Sun *et al*[16], the period required to obtain purified cells was shortened to 10-11 d. Compared to the method of Zhu *et al*[17], we omitted the digestion step of collagenase II. Additionally, the passage time was shortened to 2 d (compared to Zhu's twice per week). Compared to the

method for the isolation and culture of mouse BMSCs from bone marrow[18], our protocol not only shows less contamination of hematopoietic lineage cells, but also obtains a large number of BMSCs in a short period of time. The number of BMSCs obtained from five mice can reach 10^7 in 10-11 d. We believe that the reason for the rapid proliferation of cells is that neonatal mice exhibit better cell viability. Therefore, we developed a novel and easy method to isolate mouse BMSCs from tibia and fibula bone fragments.

Among the various hepatic differentiation systems, a one-step induction method has been most extensively applied[19]. Various cytokines and chemicals can be used to induce MSCs into hepatocyte-like cells. Current studies have reported that HGF, FGF4, EGF, OSM, Dex, aFGF, bFGF, DMSO, Vpp, and Vc can be applied for the hepatic differentiation of ADSCs[10,20]. Additionally, HGF, FGF4, EGF, OSM, Dex, ITS, trichostatin A (TSA), and L-glutamine have been applied for the hepatic differentiation of BMSCs[21-24]. In the present study, we used multiple factors, including HGF, FGF4, OSM, aFGF, bFGF, Dex, Vpp, ITS, and Vc, to develop a new induction system to promote the differentiation of MSCs. This hepatic induction system induced ADSCs and BMSCs into hepatocyte-like cells in only 10 d. However, a previously reported one-step induction system usually took more than two weeks[25-26]. This hepatic induction system shortens the induction time compared to the previously reported one-step system. Therefore, we consider it as an optimized one-step hepatic induction system.

We also identified induced hepatocyte-like cells from ADSCs and BMSCs in terms of morphology, as well as gene and protein expression. Our results revealed a similar hepatic differentiation potential of these two cell types *in vitro*. *In vivo*, we established an animal model of acute liver failure and proved that ADSCs and BMSCs engrafted into the injured liver showed similar therapeutic effects in the improvement of liver function. The results in our study suggest that BMSCs and ADSCs may serve as ideal seed cells for treating liver injury.

In conclusion, we developed a new protocol for the preparation of mouse BMSCs and established a new hepatic induction system. Our findings proved that ADSCs resembled BMSCs in the hepatic differentiation potential *in vitro* and *in vivo*. ADSCs can be obtained more easily and are less invasive than BMSCs. Therefore, ADSCs may be a more suitable seed cell type for use in cell transplantion or liver tissue engineering. In future experiments, we will explore the roles of ADSCs in liver tissue engineering.

COMMENTS

Background

Liver transplantation remains the only effective treatment for liver failure. However, its clinical application is limited by donor organs and immune rejection. To this end, hepatocyte transplantation and a bio-artificial liver support system are two potential surrogate complementary therapies for patients with liver failure. Hepatocyte-like cells can be induced from mesenchymal stem cells (MSCs) for xenotransplantation and have been demonstrated to perform hepatocyte functions in preclinical animal studies. However, the best type of MSCs has not yet been investigated and therefore it is important to screen for an ideal seed cell type for use in cell transplantation or a bio-artificial liver support system.

Research frontiers

MSCs are non-hematopoietic multipotent stem cells that can be isolated from multiple tissues, such as bone marrow, adipose tissue, cord blood, and amniotic fluid. Bone marrow stromal cells (BMSCs) are the most extensively studied and fertile stem cell source used in regenerative medicine and liver tissue engineering. More recently, adipose-derived stromal cells (ADSCs) were identified as another promising and extensively studied stem cells for use, especially in liver tissue engineering. Although both ADSCs and BMSCs can be induced into hepatocyte-like cells, there is no uniform culture system to evaluate their hepatic differentiation potential. Therefore, it is necessary to establish an ideal system to improve the efficiency of hepatic induction.

Innovations and breakthroughs

A new protocol for the preparation of mouse BMSCs and a new hepatic induction system were established. This study proved that ADSCs resembled BMSCs in the hepatic differentiation potential *in vitro* and *in vivo*. ADSCs can be obtained more easily and are less invasive than BMSCs. Therefore, ADSCs may serve as a more suitable seed cell type for use in cell transplantion or liver tissue engineering.

Applications

ADSCs are likely to serve as suitable seed cells for use in cell transplantion or liver tissue engineering.

Terminology

MSC transplant is a promising alternative therapy for some liver diseases. Availability of large number of functional hepatocytes is essential for cytotherapy. Both ADSCs and BMSCs can be induced into hepatocyte-like cells. Therefore, both ADSCs and BMSCs may be suitable seed cells for use in cell transplantion or liver tissue engineering.

Peer-review

In this paper, the authors investigated a novel method of generating differentiated hepatocytes from two sources of mesenchymal stem cells and tested their ability to recover liver damage in an experimental mouse model. The paper thus adressed an important question as stem cell therapy could help overcome current limitations of treatment for metabolic liver diseases and liver injury.

Abstract

AIM

To investigate whether fecal microbiota transplantation (FMT) prevents hepatic encephalopathy (HE) in rats with carbon tetrachloride (CCl_4)-induced acute hepatic dysfunction.

METHODS

A rat model of HE was established with CCl_4. Rat behaviors and spatial learning capability were observed, and hepatic necrosis, intestinal mucosal barrier, serum ammonia levels and intestinal permeability were determined in HE rats receiving FMT treatment. Furthermore, the expression of tight junction proteins (Claudin-1, Claudin-6 and Occludin), Toll-like receptor (TLR) 4/TLR9, interleukin (IL)-1β, IL-6 and tumor necrosis factor (TNF)-α was examined.

RESULTS

FMT improved rat behaviors, HE grade and spatial learning capability. Moreover, FMT prevented hepatic

necrosis and intestinal mucosal barrier damage, leading to hepatic clearance of serum ammonia levels and reduced intestinal permeability. The expression of TLR4 and TLR9, two potent mediators of inflammatory response, was significantly downregulated in the liver of rats treated with FMT. Consistently, circulating pro-inflammatory factors such as interleukin (IL)-1β, IL-6 and tumor necrosis factor-α were remarkably decreased, indicating that FMT is able to limit systemic inflammation by decreasing the expression of TLR4 and TLR9. Importantly, HE-induced loss of tight junction proteins (Claudin-1, Claudin-6 and Occludin) was restored in intestinal tissues of rats receiving FMT treatment.

CONCLUSION

FMT enables protective effects in HE rats, and it improves the cognitive function and reduces the liver function indexes. FMT may cure HE by altering the intestinal permeability and improving the TLR response of the liver.

Core tip: In this article, we first established a rat model of hepatic encephalopathy, and then carried on the fecal microbiota transplantation (FMT). Our results suggest that FMT can serve as a kind of new method for the treatment of hepatic encephalopathy, probably better than VSL#3.

INTRODUCTION

Hepatic encephalopathy (HE) is a common and serious disorder with a wide spectrum of neuropsychiatric abnormalities due to chronic and acute liver dysfunction[1]. HE is associated with poor quality of life and increased mortality, thus representing a major healthcare burden in patients with liver cirrhosis[2,3]. The estimated one-year survival rate is 42% after the first episode of overt HE, and the three-year survival rate is 23%[1,4,5]. Therefore, HE with cirrhosis is considered to have a poor prognosis for subjects who do not undergo liver transplantation. The death rate is substantially lower for patients who receive a transplant. The survival rate is more than 70% in the first 5 years after transplantation[1,6].

Although the pathogenesis of HE remains incompletely understood, gut-derived neurotoxin ammonia that accumulates in the central nervous system (CNS) is the most frequent precipitating factor[7-11]. In cases of normal hepatic function, ammonia enters the portal circulation of the liver and is subsequently converted to urea through the urea cycle[1].

Gut microbiota has emerged as a critical factor in the development of HE. Dysbiosis or an altered gut microbiota population promotes a systemic pro-inflammatory milieu, resulting in neuro-inflammation and ultimately neuronal dysfunction including HE[12-17]. Lactulose and lactitol, which target gut microbiota, have been demonstrated to be effective as first-line therapies for both acute and chronic HE. However, lactulose and lactitol have significant gastrointestinal side effects[18,19]. Furthermore, approximately 20% of patients with chronic liver failure and HE have been found to be non-responsive to lactulose treatment. A systemic review demonstrated that lactulose and lactitol failed to impart any survival benefit to cirrhotic patients with HE[20].

Probiotics (*e.g.*, VSL#3, a clinically tested probiotic formula consisting of Lactobacilli, Bifidobacteria, and Streptococci) contain living beneficial bacteria and have been shown to improve mental status and cognitive functioning. Therefore, probiotics may prevent HE recurrence by decreasing urease-producing bacteria populations and ammonia absorption while also increasing hepatic ammonia clearance[21]. Although probiotics are thought to have no adverse effects when used as long-term therapeutics, they are not widely utilized clinically due to the potential risk of introducing live bacteria into immunosuppressed patients. Therefore, the use of probiotics for cirrhotic patients with HE cannot be currently recommended, and rigorous clinical evaluation in randomized controlled trials is required[22-25].

Given the limitations of current HE therapy, research efforts are now aimed at improving existing treatments or developing novel therapies. Fecal microbiota transplantation (FMT) is rapidly being accepted as a viable, safe, and effective treatment for chronic gastrointestinal infections, recurrent inflammatory bowel diseases (IBD) and Clostridium difficile infection (CDI)[26-29]. It has also gained attention for its therapeutic potential for cardiometabolic, autoimmune, and other extra-intestinal conditions that were not previously considered to be associated with the intestinal microbiota[30-32]. However, whether FMT has a healing effect on HE has not been investigated.

In this study, we present *in vivo* evidence that FMT is effective for improving HE symptoms as evidenced by increased rat motor activity, spatial learning and memory following FMT. Moreover, FMT reduces systematic inflammation, leading to restored hepatic and intestinal dysfunction. Mechanically, FMT reduced liver expression of Toll-like receptor (TLR) 4 and

TLR9, which are two critical factors implicated in the accumulation of ammonia and regulating the levels of circulating pro-inflammatory mediators; therefore, FMT decreased liver inflammation and damage. Additionally, FMT recovered the expression of tight junction proteins such as Claudin-1, Claudin-6 and Occludin, resulting in attenuated intestinal permeability. Taken together, our study demonstrates for the first time the efficacy of FMT in the treatment of rats with HE and reveals the mechanisms underlying this process. Notably, we also provide an experimental basis for the potential use of FMT in HE patients.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats weighing 240-270 g were used for the experiments. Rats were fed regular chow and water ad libitum in cages placed in a room with a 12-h light/dark cycle at constant humidity and temperature (25 ℃). All of the animals received humane care according to the criteria outlined in the "Guide for the Care and Use of Laboratory Animals" prepared by The National Academy of Sciences and published by The National Institutes of Health.

Preparation of donor fecal material

The fecal material was collected and isolated as previously reported[33,34]. Briefly, approximately 30 g of fecal material was collected from a healthy female donor in a non-menstrual period with no history of hypertension, diabetes or cytomegalovirus, hepatitis or HIV infection. The volunteer also must not have presented with fever, abdominal pain, diarrhea, constipation, *etc*. In addition, the volunteer must not have used antibiotics, antiviral drugs and any drugs that may affect the function of the gut and bacteria within 2 wk of fecal matter donation. The volunteer was told to eat a liquid diet the day before the bacteria were extracted, and the fecal matter was then passed through 2.0-, 1.0-, 0.5- and 0.25-mm stainless steel laboratory sieves (WS Tyler, Mentor, OH) to remove undigested food and smaller particulate material. The resulting material passing through the 0.25-mm sieve was centrifuged at 6000 *g* for 15 min and homogenized in 150 mL of sterile normal saline. Glycerol (85%) was added to obtain a final concentration of 10%. The resulting fecal bacteria were resuspended and quantified by calculating the optical density (OD) relative to that of *Enterococcus faecalis* (*E. faecalis*) stored at -80 ℃.

Experimental design

The rat model of HE was established as previously described. Briefly, rats were given subcutaneous injections of 5 mL/kg of CCl_4 solution (a mixture of CCl_4 and peanut oil at a ratio of 2:3) twice a week and were fed 5% alcohol in drinking water with a week normal complete diet for 9 consecutive weeks. Control animals received normal saline. Nine weeks after injection, the rats were randomized into five groups (four rats per group) to receive saline, low-dose FMT (containing 2.7 billion fecal bacteria), moderate-dose FMT (containing 5.4 billion fecal bacteria), high-dose FMT (containing 7.1 billion fecal bacteria) or probiotics (VSL#3200 μL/d) for 3 wk. Each capsule of VSL#3 contained 112.5 billion freeze-dried bacteria (Streptococcus thermophilus, Bifidobacterium longum, Bifidobacterium breve, Bifidobacterium infantis, Lactobacillus acidophilus, Lactobacillus plantarum, Lactobacillus casei, and Lactobacillus bulgaricus) suspended in corn starch dissolved in 8.33 mL phosphate buffered saline (PBS). The rats received 200 μL/d of this solution (containing 2.7 billion CFU) *via* intestinal intubation. Prior to introducing an intestinal tube, rats were anesthesized and incised to allow duodenal exposure. Then a small cut was made in the duodenum, allowing a PE50 tube for implantation, followed by stitching the cut. The tube was made to pass into the air and stuffed with sterilized cotton for further administration.

Observations and measurement of rat behaviors

Rat behaviors were observed one week before or after administrations and recorded in an open field. Behaviors include mortality, body weight, motor activity, stools, hematochezia and infection. During the activity measurements, the animals had no access to food or chow. All studies were performed under strictly standardized conditions in a dark room for 30 min. The numbers of total movements, ambulatory movements, and vertical movements were separately recorded to reflect the motor activities of rats with hepatic failure. The motor activities were defined as zero in dead mice.

Morris water maze

HE rats were evaluated for spatial learning and memory capabilities using a Morris water maze as described previously. Two training trials a day were conducted on 3 consecutive days during the 8th week of the study. The experimental apparatus consisted of a cylindrical water tank (145 cm in diameter, 60 cm in height) filled with water maintained at 21 ± 1℃. The water was made opaque with black ink. A platform (10 cm in diameter) was submerged 2 cm below the water surface and placed at the midpoint of one quadrant. Room lights illuminated the pool, and the visual cues around the room (window, cabinets, furniture) were kept consistent. A video camera was placed above the center of the pool and connected to a video tracking system. During each training session, the rats were placed in the pool at a specified starting position and allowed to swim freely until they found the Morris water maze. The time required to escape (escape latency) was recorded. Rats that found the platform within 120 s were allowed to remain on it for 20 s

and were then returned to their home cages. If a rat did not reach the platform within 120 s, it was gently guided there by the experimenter, and allowed to stay on it for 20 s. The test was performed again at 12 wk to assess spatial cognitive function.

Histology examination of liver injury and intestinal damage

For histological examination, liver and distal ileum samples were fixed in 4% paraformaldehyde, dehydrated using graded ethanol, and then embedded in paraffin. The paraffin blocks were sectioned and stained with hematoxylin and eosin (HE) using standard histological techniques.

Measurement of intestinal permeability

Intestinal permeability was determined by Evans blue staining as previously described. Rats were anesthetized and transcardiacally perfused with Evans Blue dye. Colonic tissue was removed and maintained in formamide solution at 60℃ for 24 h, followed by centrifugation at 5000 r/min for 20 min. Optical density at 632 nm was measured and calculated.

Liver functional tests and serum ammonia level detection

Biochemical parameters were measured using standard clinical methods, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), serum albumin (ALB), total bilirubin (TBIL) and direct bilirubin (DBIL). Blood samples (0.5 mL) were collected from the portal and tail veins and analyzed with an automatic biochemical analyzer.

Enzyme-linked immunosorbent assay (ELISA) analysis of circulating pro-inflammatory mediators and stool proteins

For detection of interleukin (IL)-1β, IL-6 and tumor necrosis factor (TNF)-α, serum samples from each individual group were collected and separated from portal and tail veins, followed by analysis with ELISA kits according to the manufacturer's instructions (Sangon, Shanghai). For Calprotectin and alpha-1-antitrypsin (A1AT) detection, equal weight stools from each group were collected and dissolved in PBS and then separated by centrifugation for ELISA testing according to the manufacturer's instructions (Sangon, Shanghai).

Western blot analysis

Protein expression was determined in lysates of liver and intestinal tissues using rabbit anti-TLR4, anti-TLR9, anti-Claudin-1, anti-Claudin-6 and anti-Occludin antibodies (Abcam) diluted in blocking buffer (5% milk in 0.2% Tween 20/TBS, 4℃, overnight). The results were normalized to GAPDH expression (mouse anti-GAPDH, Abcam).

Statistical analysis

SPSS statistical software, version 19.0, was used for statistical analyses. The Pearson χ^2 test or Fisher's exact test was used to compare qualitative variables and Student's *t*-test was used for comparisons of quantitative variables. All statistical tests were two-sided. $P < 0.05$ was considered statistically significant

RESULTS

FMT significantly alleviates behaviors of rats with chronic liver failure-induced HE

Chronic liver failure-induced HE was induced in rats by treatment with carbon tetrachloride-alcohol as previously described. All rats treated for 9 wk showed similar symptoms of HE, such as impaired spontaneous movement, cachexia and somnolence, when compared with saline-treated control mice. Histological examination verified the successful establishment of the rat HE model. The rats were then randomly divided into five groups including the model group, the probiotic-treated group (termed VSL) and the FMT treated groups across three doses (termed FMT-L, FMT-M and FMT-H for the low, mid and high FMT doses, respectively). Infections were observed during the experimental period; one rat each in the VSL, FMT-L, FMT-M and FMT-H groups died from infection. Data from these rats were excluded from the final statistical analysis. The behaviors of each group were observed clinically until the end of the experiment and were compared for mortality rate and the clinical grade by the scoring method represented in Table 1 and as previously described[35,36]. Significant weight loss and decreased appetite were observed in the control group relative to the other treated groups, whereas rats treated with either probiotics or any of the three FMT doses, but not the model group, started to increase food intake and gain weight during the first week. The feeding behavior of rats in the high-dose FMT treatment group normalized during the second week (Figures 1 and 2). Together, the data presented here demonstrate that FMT enables the healing of chronic liver failure-induced HE.

FMT markedly improves learning and memory functioning in the rat HE model

The Morris water maze was used to evaluate the spatial learning of rats from different treatment groups. The Morris water maze test lasted six days. The first five days of acquisition training with an invisible platform were followed by 4 d of reversal training with an invisible platform. A probe trial was then carried out with no escape platform. Finally, four trials were conducted using the visible platform.

In contrast to the control group, the total travel distance was significantly decreased in the model group ($P = 0.014$), whereas the VSL or FMT treated

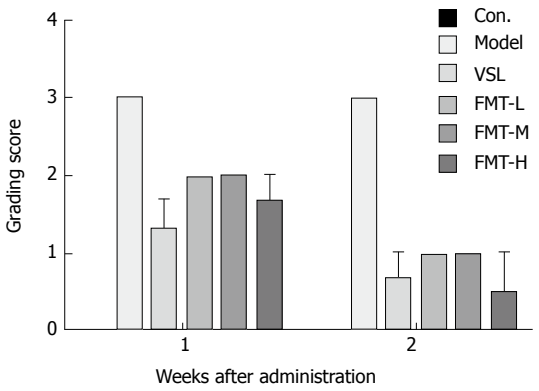

Figure 1 Animal behavior score after fecal microbiota transplantation. FMT: Fecal microbiota transplantation.

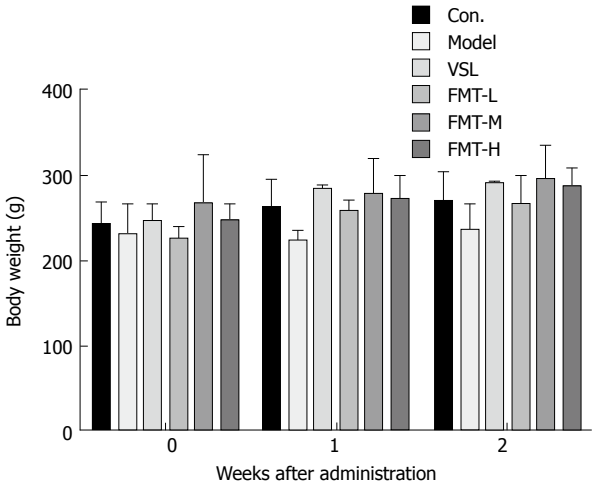

Figure 2 Fecal microbiota transplantation treatment enables body weight gain. FMT: Fecal microbiota transplantation.

rats showed longer travel distances compared with the model group ($P < 0.003$, Figure 3A). The swim speed was remarkably reduced in the model group, whereas it was markedly increased in rats that received probiotics or FMT (Figure 3B). The VSL and FMT groups exhibited twice as many line crossings than did the model group ($P < 0.05$, Figure 3C). Although crossing times increased along with FMT dose, this relationship did not reach statistical significance among FMT-L, FMT-M and FMT-H. Collectively, these observations indicate that FMT is capable of improving learning and memory deficits in the rat HE model.

FMT restores hepatic function in a dose-dependent manner

Since FMT effectively improved the behavior and spatial cognitive capability of rats with HE, we next determined whether FMT affected rat hepatic function in the HE model. It was noted that FMT improved hepatic function in a dose-dependent manner as revealed by hematoxylin and eosin staining.

Hepatic function was examined by liver histology and serological parameters including ALT, AST, ALB, TBIL and DBIL. All of these parameters were significantly elevated in the model group ($P < 0.0001$), which was indicative of severe liver damage. However, rats that received probiotics or FMT showed reduced levels of ALT, AST, ALB, TBIL and DBIL ($P < 0.0001$) compared with the model rats (Figure 4A-E). Notably, the FMT-H group revealed a marked decrease in these parameters when compared with FMT-L and FMT-M groups ($P < 0.0002$), suggesting a dose-dependent improvement in hepatic function. Moreover, liver hepatomegaly and severe liver disease were clearly observed on the liver surfaces of the model group whose livers also turned brown, indicating liver damage. On the contrary, liver necrosis of probiotic-treated rats was dramatically relieved. When treated with FMT, the livers showed decreased necrosis as the concentration of FMT increased (Figure 4F). However, the liver color was still brown. In agreement with altered liver morphology, liver histology analysis suggested that inflammation and spotty or patchy necrosis were observed in the model group, whereas none of these manifestations were observed in the control group. Livers from rats that received probiotics or FMT showed less necrotic areas than did the model rats (Figure 4G-L).

FMT prevents intestinal mucosal barrier dysfunction

The intestinal barrier controls physical and biochemical activities to maintain a balance with the external environment. Patients with liver cirrhosis develop a series of alterations in the intestinal barrier associated with the severity of liver disease that ultimately increase intestinal permeability. We therefore examined whether FMT could protect intestinal integrity in the HE model. As showed in Figure 5A, the intestinal permeability tripled in the model group compared with the control group ($P < 0.0001$), as detected by Evans blue extravasation method. FMT treatment remarkably decreased the intestinal permeability ($P < 0.0001$), whereas the VSL-treated group appeared to have even less intestinal permeability. Histological observations suggested mild edema and mucosal separation in the model group. FMT-treated HE rats displayed decreased edema, mucosal damage and inflammatory infiltration. Similar effects were observed when the HE rats were treated with probiotics (Figure 5F). Intestinal permeability was not different between the VSL and FMT treatment groups, irrespective of dose. Taken together, these findings support a protective role for FMT in maintaining intestinal integrity and attenuating the mucosal barrier dysfunction induced by HE. In accordance with altered intestinal permeability, expression ofA1AT in the stool was elevated in the model rats, which was indicative of excessive gastrointestinal protein loss. A1AT levels decreased in the rats that received probiotics or FMT, suggesting improved intestinal permeability and reduced gastrointestinal protein loss (Figure 5B).

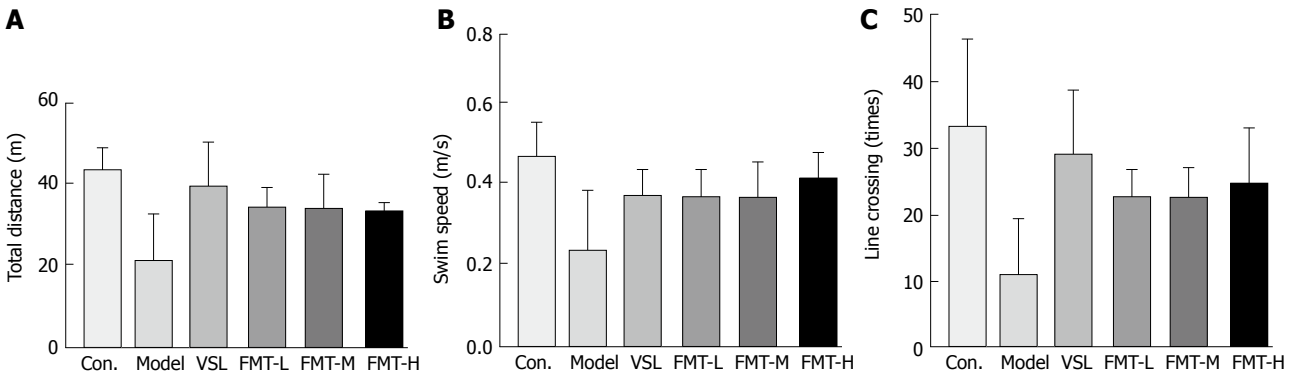

Figure 3 Cognitive function before and after VSL#3 or fecal microbiota transplantation treatment. A: FMT treatment increases rat total swim distance as revealed by the Morris water maze; B: Rats that received FMT showed improved swim speed; C: The number of line crossings in the FMT group was significantly increased relative to that of the model group. FMT: Fecal microbiota transplantation.

Table 1 Animal behavior scoring

Clinical score	Definition
0	Normal behavior
1	Mild lethargy
2	Decreased motor activity, poor gesture control, diminished pain perception
3	Severe ataxia, no spontaneous righting reflex
4	No righting reflex, no reaction to pain stimuli
5	Death

Elevated Calprotectin levels in the stool, which are commonly used in the clinic to measure the intestinal inflammation index, were found to be reversed by probiotics and FMT, implying attenuated intestinal inflammation (Figure 5C). Overall, the data presented here indicate that FMT preserves intestinal mucosal barrier function.

FMT attenuates serum ammonia levels and the systemic proinflammatory response

It is well known that ammonia serves as the most important precipitating factor leading to HE. In addition, accumulating evidence has demonstrated that inflammation, including systemic inflammation, neuroinflammation and endotoxemia, acts concomitantly with ammonia to drive HE pathogenesis in cirrhotic patients. We next determined whether FMT affects serum ammonia levels and proinflammatory responses. Serum ammonia levels and proinflammatory cytokines including IL-1β, IL-6 and TNF-α were detected using Berthelot reaction and ELISA assay. The mean ammonia level from the portal vein was 12.37 μmol/L in the control group, which was increased to 36.28 μmol/L in HE rats. When the HE rats were given probiotics, the mean serum ammonia level decreased to 22 μmol/L. FMT therapy resulted in a notable decline in ammonia levels ($P < 0.0001$). In particular, high-dose FMT administration was almost as effective as probiotic treatment in decreasing ammonia levels. Moreover, similar effects were observed when the ammonia level was evaluated from the tail vein, indicating that FMT enables effective clearance of serum ammonia and ultimately improves clinical symptoms (Figure 6A). Consistent with the decreased serum ammonia concentration, circulating levels of proinflammatory mediators such as IL-1β, IL-6 and TNF-α were elevated in the model group and reduced in groups that received probiotics or FMT treatment ($P < 0.0001$, Figure 6B-D). Significant differences in proinflammatory mediator levels were observed among the groups that received different FMT doses ($P < 0.002$). The data described here demonstrate a systematic relief of HE severity in rats, and it was clear that systemic inflammation, but not ammonia, was strongly correlated with increasing grades of HE.

FMT protects HE progression through distinct mechanisms

Although FMT has been shown to be effective in a rat model of HE, leading to improved hepatic and intestinal function and impaired systemic inflammation, the underlying mechanisms of these processes have not been investigated. Liver TLRs are reported to be important determinants of HE severity and are intimately related to arterial ammonia concentration and levels of circulating pro-inflammatory mediators[37-39]. Additionally, tight junction proteins (Occludin and Claudins) are implicated in the regulation of intestinal permeability[40,41].

Therefore, we examined the protein expression levels of TLR4 and TLR9 in the liver tissues, and the expression levels of Claudin-1, Claudin-6 and Occludin were analyzed in the intestinal tissues (Figure 7). As expected, liver dysfunction stimulated the expression of TLR4 and TLR9 in the liver, which was downregulated in liver tissue from rats treated with probiotics and FMT, indicating that FMT can limit systemic inflammation by decreasing the expression of TLR4 and TLR9. TLR4 and TLR9 are potent mediators that promote the expression of pro-inflammatory factors such as IL-6 and TNF-α. Accordingly, the expression of Claudin-1, Claudin-6 and Occludin was lost in the intestinal tissues from the model rats,

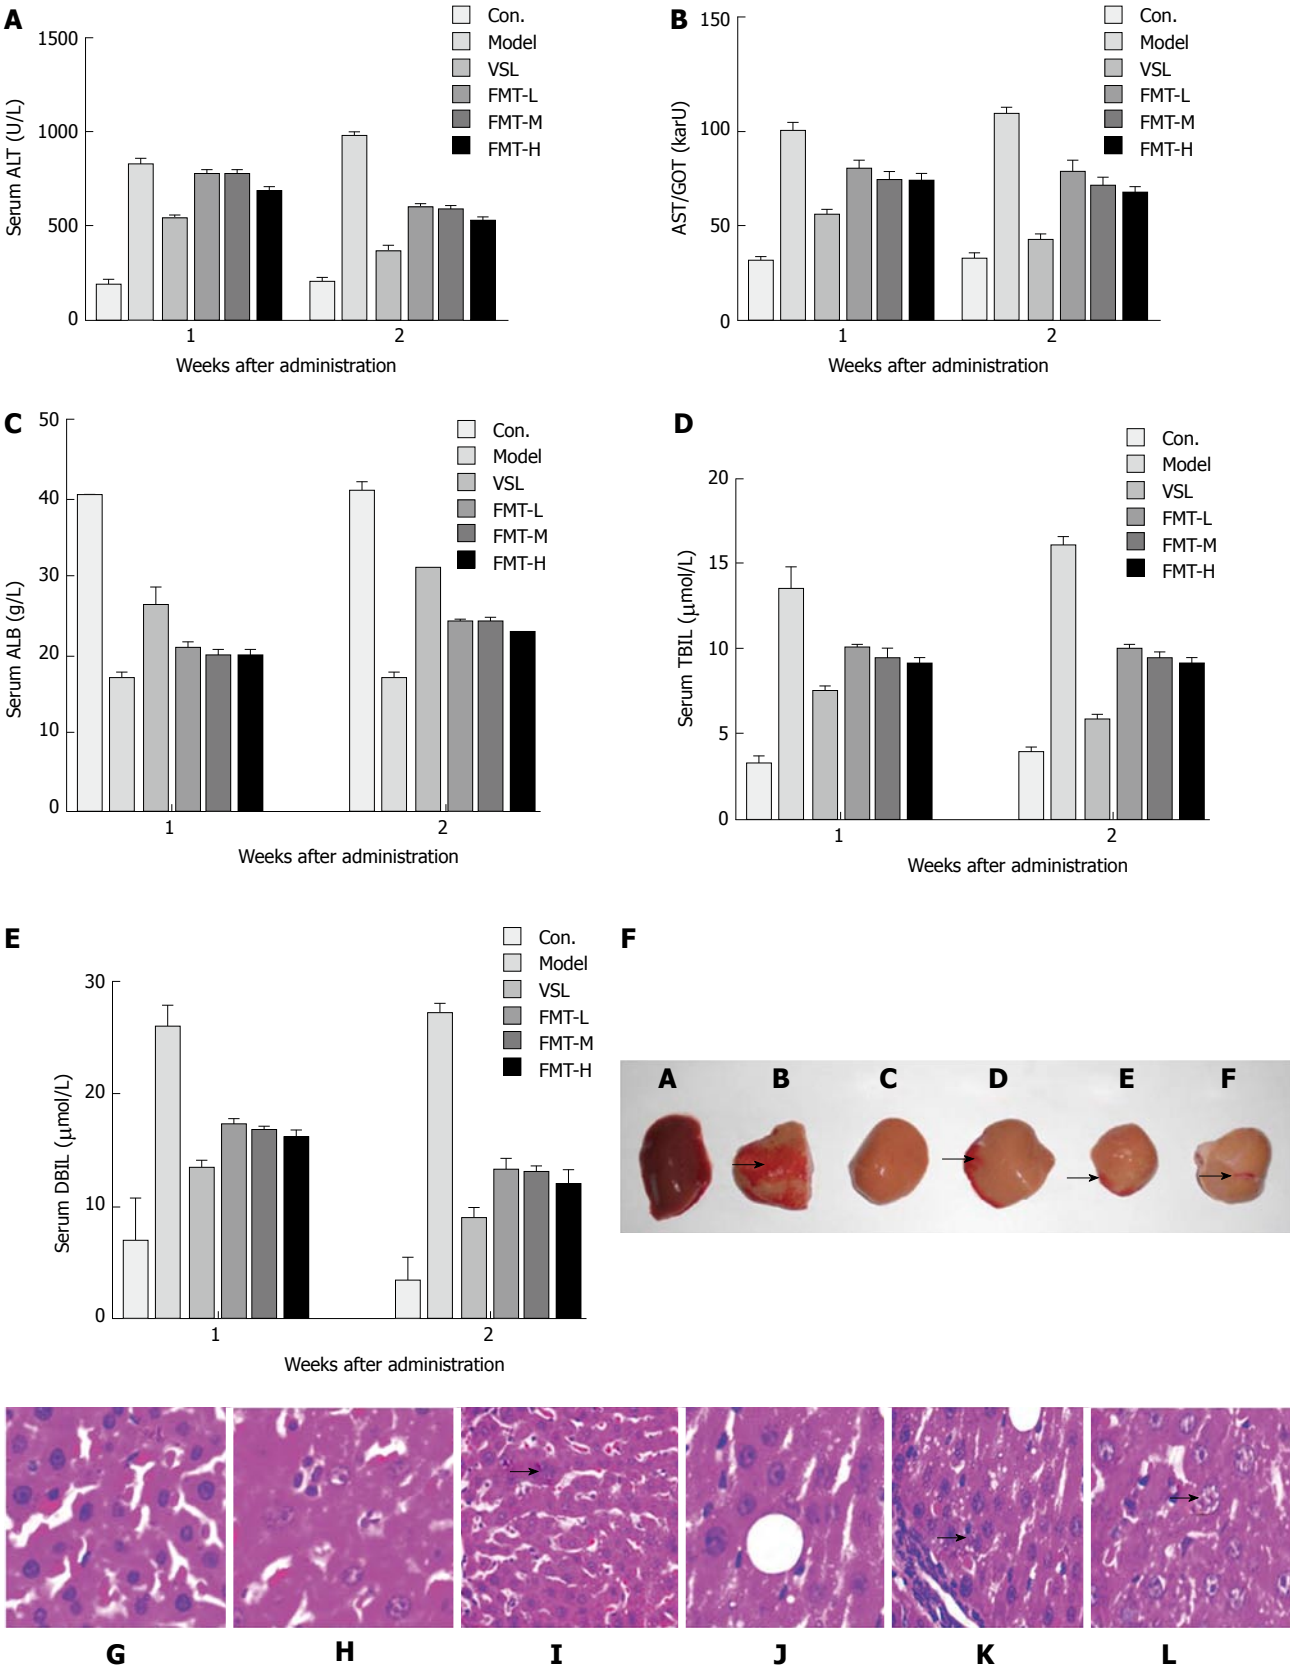

Figure 4 The changes of hepatic function and hepatic pathology before and after treatment with VSL#3 or fecal microbiota transplantation. Figure 5 Expression of proteins related to intestinal permeability and intestinal wall stained with hematoxylin and eosin. A: FMT reduced intestinal permeability in HE rats as evidenced by Evans blue staining; B: Stool A1AT levels in rats were decreased following FMT treatment, which was indicative of improved intestinal permeability and reduced gastrointestinal protein loss. The stools in the indicated groups were collected and diluted in PBS and analyzed by ELISA; C: Stool Calprotectin levels in rats with HE were decreased following FMT treatment, which was indicative of reduced intestinal inflammation. Stools in the indicated groups were collected and diluted in PBS and analyzed by ELISA; D-I: Five-micron thick tissue sections were obtained and stained with hematoxylin and eosin for microscopic examination. The data shown are representative of hematoxylin and eosin staining in the indicated groups, but there were no differences among the tissues. FMT: Fecal microbiota transplantation.

suggesting impaired tight junction function. Tight junction protein loss was reversed by probiotic as well as FMT treatment. High dose FMT appeared to induce more expression of Claudin-1, Claudin-6 and Occludin than did other doses of FMT (Figure 6A and B). In summary, these data demonstrate that FMT delays HE progression in rats by reducing the liver expression of TLR4 and TLR9 and triggering tight junction protein expression, resulting in attenuated systemic inflammation and decreased intestinal permeability.

DISCUSSION

HE is a potentially reversible spectral neuropsychiatric complication caused by acute and chronic liver diseases, significantly affecting the prognosis. Although decades of clinical practice have demonstrated that nonabsorbable disaccharides, such as lactulose or lactitol, are effective for approximately 80% of HE patients, little survival benefit in cirrhotic HE patients has been observed following treatment with these agents. Probiotics, thought to have a therapeutic effect with no adverse effects, are not widely used clinically due to the potential risk of introducing live bacteria[42]. Acute liver organ shortage and increased morbidity have expanded research efforts aimed at improved treatment[28,43].

FMT is the introduction of a fecal suspension derived from a healthy donor into the gastrointestinal tract of a diseased individual. The clinical application of FMT has grown significantly within the last decade and is now gaining mainstream acceptance as a valuable, low cost procedure with apparently safe, and readily available materials, especially for the treatment of recurrent or refractory CDI[26,28,29]. Whether FMT is effective for HE patients has not yet been investigated. Here we provide experimental evidence that FMT has potent protective effects in improving motor activity in a rat model of HE and was comparable to probiotic administration. A significant negative correlation was found between the FMT dose and behavioral score. In addition, FMT has been shown to enhance spatial learning and memory as revealed by the Morris water maze assay. Since FMT effectively improves behavior and spatial cognitive capabilities, we next determined whether it affected hepatic function in

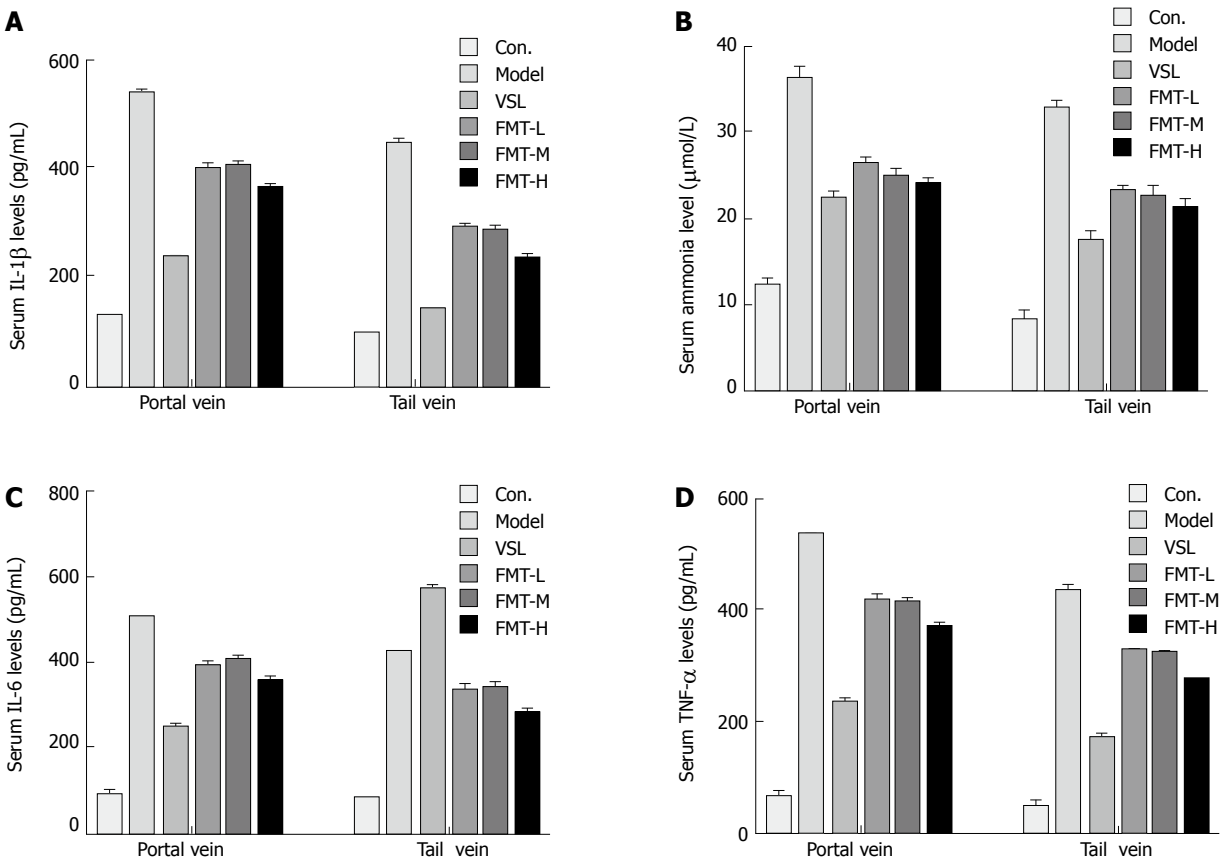

Figure 6 The changes of ammonia levels and inflammatory cytokines in plasma from the portal or tail veins. A: Plasma ammonia levels decreased significantly upon FMT treatment. Blood samples were collected from the portal and tail veins in the indicated groups and analyzed with an automatic biochemistry analyzer; B: Decreased circulating IL-1β was observed in the FMT groups. Blood samples were collected from the portal and tail veins in the indicated groups and analyzed by ELISA; C: Serum IL-6 was reduced in the FMT-treated groups. Blood samples were collected from the portal and tail veins in the indicated groups and analyzed by ELISA; D: Serum TNF-α was downregulated in the FMT-treated groups. the rat HE model. Hepatic function was examined by liver histology and serological parameters. Rats that received FMT showed reduced levels of ALT, AST, ALB, TBIL, and DBIL ($P < 0.0001$) compared with the model rats. Notably, the FMT-H group revealed a marked decrease in these parameters when compared with the FMT-L and FMT-M groups ($P < 0.0002$). Moreover, liver necrosis in the FMT-treated rats was dramatically relieved compared with the model rats, suggesting a dose-dependent improvement in hepatic function. However, in general, the levels of cognitive function of rats that received FMT were altered more than other indicators.

Alterations in the intestinal barrier were associated with the severity of liver disease, leading to increased intestinal permeability[44-46]. We therefore examined whether FMT could protect against the intestinal permeability induced by HE. FMT treatment remarkably decreased the intestinal permeability ($P < 0.0001$), whereas histological observations suggested that FMT treatment in HE rats displayed decreased edema, mucosal damage and inflammatory infiltration. In accordance with decreased intestinal permeability, A1AT levels in the stool were reduced following FMT, suggesting improved intestinal permeability and reduced gastrointestinal protein loss. Elevated Calprotectin levels in the stool were also found to be reversed by FMT, implying that FMT prevents intestinal mucosal barrier dysfunction. Furthermore, FMT was found to attenuate serum ammonia levels and impair systematic inflammation as demonstrated by reduced proinflammatory cytokines including IL-1β, IL-6 and TNF-α, indicating a systematic relief of HE severity in rats. It was clear that systemic inflammation, but not ammonia, was strongly correlated with increasing grades of HE. Taken together, the data in present study clearly show a potent healing effect for FMT in the rat HE model. Next we tried to determine the possible mechanisms underlying the protective functions of FMT. It has been widely accepted that an impaired gut-liver-brain axis in patients with liver disease is the leading cause of complications including HE. In HE patients, bacterial translocation and increased intestinal permeability are frequently found, the latter of which promotes bacterial translocation, such as migration of microbes or their products including

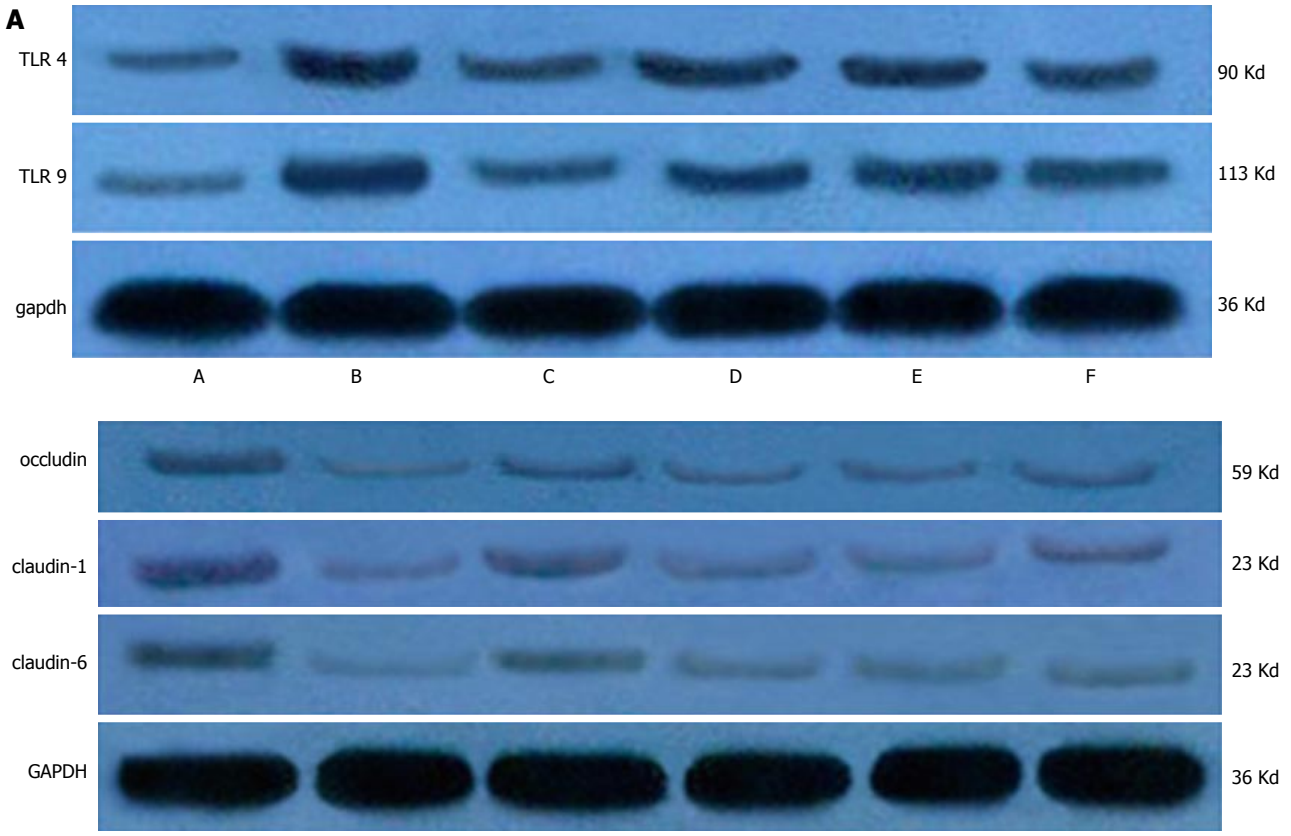

Figure 7 The expression of tight junction proteins in intestinal wall and Toll-like receptors. A: FMT induced the downregulation of liver TLR4 and TLR9 expression in a dose-dependent manner; B: FMT improved intestinal permeability by restoring the expression of Claudin-1, Claudin-6 and Occludin. FMT: Fecal microbiota transplantation.

pathogen-associated molecular patterns (PAMPs), the natural ligands for TLRs[40]. Liver expression of TLR4 and TLR9 is a critical determinant of HE severity, triggers the inflammation cascade and is intimately related to arterial ammonia concentration and circulating proinflammatory mediators such as IL-1β, IL-6 and TNF-α. We therefore evaluated the levels of liver TLR4 and TLR9 and circulating IL-1β, IL-6 and TNF-α in the HE model and FMT-treated rats.

Our data here suggest that VSL treatment efficiently reduced circulating IL-1β and TNF-α but not IL-6, a well-established independent risk factor for HE that was negatively associated with cognitive functions in HE patients[47-49]. Serum IL-6 was more evidently decreased in the FMT group than the VSL group in our study, which was consistent with more improved spatial learning and motor activity, suggesting that FMT is more effective than VSL, at least partially. Lata *et al*[50] also reported the limited effectiveness of VSL for HE.

Note that our study was the first to provide experimental data for potential use of FMT for HE, yet more accurate investigations are supposed to be done for optimized usage of FMT. Instead, VSL is commercially available with more detailed study.

FMT significantly reduced the liver expression levels of TLR4 and TLR9 and proinflammatory mediators, suggesting that FMT improves HE symptoms by impairing liver inflammation and reducing systemic inflammation. Importantly, the expression of tight junction proteins Claudin-1, Claudin-6 and Occludin was increased in the intestinal tissues of rats that were given FMT, indicating improved intestinal mucosal barrier function. The limitation of this study was the similar infection rate observed between the probiotics group and the FMT group. Our experiment still cannot fully explain whether FMT is superior to VSL#3 or not, which requires more experimental or clinical evidence.

Collectively, our study provided experimental evidence for the first time that supports an FMT-enabled protective role in treating HE rats and revealed the mechanisms behind FMT function, thus providing a basis for potential clinical application of FMT in HE patients.

COMMENTS

Background

Hepatic encephalopathy (HE) is a disease of liver dysfunction, and there is currently no effective therapy for treatment of this condition. To all knowledge, gut microbiota has emerged as a critical factor in the development of HE. Fecal microbiota transplantation (FMT) has been confirmed to treat some diseases. However, the effect of FMT on HE has not been researched deeply.

Research frontiers

Previous clinical evidence has shown that many diseases of the digestive tract, including liver diseases, have intestinal flora abnormalities, while FMT

can improve the composition and quantity of intestinal bacteria to achieve therapeutic purposes.

Innovations and breakthroughs

This is the first experimental study to confirm that FMT can be used to treat hepatic encephalopathy, and it also reflects the superiority of FMT relative to VSL#3.

Applications

According to the results of the article, FMT has the potential to become a new method for treating hepatic encephalopathy. At the same time, our results suggest that FMT has special advantages in some areas, providing more possibilities for further searching for new targets for treatment of hepatic encephalopathy.

Terminology

FMT is the introduction of a fecal suspension derived from a healthy donor into the gastrointestinal tract of a diseased individual. Initially as a treatment for Clostridium difficile infection, it has been shown to be effective in many diseases of the human body.

Peer-review

This is a very interesting paper about FMT for HE. The authors demonstrated that FMT has good effects in improving intestinal barrier function, by regulating the expression of tight junction proteins (Claudin-1, Claudin-6 and Occludin). Therefore, FMT has a protective role in treating HE.

Abstract

AIM

To investigate the protective mechanism of mitofusin-2 (Mfn2) in rat remote ischemic perconditioning (RIC) models and revalidate it in alpha mouse liver-12 (AML-12) hypoxia cell lines.

METHODS

Sprague-Dawley rats were divided into three groups (n = 6 each): sham, orthotopic liver transplantation and RIC. After operation, blood samples were collected to test alanine aminotransferase and aspartate aminotransferase. The liver lobes were harvested for histopathological examination, western blotting (WB) and quantitative real-time (qRT)-PCR. AML-12 cell lines were then subjected to normal culture, anoxic incubator tank culture (hypoxia) and anoxic incubator tank culture with Mfn2 knockdown (hypoxia + Si), and data of qRT-PCR, WB, mitochondrial membrane potential (ΔΨm), apoptosis, endoplasmic reticulum Ca^{2+} concentrations and mitochondrial Ca^{2+} concentrations were collected.

RESULTS

Both sham and normal culture groups showed no injury during the experiment. The RIC group showed amelioration of liver function compared with the orthotopic liver transplantation group (P < 0.05). qRT-PCR and WB confirmed that Mfn2-mitochondrial Ca^{2+} uptake 1/2 (MICUs) axis was changed (P < 0.005). In AML-12 cell lines, compared with the hypoxia group, the hypoxia + Si group attenuated the collapse of ΔΨm and apoptosis (P < 0.005). The endoplasmic reticulum Ca^{2+} decrease and mitochondrial Ca^{2+} overloading observed in the hypoxia group were also attenuated in the hypoxia + Si group (P < 0.005). Finally, qRT-PCR and WB confirmed the Mfn2-MICUs axis change in all the groups (P < 0.005).

CONCLUSION

Mfn2 participates in liver injury in rat RIC models and AML-12 hypoxia cell lines by regulating the MICUs pathway.

Key words: Remote ischemic per-conditioning; Ischemia-reperfusion injury; Ca^{2+}; Mitofusin-2; Mitochondrial Ca^{2+} uniporter

Core tip: Compared to the orthotopic liver transplantation, the remote ischemic perconditioning (RIC) model can significantly improve liver functions. But, knowledge of its mechanism remains largely unknown. This research is the first to prove the protective mechanism of the mitofusin-2-mitochondrial Ca^{2+} uptake 1/2 axis by affecting the metabolism of intracellular calcium in the RIC model of liver transplantation and to revalidate it in alpha mouse liver-12 hypoxia cell lines.

INTRODUCTION

Liver transplantation (LT) has become an important countermeasure for end-stage liver disease[1]. Ischemia-reperfusion injury (IRI) is one of the severe complications of LT, leading to graft dysfunction and thus increasing the morbidity and mortality[2-4]. Our previous studies confirmed that ischemia preconditioning (IPC) can effectively alleviate IRI by reducing hepatic enzymatic leakage, leukocyte infiltration and apoptosis formation[5,6]. However, because of its traumatic nature and ethical reasons, its application has failed to develop extensively[7]. Remote ischemic perconditioning (RIC) was first proposed by Przyklenk in 1993, and compared with IPC, it is a temporary ischemic treatment for distant organs and plays a protective role without damaging the target organs[8]. We have optimized the application of RIC and proved that the PI3K/Akt/eNOS/NO pathway could reduce the damage[9,10].

Mitofusin-2 (Mfn2), localized in the outer membrane of the mitochondria, maintains the network stability of mitochondria by participating in mitochondrial fusion and fission[11]. Ca^{2+} is an important intracellular signaling pathway, involved in important pathophysiological functions such as maintenance of biological potential, cell growth/proliferation regulation and apoptosis regulation[12-15]. Vasington *et al*[16] discovered mitochondrial Ca^{2+} uptake 1/2 (MICUs) in 1962. They used two Ca^{2+}-binding EF hands to sense Ca^{2+} concentration, thereby maintaining mitochondrial Ca^{2+} stability, which were considered as "gatekeepers" for mitochondrial Ca^{2+} influx[17-20]. Furthermore, they are mediated by the mitochondrial Ca^{2+} uniporter (MCU) and form an MCU protein complex together with MCU, MICU-1 and MICU-2[21,22]. In our previous

work, we also observed that Mfn2 induced apoptosis in HCC cells due to down-regulation of the MICUs gatekeepers[11].

There is little information about relationships between the protective effect of RIC and the Mfn2-MICUs axis during LT. Ca^{2+} plays an important role in apoptosis. In our previous RIC experiment, compared with the orthotopic liver transplantation (OLT) group, the RIC group showed decreased apoptosis. In the present study, we hypothesized and verified whether RIC model *via* Mfn2-MICUs axis has a protective effect for LT. As it is hard to perform gene knockout operations using primary cells, genetically engineered rats are expensive and the experiment is time-consuming, we designed the use of alpha mouse liver-12 (AML-12) hypoxia cell lines to simulate the RIC model and to revalidate it to prove our hypothesis.

MATERIALS AND METHODS

Rat sham, OLT and RIC models

All experimental protocols were conducted in accordance with the Animal Research: Reporting *in vivo* Experiments (ARRIVE) guidelines (http://www.nc3rs.org/ARRIVE). Adult male Sprague-Dawley rats weighing 250-300 g were chosen, placed in standard environment, and allowed *ad libitum* access to food and water. Thirty rats (including 12 donors) were randomly allocated to three groups (n = 6 in each group): sham, OLT and RIC. The following operations were performed: After fasting for 12 h, all rats were anesthetized for 3 h by intraperitoneal injection with 4% chloral hydrate (Shanghai Guchen Biological, China).

In the OLT group, the modified method of Kamada was adopted[23]. Donor liver was obtained, and cold physiological saline containing 25 U/mL heparin was used to perfuse the graft liver through portal vein and stored in 0-4 ℃ cold saline for about 45 min before the graft was transplanted into the recipient. After the suprahepatic inferior vena cava and portal vein were anastomosed by cuff method, the liver was reperfused along with the ligation of the hepatic artery. Then, the infra-hepatic inferior vena cava was connected, and common bile duct was reconstructed by tying the duct over a stent. Physiological saline (1 mL) was injected *via* the dorsal penile vein of the recipient after operation in order to prevent acid-base imbalance.

In the RIC group, the method used in our previous study was adopted. In the recipients who underwent OLT, hindlimb ischemia (using a standard tourniquet appending 1 kg weight to both legs) and reperfusion was performed for three 5-min cycles starting at the anhepatic phase[10] (Figure 1). After recovery from anesthesia, the rats allowed free access to sterile water and standard diet.

In the sham group, the abdomen was opened after 70 min, and then closed in order to acquire the mean time of the total ischemia in the OLT/RIC group (2-min warm ischemia, 45-min cold ischemia, and 70-min total ischemia).

Collection of liver lobe and blood samples

Sham group rats were euthanized after anesthesia. After 3 h of blood flow into the recipient's portal vein, euthanasia was performed in OLT and RIC groups. Blood samples were drawn from the portal vein and then centrifuged for 15 min at 3000 × g, and serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured to assess liver function (7600 automatic analyzer; Hitachi, Japan). Some of the liver lobes were kept in formalin solution for histopathological examination, and the other parts of the lobes were used for western blotting (WB) and PCR studies.

Quantitative real-time (qRT)-PCR

qRT-PCR was used to detect the level of mRNA expression (Table 1). Total RNA was extracted from the previous phase of the experiment (liver lobes and cell lines) using Trizol reagent (Thermo Fisher Scientific, United States) and PrimeScript RT Reagent Kit with gDNA Eraser (Takara Bio, Japan) for reverse transcription to cDNA. Following the protocol, we performed qRT-PCR in a total volume of 10 μL with 7900Fast (Applied Biosystems Inc, United States) to test the efficiency of small interfering (si)RNA in the hypoxia + Si group. The mRNA levels of Mfn2, MCU, MICU-1 and MICU-2 in the three model groups of sham, OLT and RIC and three cell line groups of normal culture (NC), hypoxia and hypoxia + Si were compared.

WB

WB was used to detect the level of protein expression of Mfn2, MCU, MICU-1, MICU-2 and β-actin. Total proteins were extracted from the previous phase of the experiment (liver lobes and cell lines). Cells and tissues (the liver tissues had first been ground in liquid nitrogen) were transfected after incubation in RIPA lysis buffer (Thermo Fisher Scientific) supplemented with protease inhibitor cocktail (Thermo Fisher Scientific) for 1 h on ice and then underwent ultrasonic oscillation crushing (Shanghai Experimental Instruments, China) for three 5-s cycles on ice. After centrifugation (14000 × g, 4 ℃, 15 min), the supernatant was collected for protein concentration measurement by Bicinchoninic Acid Protein Assay Kit (Pierce Biotechnology, United States).

The denatured protein samples (30 μg/10 μL) were separated by SDS-PAGE (Invitrogen, United States) and transferred to polyvinylidene fluoride membranes. Then, the membranes were blocked with 5% non-fat milk (BD Biosciences, United States) dissolved in 30 mL Tris-buffered saline with Tween (TBST) for 2 h at room temperature. Using primary antibodies against β-actin/Mfn2 (1:1000; Abcam, United States),

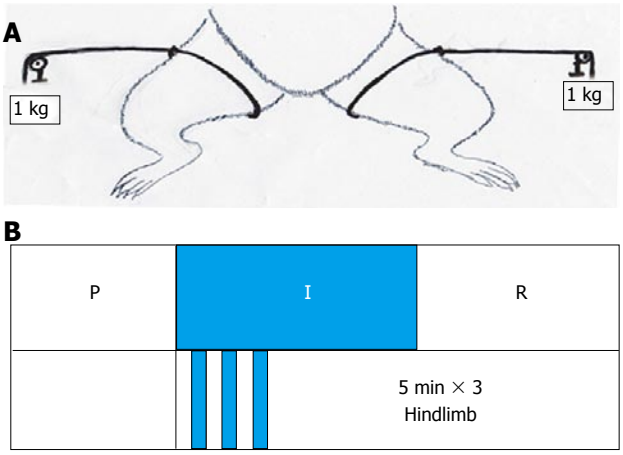

Figure 1 Remote ischemic perconditioning models. A: Tourniquet was used for ligature of each hindlimb with 1 kg additional weight; B: P - Perfusion phase, I - Ischemic phase, R - Reperfusion phase. The remote ischemic perconditioning group underwent orthotopic liver transplantation with hindlimb ischemia and reperfusion for three 5-min cycles starting at the beginning of the anhepatic phase.

MCU/MICU-1 (1:1000; Cell Signaling Technology, United States) and MICU-2 (1:1000; Santa Cruz Biotechnology, United States), the membranes were incubated overnight at 4 ℃.

After agitation washing of the membranes for three 5-min cycles with TBST, appropriate secondary horseradish peroxidase-linked antibodies (1:2000; all purchased from Abcam), including goat anti-mouse IgG for total Mfn2, goat anti-rabbit IgG for β-actin and MCU/MICU-1/MICU-2, were used to incubate the membranes for 1 h at room temperature. An ECL kit (Pierce Biotechnology) was used to acquire enhanced chemiluminescence.

Cell lines and culturing

The mouse liver hepatocyte cell line AML-12 [established from hepatocytes from a male mouse (CD1 strain, line MT42) non-tumorigenic], preserved by our laboratory, was cultured according to the ATCC guideline, with 10% fetal bovine serum (Gibco, United States) added in a 90% 1:1 mixture of Dulbecco's modified Eagle's medium and Ham's F12 medium (DMEM/F12; Hangzhou Genom Biochemical and Pharmaceutical, China) with 0.005 mg/mL insulin, 0.005 mg/mL transferrin, 5 ng/mL selenium and 40 ng/mL dexamethasone (all purchased from Sigma-Aldrich). All cells were cultured in 5% CO_2 at 37 ℃ in a moderately moist environment.

Cells were assigned to three groups (NC, hypoxia and hypoxia + Si) in the logarithmic phase, and less than 70% had good conditions. The NC group cells were cultured using the normal protocol. The hypoxia group cells were first cultured for 3 h in a humidified atmosphere containing 2% O_2, 5% CO_2 and 93% N_2 at 37 ℃ in a noxic incubator tank (Thermo Fisher Scientific), and then cultured for another 3 h in normal atmosphere as NC group cells to simulate the IRI process. The hypoxia + Si cells were first used in siRNA experiments (Table 2; Shanghai GenePharma Biochemical and Pharmaceutical, China) to knock down the Mfn2 expression. The same culturing was performed in the hypoxia group. Cells were collected for subsequent experiments.

Mitochondrial membrane potential

The mitochondrial membrane potential (ΔΨm) was quantified using a JC-1 kit (Beijing Beyotime Institute of Biotechnology, China). JC-1 was used to cultivate the cells for 30 min, which was measured by flow cytometry (FCM) in the channels of FITC (green) and PE-A (red) of the FC500 flow cytometer (Cytomics, United States). Furthermore, cells were cultured for 30 min using JC-1 and for 15 min using Hoechst-33342 (Beijing Beyotime Institute of Biotechnology), and observed under confocal microscopy (FV1000; Olympus, Japan) to confirm the results obtained from FCM.

Apoptosis

Cell apoptosis was assayed using the Annexin V/Propidium Iodide Apoptosis (AV/PI) Detection Kit (BD Biosciences) and measured by FCM. Furthermore, cells were treated with 7.5 μmol/L of the CellEvent Caspase

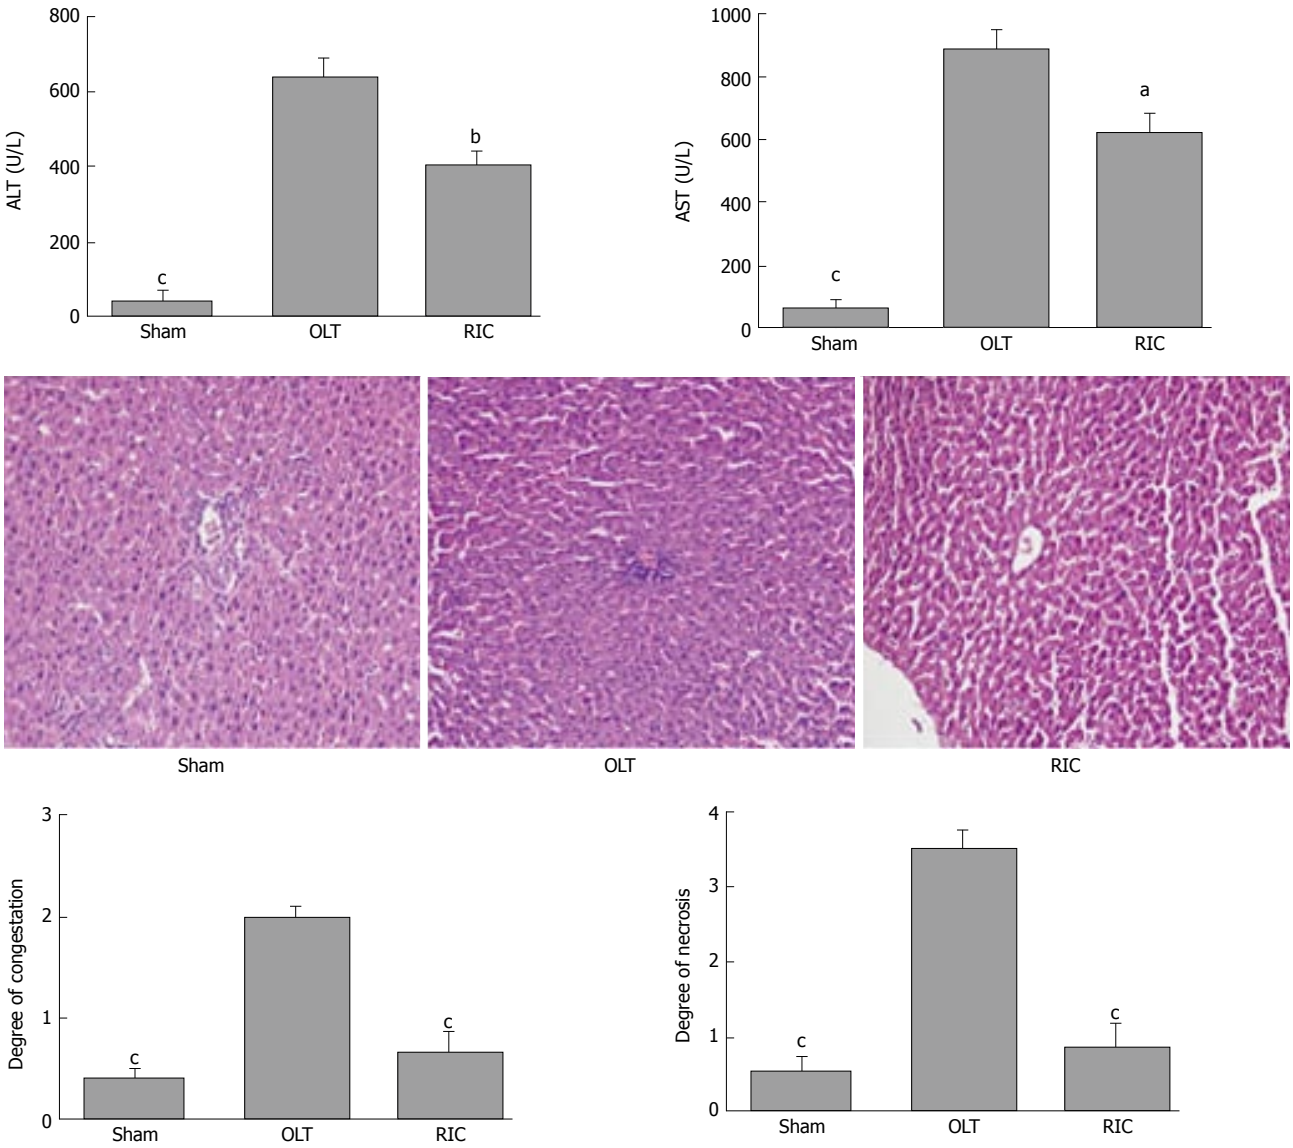

Figure 2 Remote ischemic perconditioning models model improves the liver graft function. 3/7 Green Detection Reagent (Invitrogen, United States) and 10 nmol/L tetramethylrhodamine methyl ester perchlorate (Invitrogen), and observed under confocal microscopy to confirm the results obtained from FCM.

Measurement of mitochondrial Ca^{2+} concentrations

Rhod-2 acetoxymethyl ester (Rhod-2, AM; GeneCopoeia, United States) was used to measure the mitochondrial Ca^{2+} concentrations. According to our previous experience, the fluorescence value of Rhod-2 AM approximately represented the fluorescence value of mitochondrial Ca^{2+}[11,24]. The day before the experiment, 1 x 10^5 cells were plated in 10-mm confocal dishes (Nest Biotechnology, China). After overnight incubation, the growth medium was removed from the cell plates, and added with 500 μL medium with 4 μM Rhod-2 AM and 0.1% Pluronic® F-127 (GeneCopoeia) and allowed to incubate at 37 ℃ in humidified air (containing 5% CO_2) for 2 h. Next, D-Hanks balanced salt solution (Hangzhou Genom Biochemical and Pharmaceutical, China) was used to wash the cells three times, followed by addition of 500 μL Hoechst-33342 and 200 nmol/L MitoTracker Green (Beijing Beyotime Institute of Biotechnology), and allowed to incubate in the same environment for 30 min of cultivation. Confocal microscopy confirmed that the vast majority of Rhod-2 AM fluorescence was associated with the mitochondria. Furthermore, cells were incubated in 96-well plates with Rhod-2 AM and F-127 in the same process and observed by VarioskanFlash (Thermo Fisher Scientific) with the illumination at excitation 552 nm and emission 581 nm to confirm the results obtained from confocal

microscopy.

Quantification of endoplasmic reticulum (ER) Ca^{2+} concentrations

We used the FLUOFORTE® Calcium Assay (Enzo Life Sciences, United States) to detect ER Ca^{2+} concentrations. The day before the experiment, 5 × 10^4 cells were plated per well in 96-well assay plates (Corning, United States). After overnight incubation, the growth medium was removed from the cell plates and 100 μL FLUOFORTE® Dye-Loading Solution (prepared by Enzo's protocol, containing 0.5 mmol/L EGTA to eliminate Ca^{2+} concentrations in the medium) was added to each well, and the cells were incubated at room temperature for 45 min. The illumination at excitation 490 nm and emission 525 nm was observed by VarioskanFlash for quantification of cytosolic Ca^{2+} concentrations at baseline. Then, 5 μM thapsigargin (Thermo Fisher Scientific) was added to each measurement well to detect the total values, including cytosolic baseline and Ca^{2+} released from the ER, by VarioskanFlash with the same parameters. SkanIt software (Thermo Fisher Scientific) was used to measure the ER Ca^{2+} concentrations.

Statistical analysis

The results were expressed as mean ± SEM. One-way analysis of variance was used for comparisons among three groups and the *t*-test was used for comparison between the two groups. All statistical analyses and related statistical diagramming were performed using the GraphPad Prism software (ver. 5.0 for Windows; GraphPad Software Inc., United States). $P < 0.05$ was considered statistically significant.

RESULTS

RIC model improves liver graft function

According to the literature and our previous research, RIC does not cause muscle and remote organ function damage, so this experiment focused on liver function[9,10]. In the present study, the sham group showed no injury during the experiment. Compared with the OLT group, ALT and AST levels were lower in the RIC group (ALT: $P = 0.0029$, AST: $P = 0.0121$; Figure 2A). Liver histopathological examinations showed that the RIC group had fewer sinusoids, central vein congestion and hepatocyte necrosis than the OLT group ($P < 0.001$; Figure 2B and C).

RIC model lowers expression of Mfn2 and alters MICUs expression

Expression of Mfn2 and MICUs was measured by WB (Figure 3A) and qRT-PCR (Figure 3B). Taking the OLT group as the reference, both the sham and RIC groups showed lower expression of Mfn2 (WB: sham *vs* RIC: $P < 0.001$; qRT-PCR: sham $P < 0.001$, RIC $P = 0.0348$). The MICUs expression was also altered. Compared with the OLT group, both the sham and RIC groups showed higher expression of MICU-1 (WB: sham *vs* RIC, $P < 0.001$; qRT-PCR: sham $P = 0.0005$, RIC $P = 0.0030$) and similar expression of MICU-2 (WB: sham $P = 0.0011$, RIC $P = 0.0033$; qRT-PCR: sham $P = 0.0255$, RIC: $P = 0.0137$). However, we did not observe any significant changes in the expression of MCU (WB: sham $P = 0.1044$, RIC $P = 0.9243$; qRT-PCR: sham $P = 0.0005$, RIC $P = 0.1507$).

Mfn2 knockdown alters MICUs expression in AML-12 hypoxia cell lines

The NC group was cultured in normal environment. The hypoxia group followed our protocol to simulate the IRI process. In the hypoxia + Si group, siRNA was used to knock down Mfn2 expression (WB and qRT-PCR; Figure 4A) and culturing was performed by the same protocol as in the hypoxia group. Expression of MICUs was measured by WB and qRT-PCR. Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups showed higher expression of MICU-1 (WB: NC $P = 0.0001$, hypoxia + Si $P = 0.0010$; qRT-PCR: NC $P = 0.0026$, hypoxia + Si $P = 0.0430$) and similar expression of MICU-2 (WB: sham $P < 0.0001$, hypoxia + Si $P = 0.0020$; qRT-PCR: sham $P = 0.0004$, RIC $P = 0.0137$). We observed the change in expression of MCU by WB (sham: $P = 0.0158$, RIC: $P = 0.0040$), but did not obtain significant findings by qRT-PCR (sham: $P = 0.2597$, RIC: $P = 0.2420$) (Figure 4B and C).

Mfn2 knockdown attenuates the collapse of ΔΨm in AML-12 hypoxia cell lines

We first used the JC-1 kit to measure the ΔΨm in AML-12 hypoxia cell lines cultured by FCM with our protocol. JC-1 fluorescence shifted from red (JC-1 aggregates bound to mitochondria) to green (JC-1 monomers bound to cytoplasm), indicating a decline of ΔΨm. Taking the hypoxia group as the reference, the green to red fluorescence ratio was lower in the NC and hypoxia + Si groups (FCM: NC $P = 0.0329$, hypoxia + Si $P = 0.0391$; Figure 5A and C). We obtained the same result by confocal microscopy as that obtained from FCM using the JC-1 kit and Hoechst-33342 (Figure 5B).

Mfn2 knockdown attenuates apoptosis in AML-12 hypoxia cell lines

The Annexin V/Propidium Iodide Apoptosis Detection Kit was used to detect cell apoptosis by FCM. Annexin V fluorescence reflects early cell apoptosis while propidium iodide fluorescence reflects late apoptosis and dying cells. Taking the hypoxia group as the reference, the ratio of apoptosis cells was lower in the NC and hypoxia + Si groups (FCM: NC $P = 0.0092$, hypoxia + Si $P = 0.0369$; Figure 6A and C). We obtained the same result by confocal microscopy as that obtained from FCM using the caspase 3/7

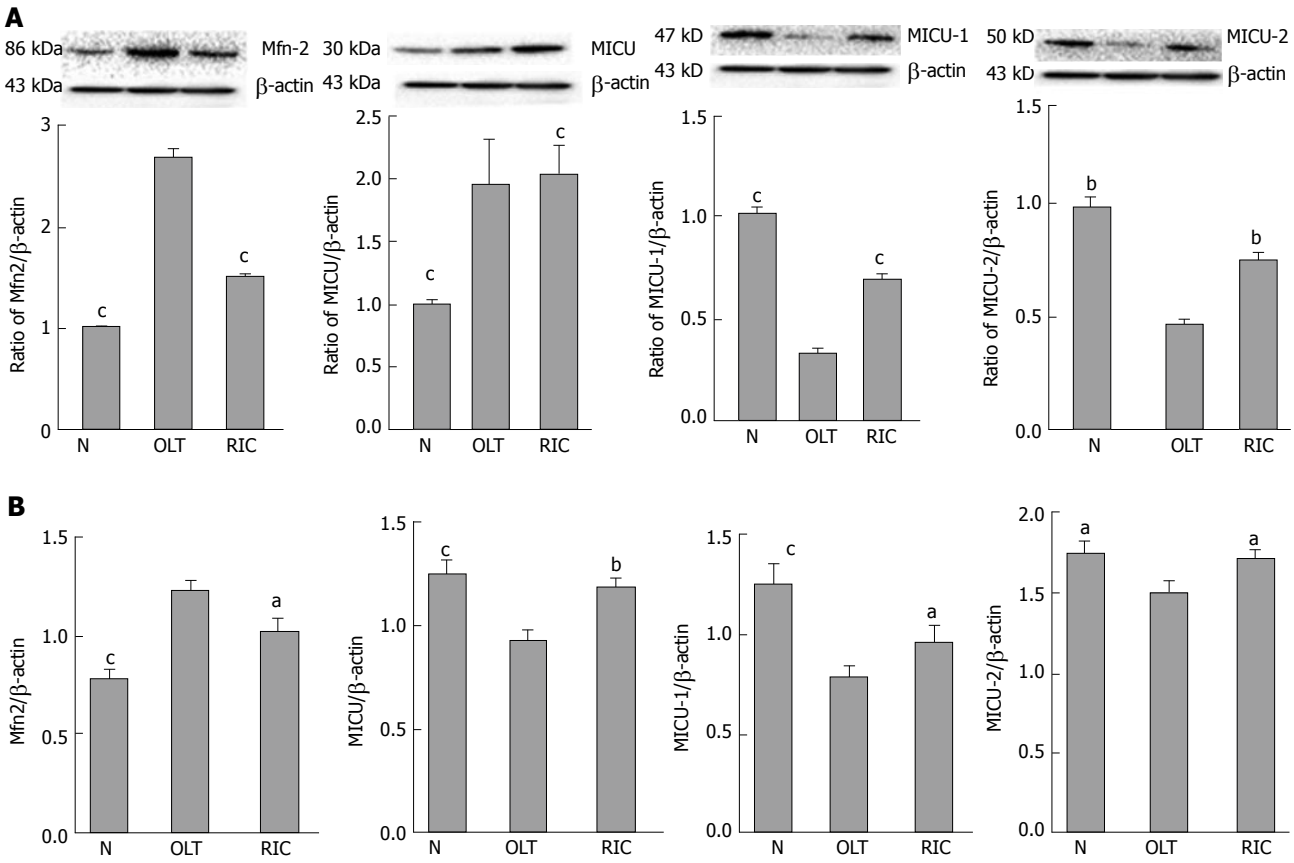

Figure 3 Remote ischemic perconditioning models model causes low expression of Mfn2 and alters MICUs expression. Expression of Mfn2 and MICUs was measured by WB (A) and qRT-PCR (B). Both sham and RIC groups showed lower expression of Mfn2 and altered MICUs expression, but no significant change was observed in expression of mitochondrial Ca^{2+} uniporter. Mfn2: Mitofusin-2; MICUs: Mitochondrial Ca^{2+} uptake 1/2; OLT: Orthotopic liver transplantation; qRT-PCR: Quantitative real-time-PCR; RIC: Remote ischemic perconditioning; WB: Western blotting. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$.

detection kit (green) and tetramethylrhodamine methyl ester perchlorate (red) (Figure 6B).

Mfn2 knockdown relieves mitochondrial Ca^{2+} overloading

We used Rhod-2 AM to detect mitochondrial Ca^{2+} concentrations by confocal microscopy and VarioskanFlash. Rhod-2 AM, Hoechst-33342 and MitoTracker Green were used to confirm that the fluorescence value of Rhod-2 AM approximately represented the fluorescence value of mitochondrial Ca^{2+} (Figure 7A). Then, VarioskanFlash was used to analyze the illumination at excitation 557 nm and emission 581 nm and detect mitochondrial Ca^{2+} concentrations (Figure 7B). Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups relieved mitochondrial Ca^{2+} overloading (NC *vs* hypoxia + Si: $P < 0.0001$).

Mfn2 knockdown relieves endoplasmic reticulum Ca^{2+} decrease

We used the FLUOFORTE® Calcium Assay to detect ER Ca^{2+} concentrations by analyzing the illumination at excitation 490 nm and emission 525 nm with VarioskanFlash. The cytosolic baseline was measured first, and then thapsigargin (Ca^{2+} was released by inhibiting endoplasmic reticular Ca-ATPase) was added to detect the total values, including cytosolic baseline and Ca^{2+} release from the ER. SkanIt software was used to measure the ER Ca^{2+} concentrations. Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups showed higher ER Ca^{2+} concentrations (NC *vs* hypoxia + Si: $P < 0.0001$) (Figure 7).

DISCUSSION

The incidence of liver cancer is increasing and liver cancer currently represents the sixth most frequent type of cancer worldwide[25]. LT has become an important countermeasure for end-stage liver diseases, and numerous research studies have been carried out to improve LT outcome by reducing the damages, such as IPC and RIC[26,27]. We have demonstrated in our previous studies that the RIC model protects the liver against IRI, causing no muscle or remote organ function damage[9,10], but the mechanism is not yet fully understood.

Mitochondrial Ca^{2+} plays an important role in intracellular homeostasis[28]. Mfn2 maintains the network stability of mitochondria by participating in

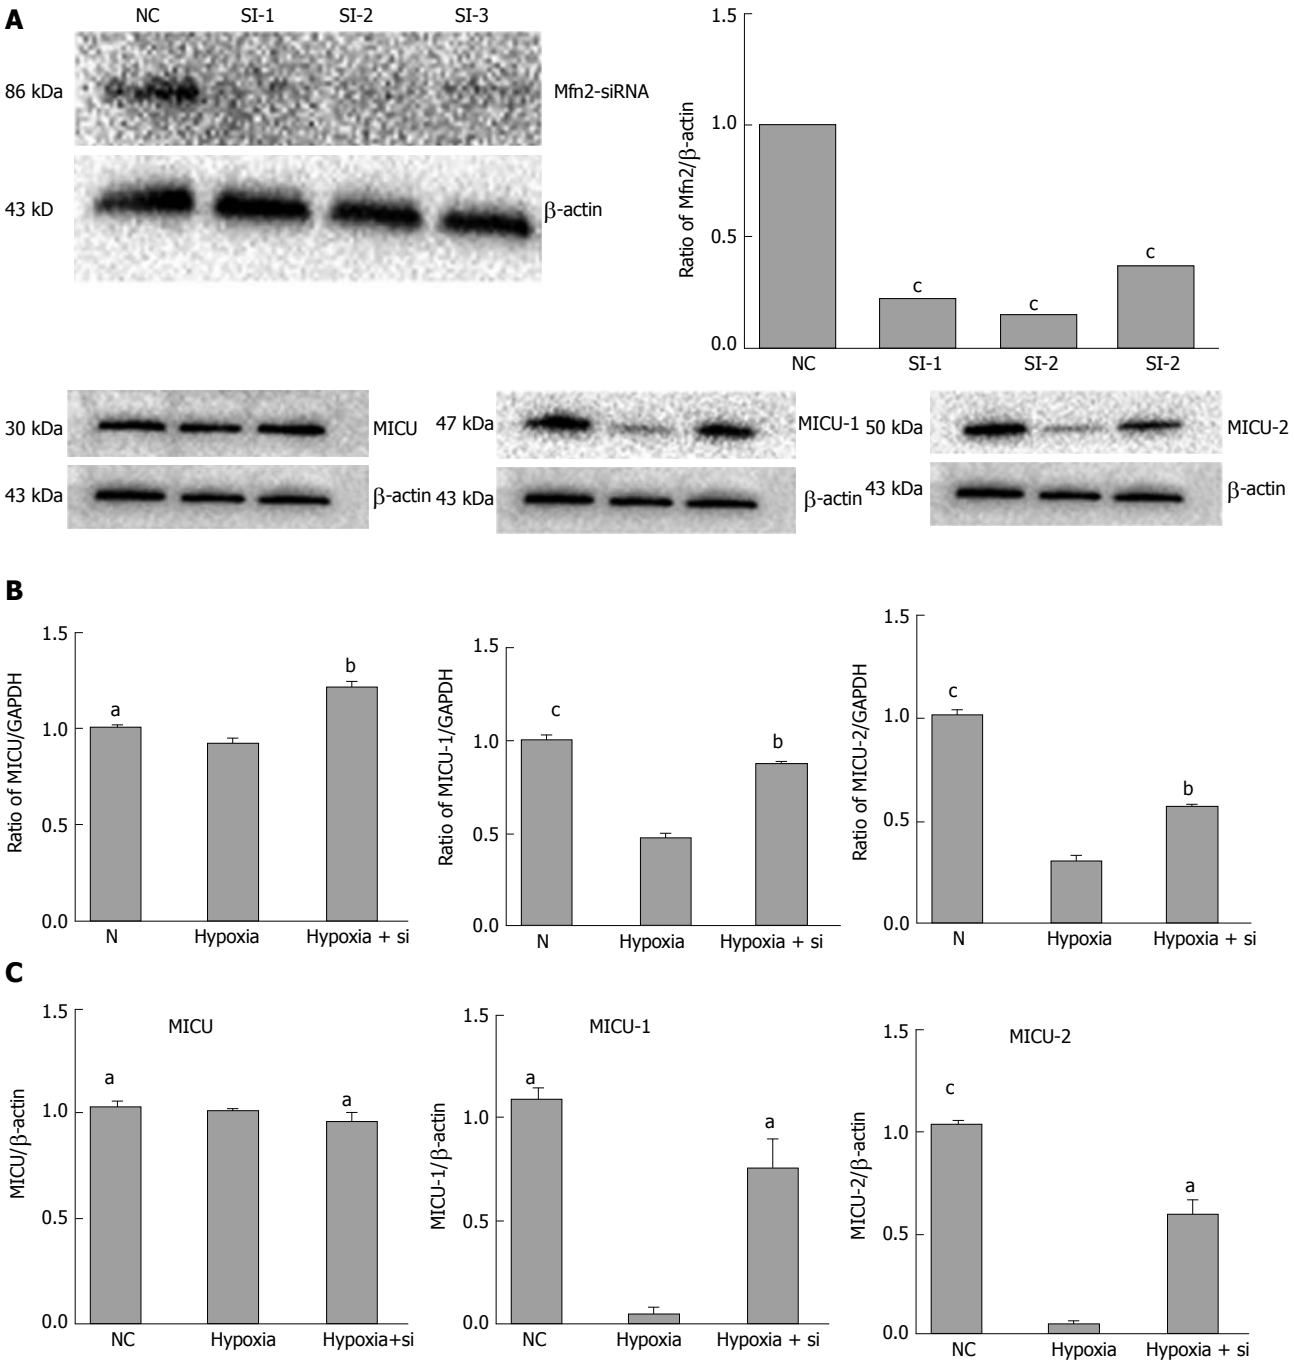

Figure 4 Mfn2 knockdown alters MICUs expression in AML-12 hypoxia cell lines. A: Mfn2 knockdown was tested by WB and qRT-PCR. Expression of MICUs in AML-12 hypoxia cell lines was measured by WB (B) and qRT-PCR (C). Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups showed higher expression of MICU-1 and similar expression of MICU-2; MCU altered expression in WB, but no significant change in qRT-PCR. AML: Alpha mouse liver; MCU: Mitochondrial Ca^{2+} uniporter; Mfn2: Mitofusin-2; MICU: Mitochondrial Ca^{2+} uptake; NC: Normal culture; qRT-PCR: Quantitative real-time-PCR; WB: Western blotting. $^{a}P < 0.05$; $^{b}P < 0.01$.S $^{c}P < 0.001$.

mitochondrial fusion and fission[29]. MCU, MICU-1 and MICU-2 form the mitochondrial calcium uniporter complex. Along with the increase in intracellular Ca^{2+}, Ca^{2+} combined with EF-hand of MICUs promotes the opening of MCU pores and leads to an increase in the mitochondrial Ca^{2+}[30,31]. Furthermore, excessive intake of Ca^{2+} can increase mitochondrial permeability transition, thereby inducing pathophysiological phenomena such as apoptosis[32]. Previous studies have shown that Mfn2 provides a convenient pathway for Ca^{2+} transport from mitochondria to ER in intracellular high Ca^{2+} environment[33-37]. However, there is little information about relationships between the protective effect of RIC and the Mfn2-MICUs axis during LT.

We, therefore, designed and performed the present RIC experiment (Figure 1) and found that, compared with the sham group, LT (including RIC) could cause liver damage and change the Mfn2-MICUs axis at the same time. While the RIC model reduced liver damage, Mfn2 expression was lower and MICUs

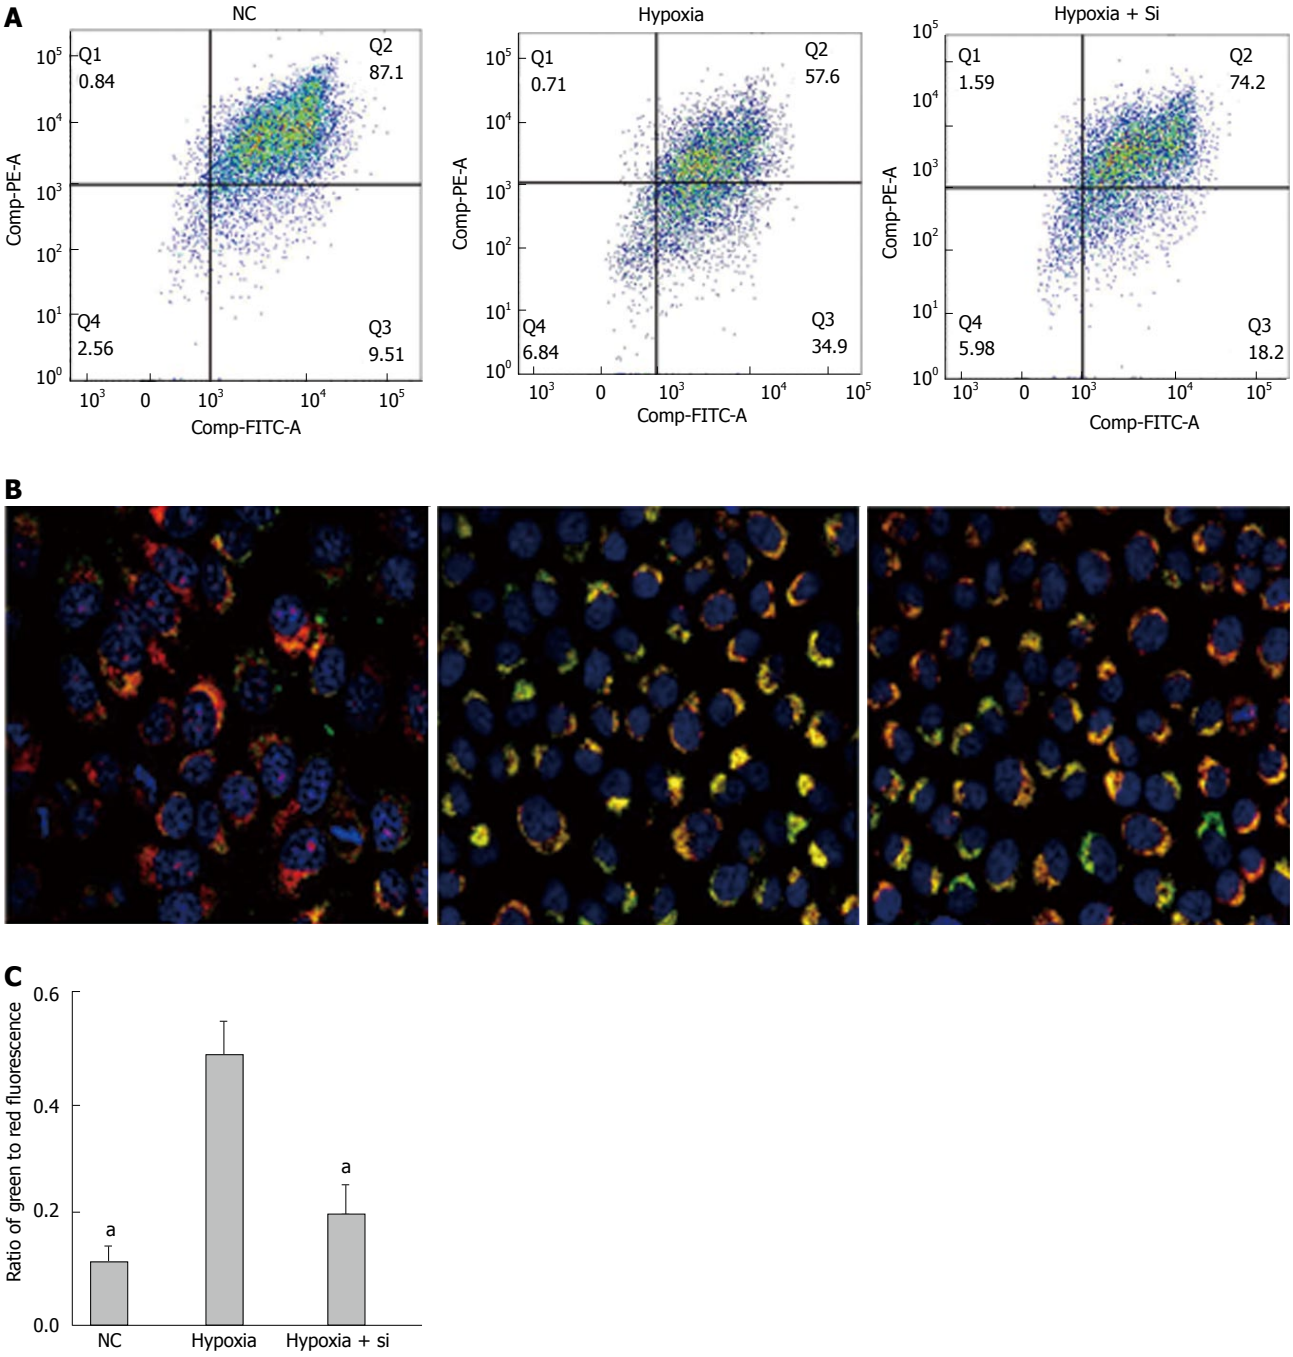

Figure 5 Mfn2 knockdown attenuates the collapse of ΔΨm in AML-12 hypoxia cell lines. JC-1 kit and Hoechst-33342 were used to measure the ΔΨm by flow cytometry (A and C) and confocal microscopy (B). Collapse of ΔΨm in the hypoxia group was attenuated both in the NC and hypoxia + Si groups. Mfn2: Mitofusin-2; NC: Normal culture; ΔΨm: Mitochondrial membrane potential. [a]$P < 0.05$.

expression was higher than in LT (Figures 2 and 3). These results demonstrated that the RIC model might exert its protective effect for LT *via* the Mfn2-MICUs axis.

To further verify our findings, we decided to knock down the Mfn2 expression by siRNA. Since genetically engineered mice are expensive, the experiment is time-consuming, and it is hard to perform gene knockout operations using primary cells, we designed the use of AML-12 hypoxia cell lines to simulate a RIC model. After determining the Mfn2 knockdown efficiency (Figure 4A), we proved that the hypoxia + Si group alleviated the hypoxia damage and showed higher expression of MICU-1 and MICU-2 compared with the hypoxia group (Figure 4B and C). Revalidating the same result from the RIC experiment provides the basis for our future mechanism studies.

Depolarization of mitochondrial membrane potential is usually associated with early apoptosis. According to the JC-1 kit instructions, in the absence of apoptotic cells, JC-1 aggregates are bound to mitochondria and red fluorescence occurs at 590 nm.

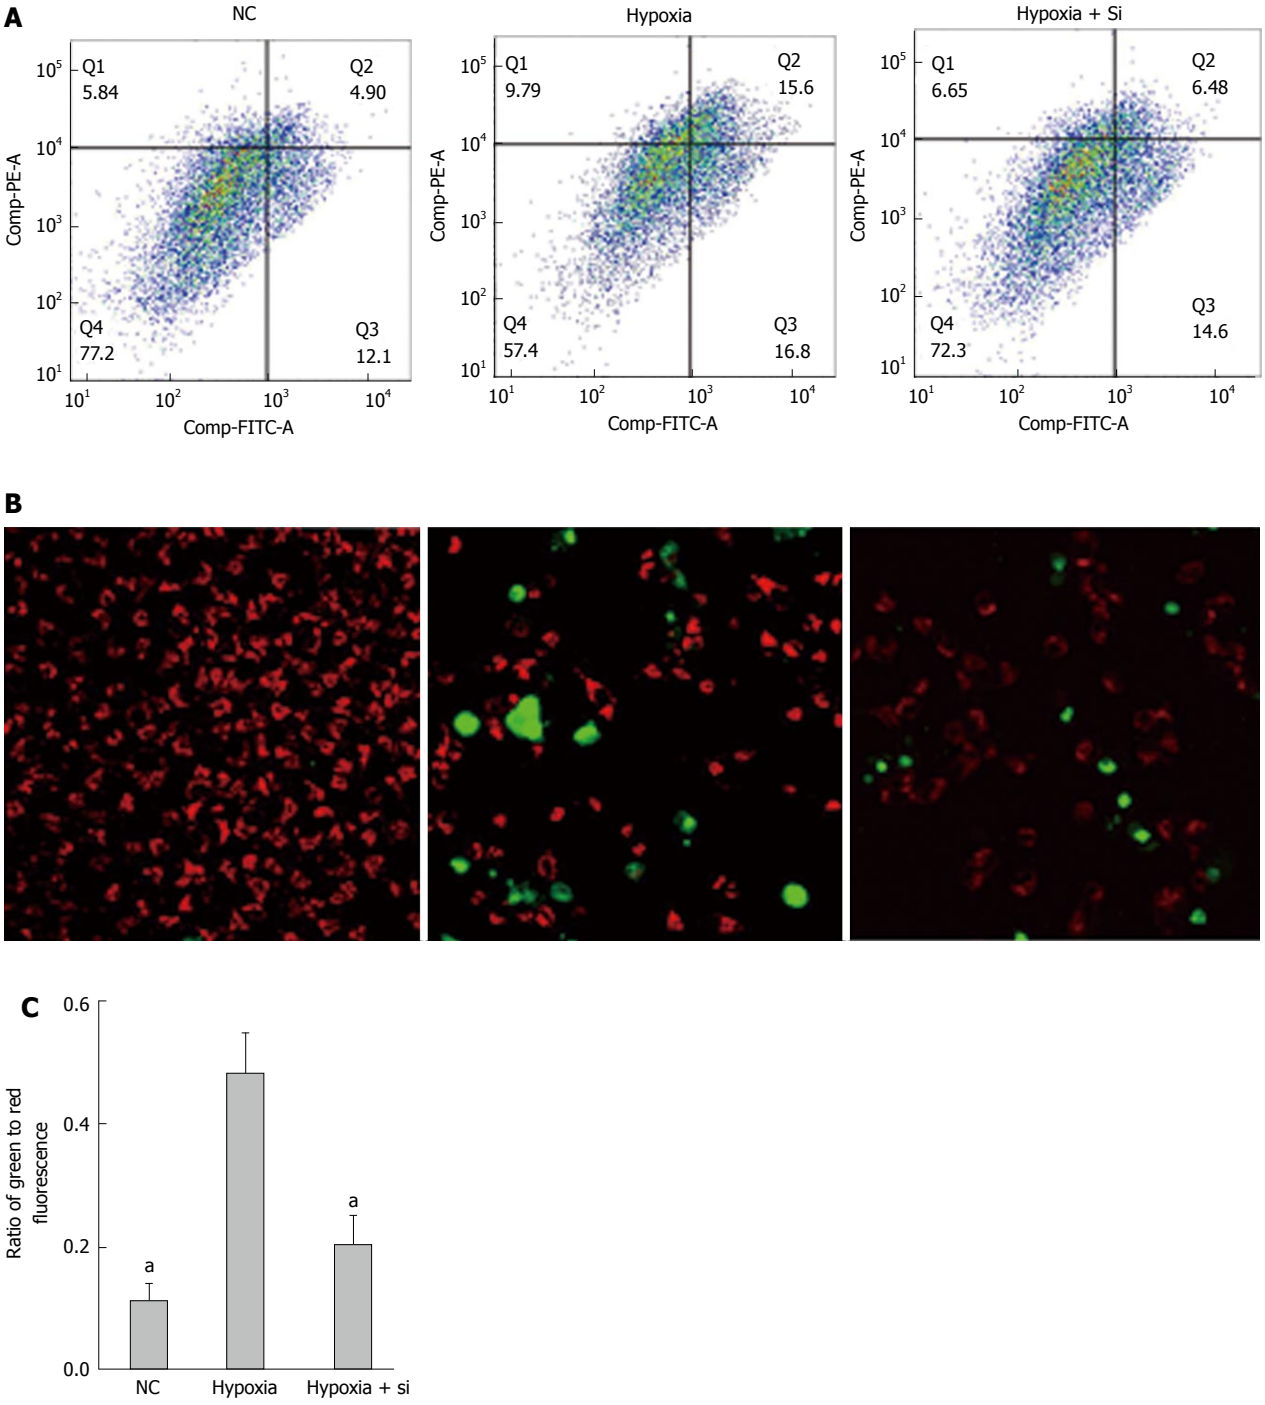

Figure 6 Mnf2 knockdown attenuates apoptosis in AML-12 hypoxia cell lines. The Annexin V/PI Apoptosis Detection Kit by flow cytometry (A and C); Caspase 3/7 detection kit and tetramethylrhodamine methyl ester perchlorate by confocal microscopy (B) used to detect apoptosis. The ratio of apoptosis cells was lower in both the NC and hypoxia + Si groups. AML: Alpha mouse liver; Mfn2: Mitofusin-2; NC: Normal culture. $^{a}P < 0.05$.

Whereas in apoptotic cells, JC-1 monomers are bound to cytoplasm and green fluorescence occurs at 530 nm. The green to red fluorescence ratio then indicates the collapse of ΔΨm. In the present study, we used the JC-1 kit to measure the ΔΨm in hypoxia cell lines by FCM, and found that the green to red fluorescence ratio was lower in the NC and hypoxia + Si groups (Figure 5A and C). The sham group showed no injury during the experiment. Compared with the hypoxia group, the hypoxia + Si group had less collapse of ΔΨm. For more intuitive observation, we used JC-1 and Hoechst-33342 to repeat the experiment by confocal microscopy, and revalidated the same result from FCM (Figure 5B). The results illustrated that Mfn2 knockdown lowered the mitochondrial membrane potential in hypoxia cells.

Apoptosis is a programmed cell death controlled by genes, which is designed to maintain homeostasis[38].

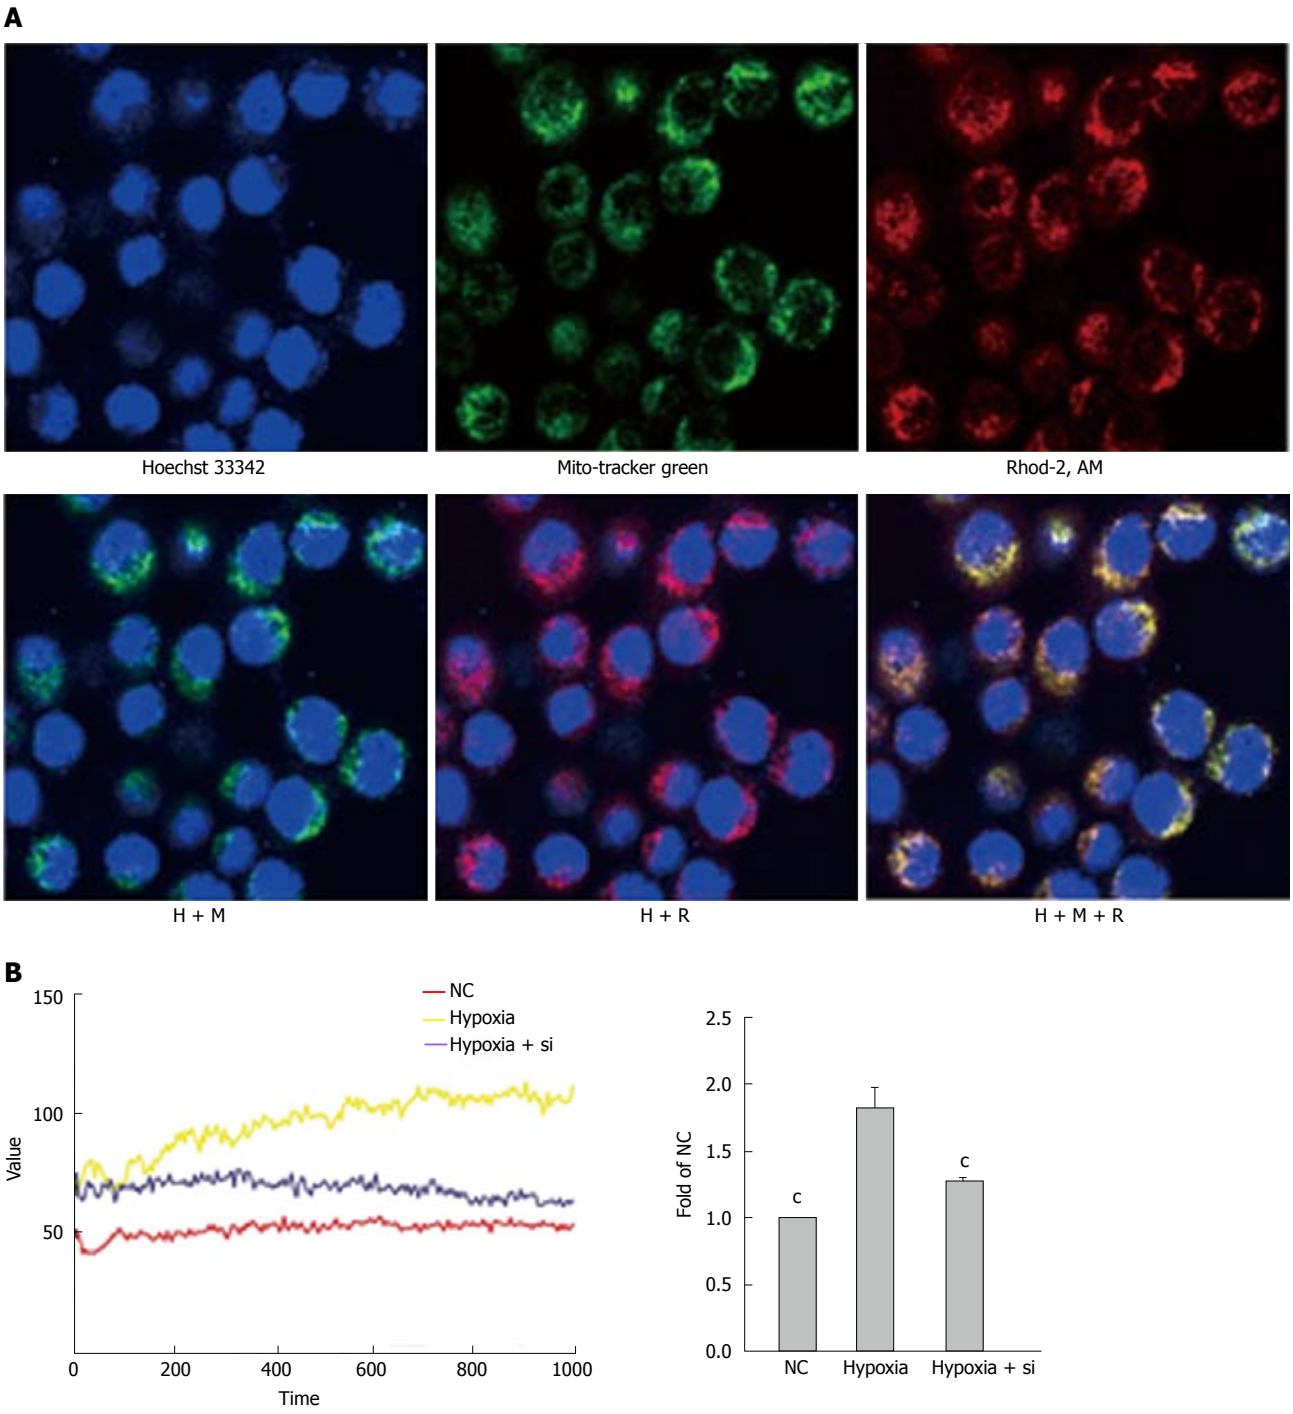

Figure 7 Mfn2 knockdown relieves mitochondrial Ca^{2+} overloading. Rhod-2 AM was used to detect mitochondrial Ca^{2+} concentrations by confocal microscopy and VarioskanFlash. A: Confocal microscopy confirmed that the vast majority of Rhod-2 AM fluorescence was associated with the mitochondria; B: VarioskanFlash was used to detect Rhod-2 AM to determine the fluorescence of mitochondrial Ca^{2+} concentrations. Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups relieved mitochondrial Ca^{2+} overloading. Mfn2: Mitofusin-2; NC: Normal culture; Rhod-2 AM: Rhod-2 acetoxymethyl ester. $^{c}P < 0.001$.

In the early stage of apoptosis, phosphotidylserine can be translocated from the inside of the cell membrane to the outside of the cell membrane and combined with annexin V (FITC). In late apoptotic and dead cells, the membranes are permeable to propidium iodide (PE-A). According to the staining status of the cells, we can distinguish the apoptosis status (annexin V/propidium iodide positive or negative). In the present study, we found that the ratio of cell apoptosis was lower in the NC and hypoxia + Si groups (Figure 6A and C). The sham group showed no injury during the experiment, indicating that compared with the hypoxia group, the hypoxia + Si group had fewer cells undergoing apoptosis. We used the caspase 3/7 detection reagent (green) and tetramethylrhodamine methyl ester perchlorate (red) to repeat the experiment by confocal microscopy and revalidate the same result from FCM (Figure 6B). The results demonstrated that Mfn2

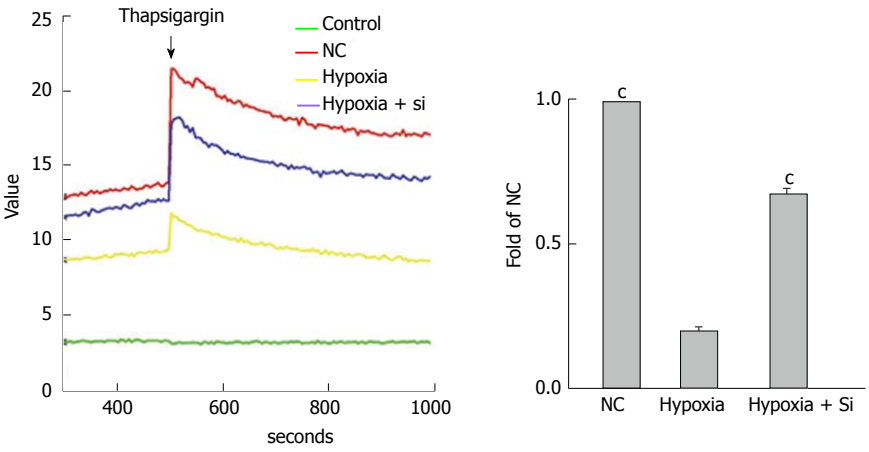

Figure 8 Mfn2 knockdown relieves endoplasmic reticulum Ca^{2+} decrease. FLUOFORTE® Calcium Assay and thapsigargin were used to detect ER Ca^{2+} concentrations by VarioskanFlash. Taking the hypoxia group as the reference, both the NC and hypoxia + Si groups showed higher ER Ca^{2+} concentrations. ER: Endoplasmic reticulum; Mfn2: Mitofusin-2; NC: Normal culture. $^{c}P < 0.001$.

knockdown reduced the apoptosis in hypoxia cells.

As mentioned earlier, whether IRI in LT or hypoxia in cells leads to injury should be verified. Mfn2 provides a convenient pathway for Ca^{2+} transport from mitochondria to ER in intracellular high Ca^{2+} environment. Excessive uptake of Ca^{2+} caused mitochondrial pathogenesis and affected 'gatekeeper' expression, thus leading to a higher Ca^{2+} concentration. In the present study, after confirming that the Mfn2-MICUs were altered in both rat models and cell models, we continued to validate Ca^{2+} changes at the mitochondrial level. We used Rhod-2 AM to analyze the mitochondrial Ca^{2+} concentration (Figure 7A), and VarioskanFlash to analyze the illumination of Rhod-2 AM to get the fluorescence of mitochondrial Ca^{2+} concentrations. We found that the hypoxia + Si group relieved mitochondrial Ca^{2+} overloading compared with the hypoxia group (Figure 7B). This indicated that Mfn2 knockdown reduced the mitochondrial Ca^{2+} overload by Mfn2-MICUs axis in cell models.

The ER is an important organelle of Ca^{2+} storage, the stored Ca^{2+} in ER is mainly released through the inositol 1, 4, 5-trisphosphate (InsP3) receptor and ryanodine receptor pathways[13]. In the present study, we investigated the relationships between ER Ca^{2+} concentrations and mitochondrial Ca^{2+} overloading. After the cytosolic Ca^{2+} concentration at baseline was quantified by VarioskanFlash using the FLUOFORTE® Calcium Assay, we added thapsigargin to release the ER Ca^{2+} and performed repeat measurement. The hypoxia + Si group showed relief of the ER Ca^{2+} decrease compared with the hypoxia group (Figure 8). This result proved that Mfn2 knockdown relieved the ER Ca^{2+} decrease by affecting the Mfn2-MICUs axis, thus altering the mitochondrial Ca^{2+} status in cell models.

The MCU protein complex is a highly selective calcium channel consisting of three components: MCU, MICU-1 and MICU-2. The complex can sense Ca^{2+} level and determine whether it passes through the mitochondrial membrane[19]. In our experiment, we failed to observe the consistency of MCU expression changes in rat and cell models. According to the literature, ER was mediated by the InsP3 receptor, Mfn2 showed no effect on expression of InsP3R, but when specific inhibitors of InsP3 receptor were used, the decline of ER Ca^{2+} induced by Mfn2 no longer occurred, suggesting that InsP3R Ca^{2+} release pathways affected the ER Ca^{2+} efflux[11]. The specific mechanism in InsP3R and IRI/cell hypoxia injury is not clear. Nevertheless, our research provides a clear clue that Mfn2 down-regulated expression of MICUs can affect the state of Ca^{2+} in organelles, thus playing a protective role in the two models. We will continue to apply gene-editing mouse models and specific inhibitors to conduct an in-depth research in the future.

In conclusion, we used an RIC model and confirmed that IRI was prevented by altered organelles' Ca^{2+} status *via* the Mfn2-MICUs axis, and revalidated the effect in AML-12 hypoxia cell models.

COMMENTS

Background

Remote ischemic perconditioning (RIC) alleviates the damage of ischemia-reperfusion injury (IRI). The Mfn2-MICUs axis is involved in the regulation of intracellular calcium, thereby affecting the process of apoptosis. But there is little information about the role of the mitofusin-2-mitochondrial Ca^{2+} uptake 1/2 (Mfn2-MICUs) axis in the protective effect of RIC during liver transplantation (LT).

Research frontiers

Most previous studies only confirmed the protective effect of RIC, but few showed the detailed mechanism. In the protective role of RIC, the mechanism of apoptosis related to the Mfn2-MICUs axis is worthy of being explored.

Innovations and breakthroughs

This research is the first to prove the protective mechanism of the Mfn2-MICUs axis as affecting the metabolism of intracellular calcium to reduce apoptosis in RIC of LT and revalidate it in AML-12 hypoxia cell lines.

Applications

This study showed the relationship between the protective effect of RIC and cell hypoxia injury, and that the Mfn2-MICUs axis and apoptosis are affected by the intracellular calcium homeostasis, thus laying a basic foundation for future studies.

Terminology

RIC was first proposed by Przyklenk in 1993, and it alleviates the damage of IRI in a temporary ischemic treatment for distant organs without damaging the target organs. RIC operations include remote-ischemic-preconditioning (RIPreC), remote-ischemic-postconditioning and RIPerC.

Peer-review

This is an interesting paper looking at the role of Mnf2 in liver IRI.

ACKNOWLEDGMENTS

We are grateful to the Collaborative Innovation Center for Diagnosis and Treatment of Infectious Diseases of the First Affiliated Hospital of Zhejiang University for providing the experimental sites and reagents for this study. We also wish to thank Wen-Feng Song for technical assistance.

Abstract

AIM

To investigate the expression of annexin II in gastric carcinoma and its role in the metastasis of gastric cancer.

METHODS

The expression of annexin II in 51 cases of gastric carcinoma and 24 cases of adjacent tissues was detected by immunohistochemistry. The relationship between annexin II and clinical features of gastric cancer was analyzed. Annexin II specific siRNA was used to inhibit the expression of annexin II in gastric cancer HGC-27 cells, and the effects of annexin II on the migration and secretion of matrix metalloproteinases (MMPs) were observed.

RESULTS

The positive rate of annexin II protein was 82.4% in gastric cancer tissues and 37.5% in adjacent tissues. There was significant difference between the two groups ($P < 0.01$); and the positive expression of annexin II was not related to the sex and age of the patients ($P > 0.05$). The expression of annexin II

protein was correlated with tumor size, histological differentiation, TNM stage, Lymph node metastasis and other clinical features were significantly correlated, the difference was statistically significant ($P < 0.05$). Inhibition of annexin II expression, gastric cancer HGC-27 cells migration and secretion of MMPs were significantly decreased, the difference was statistically significant ($P < 0.05$).

CONCLUSION

Annexin II is highly expressed in gastric cancer tissues, annexin II protein expression is related to tumor size, histological differentiation, TNM staging, lymph node metastasis and other clinical features were significantly correlated. Annexin II high expression can promote the invasion and metastasis of gastric cancer.

Expression of annexin II in gastric carcinoma and its role in gastric cancer metastasis. *World J Gastroenterol* 2017; 23(38): 7009-7015 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/7009.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.7009

INTRODUCTION

Gastric cancer is one of the most common malignancies in my country, the first in the digestive tract malignant tumor, ranking the fourth in the world[1], Because of its symptoms hidden, the disease developed rapidly, when diagnosed in the late, the treatment effect is often poor, a serious threat to human health, but the early treatment of gastric cancer is good, 5 years after radical resection rate of up to 90% or more, So in-depth study of the occurrence and development of gastric cancer mechanism, For the prognosis of gastric cancer and the treatment of gastric cancer has a very important clinical significance.

Annexin Ⅱ is a calcium-dependent phospholipid-binding protein, Mainly in the form of monomer, dimer and tetramer, the study shows[2-6]: Annexin II are highly expressed in liver cancer, breast cancer, colon cancer, lung cancer and other malignant tumors, And play an important role in the occurence, development and infiltration of tumor. In this study, the expression of annexin II in 51 cases of gastric carcinoma and 24 cases of adjacent tissues was detected by immunohistochemistry, to investigate the relationship between the positive expression of annexin II and the clinical characteristics of gastric cancer. And annexin II specific siRNA was used to inhibit the expression of annexin II in gastric cancer HGC-27 cells, Detection of cell adhesion, invasion, migration, matrix metalloproteinases (MMPs) secretion and other capacity changes.

MATERIALS AND METHODS

Materials

Fifty-one cases of surgical specimens of gastric cancer were collected during the period from January 2012 to June 2014, among them, 30 males and 21 females; aged 32-78 years, mean age 58.6 ± 3.2 years; the above cases were not treated before radiotherapy, chemotherapy and other anti-tumor therapy. From the above 51 cases of gastric cancer, twenty-four patients were randomly selected from the normal tissue of the stomach. All specimens were fixed with formaldehyde, Paraffin embedded, sliced. Gastric cancer HGC-27 cells were purchased from the Shanghai Institute of Biochemistry and Cell Biology. Study has been reviewed by the appropriate ethics committee and has therefore been performed in accordance with the ethical standards laid down in an appropriate version of the Declaration of Helsinki. All persons gave their informed consent prior to their inclusion in the study.

Methods

Immunohistochemical staining: Annexin II antibody was purchased from Abcam Reagent Company; Immunohistochemistry kit, DAB kit was purchased from Pikiton Reagent Company. Sliced was kept in high temperature and high pressure tissue antigen repair. The dyeing step is carried out according to the kit instructions. Positive plates were used as positive control, PBS instead of primary antibody as a negative control. The results showed that annexin II positive expression of brown matter in the cytoplasm appears brown matter. Each slice 5 representative of the high power field, Each field count 100 cells, The percentage of positive cells and the intensity of staining were scored separately. Specific criteria are as follows: (1) according to the degree of staining score: no staining for 0 points, Dyeing strength is 1 point; Medium dyeing intensity of 2 points; Strong staining intensity of 3 points. (2) Score according to the percentage of colored cells: The percentage of cells in the stained cells was < 5% for 0 points, 5%-25% for 1 points, 26%-50% for 2 points, 51%-75% for 3 points, > 75% for 4 points. (1) + (2) for the total points, The total score of 0-7 points. 0 is negative (-),

1-2 is divided into weak positive (+), 3-5 are divided into positive (++), 6-7 is divided into strong positive (+++).

Cell culture: Gastric cancer HGC-27 cells were cultured in RPMI1640 cell culture medium containing 10% fetal bovine serum and cultured in 5% CO_2, 37 ℃, saturated cell culture incubator.

Cell transfection: Gastric cancer HGC-27 cells (1×10^5 cells/mL) were seeded in 24-well plates, Cultured overnight at 37 ℃, 5% CO_2 and saturated humidity. Serum-free medium wash cells, 1 μL (20 pmol) of Annexin II siRNA was dissolved in 49 μL serum-free medium, 1 μL of liposomes was dissolved in 59 μL of serum-free medium, After keeping at room temperature for 10 min, Mix the two type of liquids, room temperature for 20 min. The mixture was then added to the 24-well plate of the cells to be transfected, Add serum-free medium to 500 μL, Placed in 37 ℃, 5% CO_2 cell incubator culture, 6 h later replaced with 10% newborn bovine serum RPMI1640 medium.

Real-time quantitative PCR: Use Trizol method to extract total RNA from cells, The total RNA samples of the extracted osteoblasts were reverse transcribed into cDNA, Using the following reaction system: 2 μg template RNA,1 μL oligo dT primer, 2 μL dNTP mixture,1 μL Ace reverse transcriptase,1 μL RNase inhibitor,4 μL 5 × RT buffer, 10 μL RNase-free water. The reaction conditions were as follows: first step 37 ℃ 30 min, The second step is 84 ℃ for 30 s. The reaction product was stored at 4 ℃. And then real -time quantitative PCR reaction. Using the following reaction system: 12.5 μL Real Master Mix (SYBR I), 2 μL template cDNA, 1 μL forward primer, 1 μL reverse primer, 8.5 μL RNase-free water. The reaction conditions are: first step 94 ℃ 5 min; second step 94 ℃ 60 s, 57 ℃ 30 s, 72 ℃ 30 s, a total of 30 cycles; the third step 72 ℃ 5 min; the last 4 ℃ end of the reaction. The experimental data were analyzed by Option Monitor V3.1 software of real-time PCR.

Cell invasion experiment: A 1:3 diluted matrigel (RMPI 1640 dilution) was added to the matrigel invasion chamber, 37 ℃ for 2 h, 2×10^4 gastric cancer cells were resuspended in 0.1% fetal bovine serum culture medium and inoculated in the chamber, RMPI 1640 medium containing 10% fetal bovine serum was added to the 24-well plate of the lower chamber, 37 ℃ for 24 h. Remove the invasion chamber, With a cotton swab gently wipe the room did not pass through the cells, formaldehyde fixed for 10 min, Hematoxylin-eosin staining, Cut the filter, the neutral gum seal, light microscopy count the number of cells through the membrane. The number of cells in the membrane was calculated by taking 10 fields under light microscope. Each independent experiment was repeated three times.

Cell migration experiments: First with a marker pen in the 6-well plate even behind a horizontal line, Cross through the hole. About 2×10^4 gastric cancer cells were seeded in 6-well plates when the cells are completely fused, the tip of the nose is as far as possible to the horizontal line behind the horizontal scratches. Wash the cells three times with PBS, wash off the cells under the cells, and then add serum-free medium. And incubated in a CO_2 incubator at 37 ℃. 0 and 24 h under inverted microscope to observe and take pictures. The scribe width was measured with Image J software and the cell mobility was calculated. Cell mobility = (0 h scratch width - 24 h scratch width)/0 h scratch width × 100%. Each independent experiment was repeated three times.

Cell gelatin zymography experiments: Cells were treated with annexin II siRNA Digest the cells and count, the corresponding conditioned medium was collected, 1500 *g* low-speed centrifugation 10 min after removal of cell debris, Take the supernatant 4 ℃ spare. And then take the protein quality samples separately with non-reduction Loading Buffer Homogeneously mixed, incubated at 55 ℃ for 5 min. Prepare 5% concentrated gum and 8% separated gel containing 0.1% gelatin. Constant pressure electrophoresis until the edge of bromophenol blue separation from the front of the separation of about 0.5 cm. The gel was removed and transferred to the elution solution, eluting twice every 30 min. Rinse with gelatin incubation once, and then placed in gelatin incubation buffer at 37 ℃ for 18 h. Dyeing solution 4 h After the rinsing of distilled water, And then take a photo by a gel image analyzer.

Statistical analysis

Each independent experiment was repeated more than three times. Student-t test was performed with SPSS 16.0 software, the results are expressed as mean ± SD, qualitative data were compared using χ^2 test, $P < 0.05$ indicating that the difference was statistically significant.

RESULTS

Expression of annexin II Protein in gastric carcinoma and its relationship with clinical characteristics of gastric cancer

Expression of AnnexinII in gastric carcinoma and adjacent tissues: Annexin II protein positive expression of cytoplasm in the yellow granular material, Mainly located in the cytoplasm (Figure 1). In 51 cases of gastric cancer, 42 cases were positive, The positive rate was 82.4% of which strong positive in 3 cases, Positive in 12 cases, Weakly positive in 27 cases, Negative in 9 cases. In 24 cases of

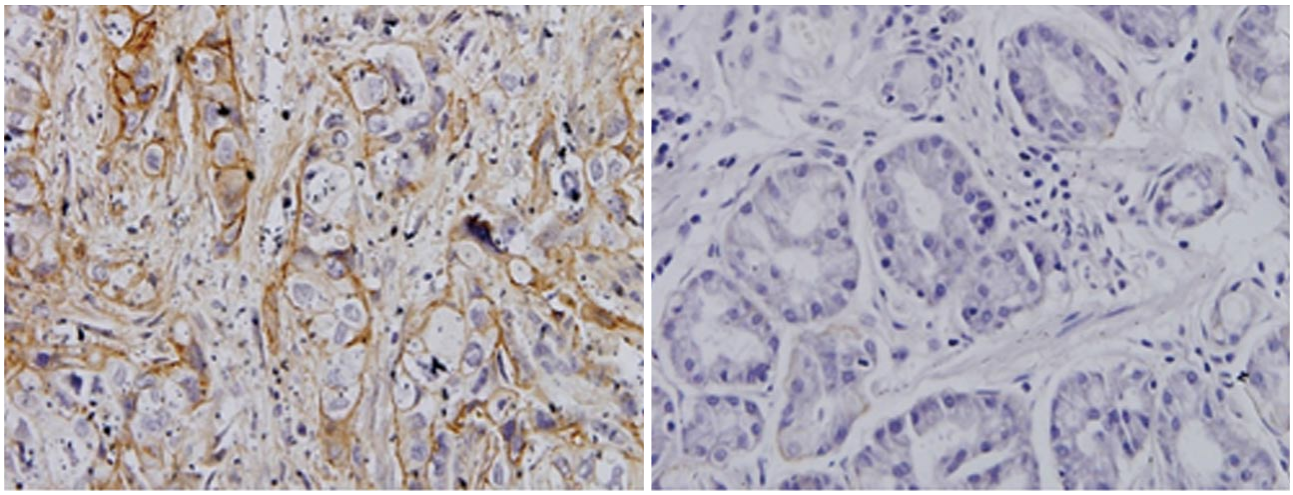

Figure 1 Immunohistochemistry to detect annexin II protein in gastric cancer tissues and adjacent tissues.

Table 1 Expression of annexin II protein in gastric carcinoma and paracancerous tissues

Group	*n*	Annexin II protein				Positive rate, %	*P* value
		-	+	++	+++		
Gastric cancer	51	9	27	12	3	82.4	
Paracancerous	24	15	6	3	0	37.5	< 0.01

paracancerous tissue, there were 9 positive expression, of which strong positive 0 cases, positive in 3 cases, weak positive in 6 cases, The positive rate was 37.5%. The expression of AnnexinII protein in gastric cancer tissues was significantly higher than that in adjacent tissues, Differences were significant (Table 1, $P < 0.01$).

Expression of annexin ii protein in patients with clinical characteristics of gastric cancer: The study found, annexin II positive expression was not related to the sex of the patient ($P > 0.05$) while annexin II protein expression was associated with tumor size, histological differentiation, TNM staging, lymph node metastasis and other clinical features were significantly correlated, the difference was statistically significant ($P < 0.05$, Table 2).

The role of annexin II in gastric cancer metastasis

SiRNA inhibits annexin II expression: The siRNA fragment targeting annexin II was transfected into human gastric cancer HGC-27 cells, the mRNA and protein expression of annexin II in human gastric cancer HGC-27 cells were detected by real time-PCR and Western blot after 24 h. And transfected unrelated interfering siRNA fragments (control siRNA) as a negative control. The results show, annexin II siRNA can significantly inhibit the transcription and protein expression of annexin II mRNA in human gastric cancer HGC-27 cells, the difference was statistically significant ($P < 0.05$; figure 2).

Table 2 Relationship between annexin II protein and clinical characteristics of gastric cancer patients

Group	*n*	Annexin II positive	Positive rate, %	*P* value
Age in yr				
≤ 60	27	23	85.2	> 0.05
> 60	24	19	79.2

Clinical stage				
Ⅰ + Ⅱ period	17	10	58.8	< 0.05
Ⅲ + Ⅳ period	34	32	94.1	
Lymph node metastasis				
Have	33	31	93.9	< 0.05
Not have	18	11	61.1	

Effect of annexin II on the migration ability of gastric cancer cells: Scaling experiments were performed to detect changes in cell migration ability. Compared with the control group transfected with Control siRNA, the migration ability of human gastric cancer HGC-27 cells transfected with Annexin II siRNA was significantly decreased, differences were statistically significant ($P < 0.01$; figure 3).

Effect of annexin ii on secretion of mmps in gastric cancer cells: The changes of MMPs secretion were detected by gelatin zymography. Compared with the control group transfected with Control siRNA, Human gastric cancer HGC-27 cells transfected with AnnexinII siRNAs after MMPs secretion was significantly reduced, Differences were statistically significant ($P < 0.01$; figure 4).

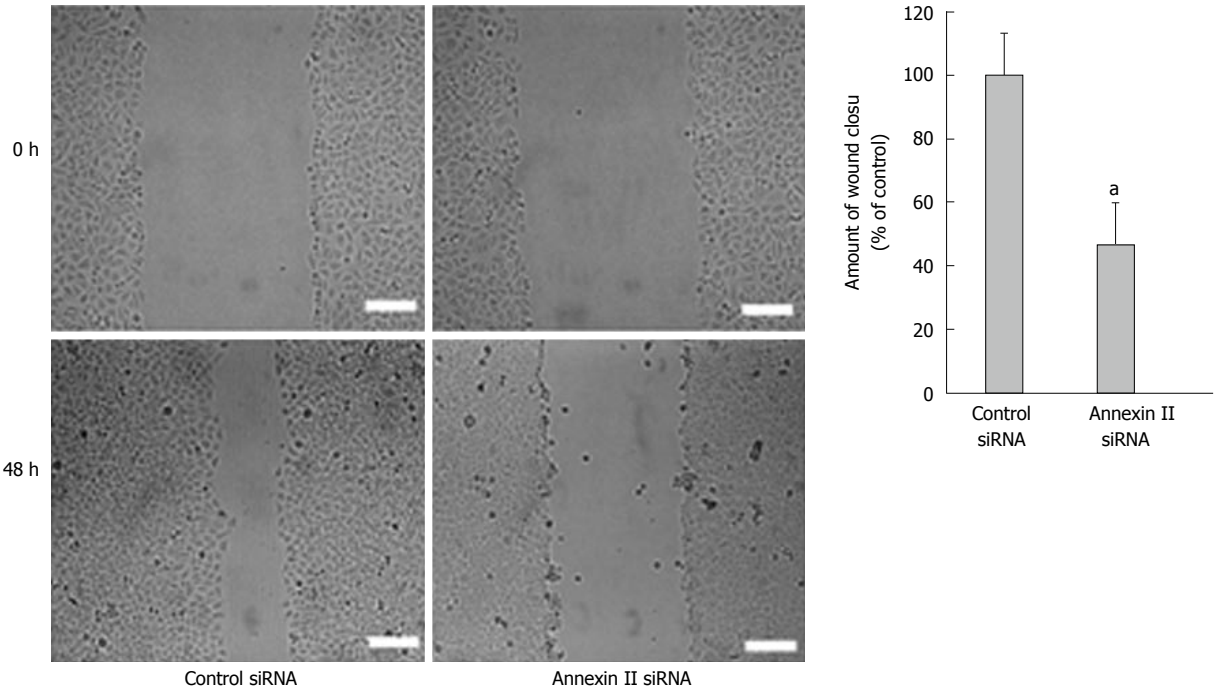

Figure 3 Effect of annexin II siRNA on the migration ability of human gastric cancer HGC-27 cells. [a]*P* < 0.05. siRNA: Small interfering RNA.

DISCUSSION

Annexins is a class of calcium-dependent phospholipid-binding proteins, which are widely present in the cell membrane, cytoplasmic or extracellular matrix. There are two basic functional domains on the structure: Highly conserved C-terminal core regions and highly variable N-terminal domains. The former has a binding site of Ca^{2+} and membrane, in the form of calcium-dependent reversible binding to cell membrane phospholipids, the latter determines annexins specific biological functions. Annexins participate in a series of activities of cells, such as endocytosis, exocytosis, cell proliferation, differentiation and apoptosis, and cytoskeleton activity, signal transduction and etc[7]. Annexin II as a member of the annexins family A subfamily, Also known as p36, AXA2, LIP2, etc. Its gene is located in 15q21-q22, containing 1.4 kb encoding gene[8,9].

In this study, the expression of annexin II in gastric

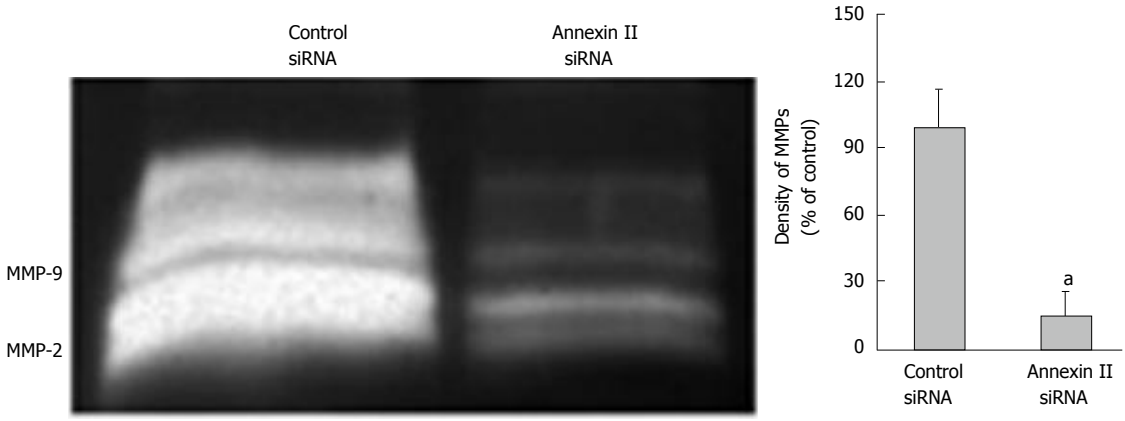

Figure 4 Effect of annexin II siRNA on secretion of matrix metalloproteinases in human gastric cancer HGC-27 cells. $^{a}P < 0.05$. MMPs: Matrix metalloproteinases; siRNA: Small interfering RNA.

cancer tissues and adjacent tissues was analyzed. The results showed that the expression of annexin II protein in gastric cancer tissues was significantly higher than that in adjacent tissues. To analyze the correlation between the expression of annexin II protein and the clinical characteristics of gastric cancer patients. The positive expression of annexin II was not related to the sex and age of the patients, while annexin II protein was expressed with tumor size, histological differentiation, TNM stage, lymph node metastasis and other clinical features were significantly correlated, the difference was statistically significant. The results suggest that annexin II protein is closely related to the malignant degree of gastric cancer.

Tumor metastasis is the most important malignant phenotype of the tumor and is the direct cause of this high mortality. Tumor metastasis is required in tumor cells themselves, host cells and extracellular matrix between the interaction can be completed, Involves a series of complex processes and steps, Including tumor cells from the primary tumor lesions, through the secretion of MMPs degradation of the extracellular matrix into the blood vessels or lymphatic vessels migrate to the distant, and then attack to the secondary organization or organ in the formation of metastases[10-14]. Therefore, the study of tumor metastasis for clinical diagnosis and treatment is important. To clarify whether annexin II in the process of gastric cancer metastasis play a role, In this study, annexin II-specific siRNA was used to inhibit annexin II expression in gastric cancer HGC-27 cells, after the expression of annexin II was reduced, gastric cancer HGC-27 cells migration, MMPs secretion and other capacity changes. The study found: In gastric cancer HGC-27 cells using annexin II- specific siRNA inhibited annexin II expression, gastric cancer cell migration, MMPs secretion and other capacity were reduced, suggesting that annexin II in the process of gastric cancer metastasis plays an important role.

In summary, annexin II in gastric cancer showed high expression, and the degree of differentiation of gastric cancer, TNM stage, lymph node metastasis and other clinical features are closely related, application of annexin II specific siRNA in gastric cancer HGC-27 cells inhibited annexin II expression, gastric cancer cell migration, MMPs secretion and other capacity are reduced, suggesting that annexin II plays an important role in the process of gastric cancer metastasis. The development and progression of gastric cancer is a complex multi-factor comprehensive results. At present, the etiology and pathogenesis of gastric cancer are more studied, but it is not clear. This study confirmed that annexin II was highly expressed in gastric cancer tissues and had the important role in gastric cancer metastasis. With the deepening of related research, annexin II gene expression, biological function and the role of progress in gastric cancer will be gradually clear, is expected to be used in the diagnosis and treatment of gastric cancer, predict the prognosis of markers and therapeutic targets.

COMMENTS

Background

Gastric cancer is one of the most common malignancies in my country, the first in the digestive tract malignant tumor, ranking the fourth in the world, Because of its symptoms hidden, the disease developed rapidly, when diagnosed in the late, the treatment effect is often poor, a serious threat to human health, but the early treatment of gastric cancer is good, 5 years after radical resection rate of up to 90% or more.

Research frontiers

Annexin II is a calcium-dependent phospholipid-binding protein, mainly in the form of monomer, dimer and tetramer, the study shows: Annexin II are highly expressed in liver cancer, breast cancer, colon cancer, lung cancer and other malignant tumors, and play an important role in the occurence, development and infiltration of tumor.

Innovations and breakthroughs

The authors restropectively analysed the expression of annexin II in 51 cases of gastric carcinoma and 24 cases of adjacent tissues, to investigate the relationship between the positive expression of annexin II and the invasion and metastasis of gastric cancer.

Applications

Annexin II in gastric cancer showed high expression, And the degree of

differentiation of gastric cancer, TNM stage, lymph node metastasis and other clinical features are closely related, suggesting that annexin II plays an important role in the process of gastric cancer metastasis.

Terminology

Annexins is a class of calcium-dependent phospholipid-binding proteins, they are widely present in the cell membrane, in the form of calcium-dependent reversible binding to ceembrane phospholipids, the latter determines Annexins specific biological functions.

Peer-review

This is an interesting study with great promise. AnnexinII was highly expressed in gastric cancer tissues and had the important role in the effect of promoting gastric cancer metastasis.

Abstract

AIM

To evaluate the risk factors for postoperative recurrence after primary bowel resection in a cohort of Korean Crohn's disease (CD) patients.

METHODS

This study included 260 patients with no history of previous bowel surgery who underwent primary surgery for CD between January 2000 and December 2010 at Asan Medical Center (Seoul, South Korea). The median follow-up period was 101 mo.

RESULTS

During the follow-up period, 66 patients (25.4%) underwent a second operation for disease recurrence.

At 1, 5 and 10 years after the first operation, the cumulative rate of surgical recurrence was 1.1%, 8.3% and 35.9% and clinical recurrence occurred in 1.2%, 23.6% and 68.1%, respectively. In multivariate analysis, undergoing an emergency operation was a significant risk factor for surgical recurrence-free survival (SRFS) [HR = 2.431, 95%CI: 1.394-4.240, *P* = 0.002], as were the presence of perianal disease after the first operation (HR = 1.715, 95%CI: 1.005-2.926, *P* = 0.048) and history of smoking (HR = 1.798, 95%CI: 1.088-2.969, *P* = 0.022). The postoperative use of anti-tumor necrosis factor (TNF) agents reduced SRFS risk (HR = 0.521, 95%CI: 0.300-0.904, *P* = 0.02).

CONCLUSION

History of smoking, postoperative perianal disease and undergoing an emergency operation were independent risk factors for surgical recurrence. Using anti-TNF agents may reduce surgical recurrence.

Key words: Crohn's disease; Recurrence; Risk factor

Core tip: Our study demonstrated the clinical feature and long-term prognosis of Crohn's disease (CD) in a large cohort of non-Caucasian patients. We investigated risk factors for the postoperative recurrence of CD in a patient population from a single tertiary referral center. History of smoking, postoperative perianal disease and undergoing an emergency operation were found to be independent risk factors for surgical recurrence in CD. Using anti-TNF agents for these patients may reduce surgical recurrence. These findings indicate that affected patients with CD may benefit from close postoperative surveillance and probably from the early administration of anti-TNF agents.

Risk factors for postoperative recurrence after primary bowel resection in patients with Crohn's disease. *World J Gastroenterol* 2017; 23(38): 7016-7024 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/7016.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.7016

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory gastrointestinal disease with a heterogeneous disease course. Some patients experience low morbidity, whereas others need repeated operations[1]. Conservative medical treatment is regarded as the principal therapeutic approach to treat patients with CD, but the lifetime risk of surgical resection for patients with CD can be 70% to 80%[2,3]. Approximately 10% to 30% of patients who undergo an operation experience clinical recurrence during the first postoperative year, and more than 60% experience during the first postoperative decade. Surgical recurrence rates at 5 and 10 years have been reported as 20% to 25% and 34% to 49%, respectively[4,5]. Thus, to provide optimal patient care, it is important to be able to predict which patients have a higher risk of recurrence.

A range of possible risk factors thought to impact the surgical recurrence rate have been investigated: age at diagnosis, sex, smoking behavior, duration of disease before surgery, family history, behavior of disease (perforating or non-perforating disease), history of medication (use of 5-aminosalicylic acid, corticosteroids, immunomodulators or anti-tumor necrosis factor (anti-TNF) agents), priority of operation (emergency or elective), presence of granulomas in the resected bowel specimen, length of resected bowel, technique of anastomosis used in the surgery and postoperative complications[6,7]. However, such studies on risk factors have largely been inconclusive owing to different patient populations and clinical manifestations.

In this study, we investigated risk factors for the postoperative recurrence of CD, as determined by the need for an additional operation, in a patient population from a single tertiary care center.

MATERIALS AND METHODS

Patients

Patients who underwent intestinal resection for CD at Asan Medical Center (Seoul, Korea) between January 2000 and December 2010 were enrolled in this retrospective study. A total of 401 patients underwent intestinal resection for pathologically confirmed CD during the study period. Exclusion criteria included a history of previous bowel surgery, such as small or large bowel resection or strictureplasty, a concurrent or previous history of other malignancies, and patients who have had follow up for a short period of time (< 12 mo). A total of 260 patients were included in our analysis (Figure 1). The following variables were retrospectively reviewed from the prospectively collected database for these patients: demographics, preoperative disease characteristics, disease phenotype (Montreal classification)[8], any history of perianal disease (*e.g.*, an abscess or fistula), the presence of extraintestinal manifestations, a history of smoking, comorbidity, the operative approach (open or laparoscopy), operative indications (perforating or non-perforating), the rate of stoma formation, the reoperation rate, the duration of follow-up, postoperative complications and regimens of pre- and post-medical treatment.

The study protocol was approved by the institutional review board of Asan Medical Center (registration no: 2016-1139), in accordance with the Declaration of

Helsinki.

Assessment and follow-up

CD distribution was assessed based on pathological and intraoperative findings, radiologic imaging using a small bowel series (SBS), abdomen and pelvis computed tomography (CT), CT enterography, magnetic resonance imaging (MRI) enterography and colonofiberscopy (CFS). Perianal disease included stricture, fistula or an abscess in the perianal area, anal canal or perirectal space at any time during the course of CD. After primary intestinal resection, reassessment was performed by CT enterography, MRI enterography or CFS after 6 to 12 mo. Surgical recurrence was defined as a repeated operation for pathologically confirmed CD on any part of the bowel or a repeated operation for pathologically confirmed anastomotic disease, including instances where the small bowel was diseased at the anastomosis or the stoma site. Clinical recurrence was defined as the recurrence of CD-related symptoms, confirmed by objective signs of radiology or endoscopy findings. As this was a retrospective study the Crohn's disease Activity Index (CDAI) and Rutgeerts' score were not available.

Medical treatment of CD

Our medical treatment policy for treating CD was based on a step-up approach, with more potent therapies added if patients became unresponsive to first-line or less toxic agents, as described in a previous report from our institution[9]. The use of anti-TNF agents in this study was less frequent than in Western studies because of the strict Korean government health insurance reimbursement policy during our study period. During this period, two anti-TNF agents (infliximab and adalimumab) were available in Korea.

Statistical analysis

Survival curves were plotted using the Kaplan-Meier method and compared using the log-rank test. Multivariate analyses for survival that included the variables that showed statistical significance in the log-rank test were performed using Cox proportional hazards model with a 95%CI to assess the risk factors associated with surgical recurrence-free survival (SRFS) and clinical recurrence-free survival (CRFS). Statistical significance was defined as $P < 0.05$; all analyses were performed using SPSS software version 21 (IBM Corp., Armonk, NY).

RESULTS

Patient characteristics

The clinicopathological characteristics of the patients are summarised in Tables 1 and 2. The median follow-up time for the 260 patients was 101 mo (range, 12-193 mo). The interval between the first intestinal resection and clinical recurrence was 64 mo (range, 12-148 mo) and the interval between the first intestinal resection and surgical recurrence was 77.5 mo (range, 15-149 mo).

Elective operations were performed for 210 (80.8%) patients; the remaining 50 (19.2%) patients underwent emergency operations because of generalised peritonitis or severe obstruction. Among 260 patients, 122 (46.9%) patients had perianal disease before first surgery. Of these, 42 (34.4%) patients had perianal disease after first operation. Because of the strict Korean government health insurance reimbursement policy, only 27 (10.4%) patients treated with anti-TNF agents before first surgery, and 17 (63%) patients continued anti-TNF agents after first operation. Antibiotics such as ciprofloxacin or metronidazole were administered to 163 patients (62.7%) in case of infectious complications such as intra-abdominal abscess, perianal abscess or fistula before first surgery. All the patients who underwent first surgery used antibiotics for a certain period of time. During the follow-up period, three patients (1.5%) experienced colorectal cancer, one patient experienced lung cancer (0.4%).

Montreal classification of the patients

The majority (215/260, 82.7%) of the patients were diagnosed between the ages of 17 and 40 years, with 9.6% experiencing childhood onset of CD ($\leqslant$ 16 years) and 7.7% diagnosed as older adults (> 40 years). Montreal classifications were distributed as follows: 43.5% exhibited disease in the terminal ileum region (L1), 41.2% in the ileocolon (L3) and 14.6% in the colon region (L2); 67% had penetrating disease (B3, fistula, abscess or perforation), 31% had stricturing disease (B2) and 2% had inflammatory disease (B1, non-stricturing and non-penetrating). Because these patients were treated with surgical intervention, proportion of disease behavior was different from the whole patients with CD in Korea. Disease behavior of whole CD patients at diagnosis was inflammatory (B1) in 1591 patients (77.1%), stricturing (B2) in 174 (10.3%), and penetrating (B3) in 211 (12.6%)[9].

Clinical and surgical recurrence

Clinical recurrence occurred in 1.9%, 24.2% and 68.3% of the patients at 1, 5 and 10 years, respectively, after the first intestinal resection (Figure 2). In multivariate analysis (Table 3), history of smoking, presence of perianal disease after the first operation and undergoing an emergency operation were associated with CRFS.

During the follow-up period, 66 patients (25.4%) underwent a second intestinal resection for disease recurrence. Among these, 13 (20%) patients underwent a third intestinal resection, four patients (31%) a fourth and one patient (25%) a fifth. The cumulative rate of surgical recurrence was 1.1%, 9.2%

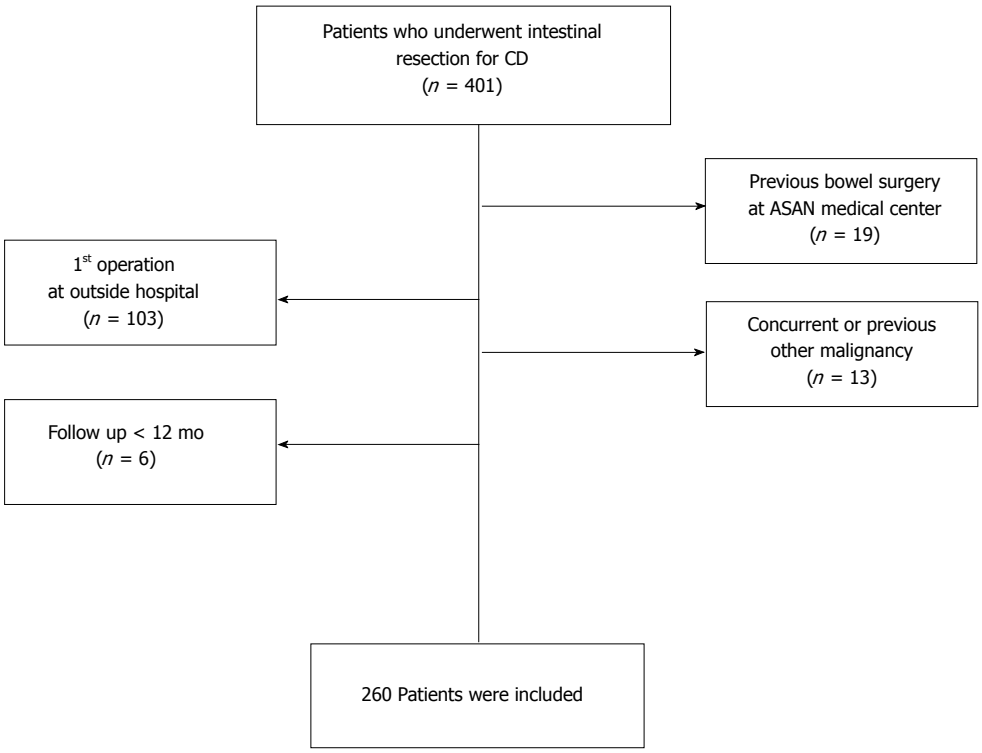

Figure 1 Inclusion criteria.

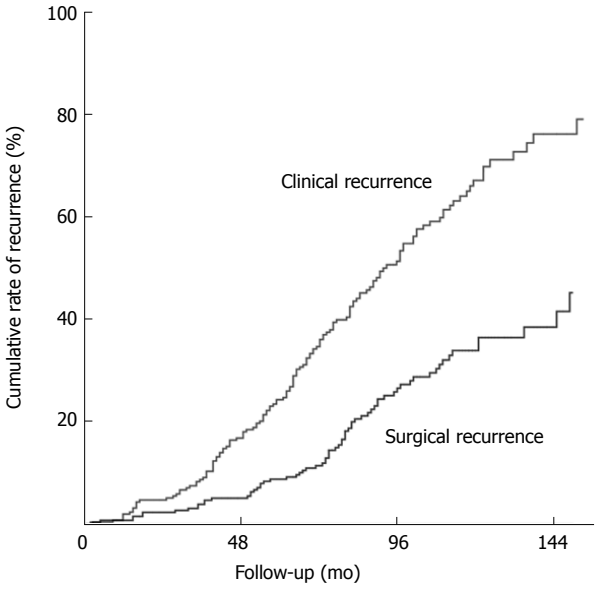

Figure 2 Cumulative rate of clinical and surgical recurrence.

and 36.4% at 1, 5 and 10 years, respectively, after the first operation (Figure 1). In univariate analysis, the presence of perianal disease after the first operation, undergoing an emergency operation and postoperative use of anti-TNF agents were all associated with SRFS.

Multivariate analysis revealed the following risk factors for SRFS (Table 3): undergoing the first resection as an emergency operation (HR = 2.431, 95%CI: 1.394-4.240, P = 0.002), history of smoking (HR: 1.798, 95%CI: 1.088-2.969, P = 0.022) and the presence of perianal disease after the first intestinal resection (HR = 1.715, 95%CI: 1.005-2.926, P = 0.048); in addition, the risk was reduced with the postoperative use of anti-TNF agents (HR = 0.521, 95%CI: 0.300-0.904, P = 0.020). Younger age at diagnosis seemed to be associated with an increased risk of surgical recurrence, but it was not statistically significant (HR = 3.512, 95%CI: 0.944-13.068, P = 0.065). However, no impact on SRFS was found for disease location, presence of postoperative complications, length of resected small bowel, perforating disease or preoperative duration of the disease. Azathioprine and 6-mercaptopurine did not demonstrate a clear clinical effect for the prevention of surgical recurrence after the first intestinal resection.

Discussion and conclusions

The increasing tendency in Korea over the past few decades calls for more attention to be paid to the natural course of CD in these newly developed disease population. Our study demonstrated the clinical feature and long-term prognosis of CD in a large cohort of non-Caucasian patients.

Korean patients with CD differ from Western patients in sex distribution (a predominance of men), disease location (a lower proportion of isolated colonic disease) and the occurrence of perianal fistula (a higher incidence)[10,11]. Although the pathogenesis of CD is largely unknown, differences have been reported in susceptibility genes and phenotypic features of CD between Asian and Western populations. For example, NOD2 or ATG16L1, which are regarded as well-

established CD susceptibility genes among Caucasians, are not replicated in Asians, whereas the association of TNFSF15 with CD is stronger in Koreans and Japanese than in Caucasians[12,13].

The surgical recurrence rate was 25% to 45% 10 years after the first intestinal resection[14,15], although postoperative clinical recurrence occurred earlier during the disease course. Our study found that cumulative surgical and clinical recurrence rates were 36.4% and 68.4%, respectively, at 10 years after the first intestinal resection.

Our study demonstrated that patients with CD who had a higher risk of surgical recurrence after primary bowel surgery were those who underwent the first resection as an emergency operation, those with history of smoking and those with postoperative perianal disease. The use of postoperative anti-TNF agents seemed to reduce surgical recurrence.

Korean patients with CD show higher incidence of perianal disease than Western patients[9]. Previous study in our center[11], perianal fistulas occurred in 46.8% of patients. Also, the cumulative frequency of perianal fistula was 54.3% after 15 years. These results are in contrast to those of Western studies in which the cumulative frequency of perianal fistula in patients with CD attending referral centers was reported to be 13%-38%[16]. Furthermore, the presence of perianal disease was one of the predictors of postoperative recurrence, as has been suggested by previous studies in Asian population[17-19]. Gao *et al*[17] also assessed risk factors for surgical recurrence and advocated perianal CD correlated with a higher clinical recurrence rate. Korean CD patients with perianal disease had a higher risk of surgical recurrence[18,20]. The present study showed that patients with CD who developed perianal disease after the first resection had a high risk of surgical and clinical recurrence, indicating that these patients had a poor disease

outcome after the primary operation. Similarly, despite a wide variation on reported risk of recurrence, the presence of perianal disease is thus considered to be a risk factor for postoperative recurrence in Caucasian population[3,21,22]. The presence of perianal disease is a sign of an increased inflammatory process and this may also influence intestinal CD.

Most patients with CD can be operated on electively, with only few patients requiring acute surgical intervention. In the present study, an indication for an emergency first intestinal resection was significantly associated with surgical recurrence. Riss *et al*[23] reported that an urgent indication for surgery was found to be significantly associated with the rate of surgical recurrence. Another retrospective study of 116 consecutive patients undergoing their first ileocolectomy at a large Austrian referral centre between 1997 and 2006 demonstrated that urgent index ileocolectomy increased the risk of repeat surgery approximately six-fold[24]. An emergency presentation could be a sign of a significant lack of an immune response to the on-going inflammation, making an emergency operation necessary. Furthermore, preoperative work up and intraoperative evaluation were limited in emergency situation and an emergency operation was usually performed by less experienced surgeons. As a consequence, these patients may be prone to developing early recurrence after the surgical treatment.

Smoking is the most widely recognized environmental risk factor for the initiation and recurrence of Crohn's disease[25]. Sutherland *et al*[26], reported that the 5- and 10-year recurrence rates were significantly higher in smokers (36% and 70%) than in non-smokers (20% and 41%; OR = 2.1, *P* = 0.007). Indeed, smoking is a significant predictive risk factor for all types of recurrences: endoscopic, clinical and surgical[6,27]. Cottone *et al*[25], conducted multivariate analyses to examine predictive factors for three types of recurrence (clinical, endoscopic and surgical recurrences) after primary surgery. They found that smoking was an independent significant factor for clinical, endoscopic and surgical recurrence. In the present study, history of smoking was significant risk factor for clinical and surgical recurrence.

Another important finding was that postoperative exposure to anti-TNF agents significantly reduced the likelihood of surgical recurrence. The introduction of anti-TNF agents has significantly changed the treatment strategy for CD. Recent studies have shown that anti-TNF agents reduced postoperative recurrence[28-30]. In the present study, postoperative use of anti-TNF agents seemed to reduce the risk of reoperation, indicating that medical treatment is one of the important factors affecting surgical recurrence[31]. A randomised controlled trial was able to demonstrate clearly an advantage of anti-TNF agents in maintaining clinical remission in patients with CD[32].

Immunomodulators such as azathioprine or 6-MP has been widely used, and several studies[33,34] showed that immunomodulators could reduce rate of surgery. Similarly, previous study [9] in our center revealed that early use of immunomodulators was independently related to the decreased surgery rate (*P* = 0.01). However, because immunomodulators were generally used after first surgery, it is difficult to determine their impact on decreasing the postoperative recurrence. In present study, 85% of patients used azathioprine or 6-MP after first surgery and use of immunomodulator showed no significant difference in postoperative recurrence. More recently, these drugs are used in combination with anti-TNF drugs to decrease

their immunogenicity and increase anti-TNF drug concentrations.

Antibiotics have not been shown to be effective for induction and maintenance of remission for active CD. The best data for antibiotics are in the short-term treatment of perianal disease and in combination with anti-TNF[35]. Aside from these indications, antibiotics should really be used to treat the inflammatory complications of CD such as enteric fistula or abscess. The main limitations to using these agents long standing are antibiotic resistance and side effect.

Surgical recurrence rates differ immensely between studies. One reason could be that there is crossover with a period of rapidly changing management options, both medical and surgical. Stapled anastomosis has now virtually replaced the hand-sewn technique in the majority of centres performing surgery for CD. Stapled anastomosis following ileocecal resection is an example, as it has been reported to be safe and feasible in patients with CD[36], with a few studies demonstrating a lower incidence of anastomotic recurrence after stapled functional rather than hand-sewn end-to-end anastomosis[37]. The vast majority of patients in the present study (225/230, 97.8%) received a stapled anastomosis. Among them, 210 patients (93.3%) received a functional end-to-end anastomosis with linear stapler, with 15 patients (6.7%) receiving an end-to-end or a side-to-end anastomosis with circular stapler. Only 5 patients (2.2%) received a hand-sewn anastomosis because of severe bowel edema or dilatation.

Several other risk factors for postoperative recurrence have been found over the past decades, such as a family history of CD, perforating type, younger age at diagnosis, the type of anastomotic configuration, sex, disease location, and the presence of postoperative complications[15,38,39], but none of these factors was associated with an increased risk for repeat surgery in the present analysis.

The present study had several limitations. First, the number of patients was relatively small. Owing to this limited study population, we were unable to demonstrate an increased risk of recurrence when there were known risk factors such as a perforating type disease, family history and a presence of complication. As this study was retrospective in design, there was no standardised follow-up protocol of endoscopy or image study for the patients who underwent primary bowel resection.

However, relatively large cohort of patients in Korea was included in this study with near complete follow up, so that these results showed a clinical importance in Asian population.

In conclusion, our present referral center study of long-term course of CD in Korea revealed a several factors that were significantly associated with a higher risk for surgical recurrence: the initial surgery as an emergency, history of smoking and the presence of perianal disease after the first intestinal resection. Anti-TNF agents seemed to reduce surgical recurrence. These findings indicate that affected patients with CD may benefit from close postoperative surveillance and probably from the early administration of anti-TNF agents.

COMMENTS

Background

Majority of Crohn's disease (CD) patients experienced recurrence after their first bowel resection and postoperative recurrence affects the quality of patients' lives. Thus, to provide optimal patient care, it is important to be able to predict which patients have a higher risk of recurrence. They investigated risk factors for the postoperative recurrence of CD in a patient population from a single tertiary referral center in Korea.

Research frontiers

The increasing tendency in Korea over the past few decades calls for more attention to be paid to the natural course of CD in these newly developed disease population. This study demonstrated the clinical feature and long-term prognosis of CD in a large cohort of non-Caucasian patients. In this study, history of smoking, postoperative perianal disease and undergoing an emergency operation were found to be independent risk factors for surgical recurrence in CD. The postoperative use of anti-TNF agents reduced surgical recurrence.

Innovations and breakthroughs

This study evaluated the risk factors which contribute the surgical recurrence and showed that Korean CD patients with postoperative perianal disease had increased risk of surgical recurrence.

Applications

Presence of postoperative perianal disease associated with surgical recurrence and using anti-TNF agents for patients with risk factors may reduce surgical recurrence. Physicians should consider aggressive and early top-down therapy for perianal CD patients.

Terminology

Postoperative perianal disease: Presence of perianal disease after first bowel resection.

Peer-review

This is an interesting study in which the investigators evaluated the risk factors for postoperative recurrence after primary bowel resection in a cohort of Korean CD patients.

Abstract

AIM

To evaluate the evolution, trends in surgical approaches and reconstruction techniques, and important lessons learned from performing 1000 consecutive pancreaticoduodenectomies (PDs) for periampullary tumors.

METHODS

This is a retrospective review of the data of all patients who underwent PD for periampullary tumor during the period from January 1993 to April 2017. The data were categorized into three periods, including early period (1993-2002), middle period (2003-2012), and late period (2013-2017).

RESULTS
The frequency showed PD was increasingly performed after the year 2000. With time, elderly, cirrhotic and obese patients, as well as patients with uncinate process carcinoma and borderline tumor were increasingly selected for PD. The median operative time and postoperative hospital stay decreased significantly over the periods. Hospital mortality declined significantly, from 6.6% to 3.1%. Postoperative complications significantly decreased, from 40% to 27.9%. There was significant decrease in postoperative pancreatic fistula in the second 10 years, from 15% to 12.7%. There was a significant improvement in median survival and overall survival among the periods.

CONCLUSION
Surgical results of PD significantly improved, with mortality rate nearly reaching 3%. Pancreatic reconstruction following PD is still debatable. The survival rate was also improved but the rate of recurrence is still high, at 36.9%.

Key words: Pancreaticoduodenectomy; Pancreaticogastrostomy; Pancreaticojejunostomy; Postoperative pancreatic fistula; Periampullary tumor

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Pancreaticoduodenectomy (PD) is a complex abdominal procedure. The hospital mortality rate has decreased to less than 5%; however, the rate of postoperative morbidities remains high, from 40% to 50%. Pancreatic reconstruction following PD is still debatable. The long survival rate after PD is clearly improved with time but still poor. Frequency showed PD is increasingly performed. With time, elderly, cirrhotic and obese patients, and patients with uncinate process carcinoma and borderline tumor are increasingly selected for PD. Median operative time and postoperative hospital stay decreased significantly. Hospital mortality declined significantly, from 6.6% to 3.1%. Postoperative complications significantly decreased.

Trends and outcomes of pancreaticoduodenectomy for periampullary tumors: A 25-year single-center study of 1000 consecutive cases. *World J Gastroenterol* 2017; 23(38):7025-7036 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/7025.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.7025

INTRODUCTION

The first successful localized resection of periampullary tumor was performed by Dr William S Halsted in 1898. For the first time, Allen O Whipple described pancreaticoduodenectomy (PD) in the year 1935, when he modified the procedure that was performed before by Alessendro Codinivillan in Italy and Walter Keusch in Germany[1,2]. In 1963, Whipple performed 37 PDs in his era. From this era till 1980, PD was infrequently performed because the hospital mortality was high (> 25%). After 1990, with development of high-volume centers and improvement of operative technique, surgical equipment, and perioperative care, PD has become a relatively safe and commonly performed procedure[3-5].

PD is one of the most complex abdominal operations that is performed for a heterogeneous group of periampullary lesions, either benign or malignant. PD involves extensive dissection, resection and different reconstruction procedures[3-8]. The rate of postoperative morbidities remains high, from 40% to 50%. However, the hospital mortality rate has decreased to less than 5% in many published series[5-8,9-11].

Many studies were performed to determine the risk factors of post-operative pancreatic fistula and try to present a fistula risk scoring system after PD. These various systems used many factors including pancreatic duct diameter, consistency of pancreas, body mass index (BMI) > 25 kg/m^2, and final pathology[4-6,11-15]. Pancreatic reconstruction following PD is still debatable, even for pancreatic surgeons. Ideally, pancreatic reconstruction after PD should reduce the risk of post-operative pancreatic fistula (POPF) and its severity if developed with preservation of pancreatic functions (exocrine and endocrine functions)[5-8].

The prognosis of pancreatic head adenocarcinoma is one of the most dismal of all cancers. After PD, the 5-year survival is 5% to 20%, representing the worst survival among the periampullary cancers. Numerous prognostic factors have been found to improve survival rate after PD, including lymph node status, free safety margins, tumor size, differentiation, complete excision of mesopancreas, and vascular invasion[11-14].

Many points are still debatable regarding PD, including selection of patients, pancreatic reconstruction, and factors that improve survival rate. Thus, the aim of this study was to evaluate the evolution, trends in surgical approaches and reconstruction techniques, and important lessons learned from performing 1000 consecutive PD for periampullary tumors in the Gastrointestinal Surgery Center of Mansoura University over a period of 25 years.

MATERIALS AND METHODS

Study design

This is a retrospective review of the data of all patients who underwent PD for periampullary tumor in the Gastrointestinal Surgery Center (Mansoura University, Egypt) during the period from January 1993 to April

2017. Patient data were recorded in a prospectively maintained database for all patients undergoing PD since the year 2000; for patients from before 2000, the data were obtained from the archived files. An informed consent for the surgical procedures was obtained from each patient. The Gastrointestinal Surgery Center of Mansoura University is a high-volume center of pancreatic surgery that was established in 1992. The first PD was performed in 1993, and was regularly performed afterwards in our center over a period of 25 years.

Inclusion criteria

This study included 1000 patients who underwent PD for different periampullary tumors (benign and malignant lesions) at our Center in Mansoura University, Egypt during the period from January 1993 to April 2017. Over the 25-year period, 1000 consecutive PD were performed by 20 surgeons. For this study, the data were categorized into three periods, early period (1993-2002), middle period (2003-2012), and late period (2013-2017). This study was approved by the local institutional review board (IRB).

Exclusion criteria

Patients with periampullary lesions who were explored during the same period and failed to complete the PD procedure due to the presence of locally advanced or distant metastatic disease that was not detected in preoperative radiological workup.

Preoperative assessment

Preoperative diagnostic workup included clinical assessment, detailed laboratory investigations, including tumor markers, and radiological investigations (abdominal ultrasound, abdominal triphasic computed tomography (CT), CT angiography, magnetic resonance cholangiopancreatography, chest X-ray and bone survey). Preoperative biliary drainage was performed by endoscopic retrograde cholangiopancreatography in selected patients[16].

Surgical procedures

Over the study period and with accumulating experience, evolution of the surgical approach and techniques occurred.

Dissection technique

In the early period, the anterior approach was utilized in surgical dissection. Afterwards, we shifted to utilize the posterior approach (one of the artery first approaches), aiming to identify vascular invasion at an early stage of the dissection, and to allow more radical excision of the mesopancreas[17]. Standard regional lymphadenectomy was performed, which included resection of nodes within the outlines of the hepatoduodenal ligament, right side of the superior mesenteric vessels, and inferior vena cava. In the early period, diathermy dissection and ligatures were used during the resection stage. Afterwards, a shift to use modern energy devices occurred, such as for Ligasure and Harmonic scalpel.

Approach

In most of our study period, we utilized an open surgical approach through extended right subcostal or inverted J incisions. In the late period, we started to utilize laparoscopic approach, with laparoscopy-assisted approach used in the beginning. This included complete dissection by the laparoscopy followed by reconstruction carried out through a small upper midline or transverse incision. In the last year, we performed a total of 10 laparoscopic PDs. This included completing the whole approach (dissection and reconstruction) by laparoscopy.

Meso-pancreatectomy

A complete removal of all lympho-vascular tissues between the uncinate process and superior mesenteric artery was mandatory in PD. These tissues are the most important site for local recurrence after PD. This concept had evolved in the recent years and became a standard step in the radical resection of periampullary tumors. We adopted this concept in the recent years of our study.

Division of the pancreatic neck

Initially, we divided the pancreatic neck sharply by surgical scalpel and then carried out the hemostasis after division. Recently, we started to divide the pancreatic neck by diathermy and Harmonic scalpel.

Reconstruction

In the beginning of our series, we performed simple loop pancreaticojejunostomy (PJ) for the reconstruction of the pancreatic stump. However, a high rate of pancreatic fistula was noticed. A shift of the reconstruction plan occurred to pancreaticogastrostomy (PG). Short-term outcomes were improved and lower rate of pancreatic fistula was noticed, but the long-term outcomes regarding the digestive and nutritional conditions were not appropriate.

With accumulating experience and refinement of the surgical technique, a re-shift to PJ (simple loop or isolated loop) occurred, which improved long-term outcomes[18,19]. Recently, we adopted a tailored approach for pancreatic stump management. In patients at high risk of pancreatic fistula (presence of two or more risk factors) PG is preferred. In low- and moderate-risk patients (absence of risk factors or presence of one risk factor) PJ is preferred.

Postoperative management

All patients were transferred to the intensive care unit (ICU) postoperatively. Antibiotics and analgesic were

given to all patients. Octreotide analogue was given to some patients postoperatively. Abdominal drains and nasogastric tubes outputs were recorded daily. Patients started oral feeding once bowel sounds restarted and they were able to tolerate nutrition by a fluid diet, then a regular diet.

Abdominal ultrasound was done routinely in all patients postoperatively. Serum amylase and liver function tests were measured on postoperative day (POD) 1 and POD 5. Ultrasound-guided tubal drainage was carried out in patients who had an abdominal collection.

Follow-up occurred at 1 wk, 3 mo and 6 mo postoperatively, and then at 1 year. Patients were also seen at outpatient clinics if symptoms developed between follow-up visits.

Definitions

Complications were defined as adverse events resulting in deviation from the normal postoperative course within 30 d after operation. Severity of complications was assessed using the Clavien classification system, from 1 to 5. Major complications represent those requiring endoscopic, radiologic or surgical intervention, and were defined as class 3 or higher[20].

Postoperative pancreatic fistula was defined by International Study Group of Pancreatic Fistula as any measurable volume of fluid on or after POD 3 with amylase content greater than three times the serum amylase activity, and classified into three grades: A, B or C[21-23].

Delayed gastric emptying (DGE) was defined as output from a nasogastric tube of greater than 500 mL per day that persisted beyond POD 10, the failure to maintain oral intake by POD 14, or reinsertion of a nasogastric tube[21-24].

Outcomes of the study

The aim of this study was to evaluate the milestones, trends in surgical approaches, reconstruction techniques and important lessons learned from performing 1000 consecutive PD for periampullary tumors in the Gastrointestinal Surgery Center of Mansoura University over a period of 25 years. The main outcome of the study was the rates of postoperative morbidity, according to Clavien-Dindo classifications, and of mortality after PD. Special concern was focused on POPF, biliary complications, DGE and the predictive factors of each. In addition, we evaluated the survival outcomes of the PD patients, including recurrence, overall survival (OS) and the different predictive factors of each.

Statistical analysis

Statistical analysis of the data in this study was performed using SPSS software for windows, version 20. For continuous variables, descriptive statistics were calculated and reported as median. Categorical variables were described using frequency distributions. The χ^2 test was used to compare categorical variables and one-way ANOVA for continuous variables. The predictive factors for postoperative complications were evaluated by binary logistic regression method. Survival outcomes were calculated by the Kaplan-Meier method. The predictive factors for survival were evaluated by the Cox regression method. *P* values < 0.05 were considered to be significant.

RESULTS

One thousand patients underwent PD for resection of periampullary tumors from January 1993 to April 2017. Of the 1000 patients who underwent PD, 556 involved pancreatic head mass, 312 were ampullary tumors, 61 were duodenal tumors, 41 were cholangiocarcinoma and 30 were uncinate process mass. The median age of patients was 54-years-old. The data were categorized into three periods. For the first 10 years (1993-2002), a total of 300 patients underwent PD (30 cases/year). In the next 10 years (2003-2012), the total number was 442 patients who underwent PD (44.2 cases/year). In the last 5 years (2013-2017), the total number was 258 patients who underwent PD (51.6 cases/year) (Figure 1).

Preoperative data

Elderly patients were increasingly selected for PD, as the median age was 53 in the first 10 years and 55 in the last 5 years. Obese patients were increasingly selected in the last five years. There were no significant changes for selection of patients for PBD in the period of the study. PBD was indicated for patients with high serum bilirubin (> 10 mg%) with high liver enzymes, renal impairment or associated cholangitis (Table 1).

Intraoperative data

Patients with periampullary tumors and well-compensated chronic liver disease were increasingly selected for PD (Table 2). In the early period, we performed simple loop PJ (21.7%) for the reconstruction of the pancreatic stump, then shifted to PG (78.3%). In the second 10 years, 94.3% of cases underwent PG. In the last 5 years, there was a re-shift to PJ (simple loop or isolated loop) (46.1%). Complete meso-pancreatecomy was achieved in all cases in the last 5 years Operative time was significantly reduced, from 6 h in the first 10 years to 5 h in last 5 years. The median intraoperative blood loss decreased from 500 cc in the first 10 years to 300 cc in last 5 years.

Postoperative data

The overall morbidity of all 1000 patients was 32.3%. The postoperative complications decreased markedly in the recent years, from 40% to 27.9%. There was a significant decrease in POPF in the second 10

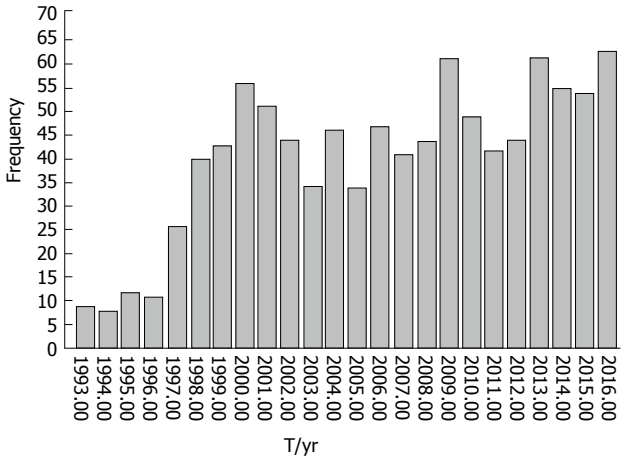

Figure 1 In the first 10 years (1993-2002), the total number of patients who underwent PD was 300 (30 cases/yr), in the next 10 years (2003-2012) 442 patients underwent PD (44.2 cases/yr), and in the last 4 years (2013-2017) 258 cases underwent PD (51.6 cases/yr).

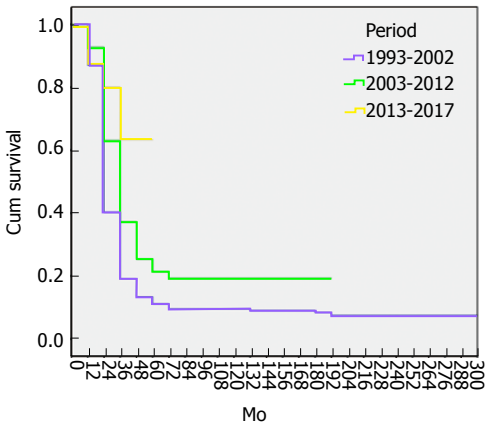

Figure 2 Overall survival curves of patients according to the 3 periods of study. The overall survival rate significantly improved and 5-yr survival rate for the early period was 11%, followed by 21% for the middle period and 64% for the late period (P = 0.0001)

years, from 15% to 12.7% with a decrease in the severity. But the incidence of POPF increased again in last 5 years to 14.7%. DGE was the most common complication (18%). It was secondary to other postoperative complications in 15.2%. Primary DGE presented in 2.8% of cases (Table 3).

The median hospital stay and the day of drain removal were significantly shortest in the late period, decreasing from 9 days to 8 days. The overall hospital mortality of all 1000 patients was 4.3% (43 patients). The hospital mortality declined significantly, from 6.6% to 3.1%. The causes of death were sepsis secondary to POPF in 17 patients, with 6 cases due to cardiac arrest, 6 cases due to liver cell failure, 5 cases due to pulmonary embolism, 3 cases due to pancreatitis, 3 cases due to respiratory failure secondary to severe chest infection, 2 cases due to secondary hemorrhage, and 1 case due to PG–related uncontrolled bleeding.

Seventy patients developed intra-abdominal collection and were managed by ultrasound-guided tubal drainage. Seventy-four patients (7.4%) required re-explorations due to internal hemorrhage (26 patients, with 7/26 due to erosion of gastroduodenal artery), bleeding GJ (17 patients), bleeding PG (15 patients), peritonitis (12 patients) or debridement and drainage (4 patients). Completion spleno-pancreatectomy was needed in 2 cases due to POPF that eroded the gastroduodenal artery and were complicated by secondary internal hemorrhage

The overall recurrence rate in 870 patients who had malignant pathology after PD was 36.9.2%. This rate decreased from 50.4% to 28.7%

Univariate analysis of risk factors for development of POPF found that six variables were significantly associated with POPF (BMI > 25 kg/m^2, liver cirrhosis, soft pancreas, main pancreatic duct < 3 mm, pancreatic duct close to posterior edge < 3 mm, and period of the study). These six risk factors of POPF identified in univariate analysis were further analyzed in multivariate analysis. Soft pancreas, main pancreatic duct < 3 mm pancreatic duct close to posterior edge < 3 mm, BMI > 25 kg/m^2 and period of the study were found to be independent risk factors (Table 4).

Postoperative pathology

There was significant difference among groups regarding site of periampullary tumor, type of pathology, number of dissected lymph nodes, number of infiltrated lymph nodes, lymph node ratio, safety margin, perivascular infiltration and perineural invasion (Table 5).

Survival rate

The 1-, 3- and 5-year OS rates for all cases were 90%, 33% and 19% respectively, with a median survival of 26 mo. There was a significant difference among the groups regarding the median survival and the OS rates at 1-, 3- and 5-years (Tables 3 and 6, Figure 2). The survival analysis in this study revealed that female sex, patients who did not develop major complications, presence of ampullary tumor, type of pathology, negative safety margin, negative lymph nodes, chemoradiotherapy and period of the study were all favorable prognostic variables in univariate and multivariate analyses. The improvement of survival with recent years may be due to complete excision of mesopancreas, greater use of postoperative chemoradiotherapy, improvement of surgical techniques, and strict follow up of most of cases (Table 6).

DISCUSSION

PD is a complex procedure including extensive dissection, resection and multiple reconstruction. Allen O Whipple described PD in the year 1935. From Whipple's era till 1980, PD was performed infrequently

because the hospital mortality was high above 25%[2].

Patient selection is still an important factor in decreasing postoperative morbidity and mortality. In our series, the frequency of PD had been increasingly performed after the year 2000. Elderly patients were increasingly selected for PD, as the median age was 53 years in the first 10 years and became 55 years in the last 5 years. In the last 5 years, we accepted patients over the age of 75.

The significant improvement in the surgical

outcome of PD has encouraged surgeons to approach periampullary tumors as aggressively in elderly patients[7,12]. Patients with periampullary tumors and well-compensated chronic liver disease are increasingly selected for PD with accepted surgical outcomes. PD is only recommended in patients with Child A cirrhosis without portal hypertension[13]. PD is associated with an increased risk of postoperative morbidity in obese patients. With time, obesity has lost its status as a limitation for PD and such patients have been increasingly selected[25-27].

Patients with uncinate process carcinoma are increasingly selected for PD as well. However, the loco-regional recurrence rate was found to be common and the OS rate to be lower than other periampullary tumors[28]. The role of postoperative chemoradiotherapy may improve the results. Borderline resectable pancreatic cancer should be included as an indication of PD with advancements in chemoradiotherapy and techniques of vascular resection[29].

The impact of PBD on postoperative outcomes remains controversial. PBD before PD was associated with major postoperative morbidities and stent-related morbidities, including infection, pancreatitis or adhesions. There are no significant changes for selection of patients for PBD in the period of the study. PBD is indicated for patients with high serum bilirubin (> 10 mg%) with high liver enzymes, renal impairment, or associated cholangitis[16,30,31].

In our Center, laparoscopic pancreaticoduodenectomy (LPD) has been introduced as a feasible alternative to open PD since 2013, involving dissection in some cases, then complete LPD was performed at the end of 2013; unfortunately, however, the patients died on POD 7. We restarted again in January 2016 to perform 10 complete LPDs; in all cases, the pancreatic reconstruction was PG. The median operative time was 8 h, so the procedure was performed by two teams (one team for complete dissection and the other one to perform all reconstruction). Only one hospital mortality occurred due to severe pancreatitis, and all cases passed smoothly without any complications. The median hospital stay was 5 days. The most important point to performing a safe LPD is to perform the procedure under skilled hands in selected patients and

Table 4 Univariate and multivariate analyses of risk factors of development of post-operative pancreatic fistula

using suitable surgical techniques[32,33].

The ideal and safe pancreatic reconstruction following PD is still debatable. We performed a comparative randomized study between PG and isolated loop PJ which revealed no significant difference between both methods in regards to POPF, but the pancreatic function was preserved with isolated loop PJ[18,19]. Recently, with accumulating experience and refinement of the surgical technique, we adopted a tailored approach for the management of pancreatic stump management. Another prospective randomized study comparing duct to mucosa and invagination PJ

BMI: Body mass index; CBD: Common bile duct; CEA: Carcinoembryonic antigen; ERCP: Endoscopic retrograde cholangiopancreatography; PG: Pancreaticogastrostomy; PJ: Pancreaticojejunostomy; POPF: Postoperative pancreatic fistula.

carried out in our center concluded that invagination PJ is preferred in small pancreatic duct and provides less incidence of postoperative steatorrhea and was associated with less severity of POPF, if developed, than duct to mucosa[19].

In our series, 32.3% of patients undergoing PD had complications. The majority of complications were minor and not life threatening. The postoperative complications decreased markedly in the recent years, from 40% to 27.9%. There was significant decrease in POPF in the second 10 years, from 15% to 12.7% with decrease in severity due to shift of pancreatic reconstruction from PJ to PG. But, the incidence of POPF increased again in last 5 years to 14.7%, due to re-shift again to PJ in order to achieve better long-term outcomes regarding function and morphology of pancreas[18,19]. In this study, the development of major complications had a negative impact on OS.

The median hospital stay was significantly shortest in the last 10 years. In many high-volume centers, there has been significant decrease in postoperative stay after PD as a result of the increase in the frequency of PD, the decrease in incidence of complications, especially of DGE, the decrease in use of pylorus-preserving PD, which is complicated by high incidence of DGE, and the improvements in postoperative care and management of postoperative complications[6,7,34-36].

In this study, the overall hospital mortality was 4.3%. Of the patients who died, 17/43 (39.5%) of the deaths were due to sepsis secondary to POPF. The decrease in hospital mortality following PD over the time is the most prominent achievement in PD. In this study, the hospital mortality rate decreased significantly from 6.6% to 3.1%, which is comparable to the reported mortality rates in other high-volume centers[6-8].

Long-term survival after PD for periampullary tumor adenocarcinoma is still poor. However, the survival after PD has clearly improved with time, due to improvement of surgical techniques, complete excision of mesopancreas, greater use of neoadjuvant and/or adjuvant chemoradiotherapy, and strict follow up of most of cases. There are many high-volume centers in which patients with pancreatic head carcinoma treated by PD have a 5-year survival rate of around 20%[6,7,35,36].

In conclusion, the frequency of PD has increased and become a relatively safe procedure in our Center. With time, elderly, cirrhotic, obese patients, patients with uncinate process carcinoma and borderline tumors have been increasingly selected for PD. Surgical results of PD, including operative time, hospital stay and postoperative complications, have significantly improved, with the mortality rate reaching nearly 3%. Pancreatic reconstruction following PD is still debatable. PG provides better short-term outcomes including POPF, but the long-term outcomes regarding the pancreatic function and nutrition were not appropriate. However, PJ provides better long-term outcomes. The survival rate also improved due to complete meso-pancreatectomy and utilization of adjuvant chemoradiotherapy, but the rate of recurrence is still high at 36.9%. LPD has been introduced as a feasible alternative to open PD.

Abstract

AIM

To determine whether hepatitis B virus (HBV)-testing could serve as a gateway to vaccinate non-immunized individuals in a low-prevalent country.

METHODS

Non-immunized subjects participating in a multi-center, HBV-testing campaign in Paris, France were identified and contacted via telephone 3-9 mo after testing in order to determine vaccination status. Vaccination coverage was evaluated in per-protocol (for all respondents) and intent-to-treat analysis (assuming all non-responders did not vaccinate).

RESULTS

In total, 1215/4924 (24.7%) enrolled subjects with complete HBV serology were identified as non-immunized and eligible for analysis. There were 99/902 successfully contacted subjects who had initiated HBV vaccination after screening: per-protocol, 11.0% (95%CI: 9.0-13.2); intent-to-treat, 8.2% (95%CI: 6.7-9.8). In multivariable analysis, vaccination was more likely to be initiated in individuals originating from moderate or high HBV-endemic countries (P < 0.001), patients with limited healthcare coverage (P = 0.01) and men who have sex with men (P = 0.02). When asked about the reasons for not initiating HBV vaccination, the most frequent response was "will be vaccinated later" (33.4%), followed by "did not want to vaccinate" (29.8%), and "vaccination was not proposed by the physician" (21.5%). Sub-group analysis indicated a stark contrast in vaccination coverage across centers, ranging from 0%-56%.

CONCLUSION

HBV-vaccination after HBV screening was very low in this study, which appeared largely attributed to physician-patient motivation towards vaccination. Increased vaccination coverage might be achieved by emphasizing its need at the organizational level.

Core tip: Testing for hepatitis B virus (HBV) not only serves as a means to identify HBV-infected individuals, but also those who are non-immunized and could further benefit from HBV vaccination. In this mass HBV-screening study within the Paris metropolitan region, vaccine uptake was achieved in 11% of non-immunized patients and was deemed poor. Strategies to increase vaccination after testing need to be considered.

Testing for hepatitis B virus alone does not increase vaccine coverage in non-immunized persons. *World J Gastroenterol* 2017; 23(38): 7037-7046 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/7037.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.7037

INTRODUCTION

Hepatitis B virus (HBV) is one of the most frequent chronic infectious diseases in Western countries[1], with a prevalence of roughly one million in the United States[2] and 14 million in Europe[3]. The effectiveness of HBV vaccination in reducing infection incidence has been demonstrated in several countries with varying HBV prevalence[4-6], making it the single most effective tool for prevention. Nevertheless, coverage rates remain insufficient despite the wide availability of vaccines[3,7] and are particularly low in certain at-risk infection groups[8,9].

In France, the proportion of vaccinated individuals is surprisingly modest compared to other industrialized countries[10], even though vaccination is reimbursed in part by the national healthcare system. Recent epidemiological studies have estimated vaccine coverage at 50%[6], compared to 83% worldwide and higher than 90% in the Western Pacific region[1]. Prevalence of individuals with hepatitis B surface antigen (HBsAg) positive serology has remained exceedingly low over the past decade (0.7%)[11]. Nevertheless, 2500 persons are acutely infected each year, with the majority belonging to high-risk groups[12]. Vaccination campaigns targeted at these risk groups could help curb incident infections.

Accordingly, in current national guidelines, vaccination of non-immunized individuals who fall into these high-risk categories is strongly recommended[13]. Considering that HBV testing is necessary in determining those eligible for vaccination and HBV tests are given frequently in France (at almost 3.4 million tests per year), HBV screening could serve as a wide-reaching gateway to vaccination. Unfortunately, vaccination practices, specifically following HBV-testing, are poorly understood. The objective of this study was then to describe rates of vaccination among non-immunized individuals during a mass-screening program. We also intended to evaluate the reasons for

not initiating HBV vaccination after testing.

MATERIALS AND METHODS

Study design and participants

Participants were selected from the multi-center OPTISCREEN-B study, which took place in the Paris, France metropolitan region from 2011-2012[14,15]. Briefly, the study was conducted in two phases. The first phase was a cross-sectional study aimed at evaluating several rapid test candidates that could detect serological markers commonly used in HBV screening. The second phase was a parallel-group, randomized trial aimed at comparing the use of standard HBV serological tests versus rapid tests (NCT01767597). Participant recruitment occurred at 10 primary healthcare centers, with various objectives related to HBV screening, vaccination, and care - three were sexually transmitted disease (STD) clinics, three were clinics with predominately general practitioners, three focused on immigrant health, and one on incarcerated individuals. The study procedures of both phases have been described in detail[14,15]. The study was approved by the Hôtel-Dieu Hospital Ethics Committee (Paris, France) in accordance with the Helsinki Declaration.

Volunteers were asked to participate during their regular consultations if ⩾ 18 years old and could be available for further contact and medical follow-up at a single university teaching hospital. For both studies, only individuals eligible for HBV screening were invited to participate. Individuals were not included for the following reasons - for both phases: unwilling to participate; for Phase II only: already participated in the OPTISCREEN-B Phase I validation study or were not covered under the national healthcare system. Signed written informed consent was obtained for all eligible participants.

In this sub-study, we restricted our sample population to participants who were identified as non-immunized by complete HBV serological testing [*i.e.* HBsAg, anti-hepatitis B core (HBc) antibody, and anti-hepatitis B surface (HBs) antibody negative serology].

Hepatitis B virus serological testing

During the study visit, roughly 10 mL of blood was drawn and then tested for HBsAg, anti-HBs antibody, and anti-HBc antibody. Serostatus was determined using a commercially-available enzyme-linked immunoassay assay (MONOLISA AgHBs Ultra, anti-HBs plus, anti-hepatitis B core antibody-anti-HBc-plus; Bio-Rad, Hercules, California, United States of Americ). Results were provided 7-14 d after testing and, depending on the study center, were either mailed to the participants or left at the study center for collection.

Hepatitis B virus risk-factor questionnaire

Questionnaires were administered by a trained clinical research assistant during a face-to-face interview with the participant. Questions were asked in lay terms on a variety of sociodemographic characteristics, healthcare coverage, HBV transmission risk-factors, as well as other potential risk-factors. HBV-endemicity of birth country was established according to World Health Organization classification (prevalence of HBsAg-positive individuals): high (8%), intermediate (2%-8%), and low (2%).

Assessing post-test hepatitis B virus vaccination

Non-immunized individuals were identified by serology (HBsAg, anti-HBs antibody and anti-HBc antibody negative) and then contacted via telephone roughly 6-9 and 3-6 mo after testing in Phase I and II, respectively. If a participant could not be contacted after the third attempt, they were considered as having "no reply". Subjects were asked whether or not they initiated immunization against HBV and at which dates their injection(s) were administered. As we conducted follow-up during a telephone interview, physical verification of the participants' vaccination card was not performed. If they indicated no vaccination, they were asked to choose one or several reason(s) from a list for not initiating HBV immunization.

Statistical analysis

The primary outcome in per-protocol analysis was defined as the proportion of non-immunized participants initiating vaccination during follow-up who were able to be contacted. In intent-to-treat analysis, the outcome was defined as the proportion of non-immunized participants initiating vaccination assuming that those who were unable to be contacted did not initiate or complete vaccination. Clopper-Pearson 95% confidence intervals (CI) were calculated for these proportions.

In order to evaluate the determinants of HBV vaccination during follow-up (defined by per-protocol analysis), we used random-effects logistic regression to estimate univariate odds ratios (OR) of various risk-factors and their 95% CIs while accounting for within-center correlation. A multivariable model was then constructed in a backwards-stepwise fashion. A full model containing risk-factors with a P-value ⩽ 0.10 in univariable analysis was initially selected and covariates with a P-value > 0.10, as tested using a likelihood ratio test, were sequentially excluded from the model.

All statistical analysis was performed using STATA (v13.1, College Station, TX, United States of America) and reviewed by two biomedical statisticians. Significance was determined using a P-value < 0.05.

RESULTS

Study participants

The flow of study participants is represented in Figure

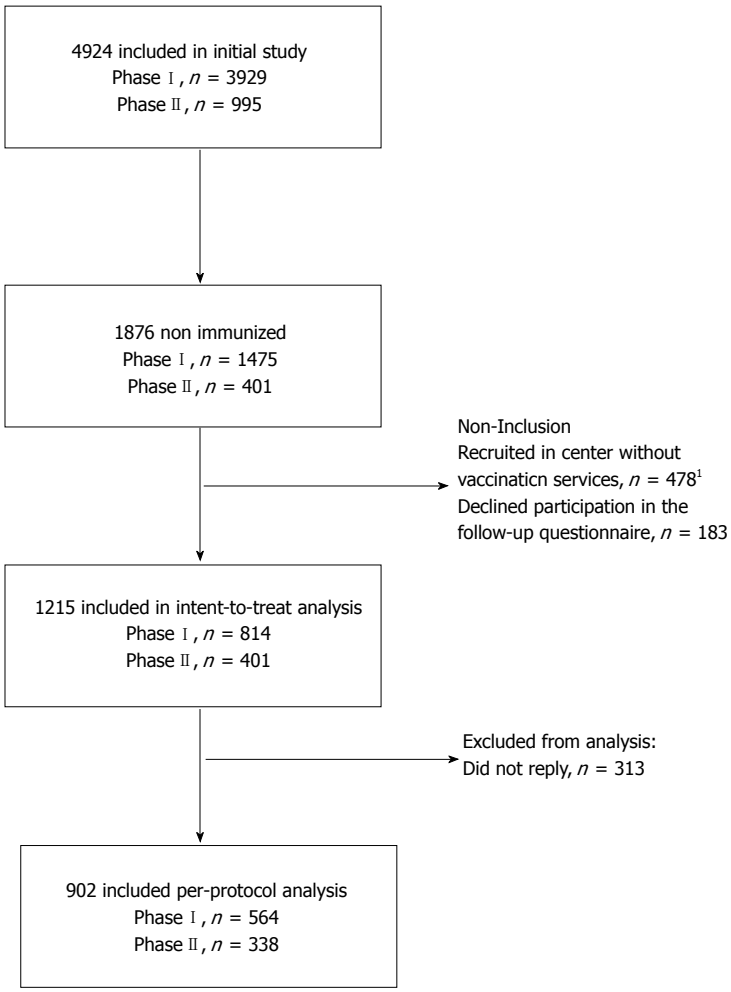

Figure 1 Study flow chart. [1]Only applies to certain participants in Phase Ⅰ.

1. A total of 4924 participants were included in the OPTISCREEN-B study, 1876 (38.1%) of whom were non-immunized and considered for the present sub-study. Of them, 661 were not included because they sought care at a center where, at the time of Phase I, did not offer vaccination services (*n* = 478) or declined participation in the follow-up questionnaire (*n* = 183). In total, 1215 participants were included in analysis.

Description of the study population

Table 1 provides a summary of the study population. The majority of individuals was male, coming from a country of low HBV-prevalence, and covered under the French national healthcare system. Included participants were born in the following geographical regions: West/East Europe, *n* = 710 (58.4%); Mediterranean, *n* = 183 (15.1%); Asia, *n* = 90 (7.4%); Sub-Saharan Africa, *n* = 135 (11.1%); South America, *n* = 43 (3.5%); other, *n* = 54 (4.4%). A total of 1043 (85.8%) of participants were indicated for vaccination according to French recommendations, the most frequent reasons for which were multiple lifetime sexual partners, originating from a moderate/high HBV-endemic country and traveling to high endemic countries. A smaller proportion was men who had sex with men (MSM) or partook in nasal or intravenous drug-use. Characteristics of study participants were compered between enrollment phases in Supplementary Table 1.

Post-test hepatitis B virus vaccination rates

Among the 1215 participants included in analysis, 99 (8.2%) claimed to have initiated HBV vaccination, while the first injection was given a median 31 d (IQR = 12-55) after testing; 803 (66.1%) did not initiate vaccination; and 313 (25.7%) did not respond after the third contact attempt. Participants who did not respond were significantly younger ($P = 0.02$), more likely to come from an intermediate HBV-endemic country ($P < 0.001$), did not have any healthcare coverage ($P < 0.001$), and had a lower number of lifetime sexual partners ($P = 0.001$) (Table 1).

In per-protocol analysis (Table 2), immunization coverage was 11.0% (95%CI 9.0-13.2) during follow-up. This proportion varied substantially across centers (0%-55.6%), with the lowest vaccine coverage observed in STD clinics (7.5%) and centers with mainly general practitioners (6.3%) and the highest

Per-protocol analysis on the 902 non-immunized participants who were able to be contacted. [1]Period of stay was longer than 3 mo; [2]Couverture médicale universelle, health insurance coverage that is given to persons living in precarious situations (*i.e.* unemployed, poverty, *etc*; [3]Couverture médicale universelle complémentaire, additional health insurance coverage that is given to stable residents in France living with limited financial resources; [4]Aide médicale d'état, health insurace generally given to immigrants without proper documentation; [5]When constructing the multivariable model, gender was not included due to collinearity with men who have sex with men.

variability (Table 2).

Table 3 describes the per-protocol analysis of risk-factors associated with HBV vaccination. Of note, there was no association between vaccination and study phase (Phase II versus I, OR = 0.66, 95%CI 0.27-1.62, *P* = 0.4). In multivariable analysis, vaccination was more likely to be initiated in MSM (*P* = 0.02), participants born in intermediate/high endemic zones (*P* < 0.001) and those without national healthcare coverage (*P* = 0.006). When replacing gender with MSM in the multivariable model, there was no significant difference between males and females (adjusted - OR = 0.66, 95%CI 0.40-1.10).

Reasons for not initiating vaccination

In the 803 non-vaccinees who were able to be contacted, Table 4 summarizes their reasons for not vaccinating. Roughly one-third stated that they would vaccinate at a later time. Other reasons included no desire to vaccinate (29.8%), vaccination was not suggested by their physician (21.5%), or the participant did not return to obtain their serological results confirming non-immunized status (14.0%). Participants who preferred not to vaccinate were significantly more likely to be male (*P* = 0.002), older (*P* < 0.001), come from a low endemic country (*P* < 0.001), be covered under the French national healthcare system (*P* < 0.001), and have higher number of lifetime sexual partners (*P* = 0.004) (Supplementary Table 2).

DISCUSSION

HBV testing has been proposed as a useful gateway to identify non-immunized individuals and encourage them to initiate vaccination[16], yet data regarding the extent of how successful this strategy would be, if applied, are sparse. Previous studies in France and California have shown that vaccine coverage ranges from 8.6%-11.2% after testing for HBV in the context of STD clinics[17,18]; however, these results were obtained from mostly younger, sexually-active individuals or more specifically, among adults diagnosed with chlamydia, gonorrhoae and/or syphilis who were still susceptible to HBV infection. In the OPTISCREEN-B studies, serving as a testing campaign against HBV infection in a population with diverse at-risk characteristics, we similarly observed a low vaccination rate of 11.0% in per-protocol and 8.2% in intent-to-treat analysis.

The reasons for low vaccine coverage are somewhat difficult to pinpoint. While examining individual characteristics, it was interesting to find that those originating from regions of moderate or high HBV

Table 4 Reasons for not initiating hepatitis B virus vaccination

Reason	*n* (%)
Serology results were never obtained	112 (14.0)
Vaccination was not proposed by physician	173 (21.5)
Vaccination was not indicated (according to physician)	26 (3.2)
Not at risk	14 (1.7)
Vaccination was already done[1]	12 (1.5)
Participant did not want to be vaccinated	239 (29.8)
Not perceived to be at risk	95 (11.8)
Vaccination was already done	21 (2.6)
Not receptive to vaccinations in general	44 (5.5)
Not receptive to HBV vaccination	89 (11.1)
Will be vaccinated later	268 (33.4)

Among the 803 contacted individuals who did not initiate HBV vaccination. More than one response was possible (only applies to 15 participants). [1]No indication for revaccination despite undetectable anti-HBs antibodies.

endemicity and those in difficult socioeconomic situations, based on their healthcare plan, were significantly more likely to initiate HBV vaccination after testing. These data are relieving considering that these two risk-factor groups constitute the largest number of newly identified infections in France[12]. However, it should be mentioned that these groups also had the highest proportions of non-response, particularly individuals without healthcare or from intermediate HBV-endemic countries. MSM were also observed to have a significantly higher vaccination initiation rates, while this key population has shown rather high vaccine uptake in previous intervention studies[19,20]. Unfortunately, two groups with high HBV-infection risk, namely persons having close contact with an infected individual or engaging in nasal or intravenous drug use, were not more likely to become vaccinated.

When addressing the reasons for not vaccinating, approximately one-third responded that they did not want to be vaccinated, mainly because they were not receptive to HBV vaccination or not perceived to be at risk. Vaccine hesitancy has already been illustrated in a study from a French STD clinic, where most non-immunized persons did not trust the safety of HBV vaccines or viewed it as "not well characterized"[21]. We also observed that individuals covered under the French national healthcare plan or those coming from a low HBV-endemic country were more likely not to vaccinate. Their lack of motivation could stem from a lower perception of HBV-transmission risk, which has been previously evidenced in persons with higher socioeconomic status in France[22].

Another one-fifth of non-vaccinated individuals claimed that their physician did not propose vaccination. This result is rather surprising given that professionals have been recommended to initiate vaccination for all non-immunized persons susceptible to transmission since 1995. Few (3.2%) participants stated that they were not indicated for vaccination by their physician, implying that recommendation criteria did not play a major role in the low vaccine coverage observed with this group. One striking feature of our data, however, was that post-testing vaccination rates varied from 0% to 56% across study centers, largely implicating organizational factors in promoting HBV vaccination.

These results support the need for structural reorganization in testing facilities as a means to encourage vaccination. Promising data on interventions at the organization level have been presented in other research, in which increased vaccination rates were achieved after providing focused training to healthcare professionals and individuals seeking testing[23] or when free vaccinations were offered directly after HBV serological results were returned[17]. Other interventions involving financial incentives have also shown substantial effects in at-risk populations, such as intravenous drug-users[24,25]. These strategies would certainly be helpful in counterbalancing vaccine hesitancy, which has been an emerging topic over the past decades[10], notably among health-care providers in general and in France[26-28]. Without these interventions, the proportion of individuals at risk of HBV-infection could rebound and persist as a public health issue[6].

Nevertheless, many of the participants in this analysis came from difficult socioeconomic backgrounds. Past research has underscored the lack of access to preventative health services especially among migrants[29], certain racial/ethnic groups[30], and homeless individuals[31]. Since the majority of vaccination occurs within the context of these services, social inclusion of disadvantaged groups, particularly at primary care centers, would probably be necessary in order to achieve greater vaccine outreach. Although the French healthcare system attempts at addressing care in these groups[32], further improvements could be made with other strategies, such as mobile clinics providing vaccinations[33] or culturally-adapted text message reminders[34]. The services provided at these healthcare centers should also emphasize education on HBV disease and the benefits of vaccination, possibly in combination with care related to other health issues.

There were several noteworthy parallels with the results from this study compared to previous analyses in the OPTISCREEN-B program. The profile of participants accepting vaccination (*i.e.* from regions of moderate to high HBV endemicity, without health care coverage) were also those who more frequently tested for HBV in the past[35], which are perhaps indicators of effective prevention efforts in these at-risk groups. In addition, the between-center variability in the proportion receiving vaccination mirrored that of the proportion of physicians who would propose HBV testing[35]. The similar variation offers evidence that any organizational changes to promoting vaccination would have to include a more comprehensive HBV prevention strategy. Finally, our study group has

observed in a past evaluation that roughly 20%-50% participants newly diagnosed with HBV returned for further consultation at a referent center[15], reflecting the potential for inadequate transition to "appropriate care"[36]. The increased need to foster individuals into appropriate care appears to be shared among non-immunized patients.

Several methodological limitations need to be noted when interpreting the results of our study. First, we used a convenience sample combining participants from two studies. Certain risk-factor groups, such as intravenous drug-users and sex-workers, might not be adequately represented and could have different vaccine coverage than those reported herein. In addition, the lack in numbers may have resulted in inadequate power in order to establish whether they were less likely to complete vaccination. Second, the time-frame of follow-up was relatively short and perhaps some participants received vaccination 6-9 mo or more after their interview. Non-immunized patients did vaccinate a median 30 d, suggesting that few individuals would have initiated vaccination after the end of follow-up and vaccine coverage would have been similar if follow-up were prolonged. Nevertheless, roughly one-third of unvaccinated individuals stated that they would do so in the future. Third, the short time-frame also made it impossible to ascertain whether participants completed HBV vaccination, as the date of last vaccination would have fallen outside the follow-up period. Lastly, the proportion with no reply, which was comparable to other studies[17], could have biased results.

Furthermore, we should highlight that individuals with low levels of anti-HBs antibodies (> 0-10 mIU/mL), who could possibly benefit from booster HBV vaccination, were not included in this analysis. The results from our study might not be generalizable to these individuals.

In conclusion, HBV vaccination after screening was very low in this study, implying that HBV testing alone cannot encourage non-immunized individuals to vaccinate. The fact that large discrepancies in vaccine coverage were observed across centers and that both physician and participant motivation towards vaccination was rather limited provides evidence that involvement at the health structure level is crucial in increasing vaccination coverage. Future interventions and campaigns should work at increasing local awareness of low vaccine coverage rates, especially in groups with poor access to health services, and the need to vaccinate non-immunized individuals as soon as they are identified.

ARTICLE HIGHLIGHTS

Research background

Testing campaigns for hepatitis B virus (HBV) have often focused on identifying infected patients [*i.e.* those with hepatitis B surface antigen (HBsAg)-positive serology] and increasing disease-status awareness. Few evaluations have been performed on how testing campaigns can impact vaccination uptake after receiving non-immunized status.

Research motivation

Since France has a low proportion of vaccinated individuals compared to other Western countries, interventions to increase HBV vaccination rates need to be evaluated in this population. This analysis addressed vaccination initiation among non-immunized participants in a large-scale screening campaign within the Paris metropolitan region. These individuals reflect a wide range of groups at-risk of HBV infection, allowing potential identification of subgroups with low vaccination coverage.

Research objectives

We aimed to describe rates of vaccination among non-immunized individuals during a mass-screening program. We also intended to evaluate the reasons for not initiating HBV vaccination after testing. This allows a first-hand account of why individuals do not vaccinate and helps tailor the needs for future intervention campaigns.

Research methods

Participants were recruited from two large phases of a multi-center, HBV-testing campaign in Paris, France. Non-immunized subjects were identified and contacted via telephone 3-9 mo after testing in order to determine whether they initiated vaccination. We considered vaccination coverage of all respondents (in a per-protocol analysis) and the overall non-immunized study population while assuming no vaccination in non-responders (in an intent-to-treat analysis).

Research results

Overall vaccination uptake was low with 11% of respondents declaring HBV vaccination initiation within 3-6 mo of testing. Few risk-factors for increased vaccination initiation were identified: from moderate or high HBV-endemic countries, with limited healthcare coverage, and men who have sex with men. Compelling differences were observed between centers with vaccination coverage ranging from 0%-56%.

Research conclusions

Given the low vaccine uptake in individuals at potential risk of HBV-infection, there is a major concern in the cascade of care among non-immunized individuals. The contrasting vaccination rates between centers indicate that the challenge to increase vaccination initiation lies within center-specific practices. At the individual level, increasing motivation to vaccinate among physicians and non-immunized persons alike

should be stressed.

ACKNOWLEDGMENTS

We wish to thank all study participants as well as all medical and paramedical centers participating in the study, Tabassome Simon and nurses from the CRC-Est, and the data management center, especially Frederic Chau, Frederic Fotre, Sylvain Bitschine, Isabelle Goderel and Gregory Pannetier. We also acknowledge Samia Hicham, Judith Leblanc, Manuela Sébire-Le Cam, Farid Djoumad, Julie Lamarque, and Christelle Pauleau for their extraordinary effort in data collection.

Abstract

Herein, we present a case of gastric adenocarcinoma of fundic gland type (GA-FG) spreading to heterotopic gastric glands (HGG) in the submucosa. A 58-year-old man with epigastric pain was referred to our hospital and underwent an esophagogastroduodenoscopy. A Borrmann type II gastric cancer at the antrum and a 10 mm submucosal tumor-like lesion in the lesser curvature of the upper third of the stomach were detected. Histological examination of the biopsy specimens obtained from the submucosal tumor-like lesion suggested a GA-FG. Therefore, endoscopic submucosal dissection was performed as excisional biopsy, and histopathological examination of the resected specimen confirmed a GA-FG and HGG proximal to the GA-FG. Although the GA-FG invaded the submucosal layer slightly, the submucosal lesion of the GA-FG had a poor stromal reaction and was located just above the HGG in the submucosa. Therefore, we

finally diagnosed the lesion as a GA-FG invading the submucosal layer by spreading to HGG.

Key words: Gastric adenocarcinoma of fundic gland type; Heterotopic gastric glands; Endoscopic submucosal dissection; Paracancerous lesion; Pepsinogen-I; H/K-ATPase

Core tip: A 58-year-old man had a 10mm submucosal tumor-like lesion in the lesser curvature of the upper third of the stomach. Histological examination of the biopsy specimens suggested a gastric adenocarcinoma of fundic gland type (GA-FG), therefore, endoscopic submucosal dissection was performed as excisional biopsy. Histopathological examination of the resected specimen confirmed a GA-FG invading the submucosal layer slightly, and heterotopic gastric glands (HGG) proximal to the GA-FG. A GA-FG spreading to HGG in the submucosa was diagnosed because the submucosal lesion of the GA-FG had a poor stromal reaction and was located just above the HGG.

Gastric adenocarcinoma of fundic gland type spreading to heterotopic gastric glands. *World J Gastroenterol* 2017; 23(38): 7047-7053 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i38/7047.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i38.7047

INTRODUCTION

Gastric adenocarcinoma of fundic gland type (GA-FG) is a new histological type of gastric cancer proposed by Ueyama *et al*[1] in 2010. As the concept of GA-FG has spread since then, new findings have been reported[2]. GA-FG tends to invade the submucosal layer while it is still small because it arises from the deep layer of the lamina propria mucosae[1]. On the other hand, heterotopic gastric glands (HGG) are regarded as paracancerous lesions[3,4], and gastric cancers associated with HGG have been reported[5,6]. However, HGG are not considered to contribute to the development of GA-FG because the pathogenesis of GA-FG is different from that of the regular histological type of gastric cancer. We encountered a case of GA-FG suggested to have invaded the submucosal layer by spreading to HGG, which coincidentally existed proximal to the GA-FG. In addition to a GA-FG with a very rare mode of submucosal invasion, this case demonstrated the possibility of GA-FG arising from the gastric mucosa with atrophic change, provided there are remnant gastric fundic glands. Herein, we report this case with a brief review of the literature.

CASE REPORT

A 58-year-old man with epigastric pain was referred to our hospital. Esophagogastroduodenoscopy (EGD) revealed a Borrmann type II gastric cancer at the antrum (Figure 1A) and a 10 mm submucosal tumor-like lesion in the lesser curvature of the upper third of the stomach (Figure 1B and C). Atrophy of the gastric mucosa was classified as O-1 (according to the Kimura and Takemoto classification[7]), although the patient had undergone *Helicobacter pylori (H. pylori)* eradication therapy 4 years ago, and has not taken any proton pump inhibitors since then. Histological examination of the biopsy specimens obtained from the submucosal tumor-like lesion showed that the superficial area retained the normal foveolar epithelium. However, atypical cells mimicking fundic gland cells with mildly enlarged nuclei were observed in the deep layer of the lamina propria mucosae. These findings suggested a GA-FG. Narrow-band imaging with magnifying endoscopy (NBI-ME) performed later showed a regular microvascular pattern and a regular microsurface pattern according to the vessel plus surface classification system[8] with a concomitant depressed area at the center of the submucosal tumor-like lesion expected to be a biopsy scar (Figure 2). Endoscopic ultrasonography (EUS) findings revealed the tumor slightly invading the third layer and a hypoechoic mass located in the third layer near the tumor (Figure 3). Blood test findings revealed carcinoembryonic antigen level of 2.2 ng/mL and carbohydrate antigen 19-9 level of 14.3 U/mL, indicating that the tumor markers were within the normal range. Although gastric wall thickening due to the advanced gastric cancer at the antrum was seen on the abdominal CT scan, nodal or distant metastasis was absent. Based on the above findings, a partial gastrectomy was required for gastric cancer at the antrum. The submucosal tumor-like lesion in the lesser curvature of the upper third of the stomach was suspected to be a GA-FG; hence, we decided to perform endoscopic submucosal dissection (ESD) as excisional biopsy. Since histopathological findings of the ESD-resected specimen may indicate the need for an additional surgery, ESD was performed before surgery for the gastric cancer at the antrum, and en bloc resection was achieved. The ESD-resected specimen was 30 mm in diameter, whilst a 7 mm × 4 mm slightly elevated lesion was identified (Figure 4). Similar to the histological findings of the biopsy specimens, atypical cells mimicking fundic gland cells, mainly chief cells and partially parietal cells, with mildly enlarged nuclei were seen mainly in the deep layer of the lamina propria mucosae. The mucosal surface was covered completely with non-neoplastic foveolar epithelium; thus, the tumor was not exposed to the mucosal surface (Figure 5A).

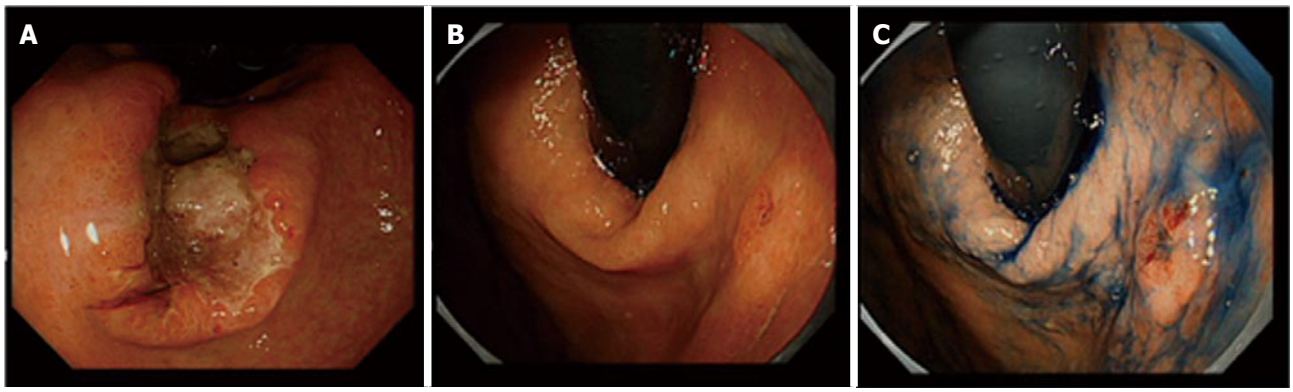

Figure 1 Esophagogastroduodenoscopy findings. A: A Borrmann type II gastric cancer was detected at the antrum; B and C: A 10 mm submucosal tumor-like lesion on the lesser curvature of the upper third of the stomach was detected. Atrophic gastritis O-1 according to Kimura and Takemoto classification was recognized.

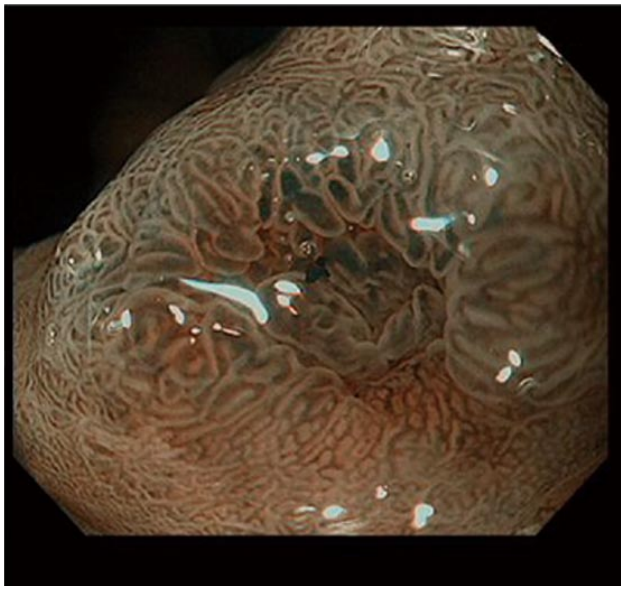

Figure 2 Narrow-band imaging with magnifying endoscopy findings. There were few irregularities in the microvessel architecture and microsurface structure. Therefore, we diagnosed a regular microvascular pattern and a regular microsurface pattern. The depressed area at the center was expected to be a biopsy scar.

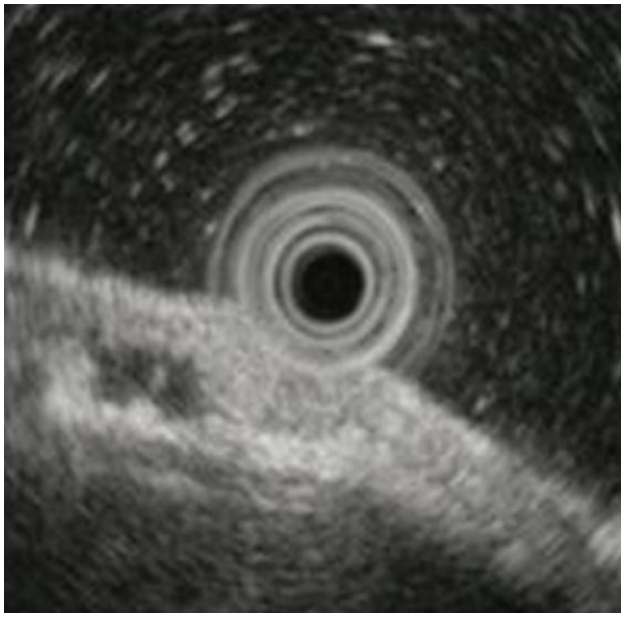

Figure 3 Endoscopic ultrasonography findings. The tumor slightly invaded the third layer, although it was located mainly in the second layer. Moreover, a hypoechoic mass located in the third layer near the tumor was detected.

Upon immunohistochemical examination, the tumor showed positivity for MUC6 and negativity for MUC2 and MUC5AC, indicating a gastric phenotype (Figure 5B-D). Moreover, diffuse positivity for pepsinogen-I and scattered positivity for H/K-ATPase was found, indicating a differentiation dominantly toward chief cells and focally toward parietal cells (Figure 5E and F). Although the lesion was located mainly in the deep layer of the lamina propria mucosae, it had partially invaded the submucosal layer up to 450 μm. Furthermore, HGG were observed in the submucosal layer, proximal to the tumor. The submucosal lesion of the tumor had a poor stromal reaction and was located just above the HGG in the submucosa (Figure 6). Based on these findings, the final diagnosis was: U, Less, 30 × 20 mm, type 0-IIa, 7 × 4 mm, adenocarcinoma of fundic gland type, pT1b1 (450 μm), UL (-), ly (-), v (-), pHM0, pVM0 (according to the Japanese classification of gastric carcinoma[9]). In addition, we have concluded that the GA-FG had invaded the submucosal layer by spreading to the HGG. After obtaining these results, we performed EUS again to examine the presence of other HGG. Thus, several hypoechoic masses considered to be HGG were seen in the entire stomach, and we diagnosed diffuse type HGG. A partial gastrectomy was required for the Borrmann type II gastric cancer at the antrum. Moreover, due to the high risk of cancer arising from the gastric remnant because of the diffuse type HGG, we performed a total gastrectomy upon the patient's request. After the total gastrectomy, the gastric cancer at the antrum was diagnosed as: L, Less, type 2, 40 × 35 mm, por1, pT3 (SS), intermediate type (int), INFa, ly2, v2, pN0, pPM0, pDM0 (according to the Japanese classification of gastric carcinoma[9]), and multiple

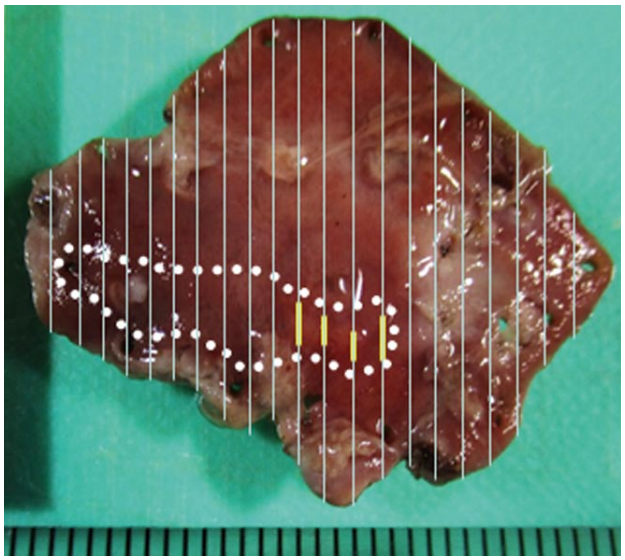

Figure 4 Spread of the gastric adenocarcinoma of fundic gland type and heterotopic gastric glands mapped on the endoscopic submucosal dissection-resected specimen. *Yellow line* spread of the gastric adenocarcinoma of fundic gland type (GA-FG), *White dotted line* spread of heterotopic gastric glands (HGG). The endoscopic submucosal dissection -resected specimen was 30 mm × 20 mm in size. The tumor was slightly elevated and measured 7 mm × 4 mm. The GA-FG and HGG partially overlapped.

HGG in the entire stomach were confirmed. However, we could not find evidence of this cancer related to diffuse type HGG. In addition, considering the risk of multiple gastric cancers associated with diffuse type HGG, the entire stomach was examined histologically. In doing so, we detected an intramucosal cancer in the lesser curvature of the lower gastric body, which was not previously detected by endoscopy before surgery. Although there was no remnant GA-FG near the ESD ulcer scar, a distribution of HGG was seen.

DISCUSSION

GA-FG is a new histological type of gastric cancer[1]. According to Ueyama *et al*[10], endoscopic properties of GA-FG include no intestinal metaplasia or atrophic change in the surrounding mucosa, faded or whitish color, submucosal tumor shape with a soft appearance, and dilated vessels with branching architecture. Although the pathogenesis of GA-FG is unclear, GA-FG tends to arise from the normal gastric mucosa of the fundic gland region without atrophic change or intestinal metaplasia[2]. Therefore, *H. pylori* infection is not considered to contribute to the development of GA-FG, unlike for the regular histological type of gastric cancer.

On the other hand, HGG are gastric glands that are observed in the submucosa and are naturally seen in the lamina propria mucosae[3,4]. Clinically, HGG are regarded as paracancerous lesions and are associated with gastric cancer, particularly, multiple gastric cancers[3,4]. HGG are classified into 4 types based on their number and range of distribution: solitary type with 3 sites or less, localized type with 4-9 sites at the focal area, broad type with 4-9 sites in the broad area, and diffuse type with at least 10 sites which exist in the entire stomach[4]. Of these, the diffuse type is seen in 98% of gastric cancer complications, and the rate of complication with multiple gastric cancers is reported to be 32%[3]. The association between HGG and gastric cancer is unclear. However, one dominant hypothesis is that both HGG and gastric cancer develop because of repeated erosion and regeneration of the mucosa, suggesting that HGG are paracancerous lesions[3,4]. Caution is required when performing EGD for patients with HGG, particularly diffuse type HGG, since there is the possibility that micro-gastric cancers that are difficult to detect endoscopically may be present. Indeed, as in our case, after total gastrectomy, histopathological examination revealed a micro-intramucosal cancer that was not detected endoscopically before surgery. There is no consensus on the treatment of HGG. As mentioned previously, because the rate of complication of gastric cancer is very high, particularly with diffuse type HGG, EGD must be conducted periodically with caution. In our case, in addition to the high risk of gastric cancer arising due to diffuse type HGG, a partial gastrectomy was required for the Borrmann type II gastric cancer at the antrum. Therefore, a total gastrectomy was performed upon the patient's request.

The GA-FG observed in our case presented a submucosal tumor shape, which corresponds to the endoscopic properties reported by Ueyama *et al*[10]. A possible reason the GA-FG presented a submucosal tumor shape is that, in addition to the proliferation of tumor cells in the deep mucosal layer, the HGG were also present in the submucosa. Retrospectively, the hypoechoic mass near the GA-FG that was seen on EUS before ESD was suggested to be HGG. The ESD-resected specimen showed no tumor exposed to the mucosal surface; thus, NBI-ME showed a regular microvascular pattern and a regular microsurface pattern. Since GA-FG arises from the deep layer of the lamina propria mucosa, there is a high rate of submucosal invasion while the tumor diameter is small[1]. In our case also, the GA-FG invaded the submucosal layer up to 450 μm. However, the submucosal lesion of the GA-FG had a poor stromal reaction and was located just above the HGG in the submucosa. Therefore, the GA-FG was considered to have invaded the submucosal layer by spreading to the HGG. There are a few case reports of regular histological type of gastric cancer spreading to HGG[11]. However, to the best of our knowledge, this is the first case of GA-FG spreading to HGG. Currently, in the Japanese classification of gastric carcinoma, there is no definition concerning the depth of tumor invasion that spreads to HGG in the submucosa[9]. However, since similarly, esophageal cancer with intraductal spreading is handled as intramucosal cancer as long as it is

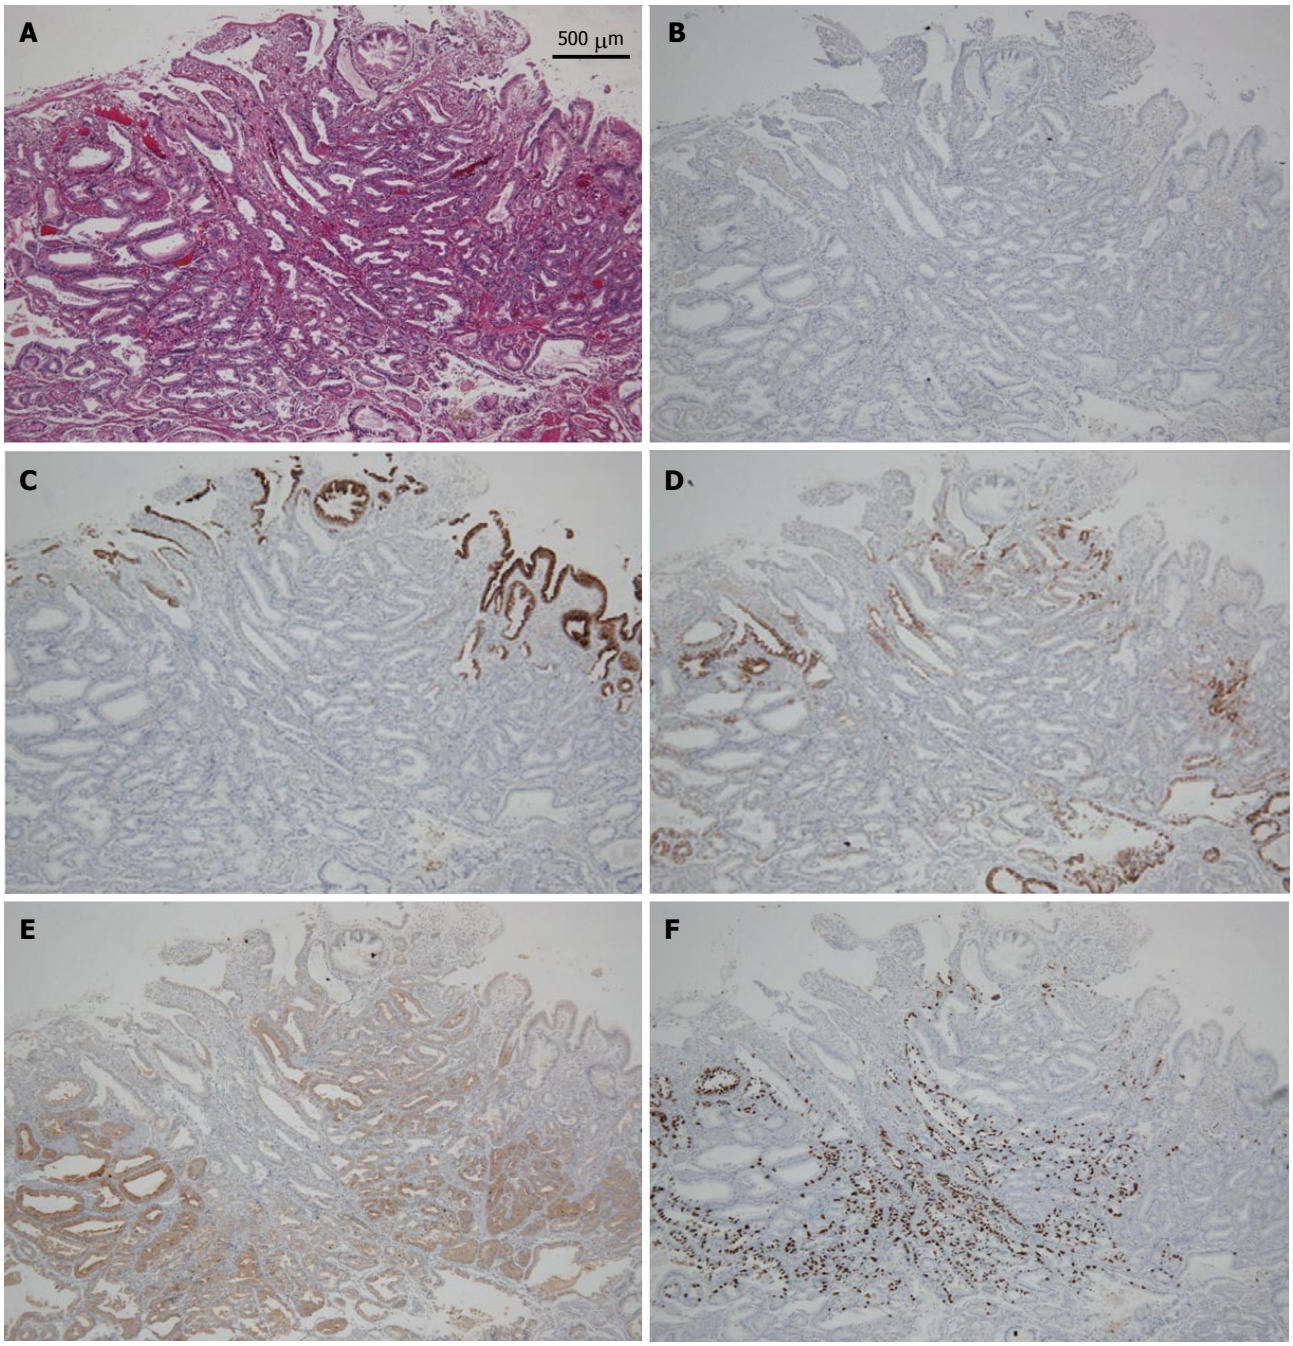

Figure 5 Histopathological and immunohistochemical findings of the endoscopic submucosal dissection-resected specimen. A: H&E staining. There were atypical cells with mildly enlarged nuclei in the deep layer of the lamina propria mucosae. They mimicked fundic gland cells, mainly chief cells and partially parietal cells. The mucosal surface was covered completely with non-neoplastic foveolar epithelium; thus, the tumor was not exposed to the mucosal surface; B: MUC2 staining: almost negative; C: MUC5AC staining: almost negative except for normal superficial foveolar epithelium; D: MUC6 staining: partially positive and indicating a gastric phenotype; E: Pepsinogen staining: diffusely positive in the deep layer of the lamina propria mucosae, corresponding to gastric adenocarcinoma of fundic gland type, and indicating a differentiation toward chief cells; F: H/K-ATPase staining: scattered positive in the deep layer of the lamina propria mucosae, indicating a differentiation toward parietal cells focally.

retained in the esophageal proper glands[12], gastric cancer spreading to HGG should likely be handled as intramucosal cancer[5,6].

As mentioned earlier, atrophic gastritis related to *H. pylori* infection is not considered to be involved in the development of GA-FG. On the other hand, gastric cancer associated with HGG is considered to result from chronic inflammation due to *H. pylori* infection. Therefore, it is thought that there is no correlation between GA-FG and HGG. In our case, the GA-FG and HGG were considered to be coincidentally present in the vicinity. Furthermore, it is thought that HGG resulted from chronic inflammation due to *H. pylori* infection before eradication therapy, and pseudopyloric gland metaplasia in the fundic gland region progressed. The GA-FG may have occurred

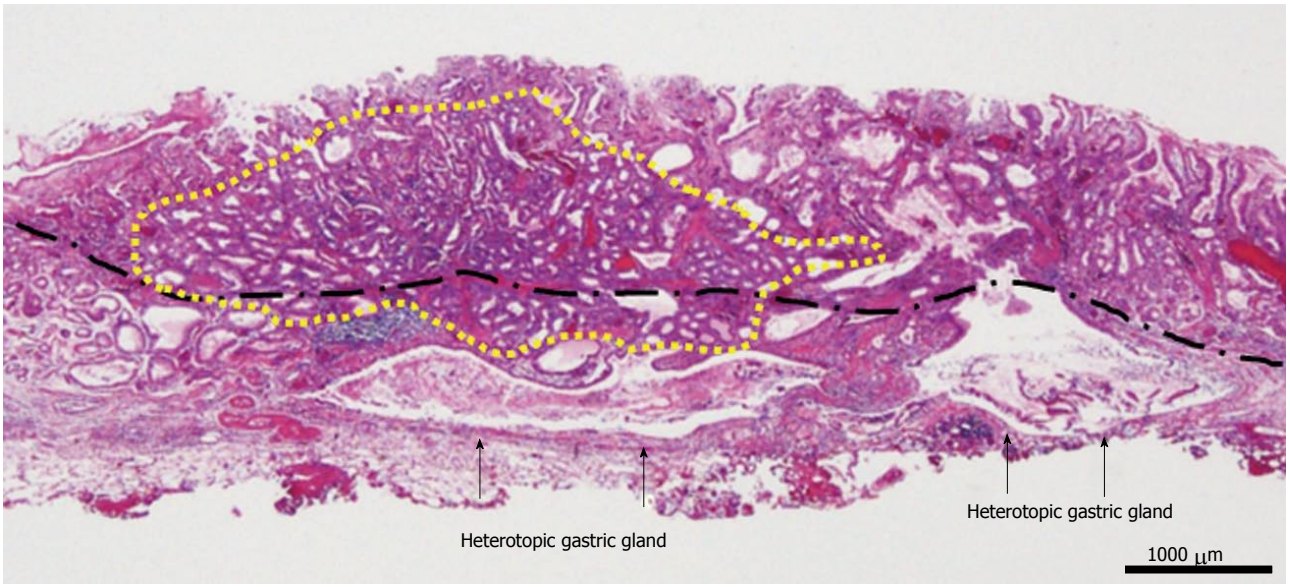

Figure 6 Histopathological findings of the endoscopic submucosal dissection-resected specimen. *Yellow line* the gastric adenocarcinoma of fundic gland type (GA-FG), *Black line* muscularis mucosae. The GA-FG partially invaded the submucosa layer up to 450 μm, although it was located mainly in the deep layer of the lamina propria mucosae. Enlarged ducts of the heterotopic gastric glands were concomitantly observed just under the submucosal lesion of the GA-FG. In addition, the submucosal lesion had a poor stromal reaction.

from the remnant gastric fundic glands despite the progression of pseudopyloric gland metaplasia and spread continuous to the proximally located HGG.

Until recently, GA-FG has been recognized as cancer arising from gastric mucosa without atrophic change[2]. However, cases of GA-FG arising from gastric mucosa with atrophic change have now been reported[13]. Together with these cases, our case suggests that GA-FG could occur even from the gastric mucosa with atrophic change, where HGG could be present, provided the remnant gastric fundic glands exist. This is an important case demonstrating that when performing endoscopy, one needs to keep in mind the possibility of GA-FG presenting on the gastric mucosa with atrophic change, chronic gastritis, or intestinal metaplasia.

COMMENTS

Case characteristics

A 58-year-old man with epigastric pain but no other symptoms.

Clinical diagnosis

A gastric adenocarcinoma of fundic gland type (GA-FG) was suspected based on the histological examination of the biopsy specimens obtained from the submucosal tumor-like lesion that revealed atypical cells mimicking fundic gland cells with mildly enlarged nuclei.

Differential diagnosis

Gastric submucosal tumors, including leiomyoma, leiomyosarcoma, gastrointestinal stromal tumor, and lipoma.

Laboratory diagnosis

Initial laboratory findings were within the normal limits.

Imaging diagnosis

Esophagogastroduodenoscopy revealed a 10 mm submucosal tumor-like lesion in the lesser curvature of the upper third of the stomach, which had a regular microvascular pattern and a regular microsurface pattern based on narrow-band imaging with magnifying endoscopy.

Pathological diagnosis

An endoscopic submucosal dissection (ESD)-resected specimen revealed GA-FG spreading to heterotopic gastric glands (HGG) in the submucosa because the submucosal lesion of the GA-FG had a poor stromal reaction and was located just above the HGG.

Treatment

ESD as excisional biopsy and total gastrectomy.

Related reports

Although there are a few case reports of regular histological type of gastric cancer spreading to HGG, this is the first case of GA-FG spreading to HGG.

Term explanation

GA-FG, which differentiates into chief cells, is a new histological type of gastric cancer proposed by Ueyama *et al* in 2010. HGG, which are observed in the submucosa, are considered to be paracancerous lesions.

Experiences and lessons

We need to keep in mind the possibility of GA-FG presenting on the gastric mucosa with atrophic change, chronic gastritis, or intestinal metaplasia.

Peer-review

Dear Editor, this is well done case report with literature review. Authors described the case extensively and compare it against the literature. Also they provided excellent documentation and provided all necessary explanations.

Abstract

Only two cases of myofibroblastic sarcoma in the liver have been reported in the literature. Here, we report the case of a male patient with high-grade myofibroblastic sarcoma mimicking echinococcosis in the liver. The 25-year-old male patient complained of right upper quadrant swelling pain for one week and was initially diagnosed with echinococcosis. He was then scheduled for an exploratory laparotomy. During the operation, a huge mass exceeding 16 cm in diameter was found to occupy nearly the entire right trisegment of the liver, with a clear boundary and a round shape, and the mass was resected by right hepatic trisegmentectomy. Immunohistochemical staining revealed that the tumor tissue was positive for desmin, α-smooth muscle actin, CD56, and vimentin and negative for ALK-1, myogenin, calponin, β-catenin, S100, and glypican-3, with a Ki-67 (MIB-1) index of approximately 20%. Based on the histological manifestations and immunohistochemical staining, a diagnosis of myofibroblastic sarcoma was established. The postoperative recovery was uneventful. There was no evidence of recurrence or metastasis through the last follow-up, 6 mo after surgery, despite a lack of postoperative chemotherapy or radiotherapy. To the best of our knowledge, the present case is the first reported case of high-grade myofibroblastic sarcoma in the liver, and it is also the first reported case in a male patient.

INTRODUCTION

Myofibroblastic sarcoma is a rare disease that was initially identified by Mentzel *et al*[1] in 1998, and all its reports are case reports or case series. It is widely accepted that myofibroblastic sarcoma predominantly develops in the head and neck region, followed by the extremities and then the trunk, with the abdominal cavity being rarely involved. The development of myofibroblastic sarcoma in the liver is exceedingly rare, and there have been only two relevant case reports to date[2,3]. Although there is generally a slight male predominance[1,4], both of the case reports described female patients. In the present report, we present a case of high-grade myofibroblastic sarcoma in a male patient. The clinical manifestations, blood test results, imaging findings, histological and immunohistochemical findings, and treatment are discussed here.

CASE REPORT

A 25-year-old male patient was referred to the liver surgery department because of right upper quadrant swelling pain for one week without any concomitant symptoms. His medical history was unremarkable, with no hepatitis or surgical history. No family or genetic history was claimed either, and a general physical examination showed no abnormal signs.

Hematological and blood biochemical tests revealed no abnormalities. Serum tumor markers were within the normal limits: α-fetoprotein (AFP), 4.14 ng/mL; carcinoembryonic antigen (CEA), 1.30 ng/mL; and carbohydrate antigen (CA19-9), 6.06 U/mA. Among all of the hepatitis B markers, only surface antibody was positive.

Abdominal color ultrasound revealed a heteroechoic mass in the right trisegment of the liver, measuring 18 cm × 15 cm × 11 cm, with a clear boundary but with no remarkable blood signal. Abdominal contrast-enhanced color ultrasound revealed a heteroechoic mass showing peripheral hyper-enhancement in the arterial phase and peripheral hypo-enhancement in the portal phase, whereas the central portion showed no enhancement throughout the two phases. Dynamic contrast-enhanced computed tomography (CT) imaging revealed a cyst-like lesion with an obvious capsule located in the right trisegment of the liver; this lesion contained a stripe-like, slightly hyperdense area and patchy hypodense areas that were hyper-enhanced in the arterial phase and hypo-enhanced in the portal phase, whereas the central portion remained unenhanced throughout the arterial and portal phases (Figure 1).

Based on the aforementioned findings, liver echinococcosis was suspected. For treatment, a right hepatic trisegmentectomy was scheduled.

Upon laparotomy, a huge solid mass exceeding 16 cm in diameter with a clear boundary was found to occupy nearly the entire right trisegment of the liver. The remnant liver had a normal appearance, showing no cirrhosis. There was also no ascites or peritoneal dissemination, and enlarged lymph nodes were not found in the peritoneal cavity. Intraoperative ultrasound showed that the right hepatic vein was occluded, whereas the middle hepatic vein was pushed away by the mass. In addition, no disseminated lesions were found to be located in the remnant liver. The resected tumor measured 19 cm × 16 cm × 11 cm and weighed 2400 g. Sections through the tumor disclosed grayish-yellow, solid tissue that showed relatively homogenous internal structures (Figure 1).

Histologically, the tumor cells were spindle shaped and located in a loose myxoid background and contained small-to medium-sized nucleoli with readily identified mitotic figures (Figures 2 and 3). Histological images revealed high mitotic activity, with more than 19 mitoses per 10 high-power fields (HPFs), along with certain small necrotic areas (< 50%). Immunohistochemical staining showed that the tumor tissue was positive for desmin (Figure 4), α-smooth muscle actin (α-SMA), CD56, and vimentin and negative for ALK-1, myogenin, calponin, β-catenin, CD34, CD10, S100, glypican-3, CDK4, PCK, and CD117, with a Ki-67 (MIB-1) index of approximately 20%. For differential diagnosis, the tumor tissue was negative for CD31 (Figure 5), Factor VIII (to deny vascular tumor, such as angiosarcoma or epithelioid hemangioendothelioma), Melan A or HMB45 (to deny angiomyolipoma). Based on the histological

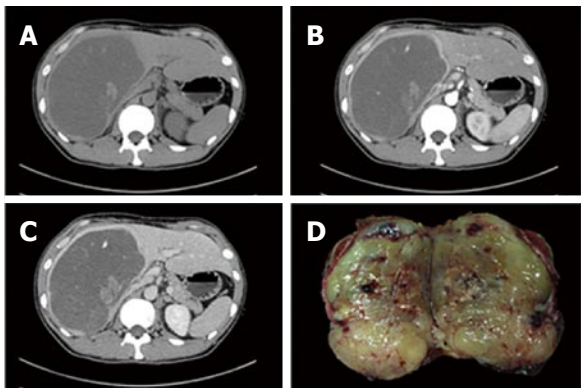

Figure 1 Computed tomography imaging and surgical specimen. Dynamic contrast-enhanced computed tomography (CT) imaging showed that a cyst-like lesion (A) contained a stripe-like, slightly hyperdense area and patchy hypodense areas that were hyper-enhanced in the arterial phase (B) and hypo-enhanced in the portal phase (C), whereas the central portion remained unenhanced throughout the arterial and portal phases. Sections through the tumor disclosed grayish-yellow, solid tissue that showed relatively homogenous internal structures (D).

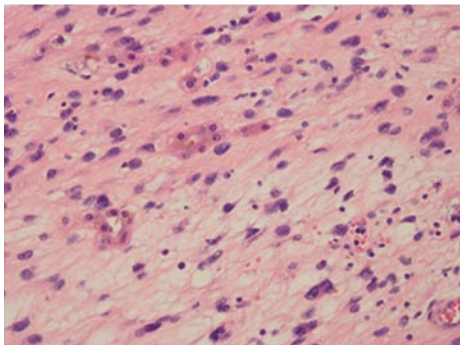

Figure 2 Histological image showing that the tumor cells were spindle shaped and located in a loose myxoid background (hematoxylin-eosin staining; original magnification, × 400).

and immunohistochemical findings, a diagnosis of myofibroblastic sarcoma was established, and this sarcoma was further classified as grade 3 according to the French Federation of Cancer Centers Sarcoma Group (FNCLCC) system[5].

The postoperative recovery was uneventful. The patient refused postoperative chemotherapy and radiotherapy; fortunately, however, there was no evidence of recurrence through the last follow-up, 6 months after surgery, despite the lack of postoperative chemotherapy or radiotherapy.

DISCUSSION

Since Mentzel *et al*[1] first defined a distinctive clinicopathological entity now known as low-grade myofibroblastic sarcoma in 1998, myofibroblastic sarcoma has been increasingly investigated, with most reports consisting of case reports or case series[2,3,6-11].

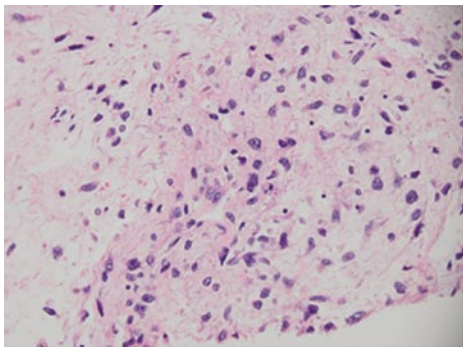

Figure 3 Histological image showing that the tumor cells contained small- to medium-sized nucleoli with readily identified mitotic figures (hematoxylin-eosin staining; original magnification, × 400).

Although the World Health Organization (WHO) included low-grade myofibroblastic sarcoma, when characterized reproducibly, in the WHO Classification of Tumors in 2002[12], the definition of intermediate- and high-grade myofibroblastic sarcoma with less reproducible characteristics has not reached a consensus, even in the latest edition of the WHO Classification of Tumors of Soft Tissue and Bone[4].

Given the rare incidence of myofibroblastic sarcoma, there have been few reports describing its etiology. Although a slight male predominance was suggested in the latest WHO classification[4], Chan *et al*[11] found that the majority of cases involve female patients. To date, the present case is the first reported case of high-grade myofibroblastic sarcoma in the liver and also the first case reported in a male patient, whereas the two existing case reports described female patients[2,3]. Painless swelling or an enlarging mass is the most common complaint[4], with other symptoms depending on the location; for example, obstruction is typical when the lesion develops in the nasal cavity[7]. In the present case, the chief complaint was right upper quadrant swelling pain, which was also present in a report by Yi *et al*[3], whereas Pan *et al*[2] reported no pain but abnormal liver function. In the present case and the report by Yi *et al*[3], the lesion showed a well-defined growth pattern, whereas this type of tumor is commonly reported to display an infiltrative and destructive growth pattern[4,7].

According to the WHO classification, ultrasound examination should be conducted first, but CT or magnetic resonance imaging (MRI) is recommended for further investigation, with equivalent value[4]. Imaging by dynamic contrast-enhanced CT in the report by Yi *et al*[3] was in close accordance with what was found in the present case. The lesion, which was well defined and round shaped and showed hypodensity on plain CT scans, was peripherally enhanced, whereas the central portion remained unenhanced throughout the arterial and portal phases.

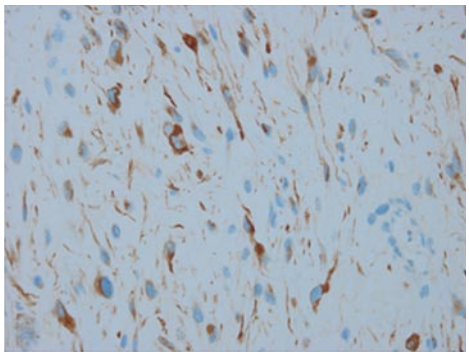

Figure 4 Immunohistochemical image showing that the tumor tissue was positive for desmin (original magnification, × 400).

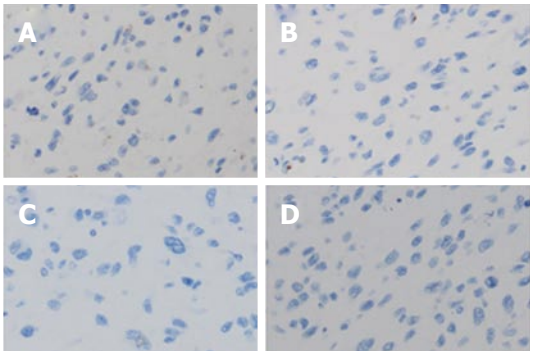

Figure 5 Immunohistochemical staining for differential diagnosis. The tumor tissue was negative for CD31 (A), Factor VIII (B), Melan A (C) and HMB45 (D) (original magnification, × 200).

Although these characteristics have been reported in only two cases, they constitute a "consensus" that could be referred to when myofibroblastic sarcoma in the liver is suspected. Yi *et al*[3] also reported a honeycomb appearance on T2WI images and a progressive enhancement pattern as characteristic manifestations on MRI.

The presence of ultrastructural features, such as fibronexus (microtendons) and stress fibers, is no longer emphasized as important for the diagnosis of myofibroblastic sarcoma[13]. Instead, the diagnosis of myofibroblastic sarcoma is now established by histopathology and immunohistochemical staining[13]. Although there is no constant immunophenotype, myofibroblastic sarcoma stains positively for muscle actin, α-SMA, and/or desmin in general, but it is typically negative for S100 protein, epithelial markers, nuclear β-catenin, and h-caldesmon[1,4,13].

Because high-grade myofibroblastic sarcoma was not included in the latest WHO classification[1,4,13], the two grading systems proposed by the National Cancer Institute (NCI) and the FNCLCC are the most widely used[4,5]. The FNCLCC system, which is precisely defined and more reproducible, with better performance in prognostic prediction, is preferred over the NCI system and other systems[14,15]. The present case, which showed high mitotic activity (more than 19 mitoses/10 HPFs) and certain small necrotic areas (< 50%), was classified as grade 3 according to the FNCLCC system[5]. Although low-grade myofibroblastic sarcomas have a local recurrence rate of 5%-10% when treated by wide-margin excision, they rarely metastasize. In fact, Fisher C reported 13 (33%) recurrences and 3 (8%) metastases in 39 published cases with follow-up information[16]. In contrast, high-grade myofibroblastic sarcoma shows a high rate of metastasis, along with recurrence; Fisher C reported 7 (32%) recurrences and 15 (68%) metastases among 22 ultrastructurally confirmed cases[16].

Surgery is the first choice for treatment, with the role of chemotherapy and radiotherapy being controversial. Generally, a wide margin of at least 1-2 cm is recommended because microscopically positive surgical margins are associated with a high risk of local recurrence, distant metastasis and death[4]. Retroperitoneal sarcomas show a much lower survival rate than extremity soft-tissue sarcomas, and high-grade myofibroblastic sarcomas are more aggressive[4]. However, little is known about myofibroblastic sarcoma, especially high-grade myofibroblastic sarcoma, in the liver. There were no signs of recurrence or metastasis in the reported intermediate-grade case[3] or in the high-grade myofibroblastic sarcoma case described in the present report 6 mo after surgery, despite the fact that both patients refused further treatment. Unfortunately, the patient in the report by Pan *et al*[2] was lost to follow-up 3 mo after discharge from the hospital. Meng *et al*[7] reported that myofibroblastic sarcoma of the nasal cavity and paranasal sinus exhibited diverse histological characteristics and strongly aggressive behavior, indicating that myofibroblastic sarcomas with different anatomic distributions may have diverse histological characteristics, biological behaviors and prognoses. We hypothesize that as long as it is resected with a sufficient margin, irrespective of grading, myofibroblastic sarcoma in the liver probably has an optimistic prognosis, as indicated by the report by Yi *et al*[3] and the present case. However, long-term follow-up and more patient data are needed before we can draw reliable conclusions.

Myofibroblastic sarcoma is a rare disease. The present case is the first reported case of high-grade myofibroblastic sarcoma in the liver, and it is also the first reported case in a male patient. The diagnosis of myofibroblastic sarcoma was established by histopathology and immunohistochemical staining. With a well-defined growth pattern and resection with a sufficient margin, regardless of its grade, the myofibroblastic sarcoma in the liver showed no signs of recurrence or metastasis 6 mo after surgery.

COMMENTS

Case characteristics

A 25-year-old male patient complained of right upper quadrant swelling pain for

1 week without any concomitant symptoms.

Clinical diagnosis
Liver echinococcosis was suspected.

Differential diagnosis
Liver echinococcosis, gastrointestinal stromal tumor, vascular tumor, such as angiosarcoma or epithelioid hemangioendothelioma, angiomyolipoma.

Laboratory diagnosis
All laboratory tests were within normal limits.

Imaging diagnosis
CT imaging found a cyst-like lesion with an obvious capsule located in the right trisegment of the liver.

Pathological diagnosis
The diagnosis of high-grade myofibroblastic sarcoma was established by histopathology and immunohistochemical staining.

Treatment
The patient successfully underwent a right hepatic trisegmentectomy.

Related reports
There have been no case reports on high-grade myofibroblastic sarcoma in the liver. Only two reports were published reporting intermediate-grade myofbroblastic sarcoma or myofibroblastic sarcoma. The diagnosis was established on the basis of morphology and immunohistochemistry features. Surgical resection was the treatment of choice with gratifying results.

Experiences and lessons
The diagnosis of myofibroblastic sarcoma is established by histopathology and immunohistochemical staining. Surgical resection is the treatment of choice with gratifying results.

Peer-review
The authors report a case of myofibroblastic sarcoma of the liver. The manuscript is well-written and the case is pathologically interesting.

ABOUT COVER

Editorial board member of *World Journal of Gastroenterology*, Ilhami Yuksel, MD, Associate Professor, Gastroenterology, Yildirim Beyazit University School of Medicine, Ankara 06100, Turkey

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1375 experts in gastroenterology and hepatology from 68 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology (*WJG*) is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central and Directory of Open Access Journals. The 2017 edition of Journal Citation Reports® cites the 2016 impact factor for *WJG* as 3.365 (5-year impact factor: 3.176), ranking *WJG* as 29th among 79 journals in gastroenterology and hepatology (quartile in category Q2).

Abstract

Exocrine pancreatic insufficiency (EPI), an important cause of maldigestion and malabsorption, results from primary pancreatic diseases or secondarily impaired exocrine pancreatic function. Besides cystic fibrosis and chronic pancreatitis, the most common etiologies of EPI, other causes of EPI include unresectable pancreatic cancer, metabolic diseases (diabetes); impaired hormonal stimulation of exocrine pancreatic secretion by cholecystokinin (CCK); celiac or inflammatory bowel disease (IBD) due to loss of intestinal brush border proteins; and gastrointestinal surgery (asynchrony between motor and secretory functions, impaired enteropancreatic feedback, and inadequate mixing of pancreatic secretions with food). This paper reviews such conditions that have less straightforward associations with EPI and examines the role of pancreatic enzyme replacement therapy (PERT). Relevant literature was identified by database searches. Most patients with inoperable pancreatic cancer develop EPI (66%-92%). EPI occurs in patients with type 1 (26%-57%) or type 2 diabetes (20%-36%) and is typically mild to moderate; by definition, all patients with type 3c (pancreatogenic) diabetes have EPI. EPI occurs in untreated celiac disease (4%-80%), but typically resolves on a gluten-free diet. EPI manifests in patients with IBD (14%-74%) and up to 100% of gastrointestinal surgery patients (47%-100%; dependent on surgical site). With the paucity of published studies on PERT use for these

conditions, recommendations for or against PERT use remain ambiguous. The authors conclude that there is an urgent need to conduct robust clinical studies to understand the validity and nature of associations between EPI and medical conditions beyond those with proven mechanisms, and examine the potential role for PERT.

Key words: Celiac disease; Inflammatory bowel disease; Exocrine pancreatic insufficiency; Malabsorption; Epidemiology; Pancreas; Pancreatic cancer; Secretion/absorption; Surgery

Core tip: Exocrine pancreatic insufficiency (EPI) results from primary pancreatic diseases or secondarily impaired exocrine pancreatic function. Pancreatic enzyme replacement therapy (PERT) may prevent serious nutritional complications when such patients have symptomatic EPI. However, EPI may be more prevalent in patients with non-pancreatic diseases, diabetes, and pancreatic cancer than has generally been appreciated. Scant published evidence on EPI in these less common etiologies precludes firm recommendations on management. Robust clinical studies are urgently needed to understand the relationships between EPI and medical conditions beyond those with proven mechanisms, and examine the potential role for PERT.

Singh VK, Haupt ME, Geller DE, Hall JA, Quintana Diez PM. Less common etiologies of exocrine pancreatic insufficiency. *World J Gastroenterol* 2017; 23(39): 7059-7076 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7059.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7059

INTRODUCTION

The pancreas is a dual function organ that possesses both exocrine and endocrine components that are critical for the digestion, absorption, and metabolism of nutrients. Normal digestion requires the exocrine function of the pancreas for macronutrient digestion. This occurs primarily *via* enzymatic hydrolysis by pancreatic enzymes, in particular lipase, amylase, and proteases (trypsin and chymotrypsin)[1]. Exocrine pancreatic insufficiency (EPI) refers to the presence of maldigestion and malabsorption of nutrients and is a consequence of primary loss of functional parenchyma and/or secondarily impaired exocrine pancreatic function and insufficient pancreatic enzyme activity. EPI is sometimes defined simply as an enzyme output less than 10% of that necessary to sustain normal digestion; however, there is no consensus in the literature on the definition of EPI. Furthermore, the clinical presentation of EPI can vary widely depending on the underlying cause, as well as disease stage, diet, and other factors.

EPI is most commonly caused by diseases that destroy the pancreatic parenchyma, such as chronic pancreatitis and cystic fibrosis, as well as pancreatic resection[1,2]. The incidence of EPI in chronic pancreatitis ranges from 30% of patients with mild disease to 85% with severe disease[3]. Approximately 85% of infants with cystic fibrosis have EPI at birth[4]. However, EPI is also observed in other conditions that include unresectable pancreatic cancer; metabolic diseases (diabetes mellitus)[1,2]; impaired hormonal stimulation of exocrine pancreatic secretion by cholecystokinin (CCK); celiac disease or inflammatory bowel disease (IBD) due to loss of intestinal brush border proteins[1,2]; small intestinal bacterial overgrowth[5,6], although not all investigators have found a clear association[7]; impaired coordination between motor and secretory functions (asynchrony); impaired enteropancreatic feedback, and/or inadequate mixing of pancreatic juices with ingested food after gastrointestinal surgery; and other diseases that affect the pancreas, such as hemochromatosis[8,9] (Tables 1 and 2)[1,2].

In this publication, we first briefly review the diagnosis of EPI and management with pancreatic enzyme replacement therapy (PERT). Most knowledge about EPI comes from studies in patients with chronic pancreatitis or cystic fibrosis, and has already been thoroughly explained in previous reviews. Therefore, our article focuses on several other disease states for which the association with EPI is less straightforward, such as inoperable pancreatic cancer, diabetes mellitus, celiac disease, IBD, and gastrointestinal surgery. Finally, we summarize the limited available data on PERT for the treatment of patients with EPI due to these less common etiologies.

LITERATURE SEARCHES

Searches of BIOSIS Previews, Derwent Drug File, Embase, Embase Alert, International Pharmaceutical Abstracts, MEDLINE, and SciSearch were performed to identify eligible literature from the earliest available date to December 5, 2016. The search terms for EPI were "EPI" or "exocrine pancreatic insufficiency" or "maldigestion" or "malabsorption" or "nutritional deficiency" or "steatorrhea" or "(fat* or oil* or elastase) pre/2 (stool* or fece* or fecal)" or "pancreatic near/3 (function or test)" with the terms NOT "chronic pancreatitis" or "cystic fibrosis". For pancreatic cancer, the search included the following terms: "pancreatic cancer" or "pancreatic adenocarcinoma" or "pancreatic tumor". For diabetes mellitus, the search strategy included "diabetes" and "type 1" or "IDDM" or "insulin-dependent" or "type 2" or "NIDDM" or "noninsulin-dependent" or "type 3" or "type 3c" or "type Ⅲ" or "pancreatogenic". For celiac disease, the search included "celiac disease" or "celiac*". For IBD, the search strategy included "inflammatory bowel disease" or "ibd" or "Ulcerative Colitis" or "Crohn*"

Table 1 Causes of exocrine pancreatic insufficiency

Definite association with EPI
Chronic pancreatitis
Pancreatic tumor/cancer
Cystic fibrosis
Pancreatic resection
Pancreatic hemochromatosis
Mechanisms associated with EPI not fully identified
Type 1 and 2 diabetes
Type 3c (pancreatogenic) diabetes
Gastrointestinal diseases
Celiac disease
Inflammatory bowel disease
Crohn's disease
Ulcerative colitis
Gastrointestinal surgery
Aging

EPI: Exocrine pancreatic insufficiency.

or "Crohn Disease". For gastrointestinal surgery, the search strategy included "gastrointestinal surgery" or "digestive system surgical procedures" or [(post or surg*) near/5 ("gastr*" or "bariatric" or "duodenal switch" or "biliopancreatic diversion")] or "bariatric surger*" or "gastrectom*" or "gastric bypass" or "stomach bypass". Reviews, practical guidelines, letters, editorials, and articles were evaluated. The searches returned 582 hits, from which 163 published articles were initially selected. Subsequently, articles were selected based on their clinical relevance, and additional papers were found after a review of the reference lists of these articles. Only a few were designed as prospective controlled studies with clearly defined methodology; this underscores the lack of data to support associations and mechanisms relevant to the conditions explored.

DIAGNOSIS OF EPI

Patients with EPI may exhibit a wide variety of clinical symptoms and nutritional deficiencies (Table 3). Clinical symptoms associated with EPI include steatorrhea (large-volume, foul-smelling stools), diarrhea, weight loss, flatulence, and abdominal pain. EPI may be diagnosed when fecal fat excretion is > 7 g/d on a 100-g fat/d diet. In EPI, fat malabsorption often develops prior to protein and carbohydrate malabsorption because lipase has a higher susceptibility to intraluminal denaturation and proteolytic destruction compared with other enzymes[10,11]. Furthermore, the deficiency in pancreatic lipase cannot be compensated by gastric lipase, the only other lipolytic enzyme in adult humans[12]. Because the exocrine pancreas has a large functional reserve capacity, clinical symptoms may not manifest until exocrine pancreatic function is < 10% of normal[13]. Untreated malabsorption places patients at high risk for developing nutritional deficiencies[14], which can manifest as other health problems, including decreased bone mineral density resulting in osteoporosis or osteomalacia[15-17]; bone metabolism deficiencies and muscle spasms; impaired night vision and decreased immune competence[16,18,19]; coagulation problems[16]; and ataxia and peripheral neuropathy[16]. Additionally, EPI has been associated with high morbidity and mortality secondary to malnutrition-related complications and an increased risk of cardiovascular events[20].

In routine clinical practice, EPI may be difficult to diagnose, particularly in the early stages when patients are less symptomatic. Often patients make dietary modifications to reduce symptoms. Patients may have low serum levels of fat-soluble vitamins, micronutrients, and lipoproteins[21]. Severe symptomatic EPI can be diagnosed by the presence of steatorrhea, diarrhea, flatulence, or weight loss[22], which often manifest when fecal fat excretion is > 7 g/d (Table 4). Early diagnostic studies relied on direct pancreatic function tests (*i.e.*, those involving collection and analysis of secretions directly from the duodenum or pancreatic duct, including the secretin-pancreozymin and Lundh tests[2]), which remain the most sensitive and specific methods for assessing exocrine pancreatic function. Direct tests, however, are limited by their cost, duration, and invasive nature, which involve endoscopic aspiration or tube aspiration of secretions from the duodenum for several hours. During the past 20 years, the use of non-invasive indirect methods has become more common. These tests are more readily performed in multiple settings and are based on the measurement of fecal elastase and fecal fat[2,23,24].

The coefficient of fat absorption is the gold standard for diagnosing fat maldigestion; however, it is poorly accepted by patients and laboratory personnel because it requires a strict diet containing 100 g of fat daily for 5 d and collection of all feces for the last 3 d (classical Van de Kamer test)[2]. In addition, fat excretion > 7 g/d indicates steatorrhea but is not informative about whether this is due to EPI or extrapancreatic causes. Fecal elastase is a pancreatic enzyme that is stable during passage through the gastrointestinal tract; some consider its measurement as the new gold standard for EPI diagnosis[2]. However, the current cutoffs that are used to define EPI might be improved if the cutoff were reduced to 128 μg/g stool[25] or 84 μg/g stool[26]. For better sensitivity, formed stool samples are best, as loose samples may spuriously dilute and lower the elastase levels and give a false positive result[16,24]. Fecal elastase, measured by enzyme-linked immunosorbent assay, has a good sensitivity for moderate EPI (75%) and high sensitivity for severe EPI (95%), and has a higher specificity (79%-96%) compared with the direct tests[27]. It should be noted that decreased fecal elastase values have been reported in patients with conditions not typically associated with EPI, such as HIV infection (23%-54%), advanced renal disease (10%-48%), and irritable bowel syndrome (6%)[28]. It is commonly accepted

Table 2 Factors involved with exocrine pancreatic insufficiency in different medical conditions[1,16,77,78,107,129,131,133,143,144,152-154,164]

Mechanism involved	Pancreatic cancer	Diabetes mellitus	Celiac disease	IBD	GI surgery
Normal pancreas		√	√	√	√
Abnormal pancreas	√	√	√	√	
Low or absent pancreatic enzyme production	√	√	√	√	√
Lack of stimulus for pancreatic enzyme production			√	√	√
Postcibal asynchrony	√	√	√	√	√
Pancreatic or biliary tract abnormalities	√	√		√	
GI malabsorption			√	√	√

EPI: Exocrine pancreatic insufficiency; GI: Gastrointestinal; IBD: Inflammatory bowel disease.

Table 3 Common signs and symptoms of exocrine pancreatic insufficiency[1,14-16,18,19,22]

Sign/symptom	Associated findings
Excessive flatulence	Abdominal bloating or distension, cramps, belching
Steatorrhea	Fatty, bulky stools; increased bowel movements
Malnutrition	Weight loss, anorexia, fatigue
Vitamin D deficiency	Deficient bone mineralization, osteomalacia, osteoporosis
Vitamin K deficiency	Coagulation abnormalities, ecchymoses, bone metabolism deficiencies
Vitamin A deficiency	Night blindness, decreased immune competence
Vitamin E deficiency	Ataxia and peripheral neuropathy
Hypocalcemia	Muscle spasms, osteomalacia, osteoporosis
Hypoalbuminemia	Nail leukonychia

that a fecal elastase-1 level ⩽ 200 μg/g stool indicates EPI, with levels of 100 to 200 μg/g typically indicating mild to moderate impairment and levels < 100 μg/g reflecting severe impairment[29-31]. Fecal elastase testing is considerably more sensitive than the fecal chymotrypsin or PABA test and is the standard clinical marker for moderate to severe EPI[32-34]. However, there is poor correlation between fecal elastase levels and coefficient of fat absorption, making fecal elastase less attractive for clinical research and regulatory purposes[35]. Additionally, because fecal elastase values are unaffected by PERT, enzymes do not need to be stopped before testing; unfortunately, this also means that fecal elastase testing is ineffective for monitoring response to PERT, unlike direct measurement of fat absorption[3].

Although not widely available, other tests for the diagnosis of EPI include the ^{13}C-mixed triglyceride (^{13}C-MTG) breath test and secretin-enhanced diffusion-weighted magnetic resonance cholangiopancreatography imaging (MRCP). In the ^{13}C-MTG test, the patient ingests a small amount of ^{13}C-marked triglycerides which are degraded by lipases in the intestine to ^{13}C-marked fatty acids. The absorbed ^{13}C fatty acids are metabolized by the liver, and $^{13}CO_2$ is exhaled[36]. Lower lipase activity is associated with less $^{13}CO_2$ in the exhaled breath. This test can also be used to assess the effects of PERT[37]. Pancreatic exocrine function can also be assessed by changes in duodenal filling, pancreatic duct caliber, and accumulation of fluid in the pancreatic parenchyma, as monitored by MRCP following stimulation with exogenous secretin[38,39].

PERT

PERT is the backbone of EPI treatment. Patients with abnormal fecal fat excretion, steatorrhea, and/or weight loss are generally considered candidates for PERT[20]. The aims of PERT are to compensate for deficiencies in endogenous enzyme secretion, correct maldigestion and malabsorption, and ameliorate symptoms resulting from a loss of exocrine function. To achieve this, the enzymatic activity delivered into the duodenum in conjunction with gastric emptying must be sufficient to optimize digestion and nutrient absorption[21]. A main goal of PERT is to restore sufficient intestinal lipase levels[11]. Unprotected lipase is irreversibly inactivated in the acidic environment of the stomach (pH ⩽ 4). Consequently, inhibition of gastric acid secretion has been used to prevent lipase inactivation. Modern preparations consist of pancreatic enzymes encapsulated in microspheres or microgranules, with an enteric coating designed to release the enzymes into the pH-neutral environment of the intestinal lumen[40]. A number of porcine lipase preparations are approved for PERT[41], and the reader is referred to publications from national and professional organizations for recommended dosages[16,42-44] Replacement of protease and amylase is also important in EPI, where some of its symptoms relate to deficiency of these two enzymes, as well. Pancrelipase of porcine origin contains the three enzymes (lipase, protease, and amylase) in adequate ratios to treat EPI.

In randomized controlled trials, PERT improved the coefficient of fat absorption, clinical symptoms,

Table 4 Symptoms and tests used in the diagnosis of exocrine pancreatic insufficiency[2,16,23,24]

Clinical symptoms
Steatorrhea
Diarrhea
Flatulence
Weight loss
Laboratory findings
Fecal fat > 7 g/d on a 100-g fat/d diet
Inconvenient; special high-fat diet and prolonged collection of feces
Considered gold standard
An abnormal coefficient of fat absorption is not specific for EPI
Fecal elastase-1 level ⩽ 200 μg/g stool; < 100 μg/g stool = severe EPI
Simple, convenient, and widely available
Measured on a random stool sample
Liquid stools may lead to falsely low results due to dilution
Less accurate in mild stages of disease
Positive qualitative fecal fat (Sudan Ⅲ) staining
Special high-fat diet
Less accurate; semi-quantitative microscopic method
Insensitive for mild disease
Fecal chymotrypsin ⩽ 6 U/g stool
Less sensitive than fecal elastase for mild EPI
Fluorescein dilaurate (pancreolauryl test)
Easy to perform
Not widely available
^{13}C-mixed triglyceride breath test
Well established
Not widely available
Imaging/endoscopy
Pancreatic duct dilatation
Main pancreatic duct calculi
Endosonographic criteria of chronic pancreatitis
Secretin-enhanced diffusion-weighted magnetic resonance cholangiopancreatography imaging
New
Not widely available

EPI: Exocrine pancreatic insufficiency.

and quality of life (QoL) of patients with EPI and significantly slowed gastric emptying[45-48]. Patients with EPI experienced a reduction in stool frequency and fat/water content, as well as abdominal pain and flatulence[47]. PERT is generally well tolerated; treatment-emergent adverse events include headache, infection, abdominal pain, flatulence, diarrhea, and dyspepsia[45-47,49]. However, because only porcine PERT products are currently available, allergic reactions, including anaphylactic shock, could potentially occur. Furthermore, fibrosing colonopathy, a rare but serious complication, has been reported in children[50] and adults[51] with cystic fibrosis receiving high-dose PERT, but there have been no reports in subjects with chronic pancreatitis.

PANCREATIC CANCER AND EPI

Pancreatic cancer ranks fourth among cancer-related deaths in the United States and has a 5-year survival rate of 7.2%[52,53]. This review focuses on inoperable pancreatic cancer, as the relationship between pancreatectomy and EPI is already well-recognized. EPI in patients with pancreatic cancer is related to the loss of pancreatic parenchyma and/or obstruction of the main duct, which impedes the production of pancreatic enzymes or their transportation into the duodenum. The most important predictors for EPI are localization of the tumor to the pancreatic head, ⩾ 90% destruction of normal tissue, degree of ductal obstruction, and surgical loss of pancreatic tissue[1,16,54]. The severity of ductal obstruction is proportional to the length of the obstructed duct; hence, enzyme secretion decreases as the cancer spreads distally, from head to body to tail[1,54,55].

The reported occurrence of malabsorption and exocrine dysfunction varies between 66% and 92% of patients with pancreatic cancer[30,56-59], with 65% to 75% of patients experiencing fat malabsorption and 50% of patients experiencing some degree of protein malabsorption[60,61]. In a prospective study of patients with an inoperable tumor of the pancreatic head region, 66% had EPI at diagnosis and 92% had a fecal elastase level < 200 μg/g by the 6-mo follow-up; 77% of patients were being treated with PERT[59]. In a systematic review, the prevalence of EPI was 25% to 50% in patients with advanced pancreatic cancer who did not undergo resection[62]. Although EPI is usually moderate in severity[61], in a prospective study, Partelli *et al*[31] detected extremely reduced (fecal elastase ⩽ 20 μg/g) in 25%, severely reduced (> 20 to < 100 μg/g) in 14%, and moderately reduced exocrine pancreatic secretion (⩾ 100-200 μg/g) in 11% of patients with advanced pancreatic cancer[31]. Pancreatic function abnormality seems to be higher in patients with tumors located in the pancreatic head versus in the body or tail[31,63]. Furthermore, in a prospective study, significantly more patients with a pancreatic head tumor had extremely reduced exocrine pancreatic secretion (fecal elastase ⩽ 20 μg/g) versus patients with a body or tail tumor; notably, a significant correlation was found between extremely reduced exocrine pancreatic secretion and poor survival.

Several studies have also reported inadequate enzyme secretion (trypsin, lipase, amylase, elastase, and chymotrypsin) in patients with pancreatic cancer compared with healthy controls[55,58,64]. Elastase production may be reduced earlier and to a greater extent compared with the output of other enzymes, for unknown reasons[64]. Additionally, fecal amylase activity was significantly decreased in pancreatic cancer patients compared with healthy controls[65].

PANCREATIC CANCER AND PERT

Approximately 80% to 90% of patients with pancreatic cancer have unresectable or advanced metastatic disease, leaving only palliative treatment options to manage symptoms[66]. Gastrointestinal and diet management problems negatively impact patients' QoL[67]; consequently, early treatment of EPI has been suggested to reduce symptoms[59] and to improve weight gain and fat absorption in patients with

pancreatic cancer[60,66]. The National Comprehensive Cancer Network has advised that PERT be given to patients with pancreatic cancer who show symptoms of EPI[68]. Other organizations have noted that PERT may help maintain weight and promote QoL in patients with pancreatic cancer[40,69].

The recommendations for PERT use in pancreatic cancer patients were made despite a paucity of data to support them. Only two randomized placebo-controlled trials have investigated the use of PERT in pancreatic cancer (Table 5). In a double-blind trial of 21 patients with unresectable cancer of the pancreatic head, patients treated with 50000 units of lipase/meal gained 1.2% in body weight in 8 wk, while those receiving placebo lost 3.7%[66]. Fat absorption also improved by 25% with PERT, whereas it dropped by 25% with placebo. Steatorrhea did not significantly differ between groups; however, there was a trend for lower stool frequency in patients receiving PERT. When patients receiving placebo were switched to open-label PERT, they demonstrated weight stabilization and improvements in steatorrhea-related symptoms. In a double-blind, placebo-controlled study in patients with unresectable pancreatic cancer (43% had severe EPI, defined as fecal elastase-1 < 100 μg/g stool), mean weight loss after 8 wk of PERT (-1.49%) was not significantly different compared with placebo (-2.99%)[70]. However, PERT did improve nutritional status in a subset of patients with unresectable cancer of the pancreatic head region. Additionally, in an uncontrolled study of patients with unresectable pancreatic cancer, patients with moderate to severe fat or protein malabsorption showed improved nutrient absorption with PERT[60].

DIABETES MELLITUS AND EPI

Type 1 diabetes is considered a primary autoimmune process characterized by typically early onset, an eventual absolute lack of insulin, and islet cell antibodies[71]. Type 2 diabetes is a metabolic disorder characterized by hyperglycemia in the context of insulin resistance and a relative lack of insulin[71]. A third type of diabetes, type 3c or pancreatogenic diabetes[71-73], occurs secondary to parenchymal pancreatic disease and is characterized by an absent pancreatic polypeptide response to nutrients and loss of islet cells by inflammatory destruction and fibrosis[74,75]. The relationship between EPI and diabetes is complex due to the close anatomic and physiologic linkages between the exocrine and endocrine pancreas; pathological conditions of the endocrine tissue can cause impairment of exocrine function and vice versa. Furthermore, depending on the particular diagnostic tests that are used, there is the chance of inadvertently classifying type 3c diabetes as type 1 or 2, confounding understanding of their relative prevalence and relationship to EPI.

Type 1 and type 2 diabetes

Marked alterations in the exocrine pancreas are observed in patients with diabetes, including changes in size, morphology, and histology[76]. No studies have examined at what point during the course of diabetes these pancreatic abnormalities develop. Diabetic pancreata are often atrophic and can have prominent fatty involutions and calcification[77,78]. Atrophy is more pronounced in type 1 *vs* type 2 diabetes[79,80]. Moreover, the pancreata of diabetic patients are significantly smaller and have higher lobulation compared with healthy controls[79,80]. In a cadaveric study, the mean weight of pancreata in type 1 diabetic patients weighed about a half of that of controls[81], while magnetic resonance imaging studies in adults with recent-onset diabetes found only a 26% to 31% reduction in pancreatic volume index after adjustment for body weight compared with healthy controls[82,83]. Additionally, pancreatic volume in diabetic patients was significantly lower when elastase and/or chymotrypsin levels were low[77]. Atrophy of the gland and acini, lymphocytic infiltration, moderate to severe fibrosis, and fatty changes were noted on autopsy in the exocrine pancreas of Japanese patients with diabetes[84].

EPI associated with diabetes is typically mild to moderate and not associated with overt steatorrhea. The prevalence of EPI is higher in type 1 diabetes (26%-57%)[85-89] compared with type 2 diabetes (20%-36%)[78,85,86,88], significantly so in a pooled literature analysis of 3662 patients with diabetes (39% *vs* 28%, respectively, using a cutoff of fecal elastase 200 μg/g stool; $P < 0.00001$)[76]. Severe reductions in fecal elastase levels (< 100 μg/g) have been observed in 11% to 30% of patients with type 1 diabetes[85-88,90] and 3% to 20% of patients with type 2 diabetes[85,86,88,91,92]. Notably, in a large screening study of diabetic patients, correlations between exocrine insufficiency and early onset/longer duration of diabetes, insulin use, and lower body mass index (BMI) have been demonstrated[86]. Fecal elastase levels have also been found to correlate with worse glycemic control, less residual β-cell function, and higher BMI[93,94].

Fecal fat excretion inversely correlates with fecal elastase levels in type 1 diabetes; however, excessive fecal fat excretion occurred in 22% of patients with normal fecal elastase levels[87]. In a cohort of diabetics with fecal elastase levels < 100 μg/g, 59% of patients excreted ⩾ 7 g of fat per day[86]. Interestingly, 45% of type 1 diabetics with pathological fat excretion were asymptomatic in one prospective study[89]. Fecal fat excretion did not correlate with the type or duration of diabetes, age at onset, glycemic control, or BMI[89,95]. The prevalence of EPI was 33% using the direct secretin-cerulein test in patients with type 1 diabetes; among patients with an abnormal secretin-cerulein test result and steatorrhea ($n = 8$), 50% had decreased lipase but none had an enzyme secretion level

Table 5 Pancreatic enzyme replacement therapy clinical trials

Study	Study design, duration (when given), and number of patients	Disease	Results	Adverse effects
Bruno *et al*[66]	DBRPC, 8 wk, 24 adults (21 analyzed)	Pancreatic cancer	The mean absolute difference for PERT *vs* placebo in percentage change in body weight was 4.9% (P = 0.02); other outcomes were numerically improved with PERT *vs* placebo [fat absorption coefficient, 12% increase *vs* 8% decrease (P = 0.13); stool frequency, decrease of 1/d *vs* increase of 2/d (P = 0.07)]	No treatment-related AEs
Woo *et al*[70]	DBRPC, 8 wk, 67 adults	Pancreatic cancer	The mean change in body weight at 8 wk was similar with PERT *vs* placebo (-1.49% *vs* -2.99%; P = 0.381), but the mean change in nutritional status was superior with PERT *vs* placebo in the subset of patients with cancer of the pancreatic head (PG-SGA score, -42.65% *vs* 32.93%; P = 0.039)	Three patients died [PERT group, 2/34 (6%); placebo group, 1/33 (3%)] There were no PERT-related serious AEs
Perez *et al*[60]	Open-label, 12 adults	Pancreatic cancer	Most patients with moderate to severe fat (6/7) or protein (3/3) malabsorption improved, but no patients with mild fat or protein (0/8) malabsorption improved	No descriptions regarding TEAEs
Ewald *et al*[49]	DBRPC, 16 wk, 80 adults	Type 1 diabetes	No significant change in HbA_{1c}, fasting glucose, or postprandial glucose; increase in mean vitamin D from baseline to week 16 (PERT, from 54.1 to 59.4 nmol/L; placebo, 60.2 to 62.7 nmol/L)	TEAEs occurred in 33 patients (84.6%) in PERT group and in 35 (85.4%) in PBO group; most frequent AEs were headache, infection, pain, diarrhea, and dyspepsia
Carroccio *et al*[150]	DBRPC, 2 mo, 40 children	Celiac disease	Significant mean ± SD weight gain in first 30 d (1131 ± 461 g with PERT *vs* 732 ± 399 g with placebo; P < 0.006), not significant at 60 d	No undesired side effects were reported
Evans *et al*[141]	Open-label, up to 4 yr, 20 adults	Celiac disease	Significant increase in fecal elastase from median of 90 μg/g to 365 μg/g (P < 0.0001) and improvement in chronic diarrhea with reduction in median stool frequency from 4/d to 1/d ($P \leqslant 0.0001$), but no weight increase (P = 0.3)	No descriptions regarding TEAEs
Leeds *et al*[135]	Open-label, up to 2 yr, 20 adults	Celiac disease	Significant improvement in chronic diarrhea with reduction in median stool frequency from 4/d to 1/d ($P \leqslant 0.0001$), but no weight increase (P = 0.3)	No descriptions regarding TEAEs
Huddy *et al*[181]	Open-label, 10 adults	Esophagectomy	Improvement in diarrhea and steatorrhea (9/10), increased weight (7/10)	Nausea in 1 patient
Armbrecht *et al*[183]	DBRPC crossover trial, 2 wk (plus 1-wk washout), 15 adults	Total gastrectomy	Improved stool consistency (score, 7.6 with PERT *vs* 9.3 with placebo; P < 0.05), but not the number of bowel movements or abdominal symptoms	No descriptions regarding TEAEs
Hillman *et al*[166]	Open-label, 6 mo, 30 adults	Partial gastrectomy	Mean ± SE weight gain of 6.73 ± 0.77 (P < 0.001), mean ± SE decrease in steatorrhea of 49.7% ± 7.7% (P < 0.001)	No descriptions regarding TEAEs
Brägelmann *et al*[184]	DBRPC, 14 d, 52 adults	Total gastrectomy	Improvement of overall well-being (15/23 with PERT *vs* 6/24 with placebo; P = 0.006), but no improvement of specific symptom	No descriptions regarding TEAEs

AE: Adverse event; DBRPC: Double-blind, randomized, placebo-controlled; GIP: Gastric inhibitory polypeptide; GLP-1: Glucagon-like peptide-1; HbA_{1c}: Glycated hemoglobin A_{1c}; PBO: Placebo; PERT: Pancreatic enzyme replacement therapy; PG-SGA: Patient-generated subjective global assessment; TEAE: Treatment-emergent AE.

< 10% of normal, which is typically when steatorrhea manifests[89]. In the same study, the fecal elastase test had low sensitivity (36%-55%) and specificity (59%-77%) to reproduce the secretin-cerulein test results; the authors concluded that low fecal elastase levels do not reliably indicate EPI in type 1 diabetes.

Secretory abnormalities have been noted in diabetics[96-100]. Frier *et al*[96] observed reductions in exogenously stimulated secretion of amylase (66%) and trypsin (54%) in type 1 diabetics, and the degree of dysfunction correlated with disease duration in a small controlled study. Bicarbonate output was also significantly reduced and showed a significant inverse correlation with the daily insulin dosage in patients with a disease duration < 10 years. Furthermore, hyperglucagonemia, which is observed in some type 2 diabetic patients, is associated with a marked inhibition of pancreatic enzyme output, including lipase, amylase, and trypsin[97]. Increased somatostatin, also found in some diabetic patients, dose-dependently inhibits secretion of pancreatic bicarbonate, amylase, and trypsin[98-100].

Several theories have been proposed to explain the reduced exocrine function in diabetes, including

imbalances between stimulatory and inhibitory islet hormones, pancreatic atrophy or fibrosis, autonomic neuropathy, altered release of gastrointestinal regulatory mediators, and autoimmunity[79,80,84,101,102]. Disturbances in acinar-islet interactions with imbalances between stimulatory (insulin) and inhibitory (glucagon, somatostatin) islet hormones are linked to EPI in some diabetic patients[101]. Insulin has a trophic effect on the acinar cells and a stimulatory effect on exocrine enzyme secretion in animal models and cell cultures, suggesting that insulin deficiency may play a role in pancreatic atrophy[101,103]; insulin deficiency in diabetic patients may lead to pancreatic atrophy[79,80,84]. If insulin deficiency were the primary reason for exocrine dysfunction, however, then all patients with type 1 diabetes would be expected to have EPI.

Regulation of pancreatic enzyme elaboration and secretion depends on gastrointestinal hormones and local neuronal signals[101]. Unsurprisingly, therefore, autonomic diabetic neuropathy and secondary gastroparesis can impair enteropancreatic reflexes, such as changes in gut peptides, that may mediate as much as 50% of the postprandial exocrine pancreatic response[75,101,104]. Diabetic microangiopathy can reduce pancreatic perfusion and cause arterial lesions that can lead to pancreatic fibrosis[105,106]. Patients with type 2 diabetes are also at an increased risk for biliary disease, which can diminish secretions from the pancreas[107]. Finally, autoimmune diseases can involve both the exocrine and endocrine glands, as antibodies against islet cells can cross-react with acinar cells[34]. Autoantibodies against exocrine pancreatic antigens were detected in 77% of patients with type 1 diabetes, but were not detected in any patients with type 2 diabetes[108]. In summary, screening for EPI in patients with type 1 or type 2 diabetes is appropriate when symptoms suggest pancreatic insufficiency.

Type 3c diabetes

Pancreatogenic or type 3c diabetes occurs secondary to pancreatic disease, injury, or resection and accounts for 5% to 10% of the Western diabetic population[8,9,109,110]. Despite the prevalence of type 3c diabetes, the American Association of Clinical Endocrinologists and American College of Endocrinology have not formally included it in their guidelines[73]. The etiologies of type 3c diabetes include chronic pancreatitis (76%-79%), pancreatic cancer (8%-9%), hereditary hemochromatosis (7%-8%), cystic fibrosis (4%), and post-pancreatic resection (2%-3%)[8,9]. Furthermore, the prevalence of type 3c diabetes in chronic pancreatitis is correlated with the degree of exocrine dysfunction (with a prevalence of 63%, 32%, and 13% with severe, moderate, and mild dysfunction, respectively)[111]. Per diagnostic criteria, all patients with type 3c diabetes display signs of EPI[112], and this EPI is more severe compared with that of patients with type 1 and type 2 diabetes, as demonstrated by lower stimulated bicarbonate and trypsin output[96] and lower fecal elastase levels[94].

Because of the close anatomical relationship between exocrine and endocrine cells, type 3c diabetes may result from progression of the primary pancreatic exocrine disease that destroys islet cells by pancreatic inflammation or fibrosis[111,113]. Indeed, the impairment of pancreatic endocrine function in chronic pancreatitis proceeds in parallel with the destruction and spread of fibrosis inside islet cells[111,114,115]. Additionally, α- and β-cell responses were reduced in patients with autoimmune pancreatitis[115]. Mechanisms besides simple islet cell destruction may also be involved, as even small adenocarcinomas are associated with type 3c diabetes[116].

DIABETES MELLITUS AND PERT

Despite a paucity of clinical data for PERT use in patients with diabetes, position statements have stated that symptomatic patients with fecal elastase levels <100 μg/g may be treated with PERT[16,117] but should be carefully monitored because of the risk of disturbances in glucose homeostasis[118]. Of course, increased glucose uptake may reduce the risk of hypoglycemia[34]. There is some evidence that PERT can improve glucose metabolism by augmenting the effects of incretins and increasing postprandial insulin secretion[48,119]; however, no significant differences in hemoglobin A1c, fasting glucose, or oral glucose tolerance test results were observed between patients with type 1 diabetes treated with PERT and placebo (Table 5)[49].

In summary, there are different gastrointestinal motility and comorbid conditions in patients with diabetes mellitus that may result in EPI or decreased digestion or absorption of fat and protein. Early EPI is very difficult to diagnose in diabetic patients, where the condition appears and progresses insidiously across years. Although endocrinologists have not formally recognized type 3c diabetes, most of the conditions that lead to type 3c diabetes have a well-known association with EPI and the need for PERT. An interdisciplinary approach is needed to better define the possible association of EPI with diabetes and potential mechanisms, and to separate them from pancreatic processes that may or may not be related to diabetes. Furthermore, guidelines are needed to help clinicians decide when to test diabetic patients for EPI, and when use of PERT is beneficial.

AGING AND EPI

There are few studies on the effects of aging on exocrine pancreas function, and most[120-122] but not all studies[123] have found that EPI appears to increase with age. For example, in a study of older individuals (age 60 to > 79 years) without gastrointestinal

diseases or diabetes, fecal elastase-1 levels correlated negatively with age and were significantly lower in individuals > 70 years of age compared with a control group (age 20-28 years)[122]. Among subjects over 60 years of age, 21.7% had fecal elastase-1 levels below 200 μg/g stool.

CELIAC DISEASE AND EPI

Celiac disease is an inappropriate T-cell–mediated reaction to gluten that causes inflammatory injury to the small intestine; the estimated worldwide prevalence is 1% to 2%[124,125]. Diarrhea is common with celiac disease and is typically attributed to gluten-related indigestion, malabsorption, and fluid secretion. The primary treatment is a gluten-free diet, which usually improves gastrointestinal function, diarrhea, and weight gain. Nonetheless, 17% to 61% of patients with treated celiac disease have persistent diarrhea[126,127]. Diagnostic testing of celiac patients with chronic diarrhea on a gluten-free diet determined that EPI was present in 12% (based on pancreatic test or trial of PERT) to 18% (based on steatorrhea and trial of PERT)[126,128].

Pancreatic dysfunction occurs in some patients with celiac disease but is typically transient and normalizes with a gluten-free diet[129,130]. However, some patients do have substantially impaired exocrine pancreatic function, leading to maldigestion, malabsorption, and malnutrition. Comorbid chronic pancreatitis has been one possible explanation for these severe cases, with several publications reporting a higher incidence of chronic pancreatitis in patients with celiac disease[131,132]. In patients with untreated celiac disease, the prevalence of EPI (measured and defined by the fecal elastase test) ranges from 4% to 80%[133-138]. Subnormal secretion of at least 1 pancreatic enzyme was observed in 22% to 33% of patients with untreated celiac disease[130,139,140]. In a small controlled study, a significant inverse correlation was demonstrated between the severity of intestinal damage and fecal elastase levels in patients with celiac disease[133]. Carroccio *et al*[140]. reported normalization of fecal chymotrypsin in almost all patients with celiac disease on a strict gluten-free diet[140],which speaks to the functional aspect of EPI due to lack of stimulus rather than to structural damage. It has been suggested that impairment of exocrine pancreatic dysfunction is related to mucosal villous atrophy[129,133], and thus can improve when mucosal regeneration occurs with a gluten-free diet and other treatments[137,141].

In a single-center study by Rana *et al*[142], 36 patients with celiac disease serologically and histopathologically diagnosed were studied with fecal elastase, endoscopic ultrasound (EUS), and elastography. At study entry, 10 of the patients (28%) were diagnosed with EPI based on abnormal fecal elastase levels; 9 (90%) of these patients had villous atrophy of the duodenum, and 1 patient had a history of several episodes of acute pancreatitis. The 10 patients were subjected to a gluten-free diet, and after 3 mo 7 patients had a repeat fecal elastase test that had normalized in all cases, except for the patient with prior acute pancreatitis events. Elastography results were normal in all 8 patients who consented to EUS, except for the patient with prior acute pancreatitis events. The authors concluded that EPI, identified based on fecal elastase levels in adult patients with celiac disease, may be unrelated to structural changes in the pancreatic parenchyma and might be reversible by a gluten-free diet in most patients.

The pathophysiological mechanisms of EPI in celiac disease may be multifactorial. A primary mechanism could be a defective postprandial response to intraluminal contents by an atrophic upper intestinal mucosa with altered synthesis, storage, and/or secretion of secretin and CCK, which are potent stimulators of pancreatic secretion. Postprandial plasma CCK levels were significantly lower in patients with untreated celiac disease compared with controls and were significantly correlated with fecal elastase levels[133]. Impaired CCK release leads to reduced pancreatic stimulation and secretion, postcibal asynchrony between gastric emptying and gallbladder contraction, and fat maldigestion[143,144]. Decreased secretin release by the extensively damaged jejunal mucosa has also been reported[145]. General malnutrition is associated with defects in pancreatic secretion[146]; consequently, it is not unexpected that protein malnutrition in celiac disease is associated with a decrease in pancreatic enzyme output, as well as structural changes in the pancreas, including atrophy of acinar cells with fewer secretory granules, pancreatic fibrosis, and a smaller pancreatic head[147,148]. One study, however, reported that EPI in celiac disease may be independent of nutritional status[139]. There is some evidence for malabsorption of amino acids in patients with untreated celiac disease[149], which might contribute to EPI by restricting the substrates for synthesis of digestive enzymes.

CELIAC DISEASE AND PERT

Pancreatic function tests are usually not performed on newly diagnosed patients or patients with uncomplicated celiac disease; these tests should be considered if there is persistent diarrhea or steatorrhea despite a gluten-free diet or if there are signs of overt malnutrition. Patients on a gluten-free diet with low fecal elastase levels should receive PERT[16]. Data from a double-blind randomized trial of children with celiac disease on a gluten-free diet demonstrated that PERT increased body weight versus placebo during the first 30 days after diagnosis (Table 5)[150]. Similarly, PERT reduced chronic diarrhea from 4 to 1 stools/day in 90% of patients with celiac disease in 2 other uncontrolled studies[135,141].

Gastroenterologists specializing in celiac disease have not recognized a definite association between

celiac disease and EPI and are silent on the possible association and the need for treatment with PERT. Further studies are required to demonstrate whether there is any direct association between celiac disease and EPI.

IBD AND EPI

Crohn's disease (CD) and ulcerative colitis (UC) are chronic relapsing immune-mediated disorders of the gastrointestinal tract, characterized by chronic gastrointestinal inflammation. It is suggested that these disorders result from an aberrant immune response and loss of tolerance to the normal intestinal flora. Patients with IBD are at an increased risk for developing EPI, particularly if they have $\geqslant$ 3 daily bowel movements (BMs), loose stools, and a history of surgery[34,151]. Autopsy studies have found pancreatic lesions in 38% of patients with CD and 53% of patients with UC without prior evidence of pancreatitis[152]. Although still widely used, the fecal elastase test has poor diagnostic accuracy in patients with diarrhea[12]. In a cross-sectional study of 237 unselected patients with IBD, 21% demonstrated exocrine dysfunction as measured by the PABA test, and 19% exhibited abnormally low bicarbonate secretion in response to a secretin test; the frequency of abnormal results was similar in patients with CD and UC[153]. Furthermore, 8.4% of patients had a pancreatic duct abnormality[153].

CD

As a group, patients with CD have significantly decreased lipase, amylase, and trypsin activity compared with controls; these changes are not correlated with disease duration or location or extent of a previous bowel resection[154,155]. Factors related to impaired pancreatic function were disease activity, localization, and extent of bowel involvement[154]. The prevalence of EPI based on low fecal elastase levels varies between 14% and 30% of patients with CD[151,156]. Angelini *et al*[157] determined that 35% of patients with CD have impaired bicarbonate and/or enzyme secretion[157]. Depending on the involvement of the gastrointestinal tract (ileum, colon, or both), abnormal fat excretion varies between 17% and 35% in patients with CD[158].

Possible mechanisms for the development of EPI in CD include pancreatic autoantibodies, duodenal reflux, and reduced secretory hormone secretion. About one third of patients with CD have autoantibodies against pancreatic components[159-161], suggesting that EPI could result from immunologic induction of pathways that impair exocrine function. These antibodies appear specific for CD, as opposed to an individual with UC or without IBD[159,160]. Other possible mechanisms for pancreatitis in patients with CD include duodenal reflux into the pancreatic duct through an inflamed and incompetent ampulla of Vater and fistula formation between the pancreatic duct and the duodenum[162]. These processes could play a role in CD-associated EPI by damaging the pancreatic duct. Indeed, pathological changes in the pancreatic duct that may impede flow have been reported in patients with CD and UC[153]. Finally, scarring or inflammation may reduce intestinal hormone secretion, thus insufficiently stimulating the pancreas[154].

UC

In unselected patients with IBD, 22% of patients with UC had fecal elastase levels $\leqslant$ 200 μg/g, and 9% had severe EPI (fecal elastase $\leqslant$ 100 μg/g)[151]. Additionally, using a secretin-cerulein test, 50% of patients with UC demonstrated bicarbonate and/or enzyme insufficiency, while 74% had an abnormal PABA test[153,157]. By magnetic resonance cholangiopancreatography, 16.5% of patients with UC had a pancreatic duct abnormality, compared with no individuals in the control group[163].

IBD AND PERT

Despite the high prevalence of EPI in patients with IBD, we identified no studies that assessed whether PERT can improve maldigestion or malabsorption in patients with either CD or UC, nor any guidelines for the use of PERT in these populations.

GASTROINTESTINAL SURGERY AND EPI

Upper gastrointestinal surgery can distort the normal anatomy and physiology of digestion, thus disrupting the intricate sequence of events that control normal digestion and absorption. Maldigestion occurs in as many as 80% of patients following such procedures, and EPI may contribute to the pathogenesis[164]. Pancreatectomy results in bulk loss of enzyme-producing cells and is already an indication for PERT, so it will not be discussed here.

Post-gastrectomy diarrhea and/or steatorrhea occur in > 47% of gastrectomy patients, and significant weight loss is common[165-167]. In one study, all patients (n = 15) developed severe EPI 3 mo after total gastrectomy[168]. Steatorrhea was also observed in all patients (n = 30) who underwent a partial gastrectomy[166]. Two additional studies reported pathological fecal fat excretion in 92% and 67% of patients after total gastrectomy[167,169]. Additionally, using the ^{13}C-mixed triglyceride breath test, 82% of patients exhibited fat maldigestion after a Whipple procedure[164]. Finally, using the same diagnostic test, Perez Aisa *et al*[170] recently reported that 38% of patients developed fat malabsorption following partial or total gastrectomy.

EPI and altered pancreatic enzymes and gastrointestinal hormone levels were reported after both total and partial gastrectomies[168,171-173]. Luminal pancreatic enzyme and bile salt concentrations were

markedly reduced after subtotal gastrectomies[173], and significant reductions in the stimulated secretion of pancreatic juice (76%), trypsin (89%), chymotrypsin (91%), and amylase (72%) were observed after total gastrectomy compared with preoperative levels[168]. In another study, total gastrectomy significantly decreased bicarbonate (48%), lipase (39%), and chymotrypsin (24%) output in comparison with non-operated controls[167]. In a third study, only 30% of patients had EPI following subtotal or total gastric resection as measured by the fecal chymotrypsin test[171]. Low levels of gastrin and pancreatic polypeptide and high levels of postprandial plasma CCK have also been reported following total gastrectomy[168].

Gastrectomy disrupts several of the normal digestive processes; different factors may contribute to the postoperative changes, including deficient trituration of nutrients, altered gastric emptying, pancreatic denervation, postcibal asynchrony between gastric emptying and gallbladder contraction, and/or decreased absorptive surface and enzyme contact[16]. When the duodenum is also resected (gastroduodenal resection), a reduction in CCK secretion from the duodenum decreases pancreatic stimulation and contributes to EPI[164]. Likewise, Roux-en-Y gastric bypass surgery to treat obesity disrupts the normal digestive process, and almost a third of patients develop EPI post-operatively[174]. However, since the purpose of the procedure is to effect weight loss, it is unlikely that EPI in this situation would be treated.

The vagus nerve plays an important role in the regulation of exocrine pancreatic secretions, as vago-vagal enteropancreatic reflexes mediate responses in the intestinal phase of exocrine pancreatic secretion[175]. Vagotomies, which reduce gastric acid secretion by severing the vagal nerve supply to the stomach, also cause dysfunction of the exocrine pancreas; during extensive gastric surgery, severing of the vagus nerve (truncal vagotomy) can contribute to postoperative EPI, and a vagotomy by itself is sufficient to cause EPI[176]. In 2 studies, patients had decreased pancreatic juice, lipase, trypsin, and bicarbonate secretion following vagotomy[177,178]. In a similar study, fecal fat excretion was significantly increased after vagotomy and 45% of patients developed steatorrhea[179].

Extensive small bowel resections leading to short bowel syndrome can also reduce endogenous exocrine pancreatic secretion. Short bowel syndrome is characterized by malabsorption, with contributing factors including a reduction in gastrointestinal hormones (particularly CCK), postcibal asynchrony, gastric acid hypersecretion, loss of intestinal regulatory feedback, massive loss of absorptive surface, and rapid transit through the small intestine[1,180]. Additionally, total parenteral nutrition and anti-diarrheal agents used to treat short bowel syndrome are associated with pancreatic and gastric hyposecretion[180]. Some of these mechanisms, though not all, involve the pancreas, suggesting a role for EPI. There is wide variability depending upon the individual and the specific region resected. In patients undergoing ileal resection for CD, fecal fat excretion showed a highly significant correlation to the ileal length resected; for patients with only a 30-cm resection or less, the prevalence of abnormal fat excretion was 37%, whereas 100% of patients who underwent a 90-cm resection or greater displayed abnormal fecal fat excretion[158].

Esophagectomy has also been associated with EPI in one study (n = 63); 10 patients (16%) who underwent an esophagectomy had weight loss and fecal elastase levels < 200 μg/g stool and had symptomatic EPI with diarrhea and/or steatorrhea[181]. Potential mechanisms include decreased gastric reservoir, vagal denervation, and the presence of pyloroplasty that may be part of the procedure and cause dumping syndrome.

GASTROINTESTINAL SURGERY AND PERT

Despite a paucity of evidence regarding PERT use following gastrointestinal surgery, PERT is often recommended for post-surgical patients with steatorrhea, diarrhea, weight loss, or maldigestion-related symptoms[164,182]. In patients with EPI post-esophagectomy, 9 of 10 patients with fecal elastase levels < 200 μg/g stool had symptomatic improvement (no diarrhea or steatorrhea) with PERT and 70% experienced weight gain (Table 5)[181]. PERT may also be appropriate for asymptomatic patients with fat excretion > 15 g/d, as these patients are at high risk for developing nutritional deficiencies[164,182]. It has been suggested that PERT in combination with a high-energy diet over 6 to 8 meals/d may improve nutritional status and symptoms in these patients[11]. Because each patient and surgery is unique and patients have different degrees of EPI, PERT dosing must be tailored to the individual symptoms of a patient.

Data regarding the overall benefits of PERT in total or partial gastrectomy patients are conflicting; while some evidence suggests improved stool consistency[183], weight gain[166], quality of life[184], and reduced steatorrhea and fecal fat excretion[166,185], the same benefits were not observed in all studies. For example, in the double-blind crossover study that showed improvements in stool consistency following a total gastrectomy, there were no beneficial effects of PERT on fecal fat output; however, in the subset of patients with massive steatorrhea, there was a significant reduction in fecal fat excretion following treatment with PERT[183]. The variable trial results

prevent definitive conclusions about the benefits of PERT in fecal fat excretion and steatorrhea following gastric surgery.

CONCLUSION

The prevalence of EPI may be higher in patients with diverse non-pancreatic diseases or pancreatic cancer (Table 2) than has generally been appreciated. EPI should be considered as a possible etiology for any patient with diabetes, celiac disease, IBD, gastrointestinal surgery, or pancreatic cancer who presents with malnutrition, weight loss, and/or abnormal fatty stools (Table 4). In patients with symptomatic EPI, dietary modifications should be implemented and PERT may be initiated and doses should be titrated to achieve the optimal response.

Evidence from clinical research on EPI in less common etiologies is scanty and precludes firm recommendations on management. The lack of studies and evidence-based practices on the association of EPI with the medical conditions discussed herein makes conclusions difficult and needs to be substituted with consensus and clinical practice guidelines derived from future prospective, controlled studies, to confirm or refute these associations. EPI is a serious condition that, once confirmed and regardless of the cause, requires PERT treatment to prevent devastating, sometimes fatal, nutritional complications associated with untreated maldigestion and malabsorption. Further studies are needed to define the association of EPI with these conditions and to support recommendations on the timing of diagnostic testing and initiation of PERT.

Abstract

Recent studies have shown that radiofrequency (RF) ablation therapy is a safe, feasible, and effective procedure for hepatic hemangiomas, even huge hepatic hemangiomas. RF ablation has the following advantages in the treatment of hepatic hemangiomas: minimal invasiveness, definite efficacy, high safety, fast recovery, relatively simple operation, and wide applicability. It is necessary to formulate a widely accepted consensus among the experts in China who have extensive expertise and experience in the treatment of hepatic hemangiomas using RF ablation, which is important to standardize the application of RF ablation for the management of hepatic hemangiomas, regarding the selection of patients with suitable indications to receive RF ablation treatment, the technical details of the techniques, therapeutic effect evaluations, management of complications, *etc*. A final consensus by a Chinese panel of experts who have the expertise of using RF ablation to treat hepatic hemangiomas was reached by means of literature review, comprehensive discussion, and draft approval.

Radiofrequency ablation for hepatic hemangiomas: A consensus from a Chinese panel of experts. *World J Gastroenterol* 2017; 23(39): 7077-7086 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7077.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7077

INTRODUCTION

Hepatic hemangioma is the most common benign tumor of the human liver, with an incidence of 0.4% to 20% in the general population and a prevalence of 0.4% to 7.3% incidentally found in autopsy[1-5]. Most incidentally identified and asymptomatic hepatic hemangiomas do not need medical interventions. However, therapies are warranted for giant hepatic hemangiomas (⩾5 cm) that cause significant symptoms or the peripherally located hemangiomas posing the risk of life-threatening spontaneous rupture and hemorrhage[6-10].

Hepatic hemangiomas have been treated with a wide spectrum of therapies. Traditionally, surgical resection and surgical enucleation are the mostly used treatments of choice[6-10]. Minimally invasive therapies for hepatic hemangioma include transcatheter arterial embolization (TAE)[11-14], radiation therapy[15,16], and radiofrequency (RF) ablation[17-37]. Orthotopic liver transplantation has been performed as the treatment choice in rare circumstances[38]. In recent years, RF ablation has been increasingly used for managing hepatic hemangiomas due to its unique advantages compared with other therapies, such as minimal invasiveness, low cost, low incidence of complications, short duration of hospital stay, and increased patient compliance[17-37]. So far, 501 patients with hemangiomas treated by RF ablation have been reported in the literature[17-37]. A widely accepted consensus or guideline, embracing the selection of patients with suitable indications to receive RF ablation treatment, the application of the techniques, therapeutic effect evaluations, and management of complications, is needed to standardize the management of hepatic hemangiomas using RF ablation.

CONSENSUS DEVELOPMENT

The literature search was performed with an inclusion of published articles during the period from 2003 to 2017. The searched database is Medline. Medical subject headings and free-text words were used for searches, including radiofrequency ablation and hepatic hemangioma. Twenty-one original research papers pertinent to RF ablation treatment for hepatic hemangiomas were included. Of the 21 included papers (501 patients), 13 (465 patients) came from China, including ten in English and three in Chinese[17-37]; two came from South Korea, in which 25 patients with hepatic hemangiomas underwent ultrasound-guided percutaneous RF ablation[21,25]; and Western experience contributed six case reports including 11 patients on the RF ablation for hepatic hemangiomas[18,23,24,26,30,36]. Studies were reviewed and selected for further screening analyses and for subsequent consensus studies.

Base on a comprehensive appraisal of the published original research articles related to RF ablation for hepatic hemangiomas, a Chinese panel of experts was contacted and convened by electronic mails and/or phone. The recruitment of the experts was determined based on the following comprehensive criteria: the number of reported cases using RF ablation for hepatic hemangiomas and the impact of the published articles. All the experts work in well-known, high-volume centers, and their clinical experiences are well documented in scientific papers. They reviewed both the literature and their institutional experience. The draft was completed by the corresponding author and his team and then was circulated to all participants for comments. The revised version was redistributed to the experts for approval or further comments. After more than nine months of electronic mail or, on occasion, face-to-face discussions, the final version of consensus was formulated.

OVERVIEW OF HEPATIC HEMANGIOMAS

Pathology and clinical features

Hepatic hemangioma is usually a solitary tumor mass, although multiple lesions may be present in both hepatic lobes in up to 40% of the patients. Hepatic hemangiomas include cavernous hemangioma, sclerosing hemangioma, hemangioendothelioma, and capillary hemangioma. It consists of blood-filled cavities fed by the hepatic arterial circulation, with walls lined by a single layer of endothelial cells, and manifests as a veritable chaotic entanglement of distorted blood vessels confined to a region as small as a few milliliters and as large as 10 cm, 20 cm, and even 40 cm[1-3].

According to the diameter of hepatic hemangioma, it could be divided into three categories: small (<5 cm), giant (5-9.9 cm), and huge (≥10 cm). Giant hemangiomas are also defined by a diameter larger than 4 cm in the literature[1-5].

Diagnosis

In most situations, hepatic hemangiomas (especially when smaller than 4 cm) do not show any signs and/or symptoms, most likely being discovered incidentally during imaging investigations for other unrelated conditions. However, a few patients may present a wide variety of non-specific clinical symptoms such as pain in the right upper abdomen, decreased appetite, premature satiation sensation, nausea, vomiting, and abdominal discomfort such as sense of fullness and postprandial bloating (early or late). Spontaneous or traumatic rupture is the most severe complication. This has a catastrophic outcome if not promptly managed, and is the reason why correct diagnosis and management are extremely important[1-3].

Hepatic hemangiomas can be specifically diagnosed by ultrasonography (US) or contrast-enhanced US, contrast-enhanced computed tomography (CT), and magnetic resonance imaging (MRI) because of their typical imaging characteristics[4]. On US images, hepatic hemangiomas present as a homogeneous, round or oval lesion with well-defined hyperechogenicity, and likelihood of posterior acoustic enhancement. Other imaging techniques, such as contrast-enhanced CT or MRI, are recommended for confirmation in case of inconclusive ultrasonographic results, or if a giant hemangioma requires treatment[4,5]. The typical hemangioma appears on CT or MRI scans as a hypointense, well-defined lesion, which after contrast injection shows peripheral nodular enhancement with progressive homogeneous centripetal filling.

TRADITIONAL TREATMENT OF HEPATIC HEMANGIOMAS

Surgical procedure used to be the first choice of treatment for hepatic hemangiomas, including hemangioma enucleation, lobectomy (segmentectomy) or partial hepatectomy, and tumor suture or ligation[6-10]. Liver transplantation is used for rare cases which need medical intervention but the tumor is too large to undergo surgical resection, ruptures, or has hemorrhage combined with Kasabach-Merritt syndrome[38]. Surgical resection is rather invasive and associated with relatively high risks of perioperative morbidity (27%), mortality (3%) and long hospitalization[6-10].

Radiation therapy can destroy the endothelial cells and smooth muscle cells of hepatic hemangiomas, consequently leading to thrombosis, necrosis, and fibrosis inside the tumors, which provides partial reduction in hemangioma size and relief of symptoms. Currently, radiation therapy is used rarely in hepatic hemangioma because it is not considered as a

curative therapy. Moveover, it may have the risks of radiation hepatitis, veno-occlusive disease, and hepatic neoplasia[15,16].

TAE has been undertaken as an effective alternative treatment for managing hepatic hemangioma. Before TAE, hepatic arterial angiography is carried out to assess the blood supply to the tumor, tumor size, tumor number, tumor position, and intrahepatic vascular variants. The superselective catheterization of the hepatic arteries leading to the tumor body is followed by embolizing the tumor vessels using an embolization agent mixed with pingyangmycin or bleomycin. With the destruction of endothelial cells lining the blood sinus, thrombosis is formed to block the blood supply to the body of hemangioma. However, TAE is not considered as curative because recurrence is common due to vascular recanalization[34]. Moreover, the treatment may have disastrous complications, such as systemic embolization, biliary damage, and hepatic rupture as the size of tumors increases[11,12]. Several reports have advocated TAE as a temporizing and auxiliary preoperative procedure for huge hepatic hemangioma or spontaneously ruptured hemangiomas to decrease the risk of surgery[11-14,34].

HISTORY OF RF ABLATION FOR HEPATIC HEMANGIOMAS

RF ablation is performed by using RF-induced thermal energy to damage the endothelial lining vascular structures as a result of promoting thrombosis[18], to induce necrotic coagulation[19], as well as to destruct erythrocytes and cause vascular smooth muscle cell disappearance and fibrosis in the ablated zone[19].

In 2003, Cui *et al*[17] reported the first cohort of 12 patients who received the percutaneous RF ablation treatment for 15 hepatic hemangiomas (2.5-9.5 cm) under US guidance. In 2004, Zagoria *et al*[18] reported the successful treatment of a symptomatic hepatic hemangioma (5.0 cm) using percutaneous RF ablation under CT guidance. A few more studies show that percutaneous RF ablation therapy is a safe, minimally invasive, and effective locoregional treatment for selected patients with hepatic hemangiomas[21,23]. In 2006, Fan *et al*[20] reported the use of laparoscopic RF ablation therapy for treating 21 patients with 50 hepatic hemangiomas (5.5 cm ± 2.0 cm) located on the surface of the liver or adjacent to the gallbladder. The results showed that laparoscopic RF ablation therapy is a safe, feasible, and effective treatment option for patients with extrorse hemangiomas. In 2016, a prospective study demonstrated the benefits and disadvantages of laparoscopic RF ablation as compared with surgical resection for managing hepatic hemangioma[35]. Sixty-six patients with symptomatic-enlarging hepatic hemangiomas (4 cm $\leqslant$ diameter < 10 cm) either underwent laparoscopic RF ablation (n = 32) or open resection (n = 34). Laparoscopic RF ablation was associated with significantly shorter operative time (138 min *vs* 201 min, P < 0.001) and less blood loss than open resection. Patients after laparoscopic RF ablation experienced significantly less pain and required less analgesia use, significantly shorter length of hospital stay, and lower hospital cost. The study showed that laparoscopic RF ablation, as a minimal invasive treatment option, is as safe and effective a procedure as open resection for patients with symptomatic-enlarging hepatic hemangiomas smaller than 10 cm.

During the initial period of RF ablation for hepatic hemangiomas, authors always selected and treated hepatic hemangiomas < 10 cm using RF ablation because of the lack of experience. Sporadic cases with huge hepatic hemangiomas were treated by RF ablation. Whether RF ablation should be accepted for treating huge hemangiomas is still in debate because of the requirement of long ablation time. Lengthy ablation time is prone to cause hemolysis, which can lead to the complications of hemoglobinuria, hemolytic jaundice, anemia, or even acute kidney injury (AKI)[25-36]. The incidence of complications post RF ablation is proportionally associated with the size of hemangiomas and the ablation time[28-36]. Park *et al*[25] described the 100% ablation of 10 hepatic hemangiomas larger than 5 cm but less than 10 cm and an ablation in 60% (3/5) of hepatic hemangiomas $\geqslant$ 10 cm. Hence, they drew a conclusion that the best indication for RF ablation was giant hepatic hemangiomas, but huge hepatic hemangiomas were the comparative contraindication. Gao *et al*[28] reported the same technical difficulties when they treated 17 huge hemangiomas $\geqslant$ 10 cm in 16 patients with RF ablation using cluster electrodes. In their study a high rate of complete ablation (82.4%, 14/17) was achieved, but ablation-related complications were seen in all the 16 patients with hemangiomas $\geqslant$ 10 cm, including significant systemic inflammatory responses and acute respiratory distress syndrome (ARDS, grade Ⅳ)[39]. Gao *et al*[31] adopted two approaches to treat 21 large hemangiomas in 21 patients with the expectation of lessening the incidence of complications and achieving a higher success rate: (1) using cool-tip cluster electrodes; and (2) closely monitoring the patient's temperature and hemoglobinuria to warrant a termination of the procedure if the temperature exceeds 39 ℃ or signs of hemoglobinuria appeared. Complete ablation was achieved in 90.5% (19/21) of cases and ablation-related complications reduced to 47.6% (10/21). According to the Dindo-Clavien classification for complications[39], all the complications were grade Ⅰ (including hemoglobinuria in ten cases,

Table 1 Indications and contraindications of radiofrequency ablation for hepatic hemangiomas

Indications
The maximum diameter of hemangiomas > 5 cm
Tumor gaining an enlargement of more than 1 cm within 2 yr
Persistent hemangioma-related abdominal pain or discomfort
Consent to receive the RF ablation
Contraindications
Severe bleeding tendency, platelets < 50 × 10^9/L, international normalized ratio > 1.5, severe platelet function disorders (prothrombin time >18 s and prothrombin activity < 40%)
Malignant tumors
Kasabach-Merritt syndrome
Infection, especially biliary system inflammation
Low immune function
Severe primary organ failure such as the liver, kidney, heart, lung and/or brain

fever in four cases, hemolytic jaundice in three cases, anemia in one case, and elevated serum transaminase in four cases). Eighteen patients required one session and three patients with hemangiomas ⩾ 14.0 cm required two sessions of RF ablation. This study by Gao *et al*[31] showed that RF ablation for huge hepatic hemangiomas is minimally invasive, safe, and effective. Other studies reported the similar results[27,30].

INDICATIONS AND CONTRAINDICATIONS FOR RF ABLATION FOR HEPATIC HEMANGIOMAS

Indications

Indications include: the maximum diameter of hemangiomas > 5 cm; on regular imaging follow-up, tumor gaining an enlargement of more than 1 cm within 2 years; persistent hemangioma-related abdominal pain or discomfort with the definite exclusion of other gastrointestinal diseases which cause the epigastric pain *via* gastroscopy examinations; patients' decline to receive surgical treatment but with the consent to receive the RF ablation (Table 1)[25-34].

Contraindications

Contraindications include: patients with severe bleeding tendency, platelets < 50 × 10^9/L, severe platelet function disorders (prothrombin time > 18 s and prothrombin activity < 40%), international normalized ratio > 1.5, malignant tumors, Kasabach-Merritt syndrome, infection, especially biliary system inflammation, low immune function, and severe primary organ failure such as the liver, kidney, heart, lung and/or brain[28-34]. Anticoagulation and/or antiplatelet drugs should be discontinued at least 5-7 d prior to ablation (Table 1).

ANESTHESIA PROTOCOLS

For percutaneous procedures, general anesthesia is recommended to prevent pain and discomfort during RF procedure. Controlled ventilation would reduce ablation attempts and increase the success rate while RF ablation is performed for patients under general anesthesia[31-35].

PROCEDURES OF RF ABLATION

RF ablation for hepatic hemangiomas can be performed *via* a percutaneous, laparotomy or laparoscopic approach. The diversity of approaches helps extend the scope of treatment indications[25-34].

Hepatic hemangiomas deeply located in liver parenchyma are suited to be treated by percutaneous CT-guided RF ablation. After induction of general anesthesia, patients are placed in a supine position. Grounding is achieved by attaching two pads to the patient's thighs. The skin entry point of the RF electrodes is determined by the guidance of CT imaging. Under the monitoring and guidance of CT, the RF electrodes are percutaneously inserted through the liver to target the tumor. After CT images confirm the acting tip of the RF electrode is located in the tumor center, RF procedure is performed[28].

Subcapsular hepatic hemangioma is suitable to be treated *via* a laparoscopic approach using US guidance[20,33,35]. Under general anesthesia, patients were placed in a supine position. After a pneumoperitoneum (CO_2 at 12 mmHg) is established, a thorough intraperitoneal exploration with a 30° laparoscope through a 10-mm umbilical port is performed. Another 10 mm subxiphoid port is created at the midline of abdomen and an additional 10 mm right or left lateral subcostal port is placed if needed, depending on the location of the hepatic hemangiomas. Under US guidance, the RF electrodes are introduced into the peritoneal cavity through the subcostal abdominal wall under the direct laparoscopic view and deployed into the tumor. The RF procedure is monitored by intraoperative US, which can increase the ability to guide the RF electrode placement and evaluate the efficacy of ablation. After ablation, the ablated lesion became hyperechoic because of outgassing from heated tissues. Laparoscopic biopsy of liver lesions before the ablation is not needed with the consideration of avoiding unnecessary bleeding. For the patients with gallbladder stones or simple hepatic cysts, laparoscopic cholecystectomy (LC) or deroofing of the hepatic cysts may be performed during ablation. LC had to be performed beforehand if the lesions are encroaching on the gallbladder fossa.

Laparotomy is more invasive than percutaneous and laparoscopic approaches. With the increasing

experiences in RF ablation and the improvement of laparoscopic techniques, laparotomy is only used for an alternative approach. In case of unexpected incidence of uncontrollable bleeding during the procedure *via* percutaneous and laparoscopic approaches, laparotomy needs to be performed for controlling the bleeding efficiently and preventing the occurrence of severe complications.

TECHNICAL DETAILS TO BE NOTED

Common strategies of ablation for hepatic hemangiomas

A transhepatic route for RF electrode placement to target the tumor is recommended to prevent bleeding from the electrode-poking site of hemangiomas. RF ablation is initiated at the treatment point close to the margin of the tumor to minimize the risk of bleeding and the heat sink effect. The heat sink effect refers to cooling by adjacent visible (>1 mm diameter) blood vessels when ablated tissues are heated. Overlapped ablation zones are warranted by repositioning the RF electrodes in the tumor mass repeatedly under the guidance and monitoring of CT or US imaging, ensuring a complete ablation of the tumors. An intratumoral ablation is necessary to minimize injuries to normal liver parenchyma and the needle tract ablation can prevent the incidence of needle puncture-induced bleeding[31].

In the laparoscopic approach, the Pringle maneuver can be used to decrease the heat sink effect[28]. Furthermore, the laparoscopic approach also offers a direct vision of the entire RF procedure, which is helpful to identify and manage bleeding from the puncture site or tumor rupture[31-33].

Based on our experience on treating 76 huge hepatic hemangiomas[31-33], we prefer to use internally cooled cluster electrodes to treat the tumors by taking their advantage of achieving an efficient and much concentrated thermal energy in the tumor tissue, which is expected to reduce the incidence of ablation-related complications. Internally cooled cluster electrodes, for example Cool-tip ones, are straight electrodes without an array of prongs, and the tip is internally cooled by continuous infusion of cold saline. Thus, the temperature of the electrode itself is not extremely high, which is helpful to avoid the instant charring at the tissue around the probe and reduce tissue impedance. The efficient heat deposition creates a larger ablated zone within a shorter period of time. Another advantage of internally cooled electrodes is that they induce a sustaining high temperature in the tumor with limited "heat sink effect" caused by blood flow in the adjacent vessels, which can enhance the ablation effectiveness for the tumor tissue abutting the vessel. Moreover, a specially-designed Cool-tip electrode is more visible under the guidance of CT or US imaging, which allows the accurate placement of the electrodes in the tumor without injuring the adjacent organs[31].

Special strategies of ablation for huge hepatic hemangiomas

Larger tumor size is a risk factor for ablation-induced complications. For huge hemangiomas, a few precautions should be taken to lessen the risk of severe complications and enable a successful treatment.

It is unnecessary to achieve a complete ablation of a large tumor using one ablation session if the patient shows the sign of elevating body temperature and hemolysis, considering the severe risk of hemolysis-induced AKI[36]. A repeat RF ablation session can be rescheduled to obtain the expected treatment effect[30].

RF ablation combined with TAE could be an option to achieve a synergistic treatment effect for huge hepatic hemangiomas because the blockade of tumor blood supply by TAE can decrease the lesion size to some extent, facilitating the subsequent RF ablation and minimizing the risk of ablation-related complications. Additionally, the hyper-attenuation of iodized oil deposited in the tumor on CT images can facilitate the targeting placement of the RF electrodes in the tumor and thus increase the success rate of complete ablation[34].

Laparoscopic resection of hemangioma boosted by intratumoral coagulation by RF ablation is a safe, effective option for treating huge hepatic subcapsular hemangiomas with low loss of blood and minimal complications. This technique lies in the advantage that a completely coagulated zone created by sequential RF ablation along the dissection margin warrants the successful removal of the tumor tissue without occluding the hepatic vessels before the tumor dissection. Compared with treating the tumor using RF ablation alone, this technique involves the ablation of the tumor tissue at the resection margin rather than the total hepatic hemangioma, thus shortens the ablation time and avoids the incidence of severe ablation-related complications[37].

COMPLICATIONS

Hemorrhage of hepatic hemangioma

Bleeding at the electrode entry site: Due to the hypervascular nature of hepatic hemangioma and intratumoral high blood pressure, there is high risk of bleeding from the puncture site of the tumor. To prevent bleeding, the electrode needs to be advanced *via* a transhepatic approach to target the tumor and a needle tract ablation needs to be performed while withdrawing the electrode. When the RF electrode

placement is performed *via* laparotomy or laparoscopic approach, RF ablation should be launched from the exterior margin of the tumor from the beginning of a lower RF power[31-34].

Rupture of hepatic hemangioma: Abrupt rupture of hepatic hemangioma could result in massive hemorrhage. For hemangiomas located in the surface of the liver, an improper advancement of the RF electrode directly through the tumor will lose the protection of liver parenchyma. In this context, the RF electrode puncture could induce massive bleeding from the electrode puncture site. On the other hand, when an extra-high RF output power is applied at the beginning of RF ablation, a rapid increase of intratumoral temperature and pressure will induce the burst force in the tumor, which will cause an abrupt rupture of the tumor and life-threatening bleeding. Under the direct view of laparoscopy, hemostasis procedure can be applied to the bleeding site such as applying ablation to stop bleeding. In case the bleeding is not controlled by these measures, a conversion to open surgery is advocated to achieve hemostasis.

Puncture injury to adjacent organs

The accidental injuries to the adjacent organs including the gallbladder, gastrointestinal organs, kidney, diaphragm, lungs, and heart need to avoid. While using multipolar expandable electrodes, the deployment of each prong of the electrodes need to be verified carefully[28,40]. The high visibility of Cool-tip electrodes on CT or US images facilitates the insertion of the electrodes in the tumor without causing accidental injury to adjacent organs[31].

Thermal injury to the pleura and diaphragm

For hepatic hemangiomas situated in the subdiaphragm hepatic dome area, thermal injuries to the diaphragm frequently occur during RF ablation *via* the percutaneous approach[32]. The thermal injury to the diaphragm may manifest as the shoulder pain because the diaphragm and the shoulder skin are innervated by the same phrenic nerves arising from nerve roots C3, C4, and C5[32,41]. Diaphragmatic perforation and herniation were reported as major complications of RF ablation for hepatic tumors abutting the diaphragm in nine cases[41]. RF ablation injuries more frequently occur in cases with hepatic hemangiomas than hepatic cancers due to the high thermal energy and duration needed for large-sized hemangiomas. RF ablation *via* a laparoscopic approach can minimize the risk of diaphragm injury because the pneumoperitoneum can elevate the diaphragm to increases the operation space. Therefore, laparoscopic RF ablation therapy should be used as the first-line treatment for hepatic hemangiomas abutting the diaphragm[32].

Thermal injury to the lung

A patient with two huge hemangiomas in the right lobe (16.0 cm and 11.0 cm), treated with percutaneous RF ablation, developed ARDS immediately after an ablative time of total 250 min[28]. The major complication was resolved by conservative treatment[28]. The pathogenesis of ARDS needs to be investigated, and it is speculated that RF ablation of large quantity of tumor tissues induces significant systemic inflammatory responses[42-45]. Pre-ablation TAE as an adjuvant therapy or multiple ablation sessions is recommended to prevent the risk of ARDS[31,34].

Hemolysis

Hemolysis and anemia: RF ablation poses a risk of predisposing huge hypervascular hepatic hemangiomas to the severe complication of hemolysis. Hemolysis can lead to various degrees of hemoglobinuria, hemolytic jaundice, anemia, or even AKI[28-31,36].

AKI: AKI caused by ablation-induced hemolysis in patients with huge hepatic hemangiomas has been reported[36]. Hemoglobin is released upon erythrocyte destruction and is filtered by the glomerulus into the urinary space. In the urinary space, hemoglobin is degraded and releases heme pigments which can cause tubular injury. Furthermore, volume depletion enhances both vasoconstriction and the formation of obstructing casts, and also is of critical importance for the development of heme-induced AKI[36].

Patients with huge hepatic hemangiomas should be sufficiently hydrated before RF ablation and during the procedure. When any signs or symptoms indicating hemolysis emerge in the course of RF ablation, such as rising body temperature and hemoglobinuria, the RF procedure should be terminated and a repeat RF ablation treatment may need to be rescheduled based on a comprehensive evaluation of the tumor[31].

Other complications

Except for relatively severe RF ablation-related complications, some minor complications may take place, such as liver damage, fever, and skin burn injury at the site where the grounding pad is attached. The ablation-induced self-limiting liver injury can resolve within a short period of time without the need of any medication. The necrotic tissue of tumors can cause unspecific inflammatory reaction and mild hyperthermia. In case that the body temperature is higher than 39 ℃, physical cooling can be used to alleviate the discomfort of hyperthermia. To prevent the burn injury to the skin in patients receiving long time RF ablation, multiple grounding pads can be

Table 2 Ablation-related complications and preventive measures

Complication	Preventive measures
Bleeding at the electrode entry site	The electrode needs to be advanced *via* a transhepatic approach to target the tumor and a needle tract ablation needs to be performed while withdrawing the electrode. Radiofrequency (RF) ablation should be launched from the exterior margin of the tumor from the beginning of a lower RF power.
Rupture of hepatic hemangioma	Under the direct view of laparoscopy, hemostasis procedure can be applied to the bleeding site such as applying ablation to stop the bleeding. If it fails, a conversion to open surgery is advocated to achieve the hemostasis.
Puncture injury to adjacent organs	The high visibility of Cool-tip electrodes on computed tomography or ultrasonography images facilitates the insertion of the electrodes in the tumor without causing accidental injury to adjacent organs.
Thermal injury to the pleura and diaphragm	Laparoscopic RF ablation should be used as the first-line treatment for hepatic hemangiomas abutting the diaphragm.
Thermal injury to the lung	Pre-ablation transcatheter arterial embolization as an adjuvant therapy or multiple ablation sessions is recommended to prevent the risk of acute respiratory distress syndrome.
Hemolysis	The patients should be sufficiently hydrated before RF ablation and during the procedure. When any signs or symptoms indicating the hemolysis emerge in the course of ablation, the RF procedure should be terminated and a repeat RF ablation treatment may need to be rescheduled based on a comprehensive evaluation of the tumor.
Liver damage	The ablation-induced liver injury can resolve spontaneously without the need of any medication.
Fever	Physical cooling can be used to alleviate the discomfort of hyperthermia.
Skin burn injury	Multiple grounding pads can be applied or ice pad can be used to cool the skin with the contact of grounding pad.

applied or ice pad can be used to cool the skin with the contact of grounding pad[31-33]. The ablation-related complications and preventive measures are listed in Table 2.

POST-TREATMENT EVALUATION

Contrast-enhanced CT or MRI can be used to evaluate the therapeutic effect of RF ablation for tumors one month after the treatment. On contrast-enhanced CT or MRI, complete ablation is defined as no nodular or irregular enhancement adjacent to the ablation zone and incomplete ablation is defined as irregular peripheral-enhanced foci in the ablation zone. In cases of complete ablation, subsequent CT or MRI examinations are repeated at a 6-mo interval[31-33]. Repeated RF ablation procedures are not needed unless the residual tumor is growing significantly or posing a risk of spontaneous rupture.

CONCLUSION

RF ablation therapy is a safe, feasible, and effective procedure for hepatic hemangiomas, even for huge hepatic hemangiomas. RF ablation has the following advantages in the treatment of hepatic hemangiomas: minimal invasiveness, definite efficacy, high safety, fast recovery, relatively simple operation, and wide applicability.

Abstract

AIM

To assess *KRAS* G12D mutation detection by droplet digital PCR (ddPCR) in stool-derived DNA from colorectal cancer (CRC) patients.

METHODS

In this study, tumor tissue and stool samples were collected from 70 patients with stage Ⅰ-Ⅳ CRC diagnosed by preoperative biopsy. *KRAS* mutational status was determined by pyrosequencing analysis of DNA obtained from formalin-fixed paraffin-embedded (FFPE) tumor tissues. The *KRAS* G12D mutation was then analyzed by ddPCR in FFPE tumors and stool-derived DNA from patients with this point mutation. Wild-type (WT) tumors, as determined by pyrosequencing, were included as controls; analysis of FFPE tissue and stool-derived DNA by ddPCR was performed for these patients as well.

RESULTS

Among the total 70 patients included, *KRAS* mutations were detected by pyrosequencing in 32 (45.71%), whereas 38 (54.29%) had WT tumors. The frequency of *KRAS* mutations was higher in left-sided tumors (11 located in the right colon, 15 in the left, and 6 in the rectum). The predominant point mutation was *KRAS* G12D (14.29%, n = 10), which was more frequent in early-stage tumors (I-IIA, n = 7). In agreement with pyrosequencing results, the *KRAS* G12D mutation was detected by ddPCR in FFPE tumor-derived DNA, and only a residual number of mutated copies was found in WT controls. The *KRAS* G12D mutation was also detected in stool-derived DNA in 80% of all fecal samples from CRC patients with this point mutation.

CONCLUSION

ddPCR is a reliable and sensitive method to analyze *KRAS* G12D mutation in stool-derived DNA from CRC patients, especially at early stages. This non-invasive approach is potentially applicable to other relevant biomarkers for CRC management.

Key words: Droplet digital PCR; *KRAS*; Stool; Formalin-fixed paraffin-embedded; Pyrosequencing; Colorectal cancer

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The potential of droplet digital PCR (ddPCR) to detect *KRAS* G12D mutation in stool DNA from colorectal cancer (CRC) patients was examined as a proof-of-concept for the applicability of this technology to study DNA biomarkers in stool-derived DNA. It was shown that *KRAS* G12D detection in stool-derived DNA from CRC patients by ddPCR is feasible and provides comparable results to the analysis of formalin-fixed paraffin-embedded tissue by pyrosequencing. These results suggest that analysis of *KRAS* mutations and other molecular biomarkers in stool by ddPCR could represent a complementary non-invasive approach to standard screening tests for CRC.

Detection of *KRAS* G12D in colorectal cancer stool by droplet digital PCR. *World J Gastroenterol* 2017; 23(39): 7087-7097 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7087.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7087

INTRODUCTION

Colorectal cancer (CRC) is the second and third most common cancer in women and men, respectively, with more than one million cases diagnosed each year worldwide[1]. Current therapeutic options have increased overall survival (OS), but have also made clinical decisions more complex, especially in patients with an initial diagnosis of metastatic colorectal cancer (mCRC)[2]. Biological agents targeting the epidermal growth factor receptor (EGFR), such as cetuximab and panitumumab, used either as monotherapy or in combination with standard chemotherapy, are indicated in mCRC patients with *RAS* (*KRAS* and *NRAS*) or *KRAS* wild-type (WT) tumors, respectively[3,4]. These strategies significantly improve progression-free survival (PFS) and OS in *KRAS* WT mCRC patients depending on the therapeutic regimen applied (chemotherapy and line of treatment)[2,5].

KRAS oncogene mutations, mostly found in codons 12 and 13[6], have been described in approximately 30%-40% of CRC tumors[7-9]. These mutations are associated with absence of response to therapy with biological agents[10,11] and have been correlated with worse prognosis[12,13]. In fact, in Europe and the United States, monoclonal antibody-based therapy has been restricted to patients with WT tumors[14], as when administered in association with standard chemotherapy, this treatment may result in an increased cost and toxicity[10]. Drug resistance can occur months after start of combined therapy, likely due to intratumoral heterogeneity and proliferation of small sub-groups of clonal cells carrying resistance mutations that are difficult to identify by most of the currently applied methods[14,15]. Therefore, highly sensitive and specific methodologies are needed to detect and quantify molecular markers, including *KRAS* mutations, which play a pivotal role in early detection and clinical management of CRC patients.

Droplet digital PCR (ddPCR) is increasingly seen as one of the most powerful techniques to accurately detect a wide variety of genetic alterations in many cancer types. These molecular biomarkers have been analyzed by ddPCR in different body fluids such as blood, urine, cerebrospinal fluid, pleural effusions, ascites and sputum (reviewed in[16]).

Stool-derived DNA is a potential non-invasive alternative source of DNA for tumor genotyping in CRC due to the high rate of exfoliation of tumor cells into the bowel lumen[17]. Digital PCR was first described in 1999 by Vogelstein and Kinzler in a study aimed at identifying *KRAS* in DNA obtained from fecal samples of CRC patients[18]. Based on the isolation of single molecules by limiting dilution of DNA samples and individual amplification by PCR, mutations were detected using fluorescent probes. However, this methodology was found to be quite laborious and difficult to translate into clinical practice[19]. The introduction of new instrumentation involving nanofluidic devices and improved emulsion chemistries has allowed for more widespread use of digital PCR, giving way to the current commercially available platforms[19]; of these, emulsion-based ddPCR has undergone huge growth in cancer research. In fact, a recent study has investigated the application of ddPCR to quantify mRNA biomarkers in stool from patients with CRC as a potential non-invasive screening test[17]. Thus, analysis of DNA obtained from fecal samples in patients with CRC may complement currently used procedures for diagnosis and disease follow-up.

In our experience, ddPCR has shown high sensitivity for detection of mutated *KRAS* alleles in circulating cell-free DNA (cfDNA) in plasma from CRC patients[20]. However, early-stage patients sometimes have undetectable levels of circulating tumor DNA (ctDNA)[20,21]. The aim of this study was to evaluate the feasibility of *KRAS* G12D mutation detection in stool-derived DNA from CRC patients by ddPCR, including early-stage patients.

MATERIALS AND METHODS

Patients

Seventy CRC patients were consecutively included in this study from 2014 to 2015 in the Department of General Surgery at Fundación Jiménez Díaz University Hospital (Madrid, Spain). Inclusion criteria were endoscopic histological diagnosis of CRC and eligibility for primary tumor resection with curative intent. Patients with primary tumors located in the rectum who had received prior neoadjuvant treatment were excluded. All subjects signed an informed consent in accordance with a protocol approved by the Ethics Committee for Clinical Research of this institution (PIC 63/2016_FJD).

Fecal sample collection

All fecal samples were collected during hospitalization before surgery without any bowel preparation (with the exception of patient 17, who was subjected to cathartic preparation due to an oversight). Stool samples were collected in sterile containers and stored at -20 ℃ until analysis.

DNA extraction

A total amount of 200-500 mg of fecal sample was used for DNA extraction. DNA was isolated using the QIAamp DNA Stool Mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. DNA from the LS-174T cell line (kindly provided by the Translational Oncology Division, OncoHealth Institute, IIS-FJD, which had previously purchased this cell line from the American Type Culture Collection, ATCC in Manassas, VA, United States) and DNA from peripheral blood mononuclear cells of a healthy donor were extracted with the QIAamp DNeasy Blood and Tissue Kit (Qiagen) according to the manufacturer's protocol. DNA from formalin-fixed paraffin-embedded (FFPE) tumors was extracted using the Cobas DNA Sample Preparation Kit (Roche Molecular Systems, Inc., Branchburg, NJ, United States) following the manufacturer's instructions. The quantity and purity of the DNA obtained was estimated by NanoDrop (ND-2000 UV-Vis Spectrophotometer; Nanodrop Technologies Inc., Waltham, MA, United States).

Mutation detection in FFPE tumor samples by pyrosequencing

Quantitative analysis of *KRAS* mutations was performed by pyrosequencing in accordance with routine practice at the Department of Pathology at Fundación Jiménez Díaz University Hospital, using the CE-IVD marked Therascreen *KRAS* Pyro kit (Qiagen), according to the manufacturer's protocols. Each PCR product was analyzed by pyrosequencing using the Therascreen *KRAS* Pyro reagents (Qiagen), Streptavidin Sepharose High Performance (GE Healthcare Bio-Science AB, Uppsala, Sweden), and a PyroMark Q24 instrument (Qiagen).

Mutation detection in FFPE tumor tissues and stool samples by ddPCR

ddPCR assays were performed using the QX200 Droplet Digital PCR System (Bio-Rad, Hercules, CA, United States) with the Prime-PCR™ ddPCR™ Mutation Detection Assay Kit (Bio-Rad); amplicon size was 57 bp. DNA from LS-174T, a human colon adenocarcinoma *KRAS* G12D heterozygous cell line, was used as a positive control. *KRAS* WT control DNA was obtained from peripheral blood mononuclear cells of a healthy donor. Background was measured by adding water to the reaction mixture instead of

DNA. The PCR reaction mixture (20 μL) contained 10 μL of ddPCR Supermix (no dUTP) for probes, 1 μL of each primer/probe mix (target and reference, labeled with HEX and FAM fluorophores, respectively), and 2-8 μL of stool-extracted DNA. Different amounts of stool-derived DNA were assayed per sample, as the proportion of human DNA with respect to bacterial DNA was unknown and could vary among patients. A total amount of 100 ng of cell-derived control DNA was added per well. In case of DNA from FFPE tumors, 50 ng per well was used. Thermal cycling consisted of 10 min at 95 ℃, 40 cycles of 94 ℃ for 30 s, and 55 ℃ for 60 s. Results were analyzed using QuantaSoft v.1.7 software (Bio-Rad) and reported as number of copies per 20 μL reaction as well as copies per ng of DNA. Three to four replicates of each stool sample were analyzed. FFPE tumors and controls were assayed in duplicate.

Statistical analysis

A non-parametric Mann-Whitney test for significance was performed using R software.

RESULTS

Patient characteristics

A total of 70 stool and tissue samples from CRC patients were collected and included in the study. All patients were classified according to the distance between the primary tumor and anal margin (cm) reported in the preoperative colonoscopy. Forty-one (58.57%) were male, with a median age of 73 years. Only 5 (7.14%) had a diagnosis of mCRC at baseline.

The patients included in this study were representative of all tumor locations, with 28 (40%) located in the right colon, 34 (48.57%) in the left colon, and 8 (11.43%) in the rectum. Interestingly, 45 (64.29%) patients were diagnosed at an early stage (I-IIA). Clinical and pathological features are summarized in Table 1.

KRAS mutations in FFPE tumor samples analyzed by pyrosequencing

KRAS mutations were found in the tumors of 32 patients (45.71%), including 11 in the right colon, 15 in the left, and 6 in the rectum. Most mutations were located at codon 12 (n = 17, 53.12%) or codon 13 (n = 6, 18.75%). The most prevalent mutation was G12D (n = 10, 14.29%). Two were located in the right colon, 6 in the left colon, and 2 in the rectum. This mutation was found more frequently in early-stage tumors (I-IIA, n = 7). The incidence of the different types of mutations is shown in Table 2.

KRAS G12D detection in FFPE tumor samples by ddPCR

FFPE tumors from patients found to have a *KRAS* G12D mutation by pyrosequencing were analyzed using ddPCR. Five CRC patients with WT *KRAS* exon 2 tumors were selected as controls. One control carried a *KRAS* Q61L mutation (exon 3) that did not interfere with our assays. Results obtained from ddPCR analysis of FFPE tumor DNA from these 15 CRC patients were in agreement with pyrosequencing results. A residual number of *KRAS* G12D copies was found in WT tumors. Due to this level of unspecific background signal, mean copies/ng DNA from control patients plus 2 standard deviation (SD) was considered as a threshold for positivity (0.41 copies/ng DNA). All samples from patients with G12D-positive tumors were above this threshold and showed a significantly higher number of mutant copies/ng DNA than patients with WT *KRAS* tumors (median, 106 and 0.19 copies/ng DNA, respectively; P = 0.001). However, the difference in number of WT *KRAS* copies/ng DNA between both groups was not statistically significant (210.00 copies/ng *vs* 208.40 copies/ng DNA, median; P = 0.699).

KRAS G12D detection in stool samples by ddPCR

Subsequently, we analyzed the presence of the *KRAS* G12D mutation by ddPCR analysis of fecal samples from the 10 patients with mutated tumors by pyrosequencing. Stool DNA from 5 patients with tumors carrying the WT *KRAS* exon 2 were also included as controls. A limited number of *KRAS* G12D-positive events were detected in stool DNA from control WT *KRAS* exon 2 samples. Consequently, mean control value plus 2 SD was established as the positivity threshold. Thus, in our study, stool samples were required to contain more than 1.9 copies/20 μL of reaction to be considered positive for the mutation. According to this threshold, which was equivalent to > 3 positive events per sample, the *KRAS* G12D mutation was detected in 8 of 10 patients. Of these 8 positive samples, 6 were from early-stage tumors. Samples from Patients 46 and 64 were considered negative because they had values less than or equal to the positivity threshold. *KRAS* G12D mutation levels in stool samples are shown in Tables 3 and 4. The median number of copies of *KRAS* G12D/20 μL of reaction as well as copies/ng of stool DNA in control patients differed significantly from those with mutated tumors (P = 0.017). The *KRAS* WT sequence was also detected in stool samples of all CRC patients, though there were no significant differences in the median number of *KRAS* WT copies/ng of stool DNA between both groups (P = 0.129).

In summary, the results of pyrosequencing were in 100% agreement with ddPCR analysis in FFPE tissues, whereas ddPCR detected the *KRAS* mutation in 8 out of 10 stool samples.

DISCUSSION

Despite the advances made in CRC research, the

disease remains a major cause of death worldwide. Recently, the analysis of *KRAS* oncogene mutations has taken on a major prognostic role in CRC clinical management[22] owing to the fact that the presence of these mutations, which have been described in approximately 30%-40% of cases[7,9,23], could determine the absence of response to anti-EGFR therapies and worse outcome in cases of metastatic disease[10-13]. The most frequent *KRAS* mutations are located at codons 12 and 13; of these, G12D and G13D are particularly relevant, representing around 13%-14% and 6%-7% of all cases, respectively[7,23]. Moreover, worse prognosis has been documented among patients with tumors with the G12D mutation[8,23]. In agreement with previous observations, the incidence of *KRAS* G12D mutation in our study population was 14.29%.

Molecular biomarkers in blood and stool may be used as a complementary screening strategy and prognostic tool for the prediction of clinical outcome in patients with or at high risk for CRC[24]. Not only in CRC, but also in many other human malignancies, the analysis of molecular biomarkers in plasma and other body fluids is attracting increasing interest as a highly valuable, non-invasive predictive tool for monitoring disease progression and response to treatment[16]. In CRC, *KRAS* mutations have been analyzed in blood, both in DNA obtained from circulating tumor cells[25] and in cfDNA[26]. *KRAS*-mutation detection by digital PCR has been described using several commercially available platforms[14,27-32], most of which are focused on detecting mutations in plasma. One of these strategies is ddPCR, which has shown a remarkably high sensitivity when detecting these minority *KRAS* alleles present at low levels in plasma DNA.

In a previous study, using ddPCR, we detected the *KRAS* G12V mutation in plasma cfDNA from 9 of 10 patients whose tumors were also mutated[20]. In this study, we found that metastatic patients had a significantly higher number of mutated copies in circulating cfDNA than M0 patients. The only negative sample was obtained from a T1N0M0 patient. These results are in line with other studies: Bettegowda *et al*[21] also reported that ctDNA in plasma increases with disease stage, and only 47% of early-stage patients with a wide variety of cancers had detectable levels of ctDNA. Similarly, Galanopoulos *et al*[26] recently described that the *KRAS* codon 12 mutation rate in cfDNA is significantly higher in CRC patients compared to healthy subjects, though this methodology seems to have limited potential for predicting the existence of premalignant lesions (neoplastic colonic polyps). Taken together, these findings suggest that at early disease stages, levels of mutated copies in circulating cfDNA may be, in some cases, too low for detection. Thus, alternative non-invasive methods are still needed.

Interestingly, in a very recent study, ddPCR was also used to quantify an mRNA biomarker, *ITGA6*, in stool from patients with CRC[17]. Tumor-derived nucleic acids present in stool samples come from the exfoliation of tumor cells of the intestinal mucosa and are a non-invasive, alternative source of genetic material for *KRAS* oncogene mutation screening in CRC patients[33]. Exfoliation of colonocytes into the large bowel lumen is a continuous, naturally-occurring phenomenon that seems to be exacerbated in tumors[34,35]. Thus, colonocyte shedding from malignant lesions is more frequent than from healthy mucosa[36,37]. Hypothetically, DNA from colorectal tumors should be shed into the bowel fecal content before reaching the bloodstream. This would make testing stool DNA for CRC screening more time-sensitive than plasma or other biological fluids[38].

The proof-of-concept study for stool DNA analysis for CRC detection screened 15 point mutations in several genes, including *KRAS*[39]. Subsequently, several case-control and prospective studies[40-42] led to the 2014 approval by the United States Food and Drug Administration of a fecal DNA analysis system called Cologuard™ (Exact Sciences Corporation, Madison, WI, United States) for CRC detection. This system includes an immunochemical assay for human hemoglobin and molecular biomarkers associated with CRC, such as methylation markers (*BMP3* and *NFRG4* gene promoter regions), *KRAS* mutations, and β-actin. The test is based on amplification and detection by Quantitative Allele-specific Real-time Target and Signal

Amplification (QuARTS™) technology. However, this system still has limited application in clinical practice due to its elevated cost. Additionally, the technical difficulties of this test include the need for a large volume of stool sample and the high rate of false-positive results, creating a need for more confirmative colonoscopies and additional costs[38]. Further studies evaluating the cost-effectiveness of this test for large-scale population screening are needed[43].

Fecal DNA analysis for mutation detection has also been reported using several digital PCR systems[18,27,44-48], the first of which were the studies carried out by Vogelstein and Kinzler[18,44], which led to the development of BEAMing (named for 'beads, emulsions, amplification, and magnetics')[27]. Other examples are target-enriched multiplex PCR (Tem-PCR)[47], MDHB (multiplex digital PCR coupled with hydrogel bead-array)[46], and MLPA-DABA (multiplex ligation-dependent probe amplification-digital amplification coupled with hydrogel bead-array)[48]. It is worth mentioning that, to date, none of these systems has been further developed and subjected to clinical validation for stool DNA screening.

In our study, DNA from fecal samples of CRC patients was successfully obtained in all cases. Presence of the *KRAS* G12D mutation was determined by pyrosequencing of FFPE tissue as a reference standard. Results of *KRAS* G12D mutation detection in FFPE tumors using ddPCR were in total agreement with pyrosequencing analysis. This was expected, given the fact that ddPCR has been proven to achieve higher sensitivity than pyrosequencing[49]. Once the *KRAS* G12D mutation had been screened in tumor tissues, DNA from stool samples obtained from the same patients prior to surgery was also analyzed. Thus, we were able to detect the *KRAS* G12D mutation in 8 out of 10 stool samples from patients known to carry this mutation in their tumors using both methods. It is noteworthy that 6 of these 8 samples were from early-stage patients (Ⅰ-ⅡA), highlighting the potential of this approach to identify *KRAS* mutations at the initial stages of the disease.

Absorbance at a wavelength of 230 nm has been reported as an indicator of the level of potential PCR inhibitors in fecal samples[50], and it should be noted that the two negative samples showed peak of absorbance at this same wavelength. Thus, the sensitivity of detection in our assay could have been greatly reduced by the presence of PCR inhibitors in these samples.

The sample from Patient 17 is noteworthy for its remarkably high concentration of both mutated and WT copies. It is worth mentioning that this patient was subjected to cathartic preparation prior to sample collection due to an oversight. The rest of the samples were collected without any bowel preparation. We hypothesize that purging could have increased the exfoliation of tumor cells into the bowel lumen. This unexpected observation raises the question of whether bowel preparation could be advisable prior to sample collection to increase the sensitivity of detection in stool screening of *KRAS* mutations by ddPCR.

To our knowledge, this is the first study to evaluate the feasibility of detection of the *KRAS* G12D mutation in stool DNA from CRC patients using this particular ddPCR platform. Our results are in line with the above-mentioned recently published study by Herring *et al*[17], reporting the detection and accurate quantification of an mRNA biomarker in stool from CRC patients using the same ddPCR system. In light of these results, the analysis of CRC biomarkers in stool using ddPCR merits further study in larger cohorts of patients to evaluate the clinical utility of this approach.

We analyzed only the most prevalent *KRAS* mutation (G12D) in our population, as it was the only one with a sufficient number of samples available for analysis (n = 10). Another reason for choosing G12D as a target was that it has the highest incidence in CRC patients worldwide and is associated with poor clinical outcome[8,23]. For lower-incidence mutations, such as G12V, there were too few samples in our study population to provide conclusive results. The analysis of *KRAS* G12D performed in this study represents a proof-of-concept of the feasibility of this strategy as a first step prior to the screening of other relevant hotspot mutations.

This preliminary study demonstrates the capability of ddPCR to detect *KRAS* mutations in stool-derived DNA, acting as a complementary approach to tissue biopsy for tumor genotyping. These results pave the

way for the ddPCR analysis of other molecular biomarkers of CRC in stool, including other *KRAS*, *NRAS* and *BRAF* mutations. A multiplex assay simultaneously covering all *KRAS* mutations relevant for anti-EGFR therapy decision-making would maximize the benefits and optimize the cost-effectiveness of this approach. Further studies involving larger cohorts of patients and samples collected at different time points throughout the progression of the disease should be performed in order to confirm the prognostic value and economic viability of this tool before implementation in clinical practice.

This study is the first to describe the detection of *KRAS* G12D mutation in stool-derived DNA from CRC patients using a commercially available ddPCR platform, including individuals at early stages of the disease. We hypothesized that ddPCR could be a reliable and sensitive method to analyze *KRAS* mutations in stool-derived DNA providing reproducible and accurate results. Our findings suggest this approach, which is fast, simple and affordable, could be adaptable to the detection of other clinically relevant molecular biomarkers for CRC management. These advantages with respect to other previously described stool-based strategies, together with instrumentation and protocols easily adoptable by any lab, make our approach more feasible for implementation into routine clinical practice. In light of our results, it could be proposed that biomarker analysis by ddPCR of stool samples may complement current CRC screening methods; stool-derived nucleic acid testing by ddPCR offers an alternative tool to tissue genotyping and blood-based biomarker quantification, being less invasive than the former and, probably, more time-sensitive than

the later, especially at early stages, as tumor DNA will reasonably reach the fecal content more quickly than the bloodstream, at least during the initial phases of cancer development.

ARTICLE HIGHLIGHTS

Research background

Clinical management of colorectal cancer (CRC) requires analysis of molecular biomarkers, such as *KRAS* or *NRAS* mutations, which are associated with the emergence of resistance to therapy with biological agents. Tumor genotyping is usually performed using DNA from tissue biopsies, and, in recent years, from blood as well. However, at early disease stages, levels of mutated copies in circulating cell-free DNA may be, in some cases, too low for detection. Thus, extremely sensitive and non-invasive alternative methods are still needed to improve detection and achieve accurate quantification of these biomarkers.

Research motivation

Stool is an alternative and non-invasive source of genetic material for tumor genotyping in CRC. To date, several strategies based on analysis of molecular markers in fecal samples have been proposed, though their application in clinical practice remains limited due to their elevated cost and reduced sensitivity at early stages of disease.

Research objectives

The aim of this study was to assess the potential of droplet digital PCR (ddPCR) to detect the *KRAS* G12D mutation in stool-derived DNA from CRC patients as a proof-of-concept for the applicability of this technology as a non-invasive method of studying clinically relevant DNA biomarkers in stool.

Research methods

KRAS mutations were determined by pyrosequencing in DNA obtained from formalin-fixed paraffin-embedded (FFPE) tumor tissues. Then, *KRAS* G12D mutation was analyzed by ddPCR in FFPE tumors and stool-derived DNA in samples obtained from patients carrying this point mutation.

Research results

The *KRAS* G12D mutation was detected by ddPCR in FFPE tumor-derived DNA and in stool-derived DNA in 80% of all fecal samples from CRC patients with this mutation.

Research conclusions

This is the first study to describe the detection of the *KRAS* G12D mutation in stool-derived DNA from CRC patients using a commercially available ddPCR platform, including in individuals with early stages of the disease. ddPCR served as a reliable tool for detecting this clinically relevant mutation in stool-derived DNA from CRC patients. Several stool-based strategies involving digital PCR have been investigated to analyze relevant mutations for CRC management. However, none of these approaches has been further developed and subjected to clinical validation for stool DNA screening to date.

The advantages of ddPCR technology, together with instrumentation and protocols easily adoptable by any lab, support a potential translation of this approach to clinical scenarios. Our results show that *KRAS* G12D detection in stool-derived DNA from CRC patients by ddPCR is feasible and suggests this technology might be useful for the analysis of other molecular markers in stool. The authors hypothesized that ddPCR could be a reliable and sensitive method of analyzing *KRAS* mutations in stool-derived DNA, providing reproducible and accurate results.

This study proposed a new strategy based on detecting *KRAS* mutations in stool-derived DNA using a commercially available ddPCR platform. ddPCR is an emulsion-based amplification technology with fluorescently labelled probes. *KRAS* G12D mutation detection in stool-derived DNA by ddPCR is a fast, simple, and affordable approach which could be adapted to detect other clinically relevant molecular biomarkers for CRC management. This technique is more feasible for implementation into routine clinical practice than other previously described stool-based strategies.

ddPCR provided sensitive, accurate, and reproducible results for detection of the *KRAS* G12D mutation in stool-derived DNA from CRC patients, especially at early stages of the disease. In light of our results, it could be proposed that biomarker analysis by ddPCR in stool samples may complement current CRC screening methods; stool-derived nucleic acid testing by ddPCR offers an alternative to tissue genotyping and blood-based biomarker quantification, is a less invasive tool than the former and is likely more time-sensitive than the latter, especially at early stages, as tumor DNA will reasonably reach the fecal content more quickly than the bloodstream, at least during the initial phases of cancer development.

Research perspectives

KRAS mutations are analyzable by ddPCR in stool-derived DNA from CRC patients, including early-stage patients. This observation merits further studies aimed at evaluating and improving the efficiency of this approach prior to its clinical application. These results pave the way for ddPCR analysis of other molecular biomarkers of CRC in stool. Further studies involving larger cohorts of patients and samples collected at different time points throughout the progression of the disease should be performed in order to confirm the prognostic value and economic viability of this tool before implementation in clinical practice. A multiplex assay simultaneously covering all *KRAS* mutations relevant for anti-EGFR-therapy decision-making would maximize the benefits and optimize the cost-effectiveness of this approach. This strategy should be further investigated as a complementary screening test for early detection of CRC.

ACKNOWLEDGMENTS

The authors would like to acknowledge Dr. Federico Rojo from the Department of Pathology at Fundación Jiménez Díaz University Hospital for his collaboration in this study. The authors also acknowledge Yolanda López Revuelta and all the Nursing staff from the Department of Surgery at Fundación Jiménez Díaz University Hospital for collaborating in sample collection. The authors also acknowledge Dr. Ignacio Mahíllo for statistical analysis and Oliver Shaw for his revision of the text for aspects related to the English language.

Abstract

AIM

To identify the optimal oral dosing time of Da-Cheng-Qi decoction (DCQD) in rats with acute pancreatitis (AP) based on the pharmacokinetic and pharmacodynamic parameters.

METHODS

First, 24 male Sprague-Dawley rats were divided into a sham-operated group [NG(a)] and three model groups [4hG(a), 12hG(a) and 24hG(a)]. The NG(a) and model groups were administered DCQD (10 g/kg.BW) intragastrically at 4 h, 4 h, 12 h and 24 h, respectively, after AP models induced by 3% sodium taurocholate. Plasma samples were collected from the tails at 10 min, 20 min, 40 min, 1 h, 2 h, 4 h, 8 h, 12 h and 24 h after a single dosing with DCQD. Plasma and pancreatic tissue concentrations of the major components of DCQD were determined by high-performance liquid chromatography tandem mass spectroscopy. The pharmacokinetic parameters and serum amylase were detected and compared. Second, rats were divided into a sham-operated group [NG(b)] and three treatment groups [4hG(b), 12hG(b) and 24hG(b)] with three corresponding control groups [MG(b)s]. Blood and pancreatic tissues were collected 24 h after a single dosing with DCQD. Serum amylase, inflammatory cytokines and pathological scores of pancreatic tissues were detected and compared.

RESULTS

The concentrations of emodin, naringin, honokiol, naringenin, aloe-emodin, chrysophanol and rhe-ochrysidin in the 12hG(a) group were higher than those in the 4hG(a) group in the pancreatic tissues (P < 0.05). The area under the plasma concentration-time curve from time 0 to the time of the last measurable concentration values ($AUC_{0\rightarrow t}$) for rhein, chrysophanol, magnolol and naringin in the 12hG(a) group were larger than those in the 4hG(a) or 24hG(a) groups. The 12hG(a) group had a higher C_{max} than the other two model groups. The IL-10 levels in the 12hG(b) and 24hG(b) groups were higher than in the MG(b)s (96.55 ± 7.84 *vs* 77.46 ± 7.42, 251.22 ± 16.15 *vs* 99.72 ± 4.7 respectively, P < 0.05), while in the 24hG(b) group, the IL-10 level was higher than in the other two treatment groups (251.22 ± 16.15 *vs* 154.41 ± 12.09/96.55 ± 7.84, P < 0.05). The IL-6 levels displayed a decrease in the 4hG(b) and 12hG(b) groups compared to the MG(b)s (89.99 ± 4.61 *vs* 147.91 ± 4.36, 90.82 ± 5.34 *vs* 171.44 ± 13.43, P < 0.05).

CONCLUSION

Late-time dosing may have higher concentrations of the most major components of DCQD, with better pharmacokinetics and pharmacodynamics of anti-inflammation than early-time dosing, which showed the late time to be the optimal dosing time of DCQD for AP.

Core tip: Our study group had raised the hypothesis of tissue pharmacology of an herbal recipe, which assumed the effect of an herb formula is related to its target tissue distribution or concentration of effective components in target tissues. This study was then designed to screen the optimal oral dosing time of Da-Cheng-Qi decoction (DCQD) in rats with acute pancreatitis based on the pharmacokinetics of the main absorbed components and the pharmacodynamics of DCQD targeting of the pancreas.

Zhang YM, Zhu L, Zhao XL, Chen H, Kang HX, Zhao JL, Wan MH, Li J, Zhu L, Tang WF. Optimal timing for the oral administration of Da-Cheng-Qi decoction based on the pharmacokinetic and pharmacodynamic targeting of the pancreas in rats with acute pancreatitis. *World J Gastroenterol* 2017; 23(39): 7098-7109 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7098.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7098

INTRODUCTION

Da-Cheng-Qi decoction (DCQD) was first described in Shang-Han-Lun, a classical work of Traditional Chinese Medicine (TCM). DCQD consists of four Chinese herbs: dahuang (*Rheum palmatum* L.), mangxiao (*Mirabilite*, $Na_2SO_4 \cdot 10H_2O$), houpu (*Magnolia officinalis* Rehd. et Wils.), and zhishi (*Citrus aurantium* L.). It has been widely used as a purgative to treat diseases with constipation and to clear away internal heat[1], such as in acute pancreatitis (AP), which has a consensus in the relative treatment guidelines in China. The efficacy of DCQD, administered orally or by coloclyster to patients with AP, is obvious. According to clinical observation, it can reduce intra-abdominal hypertension[2] and decrease the risk of developing acute respiratory distress syndrome in severe AP (SAP) patients with systemic inflammatory response syndrome, and shorten their length of hospitalization[3].

In animal experiments, it can ameliorate acute pancreatic, intestinal, lung and liver injury complicated with SAP[4,5]. It can also reduce the generation of reactive oxygen species in AR42J cells and regulate the apoptosis/necrosis switch, to ameliorate the pancreatic inflammation and pathological damage[6]. Other therapeutic activities of DCQD for AP, such as its antioxidant, anti-inflammatory and anti-ulcer properties[7] are important. Its numerous roles indicate the wide applicability of DCQD in AP.

However, early oral dosing with DCQD is contradictory to the conventional therapy that considers fasting and water deprivation are necessary for pancreatic rest in the early stage of AP. Conventionally, any stimulation of the exocrine function of the pancreas by fluid or solid nutrients would promote the release of proteolytic enzymes and affect the disease course negatively[8]. Early oral dosing with DCQD may increase gastric contents, worsen stomachache and abdominal distension, and even aggravate the disease severity. However, it is not clear whether early oral administration of DCQD increases pancreatic secretion and worsens the disease severity. One clinical observation revealed that the best time for gastrointestinal unblocking by herbs was within 48 h after the onset of AP[9]. At the same time, releasing excessive turbidity should be done sooner rather than later to prevent intestinal function failure and disease deterioration[9]. Some studies have indicated that AP patients must pass feces within 24 h after the onset of AP, as one method to support intestinal function to control systemic inflammatory response syndrome and protect organ functions[9]. It is still unclear if the optimal oral dosing time of DCQD should be earlier or later. Therefore, it is important to find the optimal dosing time of DCQD at which DCQD will not worsen the disease severity.

The necrosis of pancreatic acinar cells would worsen the disease, and the induction of apoptosis would decrease the disease severity[6]. Thus, based on the effect of DCQD on regulation of the apoptosis/necrosis switch of pancreatic acinar cells to ameliorate pancreatic inflammation and pathological damage[6], the study aimed to identify the optimal oral dosing time of DCQD in rats with AP according to the pharmacokinetics of the absorbed components and the pharmacodynamics of DCQD targeting of the pancreas.

MATERIALS AND METHODS

Animals

Sprague-Dawley male rats (n = 66) aged 90 ± 5 d, with body weights of 280-300 g, were purchased from Chengdu Dashuo Bio-Technique Co. Ltd. (Chengdu, China). The animals were maintained as previously described[10]. Before AP induction, rats were fasted for 12 h. This study was performed according to the Guide for the Care and Use of Laboratory Animals of Sichuan University (Chengdu, China) and the Animal Ethics Committee Guidelines of the Animal Facility of the West China Hospital (Chengdu, China).

Preparation of drugs

Sodium taurocholate was supplied by Sigma (St. Louis, MO, United States). Spray dried particles of dahuang, mangxiao, houpu, and zhishi were purchased from Chengdu Green Herbal Pharmaceutical Co. Ltd. (Chengdu, China). Chloral hydrate (10%), paraformaldehyde (4%) and methanol were obtained from Tedia Co. Ltd. (Nos. 509221 and 609144; Fairfield, OH, United States,). Glacial acetic acid (No. 20030911) and ethyl acetate (No. 20070116) were purchased from Chengdu Kelon Chemical Reagent Factory (Chengdu, China). Reference standards of the 10 components of DCQD were purchased from the same companies. According to the proportion of crude drugs (dahuang 12 g, houpu 24 g, zhishi 12 g, and mangxiao 9 g), the granules of the four drugs were stirred with ultra-pure water by magnetic stirrers with a speed setting of grade 5 for 1 h in a water bath at a temperature of 37 ℃ for 30 min. According to the Method of Pharmacology, the least dosage of DCQD is 0.6 g/100 g.BW for rats. In this study, the dosage was 1 g/100 g.BW (10 g/kg.BW) with the concentration of 1 g/mL.

Equipment and conditions

The magnetic stirrer (C-MAG, MS 7) was provided by the IKA Company (Breisgau, Germany). The analytical balance (BSA-224S-CW) was provided by the Sartorius Company (Goettingen, Germany). The micro-infusion pump was obtained from KD Scientific (Holliston, MA, United States). Conventional operation instruments, fixation-machines for rats, and the 1.5 mL and 10 mL centrifuge tubes were purchased from Shimadzu (Kyoto, Japan). The high-performance liquid chromatography tandem mass spectroscopy (HPLC-MS/MS) system consisted of a SIL-HTc autosampler (Shimadzu), a LC-10ADvp pump (Shimadzu), and an API3000 triple-quadrupole LC-MS system (Applied Biosystems, Foster City, CA, United States). This system was controlled by Analyst 1.4. Software (Chinese Pharmacological Society, Beijing, China). The chromatographic column was an Ultimate XB-C_{18} (5 μm, 50 mm × 4.6 mm). The mobile phase consisted of methanol-water (92:8, v/v) delivered at a flow rate of 0.3 mL/min. The column was maintained at ambient temperature, and the injection volume was 80 μL. The Anke centrifuge TGL-16B was supplied by Shanghai An-Ting Science Technology Instrument Factory (Shanghai, China). All aqueous solutions and buffers were prepared with ultra-pure water from a Millipore Rios™-16 water purifier (Millipore, Billerica, MA, United States). Standard stock solutions were prepared

by dissolving the reference standards (100 μg/mL for emodin, aloe-emodin, chrysophanol, naringin, naringenin, hesperidin, magnolol and honokiol; 20 μg/mL for rhein and rheochrysidin) and internal standard (40 μg/mL for ibuprofen) in methanol[1]. Stock solutions were stored at -20 ℃. Working standard solutions were prepared freshly by diluting stock solutions in sodium hydroxide solution (0.1 mol/L). Internal standard working solution (200 ng/mL) was prepared by diluting the stock solution in methanol-water (1:1, v/v)[1].

Induction of AP and dosing of DCQD

First part: Rats were randomly allocated into the following four groups (n = 6 each): a sham-operated group [NG(a)] and three model groups [4hG(a), 12hG(a) and 24hG(a)]. AP models were induced by retrograde perfusion of 3% sodium taurocholate (1 mL/kg.BW) into the biliopancreatic duct[11] at a rate of 6 mL/h with a micro-infusion pump after anesthetization with 10% chloral hydrate (3 mL/kg.BW) injected into the abdominal cavity. The NG(a) group was established by the same procedure, but with use of saline instead of sodium taurocholate. The dosing time of DCQD for the NG(a) and model groups were 4 h, 4 h, 12 h and 24 h after operation.

Second part: Forty-two rats were divided into a sham-operated group [NG(b)], and 4h-, 12h- and 24h-dosing treatment groups [4hG(b), 12hG(b) and 24hG(b), respectively] with three corresponding control groups [MG(b)s]. Only the three treatment groups were administered the same dosage of DCQD at 4 h, 12 h and 24 h, respectively, after AP induction. The three corresponding control groups were given saline instead of DCQD at the same time. Rats were euthanized at 24 h after drug dosing.

Collection and measurement of samples

First part: Plasma samples (0.5 mL) were collected from the tails at 10 min, 20 min, 40 min, 1 h, 2 h, 4 h, 8 h, 12 h and 24 h after a single dosing of DCQD. Serum samples for amylase (AMS) and pancreatic tissues for the tissue concentrations of the absorbed components of DCQD were collected 24 h after drug dosing. A total of 0.05 mL of internal standard working solution and 0.1 mL of hydrochloric acid buffer solution were added into 0.2 mL of the plasma or tissue homogenate samples, followed by 3.0 mL of ethyl acetate. Then, the mixtures were extracted by vortex mixing for 7 min and centrifuged at 3000 rpm for 7 min at a low temperature. After that, 2.4 mL supernatants were evaporated at 45 ℃, followed by incubation with 0.1 mL of double-solvents (methanol-water: 92:8, v/v). Thereafter, 20 μL of supernatant was injected automatically into the HPLC-MS/MS system for analysis. The 10 major components of DCQD (aloe-emodin, rhein, emodin, chrysophanol, honokiol, rheochrysophanol, magnolol, hesperidin, naringenin and naringin) were detected. The mean contents of the components were detected three times, as in our previous study[12]. The detected DCQD samples were stored in the Public Experiment Platform at West China Hospital (Chengdu, China).

Second part: Serum for AMS and inflammatory cytokines measurement and pancreatic tissues for pathological scoring were collected 24 h after drug dosing. Pancreatic samples were fixed in 10% neutral formalin for paraffin sections and stained with hematoxylin and eosin (HE). All the histopathology specimens were scored in a blinded fashion by two independent pathologists using a scoring system for the extent and severity of tissue injury (0-4, edema, neutrophil infiltration, necrosis and hemorrhage, respectively), as previously described[4,13]. The IL-10 and IL-6 levels were detected by enzyme-linked immunosorbent assay kits. The following formula was used to calculate the value of AMS: AMS (U/dL) = (blankOD - measurementOD)/blankOD × 0.4 × 0.5/10 × 30 min/7.5 min × 100/0.1 × 10

Statistical analysis

The pharmacokinetic parameters were processed by pharmacokinetic statistical software DAS2.0.1 programmed by the Chinese Pharmacological Society. The data were obtained by statistical moment calculation. The following pharmacokinetic parameters were calculated: the maximum plasma concentration (C_{max}), the time to reach maximum concentration (T_{max}), the mean residence time ($MRT_{0\rightarrow t}$), the elimination half-life ($T_{1/2}$) and the area under the plasma concentration-time curve from time 0 to the time of the last measurable concentration ($AUC_{0\rightarrow t}$). The data were processed with statistical software PEMS3.1. All values were expressed as the mean ± SD. A one-way repeated-measure ANOVA, followed by multiple pairwise comparisons using the Student-Newman-Keuls procedure, was used to detect differences among the groups. $P < 0.05$ was considered a statistically significant difference.

RESULTS

Ten major components of DCQD distributed in pancreatic tissues

In this study, all 10 major components of DCQD in pancreatic tissues could be detected by HPLC-MS/MS. The concentrations of naringin, hesperidin, naringenin, aloe-emodin and chrysophanol in pancreatic tissues were relatively high. Compared to the NG(a) group, the concentrations of emodin,

Table 1 Concentrations of the 10 components of DCQD distributed in pancreatic tissues

	NG(a)	4hG(a)	12hG(a)	24hG(a)
Rhein	12.65 ± 3.7	179.15 ± 77.6[a]	199.89 ± 34.8	50.08 ± 17.6[e]
Emodin	18.68 ± 8.7	1.33 ± 0.8[a]	34.46 ± 10.3[c]	39.75 ± 12.4
Naringin	415.30 ± 17.8	19.47 ± 1.4[a]	32.10 ± 2.7[c]	269.16 ± 12.9[e]
Honokiol	2.38 ± 1.2	1.98 ± 0.1	19.79 ± 2.2[c]	4.26 ± 1.0
Magnolol	1.34 ± 0.9	0.97 ± 0.2	0.97 ± 0.2	7.51 ± 0.8[e]
Hesperidin	162.01 ± 34.3	34.94 ± 12.6[a]	24.31 ± 10.3	113.26 ± 13.8[e]
Naringenin	847.98 ± 76.9	858.58 ± 19.6	1077.06 ± 26.8[c]	262.30 ± 100.6[e]
Aloe-emodin	439.05 ± 179.8	89.53 ± 14.8[a]	502.74 ± 70.7[c]	501.45 ± 143.4
Chrysophanol	60.99 ± 16.4	5.16 ± 2.1[a]	197.29 ± 17.9[c]	113.43 ± 23.7[e]
Rheochrysidin	6.79 ± 1.2	0.55 ± 0.2[a]	17.92 ± 1.9[c]	11.67 ± 0.9[e]

Rats were orally administered with DCQD (10 mL/kg.BW). Pancreatic tissues were collected 24 h after a single dosage of DCQD. The concentrations of the 10 components of DCQD were determined by HPLC-MS/MS. The results are presented as the mean ± SD of μg/mg (n = 6). NG(a): the sham-operated group with the dosing time at 4 h after operation. 4hG(a), 12hG(a) and 24hG(a): rats were dosed orally with DCQD at 4 h, 12 h and 24 h, respectively, after AP induction. 4hG(a) *vs* NG(a): [a]P < 0.05, 12hG(a) *vs* 4hG(a): [c]P < 0.05, 24hG(a) *vs* 12hG(a): [e]P < 0.05. AP: Acute pancreatitis; DCQD: Da-Cheng-Qi decoction; HPLC-MS/MS: High-performance liquid chromatography tandem mass spectroscopy.

naringin, hesperidin, aloe-emodin, chrysophanol and rheochrysidin were lower in the 4hG(a) group (P < 0.05), while the rhein concentration was higher (P < 0.05). The concentrations of emodin, naringin, honokiol, naringenin, aloe-emodin, chrysophanol and rheochrysidin in the 12hG(a) group were higher than in the 4hG(a) group (P < 0.05). The concentrations of rhein, naringenin, chrysophanol and rheochrysidin in the 24hG(a) group were lower than in the 12hG(a) group (P < 0.05), while the concentrations of naringin, magnolol and hesperidin in the 24hG(a) group were higher (P < 0.05) (Table 1).

Eight major components of DCQD detected in plasma

Only eight of the ten components were successfully fitted to the concentration-time curves according to the testing data (Figure 1). The T_{max} values were all at 40 min (0.67 h) after a single dosage of DCQD in the NG(a) group. The T_{max} of six components (aloe-emodin, rhein, emodin, chrysophanol, naringenin and naringin) in the 4hG(a) group, all components in the 12hG(a) group and that of five components (aloe-emodin, rhein, rheochrysidin, magnolol and naringin) in the 24hG(a) were delayed (Figure 1).

In the NG(a) group, the C_{max} values of the components were as follows: aloe-emodin, 3218.33 ng/mL; rhein, 8638.42 ng/mL; emodin, 510.97 ng/mL; naringin, 204.56 ng/mL; chrysophanol, 5419.89 ng/mL; rheochrysidin, 146.75 ng/mL; naringenin, 419.94 ng/mL; and magnolol, 19.58 ng/mL. Compared to the NG(a) group, the C_{max} values of aloe-emodin, rhein, emodin, chrysophanol and magnolol were reduced in the 4hG(a) group (Figure 1). Compared to the 4hG(a) or 12hG(a) groups, the C_{max} values of aloe-emodin, rhein, emodin, naringenin and magnolol were higher in the 24hG(a) group, and they were as follows: 5885.13 ng/mL, 8245.18 ng/mL, 88.65 ng/mL, 606.41 ng/mL and 11.018 ng/mL, respectively. Among the three model groups, the C_{max} values of chrysophanol and naringin were highest in the 12hG(a) group, and for rheochrysidin the C_{max} was in the 4hG(a) group; the concentrations were 4054.73 ng/mL, 519.53 ng/mL and 557.06 ng/mL, respectively (Figure 1).

The pharmacokinetic parameters were analyzed by statistical moment calculation, and those in model groups were different from those in the NG(a) group (Table 2). Compared to the NG(a) group, the $AUC_{0\rightarrow t}$ values of aloe-emodin, chrysophanol, emodin and magnolol were smaller in the 4hG(a) group (P < 0.05), while those of rheochrysidin, naringin and naringenin were larger (P < 0.05). The $AUC_{0\rightarrow t}$ of aloe-emodin in the 24hG(a) group was larger than in the 4hG(a) or 12hG(a) groups, and those of rhein, chrysophanol, magnolol and naringin in the 12hG(a) group were larger than in the 4hG(a) or 24hG(a) groups. The $T_{1/2}$ values of rhein, emodin, aloe-emodin, rheochrysidin, naringin and magnolol in the 24hG(a) group were longer than in the 4hG(a) or 12hG(a) groups.

DCQD elevated the IL-10 levels and lowered the IL-6 levels in serum

In serum, the IL-10 and IL-6 levels in the three corresponding control groups were all higher than in the NG(b) group (IL-10: 152.8 ± 18.58/77.46 ± 7.42/99.72 ± 4.7 *vs* 48 ± 12, P < 0.05; IL-6: 147.91 ± 4.36/171.44 ± 13.43/98.48 ± 2.7 *vs* 68 ± 20, P < 0.05). Compared to the corresponding control groups, the IL-10 levels in the 12hG(b) and 24hG(b) groups were increased (96.55 ± 7.84 *vs* 77.46 ± 7.42, 251.22 ± 16.15 *vs* 99.72 ± 4.7, P < 0.05), and the IL-10 level in the 24hG(b) group was higher than in the 4h(b) and 12hG(b) groups (251.22 ± 16.15 *vs* 154.41 ± 12.09/96.55 ± 7.84, P < 0.05) (Figure 2A). The IL-6 levels displayed a decrease in the 4hG(b) and 12hG(b) groups compared to their corresponding control groups (89.99 ± 4.61 *vs* 147.4.36, 90.82 ± 5.34 *vs* 171.44 ±

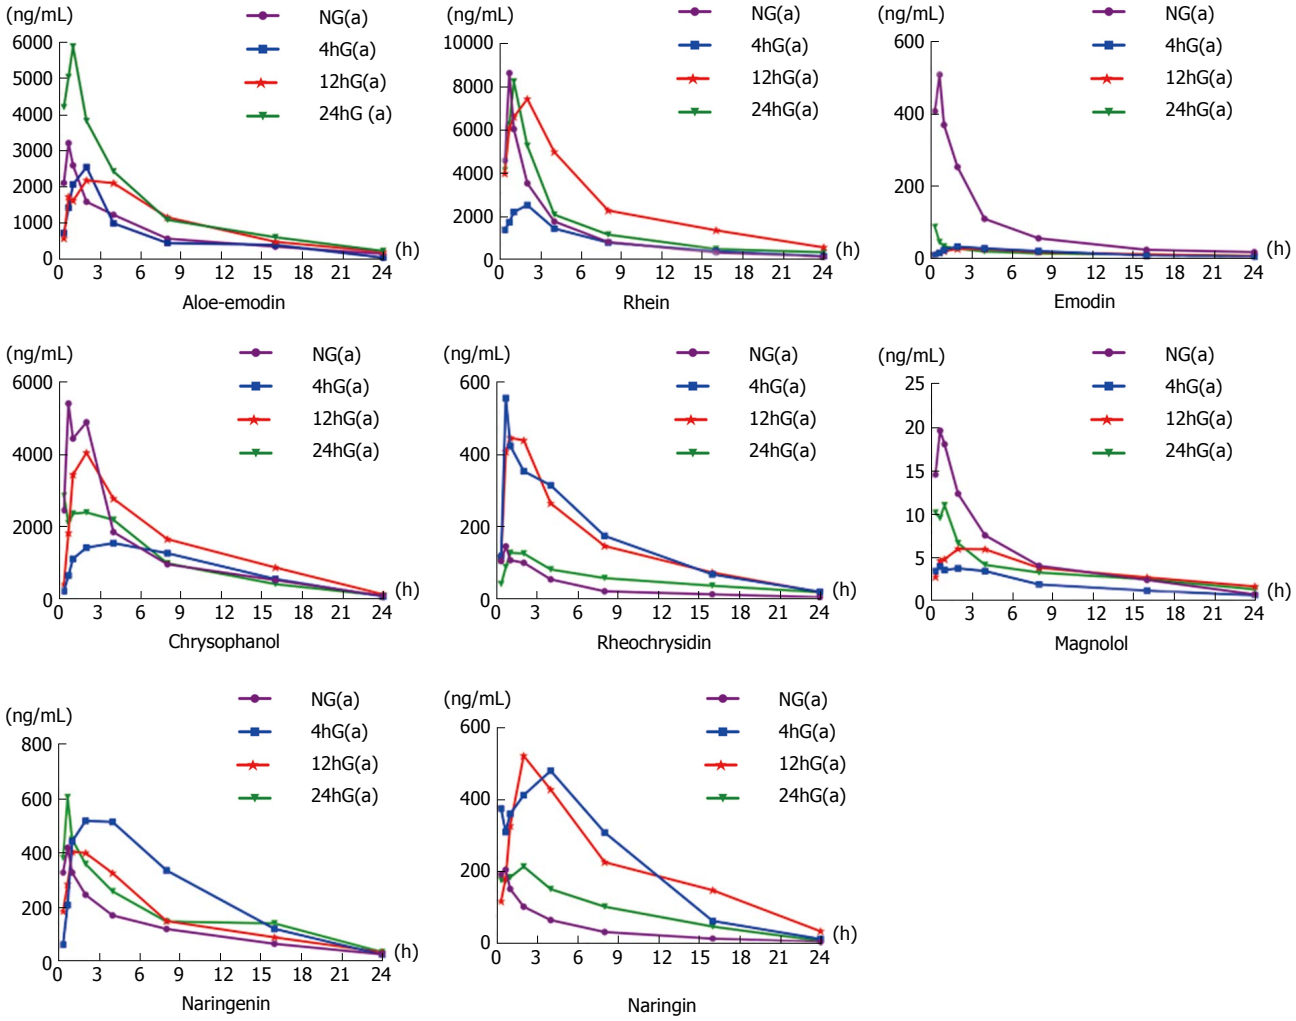

Figure 1 Concentration-time curves of the eight components of Da-Cheng-Qi decoction in plasma of the rats with acute pancreatitis. Rats (n = 6 per group) were orally dosed with DCQD (10 mL/kg.BW). Plasma samples were collected from the tails at 10 min, 20 min, 40 min, 1 h, 2 h, 4 h, 8 h, 12 h and 24 h after a single dosage of DCQD. Plasma concentrations of the components of DCQD were determined by HPLC-MS/MS. The results are presented as the mean ± SD. NG(a): the sham-operated group with the dosing time 4 h after operation; 4hG(a), 12hG(a) and 24hG(a): the dosing times were 4 h, 12 h and 24 h, respectively, after AP induction. AP: Acute pancreatitis; DCQD: Da-Cheng-Qi decoction; HPLC-MS/MS: High-performance liquid chromatography tandem mass spectroscopy.

13.43, $P < 0.05$) (Figure 2B).

Pathological damages in the pancreatic tissues and serum AMS levels

In the NG(b) group, the pancreatic tissues were edematous with a few neutrophils but without obvious hemorrhage and necrotic acinar tissues. In the MG(b) groups, edema, hemorrhage and neutrophils with some necrotic acinar tissues were obvious. In the 12hG(b) group, the pathological damages were improved, while those in the 4hG(b) or 24hG(b) groups had no obvious improvement (Figure 3A). Compared to the NG(b) group, the pathological scores in the MG(b) groups were increased (1.79 ± 0.3/2.2 ± 0.2/2.67 ± 0.67 *vs* 0.7 ± 0.26, $P < 0.05$). Those in the 12hG(b) group were evidently reduced compared to its control group (1.3 ± 0.4 *vs* 2.2 ± 0.2, $P < 0.05$) or the 4hG(b) and 24hG(b) groups (1.3 ± 0.4 *vs 2.63* ± 0.4/2.5 ± 0.3, $P < 0.05$) (Figure 3B).

The AMS levels in the 4hG(a), 12hG(a) and 24hG(a) groups were all higher than in the NG(a) group (724.17 ± 42.8/673.67 ± 26.64/659.65 ± 41.38 *vs* 273.67 ± 93.23, $P < 0.05$) (Figure 3C). Compared to the NG(b) group, that in the MG(b) groups were higher (718.65 ± 51.04/711.68 ± 55.37/666.4 ± 73.4 *vs* 389 ± 98, $P < 0.05$). The AP model was successful. That in the 12hG(b) group was reduced compared to its control group (649 ± 131.69 *vs* 711.68 ± 55.37, $P < 0.05$) (Figure 3D).

DISCUSSION

According to the present study, AP reduced the concentrations of the major components of DCQD to the target pancreas, and the oral administration time also played an important role; their absorption

Rats were orally dosed with DCQD (10 mL/kg.BW). Plasma samples were collected from the tails at 10 min, 20 min, 40 min, 1 h, 2 h, 4 h, 8 h, 12 h and 24 h after a single dosage of DCQD. The samples were assessed by HPLC-MS/MS. The pharmacokinetic parameters were processed by pharmacokinetic statistic software DAS2.0.1 and the data were obtained by statistical moment calculation. The results are presented as the mean ± SD. NG(a): the sham-operated group with the dosing time at 4 h after operation. 4hG(a), 12hG(a) and 24hG(a): rats were dosed orally with DCQD at 4 h, 12 h and 24 h, respectively, after AP induction. Compared with NG(a): [a]$P < 0.05$, 12hG(a) *vs* 4hG(a): [b]$P < 0.05$, 24hG(a) *vs* 12hG(a): [c]$P < 0.05$, 24hG(a) *vs* 4hG(a): [d]$P < 0.05$. AP: Acute pancreatitis; DCQD: Da-Cheng-Qi decoction; HPLC-MS/MS: High-performance liquid chromatography tandem mass spectroscopy.

may be better if the oral administration time of DCQD is approximately 12 h after the onset of AP (Table 1). AP delayed the T_{max} and reduced the C_{max} of the components of DCQD in the circulation of rats (Figure 1). The components of DCQD displayed a higher C_{max} and a longer $T_{1/2}$ when the oral administration time of DCQD was approximately 24 h after the onset of AP (Figure 1 and Table 2). The $AUC_{0\rightarrow t}$ was larger when that time was approximately 12 h after the onset of AP (Table 2). DCQD increased the IL-10 levels and lowered the IL-6 levels (Figure 2A and B), and the later administration of the DCQD dose corresponded to higher IL-10 levels (Figure 2A). Therefore, administering the DCQD dose too early may not be

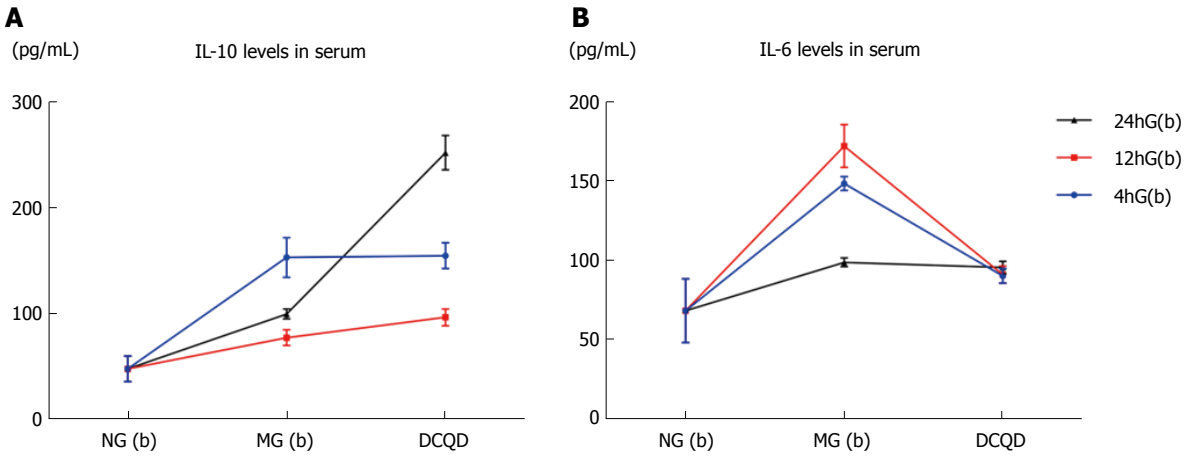

Figure 2 Da-Cheng-Qi decoction elevated IL-10 levels and lowered IL-6 levels in serum of the rats with acute pancreatitis. Rats (*n* = 6 per group) in the three treatment groups were orally dosed with DCQD (10 mL/kg.BW) 4 h, 12 h and 24 h after AP induction. Serum samples were collected at 24 h after a single dosage of DCQD. The results are presented as the mean ± SD. NG(b): the sham-operated group; MG(b): the model group or the control group; 4hG(b), 12hG(b) and 24hG(b): rats were orally dosed with DCQD 4 h, 12 h and 24 h, respectively, after AP induction. AP: Acute pancreatitis; DCQD: Da-Cheng-Qi decoction.

appropriate for AP, and administration should at least be 12 h after the onset of AP.

Pathological circumstances may affect the absorption of the components of DCQD and affect the pharmacokinetics in AP. Pancreatic ischemia, reduced pancreatic blood flow and increased capillary permeability are usually common in AP[14]. The systemic hemodynamic disturbances lead to ischemia of the intestine[15]. In addition, one retrospective analysis (197 patients) showed that 65% of patients with AP had acute gastrointestinal mucosal lesions detected by upper gastrointestinal endoscopy[16]. As well, 59% of patients with AP showed gut barrier dysfunction with increased intestinal permeability in a meta-analysis of 18 studies[17]. Both propulsion and contractility were reduced in necrotizing pancreatitis of rats[18]. It was reported that permeability of the ileum was significantly increased at 6 h, the blood endotoxin level was elevated and bacterial translocation occurred 18 h after induction of SAP-induced by injection of 3% sodium deoxycholate[19].

As we know, oral medicines, including herbs, are generally absorbed by the gastrointestinal mucosa. The process of drug absorption into the blood circulation from the plasma membrane barrier proceeds as follows: drug molecule encounters the gastrointestinal mucous layer, brush border, epithelial cell membrane, intracellular fluid, basal lamina, lamina propria, externa of vessels, cytoplasm of vessels, intima of vessels and then the blood. Therefore, these aforementioned factors may play an important role in the delay of the T_{max} of the components of DCQD in reaching the circulation and establishing their concentrations in pancreatic tissues.

Another factor may be the physicochemical properties of these components. Chrysophanol belongs to the Class Ⅱ poorly water soluble drugs in the Biopharmaceutics Classification System (BCS), with low solubility but high permeability[20,21]. Magnolol, a small-molecule neolignan[22], has an extensive first-pass metabolism and low absorption[23]. Naringin is moderately soluble in water, and it is broken into its aglycon naringenin in the intestine by the gut microflora and then absorbed from the gut[24]. These different characteristics may influence the absorption of these components. Furthermore, the pharmacokinetics of phytochemicals have substantial variation[25] and circulating concentrations of phytochemicals, which could vary widely among individuals, even in the context of controlled feeding studies[26]. In brief, the internal environments of rats and the characteristics of the components of DCQD may be the major factors affecting the absorption of these components.

It is well known that the avoidance of gastric and intestinal secretion has been the cornerstone of management of patients with AP for nearly a century[27]. To espouse the "pancreatic rest" concept, fasting and water deprivation have become the fundamental treating rules. However, the benefits of oral dosing with DCQD in the early stage of AP have been demonstrated, especially in gastrointestinal internal environments. This approach could improve intestinal propulsive function, relieve abdominal distension and abdominal pressure[28], and protect the intestinal immune barrier, with amelioration of the levels of high mobility group box-1 protein (HMGB1) RNA and cyclooxygenase 2 (COX-2) RNA expression[29]. One meta-analysis showed that purgative therapy could shorten the time of first defecation and the hospitalization time[30]. Thus, the advantages of DCQD are obvious. Future studies should be done to determine whether the oral dose of DCQD could increase gastrointestinal and pancreatic secretion.

The finding of DCQD regulating the balance of pro-inflammation and anti-inflammation was consistent with our previous studies[4]. However, the current

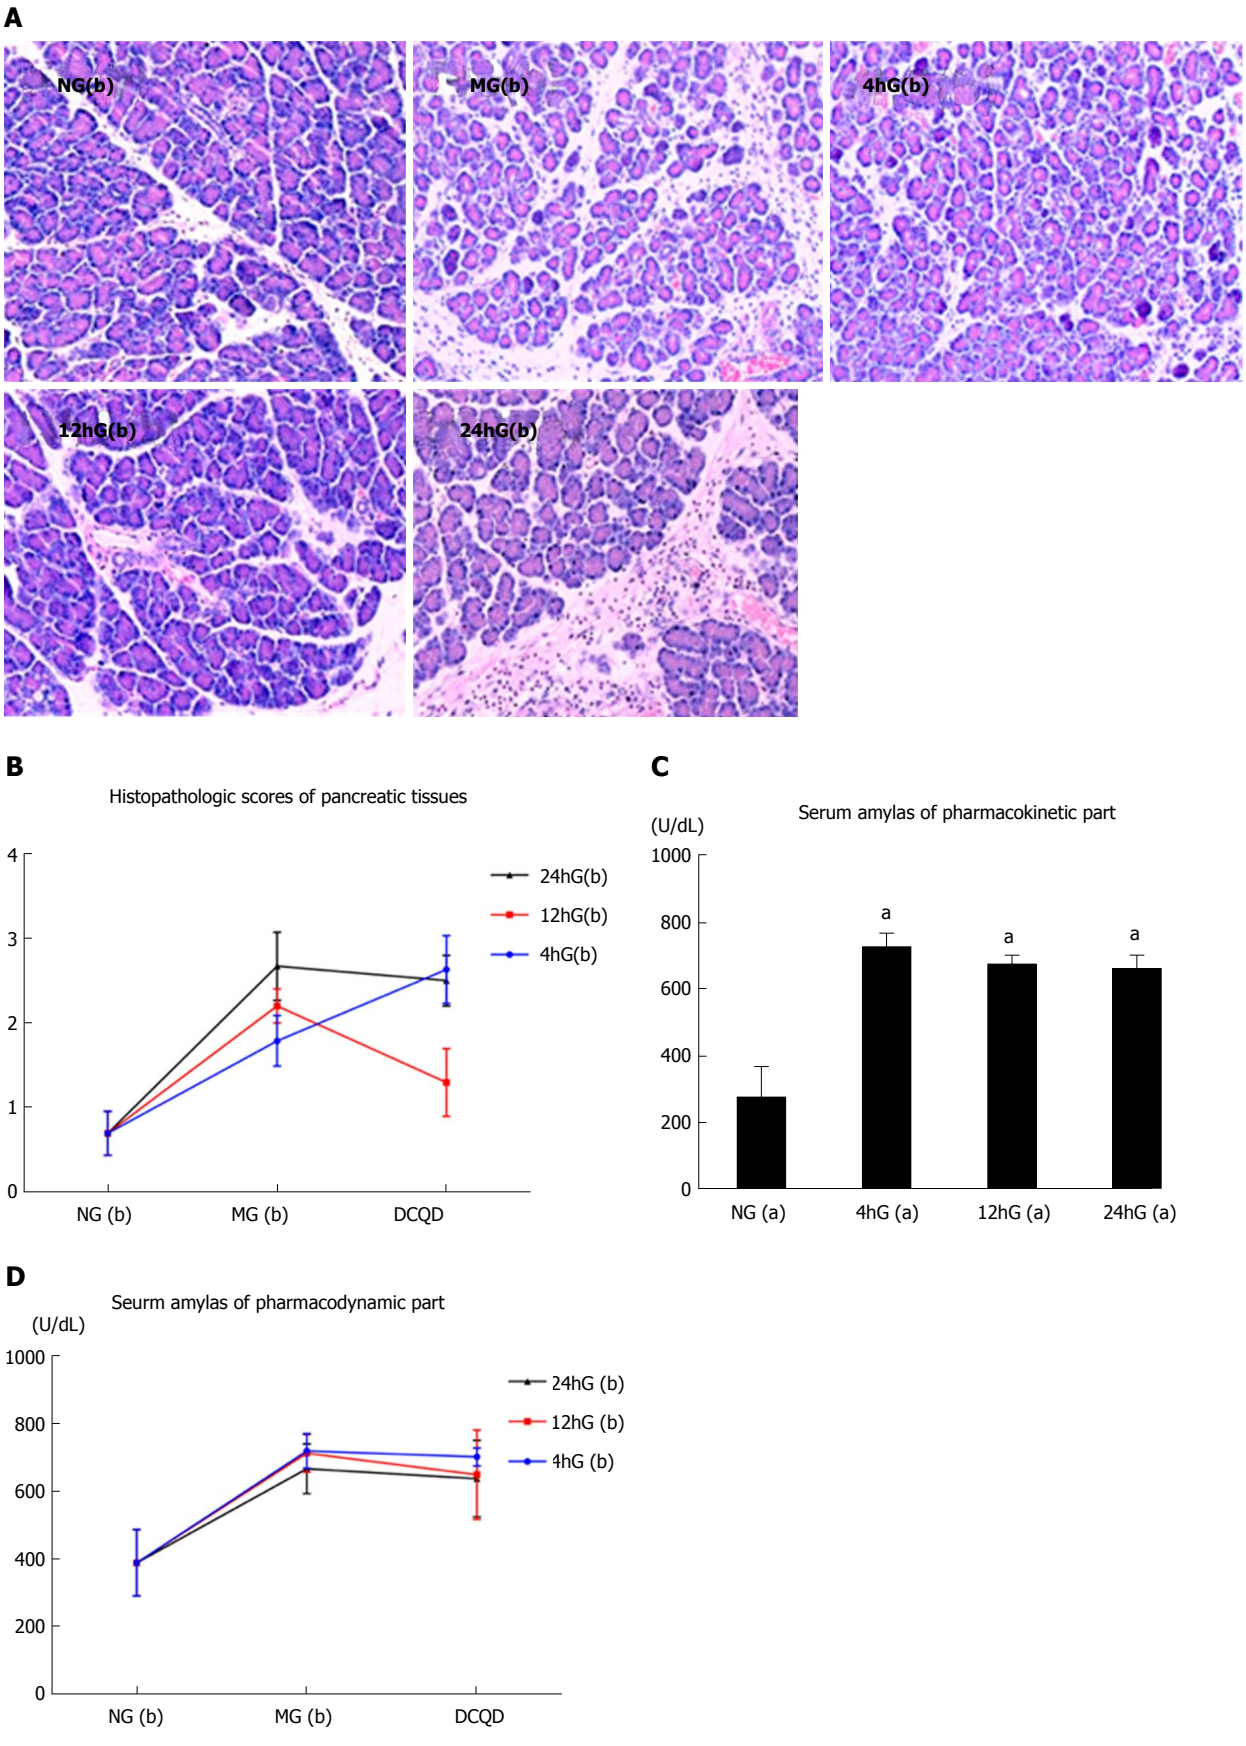

Figure 3 Pathological damages in the pancreatic tissues and changes in the serum amylase concentration. Rats (n = 6 per group) were orally administered DCQD (10 mL/kg.BW) 4 h, 12 h and 24 h after AP induction. Pancreatic tissues were collected for staining with hematoxylin-eosin (A, × 200) 24 h after a single dosage of DCQD; B: Pathological scores of the pancreatic tissues. Serum amylase was detected by enzyme-linked immunosorbent assay (C and D). The results are presented as the mean ± SD. $^{a}P < 0.05$ *vs* NG(a). NG(a/b): the sham-operated group; MG(b): the model group or the control group; 4hG(a/b) 12hG(a/b), and 24hG(a/b): rats were orally dosed with DCQD 4 h, 12 h and 24 h, respectively, after AP induction. AP: Acute pancreatitis; DCQD: Da-Cheng-Qi decoction.

study showed that its oral dosing time might affect the inflammatory cytokines and pharmacokinetics of the effective components of DCQD targeting of pancreatic tissues and plasma. The chronomedicine of TCM, with thousands of years of history and in which the midnight-noon ebb-flow theory is typical, is similar to modern chronobiology. Theoretically, the function of Chinese medicine will be most effective at driving out pathogenic factors when the function of some meridian is at its peak[31]. For example, erythrocyte C3b receptor rosette and erythrocyte immune complex rosette can reach peak value when the kidney meridian has its most active function[32].

Along with the improvement of modern technology, the research on the relationship between the dosing time of Chinese medicine and plasma concentration or curative effect has been performed. Nishioka *et al*[33] demonstrated that the dosing time of Sho-Saiko-To could affect the plasma concentrations of the effective components (glycyrrhizin and baicalein). Additionally, the pharmacokinetic processes of emodin and aloe-emodin of DCQD presented a circadian rhythm phenomenon[34]. According to our study, the oral dosing time also affects the drug tissue concentrations. Therefore, the oral dosing time of DCQD is closely related to its pharmacokinetics and pharmacodynamics.

In this study, the pathological damages of pancreatic tissues had been improved only in the 12hG(b) group, and was not improved in the 4hG(b) or 24hG(b) groups. However, this finding was not consistent with those of a previous study showing that a similar dose of DCQD 2 h after AP induction confers some protection against pancreatic tissue damage. Although the weight of rats showed no difference, this finding may be related to the different experimenters, which may have resulted in large differences among the various groups. We should ensure the consistency of experimenters. In clinical practice, orally dosing or coloclysis of DCQD are performed immediately when patients with AP are admitted to hospital. Whether these approaches could increase secretion of the gastrointestinal tract remains unclear. Recently, little research on the optimal administration time of Chinese herbs has been reported, and there are no definite opinions on this topic in the Chinese guidelines, although the guidelines are generally used in clinical practice in China. Therefore, our conjecture needs further clinical studies to be confirmed.

In conclusion, AP and the oral administration time of DCQD could affect the pharmacokinetics of the absorbed components of DCQD in the pancreatic tissues and plasma of rats. Late-time dosing may result in higher concentrations of the major components of DCQD with better pharmacokinetics and pharmacodynamics of anti-inflammation than seen with early-time dosing, thereby showing the late time to be the optimal dosing time of DCQD for AP.

ARTICLE HIGHLIGHTS

Research background

Oral administration with Da-Cheng-Qi decoction (DCQD) is the conventional therapy at the early phase of acute pancreatitis (AP) patients in China. But oral dosing with DCQD is contrary to the idea of pancreatic rest at the early stage of AP, which may inhibit the absorption of the components of DCQD, influence its pharmacokinetics or pharmacodynamics and even worsen the disease severity.

Research motivation

The necrosis of pancreatic acinar cells would worsen the disease and the induction of apoptosis would relieve the disease severity. In clinical practice, oral dosing or coloclysis of DCQD are performed immediately when patients with AP are admitted to hospital. Whether these approaches could increase secretion of gastrointestinal tract remain unclear. What's more, little research on the optimal administration time of Chinese herbs has been reported, and there are no definite opinions on this topic in the Chinese guidelines. Thus, based on effect of DCQD regulating the apoptosis/necrosis switch of pancreatic acinar cells to ameliorate the pancreatic inflammation and pathological damage, the study aimed to screen the optional oral dosing time of DCQD in rats with AP according to the pharmacokinetics of the absorbed components and the pharmacodynamics of DCQD targeting of pancreas.

Research objectives

This objective was to screen the optional oral dosing time of DCQD in rats with AP based on the pharmacokinetic and pharmacodynamic parameters. We hoped to find an optimal dosing time of DCQD without increasing the severity of AP.

Research methods

This animal experiment was divided into pharmacokinetic and pharmacodynamic parts. AP models were induced by 3% sodium taurocholate. Rats were dosed at three different times. Plasma samples were collected from the tails at nine different times. The main components' concentrations of plasma and pancreatic tissues were detected by high-performance liquid chromatography tandem mass spectroscopy, confirmed as a specific, sensitive, accurate and reproducible method. The pharmacokinetic parameters [the maximum plasma concentration (C_{max}), the time to reach maximum concentration (T_{max}), the mean residence time ($MRT_{0\rightarrow t}$), the elimination half-life ($T_{1/2}$) and the area under the plasma concentration-time curve from time 0 to the time of the last measurable concentration ($AUC_{0\rightarrow t}$)] were processed by pharmacokinetic statistical software DAS2.0.1 programmed by the Chinese Pharmacological Society. The IL-10, IL-6 and amylase concentrations in serum and pathological scores of pancreatic tissues were calculated.

Research results

According to the present study, AP reduced the concentrations of the major components of DCQD to the target pancreas, and the oral administration time also played an important role. AP delayed the T_{max} and reduced the C_{max} of the components of DCQD in the circulation of rats. The $AUC_{0\rightarrow t}$ was larger when that time was approximately 12 h after the onset of AP. DCQD increased the IL-10 levels and lowered the IL-6 levels, and the later administration of the DCQD dose corresponded to higher IL-10 levels. Therefore, administering the DCQD dose too early may not be appropriate for AP. However, our results need further clinical studies to be confirmed.

Research conclusions

Late-time dosing may result in higher concentrations of the major components of DCQD with better pharmacokinetics and pharmacodynamics of anti-inflammation than seen with early-time dosing, thereby showing the late time to

be the optimal dosing time of DCQD for AP.

Abstract

AIM

To evaluate the short- and long-term results of endoscopic ultrasound-guided transmural drainage (EUS-GTD) for pancreatic fluid collection (PFC) and identify the predictive factors of treatment outcome for walled-off necrosis (WON) managed by EUS-GTD alone.

METHODS

We investigated 103 consecutive patients with PFC who

underwent EUS-GTD between September 1999 and August 2015. Patients were divided into four groups as follows: WON (n = 40), pancreatic pseudocyst (PPC; n = 11), chronic pseudocyst (n = 33), and others (n = 19). We evaluated the short- and long-term outcomes of the treatment. In cases of WON, multiple logistic regression analyses were performed to identify the predictor variables associated with the treatment success. In addition, PFC recurrence was examined in patients followed up for more than 6 mo and internal stent removal after successful EUS-GTD was confirmed.

RESULTS

In this study, the total technical success rate was 96.1%. The treatment success rate of WON, PPC, chronic pseudocyst, and others was 57.5%, 90.9%, 91.0%, and 89.5%, respectively. Contrast-enhanced computed tomography using the multivariate logistic regression analysis revealed that the treatment success rate of WON was significantly lower in patients with more than 50% pancreatic parenchymal necrosis (OR = 17.0; 95%CI: 1.9-150.7; P = 0.011) and in patients with more than 150 mm of PFC (OR = 27.9; 95%CI: 3.4-227.7; P = 0.002).The recurrence of PFC in the long term was 13.3% (median observation time, 38.8 mo). Mean amylase level in the cavity was significantly higher in the recurrence group than in the no recurrence group (P = 0.02).

CONCLUSION

The reduction of WON by EUS-GTD alone was associated with the proportion of necrotic tissue and extent of the cavity. The amylase level in the cavity may be a predictive factor for recurrence of PFC.

Core tip: It remains unclear that which patients with walled-off necrosis (WON) can be resolved by endoscopic ultrasound-guided transmural drainage (EUS-GTD) alone and which ones should be treated by endoscopic necrosectomy or other additional treatment. In addition, some pancreatic fluid collections (PFCs) develop recurrent fluid collection, and it is also unclear which types of PFCs show recurrence. In this study, we demonstrated that PFC size and proportion of pancreatic parenchymal necrosis were related to the resolution of WON treated by EUS-GTD alone. Regarding long-term follow-up patients, mean amylase level in the cavity was associated with PFC recurrence, suggesting a prolonged stent placement in patients with predicted recurrence.

INTRODUCTION

Pancreatic fluid collection (PFC) is a local complication after pancreatitis. Although most PFCs spontaneously improve, some PFCs remain and become infectious, thereby needing therapeutic intervention. In 2012, the revision of the Atlanta classification categorized PFC into the following four types: acute peripancreatic fluid collection, acute necrotic collection, pancreatic pseudocyst (PPC), and walled-off necrosis (WON). According to this revised classification, the development of PPC is considered to be extremely rare in acute pancreatitis, and most PFCs over 4 wk are classified as WON[1]. This suggests that many PFCs after acute pancreatitis that were treated as PPC because of slight debris in the cavity should be addressed as WON, according to the revised classification.

Endoscopic ultrasound-guided transmural drainage (EUS-GTD) is now widely accepted as a minimally invasive method for managing PFC with minimal complications[2]. According to previous reports, most patients with PPC achieved treatment success by EUS-GTD alone[3-6]. Conversely, the treatment success rate of WON by EUS-GTD alone was relatively lower than that of PPC[4,7]. Endoscopic necrosectomy (EN) was performed in patients with no clinical improvement by EUS-GTD. In a recent review of 10 series of EN, the overall treatment success rate was 76%, with 5% procedure-related mortality and 27% morbidity[8]. Although EN is less invasive than surgical necrosectomy, serious complications associated with EN have been reported lately. More recently, novel, fully covered biflanged metal stents have been reported to be effective and feasible for the treatment of WON[9-12]. However, the criteria for WON that should be treated by EN or/and with these metal stents remain unclear. Therefore, it is essential to clarify the cases that can be resolved by EUS-GTD alone and those that should be treated with EN and/or metallic stents in addition to EUS-GTD. To the best of our knowledge, to date, no report has investigated the predictive factors of treatment outcome managed by EUS-GTD alone using the definition of WON in the 2012 Atlanta classification.

Despite initial treatment success, some PFCs develop recurrent fluid collection owing to disconnected pancreatic duct syndrome (DPDS)[13,14]. Although long-term PFC recurrence is unknown, recommendations for permanent stent placement have been reported; however, stent migration or obstruction should be considered[13].

In this study, we classified PFC into the following four groups according to the 2012 Atlanta classification: WON; PPC; chronic pseudocyst; and others, including trauma, pancreatic cancer, and pancreatic fistula (after pancreatic surgery). We evaluated patients characteristics, technical success, treatment success, and complications in these four groups. In particular, we compared the clinical features between the treatment success and failure to identify the factors that affect the treatment outcome in patients with WON managed by EUS-GTD alone. The long-term follow-up results of patients who underwent EUS-GTD were assessed and predictive factors for recurrence of PFC were identified.

MATERIALS AND METHODS

Patients

We retrospectively investigated 103 consecutive patients with PFC who underwent EUS-GTD between September 1999 and August 2015 at Chiba University Hospital (Chiba, Japan). Mean age of patients was 54.7 years, and a majority of patients were males. PFC caused by acute pancreatitis was classified according to the 2012 Atlanta classification and definition. We distinguished between WON and PPC by contrast-enhanced computed tomography (CT) 1-4 wk after the onset of pancreatitis and evaluated the existence and extent of pancreatic parenchymal necrosis in all patients with PFC. A chronic pseudocyst is defined as a well-demarcated fluid collection without solid debris occurring in the setting of known chronic pancreatitis and the absence of recent severe acute pancreatitis[14]. Indications for EUS-GTD were as follows: (1) infected cases (fever and leukocytosis) despite the administration of intravenous antibiotics; and (2) symptomatic cases, such as abdominal pain or obstruction of the gastric outlet, intestinal system, or biliary system. Informed procedural consents were obtained from all patients.

Procedures

Before EUS-GTD, a CT scan was obtained from all patients. The standard technique for EUS-GTD involved the following steps. A curved linear array EUS was used to visualize the extent of PFC and to determine the puncture site. Before puncturing, color Doppler was used to identify the regional vessels that needed to be avoided. The cavity was punctured with a 19-gage needle, and then PFC was performed for conducting blood biochemical tests and cultures. A guidewire was inserted through the puncture needle and coiled in PFC under fluoroscopic guidance. The punctured site was dilated by a dilator and a balloon dilator (sometimes an electric dilator was also used). Finally, a 7Fr double pigtail stent and a 7Fr nasocystic drainage catheter were emplaced. The nasocystic drainage catheter was removed after reduction of PFC, and the internal stent was removed within 6 mo after the treatment success.

We assessed the efficacy of EUS-GTD using CT. If the size of the cavity was not reduced after 1-2 wk, we performed additional procedures, such as the multiple transmural gateway technique, percutaneous drainage, or EN.

Outcomes

In this study, we defined technical success as achieving stent and/or nasocystic drainage catheter placement. We defined the treatment success as any reduction in the cavity size to less than 20 mm within 8 wk, as determined by a follow-up CT using EUS-GTD alone, without an additional treatment such as multiple transmural gateway technique, percutaneous drainage, or EN. The treatment success also included the improvement of symptoms. Recurrence was considered to have occurred if the size of the cavity increased to more than 20 mm, regardless of symptoms over 6 mo after EUS-GTD.

Statistical analysis

The factors associated with the clinical success and recurrence were determined using statistical comparisons. Continuous variables were presented as means (with standard deviations) and medians (with range) and compared using Mann-Whitney *U* test. Categorical variables were expressed as frequencies and proportions and compared using χ^2 tests with Yates' correction or Fisher's exact test. In patients with WON, multiple logistic regression analyses were performed to identify the predictor variables associated with the treatment success. The optimal cut-off value of the variables that differentiated between recurrence and no recurrence was determined by the receiver-operating characteristic analysis. In addition, the area under the curve was calculated. The statistical significance was determined as $P < 0.05$, and datasets were compiled using Microsoft Excel (Microsoft Corporation, Redmond, WA, United States). In addition, the IBM SPSS Statistics software version 20.0 (IBM Corporation, Chicago, IL, United States) was used to perform all the statistical analyses. The statistical methods of this study were reviewed by Kengo Nagashima, PhD from Department of Global Clinical Research, Graduate School of Medicine, Chiba University.

RESULTS

Patients

According to the 2012 Atlanta classification and definition for acute pancreatitis, each PFC was classified as WON (n = 40), PPC (n = 11), chronic pseudocyst (n = 33), and others (n = 19) for 103 patients who underwent EUS-GTD. More than 50% of PFCs were located mainly in the pancreatic body or tail. Mean

cavity size was 104.9 mm (Table 1).

Technical success

Of 103 patients, 4 technically failed, resulting in the technical success rate of 96.1% (95%CI: 90.3%-98.9%). In the technically failed cases, each patient required one of the following additional treatments: surgery, transpapillary drainage, percutaneous drainage, extracorporeal shock wave lithotripsy (ESWL), and observation.

Treatment success

In the WON group (n = 40), a technical failure was reported in 1 patient and treatment success in 23 patients (57.5%; 95%CI: 40.9%-73.0%). The treatment success group comprised 2 patients who underwent percutaneous drainage for PFC distant from the main lesion treated by EUS-GTD. We could not achieve the treatment success by EUS-GTD alone in 16 patients, of whom 2 needed surgical treatment, 11 needed no surgical treatment, and 1 died. In the group treated without surgery, we performed EN in 5 patients, multiple transluminal gateway technique in 2 patients, percutaneous drainage in 5 patients, and continuing conservative treatment until reduction over 8 wk in 3 patients. After additional treatment, 2 patients died. All 3 patients who died after EUS-GTD or EN had a respiratory or renal failure.

In the PPC group (n = 11), there were no technical failures, and we achieved the treatment success in 10 patients (90.9%; 95%CI: 58.4%-99.8%). In the chronic pseudocyst group (n = 33), there were two technical failures, and of 31 patients, we achieved the treatment success in 30 patients (96.8%; 95%CI: 83.8%-99.9%). In the treatment success group of chronic pancreatitis, 3 patients underwent EUS-GTD for PFC distant from the main lesion treated by EUS-GTD. In the others group (n = 19), there was one technical failure, and we achieved the treatment success in 17 patients (94.4%; 95%CI: 73.2%-99.9%).

Complications

The procedural complications were encountered in 15 of 103 patients (14.6%), with cases of bleeding (n = 2), stent migration (n = 3), infection (n = 3), pneumoperitoneum (n = 2), localized peritonitis (n = 3), puncture into another organ (n = 1), and mediastinal emphysema (n = 1). All patients were managed conservatively without surgery.

Predictors of treatment success for WON

We compared the treatment success group with the treatment failure group. Patients with more than 50% pancreatic parenchymal necrosis (P = 0.004) and a PFC of more than 150 mm (P < 0.001) on CT were significantly associated with treatment failure based on the univariate analysis. However, PFC with infection was not significant (Table 2). Patients with more than 50% pancreatic parenchymal necrosis (OR = 17.0; 95%CI: 1.9-150.7; P = 0.011) and with a PFC of more than 150 mm (OR = 27.9; 95%CI: 3.4-227.7; P = 0.002) on CT were also significantly associated with treatment failure based on the multiple logistic regression analysis (Table 3).

The treatment success by EUS-GTD alone was not achieved in any patient with WON with more than 50% parenchymal necrosis and a with PFC of more than 150 mm diameter on CT but was achieved in 90% of patients with under 50% pancreatic parenchymal necrosis and with a PFC of less than 150 mm (Table 4). There were two cases of failure with fewer than 50% necrosis and with a PFC of less than 150 mm. In one case with a multilocular type of WON, the necrotic collection remained in the posterior pararenal extraperitoneal space, and we performed percutaneous drainage. In another case, extrapancreatic necrosis without pancreatic parenchymal necrosis extended widely, and EN was conducted.

Pancreatic parenchymal necrosis ⩾ 50%	40.0% (2/5)	0% (0/6)

Recurrence at long-term follow-up

Overall, 75 patients were followed up for more than 6 mo, and the internal stent removal was confirmed. The median observation time was 38.8 mo. Of 75 patients, 10 patients suffered a recurrence, and the overall recurrence rate was 13.3%. The additional treatment for recurrence cases was additional EUS-GTD for 5 patients, transpapillary drainage for one patient, ESWL for one patient, surgery for 2 patients, and observation for one patient. In the recurrence group, the amylase level in the cavity was significantly higher than that in the no recurrence group (P = 0.01; Table 5) based on the univariate analysis. The amylase level at 63,100 in the cavity represented the most sensitive (83.3%) and specific (78.2%) point on the receiver-operating characteristic curve and corresponded to the largest area under the curve (0.820). No recurrence rate of the amylase level in the cavity ⩾ 63100 was significantly lower than that of the amylase level in the cavity < 63100 (P = 0.02; Figure 1).

DISCUSSION

In this study, we revealed the usefulness and feasibility of EUS-GTD for PFC; however, it was less effective in achieving the treatment success for WON as compared with other etiologies of PFC. The PFC size and the proportion of pancreatic parenchymal necrosis were related to the short-term outcomes of WON. In addition, mean amylase level in the cavity was associated with PFC recurrence, suggesting a prolonged stent placement for patients with predicted recurrence.

The treatment success rate of WON by EUS-GTD alone was 61.1%. Some retrospective studies have demonstrated a 45%-63% treatment success rate of EUS-GTD for WON[4,7]. A comparison of these results with our study is difficult because the definition of treatment success was different in each study, which in turn differed from our study, which was based on the 2012 Atlanta classification. A recent report, based on the 2012 Atlanta classification, revealed that the standard EUS-GTD using plastic stents or self-expandable metal stents resolved 70% of sterile WON and 40% of infected WON; however, the rest of WON required EN[15].

After treatment failure by EUS-GTD for WON, EN or other intervention, including surgical treatment, should be considered. A recent randomized controlled trial suggested that the IL-6 level following EN was significantly lower than that following surgical necrosectomy and that major complications or death occurred less frequently after EN compared to those after surgical necrosectomy[16]. Although EN should be

considered for WON that cannot be resolved by EUS-GTD, serious complications of EN have been reported. Recently, while three multiple-center trials revealed 75%-91% success rate of EN, the associated mortality and morbidity rated were 5.8%-11% and 26%-33%, respectively[17-19]. In our study, we performed EN on 4 patients, and one patient died due to multiple organ failure. Therefore, if possible, it is better to accomplish the resolution of WON by EUS-GTD alone.

Some factors associated with the failed resolution of WON by EN or standard drainage and EN have been reported, including body mass index > 32[18], American Society of Anesthesiologists physical status classification ⩾ 3[19], and multilocular morphology[15]. In this study, we elucidated that the treatment success rate of EUS-GTD alone for WON was significantly lower in patients with more than 50% pancreatic parenchymal necrosis or with a PFC of more than 150 mm on CT. All patients with WON with more than 50% parenchymal necrosis and with a PFC of more than 150 mm needed an additional treatment such as EN, whereas the treatment success was achieved in 90% patients with under 50% pancreatic parenchymal necrosis and within a PFC of 150 mm by EUS-GTD alone (Figure 2). If we can predict the treatment outcome by EUS-GTD with these parameters, we may be able to avoid unnecessary invasive therapy or make an earlier decision to perform additional treatment in a few days.

Instead of EUS-GTD, multiple transmural gateway technique for WON has been reported, and the treatment success rate of multiple transmural gateway technique was significantly better than that of EUS-GTD (94.4% *vs* 62.1%)[20,21]. More recently, novel, fully covered biflanged metal stents have been reported to be effective for the treatment of WON[9-12]. Regarding the use of these stents, high cost, stent migration, and other potential adverse events have been concerning[22]; therefore, optimal selection for using these stents is needed. According to our study, patients with PFC more than 50% pancreatic parenchymal necrosis or patients with more than 150 mm may be appropriate candidates for these treatments.

The proportion of pancreatic parenchymal necrosis could be associated with the amount of solid debris in the cavity of WON. Reportedly, the morphological findings of WON on EUS have therapeutic implications owing to the large size and more solid debris needing a more aggressive therapeutic method[23]. However, it is often challenging to estimate the necrotic component with the whole observation of PFC on EUS. In addition, even if rich debris seemed to exist in the cavity by EUS, some cases of WON could be resolved by EUS-GTD alone, as shown in Figure 2.

In this study, PPC was relatively rare (10.7%) based on the values in the 2012 Atlanta classification. Notably, 8 of 11 patients categorized as PPC were caused by acute pancreatitis occurring in the setting of known chronic pancreatitis and 3 were atypical etiology of pancreatitis (drug-induced in 2 patients and idiopathic in 1 patient). The treatment success rate of 90.9% for PPC in this study was higher than that of WON.

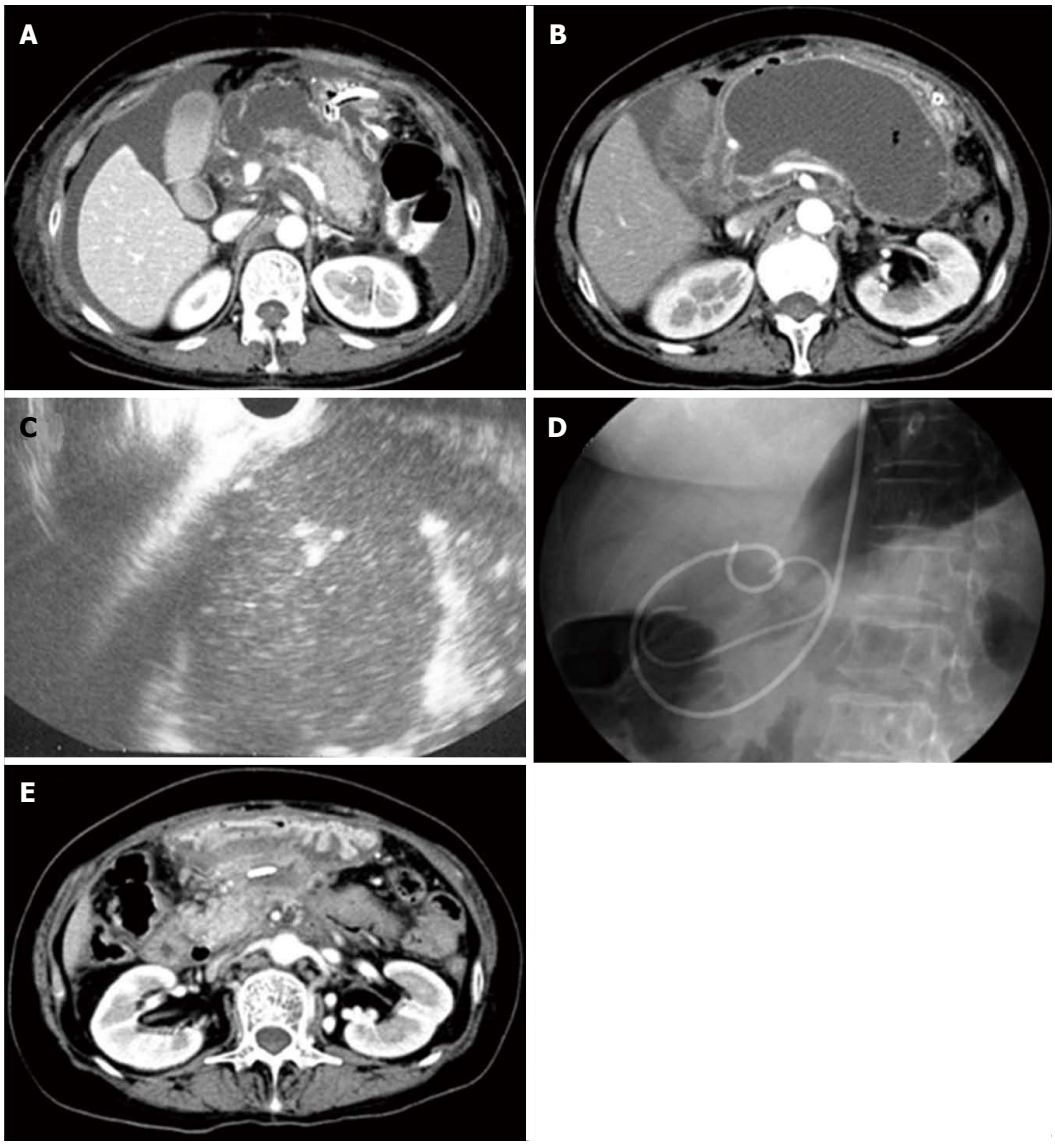

Figure 2 Representative case of walled-off necrosis resolved by endoscopic ultrasound-guided transmural drainage alone. A: Computed tomography of the abdomen (axial image) showing less than 50% pancreatic parenchymal necrosis; B: Pancreatic fluid collection was 135 mm in diameter; C: Rich debris seemed to exist in the cavity as shown by endoscopic ultrasound; D: Endoscopic ultrasound guided transmural drainage was performed and pancreatic fluid collection culture was positive; E: Cavity was reduced at 6 wk after intervention.

EUS-GTD for chronic pseudocysts was successful. In chronic pancreatitis, PFC often communicates with the main pancreatic duct and stricture of this duct exists. To manage chronic pseudocysts, a combination of EUS-GTD with transpapillary drainage or ESWL for pancreatic stones might be effective.

After successful initial treatment following EUS-GTD for PFC, recurrence of PFC in the long term was higher in patients with higher amylase level in the cavity, indicating the communication of PFC with the pancreatic duct such as chronic pseudocysts or DPDS. DPDS is characterized by the main pancreatic duct cut-off, with an inability to access the upstream pancreatic duct during an ERCP, and CT evidence of viable pancreatic tissue upstream (toward the spleen), in association with a persistent non-healing pancreatic fistula or PFC[24,25]. We routinely removed internal stents following the resolution of PFC almost 6 mo after EUS-GTD. Although a permanent stent placement significantly reduced PFC recurrence in comparison with scheduled stent removal, migrated stents caused bowel obstruction that required surgery[21]. In cases with higher amylase levels in the cavity, transpapillary treatment or prolonged stent placement for more than 6 mo should be considered. However, the timing of stent removal and permanent stent placement remains controversial, and further study is required.

There were some limitations in this study. First, this was a retrospective study conducted at a single tertiary center and the number of patients with WON was relatively less. Second, the study period was long (16 years) and a learning curve might have influenced the results, although the standard technique for EUS-GTD has not changed. Third, there may have

been a selection bias because we could not examine all patients with the amylase level in the cavity consecutively.

In conclusion, EUS-GTD is a successful and safe therapeutic technique in a majority of patients with PFC. The cavity size and proportion of pancreatic parenchymal necrosis are predictors for a successful treatment of WON. Higher amylase levels in the cavity might lead to PFC recurrence after stent removal. A prolonged stent placement should be considered in such cases.

ARTICLE HIGHLIGHTS

Research background

The 2012 Atlanta classification categorized PFC into four types. The revised classification suggests that many PFCs after acute pancreatitis that were treated as pancreatic pseudocyst (PPC) because of slight debris in the cavity should be addressed as walled-off necrosis (WON). Most patients with PPC achieved treatment success by EUS-GTD alone. Although endoscopic necrosectomy (EN) was performed in patients with no clinical improvement by EUS-GTD, serious complications of EN have been reported. However, the criteria for WON that should be treated by EN or other additional treatment remained unclear. Therefore, it is crucial to clarify the cases that can be resolved by EUS-GTD alone and those that should be treated with EN or other treatment in addition to EUS-GTD. Some PFCs develop the recurrent fluid collection in long term. Recommendations of permanent stent placement have been reported to reduce recurrence; however, stent migration or obstruction is concerned. A predictive factor of PFC recurrence should also be clarified.

Research motivation

The treatment success rate of WON by EUS-GTD alone was relatively lower than that of PPC. It is unclear that which patients with WON can be treated by EUS-GTD alone and which ones by EN or other additional treatment including metallic stents. Despite initial treatment success, some PFCs develop the recurrent fluid collection in the long term. It is also unclear which types of PFCs show recurrence.

Research objectives

We aimed to evaluate the short- and long-term results of EUS-GTD for PFC following a revision of the PFC framework by the 2012 Atlanta classification and identify the predictive factors of treatment outcome for WON managed by EUS-GTD alone and predictive factors for recurrence of PFC.

Research methods

The authors retrospectively investigated 103 consecutive patients with PFC who underwent EUS-GTD between September 1999 and August 2015 at Chiba University Hospital. The factors associated with clinical success and recurrence were determined using statistical comparisons. In patients with WON, multiple logistic regression analyses were performed to identify the predictor variables associated with the treatment success. In addition, PFC recurrence was examined in patients followed up over 6 mo and confirmed internal stent removal after successful EUS-GTD. The optimal cut-off value of the variables that differentiated between recurrence and no recurrence was determined by the receiver-operating characteristic analysis. In addition, area under the curve was calculated. The statistical significance was determined as $P < 0.05$.

Research results

The treatment success rate of WON, PPC, chronic pseudocyst, and others was 57.5%, 90.9%, 91.0%, and 89.5%, respectively. The treatment success rate of WON was significantly lower in patients with more than 50% pancreatic parenchymal necrosis (OR = 17.0: 95%CI: 1.9-150.7; $P = 0.011$) and in patients with more than 150 mm of PFC (OR = 27.9; 95%CI: 3.4-227.7; $P = 0.002$) on contrast-enhanced computed tomography using the multivariate logistic regression analysis. The recurrence of PFC in the long term was 13.3% (median observation time, 38.8 mo). Mean amylase level in the cavity was significantly higher in the recurrence group than in the no recurrence group ($P = 0.02$). In cases with higher amylase levels in the cavity, transpapillary treatment or prolonged stent placement for more than 6 mo should be considered. However, the timing of stent removal and permanent stent placement remains controversial, and further study is required.

Research conclusions

Reduction of WON by EUS-GTD alone was associated with the proportion of necrotic tissue and the extent of the cavity. Amylase level in the cavity may be a predictive factor for recurrence of PFC.

According to our study, additional treatments, such as EN, should be considered after EUS-GTD in patients with WON with more than 50% parenchymal necrosis and a PFC of more than 150 mm, whereas it may not be needed with under 50% pancreatic parenchymal necrosis and within a PFC of 150 mm.

After successful initial treatment following EUS-GTD for PFC, recurrence of PFC in the long term was higher in patients with higher amylase level in the cavity. This finding indicates the communication of PFC with the pancreatic duct such as chronic pseudocyst or disconnected pancreatic duct syndrome. Therefore, in cases with higher amylase levels in the cavity, transpapillary treatment or prolonged stent placement should be considered.

Research perspectives

In this study, we confirmed that the PFC size and the proportion of pancreatic parenchymal necrosis were related to the resolution of WON treated by EUS-GTD alone. If we can predict treatment outcome of WON by EUS-GTD alone, we might be able to avoid unnecessary invasive therapy or make an earlier decision to perform an additional treatment. Moreover, if we can predict recurrence of PFCs by the amylase level in the cavity, we might be able to reduce the recurrence of PFCs with prolonged stent placement or transpapillary treatment. Prospective studies with larger numbers of patients will be needed to confirm the reliability of these predictive factors.

Abstract

AIM

To assess the diagnostic value of a laparoscopic finding of a hepatic subcapsular spider-like telangiectasis (HSST) sign in biliary atresia.

METHODS

A retrospective study was conducted first and then a validation set was used to investigate the value of an HSST sign in predicting biliary atresia (BA). In the

retrospective study, laparoscopic images of the liver surface were reviewed in 126 patients with infantile cholestasis (72 BA patients and 54 non-BA cholestasis patients) and a control group of 38 patients with non-hepatic conditions. Analysis was first made by two observers separately and finally, a consensus conclusion was achieved. Then, the diagnostic value of the HSST sign was validated in an independent cohort including 45 BA and 45 non-BA patients.

RESULTS

In the retrospective investigation, an amplified HSST sign was found in all BA patients, while we were unable to detect the HSST sign in 98.1% of the 54 non-BA patients. There was no HSST sign in any of the control subjects. In the first review, the sensitivity and specificity from one reviewer were 100% and 98.1%, respectively, and the results from the other reviewer were both 100%. The consensus sensitivity and specificity were 100% and 98.1%, respectively. The HSST sign was defined as being composed of several enlarged tortuous spider-like vascular plexuses with two to eight branches distributed on all over the liver surface, which presented as either a concentrated type or a dispersed type. In the independent validation group, the sensitivity, specificity, positive predictive value and negative predictive value of the HSST sign were 100%, 97.8%, 97.8% and 100%, respectively.

CONCLUSION

The HSST sign is characteristic in BA, and laparoscopic exploration for the HSST sign is valuable in the diagnosis of BA.

Key words: Laparoscopic hepatic subcapsular spider-like telangiectasis sign; Infantile cholestasis; Biliary atresia; Infantile hepatitis; Laparoscopy; Diagnosis; Pediatric surgery

Core tip: Color Doppler ultrasound finding of hepatic subcapsular flow has shown much potential for discriminating biliary atresia (BA). While in clinical practice, we have noticed a similar but more intuitive phenomenon - a laparoscopic finding of hepatic subcapsular spider-like telangiectasis (HSST) sign, which may be a specific marker for BA. Based on the current data, we found that the sensitivity and specificity of the HSST sign were each generally close to 100%.

INTRODUCTION

Biliary atresia (BA), as a common neonatal cholangiopathy that leads to cirrhosis[1], is the most common indication for liver transplantation in infants[2,3]. The incidence of BA ranges from 1 in 5000 (Asian countries) to 1 in 19000 (European countries) live births, and it presents with typical symptoms and signs such as persistent jaundice, acholic stools and hepatomegaly within the first months of life[2]. This disease is characterized by a progressive fibro-obliterative obstruction of extrahepatic bile ducts. A younger age (in the first 2 mo of life) at the time of Kasai portoenterostomy has been found to be life-saving in restoring bile flow and preventing the worsening of liver function[4,5]. Thus, early discrimination is vital for the prognosis. Nevertheless, it is still challenging to differentiate BA from other cholestatic diseases as there are no characteristic manifestations found in the early stage of BA.

Clinic features, such as prolonged jaundice, pale stools and high conjugated hyperbilirubinemia, are remarkable, but they are not specific[6]. The ultrasonographic findings of an abnormal gall bladder and triangular cord sign have been widely used in early discrimination of BA[6,7], but the accuracy of these measurements varies[8-15]. A recent study showed that the absence of a gallbladder and the triangular cord sign could both have the highest specificity, up to 99%, but a sensitivity of 28% and 80%, respectively[14]. Other examinations are also compelling, but the value is limited. A duodenal fluid test is difficult to perform. Definite biliary excretion shown by scintigraphy can exclude BA, however, the absence of excretion is not specific in BA because of it can be attributed to any form of severe cholestasis[2,16]. Due to the small diameter of and inadequate fluid in biliary ducts, magnetic resonance cholangiopancreatography (MRCP) plays a limited role in showing the biliary tree in normal infants younger than 3 mo[17]. Therefore, the high false positive rate in predicting BA is inevitable. Moreover, the pathological features of BA are bile ductular proliferation, canalicular and cellular bile stasis, bile plugs, and portal or perilobular fibrosis with preservation of the basic hepatic lobular architecture[5,18,19], which overlap with α-1-antitrypsin deficiency, and occasionally Alagille syndrome, cystic fibrosis, and total parenteral nutrition (TPN)-related cholestasis[5].

Cholangiography is the gold standard, and a definitive diagnosis of BA can be made when cholangiography fails to show the biliary tree[1]. Laparotomy cholangiography was previously used and was refused by some parents because of the abdominal trauma and incision complications, which finally led to the delay of diagnosis. Recently, with the application

of laparoscopy in pediatric surgery, laparoscopy-assisted cholangiography (LAC) has become possible. In our center, we performed laparoscopy-assisted cholangiography on infants who were highly suspected of having BA before the Kasai portoenterostomy was developed[20]. During the procedure, we found that a prominent pathological change on the liver surface - a hepatic subcapsular spider-like telangiectasis (HSST) sign - had a strong correlation with BA.

The current report includes a retrospective study and a prospective study, which aimed to investigate the significance of the laparoscopic finding of an HSST sign in differentiating BA from other causes of neonatal cholestasis.

The study was approved by the Ethics Committee of Tongji Medical College, Huazhong University of Science and Technology, and all parents of the patients signed the inform consent. Before the parents signed the consent form for surgery, they were informed that the procedure was minimally invasive and that the procedure would be carried out *via* a small incision at the umbilicus ring and one stab incision in the left abdominal wall. Parents were told that there was a chance of needing additional trocars or conversion to an open technique. Advantages and disadvantages were reviewed to ensure that the parents were fully educated about the procedure.

MATERIALS AND METHODS

Retrospective and clinical investigation

An HSST sign in laparoscopic images was evaluated in cholestasis cases and a control group.

Patients: Laparoscopic images of the liver surface were reviewed in 126 patients with infantile cholestasis who underwent laparoscopic cholecystocholangiography or laparoscopic exploration at our center between February 2011 and February 2015. Among the 126 patients, 72 (31 boys, 41 girls; mean age, 58 d ± 29 d) were diagnosed with BA on the basis of laparoscopic cholangiography or exploration (when cholangiography failed due to the presence of atrophic gallbladder), and the other 54 (24 boys, 30 girls; mean age, 59 d ± 21 d) were diagnosed with non-BA conditions, which included infantile hepatitis (n = 46), biliary hypoplasia (n = 5) and total parenteral nutrition (TPN) induced cholestasis (n = 3). Their final diagnoses were confirmed by LAC, pathological examination or clinical follow-up. Another 38 patients (19 boys, 19 girls; mean age, 63 d ± 22 d) without jaundice or liver disease who underwent laparoscopic surgery served as controls. Their clinical diagnoses were Hirschsprung's disease (n = 34) and intussusception (n = 4).

Laparoscopic findings: Laparoscopic images (5 mm or 10 mm optical laparoscopy, pediatric HOPKINS Ⅱ 26003BA, STORZ, Germany) of the liver surface were evaluated by two observers separately and blindly (Zhou Y and Jiang M) to screen for the presence or absence of the HSST sign. The HSST sign was preliminarily defined as enlarged tortuous spider-like vascular plexuses distributed on the liver surface.

Statistical analysis: The results are expressed as the mean ± SD or number (percentage). For quantitative data, statistical significance between groups was tested using a two-sample t test. For qualitative data (sex), significance between groups was tested by a χ^2 test. Sensitivity and specificity were calculated for the HSST sign with the method of Newcombe[21]. Individual readings were calculated first; consensus readings were calculated thereafter (by professor Tang ST). Meanwhile, we applied Cohen's κ coefficient to assess the agreement between the analyses conducted by the two observers. Logistic regression analysis was applied to determine whether the presence of the HSST sign was useful in discriminating BA. A P-value of < 0.05 was considered statistically significant. SPSS 13.0 software (SPSS, IL, United States) was used for data analyses.

Validation of the HSST sign

The diagnostic value of the HSST sign was validated in an independent cohort composed of 45 BA and 45 non-BA patients.

Patients: Between February 2015 and April 2017, we enrolled a consecutive series of patients who were highly suspected of having BA. The enrollment criteria in our series included the following: (1) icterus was gradually aggravated after the first 3-4 wk; (2) consistent depigmented stool; and (3) traditional diagnostic examinations (*i.e.*, physical examination, blood biochemical examination, ultrasonography, hepatobiliary scintigraphy, MRCP, *etc*.) failed to achieve a definitive diagnosis[20]. The children's general information, including gender, age and biochemical parameters [the level of total and direct serum bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and gammaglutamyl transpeptidase (GGT)] were carefully documented.

Validation protocol: All enrolled patients underwent laparoscopic exploration for the HSST sign before LAC. The patient was considered to be BA when the HSST sign was detected. The final diagnosis was confirmed by LAC.

Pathologic evaluation: After surgery, patients underwent pathologic examination. The hepatic subcapsular spider-like vessels were confirmed by gross inspection, well preserved on the prepared tissue, and evaluated with a microscope.

Statistical analysis: The results are expressed as the mean ± SD or number (percentage). A two-sample *t* test was used to compare quantitative parameters between patients with BA and non-BA patients. A χ^2 test was used to compare the male-to-female ratio between patients with BA and non-BA patients. The cut-off values for optimal clinical performance (best sensitivity and best specificity simultaneously) of individual parameters were determined from the receiver-operating characteristic (ROC) curve. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated for the HSST sign using the method of Newcombe[21]. A *P*-value of < 0.05 was considered statistically significant. SPSS 13.0 software (SPSS, IL, United States) was used for data analysis.

RESULTS

Retrospective and clinical investigation

The two groups were age- and sex- matched (P > 0.05 for both). The mean levels of total bilirubin, direct bilirubin, AST and ALT in the BA group showed no significant difference compared to the non-BA group. The mean level of GGT was significantly higher in the BA group than in the non-BA group (P = 0.02). Total bilirubin, direct bilirubin, ALT, AST and GGT levels were normal in the controls (Table 1).

An amplified HSST sign was identified in all patients with BA (Figure 1A) and was not found in any of the control subjects by both observers (Figure 1 B). One observer (Jiang M) determined that there was no HSST sign in 53 (98%) non-BA patients (Figure 1C-E), except for one patient with cytomegalovirus (CMV) hepatitis (Figure 1F). The other observer (Zhou Y) had the opinion that there was no HSST sign in all patients with non-BA. After discussion, the discrepancy was resolved. The sensitivity and specificity of the HSST sign were 100% and 98.1%, respectively (Table 2).

The HSST sign was widely distributed on the surface of both left and right hepatic lobes, including on the visceral and diaphragmatic facies (Figure 2). Thus, we redefined the HSST sign as follows: it is composed of several enlarged tortuous spider-like vascular plexuses with four to eight branches distributed all over the liver surface, which presents as a dispersed type (radiating branches originate from more than one central point, but close to each other to form a spider-like sign) (Figure 3A) or a concentrated type (radiating branches originate from one central point) (Figure 3B).

Logistic regression analysis showed that the presence of the HSST sign was a significant predictor of BA (P < 0.01). In addition, the concordance between the two observers was also robust (κ = 0.94, 95%CI: 0.87–1.0).

Validation of the HSST sign

Characteristics of patients: The mean age of the BA group was 60 d ± 29 d. The mean age of the non-BA group was 61 d ± 23 d. In the non-BA group, the final diagnoses were infantile hepatitis (n = 43) and biliary hypoplasia (n = 2). As shown in Table 3, there was no significant difference between the BA and non-BA groups in age or male-to-female ratio (P > 0.05 for both). The mean levels of total bilirubin, direct bilirubin, AST and ALT in BA patients had no significant difference compared to those in the non-BA group. The mean level of GGT was significantly higher in the BA group than in the non-BA group (P < 0.001).

Diagnostic performance of the HSST sign: On high-definition laparoscopic images (5 mm or 10 mm optical laparoscopic, pediatric HOPKINS Ⅱ 26003BA, STORZ, Germany), the HSST sign in all BA patients was easily observed (Figure 4A). There were no HSST sign observed in non-BA patients, except for one patient (Figure 4B). The patient was considered to have BA due to the presence of the HSST sign, whose final diagnosis was biliary hypoplasia. The sensitivity, specificity, PPV and NPV of the HSST sign were 100%, 97.8%, 97.8% and 100%, respectively.

Pathologic evaluation: The hepatic subcapsular spider-like vessels were clearly identified in the stained tissue. The vessels in the BA group were revealed as dilated branches of hepatic arteries in the hepatic subcapsular area (Figure 4C) and the vessels in hypoplasia were revealed as hyperplastic capillaries in the hepatic subcapsular area (Figure 4D).

DISCUSSION

A large sample study focused on GGT showed that it was higher in the BA group than in other cholestatic disorders for all age groups[22], which was coincident with our results. In our validation set, we found that the area under the receiver operating characteristic curve was 0.745 and GGT at a cut-off value of > 404 U/L had a 64.4% sensitivity and 84.4% specificity in discriminating BA. A level of 300 U/L was also previously reported by Liu *et al*[16] with 85% accuracy. However high it may be, we cannot confirm BA directly by GGT alone.

In the entire study, there were 14 BA patients (6 in the retrospective study and 8 in the validation set) below the age of 40 d (with the minimum age of 20 d), in whom the HSST sign was observed but there was no liver cirrhosis at gross inspection (Figure 5A). The HSST sign was also found in 10 patients with BA (8 in the retrospective study and 4 in the validation set) who were older than 90 d (91-163 d) (Figure 5B). Based on the above data, the presence of the HSST

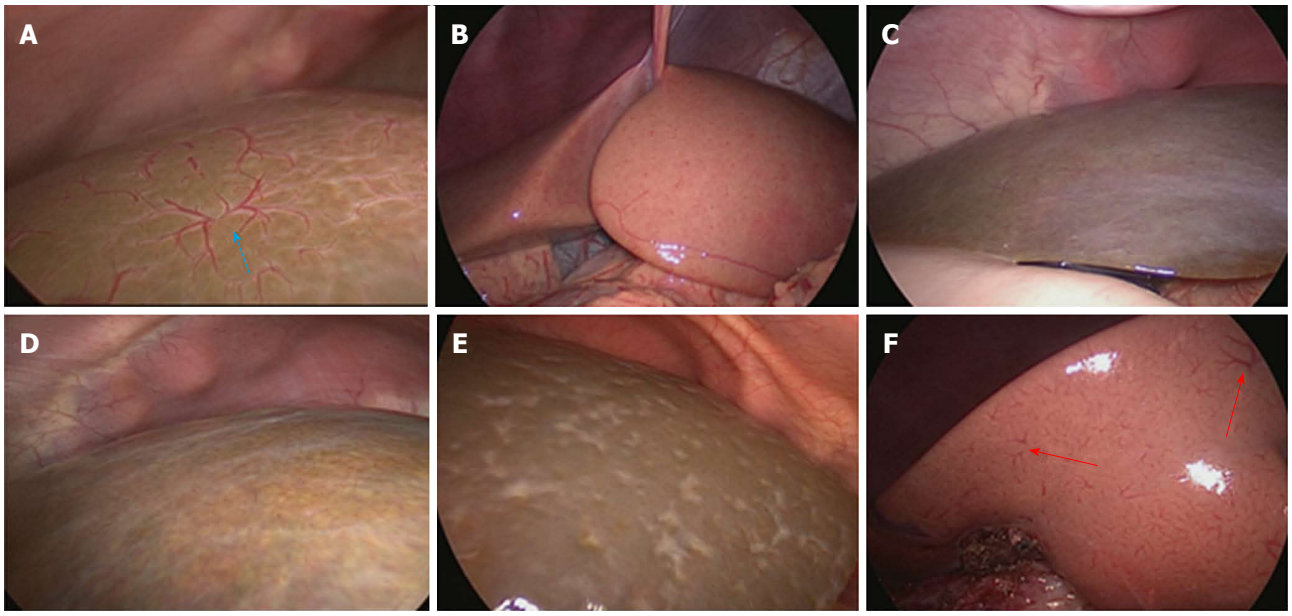

Figure 1 Laparoscopic images of the liver surface in the retrospective study. The HSST sign does not exist in the images B-E. HSST: Hepatic subcapsular spider-like telangiectasis.

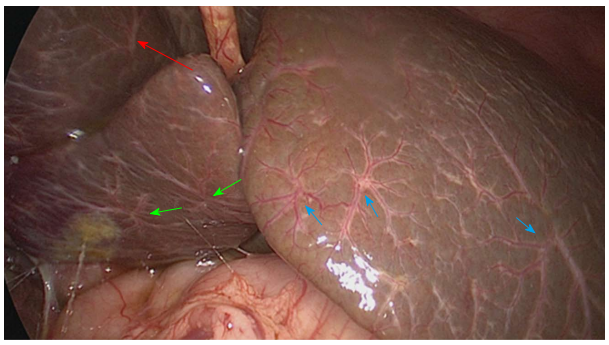

Figure 2 Hepatic subcapsular spider-like telangiectasis sign in a 68-day-old boy with biliary atresia. A hepatic subcapsular spider-like telangiectasis sign was widely distributed on the liver surface, including on the visceral facies of the right liver lobe (red arrow), on diaphragmatic facies of the left liver lobe (blue arrows) and on the surface of the caudate lobe (green arrows).

sign may not have a close relationship with hepatic fibrosis or cirrhosis. It is known that CMV infection was one causative factor of BA and may result in a delayed diagnosis and surgical treatment[23,24]. Mohanty *et al*[25] reported two cases of CMV infection, initially presenting with intrahepatic cholestasis, who subsequently developed BA. Whether the pathological change in the perivascular arterial tufts is the causative factor or results from the developmental of BA is still unknown and needs further investigation.

Ultrasonography (US) has been widely used in differentiating BA from other causes of jaundice. Hepatic subcapsular flow (HSF) in color Doppler US was documented as being useful to predict BA[8,15,18,26] and had the highest performance in discriminating BA from non-BA conditions among several parameters[18]. However, most of the neonates or infants were uncooperative during color Doppler US examination and other factors, such as the doctor's experience, machines, and patients' respiration intensities, also played an important role. Additionally, Takamizawa *et al*[9] debated that US alone could not rule out BA and laparotomy remained mandatory if BA was suspected. Therefore, we conducted this study and finally determined that the HSST sign was useful for predicting BA with a 100% sensitivity and 97.8% specificity. Here, we had a 53-day-old patient with a pre-operative icteric index of 149.9 but unobvious yellowing of the skin. As shown in the picture, the laparoscopic HSST sign (Figure 6A) and the result of LAC (Figure 6B) were easier to identify than distinguishing HSF in a color Doppler US image (Figure 6C).

A similar phenomenon was also observed in Lee's[8] and Ramesh's[27] studies. These authors reported that patients with BA who had hepatic subcapsular flow on color Doppler US images also had subcapsular telangiectatic vessels on the liver surface at the time of the Kasai procedure. In these reports, four patients with TPN-induced cholestasis and two with CMV hepatitis were considered as having HSF[8,15,18]. In our retrospective study, three patients with TPN-induced cholestasis cirrhosis were encountered, but no HSST sign was detected (Figure 2E). In our validation set, there were also two cases of infantile hepatitis who were considered as having HSF, while the HSST sign did not exist. The laparoscopic amplification effect on an intuitive view of the liver surface and ultrasonic

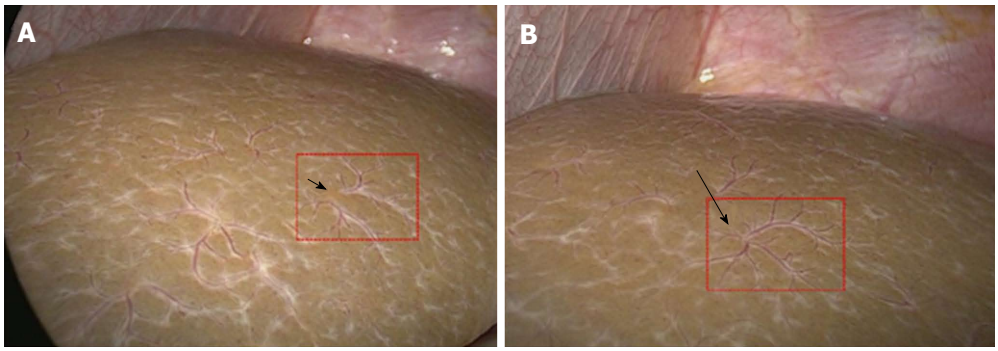

Figure 3 Different types of hepatic subcapsular spider-like telangiectasis signs. artifacts may be the cause of this difference. Moreover, better concordance (κ = 0.937) was achieved through the amplified intuitive view.

Although the signal of hepatic subcapsular vessels was found with US, these vessels on laparoscopic images had their own characteristics: (1) intuitive and stable view of liver surface that was not influenced by interference (machines, doctors' experiences, thickness of the abdominal wall, *etc.*); (2) the HSST sign could be observed not only on the diaphragmatic surface but also on the visceral surface; and (3) images were magnified 4-8 times, which made the view of liver surface clear and vessels easily identified.

Microscopic examinations revealed dilated small arteries in the hepatic subcapsular area in patients with BA, which is consistent with Lee's[8] and El-Guindi's[15] studies. These vessels were branches of hepatic arteries, instead of capillaries in the hepatic capsule. Until now, this phenomenon was not mentioned for other liver diseases. The findings of arterial hyperplasia or hypertrophy in liver specimens and the enlargement of the hepatic artery on color Doppler US imaging in BA patients were also documented[15]. It has also been

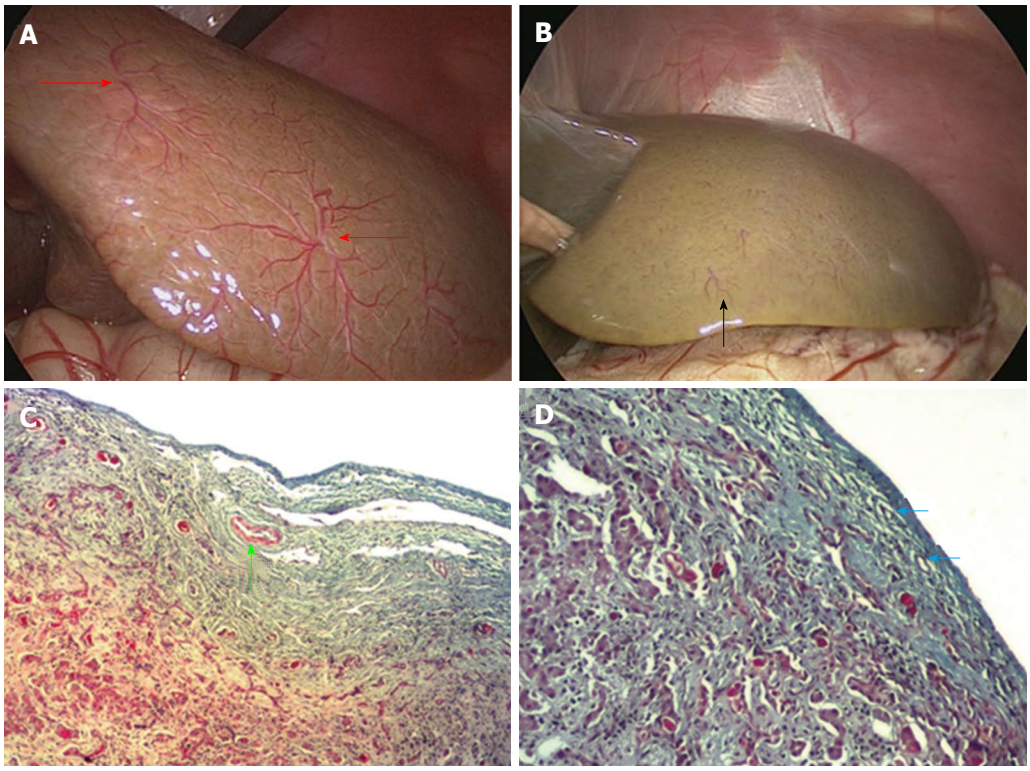

Figure 4 Hepatic subcapsular spider-like telangiectasis sign and pathologic evaluation in the validation set. (Trichrome staining; ×100). HSST: Hepatic subcapsular spider-like telangiectasis; BA: Biliary atresia.

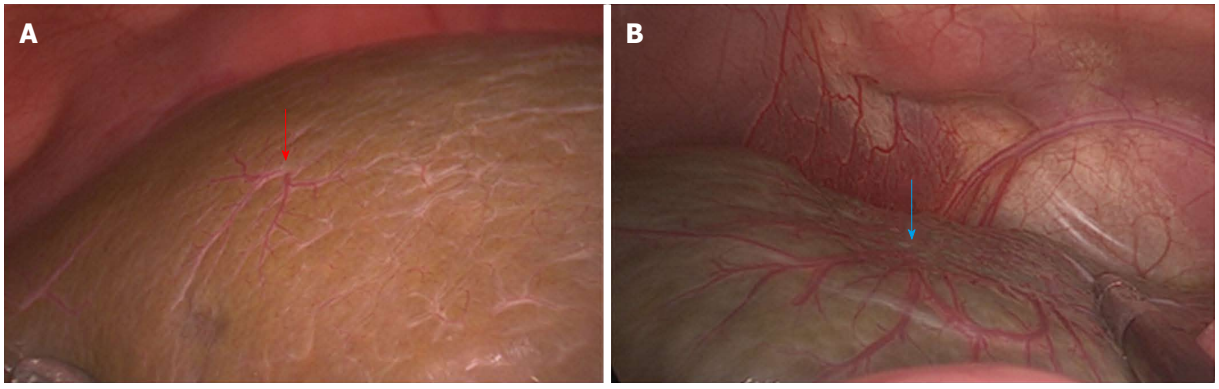

Figure 5 Laparoscopic images of hepatic subcapsular spider-like telangiectasis sign in biliary atresia patients at different ages. A: HSST sign (red arrow) in a 40-day-old boy with BA. There was no cirrhosis at gross inspection; B: HSST sign (blue arrow) in a 156-day-old boy with BA, who had hepatic cirrhosis with ascites and underwent liver transplantation. The HSST sign is obvious in both patients. HSST: Hepatic subcapsular spider-like telangiectasis; BA: Biliary atresia.

reported that the arterial changes might be driven by primary growth signals, or represent a response to a diseased micro-environment that might be rich in growth promoting signals that favor angiogenesis[28-32]. Similarly, the HSST sign is one of the arterial changes in an intuitive view. As with the HSST sign in images 1-5, they were not quite the same and this difference might help in predicting prognoses in the future. Whether it is a primary change of BA or secondary to the bile duct inflammation is unknown and will be our next focus of study.

At present, the procedure for addressing BA patients is a routine examination followed by laparotomy or laparoscopic cholangiography and a laparotomy Kasai operation. For the laparoscopic cholangiography, two or three 5-mm trocars and 30-45 min are needed with one or two instances of radiation exposure. However, with the application of the HSST sign, the

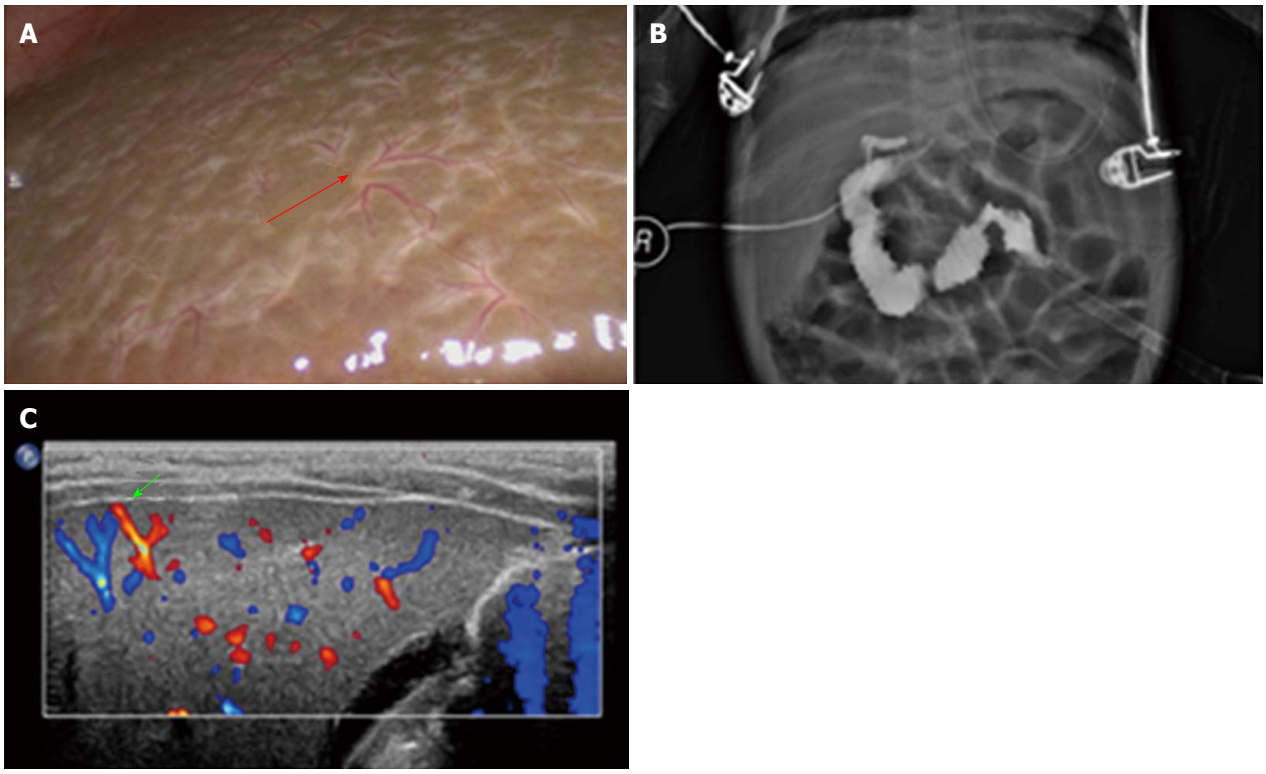

Figure 6 Images in a 53-day-old patient with biliary atresia. A: Dispersed type of the HSST sign (red arrow); B: Image of laparoscopic cholangiography indicates biliary atresia; C: Hepatic arterial flow extending to the hepatic surface on color Doppler US image (green arrow) indicates positive HSF. Laparoscopic HSST sign and the result of laparoscopic cholangiography were easier to identify than distinguishing HSF in a color Doppler US image. HSST: Hepatic subcapsular spider-like telangiectasis; US: Ultrasonography; HSF: Hepatic subcapsular flow.

procedure for addressing BA may become a routine examination followed by laparoscopic exploration for the HSST sign and a laparotomy Kasai operation in the future, which would shorten the operative time and radiation exposure and only needs one 5-mm trocar. The advantage is obvious especially for non-BA patients. In addition, it reflects the diagnostic function of laparoscopy in BA, similar to a laparoscopic diagnosis of hermaphroditism and inguinal hernias.

In conclusion, the HSST sign was preliminarily found to have a good performance in diagnosing or excluding BA with a 100% sensitivity and 97.8% specificity. According to an early laparoscopic exploration of the HSST sign, we can rapidly differentiate BA from non-BA cases and potentially further prevent the delay of a diagnosis of BA. However, given the limited sample size included in the analysis, the value of the HSST sign should be further confirmed in the future. Along with the further research, the HSST sign might be widely applied in clinical practice through a multicenter and large sample study in the future.

COMMENTS

Background

As a common neonatal cholangiopathy that leads to cirrhosis, biliary atresia (BA) is the most common indication for liver transplantation in infants. This disease is characterized by a progressive fibro-obliterative obstruction of extrahepatic bile ducts. A younger age (in the first 2 mo of life) at the time of Kasai portoenterostomy has been found to be life-saving in restoring bile flow and preventing the worsening of liver function. Nevertheless, it is still challenging to differentiate BA from other cholestatic diseases as there are no characteristic manifestations found in the early stage of BA. The demand for a specific and reliable test to diagnose BA has increased.

Research frontiers

Color Doppler ultrasound finding of hepatic subcapsular flow has shown much potential for discriminating BA. While in clinical practice, we have noticed a similar but more intuitive phenomenon - a laparoscopic finding of hepatic subcapsular spider-like telangiectasis (HSST) sign, which may be a specific marker for BA. This has not been published in previous literature.

Innovations and breakthroughs

According to these preliminary investigation, the HSST sign showed promising diagnostic performance for differentiating BA from any other cholestasis diseases, such as infantile cholestasis and cholestatic syndrome. The authors found that the sensitivity and specificity of the HSST sign were each generally close to 100%.

Applications

With the application of the HSST sign, the procedure for addressing BA may become a routine examination followed by laparoscopic exploration for the HSST sign and a laparotomy Kasai operation in the future, which would shorten the operative time and radiation exposure.

Terminology

The HSST sign is composed of several enlarged tortuous spider-like vascular

plexuses with four to eight branches distributed all over the liver surface, which presents as a dispersed type (radiating branches originate from more than one central point, but close to each other to form a spider-like sign) or a concentrated type (radiating branches originate from one central point).

Peer-review

Very interesting findings. It is worth to be published because of new findings of laparoscopic view for the surface of liver in biliary atresia

ACKNOWLEDGMENTS

We thank Professor Ping Ying for the statistical evaluation.

Abstract

AIM

To evaluate the short-term outcomes and quality of life (QoL) in gastric cancer patients undergoing digestive tract construction using the isoperistaltic jejunum-later-cut overlap method (IJOM) after totally laparoscopic total gastrectomy (TLTG).

METHODS

A total of 507 patients who underwent laparoscopic gastrectomy (D2) from January 2014 to March 2016 were originally included in the study. The patients were divided into two groups to undergo digestive tract construction using either IJOM after TLTG (group T, *n* = 51) or Roux-en-Y anastomosis after laparoscopic-

assisted total gastrectomy (LATG) (group A, n = 456). The short-term outcomes and QoL were compared between the two groups after 1:2 propensity-score matching (PSM). We used a questionnaire to assess QoL.

RESULTS

Before matching, age, sex, tumor size, tumor location, preoperative albumin and blood loss were significantly different between the two groups (P < 0.05). After PSM, the patients were well balanced in terms of their clinicopathological characteristics, although both blood loss and in-hospital postoperative days in group T were significantly lower than those in group A (P < 0.05). After matching, group T reported better QoL in the domains of pain and dysphagia. Among the items evaluating pain and dysphagia, group T tended to report better QoL ("Have you felt pain" and "Have you had difficulty eating solid food") (P < 0.05).

CONCLUSION

The IJOM for digestive tract reconstruction after TLTG is associated with reduced blood loss and less pain and dysphagia, thus improving QoL after laparoscopic gastrectomy.

Key words: Esophagojejunostomy; Overlap; Later-cut; Totally laparoscopic total gastrectomy; Quality of life

Core tip: This paper used propensity score-matched analysis and questionnaire survey to evaluate the short-term outcomes and quality of life (QoL) in patients who underwent digestive tract reconstruction using the isoperistaltic jejunum-later-cut overlap method (IJOM) after totally laparoscopic total gastrectomy (TLTG) and in patients who underwent Roux-en-Y anastomosis after laparoscopic-assisted total gastrectomy. We found the IJOM for digestive reconstruction after TLTG is associated with reduced blood loss and less pain and dysphagia, thus improving the QoL after laparoscopic gastrectomy.

INTRODUCTION

Since Kitano *et al*[1] reported laparoscopic-assisted distal gastrectomy in 1991, laparoscopic techniques and instruments have improved substantially. Consequently, totally laparoscopic distal gastrectomy is increasingly employed and has a proven history of safety and feasibility[2-8]. However, although scholars have reported a variety of totally laparoscopic total gastrectomy (TLTG) methods[3,9-13], this technique has not been widely adopted because of the technological difficulty inherent in digestive reconstruction. Interest in improving the postoperative appearance and quality of life (QoL) in patients with gastric cancer has been increased. This goal, combined with the reduced trauma associated with TLTG, has heightened interest in developing ways to improve TLTG. Surgeons have primarily adopted the overlap or functional end-to-end method for digestive tract reconstruction after TLTG. However, these methods have drawbacks, such as jejunal freeness, which is seen particularly frequently with large anastomoses. Therefore, we devised the isoperistaltic jejunum-later-cut overlap method (IJOM), which involves esophagojejunostomy anastomosis after TLTG. Using this technique, we believe that the jejunum can be positioned with greater ease, thereby reducing the difficulties encountered with the anastomosis. However, little is known about the short-term outcomes and QoL of patients following the implementation of this IJOM for digestive reconstruction after TLTG. Thus, this study aimed to assess the short-term outcomes and QoL in gastric cancer patients undergoing digestive tract reconstruction with IJOM after TLTG and with Roux-en-Y anastomosis after LATG using propensity-score matching (PSM)[14,15] and a QoL assessment scale.

MATERIALS AND METHODS

Study population and inclusion/exclusion criteria

Between January 2014 to March 2016, data were collected from 703 patients who underwent laparoscopic gastrectomy at Fujian Medical University Union Hospital. The including criteria were: (1) pathologically proved gastric cancer by endoscopic biopsy specimen analysis; (2) the aforementioned examination indicated no evidence of distant metastasis; and (3) postoperative pathological diagnosis was curative R0. The exclusion criteria were: (1) intraoperatively proved distant metastasis; (2) T4b stage; (3) missing pathological data; (4) neoadjuvant therapy; and (5) comorbidities that could influence QoL (*e.g.*, previous or combined malignancies; cardiovascular disease; cerebrovascular disease; neurological conditions, such as dementia and seizure; and severe chronic obstructive pulmonary disease requiring persistent medical aid). A number of 507 patients were eligible. Group T consisted of 51 patients who underwent the IJOM after TLTG, and group A comprised 456 patients who received a Roux-en-Y anastomosis after LATG. The 1:2 PSM was performed. Ultimately, group T included 51 patients and group A included 102 patients (Figure 1).

Table 1 Characteristics, merit and demerit of different esophagojejunostomy anastomosis techniques

Anastomosis surgeon	Characteristics	Merit	Demerit
Uyama *et al*[12]	The anastomosis line is vertical with esophageal long axis Jejunum is located in the right side of the esophagus.	Anastomotic is large enough	The number of anastomosis linear staplers is much
Matsui *et al*[37]	Complete the anastomosis before severed esophagus Close the stoma and resect specimens at the same time Jejunum is located in the right side of the esophagus	The number of anastomosis linear staplers is reduced	Probably develop dysphagia 6 mo after operation
Lee *et al*[13]	Suture esophagus, jejunum and right angle of diaphragm after anastomosis Jejunum is located in the right side of the esophagus	Reduce the incidence of esophageal hiatal hernia and anastomotic fistula	Increase the operation time
Okabe *et al*[38]	Before anastomosis, the specimens was removed Jejunum is located in the left side of the esophagus	The size of anastomotic stoma is bigger	The technique is difficult
Inaba *et al*[29]	Overlap anastomosis Divide the jejunum before anastomosis	Isoperistaltic anastomosis meets the physiological needs	The jejunum is free and difficult for anastomosis
Matsui *et al*[39]	Overlap anastomosis Divide the esophagus after anastomosis	Isoperistaltic anastomosis meets the physiological needs	The jejunum is free and difficult for anastomosis

Anastomosis step

In group T, the IJOM was performed after TLTG. After dissecting the lymph nodes laparoscopically and mobilizing the esophagus (Figure 2A) and the duodenum (Figure 2B), an endoscopic linear stapler was used to transect them sequentially in predetermined locations. Two small incisions were made on the left side of the resection margin of the esophagus (Figure 2C) and the antimesenteric border of the jejunum (Figures 2D) approximately 20 cm away from the ligament of Treitz, respectively.

Then, the two limbs of the stapler were inserted into each incision, respectively, and the forks of the stapler were closed and fired, achieving a side-to-side esophagojejunostomy (Figure 2E). After confirming that there was no bleeding *via* common stab incision (Figure 2F), the common stab was manually sutured (Figure 2G). Then, the jejunum was transected after baring the mesenteric border approximately 1 cm into the jejunum wall and approximately 3 cm away from the esophagojejunostomy (Figure 2H). After a small incision was made each on the antimesenteric border of the margin of the proximal jejunum and the distal jejunum roughly about 45 cm from esophagojejunostomy, the two limbs of the stapler were inserted into each incision, and the forks of the stapler were closed and fired to achieve a side-to-side jejunojejunostomy (Figure 2I). After confirming that there was no bleeding or damage to jejunal mucosa by common stab incision, the common stab incision was sutured laparoscopically (Figure 2J). Finally, we removed the specimen through a 3.5-cm incision on the lower abdomen. The differences between this method and other esophagojejunostomy anastomosis techniques are summarized in Table 1.

For patients in group T, the lymph nodes were dissected laparoscopically, and the esophagus and duodenum were mobilized. Then, the traditional open Roux-en-Y anastomosis was performed using a circular stapler[16].

Definition

All patients signed the informed consent form before operation. Preoperative computed tomography (CT) scanning, ultrasonography of the abdomen and endoscopic ultrasonography were routinely performed. When distant metastasis was suspected, positron emission tomography was performed. Preoperative morbidities were scored according to the Charlson score system[17]. Tumor staging was performed according to the 7th edition of the International Union against Cancer (UICC) classification[18]. Postoperative anastomosis-related complications were diagnosed by gastrografin esophagram or clinical manifestations and stratified using the Clavien-Dindo classification[19]. Perioperative death was defined as death that occurred during hospitalization. The Institutional Review Board

of Fujian Medical University Union Hospital approved this study.

QoL questionnaire

We used the validated Chinese version of the European Organization for Research and Treatment of Cancer 30-item core QoL questionnaire (EORTC-QLQ-C30)[20] to assess QoL. The questionnaire includes a global health status, five functional items, three symptom dimensions, and six individual symptom items (Table 2). Furthermore, we used the validated Chinese version of the 22-item EORTC-QLQ gastric cancer module (EORTC-QLQ-STO22)[21] to assess tumor-specific QoL. This questionnaire includes a functional scale, five symptom dimensions, and three individual symptom scales. QoL is represented by a score ranging from 0 to 100 for every scale. Better QoL is indicated by the higher scores in the functional scales of the EORTC-QLQ-C30 and lower scores in the symptom scores of EORTC-QLQ-C30 and STO22 (Table 2).

Follow-up

The follow-ups were performed *via* mailing, telephone call, or outpatient service. We explained the content of each item of the questionnaire to the patients 6 mo postoperatively, and the patients chose their own responses. Most patients underwent physical examinations, laboratory tests, chest radiography, abdominal ultrasonography or CT, and annual endoscopic examinations.

Statistical analysis

The Statistical Package for Social Science version 18.0 (SPSS, Chicago, IL, United States) was used to perform statistical analyses. The *t* tests or paired *t* tests were performed to compare continuous variables. χ^2 tests were performed to compare categorical variables. $P < 0.05$ was considered statistically significant.

RESULTS

Demographics and clinical characteristics

Before matching, age, sex, tumor location, tumor size, and preoperative albumin level differed significantly between the two groups ($P < 0.05$). After 1:2

matching, 51 and 102 patients were included in groups T and A, respectively, and well balanced in their clinicopathological characteristics (Table 3).

Perioperative results

After matching, blood loss and postoperative days of hospital stay were significantly less in group T than in group A ($P < 0.05$). The number of harvested lymph nodes, operative time, time to first flatus, time to fluid diet, and hospitalization costs were similar in the two groups (Table 4).

Postoperative complications

Before matching, one patient had an anastomotic fistula in group T. In contrast, Group A included 22 patients with anastomotic fistula, one with anastomotic hemorrhage and four with anastomotic obstruction. The incidences of anastomosis-related complications were 2.0% and 5.9% in groups T and A, respectively; the two rates were similar. After matching, there was one patient with anastomotic fistula in group T, whereas there were four patients with anastomotic fistula, one with anastomotic hemorrhage, and two with an anastomotic obstruction in group A. The incidence of anastomosis-related complications had no statistical difference in the two groups, and no perioperative deaths occurred (Table 5).

Functional scales

After matching, six patients died and one was lost to follow-up 6 mo postoperatively in group T. Eventually, 44 patients joined the questionnaire survey. In group A, ten patients died, and three were lost to follow-up. A total of 89 patients from group A participated in the questionnaire survey. The functional scales of EORTC-QLQ-C30 were all similar in both groups (Figure 2).

Symptom scales

After matching, the symptom scales of EORTC-QLQ-C30 and STO22 were compared. Based on the pain scales of EORTC-QLQ-C30 and dysphagia scales of EORTC QLQ-STO22, group T reported better QoL (Figure 3). Subgroup analyses of two items in the pain scale ("Have you felt pain?" and "Has your life been affected by pain?"), group T tended to report better QoL in "Have you felt pain?"($P = 0.018$). In the dysphagia scale, subgroup analyses of three items ("Have you had difficulty eating solid food?", "Have you had difficulty swallowing liquid or eating soft food?", and "Have you had difficulty drinking water?") revealed that group T tended to report better QoL in response to the question "Have you had difficulty eating solid food?" than group A ($P = 0.039$) (Table 6).

DISCUSSION

Laparoscopy offers several advantages over traditional laparotomy, such as reduced trauma, faster recovery, fewer postoperative complications, and greater aesthetic appeal. These benefits are attributable to the minimal invasiveness of laparoscopy and the good clinical outcomes that have been reported[22-25]. Currently, the methods of digestive tract reconstruction employed after LG include LATG and TLTG. In LATG, the digestive tract reconstruction is performed *via* a small incision after lymphadenectomy, although this decreases the advantages of laparoscopic minimally invasive surgery. Since Uyama *et al*[12] reported totally laparoscopic digestive tract reconstruction, substantial research in Japan and Korea has revealed that TLTG has desirable short-term outcomes and is also safe and effective[11,26-28].

Currently, the digestive tract reconstruction methods used after TLTG include overlap[12] and functional end-to-end[29] techniques. However, jejunal freeness is one of several drawbacks associated with these methods and makes the anastomosis more difficult. Therefore, we devised the IJOM, which involves esophagojejunostomy anastomosis after TLTG. We believe that, using this technique, the jejunum can be more easily positioned, thereby reducing the difficulty in creating the anastomosis. Moreover, because the proximal jejunum is divided after the anastomosis, the length of the blind loops can be easily grasped. We found that blood loss was reduced in group T, and this may be attributed to the clearer,

amplified field of vision achieved during laparoscopic digestive tract reconstruction. As a result, blood vessels in the muscles and mesentery can be more readily identified and are less likely to be transected during the procedure. Consistent with our findings, previous studies have shown that reduced blood loss is associated with better postoperative recovery[30]. We found that the length of the postoperative stay in group T was significantly shorter than that in group A, confirming that less trauma and blood loss during TLTG can promote faster recovery.

Lee *et al*[31] showed that distal gastrectomy decreases the QoL because of problems with eating restrictions and body image. However, compared with open surgery, laparoscopic-assisted distal gastrectomy improves QoL, specifically by reducing the incidence of postoperative intestinal obstruction[32]. Fujii *et al*[33] suggested that this reduction in postoperative intestinal obstruction may be attributable to the less abdominal manipulation required for laparoscopic surgery, which may blunt the systemic cytokine and inflammatory responses[34,35]. Similarly, totally laparoscopic technology reduces the amount of intestinal manipulation required during digestive tract reconstruction and may also

Mortality	0	0	/	0	0	/

reduce the incidence of postoperative intestinal obstruction. However, no studies have evaluated QoL following totally laparoscopic surgery. Schneider *et al*[36] reported that the diameter of the anastomotic stoma obtained using the linear stapler was significantly larger than that achieved with the circular stapler, which benefits the passage of food. At 6 mo post-surgery, we found that symptoms of dysphagia were better in group T, especially in terms of eating solid food. This finding indicates that using a linear stapler can expand the diameter of the anastomotic stoma and that the decreased intestinal manipulation involved in TLTG can reduce the incidence of intestinal obstruction.

Patients who underwent TLTG reported significantly less pain than those undergoing LATG. We believe that this is because the incision in the abdominal wall involved in TLTG is shorter, leading to less pain from inflammation and scar formation. In addition, less intra-abdominal manipulation likely contributes to decreasing the formation of intra-abdominal adhesions

and, thus, the associated discomfort.

This is the first study investigating the differences in short-term outcomes and QoL between the IJOM after TLTG and Roux-en-Y anastomosis after LATG using PSM and a QoL assessment scale. The results show that utilizing the IJOM after TLTG can reduce intra-operative blood loss and relieve symptoms of pain and dysphagia. However, this study has several limitations. First, the follow-up period was short. Second, a retrospective, single-center design was used. Therefore, a prospective, multiple-center study with a longer follow-up period is needed.

COMMENTS

Background

Surgeons have primarily adopted several methods for digestive tract reconstruction after totally laparoscopic total gastrectomy (TLTG). However, these methods have drawbacks, such as jejunal freeness and difficult to perform. Therefore, we devised the isoperistaltic jejunum-later-cut overlap method (IJOM), but little is known about the short-term outcome and quality-of-life (QoL) in patients following the implementation of this digestive reconstruction.

Research frontiers

The QoL after distal gastrectomy was reported to be affected by eating restrictions and body image. For TLTG, scholars have reported a variety of digestive reconstruction methods which are safe and effective, but the QoL is uncertain.

Innovations and breakthroughs

The authors used propensity score-matched analysis and questionnaire survey to perform this research. The authors found that IJOM for digestive reconstruction can reduce blood loss compared with Roux-en-Y anastomosis and was associated with less pain and dysphagia, thus improving QoL after laparoscopic gastrectomy.

Applications

Through this study, we can focus the symptoms which probably happen after surgery and accordingly improve the QoL of patients. However, a prospective, multiple-center study with a longer follow-up period is needed.

Terminology

EORTC-QLQ-C30: Chinese version of the European Organization for Research and Treatment of Cancer 30-item core QoL questionnaire. EORTC-QLQ-STO22: the validated Chinese version of the 22-item EORTC-QLQ gastric cancer module. PSM: A statistical matching method which can reduce the bias of variables.

Peer-review

This study is a pioneer study about esophagojejunostomy anastomosis after TLTG.

ACKNOWLEDGMENTS

The authors are thankful to Fujian Medical University Union Hospital for the management of our gastric cancer patient database.

Abstract

AIM

To report adalimumab (Ada) efficacy on articular-gastrointestinal disease and health-related quality of life (HRQoL) in patients with enteropathic spondyloarthritis (ES).

METHODS

A cohort of 52 patients with ES was evaluated in the departments of gastroenterology and internal medicine. At baseline, all patients underwent assessment by an integrated gastro-rheumatologic evaluation of articular and gastrointestinal activity, as well patient reported outcomes (PROs) of the HRQoL questionnaires. After this integrated evaluation and following a specific working flowchart, the Ada anti-tumor necrosis factor (TNF)-inhibitor was assigned to a cohort of 30 patients and its clinical efficacy was evaluated at baseline and

after 6-mo and 12-mo treatment by the following tests: (1) Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein (ASDAS-CRP); Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASFI) and Bath Ankylosing Spondylitis Metrology Index (BASMI) for articular activity; (2) Inflammatory Bowel Disease Questionnaire (IBDQ), Crohn's Disease Activity Index (CDAI) and partial Mayo (pMayo) score for gastrointestinal symptoms and activity; and (3) Health Assessment Questionnaire (HAQ), Patient Global Assessment (PGA) and Short Form-36 health survey (SF-36) questionnaires for PROs of the HRQoL.

RESULTS

Integrated evaluation and management of the patients affected by ES, carried out simultaneously by a gastroenterologist and a rheumatologist, allowed clinicians to choose the optimal therapeutic strategy. In a cohort of 30 ES patients affected by active articular and gastrointestinal disease, or axial active articular inflammation, Ada led to fast and sustained improvement of both articular and gastrointestinal disease activities. In fact, all the clinimetric evaluation tests exploring articular or gastrointestinal activity, as well as all the HRQoL scores, showed a significant improvement having been achieved at the earliest (6-mo) assessment. This important clinical improvement was maintained at the 12-mo follow-up. Importantly, global and gastrointestinal quality of life significantly correlated with articular disease activity, providing evidence to support that the integrated evaluation is the best option to manage patients with ES.

CONCLUSION

Ada treatment, upon multidisciplinary (gastro-rheumatologic) evaluation, significantly improves both articular and gastrointestinal inflammation, thereby improving the HRQoL in patients affected by ES.

Core tip: Enteropathic spondyloarthritis (ES) is characterized by articular inflammation in patients with inflammatory bowel diseases, such as Crohn's disease or ulcerative colitis. Correct management, especially covering both of the two clinical manifestations (gastro-rheumatologic), remains a challenge. In this study, we demonstrated that the integrated gastroenterological and rheumatologic evaluation of ES patients achieved the best therapeutic approach. In particular, we demonstrated that in a real-life cohort of ES patients, the tumor necrosis factor-inhibitor, adalimumab, led to fast and sustained improvement of articular and gastrointestinal inflammation, with a consequent improvement in the global and gastrointestinal quality of life.

INTRODUCTION

Enteropathic spondyloarthritis (ES) is a seronegative spondyloarthropathy (SpA) characterized by the presence of articular inflammation in patients affected by inflammatory bowel diseases (IBDs), such as Crohn's disease (CD) or ulcerative colitis (UC)[1,2]. Arthritis is the most frequent extra-intestinal manifestation in patients with IBDs[1] and it may primarily involve the axial joints, presenting with definite ankylosing spondylitis (AS) and/or isolated sacroiliitis, or peripheral joints and/or peri-articular structures, such as tendons and entheses[3]. The articular manifestations significantly affect health-related quality of life (HRQoL) of ES patients[4].

Although a link between inflammation of the joints and gut has been demonstrated[5,6], only half of ES patients are actually evaluated by a rheumatologist for proper diagnosis and, thus, for an integrated therapeutic approach through a coordinated action with the treating gastroenterologist[7]. Thus, an integrated clinical evaluation and therapeutic approach encompassing both the intestinal and articular features in ES patients, will likely be beneficial, particularly for the clinical outcomes. It has been demonstrated by recent studies that tumor necrosis factor (TNF)-alpha inhibitors could be effective therapeutic agents against ES[8], but few to date have reported on their real-life efficacy in this disease.

Herein, we have investigated the role of a gastro-rheumatologic multidisciplinary management and therapeutic approach in ES patients through evaluation of the efficacy of the TNF-alpha inhibitor adalimumab (Ada), assessing the efficacy on both gastrointestinal and rheumatologic disease activities and on the patient-reported HRQoL.

MATERIALS AND METHODS

Patients and study design

This study was carried out in a cohort of 52 patients with ES, including 31 affected by CD (59.6%) and 21 by UC (40.3%), collectively representing 23.6% of the 220 overall patient population with IBD in the

Peripheral only	8 (38)	2 (18)
Enthesitis	4 (19)	2 (18)

Data are presented as *n*, *n* (%) or mean ± SD. CDAI: Crohn's Disease Activity Index; ES-AN: Patient cohort with enteropathic spondyloarthritis from the SPIB Program, Ancona, Italy; ES-AN/Ada: Patients of the ES-AN cohort treated with adalimumab; IBD: Inflammatory bowel disease; NSAID: Non-steroidal anti-inflammatory drug.

Spondyloarthritis in IBD Project (commonly referred to as SPIB), described elsewhere[9]. The patients' clinical and laboratory data are shown in Table 1, and the patient group is henceforth defined as the "ES-AN" cohort (Enteropathic spondyloarthritis from Ancona, Italy).

At each clinical observation, both the rheumatologist and the gastroenterologist collaborated in a shared session to develop the therapeutic strategy by applying a specifically designed algorithm (Figure 1) that was mainly based upon gastrointestinal-articular disease activity and the site of articular involvement at diagnosis (axial or peripheral arthritis). Briefly, the ES-AN patients were primarily separated into the following two groups for comparative analysis:

Group I (biological drugs-naïve group): This group encompassed three treatment subgroups. In the axial-ES-AN (Ax-ES-AN) subgroup, patients were administered Ada as first-line therapy, due to the absolute contraindication for a long-course treatment with nonsteroidal anti-inflammatory drugs (NSAIDs)

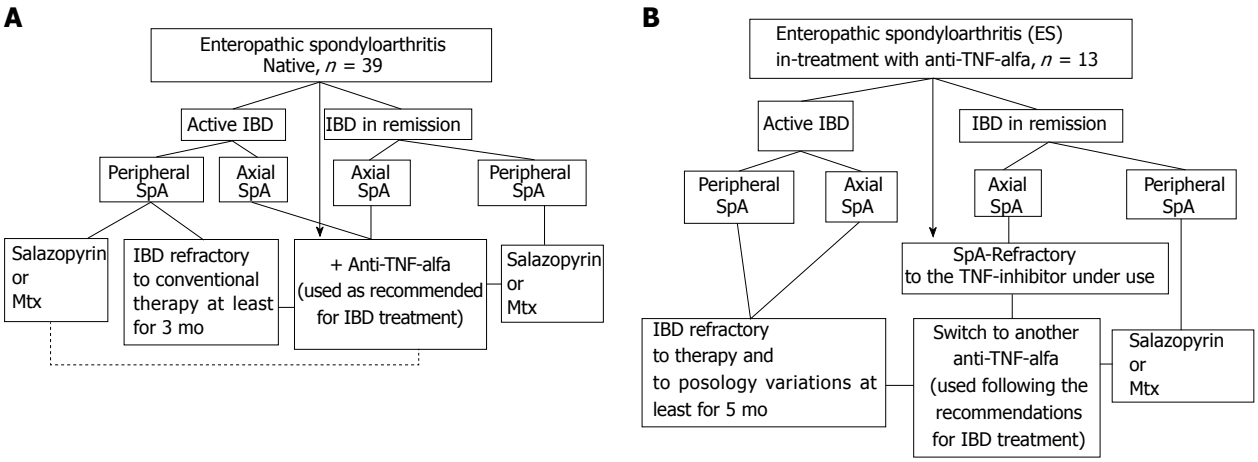

Figure 1 Therapeutic algorithm of the ES-AN patient cohort at the time of entry into the study. A: ES patients biological drugs-naïve were treated depending on IBD activity and site of the articular involvement, as follows: a) Ax-ES-AN with Ada as the TNF-inhibitor in first-line therapy, due to the absolute contraindication for a long-course treatment with NSAIDs in cases of IBDs; b) Per-ES-AN in cases of active IBD and in those patients who were non-responders to short-course corticosteroid treatment (not > 3 mo) or NSAIDs (not > 2 wk), with DMARD (methotrexate or sulfasalazine), or in cases of ESR > 30 mm/h and/or CRP > 0.5 mg/dL, and polyarticular inflammatory involvement with Ada; c) Per-ES-AN in inactive IBD, with steroids or DMARDs, depending on the number of inflamed joints and systemic inflammation (evaluated by ESR and/or CRP); B: ES patients already in treatment with infliximab for the IBD. In the ES-AN patients already treated with IFX: a) Per-ES-AN with active IBD were switched to Ada; b) Per-ES-AN with IBD in remission received a DMARD in addition to the IFX already in use; c) Ax-ES-AS were switched to Ada, regardless of IBD activity. Dashed line: Patients refractory to therapy. Therapeutic doses: DMARDs were prescribed at the standard dose regimens (salazopyrine 2 gr bid; methotrexate 10-20 mg once a week); Ada was used following the therapeutic dosage and indications for IBDs (160 mg at d 1 and 80 mg after 2 wk, followed by 40 mg every 2 wk). Ada: Adalimumab; AX-ES-AN: Patients with axial spondyloarthritis in the ES-AN cohort; CRP: C-reactive protein; ES: Enteropathic spondyloarthritis; ES-AN: Patients affected by ES in the Ancona's cohort; ESR: Erythrocyte sedimentation rate: DMARD: Disease modifying anti-rheumatic drug; IBD: Inflammatory bowel disease; NSAID: Non-steroidal anti-inflammatory drug; Per-ES-AN: Patients with peripheral spondyloarthritis in the ES-AN cohort.

in case of IBD. In the peripheral-ES-AN (Per-ES-AN) subgroup, patients with active IBD or who were non-responders to a short course of corticosteroids (not more than 3 mo) or NSAIDs (not more than 2 wk) were administered either a disease-modifying anti-rheumatic drug (DMARD), such as either methotrexate (MTX) or sulfasalazine (SSZ), or Ada if erythrocyte sedimentation rate (ESR) was > 30 mm/h and/or C-reactive protein (CRP) concentration was > 0.5 mg/dL and/or in the presence of polyarticular inflammatory involvement. In the Per-ES-AN in inactive IBDs subgroup, patients were administered steroids or DMARDs, depending on count number of inflamed joints and systemic inflammation (evaluated by ESR and/or CRP).

Group II (TNF inhibitor-treated group): This group also encompassed three treatment subgroups. For the first, the Per-ES-AN consisting of patients with still active IBD were switched to another TNF-inhibitor (Ada). For the second, the Per-ES-AN consisting of patients with IBD in remission were administered a DMARD in addition to the TNF-inhibitor already in use. For the third, the Ax-ES-AN patients were switched to Ada, regardless of IBD activity.

In all patients, the TNF-inhibitor Ada was used as recommended for IBD treatment: 160 mg in the first week, 80 mg for the next 2 wk, and thereafter 40 mg once every 2 wk.

Study measures and evaluation

All patients of the ES-AN cohort were assessed for clinical disease activity and HRQoL (Table 2). Briefly, articular (SpA) disease activity was assessed by the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)[10] and the Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein (ASDAS-CRP) calculation[11]; gastrointestinal (IBD) disease activity was assessed with the Crohn's Disease Activity Index (CDAI) for CD[12] and the partial Mayo (pMAYO) score for UC[13].

Patient-reported outcomes (PROs) were assessed with tests specific for articular-related symptoms [*i.e.* the Bath Ankylosing Spondylitis Functional Index (BASFI)][14] and gastrointestinal-related symptoms [*i.e.* the Inflammatory Bowel Disease Questionnaire (IBDQ)][15]. Global wellness was assessed by use of the Health Assessment Questionnaire (HAQ), Patient Global Assessment (PtGA), and the Short Form-36 health survey (SF-36)[16].

Statistical analysis

Endpoints of this study were the disease activity indexes at baseline and at 6-mo and 12-mo follow-ups. Variables are presented as mean ± standard deviation. Comparisons between groups at baseline

Table 2 Clinimetric test for articular-gastrointestinal activity and patient reported outcomes of health-related quality of life

Test	Items and interpretation
Bath Ankylosing Spondylitis Disease Index[10]	6 items: (1) fatigue, (2) back pain, (3) peripheral pain/swelling, (4) discomfort at pressure, (5) morning discomfort, and (6) duration of morning stiffness; Range from 0 to 10, with lower number representing less severe disease activity; Score > 4 = active disease.
Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein[11]	5 items: (1) back pain, (2) morning stiffness, (3) patient global, (4) peripheral pain/swelling, and (5) C-reactive protein; Score < 1.3 = inactive disease; Score 1.3 to < 2.1 = moderate activity; Score 2.1 to ⩽ 3.5 = high activity; Score > 3.5 = very high activit; Change ⩾ 1.1 = clinically important improvement; Change ⩾ 2.0 = major improvement.
Crohn's Disease Activity Index[12]	8 items: (1) liquid stools, (2) abdominal pain, (3) general well-being, (4) extra-intestinal manifestations (including arthralgia), (5) use of anti-diarrheals, (6) abdominal masses, and (7) hematocrit, 8) weight; Final score is the sum of items, weighted by different factors; Score < 150 = non-active disease; Score > 150 = active disease; Score > 450 = extremely severe disease.
Partial MAYO score[13]	3 items: (1) stool frequency, (2) rectal bleeding, and (3) physician global assessment; Range from 0 to 9; Score < 2 = disease remission; Score 2-4 = mild disease activity; Score 5-7 = moderate disease activity; Score > 7 = severe disease activity.
Bath Ankylosing Spondylitis Functional Index[14]	10 questions designed to determine the degree of functional limitation; Final score ranges from 0 to 10, with lower score indicating less functional limitation.
Inflammatory Bowel Disease Questionnaire[15]	32 questions divided into 4 subscales: (1) bowel symptoms (10 questions); (2) systemic symptoms, including sleep disorders and fatigue (5 questions); (3) emotional function, such as depression, aggression and irritation (12 questions); and (4) social function, meaning the ability to participate in social activities and to work (5 questions); The patient is invited to choose from 1 to 7 for every question; Total score ranges from 32 to 224 points, with lower scores reflecting worse quality of life.
Patient Global Assessment (PtGA)	Collected on a numeric rating scale ranging from 0 to 10 for the question asking the patient: "Considering all the ways your disease affects you, how much do you think is active today?"
Short Form-36 health survey[16]	Generic health status instrument with 8 domains: (1) physical function, (2) body pain, (3) role limitations–physical, (4) general health, (5) vitality, (6) social function, (7) role limitations–emotional, and (8) mental health; Greater scores reflect better health status; Summarized in two summary scores defined as the (1) physical component score (Sf-36/PCS) and (2) mental component score (Sf-36/MCS).

and between baseline and subsequent assessments were performed, respectively, with unpaired and paired Student's *t*-tests. Correlations between variables were assessed using Pearson's correlation coefficient. Data were analyzed using the SPSS software (v22.0; IBM SPSS Statistics for Windows, Armonk, NY, United States).

RESULTS

Baseline assessment of the patients

In the ES-AN cohort, 29 (57.6%) patients were affected by predominant axial SpA (Ax-ES-AN) and 23 (42.3%) by peripheral SpA (Per-ES-AN) (Table 1). Only 5 patients showed positivity for human leukocyte antigen-B27 (9.6%), including 4 affected by Ax-ES-AN and 1 by Per-ES-AN. Sacroiliitis was found in all the Ax-ES-AN patients, but 17 (55%) patients fulfilled the Modified New York Criteria for AS, whereas 13 (45%) were affected by non-radiographic axial-SpA[2]. Syndesmophytosis was found in 8 (27.6%) of the Ax-ES-AN patients at different levels, but only 2 (6.9%) presented a bamboo spine radiologic feature at baseline. Concurrent peripheral arthritis and enthesitis were present in about half of the Ax-ES-AN patients (44.8%).

According to the established criteria, IBD was active in 63.2% of the CD patients and in 98% of the UC patients, although the degrees of activity varied. At baseline, no differences were observed between the axial and peripheral spondyloarthritis patients and between the CD and UC patients for the articular disease activity (BASDAI, ASDAS-CRP) and the PROs [IBDQ, BASFI, PtGA, HAQ, SF-36 Physical Component Score (PCS) and Mental Component Score (MCS)] (data not shown). Following findings from the integrated evaluation and according to the algorithm presented in Figure 1, the criteria employed in our study to guide the therapeutic choice were (1) the presence and/or absence of active IBD (evaluated by both the gastroenterologist and by the results of the gastrointestinal tests and PROs); and (2) the site of articular involvement (axial or peripheral joints). Thus, Ada was assigned to a cohort of 30 patients, henceforth defined as the ES-AN/Ada cohort. Among this cohort, 4 were switched from infliximab for inefficacy, and the total was comprised of 20 patients with Ax-ES-AN and 10 patients with Per-ES-AN (Table 1).

Evaluation of articular and gastrointestinal disease activity

In most of the ES-AN/Ada patients, articular disease activity, as assessed by ASDAS-CRP and BASDAI, was significantly improved at 6-mo compared to baseline

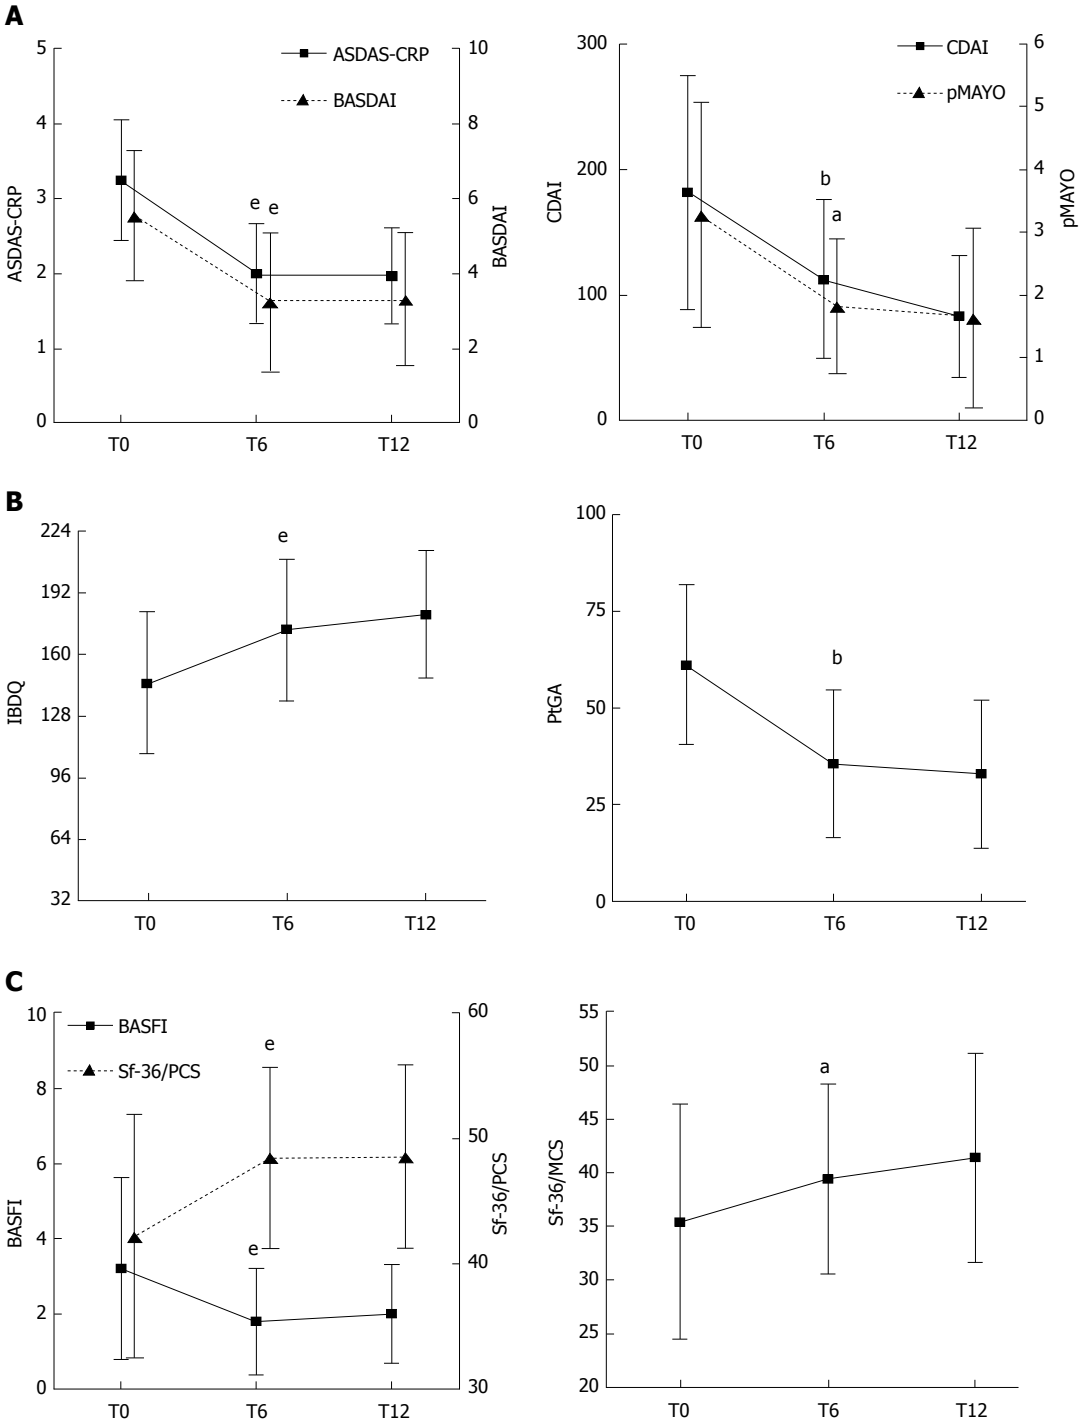

Figure 2 Evaluation of articular-gastrointestinal disease activity and HRQoL in the ES-AN patient cohort at baseline and after adalimumab therapy. All data of the ES-AN patients were collected at baseline (T0), and after 6 mo (T6) and 12 mo (T12) of therapy. A: Evaluation of the articular disease activity with BASDAI or ASDAS-CRP (Left), and of the gastrointestinal disease activity by CDAI for CD and pMAYO for UC (Right); B: Evaluation of PROs of gastrointestinal disease activity by IBDQ (Left), and of global wellness by the PtGA (Right). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{e}P < 0.001$. ASDAS-CRP: Ankylosing Spondylitis Disease Activity Score/C-Reactive Protein; BASDAI: Bath Ankylosing Spondylitis Disease Activity Index; CDAI: Crohn's Disease Activity Index; ES: Enteropathic spondyloarthritis; ES-AN: Patients affected by ES in the Ancona's cohort; HRQoL: Health-Related Quality of Life; IBDQ: Inflammatory Bowel Disease Questionnaire; pMAYO: Partial Mayo score; PROs: Patient reported outcomes.

(ASDAS-CRP: 3.2 ± 0.8 *vs* 1.9 ± 0.6, $P < 0.001$; BASDAI: 5.5 ± 1.7 *vs* 3.2 ± 1.8, $P < 0.001$). A major clinical improvement (ASDAS change of ⩾ 2) occurred in 21% and an important clinical improvement (ASDAS change of ⩾ 1.1) occurred in 52% (Figure 2A). The improvement of articular disease was significant in both the axial and the peripheral subgroups of patients ($P < 0.001$ for both comparisons). The clinical improvement at the articular level was maintained at the 12-mo examination (Figure 2A).

Regarding the gastrointestinal disease activity, in the CD patients the treatment led to a fast, consistent

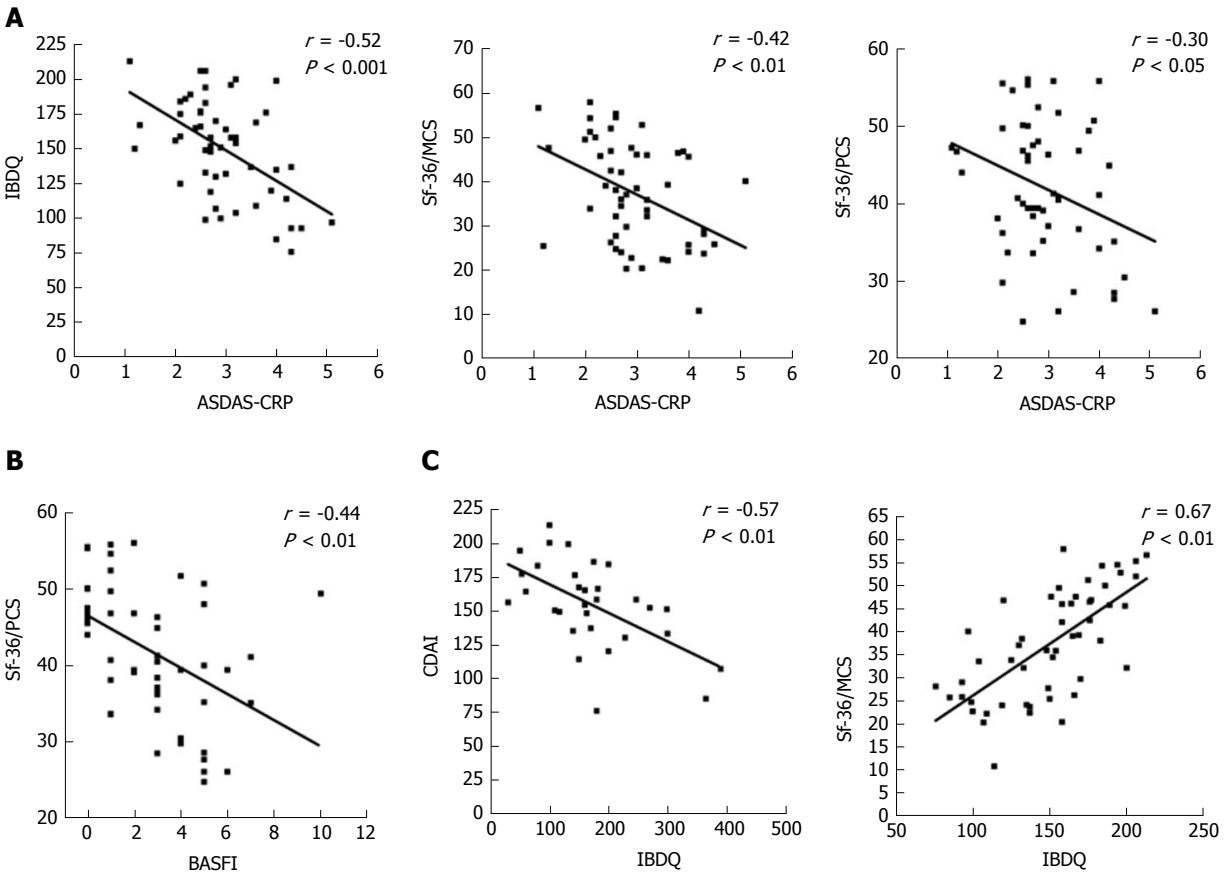

Figure 3 Correlations between articular and gastrointestinal disease activity and HRQoL scores in the ES-AN patient cohort at baseline. A: Correlation between the PROs of gastrointestinal disease activity (assessed by IBQD) scores and SF-36 summary scores (assessed by PCS and MCS) with articular activity scores (assessed by ASDAS-CRP); B: Correlation of the articular function (assessed by BASFI with SF-36/PCS); C: Correlation of the IBDQ with crohn's disease gastrointestinal disease activity (assessed by CDAI) and the SF-36/MCS. ASDAS-CRP: Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein; CDAI: Crohn's Disease Activity Index; ES: Enteropathic spondyloarthritis; ES-AN: Patients affected by ES in the ancona's cohort; HRQoL: Health-Related Quality of Life; IBDQ: Inflammatory Bowel Disease Questionnaire; PROs: Patient reported outcomes; SF-36/MCS: Summary of "Mental Component Score" of the Short Form-36 health survey; SF-36/PCS: Summary of "Physical Component Score" of the Short Form-36 health survey.

and significant improvement of the gastrointestinal symptoms at 6 mo, as assessed by the CDAI score (181.3 ± 93.2 *vs* 112.3 ± 63.0, $P < 0.01$; Figure 2A), and maintained at 12 mo, when the clinical remission was observed in almost all patients (Figure 2A). In parallel, a significant clinical improvement was observed also in the UC patients, as shown by the decrease of the pMAYO score at the 6-mo and 12-mo examinations (Figure 2A). All the values and comparisons are detailed in Table 3.

Evaluation of the HRQoL

ES-AN/Ada patients reported significant improvement, from baseline to 6 mo, in the IBDQ (145.3 ± 36.8 *vs* 172.8 ± 36.7, $P < 0.01$), PtGA (61.1 ± 20.6 *vs* 35.6 ± 19.1, $P < 0.01$; Figure 2B) and HAQ (4.8 ± 7.9 *vs* 2.0 ± 4.2, $P < 0.05$) scores, and this improvement was maintained at 12 mo. Moreover, regarding the PROs impacting articular function and global health wellness, significant improvements were observed from baseline to 6 mo in the BASFI (3.2 ± 2.4 *vs* 1.8 ± 1.4, $P < 0.01$), Sf-36/PCS (42.2 ± 9.7 *vs* 48.4 ± 7.3, $P < 0.01$) and Sf-36/MCS scores (35.4 ± 10.9 *vs* 39.4± 8.8, $P < 0.05$; Figure 2C); again, the improvements were maintained at 12 mo. The improvement of all the scores for PROs was similar in both the Ax-ES-AN/Ada and Per-ES-AN/Ada subgroups at each follow-up observation. All the values and comparisons are detailed in Table 3.

Correlations between variables

At baseline, it is noteworthy that a consistent significant correlation was observed between the IBDQ test (specific for the evaluation of the PROs related to the gastrointestinal disease activity) and the clinimetric scores of articular activity, as assessed by ASDAS-CRP (Figure 3A), BASDAI, and with most of the PROs of the HRQoL, as assessed by Sf-36/MCS and CDAI (Table 4). Moreover, articular disease activity at baseline was significantly correlated with worse results in the HRQoL tests, as shown by the Sf-36/PCS and Sf-36/MCS scores (Table 4). After 12 mo of Ada treatment, improvement of the articular activity (ASDAS-CRP) correlated significantly with decrease in the gastrointestinal disease activity scores, as assessed by CDAI in the CD patients (Figure 4A) and IBDQ in all of the patients, and with most of the PROs of the HRQoL, as

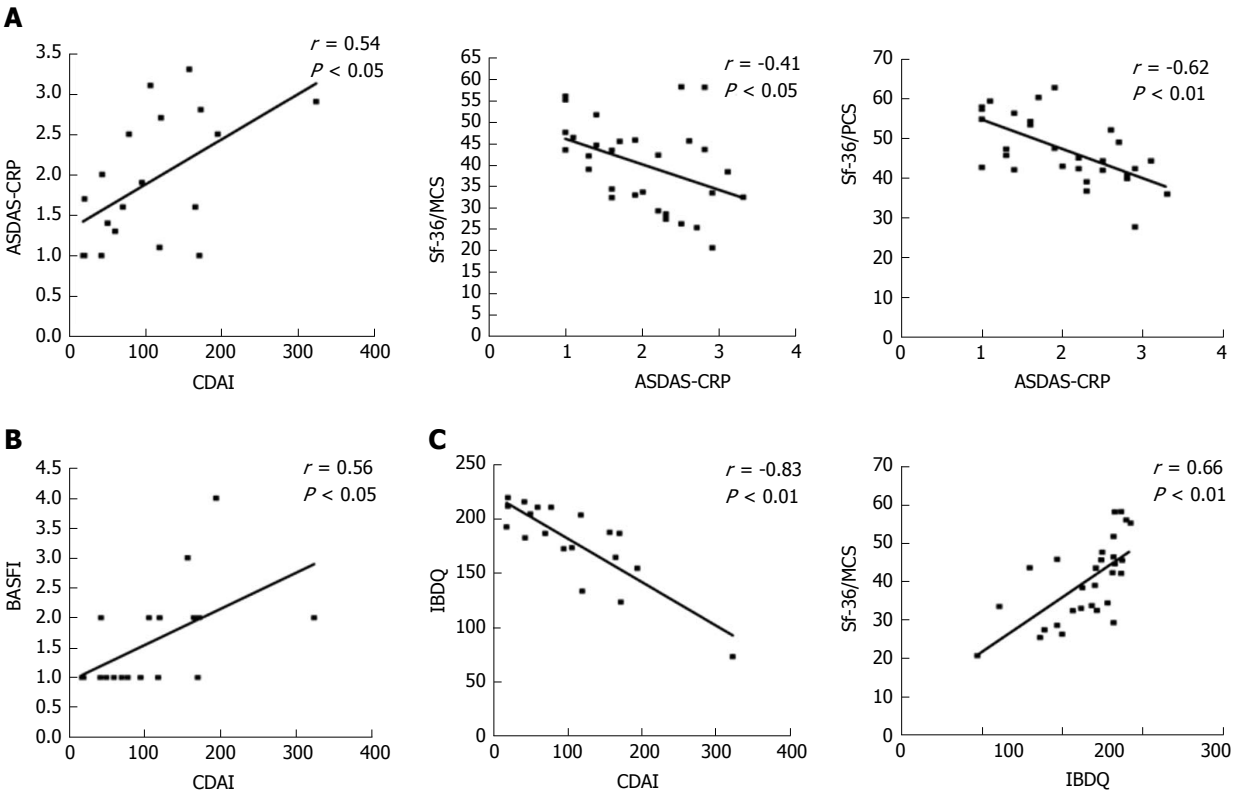

Figure 4 Correlations between articular and gastrointestinal disease activity and HRQoL scores in the ES-AN patient cohort after adalimumab therapy. A: Evaluation data collected for the 30 ES-AN/Ada patients after 12 mo of therapy, showing correlation between gastrointestinal and articular disease activity in Crohn's disease patients (assessed by CDAI) and ASDAS-CRP respectively, and between ASDAS-CRP and SF-36 summary scores (PCS and MCS); B: Correlation between CDAI and articular function (assessed by BASFI); C: Correlation between the gastrointestinal quality of life (assessed by IBDQ) and CDAI and SF-36/MCS. ASDAS-CRP: Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein; CDAI: Crohn's Disease Activity Index; ES-AN: Patients affected by ES in the Ancona's cohort; ES-AN/Ada: Patients of the ES-AN cohort treated with adalimumab; HRQoL: Health-Related Quality of Life; IBDQ: Inflammatory Bowel Disease Questionnaire; SF-36/MCS: Summary of "Mental Component Score" of the Short Form-36 health survey; SF-36/PCS: Summary of "Physical Component Score" of the Short Form-36 health survey; Sf-36/PCS: Summary of "Physical Component Score" of the short form-36 health survey; PROs: Patient reported outcomes.

Table 3 Scores of the clinimetric test for articular-gastrointestinal activity and patient reported outcomes of health-related quality of life

	Baseline	T6	T12
CDAI, *n* = 19	181.3 ± 93.2	112.3 ± 63.0[b]	82.7 ± 48.7[b]
pMAYO, *n* = 11	3.27 ± 1.79	1.81 ± 1.07[a]	1.63 ± 1.43[a]
IBDQ	145.3 ± 36.8	172.8 ± 36.7[e]	180.7 ± 33.0[e]

Sf-36/MCS	35.4 ± 10.9	39.4 ± 8.8[a]	41.4 ± 9.7[a]
CRP in mg/dL	2.7 ± 3.7	0.8 ± 1.2[a]	0.5 ± 0.6[a]

[a]$P < 0.05$, [b]$P < 0.01$, [e]$P < 0.001$. ASDAS-CRP: Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein; BASDAI: Bath Ankylosing Spondylitis Disease Activity Index; BASFI: Bath Ankylosing Spondylitis Functional Index; CDAI: Crohn's Disease Activity Index; CRP: C-Reactive Protein; pMAYO: partial Mayo score; HAQ: Health Assessment Questionnaire; IBDQ: Inflammatory Bowel Disease Questionnaire; PtGA: Patient Global Assessment; SF-36/MCS: Summary of "Mental Component Score" of the Short Form-36 health survey; SF-36/PCS: Summary of "Physical Component Score" of the Short Form-36 health survey; T6 and T12: Results of the evaluation after 6 mo and 12 mo of treatment with adalimumab respectively.

shown by the Sf-36/PCS (r = -0.30, $P < 0.05$) and Sf-36/MCS (r = -0.41, $P < 0.01$) scores (Figure 2C), as well as the BASFI (r = 0.57, $P < 0.001$), PtGA (r = 0.37, $P < 0.01$) and HAQ (r = 0.28, $P < 0.05$) scores. All the correlations for the values at 12-mo examination are detailed in Table 4.

Tolerability

Ada was well tolerated throughout the follow-up period. Side effects reported included recurrent upper respiratory tract infections (n = 2), bothersome hair loss (n = 1), and widespread itch (n = 2); but none necessitated suspension of the treatment. One patient suffered from a serious infection (axillary suppurative hidradenitis) that required prolonged antibiotic treatment. The other minor side effects reported were headache and fatigue.

DISCUSSION

The association between SpAs and IBDs has been known since the beginning of the last century[17]. However, gastroenterologists and rheumatologists continue to carry out their clinical evaluations and

Correlations between variables were assessed in the 30 patients with enteropathic spondyloarthritis from Ancona, Italy, at baseline and after 6 mo (data not shown) and 12 mo of therapy with adalimumab (ES-AN/Ada), using Pearson's correlation coefficient; [a]$P < 0.05$, [b]$P < 0.01$. ASDAS-CRP: Ankylosing Spondylitis Disease Activity Score-C-Reactive Protein; BASDAI: Bath Ankylosing Spondylitis Disease Activity Index; BASFI: Bath Ankylosing Spondylitis Functional Index; CDAI: Crohn's Disease Activity Index; CRP: C-Reactive Protein; HAQ: Health Assessment Questionnaire; IBDQ: Inflammatory Bowel Disease Questionnaire; pMAYO: partial Mayo score; PtGA: Patient Global Assessment; SF-36/MCS: Summary of "Mental Component Score" of the Short Form-36 health survey; SF-36/PCS: Summary of "Physical Component Score" of the Short Form-36 health survey.

the therapeutic management of these diseases, now known collectively as ES, independently. In this regard, the different clinical guidelines employed by the two medical specialists may lead to different therapeutic decisions for the same clinical scenario, ultimately harboring potential for different clinical outcomes of the disease. A critical issue in the clinical management of ES is the correct therapeutic choice, and an important role has emerged recently for the TNF-alpha inhibitors in this regard. Infliximab was the first TNF-alpha inhibitor used in ES[18], but Ada has recently been applied to ES patients affected by CD and has achieved rates of clinical remission up to 50%[19].

To our knowledge, this is the first study demonstrating the efficacy of the integrated gastrorheumatologic approach for evaluation and therapeutic management of ES patients, with efficacy evidenced through assessments of disease activity and HRQoL over a 12-mo period. As dictated by our operative algorithm, both the gastroenterologist and the rheumatologist evaluated each of the patients in the study cohort, with both of the specialists collaborating to choose the optimal therapy. This integrated multidisciplinary approach, therefore, considered the gastrointestinal and articular disease activities simultaneously and, most importantly in the latter case, the site of articular inflammation (axial or peripheral). Thus, for example, in the case of axial spondyloarthritis, the therapy with anti-TNF-alpha inhibitors was mandatory, following the latest rheumatologic indications[20].

Since only few studies in the literature have so far evaluated the efficacy and safety of anti-TNF-alpha in ES, we employed the up and coming Ada treatment in our study. The results indicated that in ES patients, regardless of IBD type and/or site of articular involvement, Ada significantly improves the inflammation states of both the joints (assessed by ASDAS-CRP and BASDAI) and gut (assessed by CDAI or pMAYO score), as well as the HRQoL. Moreover, the benefits were already observable at 6 mo and the improvements were maintained at 12 mo. Ada also consistently improved not only the physical function in almost all ES patients (assessed by PtGA, BASFI, HAQ and Sf-36/PCS) but also their psychological function (assessed by Sf-36/MCS and IBDQ), from baseline to 6 mo.

It is noteworthy that in our study the strong linear relationship between articular-gastrointestinal disease activity and the PROs confirms the strong link between gut and joint inflammations. In fact, the IBDQ (specific for the gastrointestinal-related quality of life) strongly correlated with results of the clinimetric tests of articular activity (ASDAS-CRP, BASDAI and BASFI); additionally, the articular disease activity (assessed by ASDAS-CRP) strongly correlated with all of the PROs studied, even those specific for IBDs. To

the contrary, however, at baseline the gastrointestinal disease activity scores (except for those of the IBDQ) did not correlate well with the other variables, but at 12 mo of therapy the CDAI correlated with most of the articular and PROs of HRQoL. This latter finding may be consequent to the different degrees of disease activities reported by the patients at baseline, which, after the treatment, tend to be globally ameliorated both at the gastrointestinal and articular levels.

Thus, since only the ASDAS-CRP test proved to be the most reliable in all patients in our study, we think that it should be necessary to develop composite scores and HRQoL questionnaires specific and suitable for ES patients at diagnosis, similar to those developed for other multidisciplinary diseases, such as psoriatic arthritis[21]. In conclusion, in our work that was carried out in a real-life cohort of a significant number of ES patients, we demonstrated that Ada produced a fast and significant improvement of both the gastrointestinal and articular scores of disease activity and, moreover, of the HRQoL. This clinical result was achieved by employing an integrated outpatient clinic specific for ES patients, as recently endorsed, particularly with regard to early diagnosis[22,23]. The integrated approach provided the optimal management of both the multidisciplinary clinical evaluation and the therapy of these patients. Further studies are certainly warranted to assess the long-term outcomes, and tolerability, of Ada and other TNF-alpha inhibitors in patients affected by ES.

COMMENTS

Background

Enteropathic spondyloarthritis (ES) is characterized by articular inflammation in patients with inflammatory bowel diseases (IBDs), such as Crohn's disease or ulcerative colitis. Arthritis is the most frequent extra-intestinal manifestation found in IBD patients, yet only half of the ES patients are actually evaluated by a rheumatologist for a proper diagnosis and, thereafter, for receipt of an integrated therapeutic approach through a coordinated action between the two specialists.

Research frontiers

Considering the multidisciplinary intrinsic "face" of IBDs and the novel therapeutic opportunities that comprise the biological drugs, as in the case of anti-tumor necrosis factor (TNF)-alpha inhibitors, an integrated approach and evaluation of all ES patients should be routinely employed and strongly encouraged to obtain the best therapeutic efficacy on all the clinical manifestations of this disease.

Innovations and breakthroughs

In this work, the authors have demonstrated that the integrated (simultaneous) evaluation of patients affected by ES, through the coordinated efforts of a gastroenterologist and rheumatologist, led to the best therapeutic approach, thereby allowing the patients to achieve a consistent clinical remission of both the articular and gastrointestinal inflammations.

Applications

Through this study authors have been able to generate a simple working flowchart of the multidisciplinary clinical care process applied during the patients' integrated assessment. They suggest that in patients with ES and in consideration of the therapeutic choice, particular attention should be paid to the presence of active intestinal disease, presence of active articular (arthritis) and/or periarticular (enthesitis) disease and localization of the joints' inflammation (peripheral or axial, as in the case of sacroiliitis).

Terminology

ES belongs to the group of seronegative spondyloarthritis (SpA) and, as such, is characterized by the presence of arthritis in patients affected by IBDs; it is also known as SpA-IBD.

Peer-review

This is an interesting and well-conducted work.

ACKNOWLEDGMENTS

We would like to acknowledge all the patients who enthusiastically participated in this study. We are also grateful with Miss Lucrezia Lombardi for her assistance in the writing and revision of the manuscript.

Abstract

AIM

To determine whether the presence of columnar-lined esophagus (CLE) is associated with the presence of

esophageal varices (EVs) in male Japanese alcoholics.

METHODS

The subjects were 1614 Japanese alcohol-dependent men (≥ 40 years of age) who had undergone upper gastrointestinal endoscopic screening. Digitalized records of high-quality endoscopic images that included the squamocolumnar junction and esophagogastric junction were retrospectively jointly reviewed by four expert endoscopists for the purpose of diagnosing CLE. The authors investigated whether and to what extent there were associations between the presence of CLE and the presence of EVs, especially in the group with liver cirrhosis (LC).

RESULTS

CLE ≥ 5 mm in length was found in 355 subjects (≥ 30 mm in 6 of them), LC without EVs in 152 subjects, LC with EVs in 174 subjects, and EVs without LC in 6 subjects. Advanced EVs, *i.e.*, nodular, large or coiled forms, red color sign, or post-treatment, were found in 88 subjects. The incidence of CLE ≥ 5 mm decreased in the following order ($P < 0.0001$): 23.3% in the group without EVs, 17.4% in the group with small and straight EVs, and 5.7% in the group with advanced EVs. The multivariate ORs (95%CI) for EVs and advanced EVs in the group with LC were lower when CLE ≥ 5mm was present [0.46 (0.23-0.93) and 0.24 (0.08-0.74), respectively, *vs* 0-4 mm CLE].

CONCLUSION

The presence of CLE in male Japanese alcoholics was negatively associated with the presence of EVs.

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: A positive association between excessive drinking and the presence of short-segmental columnar-lined esophagus (CLE) has been reported in Asians. Endoscopic screening of 1614 Japanese alcohol-dependent men revealed the presence of CLE ≥ 5 mm in length in 355 subjects and esophageal varices (EVs) in 180 subjects. The presence of CLE was negatively associated with the presence of EVs, and even more negatively associated with the presence of advanced forms of EVs. Since the first resistance vessels to EVs are the mucosal palisade vessels and submucosal veins at the lower end of the esophagus, the development of CLE may impede the development of EVs.

Yokoyama A, Hirata K, Nakamura R, Omori T, Mizukami T, Aida J, Maruyama K, Yokoyama T. Presence of columnar-lined esophagus is negatively associated with the presence of esophageal varices in Japanese alcoholic men. *World J Gastroenterol* 2017; 23(39): 7150-7159 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7150.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7150

INTRODUCTION

Esophageal varices (EVs) develop as a result of portal hypertension, which is mainly due to liver cirrhosis (LC) in alcoholics, and excessive alcohol drinking increases the risk of variceal bleeding and mortality[1-3]. Excessive alcohol consumption has been reported to be associated with the presence of gastroesophageal reflux disease (GERD) and a short-segmental columnar-lined esophagus (CLE) in East-Asian studies[4-8]. Long-segmental CLE is rare in Asians[8], and a large pooled analysis of the cases in Western studies did not show a positive association between heavy drinking and GERD or long-segmental CLE[9]. The differences between the results in East Asia and the West may be attributable to the differences between East Asia and Western countries in abdominal obesity, incidences of *Helicobacter pylori* infection, and gene polymorphisms of alcohol-metabolizing enzymes.

Our empirical impression based on the results of endoscopic screening examinations of Japanese alcoholic men is that EVs are less common among men with short-segmental CLE. The development of CLE has been shown to be accompanied by several histological changes around the palisade vessels, including the development of a double muscularis mucosae[10,11]. Since dilatation of the palisade vessels at the lower end of the esophagus has been suspected of being one of the major initial events in the development of EVs secondary to portal hypertension[12,13], some of the histological changes accompanying the development of CLE may protect against the development of EVs.

It is widely accepted that genetic polymorphisms of alcohol dehydrogenase-1B (ADH1B, rs1229984) and aldehyde dehydrogenase-2 (ALDH2, rs671) affect the susceptibility of East-Asians to alcoholism[14-16], and the presence of fast-metabolizing ADH1B encoded by the *ADH1B*2* allele in Japanese alcoholics has been reported to be positively associated with the presence of advanced liver disease[17-19].

The aim of the present study was to determine whether and to what extent associations exist between the presence of EVs and the presence of CLE in Japanese alcoholic men based on the results of endoscopic screening examinations and their ADH1B/ALDH2 genotypes.

MATERIALS AND METHODS

Subjects

The reference population of this study consisted of 1902 Japanese alcoholic men 40 years of age and over who: (1) Came to the Kurihama Medical and Addiction Center for treatment of alcohol dependence for the first

time between May 2004 and December 2011; (2) Were evaluated for the presence of physical comorbidities; (3) Underwent routine upper gastrointestinal endoscopic screening; (4) And underwent ADH1B and ALDH2 genotyping[19]. After excluding the 194 subjects with a history of either gastrectomy or treatment for esophageal cancer and the 94 subjects without a digitalized record of high-quality endoscopic images that included the squamocolumnar junction and esophagogastric junction, 1614 patients were selected as subjects.

All of the alcoholics who participated in this study met the DSM-Ⅳ criteria for alcohol dependence[20]. Just before the endoscopic screening examination we asked each participant when he was in a sober state about his drinking and smoking habits. Usual alcohol consumption during the preceding year was expressed in grams of ethanol per day calculated by using standard conversion factors for alcoholic beverages. Beer and low-malt beer were assumed to be 5% ethanol (v/v); wine, 12%; sake, 16%; shochu, 25%; and whiskey, 40%.

The clinical diagnoses of comorbidities were made after alcohol detoxification. Patients received a routine examination that included a physical examination, blood tests, chest X-ray and abdominal X-ray, upper gastrointestinal endoscopy, abdominal ultrasound examination, and abdominal computed tomography. The clinical diagnosis of LC was made on the basis of the results of the physical examination, blood tests, and imaging studies or detection of esophagogastric varices during the endoscopic examination. The severity of LC was graded according to the Child-Pugh scoring system based on the findings at the first visit[21]. Hepatitis B surface (HBs) antigen and second generation anti-hepatitis C (HCV) antibody were measured with Abbott enzyme immunosorbent assays (Abbott Japan Inc., Tokyo).

Endoscopic procedure

Endoscopy was performed with an Olympus XQ230, Q240, Q240Z, or Q260 panendoscope (Olympus Optical Co. Ltd., Tokyo, Japan). Esophagogastric varices were diagnosed according to the grading system for esophagogastric varices adopted by the Japanese Society for Portal Hypertension[22]; *e.g.*, based on their form [small and straight (F1), nodular (F2), and large or coiled (F3)] and red color (RC) sign (Figure 1). The severity of portal hypertensive gastropathy (PHG) was evaluated according to Toyonaga's grading system, which has been adopted by the Japanese Society for Portal Hypertension (Figure 2)[23]: All PHG lesions exhibit a snake-skin (mosaic) pattern in their background mucosa; Grade 1, erythematous flecks or maculae; Grade 2, red spots or diffuse redness; and Grade 3, intramucosal or luminal hemorrhage. Three patients could not be evaluated for PHG because of food residue in the stomach.

Assessment for columnar-lined esophagus and hiatal hernia

The digitalized images that included the squamocolumnar junction and esophagogastric junction acquired before advancing the endoscope into the stomach were stored by the medical imaging communication system. The endoscopic digitalized images were retrospectively assessed during a joint review by four expert endoscopists (Yokoyama A, Hirata K, Nakamura R, Omori T) to diagnose CLE and hiatal hernia according to the classification system adopted by the Japan Esophageal Society[24]. The endoscopic esophagogastric junction was defined as the lower limit of the palisade longitudinal vessels (Figure 3)[10,11]. It was defined as the upper limit of the gastric mucosal folds when the lower limit of the palisade vessels was unclear. The greatest axial lengths of CLE were classified into four categories: 0-4 mm, 5-9 mm, 10-29 mm, and $\geqslant$ 30 mm. The axial length of a hiatus hernia was defined as the distance between the esophagogastric junction and the hiatus represented by the diaphragmatic pinch. The images were examined for the presence or absence of a hiatal hernia whose axial length was $\geqslant$ 10 mm.

Alcohol dehydrogenase-1B and aldehyde dehydrogenase-2 genotyping

ADH1B and ALDH2 genotyping of every subject was performed by PCR-RFLP methods on a lymphocyte DNA sample[19].

Statistical analysis

The data have been summarized as means and standard errors or as percentage values. Student's *t*-test was used to compare normally distributed continuous variables between groups; the Mann-Whitney *U*-test was used to compare non-normally distributed continuous variables between groups; and Fisher's exact test or Cochran-Mantel-Haenszel test for trend was used to compare proportions between groups. Multiple logistic regression models were used to calculate adjusted odds ratios (ORs) and their 95% confidence intervals (CIs). A *P* value less than 0.05 was considered statistically significant. All analyses were performed by a biomedical statistician (Yokoyama T) using the SAS statistical package (version 9.4; SAS Institute, Cary, NC United States).

RESULTS

LC without EVs was diagnosed in 152 subjects, LC with EVs in 174 subjects, and EVs without LC in 6 subjects. The EVs were classified as F1 in 92 subjects, F2 or F3 in 41 subjects, RC-sign-positive in 21 subjects, and post-treatment in 26 subjects, 17 of whom were reported to have been treated for variceal rupture. All of the EVs in the subjects without LC were classified as F1. Table 1 shows the background factors of the 1614

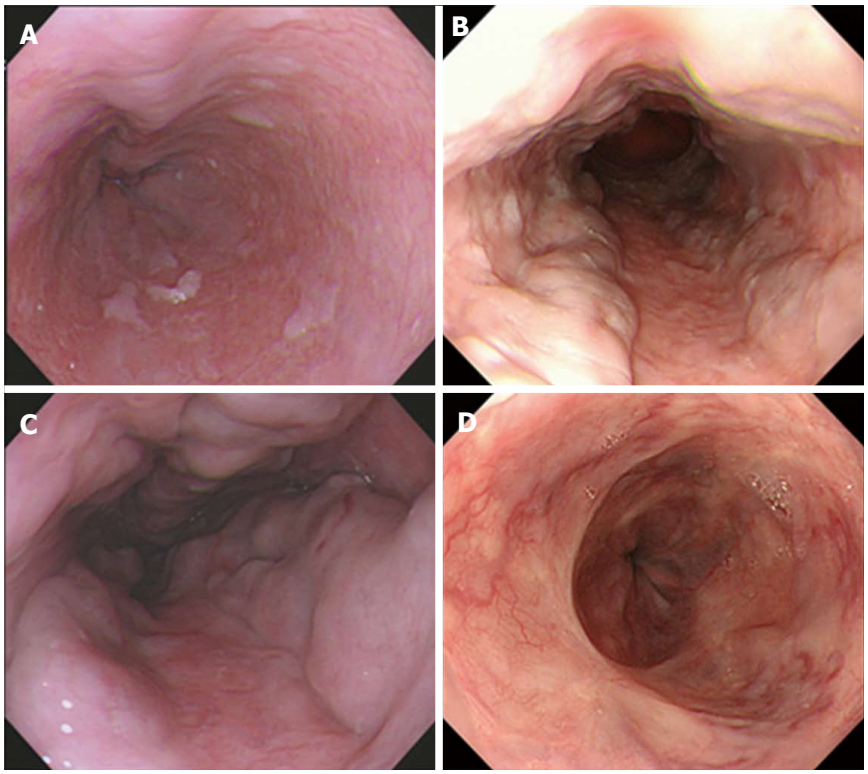

Figure 1 Classification of esophageal varices. A: F1 varices, small and straight; B: F2 varices, nodular; C: F3 varices, large or coiled; D: post-treatment varices.

ADH1B: Alcohol dehydrogenase-1B; ALDH2: Aldehyde dehydrogenase-2; *P* values were calculated by Student's *t*-test for mean values, and Fisher's exact test for percent data.

subjects according to whether they had EVs. There were no significant differences between the group with EVs and the group without EVs in age, usual alcohol consumption, smoking, hepatitis C and B infection status, or ALDH2 and ADH1B genotypes. LC, gastric varices, and higher grade PHG were more common in the group with EVs than in the group without EVs ($P < 0.0001$). Most of the gastric varices in the group without EVs were found in the fornix alone, and gastric varices located in the cardia or cardia plus fornix predominanted in the group with EVs.

CLE $\geqslant$ 5 mm was found in 355 (22.0%) of the subjects (5-9 mm, 13.6%; 10-29 mm, 8.1%; and $\geqslant$ 30 mm, 0.4%; Table 2). When advanced forms of EVs were defined as F2 - F3 varices, RC-sign-positive varices, and post-treatment varices, the proportion of subjects with CLE $\geqslant$ 5 mm decreased in the following order ($P < 0.0001$): 23.3% in the group without EVs, 17.4% in the group with F1 varices, and 5.7% in the group with advanced varices, and the findings were similar in the subgroup of subjects with LC ($P = 0.0004$). The incidence of CLE $\geqslant$ 5 mm in the group of subjects with advanced EVs did not differ significantly according to whether they had or had not received endoscopic treatment (7.7% and 4.8%, respectively, $P = 0.63$). The proportions with a hiatal hernia $\geqslant$ 10 mm (24.4%, 20.7%, and 13.6%, respectively) decreased in the same order as the order in which the proportions of subjects with CLE $\geqslant$ 5 mm decreased ($P = 0.017$), but the trend was not significant in the subgroup of subjects with LC.

Advanced varices: F2-F3 varices, red-color-sign positive varices, or post-treatment varices. *P* values are for trend calculated by the Cochran-Mantel-Haenszel test.

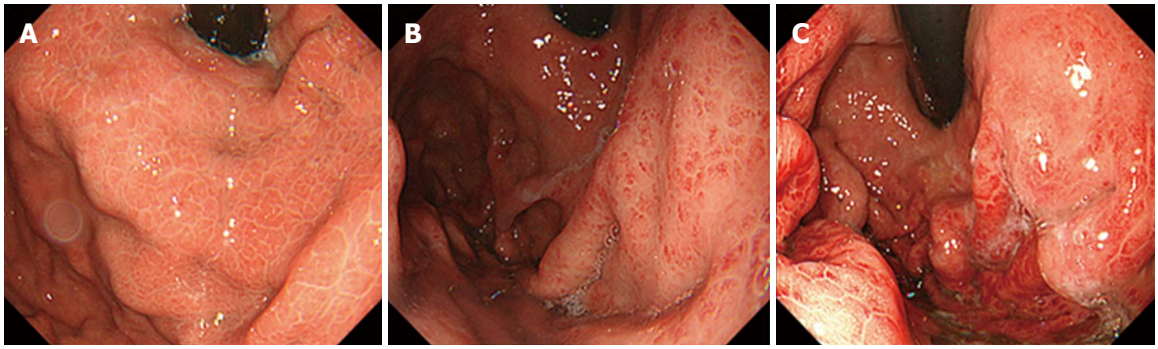

Figure 2 Portal hypertensive gastropathy lesions exhibiting a snake-skin (mosaic) pattern in their background mucosa. A: Grade 1, erythematous flecks or maculae; B: Grade 2, red spots or diffuse redness; C: Grade 3, intramucosal or luminal hemorrhage.

Table 3 shows the background factors of the 1614 subjects according to whether they had CLE ⩾ 5 mm, and there were no significant differences between the two groups in age, usual alcohol consumption, smoking, or ALDH2 and ADH1B genotypes. Hiatal hernia was more common in the group with CLE ⩾ 5 mm than in the other group (45.9% *vs* 17.3%, *P* < 0.0001). There was a significant difference between the group with CLE ⩾ 5 mm and the group without CLE ⩾ 5 mm in the proportions of 'no LC and no EVs' subjects, 'LC and no EVs' subjects, and the 'EVs' subjects they contained (*P* = 0.001). There were no significant difference between the group with CLE ⩾ 5 mm and group without CLE ⩾ 5 mm in the presence of gastric varices or the grade of PHG.

A multiple logistic regression analysis to predict the presence of CLE ⩾ 5 mm showed that the ORs (95%CI) for CLE ⩾ 5 mm increased with age per +10 years [1.15 (1.00-1.32)] and with the presence of hiatal hernia ⩾ 10 mm [4.33 (3.31-5.67)] and decreased with the presence of EVs [0.47 (0.26-0.87); Table 4]. The presence of LC, presence of gastric varices, and grade of PHG were not associated with the presence of CLE ⩾ 5 mm.

Table 5 shows the background factors of the 326 subjects with LC according to whether they had EVs, and there were no significant differences between the two groups in age, usual alcohol consumption, smoking, hepatitis C and B infection status, or ALDH2 and ADH1B genotypes. The absence of CLE ⩾ 5 mm (*P* = 0.003), presence of gastric varices (*P* < 0.0001), and higher grade PHG (*P* < 0.0001) were all more common in the LC group with EVs than in the LC group without EVs. Advanced Child-Pugh class (*P* = 0.011) was more common in the LC group with advanced EVs.

A multiple logistic regression analysis showed

that the ORs (95%CI) for EVs and advanced EVs in the subgroup of subjects with LC decreased with the presence of CLE ⩾ 5 mm [0.46 (0.23-0.93) and 0.24 (0.08-0.74), respectively, *vs* CLE 0-4 mm; Table 6]. Child-Pugh class was not associated with EV status. The ORs for EVs and advanced EVs increased with progression of the grade of PHG, and the OR for advanced EVs increased with the presence of gastric varices.

DISCUSSION

The analysis of the results of endoscopic screening of 1614 Japanese alcoholic men in this study demonstrated that the presence of CLE was negatively associated with the presence of EVs, and even more negatively associated with the presence of advanced forms of EVs. The prevalence of CLE ⩾ 30 mm has been reported to be very low (0.0%-0.2%) in Asians[8,25-27]. The prevalence of CLE ⩾ 30 mm in the present study was 0.4%, and most of the CLE was short-segmental. The presence of a hiatal hernia was a strong determinant of the presence of CLE in this study, a finding that was consistent with the results of previous studies[5,7,8,26,28], suggesting that GERD in patients with a hiatal hernia contributes to the development of CLE. Asian studies have demonstrated positive associations between excessive alcohol consumption and both GERD and short-segmental CLE[4-8,26]. The prevalence of CLE ⩾ 10 mm has been reported to be 1.8% in unselected Taiwanese, 4.0% in symptomatic Koreans[27], and 5.3% in a group of Japanese who underwent an endoscopic examination in a university hospital[8]. Thus, the high prevalence (8.1%) of CLE ⩾ 10 mm in the population of alcoholics in our study was at least in part attributable to chronic heavy drinking.

As expected, the presence of EVs was positively associated with the presence of LC, gastric varices, and PHG. However, these factors were not associated with the presence of CLE, and adjustment for these factors revealed a negative association between the presence of CLE and the presence and severity of EVs. These findings taken together suggested a special relationship between CLE and EVs in the presence of LC and portal hypertension.

In the majority of LC patients the left gastric vein is the afferent vein to the EVs[29], and the first resistance vessels to the EVs are the mucosal palisade vessels and submucosal veins at the lower end of the

esophagus, where there are many palisade vessels and few submucosal veins[12,13]. The palisade vessels penetrate the muscularis mucosae and connect to the submucosal veins 3-5 cm above the esophagogastric junction, the critical area for EV rupture[12,30,31]. Greatly enlarged palisade vessels disrupt the muscularis mucosae and form EVs across the proper mucosae and the submucosa[13], and they cause advanced EVs by

[1]Advanced forms of EVs *vs* no EVs, EVs: Esophageal varices; ADH1B: Alcohol dehydrogenase-1B; ALDH2: Aldehyde dehydrogenase-2; OR: Multivariate odds ratio; ORs and CIs were calculated by using a multiple logistic regression model; Advanced forms of EVs were F2-F3 varices, red-color-sign positive varices, or post-treatment varices.

connecting with submucosal veins or sub- and intra-epithelial channels accompanied by 'varices on varices' and positive RC signs[12,13,32].

Although there is no difference between the maximal size of the palisade vessels in the CLE and normal lower esophagus[11], it is conceivable that the development of CLE may change the microenvironment of the interstitium around the palisade vessels, *e.g.*, increased interstitial fibrosis and the formation of the shallow muscularis mucosae of a double muscularis mucosae. A double muscularis mucosae was seen in 71% of the specimens obtained by endoscopic resection of a CLE[11]. The double muscularis mucosae in CLE divides the proper mucosae into two restricted compartments, and may increase the resistance to enlargement of palisade vessels and prevent the vessels from communicating with the submucosal vessels or sub- and intra-epithelial channels[13,32], thereby inhibiting the development of enlarged EVs and RC signs. Scars secondary to endoscopic ligation or sclerotherapy were present in some of the LC subjects with post-treatment varices and their presence may have influenced the development of CLE. However, the incidence of CLE in the LC group did not differ significantly according to whether there was a history of endoscopic treatment.

The presence of the *ADH1B*2* allele in Japanese alcoholics has been demonstrated to be positively associated with the presence of advanced liver disease and the progression of Child-Pugh class[17-19], but the results of the present study showed no significant associations between the genetic polymorphism and the presence of EVs. The effect of the *ADH1B*2* allele on EVs was probably eclipsed, because 46.6% of the LC subjects lacked EVs.

Our study had several potential limitations. The first potential limitation was that it was a cross-sectional study based on the results of the endoscopic screening, and the progression of CLE and EVs was not evaluated directly. Identification of a causal relationship between these endoscopic findings would require longitudinal follow-up examinations. The second potential limitation was that we evaluated the degree of CLE by retrospectively reviewing the endoscopic images, however, the review was performed jointly by four expert endoscopists. Pathological studies of autopsied cirrhotic subjects are warranted to clarify the pathological background underlying the negative association between the presence of CEL and the presence of EVs. We did not observe any effects of alcohol consumption during the preceding year on the presence of CLE or EVs, but that may have been because of the homogeneity of the study population in terms of their extremely high alcohol consumption. Generalization of the results obtained in our study based on investigations of alcoholic men treated in the Center requires confirmation in various drinking populations, including in a population with mild alcoholism.

Helicobacter pylori infection and chronic atrophic gastritis protect against the development of GERD and CLE[5,6,33]. If the observed associations between CLE and EVs and advanced EVs reflect causal relationships, the current trend toward lower *Helicobacter pylori* infection rates in Japan may result in lower EV rates and advanced EV rates in the future, and examination for CLE may benefit alcoholics with advanced liver disease by identifying their risk for the development or

progression of EVs.

In conclusion, this cross-sectional observational study revealed a negative association between the presence of CLE and the presence of EVs in Japanese alcoholic men. Further studies should be conducted prospectively in a longitudinal fashion to confirm this finding.

ARTICLE HIGHLIGHTS

Research background

Esophageal varices (EVs) develop as a result of portal hypertension, which is mainly due to liver cirrhosis (LC) in alcoholics. Excessive alcohol consumption has been reported to be associated with the presence of a short-segmental columnar-lined esophagus (CLE) in East-Asian studies. It has not been evaluated whether associations exist between the presence of EVs and the presence of CLE in alcoholics.

Research motivation

Our empirical impression based on the results of endoscopic screening examinations of Japanese alcoholic men is that EVs are less common among men with short-segmental CLE. The development of CLE is accompanied by several histological changes around the palisade vessels at the lower end of the esophagus. Some of the histological changes accompanying the development of CLE may protect against the development of EVs.

Research objectives

To determine whether and to what extent associations exist between the presence of EVs and the presence of CLE in Japanese alcoholic men based on the results of endoscopic screening examinations.

Research methods

The subjects were 1614 Japanese alcohol-dependent men (≥ 40 years of age) who had undergone upper gastrointestinal endoscopic screening. Digitalized records of high-quality endoscopic images that included the squamocolumnar junction and esophagogastric junction were retrospectively jointly reviewed by four expert endoscopists for the purpose of diagnosing CLE. The authors investigated whether and to what extent there were associations between the presence of CLE and the presence of EVs, especially in the group with LC.

Research results

CLE ≥ 5 mm in length was found in 355 subjects, LC without EVs in 152 subjects, LC with EVs in 174 subjects, and EVs without LC in 6 subjects. Advanced EVs, *i.e.*, nodular, large or coiled forms, red color sign, or post-treatment, were found in 88 subjects. The incidence of CLE ≥ 5 mm decreased in the following order ($P < 0.0001$): 23.3% in the group without EVs, 17.4% in the group with small and straight EVs, and 5.7% in the group with advanced EVs. The multivariate ORs (95%CI) for EVs and advanced EVs in the group with LC were lower when CLE ≥ 5 mm was present [0.46 (0.23-0.93) and 0.24 (0.08-0.74), respectively, *vs* 0-4 mm CLE]. To clarify the pathological backgrounds of the negative association between the presence of CEL and the presence of EVs, the further pathological studies of autopsied cirrhotic subjects may be warranted.

Research conclusions

The presence of CLE was negatively associated with the presence of EVs, and even more negatively associated with the presence of advanced forms of EVs. Since the first resistance vessels to EVs are the mucosal palisade vessels and submucosal veins at the lower end of the esophagus, the development of CLE may impede the development of EVs. *Helicobacter pylori* infection and chronic atrophic gastritis protect against the development of GERD and CLE. If the observed associations between CLE and EVs and advanced EVs reflected causal relationships, the current trend toward to lower *Helicobacter pylori* infection rates in Japan may influence EV rates and advanced EV rates in the future, and examination for CLE may benefit alcoholics with advanced liver disease by identifying their risk for the development or progression of EVs. The further studies should be conducted prospectively in the longitudinal fashion to test this finding.

Abstract

AIM

To identify the potential risk factors of cholangiocarcinoma, we determined the characteristics of cholangiocarcinoma patients among 5 different regions of Thailand.

METHODS

All patients diagnosed with cholangiocarcinoma between 2008 and 2013 were identified using the Nationwide Hospital Admission Data registry (n = 39421). Baseline characteristics, comorbidities and survival were abstracted.

RESULTS

The annual incidence during the study period was stable in all regions. Most patients lived in the Northeast (62.8%), followed by the North (16.9%), Central (12.3%), Bangkok (5.4%), and South (n = 2.6%) regions (P < 0.0001). Significantly more cholangiocarcinoma patients had diabetes, cirrhosis, and chronic viral hepatitis B/C infection than non-cholangiocarcinoma participants (diabetes: 11.42% *vs* 5.28%; cirrhosis: 4.81% *vs* 0.92%; hepatitis B: 0.74% *vs* 0.12%; and hepatitis C: 0.50% *vs* 0.10%, P < 0.0001 for all, respectively). The overall 1-year mortality rate was 81.7%, with a stable trend over time.

CONCLUSION

Diabetes and chronic liver diseases may be associated with cholangiocarcinoma in the Thai population.

Key words: Bile duct cancer; Population-based study; Epidemiology; Liver fluke infection

© The Author(s) 2017. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Cholangiocarcinoma is highly prevalent in Thailand, particularly in the Northeast region. The high cholangiocarcinoma incidence in this region is known to be associated with a high prevalence of liver fluke infection. Cirrhosis, diabetes, and chronic viral hepatitis B and C infections have been recently identified as risk factors for cholangiocarcinoma in Western countries. In this study, we found that diabetes and chronic liver diseases may be associated with cholangiocarcinoma in the Thai population. Further study to determine the magnitude of the impact of these factors on cholangiocarcinoma development in the Thai population is necessary.

INTRODUCTION

Cholangiocarcinoma (CCA), a malignancy of the biliary tract epithelium, is of increasing importance due to its continually increasing incidence worldwide[1-7]. The incidence of CCA varies substantially from region to region, with a high incidence in Asia [*e.g.*, 22.9, 7.5, and 5.6 cases per 100000 persons in Thailand[2], China[7] and South Korea[5], respectively] and a low incidence in the United States and Europe [*e.g.*, 3.4, 1.6, 1.3, and 1.2 cases per 100000 persons in Italy[3], the United States[6], France[8], and the United Kingdom[4], respectively]. Variation in the global incidence of CCA is due to variations in risk factors, particularly host and environmental risk factors. Within Thailand, the incidence of CCA also varies geographically[9]. The Northeast region of Thailand has the most CCA cases, with an incidence rate of 85 cases per 100000 persons per year, whereas the South region has the lowest number of cases at 5.7 cases per 100000 persons per year. The high incidence of CCA in Northeast Thailand is related to the high prevalence of liver fluke or *Opisthorchis viverrini* (OV) infection[10].

In addition to liver fluke infection, primary sclerosing cholangitis (PSC) is another major risk factor for CCA[11]. PSC is a major cause of CCA in Western populations and is associated with an 80- to 160-fold increase in CCA risk[12,13]. Although PSC markedly increases CCA risk, PSC is present in only 20% of all CCA patients[14]. Most CCA patients do not have identifiable risk factors.

Cirrhosis, chronic viral hepatitis B and C infection, diabetes, obesity, and smoking have recently been shown to be associated with increased CCA risk[12-14]. These factors were believed to contribute to the increasing incidence of CCA in the United States[15]. The question regarding whether or not these pre-existing conditions contribute to CCA development in the Thai population, particularly in people living in areas that are non-endemic for liver fluke infection, has not yet been studied. Accordingly, the objectives of this study were to compare the characteristics of CCA patients among the 5 different regions of Thailand. Secondarily, survival outcomes were determined. This population-based study was conducted using data from the National Health Security Office, Thailand.

MATERIALS AND METHODS

Ethical considerations

The protocol of this study was approved by the

Institutional Review Board of the Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand (IRB No. 113/58).

Data source

The data were obtained from the Nationwide Hospital Admission Data (NHAD) registry. The data were already de-identified before the investigators accessed them. Briefly, the NHAD registry is a database that contains hospitalization data of Thai citizens who are covered by the national Medical Welfare Scheme (MWS). The MWS was established in Thailand in 2000 and is currently one of 3 major health insurance systems. During the study period, the MWS covered approximately 47 million of the 64 million total Thai people in all age groups across Thailand. Those who have health insurance coverage by the MWS can access health services in hospitals that are registered with the National Health Security Office. Patients have access to the hospitals that are assigned to each individual by the household registration system. At the time of data collection, there were 39421 hospitals in the registry, of which 14402 (36.5%) were primary or community hospitals that provide primary healthcare, 11277 (28.6%) were secondary hospitals that provide general healthcare, and 13742 (34.9%) were tertiary referral hospitals that provide specialized care for complex cases.

Study population

CCA cases: All patients diagnosed with CCA who were admitted to affiliated hospitals during the January 2008 to December 2013 study period were identified in the NHAD registry using the International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) codes of C22.1 (intrahepatic cholangiocarcinoma), C24.0 (extrahepatic cholangiocarcinoma), C24.1 (cancer of the ampulla of Vater), C24.8 (cholangiocarcinoma whose subtype cannot be classified), and C24.9 (cholangiocarcinoma, unspecified subtype). Cancer of the ampulla of Vater was included in this study because it occurs within 2 cm of the distal end of the common bile duct. Demographic data, including age, gender, and residential area, were collected and recorded. Potential risk factors for CCA, including cirrhosis, diabetes, and chronic viral hepatitis B and C infection, were collected using the corresponding ICD-10 codes, as follows: HBV infection: B18.0 and B18.1; HCV infection: B18.2; cirrhosis: K74, K74.0, K74.1, K74.2, K74.6, K70.2, K70.3, and K70.9; and diabetes mellitus type 2: E11. Date of death was obtained from the death certificate.

Controls: There were 2 control cohorts in this study. First, to compare demographic differences between CCA patients and non-CCA individuals, all Thai citizens were used as controls (n = 64076033). Demographic data of the Thai citizens were obtained in the year 2011 (the midpoint of the study period) from the Department of Provincial Administration, Ministry of the Interior, Thailand (Table 1). Second, to explore the potential associations between cirrhosis, diabetes and chronic viral hepatitis B and C infections and CCA development in the Thai population, patients without CCA who were admitted to hospitals during the study period were used as controls (n = 18508448). The data of non-CCA controls were obtained from discharge summary notes in the same manner as CCA cases.

Statistical analysis

All data analyses were performed using PASW® Statistics version 18 (SPSS, Inc., Chicago, IL, United States) and STATA version 12.1 (StataCorp LP, College Station, TX, United States). The patients were divided into 1 of the following 5 geographic region groups: Northeast, North, Central, Bangkok, or South. Bangkok is the capital of Thailand and is located in the Central geographic region. However, we designated Bangkok as a separate region because it has several major university hospitals that may be able to provide more technologically advanced treatment options than most hospitals located in other parts of the country. The annual incidence rate of CCA was calculated by dividing the number of new patients who were admitted with a diagnosis of CCA annually by the general population in the same year. Underlying diseases and one-year mortality rates were compared among regions using Student's t-test for continuous variables and chi-square test for categorical variables.

Demographic data of CCA patients and all Thai citizens were compared using chi-square and t-tests. The proportions of individuals with cirrhosis, diabetes and chronic viral hepatitis B and C infections between CCA and non-CCA patients who were admitted to the hospital were compared during the study period using a χ^2 test. Data are presented as a number, number (%), or mean ± SD.

One-year mortality was calculated using the per-patient information in which the survival time was calculated from the subtraction between the date of death and the date of the first admission. One-year mortality was then defined as 1 if the survival time was less than a year and 0 otherwise. An analysis of the trend in CCA incidence and mortality was performed using "nptrend", the nonparametric test for trend across ordered groups developed by Cuzick (1985), which is an extension of the Wilcoxon rank-sum test. A P-value of < 0.05 indicated statistical significance.

RESULTS

Baseline characteristics

There were 39421 patients diagnosed with CCA who

Table 1 Baseline characteristics of cholangiocarcinoma patients diagnosed between 2009 and 2013 *n* (%)

Variable	CCA cases (*n* = 39421)	Thai population (*n* = 64076033)	*P* value
Gender			
Male	24120 (61.2)	31529148 (49.2)	< 0.001
Age (mean ± SD, yr)	64.1 ± 11.7	34.9[1]	
Geographic region			< 0.0001

Bangkok	5.87	6.17	6.27	5.52	6.01	0.85
South	2.76	2.74	2.98	2.81	2.98	0.17

Table 3 Proportions of individuals with potential predisposing conditions to cholangiocarcinoma development *n* (%)

Conditions	CCA patients (*n* = 39421)	Non-CCA patients (*n* = 18508448)	*P* value
Cirrhosis	1896 (4.81)	170255 (0.92)	< 0.001
Chronic viral hepatitis B infection	291 (0.74)	21797 (0.12)	< 0.001
Chronic viral hepatitis C infection	196 (0.50)	18339 (0.10)	< 0.001
Diabetes	4502 (11.42)	977973 (5.28)[1]	< 0.001

[1]The number was estimated from the proportion of individuals with diabetes among 1900000 patients on whom data on diabetes were available, assuming the proportion of individuals with diabetes was similar between those with and without data on diabetes. CCA: Cholangiocarcinoma.

were admitted to the affiliated hospitals during the study period. The mean ± SD age was 64.0 ± 11.7 years, and most patients (61.2%) were male. When compared by geographic area, the number of CCA patients varied significantly. The Northeast region had the greatest number of CCA cases (24239; 61.5%), followed by the North (6699; 17.0%) and Central regions (5295; 13.4%) ($P < 0.0001$) (Figure 1). Bangkok had a relatively low number of CCA cases (1114; 2.8%), and the South region had the lowest number of CCA patients (1056; 2.7%) (Table 1). Differences in the demographic characteristics between CCA cases and the general population are shown in Table 1. During the study period, the annual incidence rate was stable over time, *i.e.*, 15.8, 15.6, 16.3, 16.1, and 16.4 cases per 100000 persons-year in the years 2009, 2010, 2011, 2012, and 2013, respectively, $P_{trend} = 0.13$. When classified by region, the annual incidence rate in each region remained stable over the course of the study period (Table 2).

Potential factors contributing to CCA in Thailand

Among the comorbid diseases potentially associated with CCA that were studied, diabetes was the most frequently detected, affecting 11.42% ($n = 4502$) of the entire CCA cohort. Cirrhosis and chronic viral hepatitis B and C infection were present in 1896 (4.81%), 291 (0.74%), and 196 (0.50%) patients, respectively (Table 3). CCA patients with cirrhosis ($n = 1896$) were significantly more likely to have hepatitis B infection, hepatitis C infection and alcoholic liver disease than CCA patients without cirrhosis ($n = 37525$), *i.e.*, 124 (6.5%) *vs* 132 (0.3%), 100 (5.3%) *vs* 84 (0.2%), and 197 (10.4%) *vs* 0 (0%) for hepatitis B infection, hepatitis C infection and alcoholic liver disease, respectively; $P < 0.0001$ for all.

In a comparison of the proportion of individuals with underlying diabetes and chronic liver diseases between CCA *vs* non-CCA patients, we found that a greater proportion of CCA patients had diabetes than non-CCA patients, *i.e.*, 4502/39421 (11.42%) *vs* 977973/18508448 (5.28%), $P < 0.001$, respectively. Similarly, a significantly greater proportion of CCA patients had viral hepatitis B and C infection and cirrhosis, *i.e.*, 291/39421 (0.74%) *vs* 21797/18508448 (0.12%), 196/39421 (0.50%) *vs* 18339/18508448 (0.10%), and 1896/39421 (4.81%) *vs* 170255/18508448 (0.92%) for viral hepatitis B, viral hepatitis C and cirrhosis, respectively; $P < 0.001$ for all comparisons (Table 3).

Compared to the Northeast region, all regions had a higher proportion of CCA cases with cirrhosis (5.39%, 6.84%, 7.46%, and 5.97% *vs* 3.97% for North, Central, Bangkok, and South *vs* Northeast, respectively; $P < 0.0001$ for all comparisons). Similarly, all regions except for Bangkok had a significantly greater proportion of CCA patients with chronic viral hepatitis B infection than the Northeast region (11.36%, 1.52%, and 1.11% in the North, South, and Central regions *vs* 0.44% in the Northeast, respectively; $P < 0.001$ for all comparisons) (Table 4). Bangkok had a borderline significantly greater proportion of individuals with chronic hepatitis B than the Northeast ($P = 0.05$) (Table 4). Taken together, these findings suggest that cirrhosis and chronic viral hepatitis B infection may be partly associated with the

Table 4 Proportion of cholangiocarcinoma patients who had underlying diabetes and chronic liver diseases *n* (%)

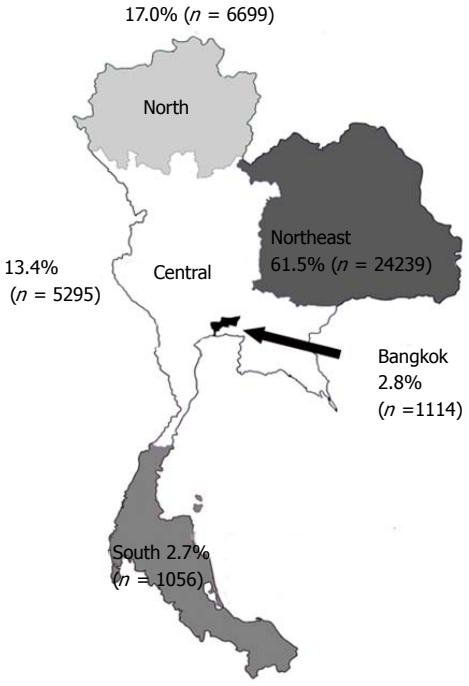

Figure 1 Northeast region had the greatest number of cholangiocarcinoma cases, followed by the North and Central regions.

development of CCA in our population.

Outcome of CCA patients

At the end of the study period, 35190 (89.27%) patients had died, of whom 31366 had died within 1 year after CCA diagnosis, corresponding to a 1-year mortality rate of 81.68%. The study period mean one-year mortality rates were stable (80.6%, 82.6%, 81.8%, 82.0%, and 81.5% for the years 2009 to 2013; P_{trend} = 0.85) (Table 5). A stable one-year mortality rate was also observed when evaluated by region (Table 5).

DISCUSSION

In this population-based study of 39421 Thai CCA patients, we observed substantial heterogeneity in the CCA incidence across various regions of Thailand. To a lesser degree, we also observed variation in mortality across the country. Our findings suggest that diabetes, liver cirrhosis, and chronic viral hepatitis B and C infection may contribute to CCA risk in the Thai population.

As expected, we found that approximately 62% of patients resided in Northeast Thailand, whereas only 3% of patients lived in the South region. The frequency of CCA cases in each region was correlated with the reported prevalence of OV infection in each area (as high as 67% in the Northeast and only 0.1% in the South)[16,17]. OV infection was shown to be associated with a 10-fold increased risk of CCA[10]. Accordingly, the eradication of OV infection could potentially reduce the incidence of CCA in Thailand. Indeed, a national program to control OV infection has been rigorously applied since 2000[17]. After the implementation of a comprehensive control program in a certain area in the Northeast in which the prevalence of OV infection was as high as 67%, the OV infection rate declined to 16%[17]. With the continuation of this control program, we may see a decline in CCA incidence in this particular study area over the next decade.

There is a body of evidence that suggests that chronic liver diseases and diabetes are potential risk factors for CCA[12-14,18,19]. Cirrhosis was shown to be associated with at least a 5-fold increase in CCA

risk[12-14,20]. Previous studies have shown that CCA patients had a higher proportion of individuals with cirrhosis than controls, with proportions ranging from 3% to 10% depending on the enrolled population, study design, and subtype of CCA studied[12-14,20]. In this study, a significantly greater proportion of CCA patients had cirrhosis than non-CCA patients. Additionally, the proportions of CCA cases with cirrhosis in non-endemic areas of OV infection (Central, Bangkok, and South regions) ranged from 5.6% to 7.5%, which were comparable to the rate of 7.8% reported in a Korean study[20]. Interestingly, the proportions of CCA patients with cirrhosis in the non-endemic areas of OV infection were significantly higher than the proportion in the Northeast region. Taken together, these findings suggest that cirrhosis may be a potential factor that contributes to CCA in Thai individuals, particularly in those who are not infected with OV.

Chronic viral hepatitis B and C infections have recently been recognized as potential risk factors for CCA[12-14,20-22]. In line with previous reports, we found that significantly more Thai patients with CCA had chronic viral hepatitis B and C infections than non-CCA patients. Two recent meta-analyses reported that hepatitis B and C infection confer risks of CCA with odds ratios of 2.0 and 5.4, respectively[21,22]. The magnitude of the effect of hepatitis B infection on CCA risk was more pronounced in Asian than in non-Asian populations. For example, the odds ratios for hepatitis B infection were 4.1 and 8.9 in Korean and Chinese cohorts[18,23], but only 2.8 in an American cohort[13]. Data related to the effect of hepatitis B and C infection on CCA risk in the Thai population are scarce[24]. The only report we were able to identify in the literature did not identify a significant association between hepatitis B/C infection and CCA; however, the study was conducted in an area endemic to OV infection, and the effect of hepatitis B and C on CCA risk may have been masked by the higher effect magnitude of OV infection[24].

We observed that an approximately 2-fold greater proportion of CCA patients had diabetes than non-CCA patients (11.4% *vs* 5.3%). A recent large case-control study of 2395 CCA cases and 4769 controls conducted in the United States reported that the proportion of subjects with diabetes among CCA cases and controls was 18.2% and 10.0%, respectively[13]. Accordingly, diabetes increased the risk of developing CCA by 2.7-fold, and this magnitude of risk was consistent with a reported odds ratio of 2.6 for developing CCA among Korean individuals with diabetes[13,18].

Taken together, our findings suggest that all of the studied underlying comorbid diseases potentially contribute to the risk of developing CCA in a Thai population. Future studies to confirm these findings and to determine the magnitude of the effect of these factors in a Thai population are warranted.

The major strength of this study is that our data were obtained from the Nationwide Hospital Admission Data (NHAD) registry, which is a database that includes the hospitalization data of 73% of all Thai citizens. As such, these findings most likely reflect an overall characterization of this cancer in Thailand. This study also has some mentionable limitations. First, the annual incidence estimated in this study might be underestimated due to the unique features of this database. The database solely includes information during hospitalization. Because data of patients seen at outpatient departments were not available, this could raise a concern that some patients, particularly those with advanced stage CCA who were only seen at outpatient departments and had never been admitted to a hospital, might be missed. We admit that this is possible; however, based on the current practice in our country, most CCA patients require at least one hospitalization, either for performing an investigation for a definite diagnosis or for receiving treatment by surgery, biliary drainage with palliative chemotherapy or even the best supportive care. Thus, we believe that the number of CCA patients who did not have any hospitalization was not large, and this number did not significantly affect the overall findings observed in this study. Second, the diagnosis of CCA was made by ICD codes that were obtained from hospital discharge summary notes and without histopathological confirmation. Consequently, the actual number of CCA patients during the study period could be higher than the number presented here. However, the proportions of CCA patients by region were consistent with the rates reported in a previous study[2]. As a result, it is likely that the different incidence rates among the 5 different regions are a valid finding. Another concern was that the proportion of CCA patients in each region shown in this study might not reflect the actual region of residence of patients because some local people might migrate to other regions; in particular, a portion of Northeastern people migrate to work in Bangkok. Thai people are covered by the national MWS only if they visit their primary hospital, which is designated by household registration. Patients who require hospitalization are usually referred back to their primary hospital. If necessary, the primary hospital will further refer patients to the nearby secondary or tertiary hospitals within the same region. Thus, the effect of migration across regions had a minimal impact on the proportion of patients in each region. Data on hepatitis B/C infection, diabetes, smoking, alcohol drinking, obesity, and metabolic syndrome were not available in the discharge summary notes of all participants, thus precluding us from estimating the effect of these conditions on CCA risk. Similarly, the prevalence of OV infection and the relationship between OV infection and CCA incidence cannot be

determined because the diagnosis of OV infection was not available in the medical records. The diagnosis of CCA was obtained from ICD codes, which group hilar and distal CCA together as extrahepatic CCA; thus, an analysis by CCA subtypes could not be performed. Choledocholiathiasis, hepatolithiasis, choledochal cysts, Caroli's syndrome and bile duct adenoma have been shown to be associated with CCA[1,14]. These conditions were not included in the analysis because this study aimed to explore the conditions that have recently been proposed to be related to CCA and may in part contribute to the increasing incidence of CCA worldwide.

In summary, CCA-related incidence and mortality among Thai patients vary by geographical region. Our findings yield indirect evidence that supports current epidemiological data that suggests that diabetes, cirrhosis, and chronic viral hepatitis B and C infection are associated with an increased risk of developing CCA. These conditions may be important factors contributing to CCA in Thai individuals.

COMMENTS

Background

The incidence of cholangiocarcinoma (CCA) has been increasing for a few decades for unclear reasons. Primary sclerosing cholangitis, liver fluke infection, and conditions with chronic biliary tract inflammation are established predisposing factors to CCA development. Accumulating evidence suggests that cirrhosis, chronic viral hepatitis B/C infection and diabetes are associated with CCA.

Research frontiers

The results of this study provide indirect evidence supporting the current epidemiological knowledge about risk factors of CCA.

Innovations and breakthroughs

This study used the Nationwide Hospital Admission Data (NHAD) registry to identify potential risk factors for CCA among 5 different regions of Thailand. The two key findings were that the incidence of CCA varied geographically in Thailand and that significantly more CCA patients had diabetes, cirrhosis, and chronic viral hepatitis B/C infection than non-CCA participants.

Applications

This study suggests that diabetes, cirrhosis, and chronic viral hepatitis B and C infection may contribute to CCA development in the Thai population. Further study to confirm these associations and determine the magnitude of the impact of these factors on cholangiocarcinoma development in the Thai population is warranted.

Terminology

Cholangiocarcinoma is a cancer of the bile duct epithelium. CCA can be categorized into 3 subtypes: intrahepatic, perihilar and distal cholangiocarcinoma. Although the three subtypes share some common features, each has its own characteristics, including genetic alterations, presentation, treatment and prognosis. Obtaining a diagnosis of cholangiocarcinoma using ICD codes precludes the analysis by subtypes because the ICD codes group perihilar and distal cholangiocarcinoma together as extrahepatic cholangiocarcinomas.

Peer-review

This study addresses an important healthcare problem in Thailand. This is an informative article about the risk factors of cholangiocarcinoma in Thailand using a nationwide database. This study aimed to identify potential risk factors of cholangiocarcinoma among 5 different regions of Thailand. The fact that even in Thailand, diabetes, viral hepatitis B/C infection and cirrhosis are risk factors of cholangiocarcinoma in a region where fluke infection is not endemic, is interesting.

Abstract

AIM

To investigate the expression of annexin A5 in serum and tumor tissue of patients with colon cancer and to analyze its clinical significance.

METHODS

Ninety-three patients with colon cancer treated at our hospital between February 2013 and March 2016 were included in an observation group, and 40 healthy individuals were included in a control group. Enzyme-linked immunosorbent assay was performed to determine the serum level of annexin A5, while immunohistochemistry was performed to determine the expression of annexin A5 in cancer tissues.

RESULTS

The serum level of annexin A5 was 0.184 ± 0.043 ng/mL in the observation group, which was significantly higher than that in the control group ($P < 0.05$). Annexin A5 expression was detected in 79.31% of the patients with lymph node metastasis, which was significantly higher than that in patients without lymph node metastasis ($P < 0.05$). Moreover, annexin A5 expression was detected in 86.96% of the patients with stage Ⅲ to Ⅳ disease, which was significantly higher than that in patients with stage Ⅰ to Ⅱ disease ($P < 0.05$). The serum level of annexin A5 was 0.215 ± 0.044 ng/mL in patients whose tumors were positive for annexin A5 expression, which was significantly higher than that in patients whose tumors were negative for annexin A5 expression ($P < 0.05$). The serum level of annexin A5 was correlated with annexin A5 expression in colon cancer tissues (*r*

= 0.312, $P < 0.05$). When a cutoff value of > 0.148 ng/mL for serum level of annexin A5 was used in the diagnosis of colon cancer, the sensitivity was 83.90%, and the specificity was 57.50%.

CONCLUSION

For patients with colon cancer, annexin A5 expression in cancer tissues is related to lymph node metastasis and tumor grade. Serum level of annexin A5 is related to annexin A5 expression in cancer tissues and is of diagnostic relevance.

Expression of annexin A5 in serum and tumor tissue of patients with colon cancer and its clinical significance. *World J Gastroenterol* 2017; 23(39): 7168-7173 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i39/7168.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i39.7168

INTRODUCTION

Colon cancer is a common malignancy of the digestive tract. Studies have shown that the incidence of colon cancer is ⩾ 0.005%[1] and that the incidence has continued to trend upwards in recent years because of risk factors such as diet and smoking[2,3] .

Basic cancer research has shown that changes in the levels of certain molecules affect tumor cell proliferation and differentiation, which in turn affect the development and progression of malignant tumors[4]. Annexin A5, first isolated from human placenta, was found to bind to phosphatidylserine in a calcium-dependent manner[5,6]. In the present study, 93 patients with colon cancer who were treated at our hospital between February 2013 and March 2016 were included to investigate the expression of annexin A5 in serum and in cancer tissues, with an aim to investigate its clinical significance.

MATERIALS AND METHODS

General information

Ninety-three patients with colon cancer (observation group) who were treated at our hospital between February 2013 and March 2016 were included in this study. The inclusion criteria were as follows: (1) pathologically confirmed colon cancer; (2) complete clinical and pathological data; and (3) being willing to provide informed consent. The exclusion criterion was incomplete clinical or pathological data. Forty healthy individuals who underwent a routine health checkup at our hospital were included as controls. No significant difference was observed with respect to age or gender between the two groups (Table 1).

Detection of serum level of annexin A5

A fasting venous blood sample was collected from each subject in the morning and centrifuged at 10000 *r*/min to separate the serum, which was then stored at -20 ℃ and tested within one week to determine the annexin A5 level. The Roche automated biochemical analyzer E170 module was used for testing, and the assay kit was purchased from Shanghai Taikang Biotechnology Co., Ltd. The assay was performed according to the instructions given in the package insert. Control serum or standard was included with the kit.

Immunohistochemistry

Paraffin sections were deparaffinized, rehydrated, and cut into 3 mm sections. The sections were incubated in 3% H_2O_2 at room temperature for 5 min, rinsed with deionized water (3 min × 3 times), blocked with 10% milk protein (1 g protein in 100 mL of purified water), and incubated at room temperature for 5 min. Next, the sections were incubated with a mouse anti-annexin A5 antibody (Nanjing Biyuntian Biotechnology Co., Ltd.) for 2 h at 37 ℃, followed by a PBS wash (5 min × 3 times). Then, the slides were incubated with a horseradish peroxidase-labeled rabbit secondary antibody (Roche) for 30 min at 37 ℃, followed by a PBS wash (5 min × 3 times). After that, the slides were incubated with NBT/BCIP reagent, which was used to develop the reaction, for 5 min. Finally, the sections were counterstained, dehydrated, cleared, mounted, and observed under an OLIPICS microscope (Shanghai Precision Instrument Co., Ltd). All the required reagents were purchased from Nanjing Taikang Biotechnology Co., Ltd.

Evaluation criteria for immunohistochemical staining

Immunohistochemical staining was considered positive if yellow granules were present in the cytoplasm of tumor cells or stromal cells. The staining intensity was graded as follows: 0, no staining; 1, light yellow; 2, yellow; and 3, brown. The percentage of positive cells was scored as follows: 0, < 5%; 1, 5% to 24%; 2, 25% to 50%; 3, 51% to 74%; and 4, and ⩾ 75%. The product of the staining intensity and the percentage of positive cells was either < 2 (negative) or ⩾ 2 (positive).

Group	*n*	Annexin A5	*t*	*P* value
Observation group	93	0.184 ± 0.043	2.904	< 0.05
Control group	40	0.159 ± 0.051		

Statistical analysis

SPSS v19.0 was used for statistical analyses. Measurement data are expressed as mean ± SD and were analyzed by the *t*-test. Count data were analyzed by the χ^2 test. Spearman rank correlation analysis was performed to analyze potential correlations between variables. A receiver operating characteristic curve was used to analyze the diagnostic value of serum annexin A5 level. $P < 0.05$ was considered statistically significant.

RESULTS

Annexin A5 expression in cancer tissue

No significant difference was observed in the positive expression rates of annexin A5 among patients of different ages or genders, or those with different tumor diameters. Moreover, 79.31% of the patients with lymph node metastasis expressed annexin A5, which was significantly higher than the percentage of patients without lymph node metastasis ($P < 0.05$); 86.96% of the patients with stage Ⅲ to Ⅳ disease expressed annexin A5, which was significantly higher than the percentage of patients with stage Ⅰ to Ⅱ disease ($P < 0.05$) (Table 2).

Serum levels of annexin A5 in the two groups

The serum level of annexin A5 was significantly higher in the observation group than in the control group ($P < 0.05$) (Table 3).

Correlation between serum level of annexin A5 and expression of annexin A5 in tumor tissue

The serum level of annexin A5 was 0.215 ± 0.044 ng/mL in patients whose colon tumors were positive for annexin A5 expression, which was significantly higher than the corresponding value in patients whose colon tumors were negative for annexin A5 (0.180 ± 0.021 ng/mL) ($t = 4.599$, $P < 0.05$). A Spearman rank correlation analysis showed that the serum level of annexin A5 was related to the expression of annexin A5 in tumor tissues ($r = 0.312$, $P < 0.05$).

Diagnostic value of serum level of annexin A5

The ROC curve for the serum level of annexin A5 in the diagnosis of colon cancer showed an area under the curve of 0.732 ($P < 0.05$). At a cutoff value of 0.148 ng/mL, the sensitivity was 83.90%, and the specificity was 57.50% (Figure 1).

DISCUSSION

Changes in diet, excessive alcohol consumption, and genetic susceptibility factors promote the development and progression of colon cancer. In particular, among elderly male smokers aged 45 or older, the incidence of colon cancer is 0.005% or higher and has continued to trend upwards in recent years[7,8]. For colon cancer, the incidence of early metastasis is high, which results in poor patient outcomes: the five years survival rate is < 35%, and the median survival time is < 32 mo[9-11]. Studies on the genetic and biological mechanisms of the development and progression of colon cancer may provide new targets for immune therapy or strategies of comprehensive biological therapy for colon cancer[12,13].

Molecular changes play an important regulatory role in the development of malignant tumors. Cell surface Connexins or membrane proteins can induce the transcription initiation activity of downstream oncogenes, which promotes aberrant activation of the cell cycle in colonic epithelial cells and leads to excessive proliferation of cancer cells[14]. Accumulating experimental data indicate that phosphatidylserine exposition is associated with apoptosis and other cell death programs[15-17], which renders it an attractive target in imaging overall cell death. Annexin A5 is identified in blood vessel as a blood anticoagulation factor and it builds voltage-dependent calcium channel in phosphatidylserine bilayers[18,19]. Corsten *et al*[20] showed that through binding with strong affinity to phosphatidylserine, annexin A5 offers an interesting opportunity for visualization of aggregate

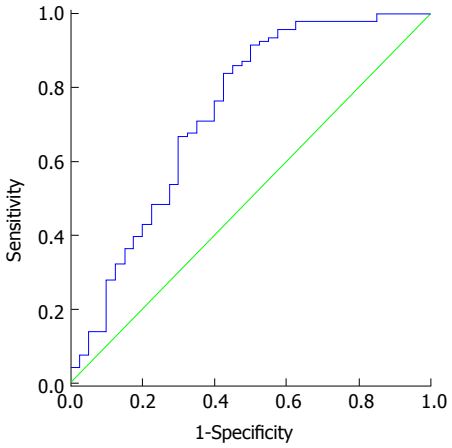

Figure 1 Receiver operating characteristic curve for the value of serum level of annexin A5 in the diagnosis of colon cancer.

cell death[21,22], thus providing a fit benchmark for *in vivo* monitoring of anticancer treatment[23-26]. Recently, annexin A5 has been reported as a new mediator of cisplatin-induced apoptosis by inducing voltage-dependent anion channel oligomerization in human kidney epithelial cells[27,28]. Annexin A5 forms N6-acetyllysine at specific positions of the amino-terminal region of the membrane protein, and as a result, it affects the formation of a transcriptional co-inhibitory complex and participates in transcriptional repression and silencing of tumor suppressor genes via H1 phosphorylation[29,30]. Previous studies have investigated the relationship between annexin A5 and liver cancer or esophageal cancer and showed that uH2B-related monotone generalization increased the risk of malignant digestive tumors and promoted clinical progression[31-34]. This study explored not only the expression of uH2B in colon cancer tissue but also the diagnostic value of its serum level in the diagnosis of colon cancer.

In this study, immunohistochemical staining showed significantly high expression of annexin A5 in colon cancer tissue and demonstrated that the positive expression rate of annexin A5 was significantly higher in patients with lymph node metastasis than in those without. This suggests that annexin A5 may play a role in the promotion of the invasion of lymph nodes by colon cancer cells. Furthermore, approximately 80% of the patients with late-stage (Ⅲ and Ⅳ) colon cancer expressed annexin A5, which was significantly higher than the percentage of patients with stage Ⅰ or Ⅱ disease, which suggests that annexin A5 significantly promotes the clinical progression and worsening of colon cancer. Annexin A5 induces the activation of second messengers in cancer cells, which promotes the production of cancer cell differentiation antigens, the proliferation and differentiation of colon cancer cells, and clinical progression.

In conclusion, annexin A5 is highly expressed in serum and tumor tissues of patients with colon cancer, and its expression is closely related to the clinical stage and presence of lymph node metastasis in patients with colon cancer. Nevertheless, this study has certain limitations. For instance, we did not investigate the relationship between the expression of annexin A5 and the long-term survival of patients with colon cancer.

COMMENTS

Background

Colon cancer is a common malignancy of the digestive tract. Studies have shown that the incidence of colon cancer is ⩾ 0.005% and that the incidence has continued to trend upwards in recent years because of risk factors such as diet and smoking.

Research frontiers

Basic cancer research has shown that changes in the levels of certain molecules affect tumor cell proliferation and differentiation, which in turn affect the development and progression of malignant tumors. Annexin A5 is a glycoprotein that contains a multiplex carboxyl terminus binding domain, which influences the differentiation of surface antigens on cancer cells and promotes tumor proliferation and invasion.

Innovations and breakthroughs

The objective was to investigate the clinical significance of annexin A5 expression in colon cancer.

Applications

For patients with colon cancer, annexin A5 expression in cancer tissues is related to lymph node metastasis and tumor grade. Serum level of annexin A5 is related to annexin A5 expression in cancer tissues and is of diagnostic relevance.

Peer-review

In this study, the authors investigated the expression of annexin A5 in serum and tumor tissues of patients with colon cancer and its clinical significance.

Abstract

Fecal microbiota transplantation (FMT) is effective in recurrent *Clostridium difficile* infection (rCDI). Knowledge of the safety and efficacy of FMT treatment in immune deficient patients is scarce. FMT has been

suggested as a potential method for an increasing number of new indications besides rCDI. Among our FMT-treated rCDI patients, we reviewed those with major comorbidities: two human immunodeficiency virus patients, six haemodialysis patients, two kidney transplant patients, two liver transplant patients and a patient with chronic lymphatic leukaemia. We also reviewed those treated with FMT for indications other than rCDI: *Salmonella* carriage (two patients), trimethylaminuria (two patients), small intestinal bacterial overgrowth (SIBO; one patient), and lymphocytic colitis (one patient), as well as a common variable immunodeficiency patient with chronic norovirus infection and ESBL-producing *Escherichia coli* (*E. coli*) carriage. Of the thirteen rCDI patients treated with FMT, eleven cleared the CDI. The observed adverse events were not directly attributable to FMT. Concerning the special indications, both *Salmonellas* and ESBL-producing *E. coli* were eradicated. One trimethylaminuria patient and one SIBO-patient reported a reduction of symptoms. Three patients did not experience a benefit from FMT: chronic norovirus, lymphocytic colitis and the other fish malodour syndrome. There were no reported side effects in this group. FMT appeared to be safe and effective for immunocompromised patients with rCDI. FMT showed promise for the eradication of antibiotic-resistant bacteria, but further research is warranted.

Core tip: Knowledge of faecal microbiota transplantation (FMT) in immunocompromised patients and patients with conditions other than recurrent *Clostridium difficile* infection (rCDI) is scarce. We reviewed 13 FMT-treated patients with rCDI and major comorbidities as well as 8 patients with new indications. In our cohort, FMT appeared to be safe and effective for immunocompromised patients: dialysis patients, human immunodeficiency virus patients, solid organ transplant patients and a patient with chronic lymphatic leukaemia. Of the patients treated for indications other than rCDI, the most promising results were successful eradication of antibiotic-resistant bacteria. Eradication of chronic *Salmonella* carriage in two patients with FMT represents the first cases reported to date.

INTRODUCTION

The intestinal microbiota is an area of active research. Knowledge of the human microbiota has been accumulating rapidly in recent years. The gut bacteria was previously regarded as passive or harmful waste, but the intestinal microbiota is currently respected as a well-orchestrated organism with an active role in the development of immunity and maintenance of health[1-4].

Microbial imbalance, dysbiosis, is suggested to play a role in many different diseases. The microbiota holds many expectations as a new treatment target. Faecal microbiota transplantation (FMT) is a straightforward way to change the microbial composition of the intestine[1-4]. FMT has been shown to induce profound and long-lasting changes in the microbiota, offering a means to modify the gut microbiota relatively permanently for the treatment of microbiota-associated diseases[5].

FMT has become a widely accepted treatment for recurrent *Clostridium difficile* infection (rCDI)[6-9]. We, among others, have shown that FMT through colonoscopy is an effective treatment for rCDI[5]. Experience in many centres has shown that FMT is also safe when performed to a high standard[10-13].

The risk of adverse events of FMT is low in well performed studies[6]. Rigorous screening of the donor is mandatory. Without proper screening, there is a possibility of transmitting infectious diseases and a possibility of transmitting conditions that FMT is suspected to ameliorate, such as obesity[14].

All FMT should be performed at a health care unit by professionals who are familiar with the procedure[15]. FMT is currently indicated only for rCDI[15]. If FMT is used for other indications, then patients should be carefully evaluated, and the results, whether positive or negative, should be reported. Our group has treated a few patients with conditions other than rCDI and outside of on-going study programmes. Such cases have been evaluated carefully on an individual basis by a gastroenterologist, an infectious disease specialist and a microbiologist.

Although FMT has been effective and generally safe in published studies, data concerning FMT in certain special groups are scarce[16]. More information is needed regarding the safety of FMT in immunosuppressed and other special groups such as patients undergoing haemodialysis[12]. In our FMT-treated patients, we gathered information on patients with significant comorbidities, such as immune-deficient patients, patients with an organ transplant and hae-

modialysis patients.

CASE REPORT

Study design

Of the patients treated with FMT in Helsinki University Hospital, we searched for those treated for rCDI and having major comorbidities and those treated for indications other than rCDI. We included dialysis patients and patients with known immune deficiencies in the rCDI group; human immunodeficiency virus (HIV), organ transplant or hematologic disease. We found 13 patients with rCDI and major comorbidities and 8 patients with conditions other than rCDI. We review the patient histories, the outcomes and adverse events of each patient.

Ethical aspects

Since FMT policy and legislation differ from country to country[17,18], we consulted the Finnish Medicines Agency (Fimea), which is the national competent authority for regulating pharmaceuticals and blood and tissue products. Fimea noted that stool does not fall under the category of pharmaceuticals and did not consider it relevant to the establishment of new regulations specifically for FMT. In Finland, FMT studies do not require approval of the drug authority Fimea.

In Finland, FMT may be used by doctors based on their own judgement. We recommend that clinicians using FMT follow international guidelines[15,19]. FMT is indicated for rCDI treatment; for other indications, it should be used only in a clinical trial setting.

FMT protocol

Some of the patients described in this article have been treated with stool from a donor familiar to them. Most of the described patients have been treated with stool from a universal donor - frozen and thawed stool from our local faecal bank. The faecal banking protocol is described in detail in our previous article[10]. Briefly, faecal material from a healthy donor is mixed with saline and glycerol and frozen at -80 ℃. In some cases, we used the faecal suspension stored at -20 ℃, which did not seem to affect the results or safety of FMT. The frozen suspension is thawed a few hours before FMT and collected into two 100-mL syringes. When necessary, the suspension is passed through a pre-sterilized, stainless steel tea strainer to remove larger particles.

Donor screening was performed as described in detail by Mattila *et al*[6] and Satokari *et al*[10]. Briefly, the donors were screened for hepatitis C and B, HIV, *Treponema pallidum* and common enteric pathogens. The donor was required to lack antibiotics for the previous six months and to present no gastrointestinal symptoms.

The preferred route of administration of FMT in our practice is colonoscopy. The suspension is administered into the cecum and ascending colon. Preceding the colonoscopy, the patients undergo bowel lavage by polyethylene glycol solution (between 3-5 L). The patients with rCDI underwent pre-treatment with vancomycin or metronidazole, and the treatment was stopped 36 h before the FMT. In some special cases, we administered FMT during gastroscopy, injecting the suspension into the duodenum as distally as possible.

Although FMT has become the routine treatment after two relapses for CDI in our hospital, the decision to assess FMT in immunosuppressed patients and in special indications is based on a very thorough consideration, especially of safety concerns, by gastroenterologist, specialist of infectious diseases and microbiologist with FMT experience.

Thirteen patients treated with FMT for rCDI and having significant comorbidities

In this article, we report the results of thirteen patients with major comorbidities who underwent rCDI and were treated with FMT (Table 1). Two of the patients had HIV, six were haemodialysis patients, two had a kidney transplant, two had a liver transplant and one had chronic lymphatic leukaemia (CLL).

Eleven of the thirteen rCDI patients (85%) treated with FMT successfully cleared the CDI. Six of the patients had major adverse events, of which two died at 2 and 5 mo post-FMT; however, these events were not directly attributable to FMT. A detailed description of each patient is published online as a supplement.

Eight patients treated with FMT and not having rCDI

Eight patients received FMT as an experimental form of treatment for various special indications. The patients and outcomes are compiled in Table 2 and described in detail below.

A carrier of salmonella #1

A 17-year-old male was found to be a carrier of *Salmonella* in a routine check-up on the 1st of September 2015. He had not had previous GI symptoms. According to Finnish health authority instructions, a *Salmonella*-positive person may not work in food processing. The patient was about to start his studies to become a cook and *Salmonella* was delaying his plans.

The *Salmonella* strain was resistant to doxycycline and ciprofloxacin. He had a mild knee symptom that was thought to be reactive arthritis. Ciprofloxacin was administered briefly and stopped as the sensitivity results of the *Salmonella* became apparent. He was receiving tetracycline for acne since the 18th of August, which was stopped on the 26th of October. In October, faecal salmonella was negative twice, but it was positive again on the 16th of November.

A 2-wk course of i.v. ceftriaxone was considered an

Table 1 The results of fecal microbiota transplantation treatments of thirteen patients with different comorbidities and *Clostridium difficile* infection

	Patient characteristics	Medical history	Post FMT situation	Adverse events in 1 mo
1	A patient with HIV, ulcerative colitis and rCDI	28-year-old male with HIV, antiviral medication and virus undetectable, previous suspicion of ulcerative colitis. Recurrent diarrhoea with *C. difficile* positivity, slow response to vancomycin.	No further relapses Two months after diarrhoea recurred at the same time with mild alcohol associated pancreatitis. In colonoscopy final diagnosis of ulcerative colitis was made. *C. difficile* remained negative.	No
2	A patient with HIV, alcoholism and rCDI	59-year-old female, depression, continuous heavy smoking and consumption of alcohol. HIV and antiviral therapy. rCDI after antibiotic treatment for respiratory infection.	No further relapses Diarrheal continued due to exocrine pancreatic insufficiency and excessive alcohol consumption 5 mo after FMT *C. difficile* reinfection treated with vancomycin and fidaxomicin	No
3	A Haemodialysis patient with rCDI #1	60-year-old female, rheumatoid arthritis and in haemodialysis due to amyloidosis. Chronic atrial fibrillation, polypectomies of rectum adenomas. Had *Enterococcus* sepsis 2012.	No further relapses. Half a year after FMT *Enterococcus faecalis* sepsis and an epidural abscess.	No
4	A Haemodialysis patient with rCDI #2	19-year-old female, haemodialysis due to Goodpasture syndrome complicated with pulmonary haemorrhage. Immunosuppressive therapy.	No further relapses.	No
5	A Haemodialysis patient with rCDI #3	77-year-old male, haemodialysis after renal carcinoma operation, diabetes Ⅱ and COPD. *Pseudomonas* septicaemia followed by rCDI.	No further relapses. One week after FMT hospitalized due to generalized enema and possible cystitis. Two months after FMT hospitalized due to gastroenteritis, faecal clostridium was negative.	One week after hospitalized due to enema and cystitis
6	A Haemodialysis patient with rCDI #4	80-year-old male. Haemodialysis because of chronic glomerulonephritis, type II diabetes, hypertension, epilepsy, AV-block and a pace maker. *Staphylococcus aureus* septicaemia followed by rCDI.	No further relapses. *Staphylococcus aureus* sepsis 5 mo after the FMT.	No
7	A Haemodialysis patient with rCDI #5	66-year-old male, haemodialysis due to microscopic polyangiitis. Chronic atrial fibrillation.	No further relapses	No
8	A Haemodialysis patient with rCDI #6	79-year-old female. Hypertension, dyslipidaemia, atrophic gastritis. TIA 2004 and 2005, a pace maker due to bifascicular block. Coronary disease. Haemodialysis due to an episode of rhabdomyolysis.	2 wk after FMT reinfection after an antibiotic treatment of cystitis. No further FMT's due to poor general condition. Patient died 2 mo after FMT to underlying diseases	2 wk after *C. difficile* reinfection
9	A Kidney transplant patient with rCDI #1	78-year-old female. Kidney transplant due to polycystic renal disease. Polycystic liver, type Ⅱ diabetes, hypertension and asthma. Operated for cholecystectomy and hysterectomy. *E. coli* sepsis and one month after another infectious episode treated with meropenem followed by severe rCDI.	No further relapses 3 d after FMT gastroenteritis, *Clostridium* was not tested. Restarted vancomycin for 2 d. 12 d after FMT the patient was hospitalized due to infection, CT scan did not reveal the aetiology.	Gastroenteritis 3 d after FMT Hospitalized 12 d after FMT
10	A Kidney transplant patient with rCDI #2	61-year-old female. A kidney transplant due to polycystic renal disease. rCDI after clindamycin for dental infection.	No further relapses	No
11	A Liver transplant patient with rCDI	56-year-old female. Liver transplant due to mushroom intoxication, a moderate renal failure.	No further relapses	No
12	A Patient with a liver transplant, renal insufficiency, haemodialysis and rCDI	69-year-old male. Liver transplantation due to alcohol cirrhosis, followed by renal insufficiency and haemodialysis.	No further relapses	No
13	A Patient with chronic lymphatic leukaemia, chronic norovirus infection and rCDI	65-year-old female. Chronic lymphatic leukaemia since 1996. Autologous stem cell transplantation in 2003. Cytostatic interventions from 2009-2011, after which she had prolonged pancytopenia, infections and hypogammaglobinaemia. In summer 2011, she had chronic norovirus infection and recurrent CDI, several vancomycin courses and gammaglobulin infusions. March 2012 FMT	No primary complications Hospitalized 2 wk after FMT due to diarrhoea. Both norovirus and *Clostridium difficile* stayed positive in stool samples. Patient died in August 2012, 5 mo after FMT for complications of her haematological disease.	CDI and norovirus related diarrhoea continued.

FMT: Fecal microbiota transplantation; HIV: Human immunodeficiency virus; rCDI: Recurrent *Clostridium difficile* infection; *C. difficile: Clostridium difficile*; *E. coli: Escherichia coli*.

Table 2 The results of fecal microbiota transplantation treatments of eight patients with different new indications

	Patient and diagnosis	Age at 1st FMT and gender	Route of administration	Outcome	FMT related complications
1	A carrier of *Salmonella* #1	17-year-old male	Colonoscopy	Successful eradication of Salmonella	No
2	A carrier of *Salmonella* #2	52-year-old female	Colonoscopy	Successful eradication of Salmonella	No
3	A patient with TMAU #1	24-year-old male	Gastroscopy	Moderate self-reported benefit up to 6 mo, at 12 mo symptoms had recurred to former severity	No
4	A patient with TMAU #2	49-year-old female	Gastroscopy	No change in self-reported symptom severity	No
5	A patient with SIBO	66-year-old male	Gastroscopy (treated 3 times using 2 donors)	Self-reported decrease in symptom severity	No
6	A patient with lymphocytic colitis	21-year-old female	Colonoscopy	Two week decrease in self-reported symptoms, then recurrence of symptoms to former severity	No
7	A carrier of norovirus	32-year-old female	Colonoscopy	No change in self-reported symptom severity, no success in virus eradication	No
8	A carrier of ESBL-producing	31-year-old female	Colonoscopy	Successful eradication of ESBL-producing *E. coli*	No

FMT: Fecal microbiota transplantation; TMAU: Trimethylaminuria; SIBO: Small intestinal bacterial overgrowth; *E. coli: Escherichia coli*.

option, but the patient did not accept this treatment due to his needle phobia. A two-week course of trimethoprim -sulfadiazine 160 mg/500 mg 1 × 2 per orally was started on the 26th of November since the *Salmonella* strain was found to be sensitive. Unfortunately, the faecal *Salmonella* test was still positive after this treatment.

On the 29th of January 2016, the patient was given FMT as described in detail in the FMT protocol section. Preceding the FMT, he received a 5-d course of ceftriaxone 2 g × 1 i.m. The colonoscopy findings were normal, as well as the histology of routine biopsies. There were no complications during the procedure, but the patient fainted soon afterward, which might have been caused in part by the pain and anxiety-relieving medications used during the colonoscopy. He recovered rapidly.

An upper abdomen ultrasound was performed and did not reveal any gallstones. Gallstones are a known risk factor for resistant *Salmonella*.

On the 9th of February - less than two weeks after FMT - the stool test was salmonella-positive and the treatment was considered a failure at first. However, the subsequent three tests (the 2nd, the 8th and the 11th of May) were all negative. According to the instructions of Finnish health authorities, the patient is considered free from *Salmonella* after having three negative samples in a row, and our patient could continue his studies.

There were no reported side effects of the FMT treatment. We consider it likely that the transplanted new gut microbiota played a role in the eradication of *Salmonella*, although we cannot exclude the possibility that the *Salmonella* would have been eradicated spontaneously.

A carrier of salmonella #2

A 52-year-old woman had *Salmonella* enteritis in March 2016. Her symptoms ceased, but she remained a chronic carrier. She had been treated with courses of trimethoprim-sulphadiatzine and amoxicillin. She had also undergone a two-week course of intravenous ceftriaxone, but the *Salmonella* culture remained positive. The bacterial strain was resistant to ciprofloxacin. She was on sick leave during this time because of her work in food production. FMT treatment was administered through colonoscopy on the 17th of November 2016. Prior to FMT, a course of ceftriaxone 2 g 1 × 1 i.v. was administered for six days. The three subsequent faecal tests after FMT (the 2nd, 12th and 19th of December 2016) for *Salmonella* were all negative, and she could return to work. No side effects were observed.

The rationale for treating salmonella carriage with FMT

The prevalence of chronic *Salmonella* carriage is estimated to be 2%-5% in endemic areas. Symptomless carriage of *Salmonella,* especially of individuals working in food production, is considered to be the main route of distribution of the disease among people. Furthermore, persistent carriage of *Salmonella* is associated with gallstones. Fluoroquinolones are the drug of choice for the treatment of chronic carriage of *Salmonella*[20], but strains that are resistant to ciprofloxacin pose a special challenge.

In animal models, *Salmonella* carriage is associated with changes in the intestinal microbiota[21]. It is not known whether people with *Salmonella* carriage possess alterations of the gut microbiota. To the best of our knowledge, there are no reported cases of eradication of *Salmonella* with FMT. FMT has been shown to reduce antibiotic resistance genes in the gut microbiota[22,23]. FMT has shown potential in eradicating faecal carriage of different multidrug-resistant bacteria in case reports[24]. Therefore, changing or diversifying the intestinal microbiota through FMT is a promising

new option to eradicate chronic *Salmonella* in cases where antibiotics have failed.

A patient with trimethylaminuria (fish malodour syndrome, TMAU) #1

A 24-year-old male had been diagnosed with fish malodour syndrome (trimethylaminuria, TMAU) two years earlier, but the symptoms had started at the age of 16 years. Choline loading resulted in a TMA/TMA-n-oxide-ratio of 0.43 mg/mmol creatinine (reference range 0.05-0.21). He had a severe odour problem, especially when sweating. He had been treated with riboflavin and activated charcoal without effect. A choline restricted diet and occasional two-week courses of metronidazole followed by lactobacilli treatment had a slight positive effect. Copper chlorophyllin was prescribed, but he did not initiate the treatment. After metronidazole pre-treatment, he was given experimental FMT through gastroscopy on the first of December 2015. Six weeks after FMT, he reported a slight reduction of the odour. Six months after the treatment, he reported fewer odour problems, but after one year, the malodour had returned to its former severity. He did not report any side effects.

A patient with TMAU #2

A 49-year-old female with TMAU. Odour problems started at the age of 12 when menstruation began. The odour problem was at its worst 7-10 d post-ovulation. The diagnosis was confirmed based on the urine TMA-oxide and TMA ratio. TMA-oxide was 59.1 mg/mmol creatinine (reference 17-147), and TMA was 16.5 mg/mmol creatinine (reference 2.5-10.8) ratio 0.28 (reference 0.05-0.21).

She was in the perimenopausal phase with hot flashes and excess paroxysmal sweating, causing the odour problem to worsen, but it was partly in control with hormonal treatment. Two-week metronidazole courses only helped temporarily. She had used a strict choline-restricted diet, vitamin B2 and high doses of lactobacilli. Copper chlorophyllin and activated charcoal had been ineffective. She had previously subjectively felt less of an odour problem for a few weeks after bowel cleansing for colonoscopy. FMT was given as an experimental therapy though colonoscopy. As a pre-treatment, the patient was prescribed metronidazole 400 mg three times per day for 7 d to facilitate engraftment of the donor's microbiota. Metronidazole was stopped 36 h prior to FMT. No relief of the malodour was achieved after FMT.

The rationale for treating fish malodour syndrome with FMT

Trimethylaminuria (TMAU) is a condition in which body odour resembles that of a dead fish. In TMAU, trimethylamine (TMA) accumulates in the body. Primary trimethylaminuria is genetic and caused by an inability to convert the fish smelling TMA into non-odorous trimethylamine-N-oxide (TMAO) in the liver due to a deficiency of the hepatic microsomal flavin-containing monooxygenase (FMO3). Secondary TMAU is defined as an accumulation of TMA without inherited FMO3 deficiency. The aetiology of secondary TMAU is not fully known. One causal factor may be the gut microbiota, which can produce TMA through the metabolism of certain food compounds such as TMAO and choline[25]. Thus, altering TMA metabolism may be possible through manipulating the intestinal microbiota. To our knowledge, there are no previous reported cases of TMAU treated with FMT.

A choline-restricted diet and copper chlorophyllin are the recommended treatments for TMAU[26]. Some patients experience partial relief for symptoms by using antibiotics followed by high doses of lactobacilli, riboflavin or charcoal tablets. Our hypothesis is that TMAU can be ameliorated by manipulating the gut microbiota through FMT. Some short-term positive effects were achieved in one patient, but the bacterial spectrum of the present single FMT did not seem to be effective for the treatment of TMAU. More data concerning the effect of FMT on TMAU are needed.

A patient with small intestinal bacterial overgrowth

The patient was 66 years old in January 2015 when he received his first FMT. He had colectomy and ileal pouch-anal anastomosis (IPAA) surgery in 2008 for ulcerative colitis and adenocarcinoma of the caecum. He had experienced bloating and flatulence during his adult life, but it had become worse since IPAA. He had bowel movements on average 6 times per day.

Endoscopic examination of the pouch showed no inflammation. On the small bowel passage X-ray, there was a small bowel dilatation of 10 cm on the left side of the abdomen. Small bowel MRI did not show an indication for surgery.

Before FMT, the patient underwent several treatments with inadequate results. He was treated with dietary changes and dimethicone to decrease bloating and flatulence. A probiotic - *Escherichia coli* (*E. coli*) *Nissle* up to 2 × 2 capsules (2.5×10^9-25×10^9 CFU/capsule) was administered to remediate dysbiosis. Antibiotics were given to decrease small intestinal bacterial overgrowth (SIBO). He received a course of metronidazole and two courses of rifaximin 200 mg 1 × 4, with one course lasting two weeks and the other four weeks with a tapering dosage. He reported a slight benefit from all of these treatments, but continued to suffer from flatulence and bloating.

On the 20th of January 2015, the patient received FMT *via* gastroscopy as an experimental treatment. For this treatment, 200 mL of the frozen and thawed faecal material was infused through a gastroscope deep into the descending duodenum. Biopsies were obtained *via* gastroscopy and revealed *Helicobacter*-negative atrophic gastritis.

Six weeks after FMT, the patient reported that his

symptoms and bowel movements decreased 50% and that the scent of his flatus was milder. The patient was considered to have reached a partial response and was scheduled for a new FMT.

The second FMT *via* gastroscopy was performed on the 2nd of October using the stool of the same donor as in the first FMT. This time, macrogol bowel preparation was used. The patient reported some benefit from the second treatment, but since disturbing flatulence continued, a third FMT was scheduled with a one-week course of per oral penicillin pre-treatment because the patient had previously experienced relief of his symptoms when using penicillin for a dental infection.

The third FMT *via* gastroscopy was performed on the 29th of January 2016. The transplant was from another donor who was an unfamiliar, tested and generally healthy person, whose stool was frozen and thawed on the day of the transplantation. The last contact with the patient was on the 21th of June 2016, *i.e.*, five months after the third FMT. He reported having fewer symptoms, but some flatulence persisted, though with a milder scent than previously.

The patient was considered to have gained a partial response to his SIBO symptoms from these three FMT treatments.

The rationale for treating SIBO with FMT

A SIBO is defined as an increase in the number or alterations of the type of bacteria in the small bowel. It may be associated with several features, such as alterations of the small bowel anatomy, motility, and immunity, among others. Alterations of the gut microbiota are associated with SIBO by definition. SIBO causes bloating and diarrhoea. Malabsorption, malnutrition and weight loss may also be present. SIBO can most accurately be diagnosed with jejunal aspirate, but this is not widely used due to the invasiveness of the procedure[27]. Hydrogen or methane breath tests are used more widely, but in many centres, including our own, these tests are not in clinical use. We diagnose SIBO clinically based on symptoms and signs. Our SIBO patient had an altered GI anatomy due to a J-pouch and altered immunity due to ulcerative colitis. He received three FMTs through gastroscopy and reported reduced symptoms. For a more objective evaluation of the FMT effect on SIBO, hydrogen breath tests before and after the treatments would have been valuable. More research on the effect of FMT on SIBO is warranted.

A patient with lymphocytic colitis

A female patient who was diagnosed with microscopic colitis in 2013 at the age of 18 had diarrhoea up to 20 times per day. Faecal calprotectin was constantly negative. She had an inadequate response to medications - mesalamine 2.4 mg/d, budesonide 9 mg/d for two months, loperamide or fibres. She had tried various diets to relieve the symptoms. The patient wished to be treated with FMT. For her case, there were no on-going scientific study protocols to follow.

After repeated requests from the patient and with no other rational treatment options available, FMT through colonoscopy was administered as an experimental treatment on the 21st of June 2016.

In the follow-up telephone conversation on the 7th of July, the patient reported to have gained a benefit from the procedure for two weeks, after which the diarrhoea recurred as before. The outcome was considered negative and no further transplants were given.

The rationale for treating lymphocytic colitis with FMT

Lymphocytic colitis is a subtype of microscopic colitis. It is a cause of diarrhoea that is more common in elderly people, but it may even affect children. Microscopic colitis may be associated with an altered gut microbiota. In a small study, patients with microscopic colitis had a decrease in *Akkermansia* species compared with the healthy controls. *Akkermansia* is considered to have a protective effect on the intestinal epithelium[28,29]. Our patient with lymphocytic colitis was treated once with FMT through colonoscopy. She experienced short-term (two weeks) relief of her symptoms, after which the symptoms recurred. The outcome was considered negative. In possible future studies, it might be worth considering a recurrent treatment-protocol with FMT, which has shown some promising results in IBD patients[30,31] and in a single case of collagenous colitis[32], as well as pre-treatment with antibiotics prior to FMT, which may facilitate engraftment of the donor´s microbiota[5].

A carrier of norovirus

A 32-year-old woman was treated with FMT for being a chronic carrier of norovirus. As a long-term diagnosis, she had common variable immunodeficiency (CVI), coeliac disease and osteoporosis. She had chronic diarrhoea since 2009, malabsorption since 2012 and partial parenteral nutrition since March 2015. Her norovirus infection was diagnosed in September 2013. Previously, she did not have acute gastroenteritis. Several medications for her norovirus infection had been attempted without success: interferon alfa, interferon with ribavirin and nitazoxsanide.

FMT was administered in March 2016 through gastroscopy. She was susceptible to bacterial infections due to CVI and bronchiectasis. She had received trimethoprim -sulfamethoxazole as a long-term prophylactic treatment, which was ceased 36 h before FMT. Bowel lavage was not administered prior to FMT. Routine biopsies of the gastroscopy revealed partial villus atrophy.

After FMT, the symptoms of the patient remained unchanged, with four to six bowel movements per day.

Faecal norovirus remained positive. Thus, the patient did not benefit from the experimental FMT treatment. No side effects related to the FMT were observed.

Rationale for treating chronic norovirus infection with FMT

Approximately 5% of CVI patients have enteropathy. In some case reports, chronic norovirus infection has been the cause of CVI-associated enteropathy, and eradication of the virus has cured the symptoms. It has even been hypothesized that chronic norovirus could be a key player in most of these cases[33].

It is suspected that the gut microbiota plays a role in regulating norovirus infection and its pathogenesis[34], and the relationship between the gut bacteria and norovirus infection is undergoing active analysis using murine models. We did not find any published cases of chronic norovirus or CVI enteropathy treated with FMT, and to our knowledge, the patient presented herein is the first reported case.

A carrier of ESBL-producing E. coli

A 31-year-old female patient with asthma was a carrier of the multidrug-resistant *E. coli*-extended spectrum beta-lactamase producing strain (ESBL). She had received pyelophritis caused by ESBL-producing *E. coli* two times, in October 2015 and June 2016. Both episodes of pyelonephritis had been treated with intravenous ertapenem. The duration of the second ertapenem treatment was ten days.

She had studied scientific literature concerning ESBL and *E. coli* virulence factors. After her second pyelonephritis, a consultant infectious disease specialist recommended ESBL eradication with FMT. Prior to FMT, faecal cultures for ESBL-producing *E. coli* were collected five times between August 2016 and February 2017. All the cultures were positive with ESBL-producing *E. coli*.

The *E. coli* strain was resistant to amoxicillin-clavulanic acid, ampicillin, cephalexin, ceftriaxone, cefuroxime, levofloxacin and trimethoprim-sulfamethoxazole, susceptible to ertapenem, meropenem, tobramycin, fosfomycin and nitrofurantoin and showed intermediate susceptibility to ceftazidime and piperacillin-tazobactam.

The patient was hospitalized for meningitis in November 2016. She was treated with ceftriaxone and acyclovir. The meningitis was shown to be caused by an enterovirus. She recovered fully, but the episode delayed her FMT treatment.

FMT was performed *via* colonoscopy on the 31st of January 2017. The endoscopic finding was normal, as were the routine biopsies. Six weeks later, on the 20th of March, the faecal culture of ESBL-producing *E. coli* was negative. The patient had symptoms of cystitis, and the urine test showed elevated leukocytes and *E. coli*, but this time they were susceptible to all the tested antibiotics. She was treated with a two and a half day course of nitrofurantoin 75 mg twice a day.

The rationale for treating ESBL-producing E. coli carriage with FMT

Antibiotic resistance is an emerging global health problem. One of the most common and clinically relevant types of antibiotic-resistant bacteria are the ESBL-producing enterobacteria, especially *E. coli*, which occurs worldwide[35]. Antibiotic resistance is largely caused by excessive use of wide spectrum antibiotics. We, among other authors, have reported the reduction of antibiotic resistance genes in the intestinal microbiome of patients with rCDI after FMT[22,23].

FMT has been successfully used for the eradication of ESBL-producing *E. coli* and other multidrug-resistant bacteria in a small number of published case reports[36-38]. Clinical use of FMT for eradicating resistant bacteria requires further study in larger groups of patients.

DISCUSSION

We report the results obtained for 21 FMT-treated patients; thirteen of the patients had rCDI with a significant underlying comorbidity, and eight of the patients had a condition other than rCDI. The 21 reviewed patients consisted of a heterogeneous group with many comorbidities. This establishes a limitation to our study; definitive conclusions cannot be drawn for the patients as a group. The strength of our study is that we review real life patients who are often excluded from studies due to their comorbidities.

There remains a paucity of data about FMT treatments of patients with different comorbidities. In particular, immunocompromised patients have been excluded from many studies due to the suspected risk of infectious complications. Published data from case series to date suggest that FMT is acceptably safe and effective, even for immunocompromised patients[11,12,39].

Of our thirteen patients with rCDI, *Clostridium difficile* (*C. difficile*) was successfully eradicated from eleven patients. Of those eleven, a patient with HIV and alcoholism experienced reinfection four months after FMT. One patient had gastroenteritis symptoms three days after the FMT and took vancomycin for two days without consulting a doctor. Faecal *C. difficile* was not tested. Her CDI relapses before FMT had been severe. There were no relapses of CDI documented over 8 mo of follow-up, and thus the outcome was considered positive. Two patients experienced a relapse, of which one had received antibiotics less than a week after FMT.

At one month of follow-up after FMT, two of the thirteen rCDI patients had relapsed. Two of the patients were hospitalized due to infections that were

not related to FMT. Two dialysis patients had sepsis in the months following FMT. One dialysis patient died two months after FMT. A patient with CLL and chronic norovirus did not clear the CDI or norovirus; she died due to complications of CLL five months after FMT. The HIV patient resolved the *C. difficile* infection through FMT but experienced an activation of underlying ulcerative colitis two months after FMT. The patient group had many comorbidities, and all the adverse events were considered likely to be unrelated to the FMT.

We also report eight cases of patients treated with FMT for a reason other than rCDI. These patients had prolonged *Salmonella* infection (two cases), ESBL-producing *E. coli* carriage, fish malodour syndrome (two cases), chronic norovirus infection, small bowel bacterial overgrowth and lymphocytic colitis. The acknowledged indication for FMT is recurrent *C. difficile* infection. When performed outside of this indication, FMT should preferably be conducted in a clinical trial setting[19]. However, experimental treatment in carefully considered cases is justified when other treatment options are limited. Such cases also provide preliminary results regarding the use of a specific treatment for new indications.

In the past few years, an increasing number of diseases have been shown to be associated with alterations of the gut microbiota, yet the causality is in most cases undefined. FMT has been suggested to be investigated in many of these diseases[1-4]. Although promising data about FMT in new indications such as autism[40], constipation[41] and epilepsy[42] have been reported, careful consideration of the associated risks is necessary.

The eight patients treated for causes other than rCDI all had a condition in which disruption of the gut microbiota was a possible etiological factor. All eight patients expressed a strong wish to try FMT for their condition, for which other treatments had previously failed. The patients were informed of the experimental nature of the procedure. The justification of each treatment was considered by at least three specialists, including the performing gastroenterologist, the referring physician and the head of the Gastroenterology Department.

The carriers of *Salmonella* and ESBL-producing *E. coli*, and the SIBO patient seemed to have benefitted from FMT. One of the fish malodour syndrome patients received only short-term relief for malodour, and the other did not gain any benefit. The patient suffering from lymphocytic colitis and the CVI patient with chronic norovirus infection did not gain a benefit from FMT. The positive outcome of the carriers of *Salmonella* and ESBL-producing *E. coli* was objectively defined with a laboratory test, as was the negative outcome for the norovirus patient. The outcomes of the other three patients was based on self-reported symptoms and thus were less objective. None of these patients reported any side effects.

The eradication of antibiotic resistant bacteria with FMT has been studied by many research groups, and the results to date are promising. Successful eradications have been described with several multidrug-resistant bacteria, such as ESBL-producing and carbapenemase-producing *Enterobacteriaceae*, vancomycin-resistant *Enterococci*, or methicillin-resistant *Staphylococcus aureus*[36-38]. To the best of our knowledge, the two eradications of *Salmonella* carriage are the first reported cases. The efficacy of FMT for chronic norovirus infection and fish malodour syndrome has also not been reported previously. The treatment options for multidrug-resistant organisms are scarce - eradication and increasing colonization resistance by FMT may offer a new means to counter the problem.

We think it necessary to further study the effect of FMT in conditions where other treatment options are limited. Placebo-controlled trials should be preferred due to the high risk of a placebo effect in conditions in which the diagnosis relies mostly on symptoms, although randomized controlled trials may not be an option for infrequent conditions due to the small number of patients. Thus, case series provide valuable guidance for clinical practice and future clinical trials.

In conclusion, in our cohort, FMT appeared to be a safe and effective treatment for rCDI for patients with significant comorbidities, although further conclusions cannot be drawn due to the small sample size. FMT also shows promise for the eradication of antibiotic-resistant bacteria, for which further research is warranted. FMT is only indicated for rCDI; for other indications, FMT should still be performed only in a clinical trial setting.

COMMENTS

Case characteristics

The authors reviewed 21 fecal microbiota transplantation (FMT)-treated patients, of which 13 had recurrent *Clostridium difficile* infection (rCDI) and major comorbidities: two human immunodeficiency virus patients, six haemodialysis patients, two kidney transplant patients, two liver transplant patients and a patient with chronic lymphatic leukaemia. In addition, the authors reviewed 8 patients treated with FMT for new indications: *Salmonella* carriage (two patients), trimethylaminuria (two patients), small intestinal bacterial overgrowth, lymphocytic colitis, ESBL-producing *Escherichia coli* carriage and a common variable immunodeficiency-patient with chronic norovirus infection.

Treatment

The patients were treated with FMT. Most of the patients received FMT *via* colonoscopy, and stool from a universal donor was mainly used. In a minority of cases, FMT was administered through gastroscopy.

Related reports

Immunocompromised patients have been excluded from the majority of FMT studies, but case reports and series have started to emerge. The number of case reports of patients treated with FMT for indications other than *Clostridium*

difficile is growing. To our knowledge, eradication of *Salmonella* carriage with FMT has not been reported previously.

Experiences and lessons

FMT is acceptably safe for the treatment of rCDI in immunocompromised patients. FMT is promising as a treatment for the eradication of antibiotic-resistant bacteria. There is a great demand for further research on FMT for many new indications.

Peer-review

This article gives a clear description of 21 cases and reasonable discussion, and it can provide a good reference in the daily performance of FMT. The case description in the article is very detailed, the analysis is also very thorough. The article has a good clinical significance.

Abstract

Gastric submucosal tumors (SMTs) less than 2 cm are generally considered benign neoplasms, and endoscopic observation is recommended, but SMTs over 2 cm, 40% of which are gastrointestinal stromal tumors (GISTs), have malignant potential. Although the Japanese Guidelines for GIST recommend partial surgical resection for GIST over 2 cm with malignant potential as well as en bloc large tissue sample to obtain appropriate and large specimens of SMTs, several reports have been published on tissue sampling of SMTs, such as with endoscopic ultrasound sound fine needle aspiration, submucosal tunneling bloc biopsy, and the combination of bite biopsy and endoscopic mucosal resection. Because a simpler, more accurate method is needed for appropriate treatment, we developed oval mucosal opening bloc biopsy after incision and widening by ring thread traction for submucosal tumor (OMOB) approach. OMOB was

simple and enabled us to obtain large samples under direct procedure view as well as allowed us to restore to original mucosa.

Key words: Gastric submucosal tumors; Gastrointestinal stromal tumor; Reversible opening biopsy; Endoscopic ultrasonography; Large sample

INTRODUCTION

Gastric submucosal tumors (SMTs) less than 2 cm are generally considered benign neoplasms, and endoscopic observation is recommended[1]; however, SMTs over 2 cm, 40% of which are gastrointestinal stromal tumors (GISTs), have malignant potential[2]. The Japanese Guidelines for GIST over 2 cm with malignant potential recommend removal by partial surgical resection as well as en bloc large tissue sample collection to obtain an accurate diagnosis before surgery[3]. To obtain appropriate and large specimens of SMTs and diagnose them accurately, there have been several reports related to tissue sampling of SMTs, such as endoscopic ultrasound sound fine needle aspiration (EUS-FNA)[4,5], submucosal tunneling bloc biopsy (STB)[6], and the combination of bite biopsy and endoscopic mucosal resection (CB-EMR) by which the crown of SMTs was partially resected by EMR[7]. Because a simpler, more accurate method is needed for appropriate treatment, we developed oval mucosal opening bloc biopsy after incision and widening by ring thread traction for submucosal tumor (OMOB) approach.

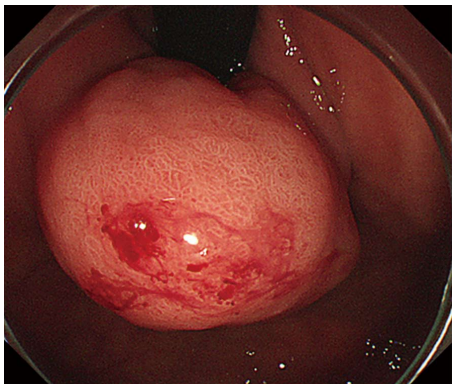

Figure 1 Endoscopic findings of gastric submucosal tumor. A gastric submucosal tumor (30 mm in diameter) is shown in the fornix of the stomach.

CASE REPORT

A forty-seven-year-old woman was diagnosed with a gastric SMT that was 30 mm in diameter in the fornix (Figure 1). As the tumor located in the fornix where EUS-FNA was unable to puncture its needle due to maximum bended endoscope position and STB was also difficult to create submucosal tunnel under maximum bended endoscope position, it was difficult to obtain sufficient tissue sample of this tumor (Figures 1 and 2A). A 5-10 mm straight incision was made on the top of the SMT by Dual knife (KD-650L, OLYMPUS Co., Tokyo, Japan) (Figures 2B and 3). After a 5-mm ring-shaped thread was delivered by grasping forceps and clipped on the left side mucosa of the incision edge (Figure 2C), second clip was hooked the ring-shaped thread (Figure 2D) and moved to be tied up the left gastric wall.

The same procedures were performed on the right side of the incision mucosa (Figure 4) making a straight incision like an oval-shaped incision (Figure 5). With more insufflation, both ring threads expanded the oval incision to a round-shaped incision from which the tumor capsule was clearly recognized (Figure 6). An approximately 5 mm incision of the tumor capsule by Dual knife made it possible to confirm the tumor itself which had abundant tumor vessels (Figures 2E and 6). A 5-mm piece of tumor tissue was obtained by cutting the tumor surface with a Dual knife. After both sides of the ring threads were detached, the opened mucosa was closed by hemoclips to restore it back to the original mucosa (Figures 2F and 7). The total procedure time was only 10 min, and there were no complications, such as bleeding or perforation. The histological result was gastrointestinal stromal tumor. Three weeks after this new bloc biopsy, the incised mucosa was completely recovered with a linear scar. Laparoscopy and endoscopy cooperative

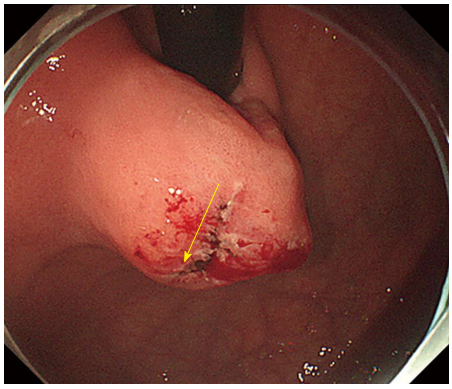

Figure 3 Incision at the top of the submucosal tumor. As endoscopic ultrasound sound fine needle aspiration and submucosal tunneling bloc biopsy were impossible due to the tumor's location, a 5-10 mm incision on the top of submucosal tumor was made (yellow arrow).

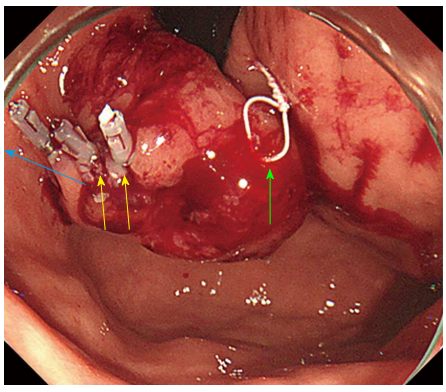

Figure 4 Ring- shaped thread counter traction. After clipping the 5-mm ring-shaped thread on the left side mucosa of the incision edge (yellow arrows), the other side of this ring thread was hooked and pulled to the posterior wall of the stomach (blue arrow). A 2nd white ring thread was placed on the other side of the incision edge (green arrow).

surgery (LECS) was successfully performed, and the histological finding of the GIST was low risk in accordance with Fletcher's classification. An endoscopic image revealed that straight incision on the top of the SMT was completely scarred and closed (yellow ring) (Figure 8) when laparoscopy and endoscopy cooperative surgery (LECS) was performed six week after oval mucosal opening bloc biopsy.

DISCUSSION

The natural history of 2-5 cm GISTs is unknown. In the Japanese Guidelines of GIST, accurate diagnosis, including the histological grade based on a sufficient

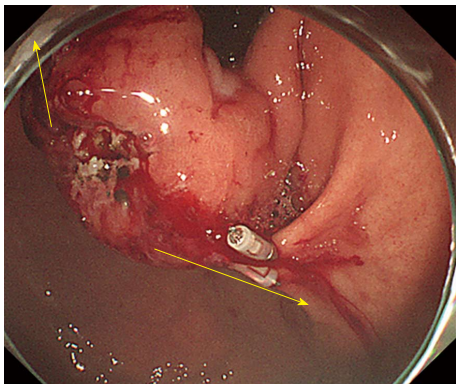

Figure 5 Oval mucosal opening after incision and widening by ring thread traction. The same procedures were performed on both sides of the incision mucosa with a straight incision to an oval shaped incision (yellow arrows).

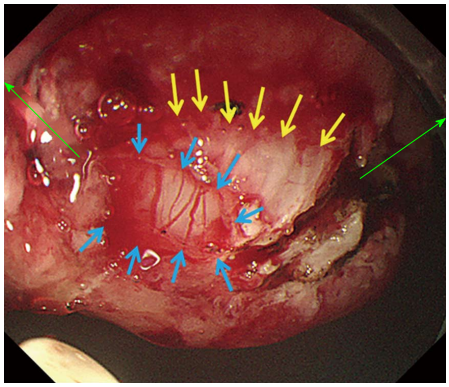

Figure 6 Direct view of capsule and abundant vessels of gastrointestinal stromal tumors. With more insufflation, both ring threads expanded the oval incision to a round shaped incision (green arrows) from which the tumor capsule was clearly recognized. An approximately 7-mm cut of the tumor capsule (yellow arrows) by Dual knife made it possible to confirm the tumor (blue arrows) with abundant tumor vessels.

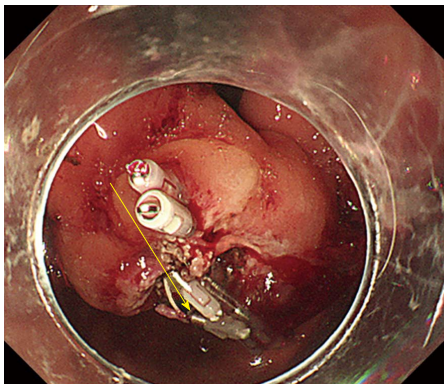

Figure 7 Reversible mucosa closure by hemoclips. After both sides of the ring threads were detached, the opened mucosa was closed by hemoclips to restore it back to the original mucosa (yellow arrow).

tissue sample, is recommended for GIST less than 2 cm, which is growing rapidly, or 2-5 cm GIST rather than endoscopic observation alone[8].

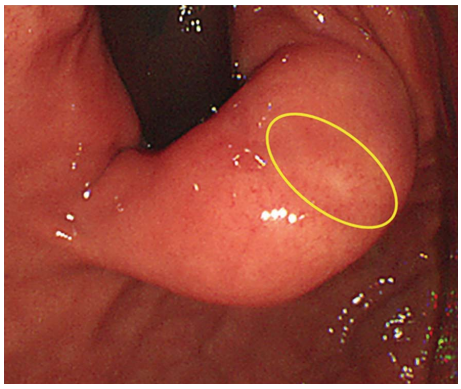

Figure 8 A mucosal incision six week after oval mucosal opening bloc biopsy. An endoscopic image revealed that straight incision on the top of the submucosal tumor was completely scarred and closed (yellow ring) when laparoscopy and endoscopy cooperative surgery was performed six week after oval mucosal opening bloc biopsy.

EUS-FNA is very useful for accurate diagnosis for SMTs since it was reported in 1992[9]. Its diagnostic sensitivity for GIST is very high at approximately 70% and the specificity is approximately 85%[10]. On the other hand, EUS-FNA does not always obtain sufficient tissue by needle sample for one of the grading factors of malignancy, such as the mitotic count under a 50 high power microscope field. The diagnostic rate for EUS-FNA was approximately 60% as the obtained samples were too small to pathologically diagnose the mitotic counts[11]. The combination of bite biopsy and endoscopic mucosal resection (CB-EMR) using a snare to cut the top of SMTs enabled us to obtain a large bloc specimen. However, the bleeding rate was very high at approximately 50%-60% from the snare resection site[12]. Bleeding after snare resection occurred due to a large mucosal defect at approximately 15-20 mm in diameter. Compared to CB-EMR, OMOB enable us to perform en bloc large tissue sampling without complications, such as bleeding, for GIST with rich vessels. OMOB consists of a 1-cm linear incision to round shaped excision using ring threads that expand with insufflation. After obtaining large bloc tissue, coagulation of bleeding vessels is performed followed by closure of the opening mucosa. Closure and recovery of mucosal incision is an important point of OMOB. STB using the ESD technique is another way to obtain a large tissue sample of GIST. As STB was safely performed using flexible endoscopic knives, only ESD experts could perform STB. It is difficult for ordinary endoscopists to perform STB[13], because making appropriate size and location of mucosal incision suitable for creating submucosal tunnel was very difficult for ESD beginner. And creating submucosal tunnel to correct direction and adjusting correct depth of submucosal dissection within the submucosal tunnel were more difficult than conventional gastric

ESD. Another disadvantage of STB is the creation of a submucosal tunnel that leaves an extra 1-cm tunnel scar outside of the GIST. This extra linear scar makes the surgical margin of LECS larger than that of OMOB.

In conclusion, OMOB was simple and enabled us to obtain a large sample under the direct procedure view; it also allowed us to restore to the original mucosa.

COMMENTS

Case characteristics

A forty-seven-year-old woman was diagnosed with a gastric submucosal tumor (SMT) that was 30 mm in diameter in the fornix.

Clinical diagnosis

The tumor located in the fornix was considered as gastric submucosal tumor.

Differential diagnosis

Gastrointestinal stromal tumor (GIST), leiomyoma, schwannoma, leiomyosarcoma, malignant lymphoma, ectopic pancreas and lipoma.

Laboratory diagnosis

All labs were within normal limits.

Imaging diagnosis

Esophagogastroduodenoscopy showed gastric SMT 30 mm in diameter in the fornix .

Pathological diagnosis

The histopathological finding of the SMT was low risk GIST in accordance with Fletcher's classification.

Treatment

Complete surgical excision of lesion.

Related reports

Several reports have been published on tissue sampling of SMTs, such as with endoscopic ultrasound sound fine needle (EUS-FNA) aspiration, submucosal tunneling bloc biopsy, and the combination of bite biopsy and endoscopic mucosal resection.

Term explanation

Oval mucosal opening bloc biopsy by ring thread traction for submucosal tumor is new method for diagnosis of gastric SMT.

Experiences and lessons

Development of oval mucosal opening bloc biopsy after incision and widening by ring thread traction for submucosal tumor (OMOB) approach was useful for simpler, more accurate method for appropriate treatment of gastric SMT.

Peer-review

This case report presented a new biopsy method for GIST of the stomach. The authors demonstrate clearly that "reversible hinged double doors method" is useful to obtain large tissue sample. This method may certainly be of use for tough case even if we use EUS-FNA. This manuscript is well-written in terms of language and seems to be informative to the readers.

Abstract

Primary biliary cholangitis (PBC) is an idiopathic autoimmune liver disease characterized by chronic cholestasis and destruction of the intrahepatic bile ducts. Similar to other autoimmune diseases, the pathogenesis of PBC is considered to be a complex etiologic phenomenon involving the interaction of genetic and environmental factors. Although a number of common variants associated with PBC have been reported from genome-wide association studies, a precise genetic mechanism underlying PBC has yet to be identified. Here, we describe a family with four sisters who were

diagnosed with PBC. After the diagnosis of the index patient who was in an advanced stage of PBC, one sister presented with acute hepatitis, and two sisters were subsequently diagnosed with PBC. Notably, one half-sister with a different mother exhibited no evidence of PBC following clinical investigation. Our report suggests the possibility of a maternal inheritance of PBC susceptibility. Moreover, judging from the high-penetrance of the disease observed in this family, we inferred that a pathogenic genetic variant might be the cause of PBC development. We describe a family that exhibited diverse clinical presentations of PBC that included asymptomatic stages with mildly increased liver enzyme levels and symptomatic stages with acute hepatitis or advanced liver fibrosis. Additional studies are needed to investigate the role of genetic factors in the pathogenesis of this rare autoimmune disease.

Core tip: The precise genetic mechanism underlying primary biliary cholangitis (PBC) has yet to be identified. Here, we describe a family with four siblings who were diagnosed with primary biliary cholangitis. This is the first case report to provide evidence of a maternal inheritance mechanism for PBC based on the identification of a non-PBC half-sibling. This report also highlights the occurrence of all clinical presentations of PBC in one family. Identification of a causal variant is important for a better understanding of the mechanism underlying PBC pathogenesis.

INTRODUCTION

Primary biliary cholangitis (PBC) is a chronic autoimmune cholestatic liver disease that predominantly affects middle-aged women. PBC is characterized by immune-mediated destruction of the intrahepatic bile ducts that gradually leads to fibrosis, cirrhosis, and eventually liver failure. Most patients are diagnosed when asymptomatic with an elevation of alkaline phosphatase (ALP) or with pruritus and mild elevations on liver biochemical tests. PBC can be diagnosed if two of the three following criteria are met: the presence of anti-mitochondrial antibody (AMA); cholestatic biochemical test results, such as an elevated ALP level; and histologic evidence of non-suppurative cholangitis with destruction of the interlobular bile ducts[1,2].

The current hypothesis regarding the etiology of PBC is that it is a multifactorial disease that occurs due to a combination of genetic, immunologic, and environmental factors[3]. The influence of genetic factors is evidenced by familial clusters and twin studies[4]. Epidemiological studies have demonstrated that family members of patients with PBC are at a higher risk of developing PBC[5-7]. Associations between a number of genetic loci and PBC have been reported in genome-wide association studies (GWAS), which is similar to the cases of many other autoimmune diseases[8-10]. However, no precise genetic mechanism underlying PBC is known.

Herein, we report a family with four sisters who were diagnosed with PBC. The possible implications of a monogenic etiology of PBC are discussed.

CASE REPORT

A 56-year-old woman (Table 1, patient 1) was referred to Hallym University Kangnam Sacred Heart Hospital with abnormal liver function test results. Her past history was unremarkable, and she had no history of alcohol or drug abuse. Here, serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), ALP, gamma-glutamyltranspeptidase (GGT), and immunoglobulin (Ig) M were elevated, and she was positive for AMA. A liver biopsy revealed non-suppurative destructive cholangitis and granulomatous inflammation with fibrosis (Figure 1A). The patient was diagnosed with PBC, and her family members, including three sisters, one brother, and one half-sister were evaluated (Figure 2).

Patient 2 had no symptoms but exhibited a mild elevation of ALP. She also exhibited positivity for AMA and non-suppurative cholangitis on a liver biopsy (Figure 1B) and was diagnosed with early-stage PBC.

Patient 3 was admitted to an outside university hospital with acute hepatitis of undetermined etiology. Here, liver enzymes were markedly elevated at the time of admission, *i.e.*, her AST was 744 IU/L, and her ALT was 1273 IU/L. Viral markers of acute hepatitis pathogens, including hepatitis A, hepatitis E, herpes simplex virus, Epstein-Barr virus, and cytomegalovirus, were negative. She then presented to our hospital, where laboratory tests revealed AMA positivity, an elevated IgM level, and liver histologic findings consistent with PBC (Figure 1C).

Patient 4 had no symptoms but exhibited mild elevations of the serum levels of AST, ALT, and GGT. She was AMA-positive, and her IgG and IgM levels were elevated. A subsequent liver biopsy revealed advanced histologic findings consistent with PBC, including portal inflammation, non-suppurative chol-

angitis, granuloma, lymphoplasmacytic infiltrates, and peri-portal fibrosis (Figure 1D).

One brother (52 years old) with the same mother and one half-sister (48 years old) with a different mother were clinically evaluated for PBC; however, they both exhibited normal liver biochemistry and negative AMA results (Table 1).

The four patients were treated with ursodeoxycholic acid (UDCA; 15 mg/kg·d), and liver biochemistry results indicated good responses (Figure 3). The patients have been followed and maintained on UDCA therapy without complications.

DISCUSSION

Here, we report a family that displayed evidence of maternal inheritance and exhibited all possible clinical presentations of PBC. The index patient (patient 1) was

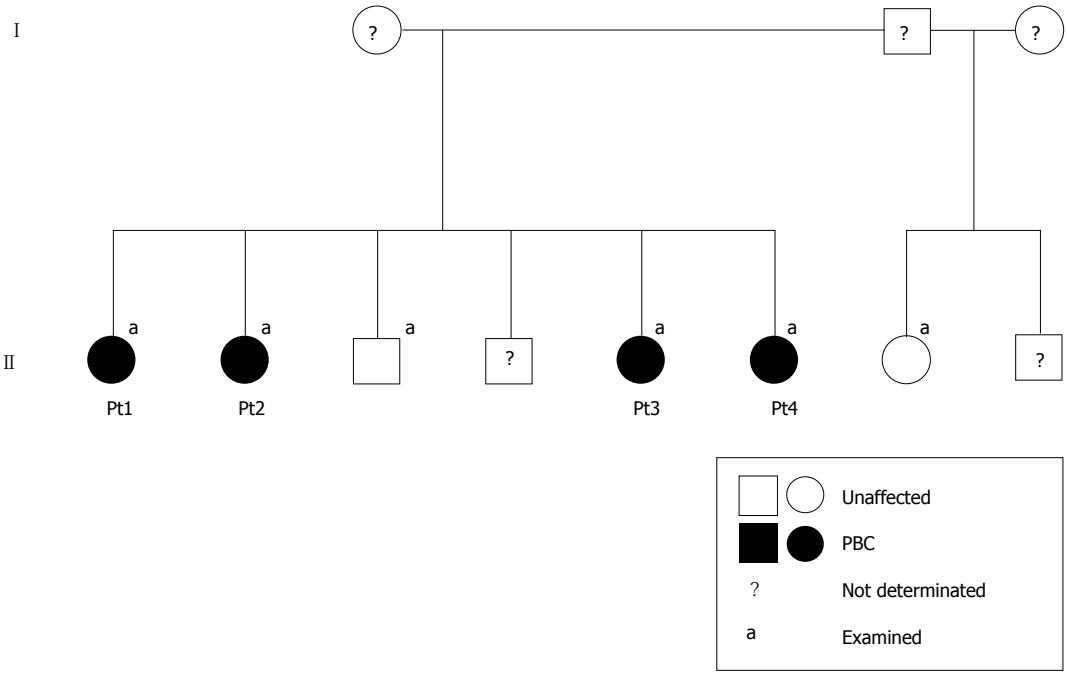

Figure 2 Pedigree of a family with four sisters with diagnoses of primary biliary cholangitis. The black symbols indicate clinically affected family members, and the white symbols indicate non-affected members. No phenotypically relevant information was available for the members with question marks. Pt: Patient; PBC: Primary biliary cholangitis.

diagnosed in a fairly advanced stage of the disease and with early cirrhosis. In contrast, two patients were diagnosed in asymptomatic stages with mildly increased liver biochemistry results (patients 2 and 4). Interestingly, one patient (patient 3) presented with an acute hepatitis-like condition with markedly elevated serum aminotransferases. In PBC, acute presentations have very rarely been reported[11]. Because acute presentations of an overlapping syndrome, *i.e.*, autoimmune hepatitis, are common, it has previously been suggested that autoimmune hepatitis might exhibit overlap with the early stage of PBC in PBC patients with acute presentations[12]. However, we were unable to find any relevant evidence of autoimmune hepatitis in patient 3, including in examinations of liver histology, auto-antibody studies, the serum IgG level, and the treatment response to UDCA[13,14].

There are some factors that are known to trigger PBC symptoms or signs that include adverse drug reactions, pregnancy, and delivery[12]. The mechanisms by which these factors affect disease state are thought to be related to an immunological influence[12]. However, our patient with the acute presentation was not pregnant and had no history of medication use. Our findings suggest that PBC should be considered in the differential diagnosis of acute hepatitis of unknown etiology. Further study is needed to identify possible undiagnosed cases and to investigate the mechanisms that trigger the acute phase of PBC.

Previous GWA studies have contributed to our understanding of the genetic architecture of PBC[8-10]. A number of susceptibility loci are located in genes with known immunologic functions, such as human leukocyte antigen (*HLA*), interleukin 12 receptor subunit beta 2 (*IL12RB2*), interleukin 12A (*IL12A*), C-X-C motif chemokine receptor 2 (*CXCR2*), and the CD80 molecule (*CD80*)[8-10]. However, the identified polymorphisms are also found in the general population at high frequencies and could partially explain the disease heritability. Based on the existence of familial cases with many affected members, as we report here[5,15-17], we infer the contribution of a rare, disease-causing variant to the development of PBC. Although the previous literature also reports a high prevalence of PBC in siblings of patients (four or more cases in 6-10 siblings)[5,15,16], the unique and interesting feature in our case is that PBC was diagnosed in all four sisters but not in one half-sister with a different mother. This finding suggests the possibility of maternal inheritance mechanism and a genetic pattern, such as X chromosome-linked or mitochondrial inheritance.

With rapid progression of next-generation sequencing (NGS) technology, the cost and time required to sequence data have substantially declined[18]. Using high-throughput NGS technology, it is technically feasible to quickly and efficiently investigate rare variants that cannot be identified by GWAS[18]. Therefore, we plan to detect the causal genetic variant in this family using whole-exome sequencing. The identification of a rare pathogenic variant is important for a better understanding of the mechanism underlying the pathogenesis of PBC and for identifying novel

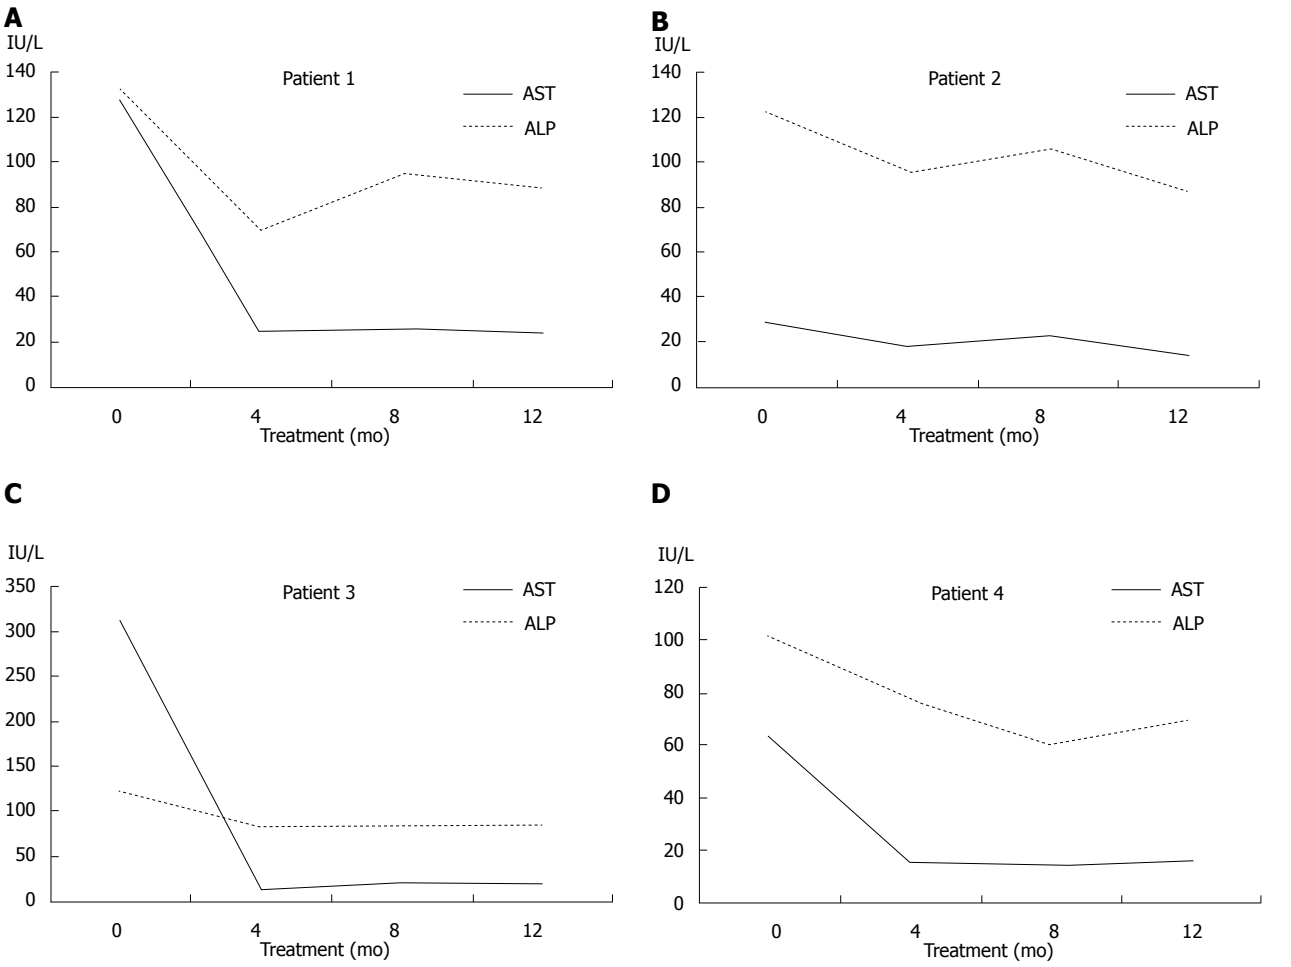

Figure 3 Biochemical responses to ursodeoxycholic acid treatment. A-D: Serum activities of aspartate aminotransferase (AST; solid lines) and alkaline phosphatase (ALP; dotted lines) showing good responses to ursodeoxycholic acid in patients 1-4.

therapeutic targets.

The early detection of PBC is important because UDCA treatment before the development of late-stage disease may normalize the life expectancy[19-21]. Long-term observational studies have demonstrated the benefits of UDCA on serum liver tests, histologic features, and improved survival[22,23]. The efficacy of a novel bile acid analogue, obeticholic acid, has also recently been demonstrated in patients who exhibit inadequate responses to UDCA[24,25]. Luckily, all of our patients responded well to UDCA therapy.

From our case and prior evidence indicating familial clustering of PBC, if one patient is diagnosed with PBC, screening with AMA and liver function tests should be recommended to other family members for the early detection and management of this condition, especially for female relatives.

The genetic etiology of PBC remains elusive despite much effort. To the best of our knowledge, this is the first case to provide evidence of a maternal inheritance mechanism for PBC based on the identification of a non-PBC half-sibling. This report also highlights the occurrence of all clinical presentations of PBC in one family. Additional studies are needed to identify a causal genetic variant in this family and the exact genetic mechanism that leads to the development of PBC.

COMMENTS

Case characteristics

Two patients presented with fatigue and nausea, and the other two patients exhibited no symptoms.

Clinical diagnosis

Four sisters in a family were diagnosed with primary biliary cholangitis (PBC), although one brother with the same mother and one half-sister with a different mother showed no evidence of PBC.

Differential diagnosis

Drug-induced cholestasis (history for medication), bile duct obstruction (ultrasound for gallstones or malignancy), autoimmune hepatitis [liver histology, auto-antibodies studies, serum immunoglobulin G level, and treatment response to ursodeoxycholic acid (UDCA)].

Laboratory diagnosis

All four patients showed the presence of anti-mitochondrial antibodies at high

titers (≥ 1:640) and elevated serum liver biochemistry results including those for alkaline phosphatase and aspartate aminotransferase.

Imaging diagnosis

For all patients, ultrasounds revealed no evidence of biliary obstruction due to gallstones or malignancy.

Pathological diagnosis

For all patients, microscopic observations of liver biopsy tissue revealed histologic findings consistent with PBC.

Treatment

The four patients were treated with UDCA.

Related reports

To date, many PBC candidate loci have been reported in genome-wide association studies. However, these loci are very heterogeneous, and the exact genetic cause of PBC remains elusive.

Explanations of terms

Whole-exome sequencing: also called WES or exome sequencing, is a technique for the sequencing of all human protein-coding exons.

Experiences and lessons

From the observations of the presentations of the four siblings diagnosed with PBC, we recommend that PBC occurrence should be considered in family members of any identified patients.

Peer-review

This is an interesting clinical observation that suggests the possibility of a maternal inheritance pattern of PBC. The presented data may provide an incentive for further research.

Abstract

Duplicate publication can introduce significant bias into a meta-analysis if studies are inadvertently included more than once. Many studies are published in more than one journal to maximize readership and impact of the study findings. Inclusion of multiple publications of the same study within a meta-analysis affords inappropriate weight to the duplicated data if reports of the same study are not linked together. As studies which have positive findings are more likely to be published in multiple journals this leads to a potential overestimate of the benefits of an intervention. Recent advances in immunosuppression strategies following liver transplantation have led to many studies investigating immunosuppressive regimes including immunosuppression monotherapy. In this letter we focus on a recently published meta-analysis by Lan *et al* investigating studies assessing immunosuppression monotherapy for liver transplantation. The authors claim to have identified fourteen separate randomised studies investigating immunosuppression monotherapy. Seven of the references appear to relate to only three studies which have been subject to duplicate publication. Several similarities can be identified in each of the duplicate publications including similar authorship, identical immunosuppression regimes, identical dates of enrolment and citation of the original publication in the subsequent manuscripts. We discuss the evidence of the duplicate publication inclusion in the meta-analysis.

Key words: Liver transplantation; Immunosuppression; Meta-analysis; Duplicate publication; Bias

TO THE EDITOR

We read with interest the article titled "Efficacy of immunosuppression monotherapy after liver transplantation: A meta-analysis" by Lan *et al*[1]. The authors have performed a meta-analysis assessing the use of immunosuppression monotherapy after liver transplantation. The authors claim to have included fourteen randomised studies comparing monotherapy *vs* combination immunosuppression for liver transplanted patients and conclude that calcineurin inhibitor monotherapy is both effective and leads to fewer adverse events than combination therapy. The authors state that the review is the first meta-analysis to include multiple studies assessing the effect of immunosuppression with or without steroids on graft rejection after liver transplantation. Finally, the authors state that the strengths of their review include duplicate study elimination. For the following reasons, we do not agree with their results or their conclusions.

The authors claim to have included fourteen separate randomised studies. On closer inspection, the authors have included seven references relating to only three randomised studies and have not made adequate efforts to eliminate duplicate studies[2-8].

The first of these studies was performed in the United Kingdom and both publications share the same start date, protocol, several co-authors and the same recruitment centres[2,3]. The earlier publication appears to record preliminary results[2]. Manousou *et al*[3] appear to have included these preliminary results as a separate study. Furthermore, the main publication relating to this study clearly states that the findings are "similar to those in our preliminary report". The citation in support of this statement is identical to that included as a separate study in the meta-analysis by Lan *et al*[1].

The second of these studies was performed in Germany and both publications share the same enrolment dates, protocol, several co-authors, recruitment centre and numbers of patients allocated to each intervention arm[4,5]. Furthermore, the publication recording long-term follow-up for patients in this study explicitly states that the authors have previously published their study and that in the publication in 2010 they "present the results of a re-evaluation of our study patients"[5].

The third of these studies was performed in Italy and all three publications share the same enrolment dates, several co-authors, recruitment centre and protocol[6-8]. Furthermore, both duplicate studies with later publication dates explicitly state that the earlier publications are interim reports relating to the same study[6,7].

The authors also claim to have published the first meta-analysis assessing steroid-free immunosuppression in liver transplanted patients. Three meta-analyses[9-11] were published prior to the date of submission by Lan *et al*[1]. Two further meta-analyses have been published since this date[12,13]. In each case where any of the three studies discussed have been included in another meta-analyses the authors have concluded that the studies have been subject to duplicate publication.

The problem with inclusion of duplicated data in meta-analyses is that it creates bias with inappropriate weight being afforded to the duplicate data. The failure in Lan 2014 to adequately avoid duplicate publication bias may mean that the results of this meta-analysis are invalid.

World Journal of Gastroenterology

Contents

Weekly Volume 23 Number 40 October 28, 2017

MINIREVIEWS

7201 Non-celiac gluten sensitivity: All wheat attack is not celiac

Igbinedion SO, Ansari J, Vasikaran A, Gavins FN, Jordan P, Boktor M, Alexander JS

ORIGINAL ARTICLE

Basic Study

7211 Glucagon-like peptide-2 modulates the nitrergic neurotransmission in strips from the mouse gastric fundus

Garella R, Idrizaj E, Traini C, Squecco R, Vannucchi MG, Baccari MC

7221 Hypothermic machine perfusion with metformin-University of Wisconsin solution for *ex vivo* preservation of standard and marginal liver grafts in a rat model

Chai YC, Dang GX, He HQ, Shi JH, Zhang HK, Zhang RT, Wang B, Hu LS, Lv Y

7232 Relationship between autophagy and perineural invasion, clinicopathological features, and prognosis in pancreatic cancer

Yang YH, Liu JB, Gui Y, Lei LL, Zhang SJ

7242 Dachaihu decoction ameliorates pancreatic fibrosis by inhibiting macrophage infiltration in chronic pancreatitis

ABOUT COVER

Editorial board member of *World Journal of Gastroenterology*, Marcos V Perini, MD, MSc, PhD, Senior Lecturer, Department of Surgery, University of Melbourne, Melbourne, Victoria 3084, Australia

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1375 experts in gastroenterology and hepatology from 68 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology (*WJG*) is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central and Directory of Open Access Journals. The 2017 edition of Journal Citation Reports® cites the 2016 impact factor for *WJG* as 3.365 (5-year impact factor: 3.176), ranking *WJG* as 29th among 79 journals in gastroenterology and hepatology (quartile in category Q2).

Abstract

Currently, 1% of the United States population holds a diagnosis for celiac disease (CD), however, a more recently recognized and possibly related condition, "non-celiac gluten sensitivity" (NCGS) has been suggested to affect up to 6% of the United States public. While reliable clinical tests for CD exist, diagnosing individuals affected by NCGS is still complicated by the lack of reliable biomarkers and reliance upon a broad set of intestinal and extra intestinal symptoms possibly provoked by gluten. NCGS has been proposed to exhibit an innate immune response activated by gluten and several other wheat proteins. At present, an enormous food industry has developed to supply gluten-free products (GFP) with GFP sales in 2014 approaching $1 billion, with estimations projecting sales to reach $2 billion in the year 2020. The enormous demand for GFP also reflects a popular misconception among consumers that gluten avoidance is part of a healthy lifestyle choice. Features of NCGS and other gluten related disorders (*e.g.*, irritable bowel syndrome) call for a review of current distinctive diagnostic criteria that distinguish each, and identification of biomarkers selective or specific for NCGS. The aim of this paper is to review our current understanding of NCGS, highlighting the remaining challenges and questions which may improve its diagnosis and treatment.

Key words: Non-celiac gluten sensitivity; Celiac disease; Gluten; Wheat; Gluten related disorder; Gluten free diet

Core tip: Non-celiac gluten sensitivity, a less known clinical entity has been estimated to have a prevalence of up to 6% in the United States. This review identifies the pathophysiology of the disease delineating clearly the important components of wheat which play a role in its innate immune response. The updated guidelines on the diagnosis of this disease is discussed here with a bridge to other management strategies apart from the gluten free diet that are now being investigated.

INTRODUCTION

In the past decade, the consumption of gluten free food has become increasingly popular in the Western world. A Gallup poll conducted in July 2015 showed that 20% of Americans opt for a gluten free diet (GFD) while 17% say they avoid gluten free foods[1]. Estimates by the nutrition industry indicate that sales of gluten-free products (GFPs) had a compound annual growth rate of 34% over the five year period ending in 2014, with annual sales totaling close to $1 billion[2]. Current market projections predict sales will again soar to approach $2 billion in the year 2020[3]. Market research by the Mintel group gives a liberal estimation of the sales of products in the gluten-free industry to be $11.6 billion in the year ending 2015, an estimated 136% increase from 2013[4]. The significant increase in the retail sales of GFPs is alarming. However, currently only approxiately 1% of the United States population is diagnosed with celiac disease[5]. Despite this, gluten-free food consumption is clearly on an exponential rise. This enormous allocation of resources reflects self-diagnosis for gluten sensitivity and may reflect an additional condition described as non-celiac gluten sensitivity (NCGS).

The first comprehensively documented case of "gluten sensitivity" (in a non-celiac disease/wheat allergy patient) was reported in 1980[6]. That report described eight adult women suffering from incapacitating abdominal pain and chronic diarrhea which rapidly remitted when a gluten-free diet was initiated, with symptomatic relapse after re-exposure to a gluten containing diet (GCD). Jejunal biopsies performed on these patients, however, failed to identify CD-like histopathology, leading to a consensus description of these patients as having "gluten-sensitive diarrhea without evidence of celiac disease". This was the beginning of the current era of what we now consider NCGS. Since then, many subsequent studies have attempted more extensive descriptions of NCGS to create effective diagnostic criteria and management strategies.

In 2011, an international consensus on NCGS reached an agreement on the definition of NCGS, defining it as a "non-allergic and non-autoimmune condition in which the consumption of gluten can lead to symptoms similar to those seen in CD." NCGS is defined as gluten sensitivity because symptoms are relieved by gluten withdrawal, and re-appear upon introduction to gluten[7]. At least part of the difficulty in handling NCGS patients is that essentially, it is often a diagnosis by exclusion. First, CD and WA need to be excluded as possible diagnoses. Beyond this, NCGS often carries an extensive and relatively broad set of symptoms which affects diverse organ systems[8]. Symptoms of NCGS could be very disabling presenting as gastrointestinal and/or extra-intestinal symptoms[9]. The onset of NCGS symptoms after gluten consumption can also range widely, appearing hours to even days following exposure to a GCD; the timing of resolution in NCGS symptoms may also vary widely.

Given that NCGS presentation could resemble CD or WA, further research into highlighting their hallmark findings is necessary. It is essential now that individuals with gluten-related disorders are identified accurately and managed appropriately. This is important in order to curtail the significant rise in the retail sales of GFPs in the food industry as millions of dollars could be salvaged given the appropriate diagnosis amongst other important reasons. This current review discusses our present understanding of NCGS, its differences and similarities to CD and other gluten-related disorders, etiopathogenesis and management strategies. It is important to recognize that NCGS is a distinct disorder from CD and it is imperative that it is accurately distinguished.

EPIDEMIOLOGY

Despite becoming a more common diagnosis, there is currently a paucity of information on NCGS especially regarding its actual prevalence in the general population. This lack of information reflects the decision of many patients to start GFD after self-diagnosis without any formal clinical testing or management recommendation by their physician. As a result of this ambiguity, the prevalence of NCGS has been reported to vary enormously from 0.6%-6% in Western populations[10-12]. It is unclear how much of the rise in consumption of gluten free foods actually reflect a higher prevalence of NCGS in the population or the choice to adhere to a GFD based on patient's preferences.

Despite the lack of accurate epidemiologic measurements of the actual US prevalence of NCGS, data in 2009-2010 from the National Health and Nutrition Examination Survey (NHANES) showed that of the

7762 NHANES participants who were free of celiac disease, 49 individuals reported a strict adherence to a GFD. This reflects a weighted prevalence of NCGS of only 0.55%[11]. Another more recent evaluation of the NHANES participants from 2009-2012 separated patients into those with CD and those without CD consuming a GFD. This study estimated a prevalence of NCGS of 0.8% in patients without CD who were consuming a GFD[10]. The prevalence in these NHANES studies were estimated based on the assessment that the individuals without CD avoiding gluten fall under the classification of NCGS.

During the period 2004 and 2010, 5896 patients were seen at the Center for Celiac Research at the University of Maryland. Of these, 347 participants met the criteria for diagnosis of "Gluten Sensitivity" reflecting about 6% of the patients seen[12]. These gluten triggered symptoms included abdominal pain (68%), eczema and/or rash (40%); headache (35%); "foggy mind" or difficulty focusing (34%); fatigue (33%); diarrhea (33%); depression (22%); anemia (20%); numbness in the legs, arms or fingers (20%); and joint pain (11%)[12]. The proportion of patients with NCGS in this study extrapolated to the general population estimated an enormous prevalence of NCGS compared with that previously seen in prior studies. Based on our review, the estimation of the prevalence of NCGS ranges widely from 0.6% to 6%, a ten-fold difference. As identified, the prevalence of NCGS in the general population may exceed that of CD - now estimated at 1%[5]. However this appears to be a high estimate based solely on symptomatology.

As NCGS is a relatively "new" entity compared to CD, it is also unclear whether or to what extent genetic or environmental risks might predispose individuals to this disorder. Studies have suggested gender contributions with the female to male prevalence ratio between 3:1[13,14] to 5.4:1[15], indicating a female predominance in NCGS. This may however reflect the observation that female patients are more prone to reporting gluten-related symptoms thus leading to referrals for further work-up as seen in a United Kingdom study in 2014[16]. There has also been a heightened interest in the association of NCGS with other medical conditions. An overlap between irritable bowel syndrome (IBS) and NCGS has been suggested since most of the gastrointestinal symptoms in NCGS resemble IBS (similar Rome III criteria), including abdominal pain/discomfort, bloating, diarrhea and constipation[15]. There is also a debate as to whether a GFD can help symptom resolution in IBS after excluding CD, as clinical trials have shown that GFD can reduce symptoms in patients with diarrhea-predominant IBS (IBS-D)[17]. Although recent research has suggested that a low fermentable oligo-, di-, mono-saccharides and polyols (FODMAPs) diet, regardless of gluten content, improves symptoms in IBS[18]. Given the close symptomatic resemblance between NCGS and IBS, prevalence estimates may be unclear as patients with NCGS could be mislabeled as IBS.

PATHOGENESIS

The pathobiology of NCGS is poorly understood, hotly debated and under intense research (Figure 1). NCGS potentially involves many triggers as are seen in CD and IBS. The initiating event in NCGS mainly involves exposure of gut epithelium to gluten containing foods leading to immune-mediated and/or non-immune mediated responses. Whereas CD shows increased gut permeability, NCGS shows a decreased gut solute permeability with increased epithelial barrier and elevated expression of the tight junctional component claudin-4[19-21]. Due to the lack of evidence for T-cell involvement and the apparent contribution from toll-like receptors (*e.g.,* TLR-2, TLR-1)[21], NCGS may be more of an innate rather than adaptive immune response. Since specific triggers are not clear in NCGS, this could make NCGS a relatively different pathobiological entity from other gluten related conditions like CD and WA[20,22]. Changes in the gut microbiome (dysbiosis) produced by gluten consumption[23] may also influence NCGS. This predominantly innate TLR based systemic response potentially incited by changes in microbiota was further supported by the increased levels of LBP (lipopolysaccharide binding protein) and soluble CD14 proteins[24]. Additionally there is evidence for NCGS developing in individuals with some genetic predispositions (*e.g.,* HLA-DR4, HLA-DR2)[21], which is higher than general population but lower than patients with CD who have a strong genetic component. However, currently this association does not appear to be as clear[21,22].

Gluten, the main inciting agent in CD also has a significant role in NCGS pathology[25]. In addition to gluten, several other food-derived stimuli have been shown to also be important in the etiopathogenesis of NCGS include alpha amylase/trypsin inhibitors (ATIs)[26], FODMAPS[18] and other short chain fructans. Gliadin is the alcohol soluble fraction of gluten, and contains the bulk of the "immunogenic" components[27]. Gliadin has the ability to promote an inflammatory response primarily in the upper gastrointestinal tract. Gliadin has shown to trigger both innate and adaptive response via recruitment of CD4+ T cells and increasing expression of interleukin-15 by enterocytes[28]. The effects of gliadin-induced enteric responses are not however completely seen in NCGS with innate immune response apparently playing a bigger role than adaptive response[21,29]. The heterogeneous behavior of NCGS in comparison to CD can be explained by different motifs of gliadin protein exerting different responses with alpha gliadin peptides having a significant role in innate adaptive response, and probably expressed more in NCGS individuals[30]. NCGS individuals also have increased levels of TLR2 and to a lesser extent TLR1 expression, increased

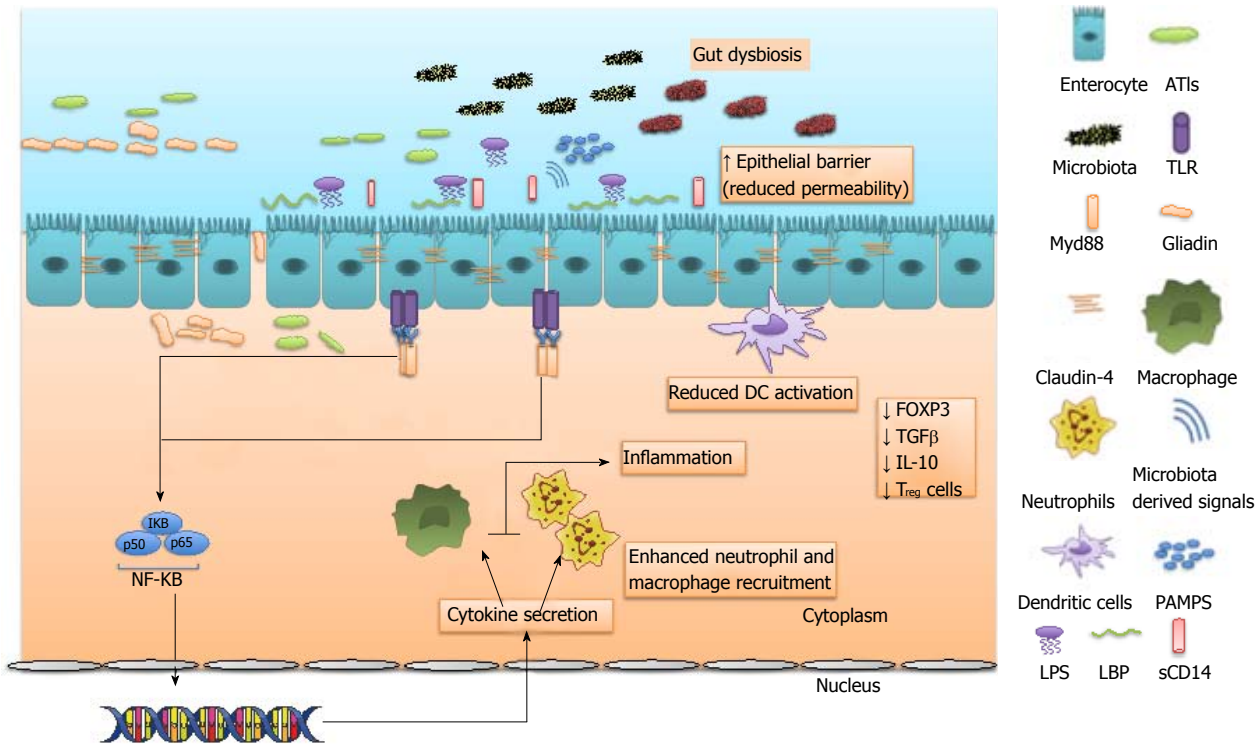

Figure 1 Toll like receptors act as primary sensors to gliadin and non-gluten proteins like alpha amylase/trypsin inhibitors, and microbiota derived signals in non-celiac gluten sensitivity. Dysregulated microbiota also release lipopolysaccharide (LPS) in circulation which result in production of LPS-binding protein (LBP) from gastrointestinal and hepatic epithelial cells and soluble CD14 (sCD14) from monocytes/macrophages. This leads to activation of transcription factor nuclear factor-kappaB (NF-κB), which controls the expression of an array of inflammatory cytokine genes resulting in recruitment of neutrophils and macrophages. In contrast to CD, there is limited dendritic cell activation, resulting in reduced expression of Treg cells, reduced FOXP3, TGFβ, IL-10. All these factors with increased expression of claudin-4 culminate in reduced intestinal permeability and increased epithelial barrier. Gut dysbiosis can also promote inflammation through expansion of pro-inflammatory pathobionts. TLRs: Toll like receptors.

number of α and β intraepithelial lymphocytes, and reduced number of T-regulatory cells[21]. Solute barrier function remains largely unchanged in NCGS, which is consistent with fairly normal adaptive immune response, normal intestinal permeability and expression of tight junction proteins[14,21]. Gluten's opioid like effect on the intestinal transit time and nocebo effect has also been studied and may have an important role on the overall pathology and clinical presentation of the disease[31].

In the recent years, other non-gluten components of wheat have also been shown to play a major role. ATIs in particular, have been implicated in NCGS pathology. The role of ATIs in mounting an immunological response has been shown in animal and human research models and is believed to be an important oral antigen both in CD as well as in NCGS[26]. This predominantly innate immune response involves macrophages, neutrophils and intestinal dendritic cells *via* activation of the toll like receptor complexes[21,26]. Their less tendency to affect the overall gut morphology falls well in line with NCGS pathology.

The gut microbiota has been shown to play a significant role in the pathogenesis of CD, in which gut dysbiosis precedes the activation of inflammatory and immune mediated pathways[32]. The role of gut dysbiosis has also recently been emphasized in NCGS pathobiology and might help to explain both intestinal and non-intestinal manifestations in the disease by upregulating gut and systemic inflammation[33].

CLINICAL PRESENTATION

The symptoms of NCGS can occur within hours to days following exposure to gluten-containing diet and can then dissipate upon withdrawal of gluten. Most of the presentation resembles CD, the main similarities and differences are presented in Table 1. Frequent symptoms reported in NCGS include bloating (87%), abdominal pain (83%), epigastric pain (52%), diarrhea (50%), and constipation (24%)[8]. Extra-intestinal manifestations are also reported which include; lack of well-being (68%), tiredness (64%), headache (54%), anxiety (39%), "foggy mind" or difficulty focusing (38%)[8].

Some of the other less commonly reported symptoms include weight loss, depression and skin rash[8]. Unlike CD, nutrient deficiencies such as iron, vitamin D and vitamin B 12 deficiencies are not significantly seen in NCGS[34]. NCGS also has a lesser association with autoimmune disorders when compared with CD[14,35].

Table 1 Comparison of gluten related disorders[34,51-72]

	NCGS	CD	IBS	WA
Colonic manifestations	Diarrhea Abdominal pain Bloating Constipation Nausea Vomiting	Diarrhea Abdominal pain Bloating Constipation Nausea Vomiting	Diarrhea Abdominal pain Bloating Constipation Mucous Discharge Dyspepsia Early satiety	Diarrhea Abdominal pain Bloating Constipation Nausea Vomiting
Extra-colonic manifestations	Headache Migraine Foggy mind Fatigue Eczema like rash Myositis Numbness Psychological changes	Anemia Osteoporosis Neurological disturbances Pubertal delay Dermatitis herpetiformis Foggy mind Lymphoma	Major depression Anxiety Somatoform disorder Fibromyalgia Temporomandibular disorder Dyspareunia	Hives Angioedema Asthma Cough Post Nasal Drip Eczema
Symptom Onset	Hours to Days	Hours to months	Unclear relation to gluten ingestion	Minutes to Hours
Cytomorphology	Small bowel intraepithelial lymphocytosis (Marsh 0-1)	Villous atrophy with crypt hyperplasia	Normal	Normal
Biomarkers	IgG-AGA Zonulin LBP sCD14	IL-17(A) TCR-γδ IELs IgA tTGA IgA EMA CD3 + IELS Zonulin	TNF- α IL-6 IL-8	IgE antibodies to wheat protein
Immunophenotype	HLA- DQ2 and DQ8 genotypes in 50% patients	HLA- DQ2 and DQ8 genotypes in 80% patients	Increase in: B cells expressing IgG or co-stimulatory molecules CD80 or CD86 T cells expressing b7 + HLADR+ and CD69+	Transforming growth factor-b (TGFb) mutations have been associated with higher rates of allergic disease
Diagnosis	See figure 2	*Serologic testing followed by small bowel biopsy	Rome III diagnostic criteria	Skin prick test Presence of serum IGE antibodies to wheat protein
Management	GFD Probiotics AN-PEP	GFD	Symptomatic treatment and elimination of stressors	GFD Subcutaneous epinephrine for any acute episodes

*4 out of 5 of the following: Typical symptoms of CD, Serum CD IgA class auto antibodies at high titer, HLA-DQ2 and/or HLA-DQ8 genotypes, Celiac enteropathy found on small bowel biopsy, Response to a GFD(14).

DIAGNOSIS

NCGS should be considered in patients with the history and physical examination indicative of a gluten related disorder. The clinical presentation of NCGS, as outlined earlier, should include the remission of symptoms upon withdrawal of gluten. The proposed diagnostic work-up includes 3 vital steps.

The 1st step in an NCGS diagnosis is the exclusion of CD and WA. The patient needs to be on a GCD for a period of 6-wk. Several tests should be performed during this period to exclude WA; wheat specific IgE and skin prick test, and CD; IgA-tTG, IgG-DGP and IgA-EMA. If highly suspicious of CD, the physician can proceed with upper endoscopy for duodenal biopsy, although this should not be routine testing for every patient. If the biopsy results indicate less CD probability (Marsh 0-1) then the clinician can proceed to the next step[5]. Of note, these tests can be tailored by the clinician based on the patients' presenting symptoms. The physician can bypass testing of CD or WA and proceed with the work-up for NCGS if patients' history and physical is not suggestive of the condition.

The 2nd step consists of starting the patient on a GFD for a period of at least 6 wk and monitoring for symptom response. This symptom response is evaluated using the gastrointestinal symptom rating scale (GSRS) and a numerical rating scale (NRS). GSRS is used to identify the symptoms while the NRS is used to quantify the symptoms, weekly from week 0 (baseline) till week 6[36]. A symptomatic response to the GFD is defined as a decrease in 30% of the baseline score with no worsening of other symptoms in at least 50% of the observation time (3 wk)[36]. If the patient fails to show an improvement in symptoms in 6 wk upon resumption of GFD, the diagnosis of NCGS is ruled out and other diagnoses such as IBS and other functional bowel disorders need to be explored.

The 3rd step required to confirm the diagnosis

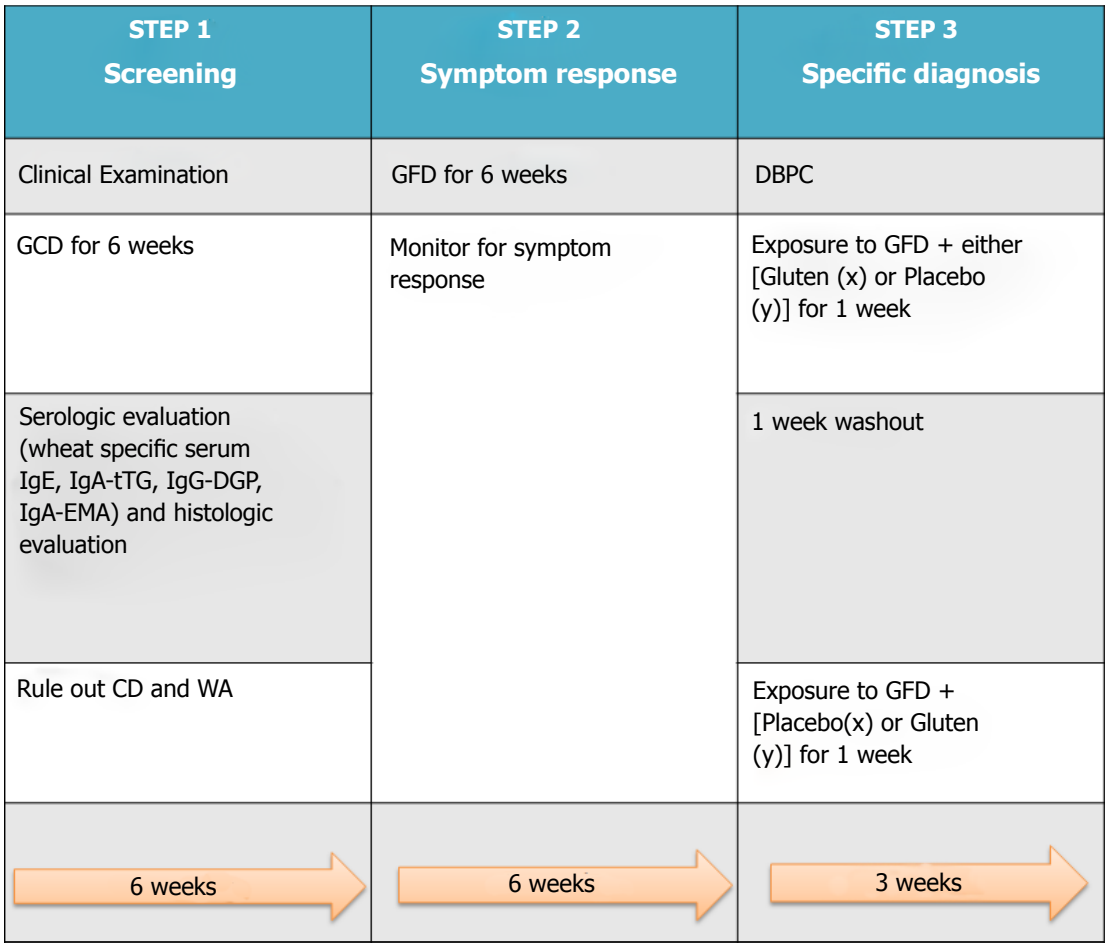

Figure 2 Proposed diagnostic algorithm for non-celiac gluten sensitivity. GCD: Gluten containing diet; GFD: Gluten free diet; CD: Celiac disease.

of NCGS in patients who respond to treatment with the GFD involves the re-introduction of the GCD. This is performed because a potential nocebo effect (test subjects believe there is a side effect and they experience them as a result of this) secondary to the exposure to gluten in step 1 cannot be ruled out[37]. In this step, the patient is randomly assigned into test group x or y. The patient is exposed to either GFD + placebo (x) or GFD + gluten (y) for a week. A 1-week washout period of strict GFD is observed, followed by the crossover to GFD + gluten (x) or GFD + placebo (y)[36]. A variation of a 30% symptomatic improvement on introduction of the diet free from gluten in test group y or a variation of 30% symptomatic appearance on introduction of the GCD in test group x (assessed by the modified GSRS and NRS scales) indicates a positive result. Below this 30% value is considered a negative result[36]. This 30% mark is not a scientific estimate but is rather a fair estimate of an appropriate response[36]. This threshold although used in the Salerno experts' criteria needs scientific validation.

In step 3, the placebo added should be gluten-free and must look very similar to the gluten content so that both the clinician and the patient are unaware of the difference between the gluten and the placebo. The dose of gluten to be used for the challenge should be close to the average daily intake of gluten (10-15 g)[38]. The dose should also be easy to mix with the gluten carrying package. The package carrying gluten can be in any form; bread, muffin. This package should also consist of ATIs as well. The suggested prepared package should contain 10-15 *g* of gluten and at least 0.3 g of ATIs. The package must also be free of FODMAPs[36]. The proposed diagnostic algorithm for NCGS is shown in Figure 2.

MANAGEMENT

Currently, the management of NCGS involves a multi-disciplinary approach. The patient is started on a GFD with the help of a registered dietician[14]. A gluten free diet usually helps resolve the intestinal and extra-intestinal symptoms of NCGS. The recommendation is to continue adherence to GFD for lifetime. There have been few if any studies showing whether or not reintroduction of gluten into the diet after a prolonged period of being asymptomatic will cause reversion into previous symptoms[39].

The importance of gluten has been outlined in recent research. Gluten consumption has been associated with a decreased risk of developing type 2 diabetes Mellitus and also a decreased risk of coronary heart disease[40,41]. Understanding these benefits of gluten beyond nutrition reflects the need for caution in the use of GFDs in patients without a proven diagnosis of NCGS. Although GFD seems to be the most important management strategy, it should be suggested only after careful examination and a definite diagnosis of NCGS.

Several ongoing clinical trials are now examining other possible treatment methods for NCGS besides the GFD. One study looks at the use of probiotics for alleviation of NCGS symptoms while maintaining a gluten free diet with introduction of gluten in a controlled environment. This randomized DBPC study evaluates NCGS patients' response to a gluten source (two slices of bread each day for 7 d) whilst getting probiotics (Bifidobacterium longum ES1 - a patented probiotic bacterial strain) or a placebo during that time[42]. Theoretically the use of probiotics could result in resolving gut dysbiosis by reintroducing gut flora, with reduction in both gut and systemic inflammation but this needs to be clinically examined. Probiotic use has long been a source of debate amongst the medical community regarding its exact role as far as therapeutic option, it's essential to see if it can be proven to have an ultimate benefit.

Another treatment option under investigation is the use of the enzyme Aspergillus niger prolyl endoprotease (AN-PEP). It has been reported in previous studies that the AN-PEP enzyme significantly enhanced gluten digestion in the stomach of healthy volunteers[43]. A randomized placebo controlled clinical trial is ongoing looking at the effect of AN-PEP on gluten degradation in our target population; gluten sensitive individuals[44]. If we can apply AN-PEP as a means of degrading gluten before it can affect the human gut, it would achieve a major goal as patients can enjoy foods without worrying about diet restriction, worrisome symptoms or soaring food costs.

The use of ancient diploid wheat species (*e.g.,* Triticum monococcum ssp.) as compared with common wheat as a new treatment strategy is gaining ground[45]. Gianfrani *et al*[45]. demonstrated the low toxicity of these wheat proteins in celiac disease patients following in vitro gastrointestinal digestion. Newer studies have shown the distinction between these older wheat variants and modern wheat[46]. Older wheat variants were shown to have lower bioactivity and a lower concentration of ATIs in comparison with modern wheat[46]. Mechanistically, the modern wheats were observed to have high levels of TLR-4-activating ATIs which are highly resistant to intestinal proteolysis[46]. The application of these studies to favor the use of ancient wheat variants in the NCGS population would be a major step in the advancement of treatment strategies in this disease.

Mayer and Tillisch highlighted the role of the brain-gut axis in abdominal pain syndromes[47]. Recent literature has attempted to further describe how various clinical manifestations seen in IBS and also syndromes like NCGS could be viewed as a dysregulation in the signaling pathway that involves the gut, the enteric nervous system and the central nervous system[33,47,48]. Newer therapeutic options currently being hypothesized in NCGS include the use of vagus nerve stimulation and corticotropin releasing factor (CRF) antagonists to normalize any possible gut brain dysregulation[33,48]. The use of vagus nerve stimulation is based on its positive effects on many inflammatory diseases of vagus-innervated organs (including the GI tract) which thus suggest a case for its application in NCGS[33]. The use of CRF antagonists (seen to induce significant signal reductions in emotional control centers of the brain[23]) is based on the theory that NCGS often has a chronic anxiety or stress related component associated with the anticipation of abdominal pain. Consequently controlling the emotional impact of NCGS may improve its symptoms. The several on-going studies/ theories in this area hopefully can shed light on the neuropsychiatric therapeutic components of NCGS.

With the release of the updated ICD 10 coding system, NCGS, along with WA, IBS and CD each have their own codes despite lingering ambiguities about NCGS diagnosis/management. NCGS's code is K90.41 and it falls under the categories "enteropathy" (code K63.9) and gluten sensitivity (Code K90.41). Although treatment strategies in NCGS are still evolving, it is important to note that NCGS is a specific and billable diagnosis for reimbursement purposes[49].

CONCLUSION

A recent study involving gastroenterologists showed that although most of these specialist physicians were able to "identify" NCGS and prescribe GFD for its treatment, 44% of them were unable to define or agree on a uniform definition[50]. This highlights the difficulty in making the diagnosis of NCGS based on a specific clinical criterion. NCGS warrants further investigation and updated diagnostic and therapeutic strategies.

As we currently stand, the NCGS diagnostic process is arduous for the patient, requiring them to be on a GCD diet through several parts of the process. This could cause distress by eliciting unpleasant symptoms. Thus, an alternative diagnostic approach without subjecting the patient to the stressor would be a significant clinical advancement. Some biomarkers identified to aid in the diagnosis of NCGS are IgG-AGA[15] and Zonulin[51]. However these markers are evidently increased in CD as well[15,51]. Establishing NCGS specific biomarkers is imminent to also monitor for both the resolution of the disease and compliance

of the patient to the GFD. Whether NCGS is a transient disease or a chronic disease warranting lifetime diet restriction still needs to be investigated.

The lack of information with regards to the prevalence of NCGS in the developing world is outstanding. Most of the studies being done on this condition are focused on the population, which includes the affluent communities of Europe and North America. Adhering to the GFD is expensive and not easily affordable, the likelihood of a low-income patient self-diagnosing as NCGS and going on a GFD is very minimal. This warrants the question as to if NCGS is really a condition more prevalent in the affluent as they are much more conscious of their diet intake as well as informed.

New and evolving science around gluten related disorders has led to better understanding of the disease process, making it easier for the clinicians to set specific management guidelines. Prospective clinical trials in a diverse population is warranted to better investigate the etiology and progression of this disease. There is still a role of further research to better understand NCGS as a medical condition.

Abstract

AIM

To investigate whether glucagon-like peptide-2 (GLP-2) influences the neurally-induced responses in gastric strips from mice, since no data are available.

METHODS

For functional experiments, gastric fundal strips were mounted in organ baths containing Krebs-Henseleit solution. Mechanical responses were recorded *via* force-displacement transducers, which were coupled to a polygraph for continuous recording of isometric tension. Electrical field stimulation (EFS) was applied via two platinum wire rings through which the preparation

was threaded. The effects of GLP-2 (2 and 20 nmol/L) were evaluated on the neurally-induced contractile and relaxant responses elicited by EFS. Neuronal nitric oxide synthase (nNOS) enzyme was evaluated by immunohistochemistry.

RESULTS

In the functional experiments, electrical field stimulation (EFS, 4-16 Hz) induced tetrodotoxin (TTX)-sensitive contractile responses, which were reduced in amplitude by GLP-2 ($P < 0.05$). In the presence of the nitric oxide (NO) synthesis inhibitor L-NNA, GLP-2 no longer influenced the neurally-evoked contractile responses ($P > 0.05$). The direct smooth muscle response to methacholine was not influenced by GLP-2 ($P > 0.05$). In the presence of guanethidine and carbachol, the addition of GLP-2 to the bath medium evoked TTX-sensitive relaxant responses that were unaffected by L-NNA ($P > 0.05$). EFS induced a fast NO-mediated relaxation, whose amplitude was enhanced in the presence of the hormone ($P < 0.05$). Immunohistochemical experiments showed a significant increase ($P < 0.05$) in nNOS immunoreactivity in the nerve structures after GLP-2 exposure.

CONCLUSION

The results demonstrate that in gastric fundal strips, GLP-2 influences the amplitude of neurally-induced responses through the modulation of the nitrergic neurotransmission and increases nNOS expression.

Key words: Immunohistochemistry; Gastric motility; Glucagon-like peptide-2; Neuronal nitric oxide synthase; Non-adrenergic non-cholinergic neurotransmission

Core tip: The results of the present study demonstrate for the first time that, in strips from the mouse gastric fundus, glucagon-like peptide-2 (GLP-2) depresses the amplitude of the neurally-induced contractile responses and enhances the amplitude of the relaxant ones through the modulation of the nitrergic neurotransmission. GLP-2 also increases neuronal nitric oxide synthase immunoreactivity in the nerve structures. All these inhibitory effects might contribute to gastric relaxation, thus increasing the organ capacity. Since gastric distension represents a peripheral satiety signal from a physiological point of view, it could be speculated that the relaxant effects of GLP-2 might concur to suppress feeding behavior in rodents.

Glucagon-like peptide-2 modulates the nitrergic neurotransmission in strips from the mouse gastric fundus. *World J Gastroenterol* 2017; 23(40): 7211-7220 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7211.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7211

INTRODUCTION

Glucagon-like peptide-2 (GLP-2), produced by enteroendocrine "L" cells[1,2], plays a role in the regulation of metabolism and energy homeostasis[3,4], and has been reported to influence many gastrointestinal functions[5,6]. GLP-2 acts on G protein-coupled receptors (GLP-2r)[7-9] largely distributed in the gastrointestinal tract[2,10]. In the gut, GLP-2r has been revealed in several cell types, including excitatory and inhibitory neurons[10-13]. In this view, GLP-2 has been demonstrated to exert a neuromodulatory action either by inhibiting intestinal transit *in vivo*[14] *or* by reducing colonic and duodenal cholinergic muscle contractions *in vitro*[10,11].

Concerning gastric motility, contrasting results have been reported in humans regarding the ability of GLP-2 to slow emptying[15-17]. *In vivo* experiments in pigs have shown that the hormone reduced antral motility through central nervous system mechanisms[18]. In addition to the central actions, experiments carried out *in vitro* have demonstrated that GLP-2 exerts peripheral effects on either gastric strips or isolated whole stomach from mice[19]. Particularly, the hormone has been shown to relax gastric smooth muscle acting indirectly through the stimulation of vasoactive intestinal polypeptide (VIP) release from myenteric neurons with site-related effects, exerting its action in the fundal region only[19]. However, to our knowledge, no data have been reported about the influence of GLP-2 on the neurally-induced gastric responses elicited by electrical stimulation in *in vitro* preparations. For the above reason, we presently investigated whether GLP-2 influences the neurally-induced contractile and relaxant responses in gastric fundal strips from mice. Along with VIP[20], nitric oxide (NO)[21] is considered one of the major non-adrenergic, non-cholinergic (NANC) inhibitory neurotransmitters responsible for the proximal stomach relaxation; thus, we also evaluated the effects of GLP-2 on both the nitrergic neurotransmission and the neuronal nitric oxide (nNOS) expression.

MATERIALS AND METHODS

Animals

Experiments were performed on 8- to 12-week-old female mice (CD1 Swiss strain; Envigo, Udine, Italy). The animals were kept under the following conditions: 12-h light/12-h dark photoperiod, constant temperature (21 ± 1 ℃), and standard laboratory feed. The mice were killed by prompt cervical dislocation to minimize animal suffering.

Mechanical experiments

As formerly reported[22-25], the stomach was promptly removed, and two full-thickness longitudinal strips (2 mm × 10 mm) were cut from each gastric fundal region. One end of each strip was tied to a platinum

rod, while the other was connected to a force displacement transducer (Grass model FT03, Quincy, MA, United States) by a silk thread for continuous recording of isometric tension. The transducer was coupled to a polygraph (Grass model 7K, Quincy, MA, United States). Preparations were mounted in double-jacketed organ baths (5 mL) containing Krebs-Henseleit solution, gassed with a 95% O_2-5% CO_2 mixture, of the following composition (mmol/L): NaCl 118, KCl 4.7, $MgSO_4$ 1.2, KH_2PO_4 1.2, $NaHCO_3$ 25, $CaCl_2$ 2.5 and glucose 10 (pH 7.4). The temperature of the Krebs-Henseleit solution in the organ baths was maintained at 37 ± 0.5 ℃.

Electrical field stimulation (EFS) was applied by means of two platinum wire rings (2 mm diameter, 5 mm apart) through which the strip was threaded. Electrical pulses (rectangular waves, 80 V, 4-16 Hz, 0.5 ms, for 15 s) were delivered by a Grass model S8 stimulator. Preparations were allowed to equilibrate for 1 h under an initial load of 0.8 g: during this period, prolonged washes with Krebs-Henseleit solution were performed to avoid the accumulation of metabolites in the organ baths.

Experimental protocol

The influence of GLP-2 (2 nmol/L and 20 nmol/L) on either neurally-induced or direct smooth muscle contractile responses was firstly investigated. EFS (4-16Hz) was also performed in the presence of 1 μmol/L tetrodotoxin (TTX) or 200 μmol/L N^G-nitro-L-arginine (L-NNA). Elapsed time between two subsequent electrical stimulations depended on the time taken by the strip tension to regain baseline. The interval between two subsequent direct muscular responses to methacholine (2 μmol/L) was at least 30 min. During this period prolonged washes with Krebs-Henseleit solution were performed. To verify the viability of the strips, contractions to methacholine (2 μmol/L) were evaluated at the beginning and at the end of each experiment.

In a second series of experiments, the effects of GLP-2 (2 nmol/L and 20 nmol/L) on the EFS-induced NANC relaxant responses were investigated. For this purpose, functional experiments were carried out in the presence of 1 μmol/L guanethidine sulphate and 1 μmol/L carbachol (CCh) to rule out adrenergic and cholinergic influences, respectively. Elapsed time between two subsequent additions of CCh was at least 15 min, during which prolonged washes with Krebs-Henseleit solution were performed. When a stable plateau phase of the contraction evoked by CCh was reached, EFS or drugs were applied. The response to GLP-2 (2 nmol/L and 20 nmol/L) was also tested 20 min following the addition of TTX or the NO synthesis inhibitor L-NNA to the bath medium. Immunohistochemical experiments were performed in parallel.

Tissue sampling for morphological studies

Two gastric fundus specimens per animal (6 mice) were taken, which were prepared as reported above and handled as follows. The specimens were stabilized in 5 mL organ baths containing Krebs-Henseleit solution; at the end of the steadying period, one half of the specimens was exposed to GLP-2 for 30 min, which was added directly to the bath reaching 20 nmol/L concentration. The second half was maintained in Krebs solution and used as a control. At the end of the exposure time, the specimens were transferred into a solution of paraformaldehyde (4%) dissolved in phosphate-buffered saline (0.1 mol/L, PBS, pH 7.4), maintained overnight (ON) at 4 ℃. The day after, the specimens were dehydrated, cleared in xylene and embedded in paraffin. The rotary microtome (MR2, Boeckeler Instruments Inc. Tucson, Arizona, United States) allowed to cut 5 μm thick sections, which were collected on slides suitable to histological and immunofluorescent staining.

Histological and immunofluorescent staining

The sections were deparaffinized through consecutive passages in xylene and in decreasing ethanol concentration solutions up to the final step in distilled water. Some sections were H&E stained to visualize the integrity of the muscle wall. Some others underwent the immunofluorescent procedure. For antigen retrieval the sections were transferred for 20 min in a EDTA 1 mmol/L, pH 9.0 + tris buffer 10 mmol/L, maintained at the temperature of 90-92 ℃; then they were allowed to cool in the same solution. After few washes in 0.1 mol/L PBS, the section were first incubated for 20 min with bovine serum albumin (1.5%, Sigma Aldrich, Milan, Italy) diluted in PBS and then ON at 4 ℃ in the presence of the nNOS antibody (rabbit polyclonal; 1:1500; Chemicon, Temecula, CA, United States). After several washes, the appropriate fluorochrome-conjugated secondary antibody (goat anti-rabbit, AlexaFluor 488; 1:333; Jackson ImmunoResearch, West Grove, PA, United States) diluted in PBS were applied for 2 h at RT. Finally, the sections were counterstained with Bisbenzimide Hoechst Trihydrochloride (BHT; Sigma Aldrich srl, Milan, Italy) to visualize the cell nuclei, and set in the aqueous medium (Immu-Mount, Thermo Scientific, Waltham, MA, United States). To verify the specificity of the primary antibody, the procedure has been performed omitting the antibody. An epifluorescence microscope (Zeiss Axioskop microscope, Oberkochen, Germany) allowed to visualize the fluorescent labelling. A digital camera (Leica DFC310 FX 1.4-megapixel camera, Leica Microsystems, Mannheim, Germany) coupled to an image acquisition software (LAS V3.8, Leica Microsystems, Germany) allowed to capture and archive the related images.

Quantitative analysis

The quantitative analysis of the labelled structures was done acquiring digitized images for the whole length of the section (1 section/animal; 6 animals/group) using 20 x objective and the acquisition of overlapping images was avoided. The total number of images obtained was comparable between control and GLP-2 treated sections as confirmed by the similar length of the fundal specimens. ImageJ (NIH, Bethesda, MD, United States) was used to analyze the fluorescent labeling in the acquired images. The area of the labelled structures in the muscle wall was quantified and expressed as fraction of the total image area x 100. The labelling was converted to a binary image; the threshold value was set in control images and maintained in treated ones. Two researchers counted in blind the myenteric labelled neurons in each section (1 section/mouse; 6 mice/group) and the result was proposed as neuron number per mm.

Drugs

The following drugs were used: guanethidine sulphate, CCh, GLP-2, methacholine, L-NNA, TTX. All of the above drugs were purchased from Sigma Chemical (St. Louis, MO, United States) with the exception of GLP-2 that was obtained from Tocris Bioscience (Bristol, United Kingdom). Solutions were freshly prepared, except for TTX, for which a stock solution was stored at -20 ℃. Drug concentrations are referred as final bath concentrations and are in the range of those previously reported to be effective in *in vitro* gastric preparations[26-28]. Particularly, the chosen doses of GLP-2 employed are those reported able to cause gastric relaxation in mice[19].

Data analysis and statistical tests

Amplitude of contractions is given as percentage of the muscular contraction elicited by methacholine (2 μmol/L) taken as 100% or as absolute values (g). Amplitude of responses to methacholine was measured 30 s after a stable plateau phase was reached. Relaxant responses are calculated as percentage decrease relative to the muscular tension induced by CCh (1 μmol/L) just before obtaining relaxations. With respect to pre-stimulus level, amplitude values of EFS-induced fast relaxations refer to the maximal peak obtained during the stimulation period and amplitude values of EFS-induced sustained relaxations refer to the maximal peak, obtained following the stimulation period. The statistical significance was evaluated by paired or unpaired Student *t*-test to compare two experimental groups or one-way ANOVA followed by Newman-Keuls posttest when more than two groups were compared (Prism 3.0; GraphPad Software, San Diego, CA, United States). Differences were considered significant when $P \leq 0.05$. Results are mean ± SE. The number of muscle strip preparations is indicated by *n* in the results.

RESULTS

Functional experiments

At basal tension ($n = 28$), EFS (4-16 Hz) induced contractile responses whose amplitude increased by increasing the stimulation frequency (Figure 1A and B). These responses were abolished by 1 μmol/L TTX ($n = 4$) indicating their nervous nature. The addition of GLP-2 (2 nmol/L or 20 nmol/L) to the bath medium ($n = 16$), other than causing a long-lasting decay of the basal tension (0.15 ± 0.02 and 0.20 ± 0.03 g at 2 nmol/L and 20 nmol/L, respectively), decreased the amplitude of the excitatory responses elicited by EFS (Figure 1A and B).

In the presence of the NO synthesis inhibitor L-NNA (200 μmol/L) the amplitude of the EFS-induced contractions was enhanced (Figure 2A and B). The effects of L-NNA, already appreciable 10 min after its addition to the bath medium, persisted up to 1 h (longer time not observed). In the presence of L-NNA (200 μmol/L), GLP-2 (2 nmol/L or 20 nmol/L) still evoked the decay of the basal tension (Figure 2A and B) but no longer depressed the amplitude of the EFS-induced contractile responses even at the highest concentration employed (Figure 2A and B).

Methacholine (2 μmol/L) caused a sustained contraction that was TTX-insensitive and reached a plateau phase (mean amplitude 0.98 ± 0.3 g) that persisted until washout. GLP-2 (2 nmol/L or 20 nmol/L) did not influence the response to methacholine (mean amplitude 1.02 ± 0.2 g, $P > 0.05$). No significant differences ($P > 0.05$) in amplitude of the contractile response to methacholine (2 μmol/L) were observed between that obtained at the end or at the beginning of the experiments, thus indicating that the viability of the preparations was not compromised.

The effects of GLP-2 were also tested on the neurally-induced relaxant responses. In the presence of guanethidine, addition of CCh (1 μmol/L) to the bath medium ($n = 28$) caused a rapidly arising contraction (mean amplitude 1.2 ± 0.2 g), which persisted until washout. In CCh precontracted strips, GLP-2 (2 nmol/L or 20 nmol/L) elicited ($n = 12$) dose-dependent slow and long-lasting relaxations (Figure 3) that were abolished by 1 μmol/L TTX ($n = 4$; data not shown) and unaffected ($P > 0.05$) by L-NNA (200 μmol/L) ($n = 4$) (mean amplitude 27 ± 1.5% *vs* 25 ± 1.9% and 47 ± 1.7% *vs* 50 ± 1.6% at 2 nmol/L and 20 nmol/L, respectively).

In CCh precontracted strips, EFS (4-16 Hz) elicited ($n = 16$) a fast relaxant response followed, at the higher stimulation frequencies, by a slow relaxation (Figure 4A). As previously observed in the mouse gastric fundus[23], the fast component of the response was abolished by 200 μmol/L L-NNA ($n = 4$), indicating its nitrergic nature. In the presence of GLP-2 (2 nmol/L or 20 nmol/L), the amplitude of the EFS-induced fast nitrergic relaxation was increased ($P < 0.05$; Figure

4A and B), whereas that of the slow relaxation was reduced (6.1 ± 0.6% *vs* 12.75 ± 2.3% and 19.68 ± 1.6% *vs* 30.46 ± 2.2%, at 8 and 16 Hz, respectively; *P* < 0.05) (Figure 4A) or even abolished at the highest dose employed.

Morphological experiments

Anatomical and histological evaluation: At the end of the tissue sampling procedure, the control and GLP-2 treated specimens appeared anatomically intact and the H&E staining confirmed the integrity of the muscle wall (Figure 5).

Immunofluorescence: In the gastric fundus of both control (Figure 6A-C) and GLP-2 (20 nmol/L) treated specimens (Figure 6D-F), the nNOS-immunoreactivity (IR) was observed in the soma of the myenteric neurons and in the fibers located in the longitudinal and circular muscle layers. No IR was detected when the primary antibody was omitted (Figure 6G-H). Quantitation of the IR showed a statistically significant increase in nNOS positive neuron number and nerve fibers (Figure 6I). The length of gastric fundal strips subjected to quantitative analysis was not different between control and GLP-2 treated specimens (4.17 ± 0.60 mm controls *vs* 4.07 ± 0.48 mm GLP-2 treated).

DISCUSSION

The present study demonstrates for the first time that GLP-2 influences the neurally-induced contractile and relaxant responses in mouse fundal strips through a modulatory action on nitrergic neurotransmission and increases nNOS expression. Particularly, the functional

A: Typical tracing showing the electrical field stimulation (EFS)-induced relaxant responses at different stimulation frequencies (left panel). EFS evokes fast relaxant responses, followed by a slow component at the higher stimulation frequencies (≥ 8 Hz). GLP-2 at 2 nmol/L causes (right panel) an increase in amplitude of the EFS-induced fast relaxation in whole range of stimulation frequencies employed and a decrease of the slow one; B: Bar chart of the effects of GLP-2 (glucagon-like peptide-2, 2 and 20 nmol/L) on the mean amplitude of the EFS-induced fast relaxation. Note that GLP-2 increases the amplitude of the EFS-induced fast relaxant responses in a dose-related manner. Relaxant responses are expressed as percentage decrease relative to the muscular tension induced by 1 μmol/L CCh taken as 100%. Amplitude values of EFS-induced fast relaxations refer to the maximal peak obtained during the stimulation period. All values are mean ± SE of six preparations. $^{a}P < 0.05$ *vs* the ctr; $^{c}P < 0.05$ *vs* the ctr and *vs* 2 nmol/L GLP-2 (ANOVA and Newman-Keuls post-test).

experiments show that GLP-2 is able to depress the amplitude of the EFS-induced contractile responses at each stimulation frequency applied.

It is known that gastric motor responses are a balance between nervous excitatory (mainly cholinergic) and inhibitory (NANC) influences exerted on the smooth muscle. Since during EFS both excitatory and inhibitory nervous fibers are simultaneously activated, the reduction in amplitude of the neurally-induced contractions caused by GLP-2 might be ascribable either to a minor activation of the excitatory component or to a major nervous inhibitory influence exerted on the smooth muscle. In this view, the increase in amplitude of the EFS-induced contractile responses by the NO synthesis inhibitor L-NNA indicates the removal of a nitrergic inhibitory nervous influence. Notably, in

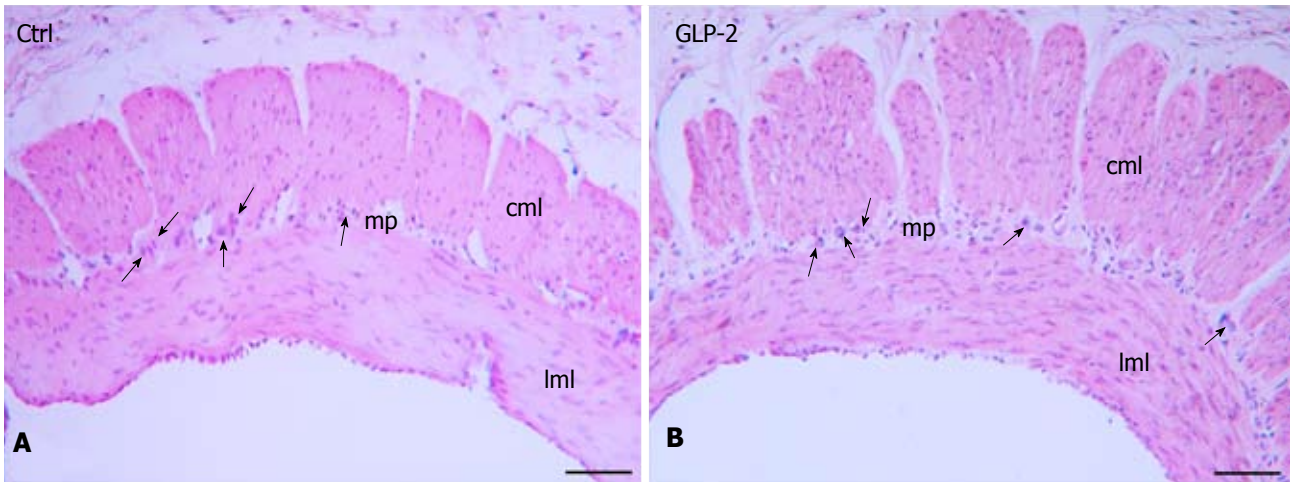

Figure 5 H&E staining of gastric fundus strip. The longitudinal and circular muscle layers (lml, cml) and the myenteric plexus (mp) are shown both in control (A) and in GLP-2 treated (B) specimens. The arrows indicated some myenteric neurons. Bar: A, B = 10 μm.

the presence of L-NNA, GLP-2 no longer depressed the amplitude of the neurally-induced excitatory responses. These data demonstrate that the hormone effects on the EFS-induced contractions occur through the modulation of the nitrergic neurotransmission and, in addition, exclude its inhibitory action on the cholinergic neurotransmission.

The lack of effects of GLP-2 on the direct smooth muscle responses elicited by methacholine further supports its neuromodulatory action. This observation also proves that the depressant actions of GLP-2 on the EFS-induced contractile responses are not ascribable to aspecific effects such as the decay of the basal tension. Moreover, the similar amplitude of the contraction to methacholine at the beginning and at the end of the experiments demonstrates that muscle responsiveness is not compromised.

In keeping with the above observations, the results of the experiments performed in the presence of guanethidine and CCh demonstrate, for the first time, that the hormone influences the amplitude of the neurally-induced relaxant responses in gastric fundal strips through a modulatory action on the nitrergic neurotransmission. As previously observed in strips from the mouse gastric fundus in the presence of guanethidine and CCh[23,26,28], EFS induced a fast NO-mediated relaxation, followed by a slow and sustained relaxant response at the highest stimulation frequencies. In the present experiments, the observation that GLP-2 increased the amplitude of the EFS-induced fast nitrergic relaxation in the whole range of stimulation frequencies in a dose-related manner further supports the involvement of the NO pathway in the hormone effects. To ascertain whether the effects of GLP-2 on both the neurally-induced contractile and relaxant responses were ascribable to an increased NO production, nNOS expression was evaluated in gastric preparations by immunohistochemistry. The results show that GLP-2 induces an increase in the nNOS labeling in the nerve structures of the gastric fundus muscle coat. Accordingly, an increased NO production in neurons induced by exogenous GLP-2 has been suggested to occur in the mouse duodenum in which the hormone inhibited the spontaneous mechanical activity[11]. In the present experiments, the increased nNOS expression in the nerve structures of the muscle wall fits well with the progressive decrease in amplitude of the EFS-induced contractile responses as well as with the increase of the fast relaxant responses caused by GLP-2. Thus, these hormone effects occur only during EFS, *i.e.*, when the nitrergic pathway is engaged, also explaining the ineffectiveness of L-NNA to influence the relaxant response induced by the addition of GLP-2 to bath medium. Indeed, gastric relaxation to GLP-2 in mice has been reported to occur through the release of VIP from myenteric neurons[19]. In this view, immunohistochemical studies in mouse, human and porcine intestine reported the presence of the GLP-2 receptor in the enteric neurons[10-12,29] and showed that some of them co-localized with VIP[11,12]. We previously observed[26] that, in strips from the mouse gastric fundus, the EFS-induced slow relaxation was abolished following VIP receptors desensitization, suggesting the involvement of the peptide in this kind of response. On this basis, it could be speculated that the reduction/abolition of the neurally-induced slow relaxation by GLP-2 observed in the present experiments occurred because VIP, released earlier from the nerve terminal by the hormone, has already occupied the muscular receptors engaged in the EFS-induced vipergic relaxant response. However, even if the validation of this hypothesis was beyond the aim of the present work, the observation that GLP-2 influences in an opposite manner the two components of the neurally-induced relaxant responses excludes an aspecific effect.

The present results demonstrate that the hormone depresses the amplitude of the neurally-induced

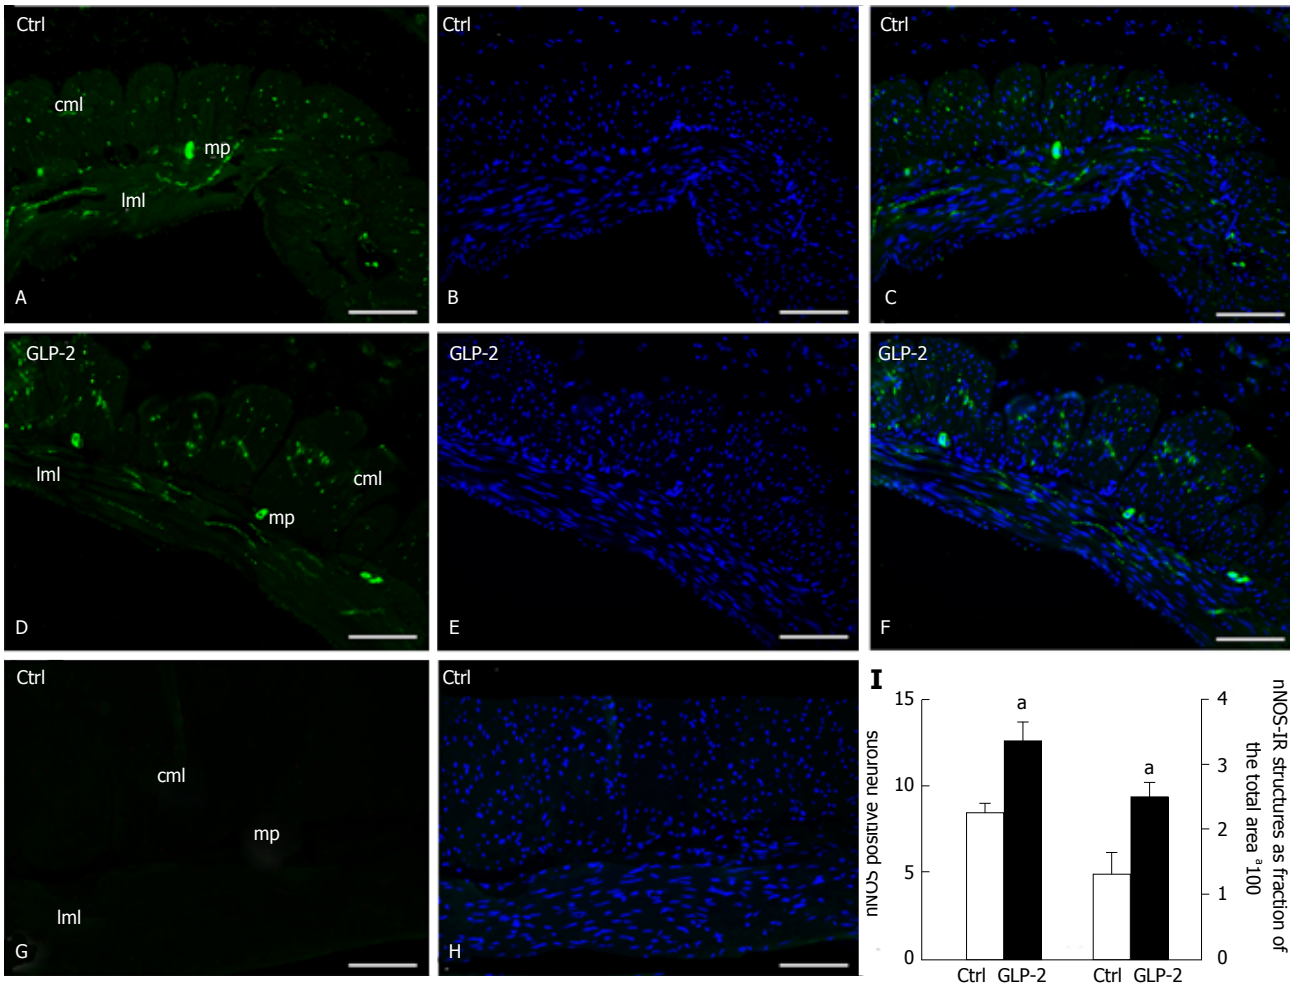

Figure 6 Neuronal nitric oxide synthase-immunoreactivity in control and glucagon-like peptide-2 treated specimens. In control (A) and glucagon-like peptide-2 (GLP-2) treated (D) specimens, neuronal nitric oxide synthase-immunoreactivity (nNOS-IR) (green) is present in the soma of some myenteric neurons and in several nerve fibers. DAPI fluorescent staining for DNA (blue) identified the nuclei of both smooth muscle and neural cells (B-E). In C and F, merged images of nNOS and Bisbenzimide Hoechst Trihydrochloride (BHT) fluorescent staining are shown. When the primary antibody is omitted (G), only the BHT labelling is observed (H). The quantitative analysis showed a significant increase (I) in nNOS-IR myenteric neurons (left side) and in IR fibers in the entire muscle coat (right side). $^{a}P < 0.05$ *vs* controls (unpaired Student's t-test). mp: Myenteric plexus; cml: Circular muscle layer; lml: Longitudinal muscle layer. Bar: A-H = 10 μm.

contractile responses, enhances the amplitude of the NO-mediated fast relaxant responses and increases the nNOS expression in the nerve fibers. All of these effects of GLP-2 might contribute to gastric relaxation, thus increasing the organ capacity. Since gastric distension represents a peripheral satiety signal[30] from a physiological point of view, it could be hypothesized that the relaxant effects of GLP-2 might contribute to suppress feeding behavior in rodents[31,32].

In conclusion, this study shows for the first time that GLP-2 influences the neurally-induced responses in gastric strips from mice through a modulatory action on the nitrergic neurotransmission and increases nNOS expression.

COMMENTS

Background

Glucagon-like peptide-2 (GLP-2) has been shown to relax gastric smooth muscle acting on myenteric neurons. However, to our knowledge, no data are present in the literature on the effects of GLP-2 on the neurally-induced gastric responses elicited by electrical stimulation in *in vitro* preparations. For the above reason, they presently investigated whether GLP-2 influences the neurally-induced contractile and relaxant responses in strips from the mouse gastric fundus. Moreover, since nitric oxide (NO) is considered one of the major NANC inhibitory neurotransmitters responsible for the proximal stomach relaxation, they also evaluated the effects of GLP-2 on both the nitrergic neurotransmission and the neuronal nitric oxide (nNOS) expression.

Research frontiers

Previous studies have indicated that GLP-2 might contribute to suppress feeding behavior in rodents. Thus, the relaxant effects of GLP-2 on gastric preparations, leading to organ distension, might represent peripheral satiety signals.

Innovations and breakthroughs

This is the first study showing that GLP-2 is able to influence the neurally-induced responses in gastric strips from mice through a modulatory action on nitrergic neurotransmission and to increase nNOS expression.

Applications

The evidence that GLP-2 is able to induce gastric relaxation, through the modulation of the nitrergic neurotransmission, contributes to the knowledge of

its peripheral effects. The results highlight an additional site of action that might be implicated in the hormone control of feeding behavior.

Terminology

Gastric motor responses are the result of a balance between nervous excitatory, mainly cholinergic, and NANC inhibitory influences exerted on smooth muscle. During EFS, both excitatory and NANC inhibitory nervous fibers are simultaneously activated. The release of neurotransmitters from enteric neurons may be modulated by a variety of substances, including hormones.

Peer-review

This is a very interesting study investigating the influence of GLP2 on neurally-induced responses in gastric fundal strips.

Abstract

AIM

To compare the effect of University of Wisconsin (UW) solution with or without metformin, an AMP-activated

protein kinase (AMPK) activator, for preserving standard and marginal liver grafts of young and aged rats *ex vivo* by hypothermic machine perfusion (HMP).

METHODS

Eighteen young (4 mo old) and 18 aged (17 mo old) healthy male SD rats were selected and randomly divided into three groups: control group, UW solution perfusion group (UWP), and UW solution with metformin perfusion group (MUWP). Aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH), interleukin-18 (IL-18), and tumor necrosis factor-alpha (TNF-α) in the perfused liquid were tested. The expression levels of AMPK and endothelial nitric oxide synthase (eNOS) in liver sinusoidal endothelial cells were also examined. Additionally, microscopic evaluation of the harvested perfused liver tissue samples was done.

RESULTS

AST, ALT, LDH, IL-18 and TNF-α levels in the young and aged liver-perfused liquid were, respectively, significantly lower in the MUWP group than in the UWP group ($P < 0.05$), but no significant differences were found between the young and aged MUWP groups. Metformin increased the expression of AMPK and eNOS protein levels, and promoted the extracellular release of nitric oxide through activation of the AMPK-eNOS mediated pathway. Histological examination revealed that in the MUWP group, the extent of liver cells and tissue damage was significantly reduced compared with the UWP group.

CONCLUSION

The addition of metformin to the UW preservative solution for *ex vivo* HMP can reduce rat liver injury during cold ischemia, with significant protective effects on livers, especially of aged rats.

Core tip: Metformin can activate the AMP-activated protein kinase pathway that could enhance the activity of endothelial nitric oxide synthase and finally increase the generation of nitric oxide, which plays an important role in the protection of liver sinusoidal endothelial cells. Hence, our study was designed to evaluate the protective effect of University of Wisconsin storage solution with metformin for preserving standard and marginal liver grafts of young and aged rats *ex vivo* by hypothermic machine perfusion (HMP). According to the results, HMP with metformin plays a significant protective role for liver grafts during cold ischemia, with significant effects especially for aged-marginal donors.

INTRODUCTION

Currently, liver transplantation is the only effective therapy for end-stage liver disease[1]. Both preservation of donor organs and post-transplant ischemic reperfusion injury (IRI) are important factors affecting the prognosis of transplantation[2]. At present, due to the shortage of liver donation, marginal donation, which includes aged donation, adipo-hepatic donation, and donation after cardiac death (DCD), increases the risk for more severe IRI because of suboptimal function and long-term warm and cold ischemia[3-5]. Cold ischemia injury plays an important role in the IRI mechanism after revascularization of transplants. In this period, the liver sinusoidal endothelial cells are the first to be injured in a donor liver, causing damage of the stable hepatic microenvironment, hepatic microcirculation disturbance, and exacerbation of IRI[6]. Therefore, there is a current pressing need to explore and improve methods of organ preservation and minimize IRI of donor livers during transplantation[7,8].

In recent years, machine perfusion (MP) has been explored as an alternate method of organ preservation to static cold storage. Clinically, hypothermic machine perfusion (HMP, 4-6 ℃) has been effective for kidney transplantation, but MP methods have not been widely used in liver transplantation. According to the latest research, MP has been meaningful for the preservation and repair of marginal liver donation[9], but this still needs further clinical verification[10,11].

Another important direction of research on donor liver cold preservation is the auxiliary protective intervention of donor livers against IRI factors of microcirculation[12] and hepatocyte metabolism[13] through drugs. Activation of adenosine 5′-monophosphate-activated protein kinase (AMPK) signaling pathways increases the activity of endothelial nitric oxide synthase (eNOS) to generate nitric oxide. This provides a cytoprotective effect to the hepatic sinusoidal endothelium of the donor liver and has been considered for preconditioning of the donor liver to reduce IRI. In addition, AMPK signaling is also known to regulate glucose metabolism and prevent cell death, thus extending the cytoprotective effect on hepatocytes[14]. Therefore, it plays an important role in protecting hepatic sinusoidal endothelium and reducing injury of donor livers[15]. As an agonist of AMPK, metformin additionally lowers the blood glucose by reducing hepatic gluconeogenesis and strengthening

glucose uptake of peripheral tissue[16].

Hence, we hypothesized that liver sinusoidal endothelial cells can be protected from injury by activating AMPK signaling pathways with the addition of metformin perfused *in vitro*, which could ultimately lead to an improvement of liver donor organ preservation. Consequently, in this study, we added metformin to University of Wisconsin (UW) solution, *ex vivo*, in HMP models of livers of young and aged rats and investigated the effects on biochemical indicators and sinusoidal cell morphology.

MATERIALS AND METHODS

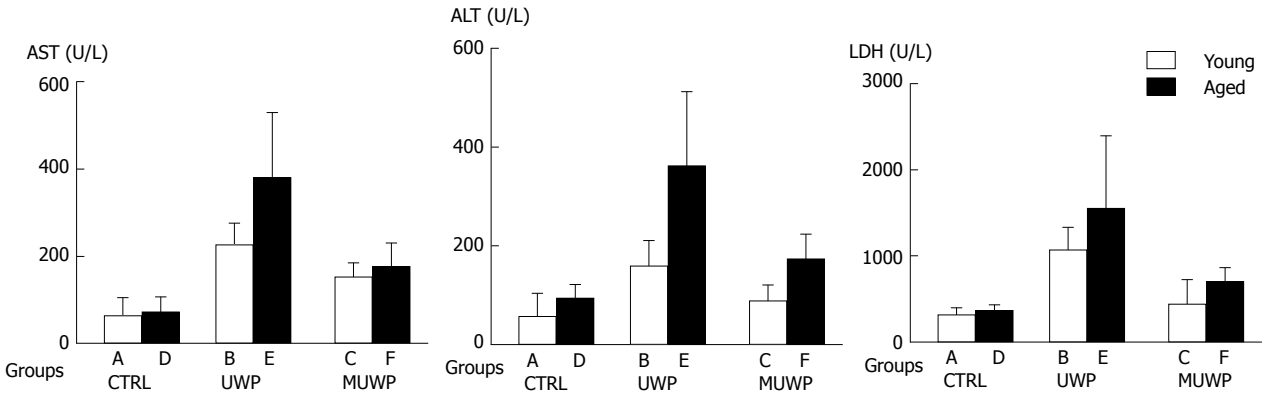
A total of 18 young healthy male SD rats (4 mo old, weighing 250–300 g) and 18 aged (17 mo old, weighing 600–630 g) SD rats were randomly selected for the study. The experimental animals were provided by Animal Experiment Center of Xi'an Jiaotong University.

LongerPump DG-2-B/D Precise Miniature Peristaltic Pump (Longer Precision Pump Co., Ltd., Baoding, China) with a rotation speed of 0-100 rpm and a flow rate of 0-48 mL/min; SPS-1 Static Preservation Solution (UW solution, Organ Recovery Systems, Inc.); and metformin (1,1-dimethylbiguanide hydrochloride, CAS # 1115-70-4, Biomol GmbH) were used. A 165 mg/L stock solution of metformin was prepared by adding 2.5 mL of metformin solution at a concentration of 1 g/10 mL to 1000 mL of sterile water, stirring until dissolved, and then adding this (0.66 mL) to 1000 mL of UW solution. A final metformin concentration of 0.165 mg/L or 1 mmol/L was used. Serum interleukin-18 (IL-18) and tumor necrosis-alpha (TNF-α) levels were measured by enzyme-linked immunosorbent assay (ELISA) using commercial kits (Rat Interleukin 18 ELISA kit, CLOUD-CLONE CORP., TX, United States; Rat TNF-alpha ELISA kit, MultiSciences Biotech Co., Ltd, Shanghai, China).

Study design

Young and aged rats were respectively randomly divided into three groups, with six rats in each group. The groups were: control groups A (young rats) and D (aged rats), UW solution perfusion (UWP) groups B (young rats) and E (aged rats), and experimental groups C (young rats) and F (aged rats) that were perfused with metformin-UW solution (MUWP).

Step one - Establishing the experimental model



Rats were fasted for 8 h and general anesthesia was induced in all rats by intraperitoneal injection of 5% pentobarbital sodium at 20 mg/kg. Fixation, skin preparation, and disinfection were completed, and then a large median and transverse abdominal incision for laparotomy was made. The liver was isolated, heparinized, perfused *in situ* with cold UW solution until the liver turned into a khaki color, and rapidly harvested at room temperature. The *ex vivo* liver was then placed into a basin filled with cold UW solution and made to lie in the basin on an ice pad. All *ex vivo* livers were grouped and underwent HMP with circulating UW solution at 4 ℃ at a flow rate of 4 mL/min maintained at 80 mL of the total circulation volume with the help of a peristaltic pump. Groups A and D did not require extended period of HMP (only 2 h); groups B and E were perfused with UW solution for 12 h; and groups C and F were perfused mechanically with UW solution with 0.165 mg/L of metformin for 12 h. After HMP, 6 mL of the perfused liquid was collected from every group and stored at -20 ℃.

Step two - Examination of the expression levels of p-eNOS, t-eNOS, p-AMPK, and t-AMPK in liver sinusoidal endothelial cells of young rats

Extraction of liver sinusoidal endothelial cells from young rats: After step one, the *ex vivo* livers of every group were perfused with Gey's balanced salt solution (150 mL free of Ca^{2+} and Mg^{2+}, mixed with pronase 400 mg and collagenase 40 mg) for 7 min at 37 ℃ at a flow rate of 20 mL/min. Then, the resulting mixture was centrifuged at 2500 rpm with Krebs-Henseleit solution (with 10% fetal calf serum and 0.002% DNase I) perfused at a flow rate of 10 mL/min. Cell pellet was then resuspended in DMEM supplemented with 20% fetal calf serum and 10 mL of 100 U/L penicillin G and loaded carefully in the centrifuge for 3 min at a flow perfusion rate of 15 mL/min, and accelerated at 18 mL/min for 1 min. The input flow rate was increased again by 20 mL/min, while 50 mL of the cell suspension of the effluent was collected. Once more, a 50 mL cell suspension was collected by 25 mL/min. The 100 mL homogenate was centrifuged at 2000 rpm for 5 min. The supernatant liquid was extracted out, and the liver sinusoidal endothelial cell-debris pellet was collected in the bottom of collection tube.

Extraction of total protein and examination of the expression levels of target proteins: The cell debris was lysed in Cell Lysis Buffer (Cell Signaling Technology; Beverly, MA, United States; carefully chilling 1 × stock buffer on ice and add 1 mmol/L PMSF immediately just prior to use) for 30 min on ice, and then centrifuged at 12000 rpm for 5 min at 4 ℃. The supernatant with total cellular proteins was collected from every group, determined, transferred to a sterile tube (1.5 mL), and stored at -20 ℃. Then, the two-dimensional electrophoresis (2-DE) maps of target proteins were obtained by Western blot to examine the expression levels, and the amounts of expression of AMPK and eNOS were analyzed with gray scale from the maps.

Tests included: (1) Biochemical indicator tests: the levels of aspartate transaminase (AST), alanine transaminase (ALT), lactate dehydrogenase (LDH),

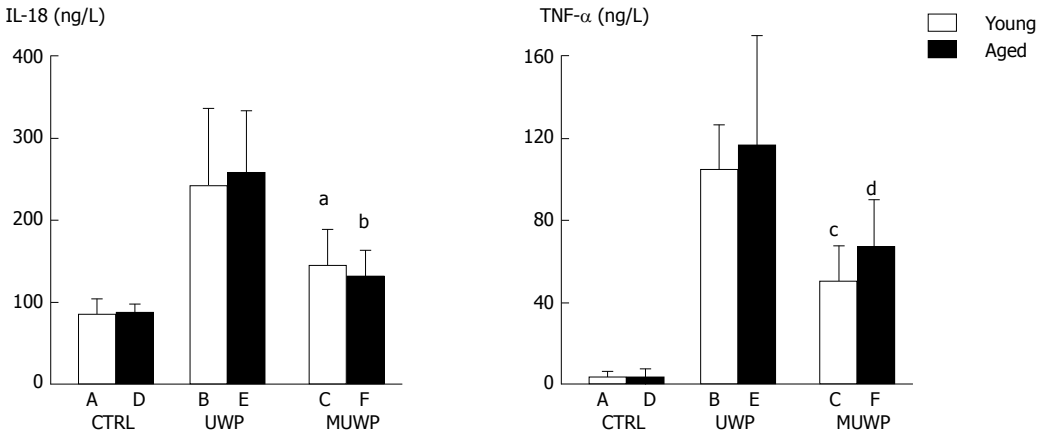
Groups	A / D	B / E	C / F
AST (U/L)	66.40 ± 40.59 / 75.47 ± 31.11	223.50 ± 55.07 / 378.15 ± 150.13	152.53 ± 35.58 / 176.93 ± 55.10
ALT (U/L)	59.97 ± 46.58 / 95.78 ± 30.62	161.20 ± 45.53 / 363.25 ± 150.12	88.25 ± 36.22 / 173.6 ± 51.72
LDH (U/L)	322.13 ± 93.48 / 385.17 ± 45.28	1039.99 ± 308.78 / 1543.05 ± 855.93	450.72 ± 287.96 / 709.3 ± 164.20

Figure 1 Analysis of biochemical indicators in the perfused liquid. Aspartate aminotransferase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH) levels (mean ± SD) in the perfused liquid of the ex vivo livers of the three groups: CTRL (control groups A and D), UWP (UW solution perfusion groups B and E), and MUWP (metformin perfusion groups C and F). Data are presented as mean ± SD (n = 6) and compared by two-way analysis of variance and the Sidak's multiple comparisons test.

IL-8, and TNF-α in the perfused liquid were examined; (2) Histo-morphological by light microscopy: the liver tissues after perfusion were fixed with 10% formalin and immersed in the wax for sections and hematoxylin-eosin (HE) dye. A scoring system was used to grade the degree of histological damage quantitatively (by blinding) at the Department of Pathology, based on the following histological features: hydropic degeneration of hepatocytes and liver sinusoidal endothelial cells, stenosis of the hepatic sinusoid, and number of Kupffer cells. Each feature was graded as absent, mild, moderate, or massive, with a score of 0-3, respectively; and (3) Electron microscopic examination: The specimens of perfused hepatic tissue were fixed to observe by transmission electron microscopy.

Statistical analysis

All calculations were performed with SPSS 22.0 software. The grayscale of 2-DE maps of target proteins was analyzed with ImageProPlus 6.0 software. Quantitative data are expressed as mean ± SD and assessed by one- or two-way analysis of variance, and multiple comparisons between groups were performed using Student-Newman-Keuls method. Scoring data were analyzed by Kruskal-Wallis one-way analysis of variance on ranks and compared between any two groups using Mann-Whitney U test. $P < 0.05$ was considered statistically significant.



RESULTS

Analysis of biochemical indicators

The control group (groups A and D) was subject to HMP for only 2 h, while the UWP (groups B and E) and MUWP groups (groups C and F) underwent HMP for 12 h.

After completing the perfusion of each group, AST, ALT, and LDH levels in the perfused liquid were determined (Figure 1). There were no significant differences in AST, ALT, or LDH between the young rat control group (group A) and the aged rat control group (group D). The AST, ALT, and LDH in the UWP group (groups B and E) were significantly higher than those in groups A and D ($P < 0.05$), Besides, the AST and ALT in the aged group E were significantly higher than those in the young group B ($P < 0.05$). The AST, ALT, and LDH in the MUWP group, which consisted of the young group C and aged group F, were, respectively, significantly lower than those in the young group B and aged group E of UWP ($P < 0.05$), although no significant differences between the young and the aged group were found.

IL-18 and TNF-α levels in the perfused liquid were measured by ELISA (Figure 2). There were no significant differences in the levels of IL-18 or TNF-α between the young rat control group (group A) and the aged rat control group (group D). IL-18 and TNF-α levels in the UWP group were significantly higher than those in the control group ($P < 0.05$). Nevertheless, there were no significant differences between the young group B and the aged group E of UWP. IL-18 and TNF-α levels in the young group C and the aged group F of MUWP were, respectively, appreciably lower than those in the young group B and the aged group E of UWP ($P < 0.05$), but no significant differences between the young group C and the aged group F of MUWP were found.

Groups	A / D	B / E	C / F
IL-18 (ng/L)	87.9 ± 14.97 / 88.5 ± 8.63	243.50 ± 91.50 / 260.37 ± 72.73	145.05 ± 44.42 / 131.38 ± 32.53
TNF-a (ng/L)	3.60 ± 2.80 / 3.76 ± 3.70	91.65 ± 18.63 / 101.43 ± 47.37	43.70 ± 15.28 / 57.80 ± 20.77

Figure 2 Analysis of inflammatory factors in the perfused liquid. The IL-18 and TNF-α levels in the perfused liquid (mean ± SD) of the *ex vivo* livers of the three groups: CTRL (control groups A and D), UWP (UW solution perfusion groups B and E), and MUWP (metformin perfusion groups C and F). Data are presented as mean ± SD (n = 6) and compared by two-way analysis of variance and the Tukey's and Sidak's multiple comparisons tests. [a]P < 0.05 *vs* group B; [b]P < 0.05 *vs* group E; [c]P < 0.05 *vs* group B; [d]P < 0.05 *vs* group E.

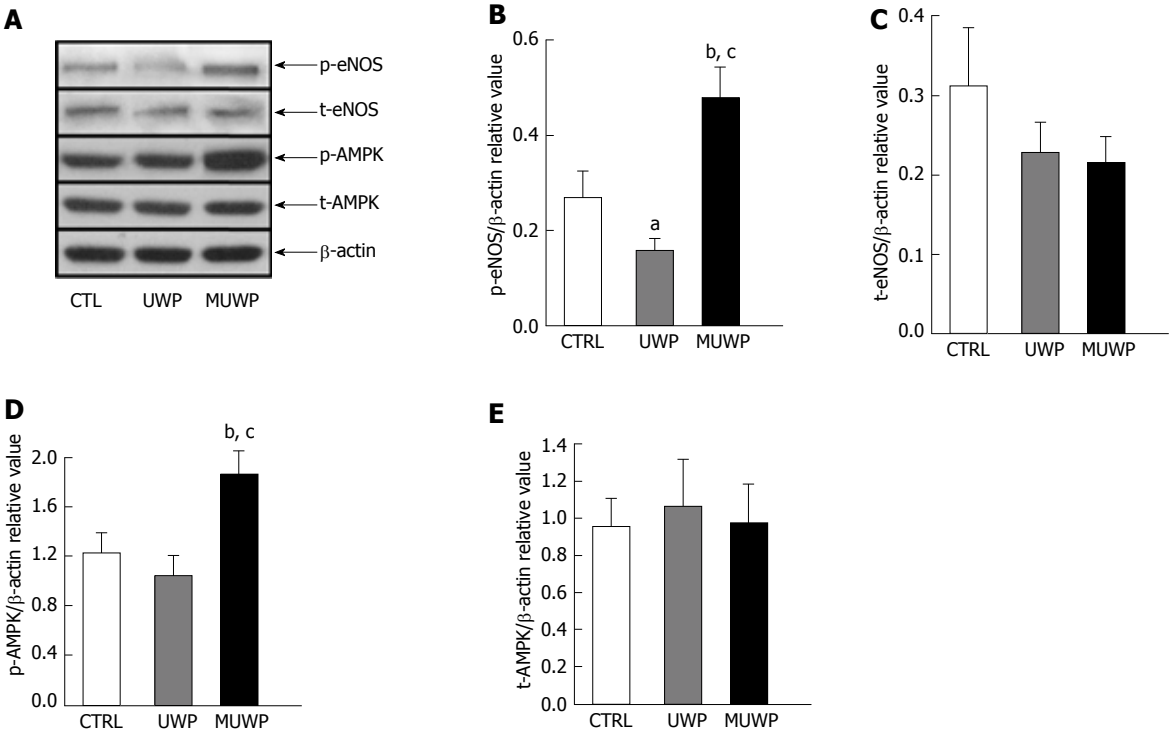


Figure 3 Histograms of relative gray values of the expression levels of p-eNOS, t-eNOS, p-AMPK, and t-AMPK in the liver sinusoidal endothelial cells of young rats. AMPK/eNOS pathway was activated *ex vivo* by metformin. A: Phosphorylation of AMPK and eNOS was increased in the MUWP group at 12 h after HMP; B-E: Quantitative analysis of total AMPK, total NOS, phosphorylated AMPK, and eNOS expression in CTRL (control groups A and D), UWP (UW solution perfusion groups B and E), and MUWP (metformin perfusion groups C and F) groups. Data are presented as mean ± SD (n = 3) and compared by ordinary one-way analysis of variance and the Dunnett's multiple comparisons test. [a]P < 0.05 *vs* CTRL group; [b]P < 0.05 *vs* CTRL group; [c]P < 0.05 *vs* UWP group.

Expression levels of target proteins

Discriminant analysis of relative gray values was used to determine the expression levels of p-eNOS, t-eNOS, p-AMPK, and t-AMPK in liver sinusoidal endothelial cells of young rats (Figure 3). The expression level of p-eNOS in the MUWP group was significantly higher (80.1%) than that in the control group (P = 0.036) and 205.88% higher than that in the UWP group (P = 0.008), which was significantly (41.1%) lower than that in the control group (P = 0.045) (Figure 3B). The expression level of t-eNOS in the control group exhibited no significant difference compared with the

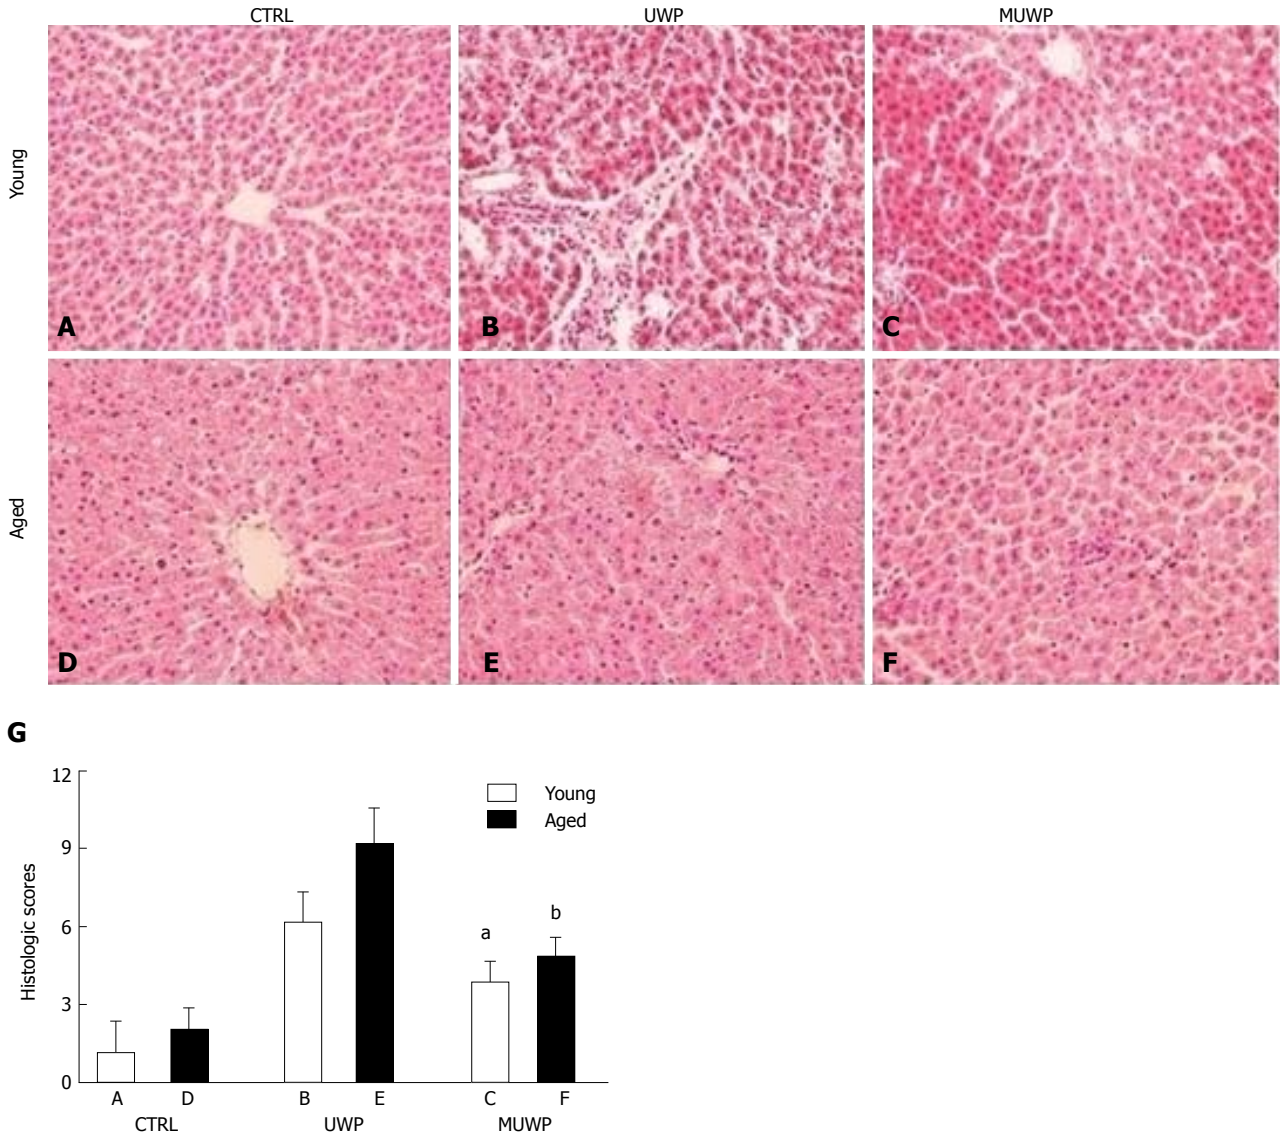

Figure 4 Staining of the slices of *ex vivo* rat liver tissue. A and D: The young control group A and the aged control group D, respectively; B and E: The young group B and aged group E of UWP, respectively; C and F: The young group C and the aged group F of MUWP, respectively; G: Histopathologic scoring of structural injury in each group. Data are presented as mean ± SD (n = 6) and compared by Kruskal-Wallis one-way analysis of variance on ranks and Mann-Whitney U test. [a]P < 0.05 *vs* group B of UWP; [b]P < 0.05 *vs* group E of UWP. Original magnification (A-F): × 400. UWP: University of Wisconsin solution perfusion; MUWP: Metformin perfusion solution.

UWP and MUWP groups (P = 0.251) (Figure 3C). The expression level of p-AMPK in the MUWP group was significantly higher (51.7%) than that in the control group (P = 0.038) and 78.5% higher than that in the UWP group (P = 0.018), even though there were no significant differences between the control and UWP groups (P = 0.217) (Figure 3D). The expression level of t-AMPK in the control group demonstrated no significant differences compared with the UWP and the MUWP groups (P = 0.868) (Figure 3E).

Histo-morphological examination

The HE-stained sections were observed under a microscope. The hepatocytes in the young rat control group (group A) and the aged rat control group (group D) were shaped normally, with no stenosis observed in the hepatic sinusoid and no swelling in the sinusoidal endothelial cells. The size of hepatocytes in group D was slightly larger than that in group A (Figure 4A-D). Cellular swelling was obvious, accompanied by narrowing of the hepatic sinusoid, in the UWP group (groups B and E), particularly, more severe in the aged group E. The swelling of the sinusoidal endothelial cells, as well as Kupffer cells was observed in both groups B and E (Figure 4B-E). Hepatocytes in the MUWP group showed mild edema, which was slightly more severe in group F than in group C, although there were no obvious differences in the hepatic sinusoid between them. Swelling of sinusoidal endothelial cells was inconspicuous in both groups; however, a small number of Kupffer cells were observed (Figure 4C-F). There were no significant differences in the histologic

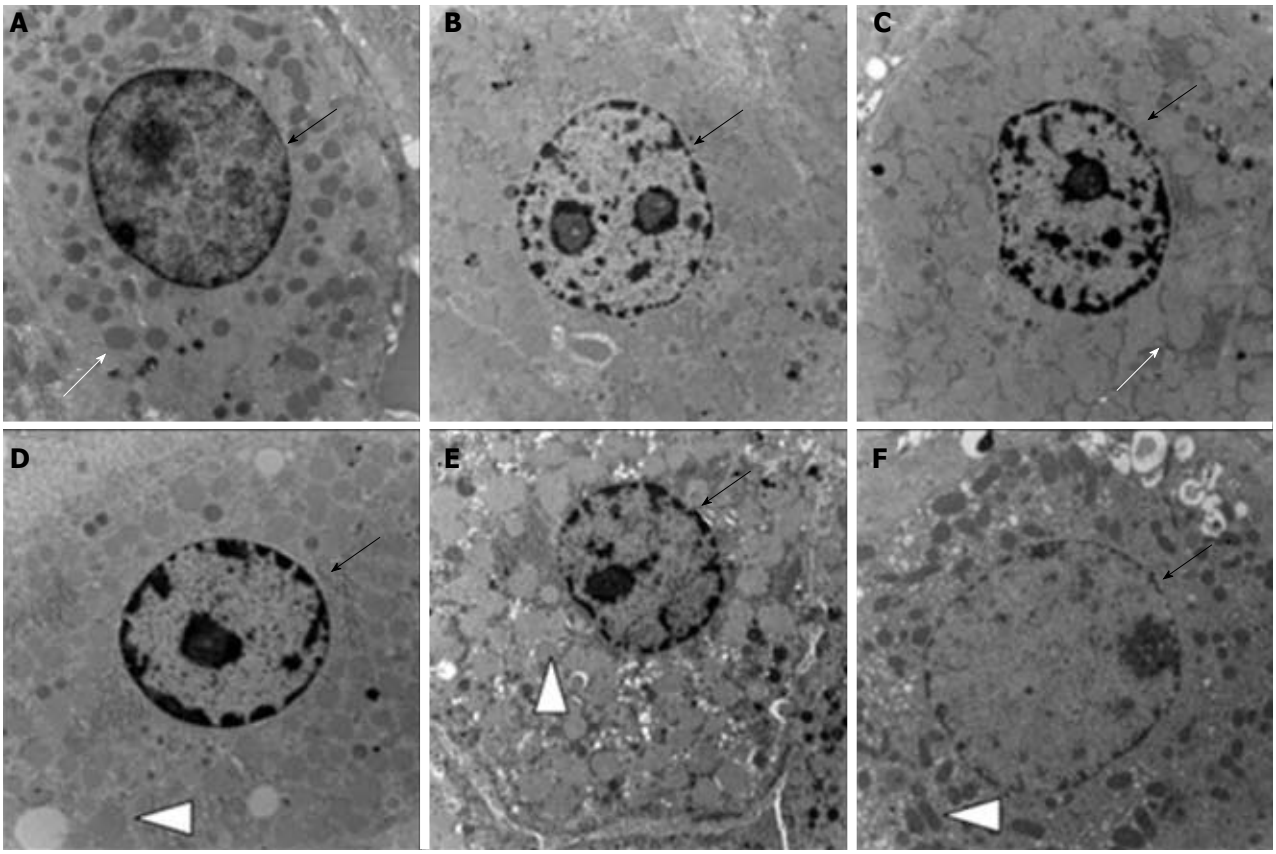

Figure 5 Ultrastructural changes of hepatocytes. A and D: Hepatocytes of the young control group A and the aged control group D, respectively; B and E: Hepatocytes of the young group B and aged group E of UWP without metformin, respectively; C and F: Hepatocytes of the young group C and aged group F of MUWP, respectively. The black arrows indicate the nuclei, the white arrows indicate the intracellular mitochondria of the young groups, and the white triangles indicate the intracellular mitochondria of the aged groups. UWP: University of Wisconsin solution perfusion; MUWP: Metformin perfusion solution. Original magnification (A-F): ×10000.

scores between the young rat control group (group A) and the aged rat control group (group D) ($P < 0.05$). The histologic scores of the young rat group and the aged rat group of UWP and MUWP were, respectively, appreciably higher than those of the young rat control group (group A) and the aged rat control group (group D), and that histologic scores of the young group C and the aged group F of MUWP were, respectively, appreciably lower than those of the young group B and the aged group E of UWP ($P < 0.05$). Besides, the histologic scores of aged group E were significantly higher than those of young group B of UWP ($P < 0.05$), but no significant differences were found between the young group C and the aged group F of MUWP (Figure 4G).

Histological observation by electron microscopy

The ultrastructural changes of hepatocytes were observed under an electron microscope. Structure of hepatocytes in the young control group (group A) and aged control group (group D) was generally normal with a round and clear nucleus located in the center of the cells, while lipid droplets in the cytoplasm increased in the aged control group (group D), and fat-storing cells were seen in the Disse's space with irregular shapes, and the cytoplasm in it contained a large amount of lipid droplets. In contrast, lipid droplets and fat-storing cells were not found in the young control group (group A), but the cells contained rich cytoplasmic organelles (Figure 5A-D). Hepatocyte swelling, nuclear chromatin condensation, extensive mitochondrial swelling, and crista fragmentation were observed in groups B and E of UWP, more severe in the aged group E. Likewise, fat-storing cells in the Disse's space increased in the aged group E, but not found in the young group E (Figure 5B-E). In contrast, hepatocytes of the MUWP group showed mild edema with round nucleus, slightly more evident in the young group C than in the aged group F, and also the mitochondrial swelling degree was slightly higher in the young group C. In addition, the increase in lipid droplets in the cytoplasm and the number of fat-storing cells, dilation of the smooth endoplasmic reticulum, and intercellular collagenous fibrosis were only seen in the aged group F (Figure 5C-F).

The ultrastructural changes of the hepatic sinusoid were also observed under an electron microscope. Structure of the hepatic sinusoidal endothelial cells in the young control group A and the aged control group D remained generally intact with protrusion into the sinusoid, being clear in the young group A. Kupffer cells

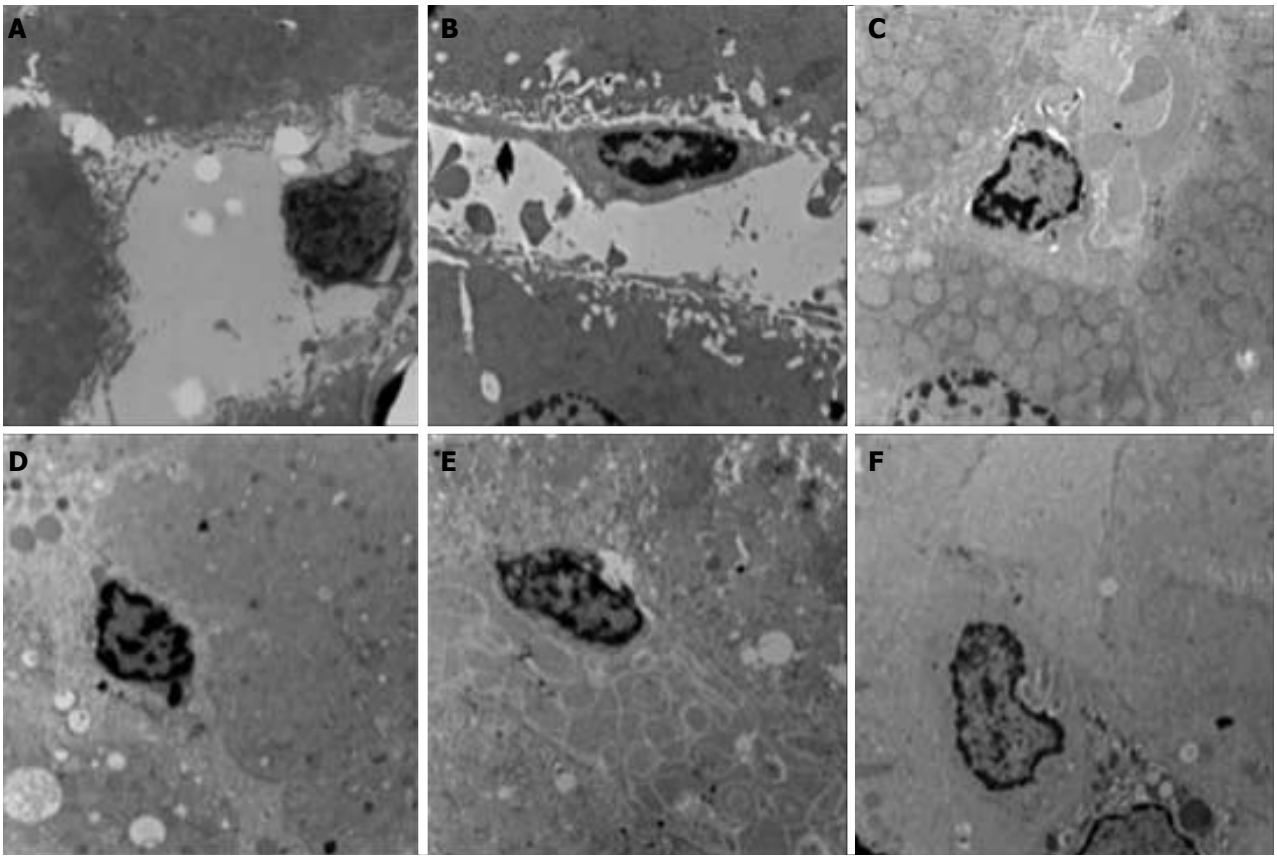

Figure 6 Ultrastructural changes of liver sinusoidal endothelial cells. A and D: Sinusoidal endothelial cells of the young control group A and the aged control group D, respectively; B and E: Sinusoidal endothelial cells of the young group B and aged group E of UWP, respectively; C and F: Sinusoidal endothelial cells of the young group C and aged group F of MUWP, respectively. UWP: University of Wisconsin solution perfusion; MUWP: Metformin perfusion solution. Original magnification (A–F): ×10000.

were seen in the aged group D, though (Figure 6A-D). Sinusoidal endothelial cells were kept meristematic and flat-shaped, with chromatin showing mild margination, and cell debris-like structure together with Kupffer cells in the sinusoids was increased in groups B and E of UWP, particularly, more severely in aged group E. Likewise, fat-storing cells increased in the aged group E, while they were not found in the young group E (Figure 6B-E). The structure of the hepatic sinusoidal endothelial cells in the MUWP group remained generally normal, while a slightly larger cell volume was seen in the aged group F, and cubic-shaped sinusoidal endothelial cells with protrusion into the sinusoid were seen in the young group C. In addition, the low-electron-density protein substance could be seen in the sinusoid in the aged group F.

DISCUSSION

An increasing number of patients with liver disease await liver transplantation; the acute shortage of donor livers is only likely to continue. It was believed that aged livers from donors above 60 years old were characterized by small sizes, atherosclerosis, steatosis, and decreased function of metabolism, and were not suitable for donation[17]. However, to cope with the demand for donor livers, marginal liver donation has been applied clinically after following strict screening protocols with good transplantation outcomes and breaking the myth for the age limit of liver donors[18,19]. Unlike hearts, lungs, and kidneys, livers are much less influenced by age with respect of pathophysiological changes. However, aged livers also show morphologic changes, such as hepatic fibrosis, hepatocyte swelling, trend for multinucleation, increase of lipofuscin, and reduction in the size of the hepatocyte. Compared with young donors, aged donors show reduced and shrunken fenestra of liver sinusoidal endothelial cells, thickened hepatic sinusoidal endothelium, and pseudo capillarization formed by discontinuous basement membranes, leading to potential microcirculatory disturbance and a risk of aggravating IRI[20]. Thus, easier apoptosis and detachment of liver sinusoidal endothelial cells of aged livers further aggravate microcirculatory disturbance, seriously influence post-transplant effects, and even cause failure of some liver transplantation[21]. According to the results of this study, aged groups appeared to be more sensitive to the possible protective effect of metformin. Furthermore, the histological observations by light and

electron microscopy also support this conclusion.

In order to prevent cold ischemia injury, auxiliary protective intervention by drugs with different mechanisms of action, including the MAPK agonist, is being explored[22]. Scientists from different academic institutions have published research articles in which they revealed the molecular mechanism by which metformin could activate AMPK and inhibit the mTORC1 signaling pathway in livers *via* the AXIN/LKB1-v-ATPase-Ragulator pathway[23,24], protect the integrity of epithelial cells in multiple stressed conditions (such as inflammation, infection, and anoxia), and even demonstrate an anticancer effect[25-27]. Before revealing this molecular mechanism, it was known that AMPK activation plays a critical role in reducing liver IRI. However, how AMPK and eNOS phosphorylation direct their effects on the endothelial function is still elusive[28], even if there is plenty of evidence to show that AMPK activation can enhance the activity of eNOS, resulting in generation of nitric oxide[15,29,30]. Extension of cold preservation by maintaining a supercooled state can make donor liver cells remain viable up to 96 h, and human livers showed improvement in endothelial function with 2 h of HMP[31]. In the current study, the AMPK activator metformin was added to e*x vivo* HMP models of rat livers in UW solution after HMP for 12 h. Our results showed that all the biochemical indexes and inflammatory factors in the UWP group were significantly higher than those in the control group, but all the indexes in both the young and aged groups of MUWP, respectively, were appreciably lower than those in the young and aged groups of UWP. Histological observation by light and electron microscopy showed that injury of the related microstructure was milder in the MUWP group than in the UWP group. To a certain extent, it can be deduced that metformin activated protective mechanisms. Detection of expression levels of eNOS and AMPK in the liver sinusoidal endothelial cells of young rats showed that phosphorylation of AMPK and eNOS was increased in the MUWP group at 12 h after HMP, and this can be inferred as the AMPK/eNOS pathway was activated *ex vivo* by metformin.

This study confirmed that the addition of metformin to organ preservation solution can activate the AMPK/eNOS pathway, and this can not only significantly decrease the inevitable injury to donor livers caused by long-term HMP, but can reduce the difference between aged and young livers after HMP, protecting livers of aged rats, which should probably improve the utilization of marginal liver donor tissues. However, whether metformin can sequentially improve hepatic injury during reperfusion-ischemia requires further investigation. But at least, we provided a novel idea, which is also a simple procedure for drug auxiliary intervention with HMP in *ex vivo* rat donor liver and deserves further research with a promising prospect.

In conclusion, this study confirmed that metformin can activate the AMPK/eNOS pathway and reduce injury to *ex vivo* rat liver during cold ischemia in MP. The combination of metformin with the organ preservation solution effectively enhanced the quality of donor livers, with significant protective effects on livers especially of aged rats, which could be used to improve the utilization of marginal livers.

ARTICLE HIGHLIGHTS

Background

Liver transplantation is the only effective therapy for end-stage liver disease. At present, due to the shortage of liver donation, marginal donation, which includes aged donation, adipo-hepatic donation, and donation after cardiac death, increases the risk for more severe ischemic reperfusion injury (IRI) because of suboptimal function and long-term warm and cold ischemia. Therefore, there is a current pressing need to explore and improve methods of organ preservation and minimize IRI of donor livers during transplantation.

Research frontiers

According to the latest research, machine perfusion has been meaningful for the preservation and repair of marginal liver donation. Another important direction of research on donor liver cold preservation is the auxiliary protective intervention of donor livers against IRI factors of microcirculation and hepatocyte metabolism through drugs. Activation of adenosine 5'-monophosphate-activated protein kinase (AMPK) signaling pathways increases eNOS activity to generate nitric oxide (NO), which plays an important role in the protection of liver sinusoidal endothelial cells. Metformin is an agonist of AMPK. Hence, we assumed that liver sinusoidal endothelial cells can be protected from injury by activating AMPK signaling pathways with the addition of metformin perfused *in vitro*, which could ultimately cause an improvement of liver donor organ preservation.

Research objectives

In this study, we added metformin to University of Wisconsin (UW) solution, to compare the effect of UW solution with or without metformin, an AMPK activator, for preserving standard and marginal criteria liver grafts of young and aged rats *ex vivo* by hypothermic machine perfusion (HMP).

Research methods

Eighteen young (4-mo-old) and 18 aged (17-mo-old) healthy male SD rats were selected and randomly divided into three groups: control group, UW solution perfusion group (UWP), and UW solution with metformin perfusion group (MUWP). Aspartate aminotransferase (AST), alanine aminotransferase (ALT), *lactate dehydrogenase* (LDH), interleukin-18 (IL-18), and tumor necrosis factor-alpha (TNF-α) in the perfused liquid were tested. The expression levels of AMPK and eNOS in liver sinusoidal endothelial cells were also examined. Additionally, microscopic evaluation of the harvested perfused liver tissue samples was done.

Research results

AST, ALT, LDH, IL-18 and TNF-α levels in the young and aged liver-perfused liquid in the MUWP group were, respectively, significantly lower than those in the UWP group ($P < 0.05$), but no significant differences between the young and aged MUWP groups were found. Metformin increased the expression of AMPK and eNOS protein levels, and promoted the extracellular release of nitric oxide through activation of the AMPK-eNOS mediated pathway. Histological examination revealed that in the MUWP group, the extent of liver cells and tissue damage was significantly reduced compared with the UWP group.

Research conclusions

This experiment confirmed that the addition of metformin to organ preservation solution can activate AMPK/eNOS pathway, which can not only reduce injury to *ex vivo* rat livers during cold ischemia, but can reduce the difference between aged and young livers after HMP, with especially significant effects of protecting livers of aged rats, which should probably improve the utilization of marginal liver donor tissues. However, whether metformin can sequentially improve hepatic injury during reperfusion-

ischemia requires further investigation. But at least, we provided a novel idea, which is also a simple procedure for drug auxiliary intervention with HMP in *ex vivo* rat donor livers and deserves further research with a promising prospect.

Abstract

AIM

To investigate the relationship between autophagy

and perineural invasion (PNI), clinical features, and prognosis in patients with pancreatic cancer.

METHODS

Clinical and pathological data were retrospectively collected from 109 patients with pancreatic ductal adenocarcinoma who underwent radical resection at the First Affiliated Hospital of Zhengzhou University from January 2011 to August 2016. Expression levels of the autophagy-related protein microtubule-associated protein 1A/1B-light chain 3 (LC3) and PNI marker ubiquitin carboxy-terminal hydrolase (UCH) in pancreatic cancer tissues were detected by immunohistochemistry. The correlations among LC3 expression, PNI, and clinical pathological features in pancreatic cancer were analyzed. The patients were followed for further survival analysis.

RESULTS

In 109 cases of pancreatic cancer, 68.8% (75/109) had evidence of PNI and 61.5% (67/109) had high LC3 expression. PNI was associated with lymph node metastasis, pancreatitis, and CA19-9 levels ($P < 0.05$). LC3 expression was related to lymph node metastasis ($P < 0.05$) and was positively correlated with neural invasion ($P < 0.05$, $r = 0.227$). Multivariate logistic regression analysis indicated that LC3 expression, lymph node metastasis, pancreatitis, and CA19-9 level were factors that influenced neural invasion, whereas only neural invasion itself was an independent factor for high LC3 expression. Univariate analysis showed that LC3 expression, neural invasion, and CA19-9 level were related to the overall survival of pancreatic cancer patients ($P < 0.05$). Multivariate COX regression analysis indicated that PNI and LC3 expression were independent risk factors for poor prognosis in pancreatic cancer ($P < 0.05$).

CONCLUSION

PNI in patients with pancreatic cancer is positively related to autophagy. Neural invasion and LC3 expression are independent risk factors for pancreatic cancer with a poor prognosis.

Key words: Pancreatic cancer; Perineural invasion; Autophagy; Clinical pathological features; Prognosis

Core tip: The relationship between autophagy and perineural invasion (PNI) was explored for the first time in pancreatic cancer. Pancreatic cancer PNI is related to microtubule-associated protein 1A/1B-light chain 3 (LC3) expression-determined autophagy. PNI and LC3 expression were independent prognostic factors in pancreatic cancer. There might be a special association between autophagy and PNI, which contributes to pancreatic cancer progression. This study might provide a new insight for the mechanism of PNI in pancreatic cancer.

INTRODUCTION

Pancreatic cancer, also known as "the king of cancer", is a malignant tumor with a poor prognosis that has almost equal mortality and morbidity in patients. The incidence of pancreatic cancer is increasing yearly[1]. Surgical resection is the only possible cure of pancreatic cancer, although less than 20% of patients are eligible for radical surgery[2]. At the time of diagnosis, most pancreatic cancer patients have distant metastasis due to early occult symptoms, a lack of effective screening, and perineural growth characteristics. The incidence of perineural invasion (PNI) in pancreatic cancer is up to 80%-100% and is an important factor leading to postoperative pancreatic cancer recurrence. Previous studies have shown a higher recurrence rate after surgery and shorter disease-free and overall survival rates in cases of pancreatic cancer with PNI compared with those of cases without PNI. PNI evaluation of pancreatic cancer can predict disease recurrence and prognosis after surgery[3,4]. However, the pathogenesis of PNI has not yet been defined.

Autophagy has a dual role in promoting and inhibiting tumor growth[5,6]. Autophagy, as a mechanism of avoidance of anoikis in pancreatic cancer, is closely related to the survival of pancreatic cancer cells. Microtubule-associated protein 1A/1B-light chain 3 (LC3) is a typical marker of autophagy. LC3 labeling has been used to evaluate autophagy, and high levels of LC3 expression have been found in pancreatic cancer cells[7]. In addition, a previous study also showed that pancreatic cancer cells with PNI have higher levels of autophagy[7].

No study has examined the relationship between autophagy and PNI in pancreatic cancer cells. However, it can be inferred that only those pancreatic cancer cells that can survive within nerve tissues can eventually develop into a clinically visible form of pancreatic cancer PNI. Autophagy is likely one of the mechanisms involved in cancer cell survival. Therefore, this study focused on the relationship between pancreatic cancer cell autophagy and PNI, clinicopathological features, and prognosis, with an aim to provide a clinical basis for further study of the autophagy mechanisms affecting

the pathogenesis of pancreatic cancer PNI.

MATERIALS AND METHODS

General data

Retrospective data were collected from 109 cases of pathologically confirmed pancreatic ductal adenocarcinoma patients who underwent radical surgery for pancreatic cancer from January 2011 to August 2016 at the First Affiliated Hospital of Zhengzhou University. The included pancreatic cancer patients were not treated with radiation or chemotherapy prior to surgery, but received postoperative adjuvant gemcitabine- or non-gemcitabine-based chemotherapy, and/or radiotherapy. Tissue specimens were fixed in formalin and paraffin-embedded for histological study. Clinical and pathological data were collected, and all cases were followed. The date of surgical resection was considered as the starting time, and August 2016 was the deadline. The primary endpoint was death due to pancreatic cancer. Eighty cases were followed for more than 12 mo. All patients provided informed consent for the collection of biological samples, and this study was approved by the Institutional Review Board of the First Affiliated Hospital of Zhengzhou University (Scientific Research No. 5, 2015).

Out of the 109 patients studied, 61 were male, and 48 were female. Their ages ranged from 19 to 81 years, and the median age was 59 years. Tumor diameters ranged from 0.7-12 cm with a median value of 4.0 cm. The survival time of 80 patients who were followed for more than 12 mo was 1 to 54 mo, and the median survival time was 20 mo. By the end of the follow-up period, 38 patients had died. The clinical stages were classified according to the AJCC 2011 standard.

Immunohistochemistry

Expression levels of LC3 and the nerve fiber marker ubiquitin carboxy-terminal hydrolase (UCH) were detected by immunohistochemistry using a standardized streptavidin-peroxidase (SP) method and the SP immunohistochemical Kit (ZSGB-Bio, Beijing, China) according to the manufacturer's instructions. The pancreatic cancer tissues were routinely embedded in paraffin and sliced into 4-μm-thick continuous sections. The sections were then warmed in an autoclave to remove residual wax and were hydrated before antigen retrieval. Endogenous peroxidase activity was eliminated by incubating the tissue sections at room temperature with 3% H_2O_2 for 10 min. The tissue sections were washed three times with PBS continuously and incubated with a small amount of goat serum at room temperature in a closed chamber for 15 min. The goat serum was then poured off (not washed), and anti-LC3 (Proteintech Group, diluted 1:120) and anti-UCH antibodies (Proteintech, diluted 1:100) were added and incubated overnight at 4 ℃. The next day, the slides were thoroughly washed with PBS, and a biotinylated secondary antibody in a working liquid was added and incubated at room temperature for 15 min. After the slides were washed carefully with PBS again, horseradish peroxidase was added, and the slides were incubated for 5 min at room temperature. The slides were then rinsed with PBS three times, and a drop of DAB buffer was placed on the tissue slice and rinsed after 1 min to stop the color reaction. Then, the nuclei were stained with hematoxylin, and the samples were dehydrated in gradient alcohol, covered with transparent balata, and observed by microscopy. PBS was used in place of the primary antibody to serve as the negative control, and a known positive slice served as the positive control. The immunohistochemical results were evaluated in a double-blind manner by two pathologists. If the results were inconsistent, a third pathologist reviewed the data to reach a consensus.

LC 3 immunohistochemical score

LC3-positive cells detected by immunohistochemistry required the following characteristics: (1) clear cell structure; (2) accurate localization of the positive particle; and (3) obviously higher pigmentation than that of the background and clear contrast. Positive LC3 expression was mainly localized in pancreatic cancer cell cytoplasm. Five random power fields (400 × magnification) were observed for each case using an optical microscope. One hundred homogeneous cells were counted, and the staining intensity and the proportion of positive cells were observed. A semi-quantitative analysis was conducted using the product method. Dye intensity was scored as follows: no yellow, 0 points; light yellow, 1 point; yellow or deep yellow, 2 points; and brown or tan, 3 points. The expression range was scored as follows: <10%, 0 points; 10% to 25%, 1 point; 26% to 50%, 2 points; 51% to 75%, 3 points; and >75%, 4 points. The value from dye intensity was then multiplied by the value from the expression range to obtain the overall score: 0 points, negative (-); 1 to 3 points, weakly positive (+); 4 to 6 points, moderately positive (+ +); and 7 to 12 points, strongly positive (+ + +). More than 3 points indicated high expression, and 3 points or fewer indicated low expression.

PNI evaluation

UCH was expressed in the cytoplasm of all nerve fibers. The location of nerve fibers can be clearly defined by UCH to determine the invasion of cancer cells to the nerve tissue. According to previous reports, positive PNI status was determined as cancer cells being found in the perineural spaces, perineurium or nerve tract[8].

Survival analysis

The effects of clinicopathological factors such as LC3 expression and PNI on the overall survival in pancreatic cancer were analyzed in 80 patients with

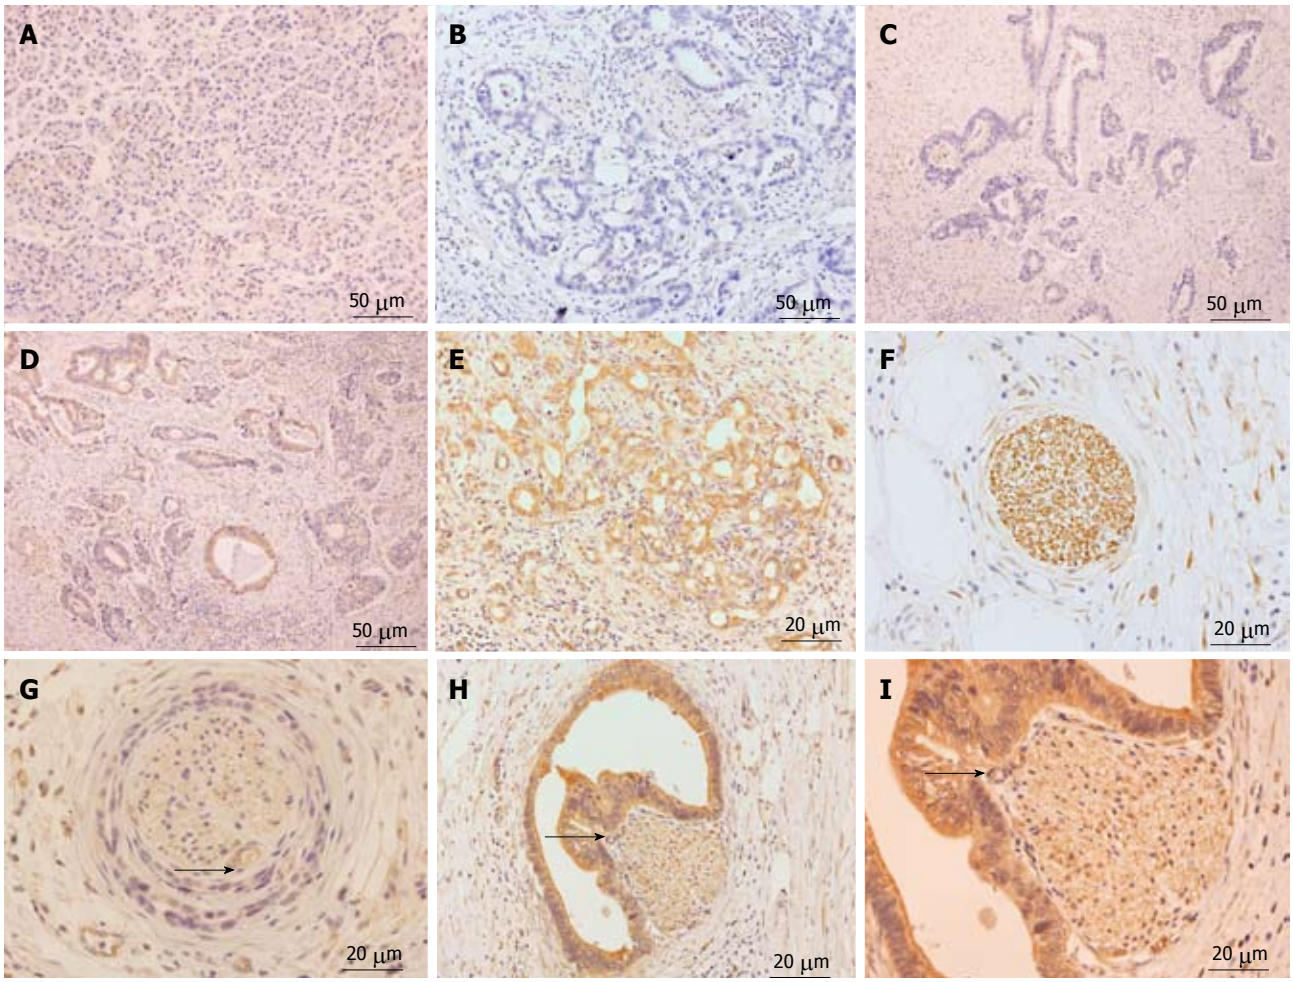

Figure 1 Representative immunohistochemical results of microtubule-associated protein 1A/1B-light chain 3 and perineural invasion. A: Negative expression of LC3 in normal paraneoplastic pancreatic tissue (× 200); B: Negative expression of LC3 in pancreatic cancer tissue (× 200); C: Weakly positive expression of LC3 in pancreatic cancer tissue (× 200); D: Moderately positive expression of LC3 in pancreatic cancer tissue (× 200); E: Strongly positive expression of LC3 in pancreatic cancer tissue (× 200); F and G: Perineural invasion in pancreatic cancer tissues (× 400, arrow represents cancer cells infiltrating into nerve tissue); H: Pancreatic cancer cells with high LC3 expression enclosing and invading into nerve tissue (× 200, arrow represents cancer cells infiltrating into nerve tissue); I: Pancreatic cancer cells with high LC3 expression enclosing and invading into nerve tissue (× 400, arrow represents cancer cells infiltrating into nerve tissue). LC3: Microtubule-associated protein 1A/1B-light chain 3.

more than 12 mo of follow-up data. The following factors were included in the survival analysis: LC3 expression, age, gender, tumor location, tumor size, histological grade, clinical stage, vascular invasion, lymph node metastasis, pancreatitis, diabetes status, and preoperative CA19-9 level.

Data analysis

Statistical analyses were performed using SPSS 19.0 and GraphPad Prism 5.0 statistical software. Enumeration data were checked by the Chi-square test or the four-grid table Fisher exact probability method. Correlations between clinicopathological factors such as LC3 expression and PNI were analyzed using the Spearman correlation method. LC3 expression and the factors that independently influenced neural infiltration were analyzed using two categories and unconditional logistic regression. Univariate and multivariate analyses were performed on factors that might affect the prognosis according to a COX risk regression model. The survival curve was plotted according to the Kaplan-Meier method. Results were considered significant when $P < 0.05$.

RESULTS

Evaluation of LC3 expression and PNI in pancreatic cancer

LC3 expression was mainly localized to the cytoplasm. In contrast to normal paraneoplastic pancreatic tissues (Figure 1A), the expression of LC3 in pancreatic cancer tissues ranged from low to high in four grades: negative, weakly positive, moderately positive, and strongly positive (Figure 1B-E). The immunohistochemical results indicated that LC3 protein expression was observed in pancreatic ducts, acinar epithelial cells, islet cells, and pancreatic cancer tissues. There was significantly increased LC3 protein expression in pancreatic cancer tissues and peritumoral tissues. In 109 pancreatic cancer tissues, 42 had

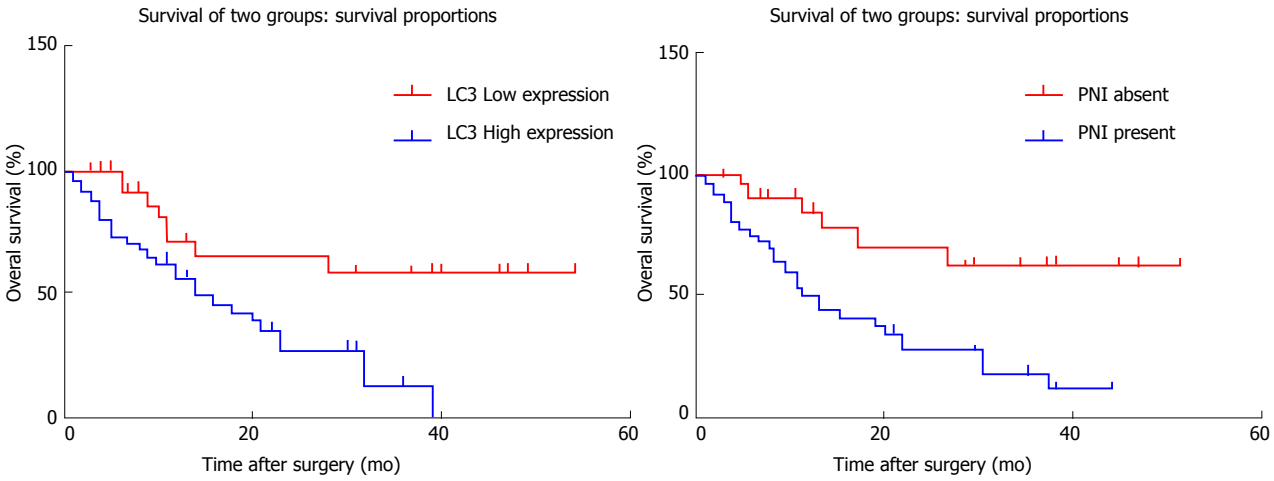

Figure 2 Kaplan-Meier estimates of overall survival in patients who underwent radical surgery. A: The overall survival rate of the LC3 low-expression group was better than that of the high-expression group ($P < 0.05$); B: The overall survival rate of the patients without nerve invasion group was better than that of those with nerve infiltration ($P < 0.05$).

Table 1 Relationship between microtubule-associated protein 1A/1B-light chain 3 expression and perineural invasion in pancreatic cancer

LC3	PNI		*P* value	*r*
	Absent	Present		
Low expression	18	22	0.018	0.227
High expression	16	53		

$P < 0.05$, PNI absent *vs* present. PNI: Perineural invasion

low LC3 expression (termed "low autophagy level"), including 6 (5.5%) negative cases and 36 (33%) weakly positive cases (Figure 1B and C); while 67 had high LC3 expression (termed "high autophagy level"), including 50 (45.9%) that were moderately positive and 17 (15.6%) that were strongly positive (Figure 1D and E). PNI by pancreatic cancer cells occurred mainly in the pancreatic cancer stroma. According to a previous study[9], four types of relationships exist between PNI and cancer nests: no PNI, perineurium invasion, perineural space invasion, and invasion to the nerve fiber tracts. In 109 cases of pancreatic cancer, 75 were positive (Figure 1F-I), and 34 were negative for nerve invasion. The positive rate of nerve invasion was 68.8%. High LC3 expression was also found in the nests surrounding the PNI (Figure 1I).

Relationship between LC3 expression and PNI in pancreatic cancer

The analysis of LC3 expression and PNI of pancreatic cancer demonstrated a significant positive correlation between these two parameters ($P = 0.018$, $r = 0.227$). LC3 expression in pancreatic cancer tissues with PNI was significantly higher than that in pancreatic cancer tissues without PNI (Table 1).

Relationship between pancreatic cancer cell autophagy and PNI and clinicopathological features

LC3 expression was associated with lymph node metastasis ($P < 0.05$). LC3 expression was not related to sex, gender, tumor location, tumor size, histological grade, clinical stage, vascular invasion, or diabetes mellitus status. PNI was related to lymph node metastasis, pancreatitis, and CA19-9 levels ($P < 0.05$) and was not related to sex, age, tumor location, tumor size, histological grade, clinical stage, vascular invasion, or diabetes mellitus status (Table 2).

Multivariate logistic regression analysis of LC3 expression and PNI

The clinicopathological factors possibly associated with LC3 expression and PNI were evaluated by multivariate analysis using a logistic regression model. The clinicopathological factors included LC3 expression and nerve infiltration, age, tumor site, tumor size, histological grade, clinical stage, vascular invasion, lymph node metastasis, diabetes, pancreatitis, and preoperative CA19-9 level. The results showed that LC3 expression, lymph node metastasis, pancreatitis, and CA19-9 level were the factors that influenced the occurrence of PNI, which was an independent factor affecting LC3 expression (Tables 3 and 4).

Survival analysis

According to LC3 expression, patients were divided into a high-expression or a low-expression group. The overall survival rate of the low-expression group was better than that of the high-expression group, and the risk of death was 2.78-times higher in the LC3 high-expression group than that in the low-expression group. This difference between the two groups was significant (Figure 2A). The patients were also

divided into a nerve-invasion group and a no-nerve-invasion group according to whether there was nerve infiltration. The overall survival rate of the patients without nerve invasion was better than that of the nerve-invasion group. The risk of death was 2.93-times greater in the PNI-positive group than in the PNI-negative group, and the difference between the two groups was significant (Figure 2B). Univariate analysis showed that CA19-9 level, PNI, and LC3 expression influenced the prognosis (Table 5). A factor of *P* < 0.2 was added into the COX risk regression model. Multivariate analysis was performed using the stepwise conditional method. The results showed that PNI and LC3 expression were independent prognostic factors that influenced pancreatic cancer (Table 6).

DISCUSSION

Pancreatic cancer has a poor treatment outcome because of a low resection rate, early invasion and metastasis, and insensitivity to radiotherapy and chemotherapy[10-13]. PNI is common in pancreatic cancer, and also found in breast, prostate, and rectal cancers[14]. Many studies have suggested that PNI is the main cause of abdominal pain in patients and is also one of the important causes of local recurrence of pancreatic

cancer[15-19]. PNI is a continuous process involving multiple molecular factors and tumor microenvironment, but it is unclarified how cancer cells maintain their survival and proliferation from pancreatic cancer tissues to the external pancreatic plexus[20]. Autophagy is the process of degrading cytoplasmic proteins or organelles through lysosomes. Under physiological conditions, autophagy plays a major role in maintaining the intracellular environment stability[21,22]. Autophagy is an important mechanism of escaping apoptosis for tumor cells. Moreover, autophagy may mediate resistance to chemotherapy in pancreatic cancer[23-25]. Therefore, this study was designed and completed in a retrospective manner to evaluate the relationship between pancreatic cancer cell autophagy and PNI and patient survival.

This study found that high expression of LC3 was present in the cancer nests around the nerve infiltration, consistent with the discovery of Yang *et al*[7]. In histology terms, it has been suggested that high LC3 expression is related to PNI. Further analysis of immunohistochemical data showed that there was a significant positive correlation between LC3 expression and PNI in pancreatic cancer tissues. Therefore, we speculated that, in the PNI process, a high autophagy level may assist cancer cells in escaping apoptosis, avoiding the damage of adverse stress and providing energy for the invasion and metastasis of pancreatic cancer.

There is dissidence in the correlation between PNI and lymph node metastasis[26-28]. This study showed that PNI was associated with lymph node metastasis, pancreatitis, and CA19-9 levels ($P < 0.05$), while it had no association with sex, age, tumor location, tumor size, histological grade, clinical stage, vascular invasion, or diabetes mellitus. LC3 was related to lymph node metastasis but no other clinicopathological features. Multivariate logistic regression analysis also showed that LC3, lymph node metastasis, pancreatitis, and CA19-9 levels were the factors that influenced PNI, while PNI was an independent factor affecting LC3 expression. Tanaka *et al*[26] and Ozaki *et al*[28] believe that lymph node metastasis can promote PNI. The cancer cells in lymph node metastases can form a lymphatic satellite around the nerve and break through the nerve membrane; then, nerve invasion occurs. This study is consistent with results suggesting the need for regional lymph node dissection during surgical treatment[27]. Through this study, we can conclude that high LC3 expression, lymph node metastasis, pancreatitis, and CA19-9 levels usually indicate the possibility of nerve invasion. Gender, age, tumor site, tumor size, histological grade, clinical stage, vascular invasion, and diabetes are not effective indicators of neural invasion and autophagy and cannot be used as a determinant of resection of the peripancreatic nerve

Table 6 Multivariable analysis of survival in patients who underwent radical surgery

Parameter	Hazard ratio	95%CI	*P* value
PNI (present *vs* absent)	2.962	1.212-7.238	0.017[a]
LC3 (high *vs* low)	2.491	1.107-5.608	0.027[a]

[a]$P < 0.05$. LC3: Microtubule-associated protein 1A/1B-light chain 3; PNI: Perineural invasion.

during surgery.

The overall survival rates of the LC3 high-expression group and the nerve-invasion group were significantly lower than those of the low-expression group and the no-nerve-invasion group. Univariate analysis showed that the level of CA19-9, PNI, and autophagy were associated with prognostic factors. Multivariate analysis showed that PNI and high LC3 expression were independent prognostic factors in pancreatic cancer patients. Autophagy is very complex and often plays an important role in tumor progression[6,29]. Interestingly, this study found that high autophagy level is closely related to PNI, while both of which are independent risk factors for pancreatic cancer with a poor prognosis. The autophagy associated with poor survival in pancreatic cancer could be explained by the properties of autophagy assisting cancer cells to evade stress-induced apoptosis in PNI environment and undoubtedly promote tumor cell survival[30,31]. Therefore, the high autophagy of cancer cells may promote the malignant progression of pancreatic cancer, resulting in PNI and the poor treatment outcome in patients with the disease.

In summary, autophagy and PNI of pancreatic cancer cells are independent risk factors for adverse prognosis. There is a significant correlation between them, and there may be a pathway between them through which they interact with each other to promote the malignant progression of pancreatic cancer. How to control the role of autophagy in PNI of pancreatic cancer and then improve cancer prognosis requires further studies into the molecular mechanisms involved.

ARTICLE HIGHLIGHTS

Research background

Pancreatic cancer is a malignant tumor with a poor prognosis that has almost equal mortality and morbidity in patients. At the time of diagnosis, most pancreatic cancer patients have distant metastasis due to early occult symptoms, a lack of effective screening, and perineural growth characteristics. The incidence of perineural invasion (PNI) in pancreatic cancer is 80%-100% and is an important factor leading to postoperative pancreatic cancer recurrence. PNI evaluation of pancreatic cancer can predict disease recurrence and prognosis after surgery. However, the pathogenesis of PNI has not yet been defined. Autophagy, as a mechanism of avoidance of anoikis in pancreatic cancer, is closely related to the survival of pancreatic cancer cells. Microtubule-associated protein 1A/1B-light chain 3 (LC3) is a typical marker of autophagy. LC3 labeling has been used to evaluate autophagy, and high levels of LC3 expression have been found in pancreatic cancer cells. In addition, a previous study showed that pancreatic cancer cells with PNI have higher levels of autophagy. No study has examined the relationship between autophagy and PNI in pancreatic cancer cells.

Research motivation

The relationship between autophagy and PNI was explored for the first time in pancreatic cancer. Pancreatic cancer PNI is related to LC3 expression-determined autophagy. PNI and LC3 expression were independent prognostic factors in pancreatic cancer. There might be a special association between autophagy and PNI, which contributes to pancreatic cancer progression. This study might provide new insight into the mechanism of PNI in pancreatic cancer.

Research objectives

This study focused on the relationship between pancreatic cancer cell autophagy and PNI, clinicopathological features, and prognosis. The authors found that autophagy and PNI of pancreatic cancer cells are independent risk factors for adverse prognosis. There is a significant correlation between them, and there may be a pathway between them through which they interact with each other to promote the malignant progression of pancreatic cancer. Controlling the role of autophagy in PNI of pancreatic cancer may improve cancer prognosis, which requires further studies into the molecular mechanisms involved.

Research methods

Clinical and pathological data were retrospectively collected from 109 patients with pancreatic ductal adenocarcinoma who underwent radical resection at the First Affiliated Hospital of Zhengzhou University from January 2011 to August 2016. Expression levels of the autophagy-related protein LC3 and perineural invasion marker ubiquitin carboxy-terminal hydrolase in pancreatic cancer tissues were detected by immunohistochemistry. The correlations among LC3 expression, perineural invasion, and clinical pathological features in pancreatic cancer were analyzed. The patients were followed for further survival analysis.

Research results

In this study, they found that LC3, lymph node metastasis, pancreatitis, and CA199 level were factors that influenced neural invasion, whereas only neural invasion itself was an independent factor of high LC3 expression. Perineural invasion and LC3 expression were independent risk factors for poor prognosis in pancreatic cancer. There is a significant correlation between them.

Research conclusions

This study focused on the relationship between pancreatic cancer cell autophagy and PNI, clinicopathological features and prognosis. The authors found that autophagy and PNI of pancreatic cancer cells are independent risk factors for adverse prognosis. There is a significant correlation between them, and there must be a pathway between them through which they interact with each other to promote the malignant progression of pancreatic cancer. Controlling the role of autophagy in PNI of pancreatic cancer may improve cancer prognosis, which requires further studies into the molecular mechanisms involved.

Abstract

AIM

To explore the role of macrophages in chronic pancreatitis (CP) and the effect of Dachaihu decoction (DCHD) on pancreatic fibrosis in mice.

METHODS

KunMing mice were randomly divided into a control group, CP group, and DCHD group. In the CP and DCHD groups, mice were intraperitoneally injected with 20% L-arginine (3 g/kg twice 1 d/wk for 6 wk). Mice in the DCHD group were administered DCHD intragastrically at a dose of 14 g/kg/d 1 wk after CP induction. At 2 wk, 4 wk and 6 wk post-modeling, the morphology of the pancreas was observed using hematoxylin

and eosin, and Masson staining. Interleukin-6 (IL-6) serum levels were assayed using an enzyme-linked immunosorbent assay. Double immunofluorescence staining was performed to observe the co-expression of F4/80 and IL-6 in the pancreas. Inflammatory factors including monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1α (MIP-1α) and IL-6 were determined using real time-polymerase chain reaction. Western blot analysis was used to detect fibronectin levels in the pancreas.

RESULTS

Compared with the control group, mice with 20% L-arginine-induced CP had obvious macrophage infiltration and a higher level of fibrosis. IL-6 serum concentrations were significantly increased. Double immunofluorescence staining showed that IL-6 and F4/80 were co-expressed in the pancreas. With the administration of DCHD, the infiltration of macrophages and degree of fibrosis in the pancreas were significantly attenuated; IL-6, MCP-1 and MIP-1α mRNA, and fibronectin levels were reduced.

CONCLUSION

The dominant role of macrophages in the development of CP was mainly related to IL-6 production. DCHD was effective in ameliorating pancreatic fibrosis by inhibiting macrophage infiltration and inflammatory factor secretion in the pancreas.

Core tip: Macrophages, important inflammatory cells, can also promote fibrogenesis by interfering with the synthesis and degradation of the extracellular matrix, as confirmed in both liver fibrosis and renal fibrosis models. Our study suggested that macrophages also play an important role in the development of pancreatic fibrosis. We found that macrophages are an important source of interleukin-6, which is involved in the progression of chronic pancreatitis (CP). Dachaihu decoction (DCHD), a traditional Chinese medicinal formula, effectively improves the clinical symptoms of CP patients, but the underlying mechanism remains unclear. We found that DCHD ameliorates pancreatic fibrosis by inhibiting macrophage infiltration and inflammatory factor secretion.

Dachaihu decoction ameliorates pancreatic fibrosis by inhibiting macrophage infiltration in chronic pancreatitis. *World J Gastroenterol* 2017; 23(40): 7242-7252 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7242.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7242

INTRODUCTION

Chronic pancreatitis (CP) is a progressive inflammatory disease that is characterized by irreversible injury of the pancreas leading to endocrine and exocrine dysfunction[1]. It has been reported that pancreatic fibrosis is a common pathological feature and characterizes the end-stage of CP of different etiologies[2]. The progressive fibrotic cascade can eventually lead to loss of pancreatic function as well as systemic complications, including malabsorption, diabetes mellitus, and others. However, the underlying molecular mechanisms of CP remain unclear, and the available therapeutic strategies are very few in number[3].

Based on the necrosis-fibrosis sequence playing a key role in the underlying pathogenesis of CP, pancreatic fibrosis commonly arises from inflammation or tissue injury[4]. Recent studies have highlighted the role of macrophages in promoting wound healing and fibrosis[5,6]. Large numbers of macrophages have been observed around areas of pancreatic injury in rat models of CP[7,8]. Detlefsen and colleagues[9] demonstrated that many infiltration macrophages are also found in the pancreas of alcoholic CP patients, which facilitate fibrosis formation by producing transforming growth factor (TGF)-β and platelet derived growth factor (PDGF)-β. Thus, we propose that macrophages may play a critical role in the progression of pancreatic fibrosis, but its definite mechanism remains unclear.

Interleukin-6 (IL-6) is a key pro-inflammatory cytokine that is involved in inflammation and the immune response. It is mainly released by macrophages, fibroblasts, endothelial cells, and myeloid cells[10,11]. In a previous study, Zhang *et al*[12] found that acinar injury results in the infiltration of myeloid cells (*i.e.*, macrophages and neutrophils) into the pancreas during severe acute pancreatitis, and infiltrating macrophages further release IL-6, which can lead to pancreatitis-associated acute lung injury. A study by Lesina *et al*[13] demonstrated that tumor-associated macrophages appear to be the major source of IL-6 in murine and human pancreatic ductal adenocarcinoma. Several reports have confirmed that serum level of IL-6 in patients with CP was significantly increased compared with that in control subjects[12,14]. However, the contribution of IL-6 and the relationship between IL-6 and macrophages in pancreatic fibrosis have not been analyzed in detail.

Dachaihu decoction (DCHD; major Radix bupleuri decoction) is a traditional Chinese medicine formula that was first described by Zhongjing Zhang in "Treatise on Febrile Disease Caused by Cold (Shanghan Lun)". DCHD has been widely used in the clinical treatment of acute pancreatitis (AP)[15]. Recently, it was used to treat patients with CP, and it was found that the effects included improving the clinical symptoms of CP

patients. But whether it can inhibit pancreatic fibrosis and its underlying mechanism remain uncertain. The aim of the present study was to ascertain the role of macrophages in pancreatic fibrosis induced by 20% L-arginine, as well as to determine the effects and mechanism of DCHD on inhibiting pancreatic fibrosis.

MATERIALS AND METHODS

Animals and materials

KunMing mice (20-28 g) were obtained from the Experimental Animal Center of Xi'an Jiaotong University (Certificate No. 0011744) and housed under specific-pathogen-free conditions. The mice received humane care in accordance with the Shaanxi University of Chinese Medicine Animal Care Committee guidelines. Antibodies against fibronectin (FN), F4/80, and IL-6 were provided by Santa Cruz Biotechnology Inc. (Santa Cruz, CA, United States). All secondary antibodies and immunofluorescence and immunohistochemistry reagents were purchased from Boster Biotechnology Inc. (Wuhan, China). L-arginine was obtained from Sigma-Aldrich Co. (St. Louis, MO, United States). Crude DCHD, including Radix bupleuri, Radix scutellariae, Fructus aurantii immaturus, Paeonia lactiflora, Rhizomapinelliae, Rheum palmatum, Rhizoma zingiberis recens and Fructus jujubae (Table 1), was purchased from the Department of Pharmaceutical Preparation of Chinese Medicine of Shaanxi University. The components of DCHD were extracted twice by boiling in distilled water for 1 h, and the drug was subsequently filtered and reduced by boiling to a volume of 70 mL (1 g crude drug/mL) and stored at 4 ℃ for later use. Masson staining and amylase enzyme-linked immunosorbent assay (ELISA) kits were purchased from the Nanjing Jiancheng Biotechnology Company (Nanjing, China). Reverse transcriptase polymerase chain reaction (PCR) kits and primers were provided by Transgen Biotech Co. (Beijing, China).

L-arginine-induced chronic pancreatitis

The KunMing mice were randomly divided into three groups (n = 36): the control group, the CP group, and the DCHD group. Mice in the CP and DCHC groups were injected intraperitoneally with 20% L-arginine (two 3 g/kg injections separated by 1 h, weekly for 6 wk), while the mice in the control group were injected with saline. Mice in the DCHD group were treated with DCHD (14 g/kg per day) intragastrically 1 wk after the 20% L-arginine injections.

Serum and tissue sample collection

Mice were anesthetized and sacrificed at 2 wk, 4 wk and 6 wk after 20% L-arginine or saline injection (n = 9 at each time point). Blood samples were obtained from the inferior vena cava, centrifuged at 1500 rpm for 10 min, and serum was collected and stored at -80 ℃ for IL-6 analysis. The pancreas was removed, weighed, and mixed well. One part of the pancreas was fixed in 4% formaldehyde solution for hematoxylin and eosin (HE) and immunofluorescence staining, while the other part was frozen in liquid nitrogen and stored at -80 ℃ for RNA and protein extraction.

ELISA test

Plasma was collected at 2 wk, 4 wk and 6 wk after modeling and serum was obtained by centrifuging samples at 1500 rpm for 10 min. IL-6 levels were evaluated using an ELISA kit (Jiancheng Bioengineering Institute, Nanjing, China) according to the manufacturer's instructions.

Histology and HE and Masson staining

To observe morphological and fibrosis changes in the pancreas, pancreatic sections were subjected to HE or Masson staining. Samples were dehydrated and embedded in paraffin, sectioned (3 μm) after fixation in 4% formaldehyde solution for 12 h. Images were collected using an optical microscope.

Immunohistochemistry and immunofluorescence staining

Immunohistochemical staining and immunofluorescence staining were performed. For immunohistochemistry, antibodies were applied at the following concentrations: F4/80, 1:150 dilution, overnight at 4 ℃; and biotinylated secondary antibody, 1:400 dilution, for 1 h. Bound peroxidase was visualized after a 3,3-diaminobenzidine reaction for 2-5 min and after light counterstaining with hematoxylin, dehydration, and mounting. The slides were examined using a Zeiss Axio1 imager (Carl-Zeiss-Promenade, Jena, Germany). For immunofluorescence, antibodies were applied at the following concentrations: F4/80 and IL-6 antibodies, 1:150 dilution, overnight at 4 ℃ in the dark; FITC-labeled and PE-labeled secondary antibody, 1:400 dilution, for 1 h. DAPI (1:1000) was used to counterstain the nuclei for 5-15 s, and the slides were mounted on coverslips with anti-fade mounting medium. Images were collected using a fluorescent microscope (Olympus IX51, Shinjuku-ku, Tokyo, Japan).

RNA isolation and real-time PCR

Total RNA of pancreatic tissue was extracted using the Trizol reagent (RNeasy Minicolumns, Transgen, Beijing, China) and reverse- transcribed into cDNA using reverse transcriptase kits. RT-PCR was performed using SYBR Green reaction mix and the ABI-7500 Sequence Detection System (Thermo Fisher Scientific, Shanghai, China). The primers, number of cycles, and annealing temperatures are shown in Table 2.

Protein extraction and western blotting

Protein was extracted from pancreas tissue using standard methods. The protein concentrations were measured using a BCA protein assay kit (Boster

Biotechnology Inc.) and adjusted to 4 μg/μL. Before loading, the samples were boiled at 95 ℃ for 5 min, subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (Bio-Rad, Hercules, CA, United States), and transferred onto PVDF membranes (EMD Millipore, Darmstadt, Germany). The membranes were blocked with 5% non-fat milk followed by incubation with anti-actin (Boster Biotechnology Inc.) and anti-FN antibodies (sc-101759; Santa Cruz Biotechnology Inc.). The sizes of the detected bands were determined by reference to a 10-180 kDa protein marker ladder.

Statistical analysis

Values are presented as the mean ± SD and were analyzed using the unpaired Student's *t*-test and one-way analysis of variance (commonly known as ANOVA). A value of $P < 0.05$ was considered to indicate statistical significance.

RESULTS

Macrophage infiltration is increased in CP

We induced CP in mice using repeated 20% L-arginine injections over 6 wk. Two weeks after modeling, morphological signs of CP were found, including leukocyte infiltration, acinar cell necrosis, and a small amount of connective tissue deposition. At 4 wk and 6 wk, loss of acinar cells, collagen deposition, and aggravated fibrosis in the pancreas were observed (Figure 1A).

Immunohistochemistry using the macrophage marker F4/80 was performed. Two weeks after L-arginine injection, F4/80-positive cells were predominant in mice with CP compared with the normal group (Figure 1B). The positive macrophage ratio was highest at week 4, and levels were sustained until week 6. Thus, macrophages were abundant during CP and

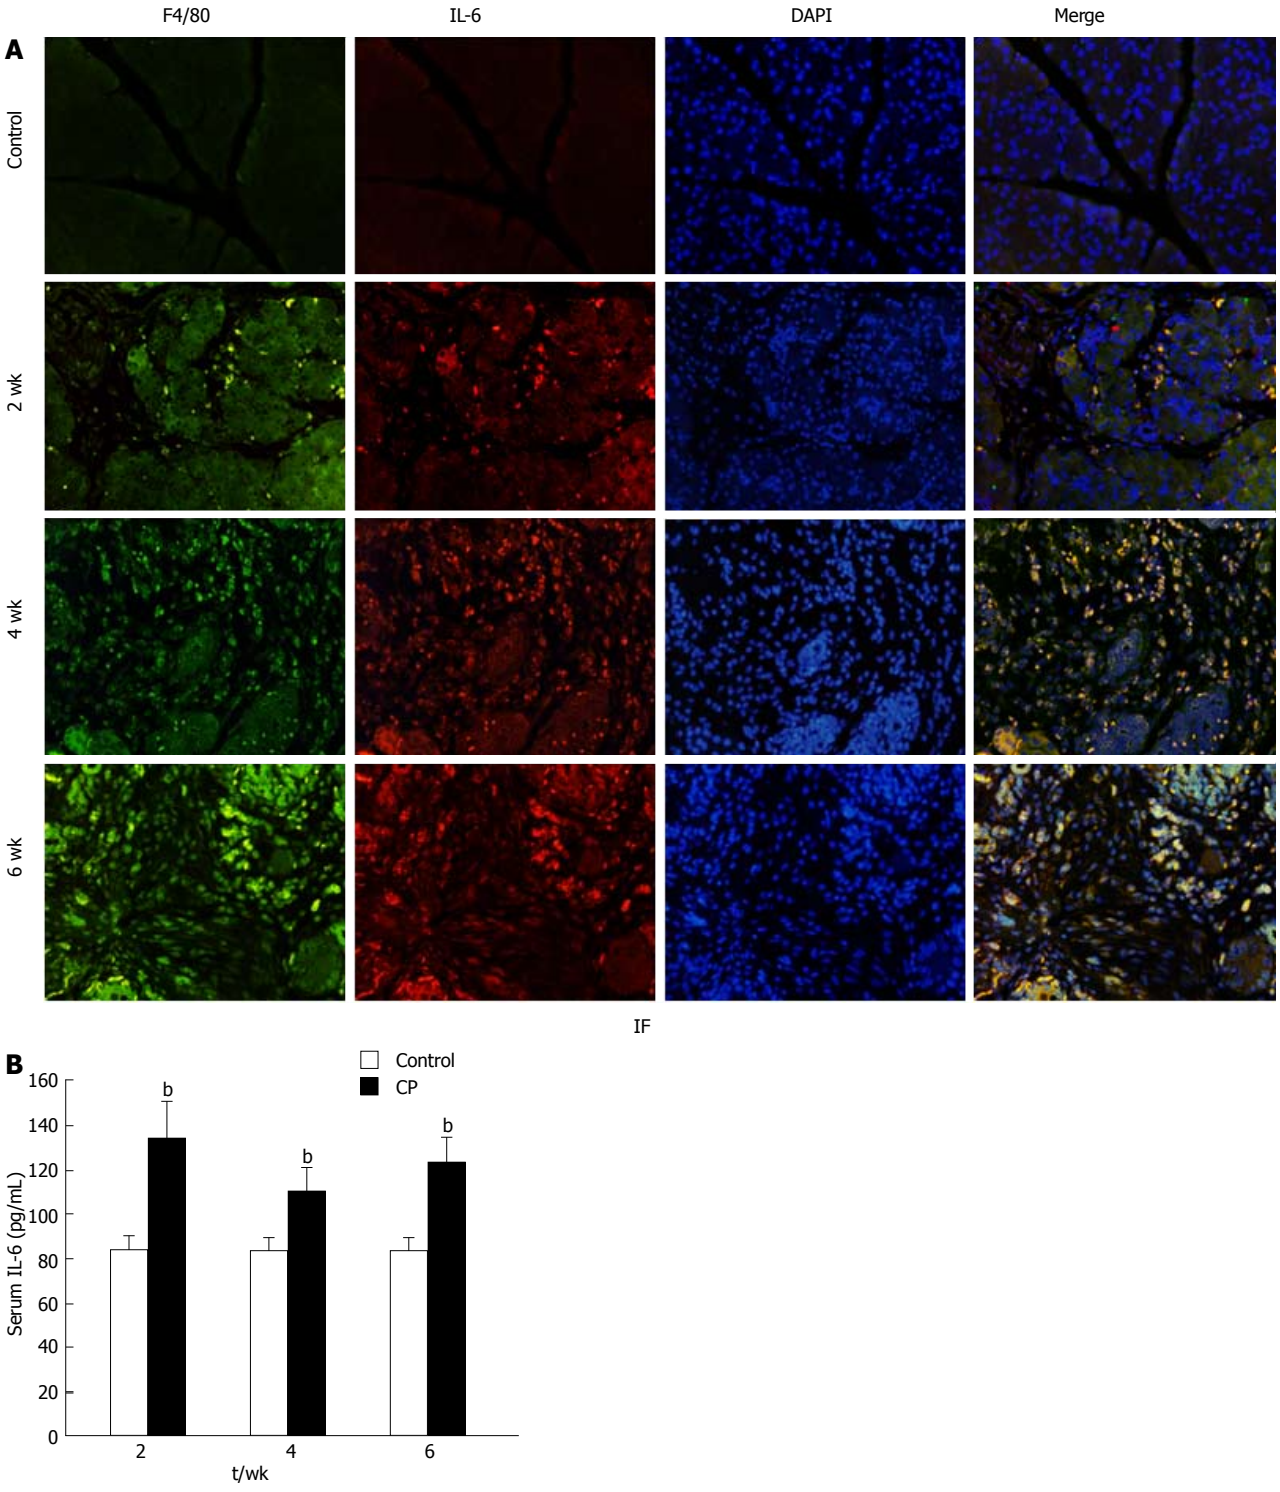

Figure 2 Interleukin-6 production is related to macrophage infiltration. were involved in the development of fibrosis (Figure 1B).

Macrophage infiltration in the pancreas results in IL-6 production

The serum concentration of IL-6 was significantly increased 2 wk after 20% L-arginine injection. At 4 wk, the IL-6 level was somewhat decreased but remained elevated to week 6 (Figure 2A). These findings demonstrate that high IL-6 levels contribute to the development of CP.

While macrophage infiltration and IL-6 levels were increased in CP, their relationship remains unclear. To determine whether IL-6 is mainly secreted by

macrophages, double staining of F4/80 and IL-6 labeled with different fluorescence markers was performed on pancreas paraffin sections. As shown in Figure 2B, no positive F4/80 and IL-6 cells were found in the pancreas of the control group. However, L-arginine administration resulted in a significant increase in the expression of F4/80 and IL-6 in the pancreas. While there was only weak expression in the samples at 2 wk, co-expression of F4/80 and IL-6 increased markedly at 4 wk and 6 wk. These results demonstrate that IL-6 is mainly secreted by macrophages in CP.

DCHD alleviates pancreatic injury and pancreatic fibrosis in mice with CP

We next sought to investigate whether pancreatic injury and subsequent fibrosis were alleviated by DCHD treatment. DCHD administration resulted in

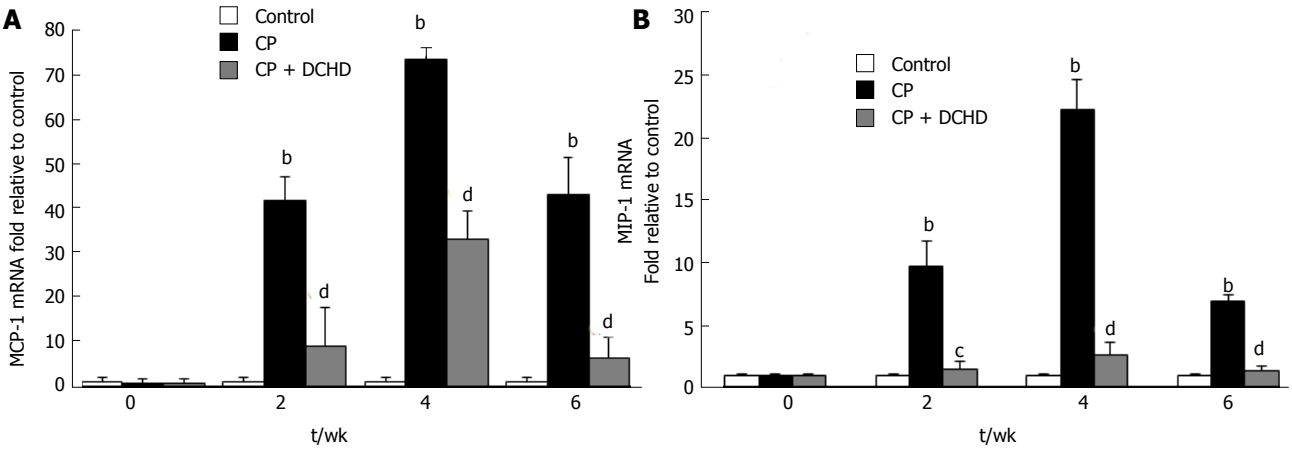

Figure 5 Effects of Dachaihu decoction on MCP-1 and MIP-1α mRNA levels in the pancreas of mice with chronic pancreatitis. A: MCP-1 mRNA levels in the pancreas as determined by real time-polymerase chain reaction; B: MIP-1α levels in the pancreas as determined by real time-polymerase chain reaction. Values are shown as mean ± SD (n = 9). $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* CP group.

significantly improved tissue damage, pancreatic fibrosis, and ratio of pancreas weight/body weight (Figure 3A-C). Moreover, Masson staining revealed that the area of pancreas fibrosis markedly decreased in the DCHD group (Figure 3B).

FN is a major indicator of extracellular matrix deposition and the degree of fibrosis. Western blotting revealed no FN expression in the pancreas of control mice; however, 20% L-arginine treatment resulted in increased FN expression in the pancreas at 2 wk, 4 wk, and (maximally) 6 wk. Interestingly, DCHD treatment attenuated FN levels compared with those in the CP group at the same time point, illustrating that DCHD can suppress the deposition of FN in pancreatic fibrosis (Figure 3D).

DCHD attenuated macrophage infiltration and IL-6 mRNA expression in the pancreas

To understand the mechanism underlying the effects of DCHD treatment in CP, we used immunohistochemistry to detect macrophage infiltration. Compared with the CP group, DCHD treatment significantly decreased pancreatic macrophage infiltration at 2 wk. Accompanied with evident and an improvement in pancreatic fibrosis at 4 wk and 6 wk, macrophage infiltration was also significantly reduced (Figure 4A). Thus, limiting macrophage accumulation in the pancreas may be an underlying mechanism of DCHD in inhibiting the development of pancreatic fibrosis.

Considering the association between IL-6 and macrophages, the expression of IL-6 mRNA in the pancreas was assessed using RT-PCR. IL-6 expression levels were increased in CP and were highest at week 4. Compared with those in the CP group, IL-6 levels in the DCHD group were significantly decreased (Figure 4B). This finding demonstrates that IL-6 is produced by macrophages and thus may be a potential treatment target for DCHD.

DCHD decreased chemokine mRNA levels were associated with macrophage infiltration

To further explore the mechanism underlying macrophage accumulation, pancreatic mRNA levels of the macrophage-associated chemokines MCP-1 and MIP-1α were detected using RT-PCR. MCP-1 and MIP-1α were up-regulated in the CP group compared with the control group at 2 wk, 4 wk and 6 wk (Figure 5A-B), while they were significantly decreased in the DCHD group at the same time points.

DISCUSSION

Generally, pancreatic fibrosis is a common pathological feature of CP. Recurrent acute pancreatic insults trigger necro-inflammation, and inflammatory cells, once in their active states, release cytokines that in turn promote fibrogenesis, which is involved in the progression of pancreatic fibrosis[16]. Recent studies have confirmed the dominant role played by activated macrophages in liver fibrosis by interfering with the synthesis and degradation of the extracellular matrix[17]. In a rat model of liver cirrhosis, activated macrophages were shown to accelerate fibrogenesis by activating hepatic myofibroblasts, while the suppression of macrophage infiltration inhibited liver fibrogenesis[17]. Treiber *et al*[18] found large numbers of macrophages among inflammatory cells infiltrating the pancreas of a mouse model of CP. In our study, the development of pancreatic fibrosis was accompanied by a significant increase in F4/80-positive cells in pancreatic tissue, suggesting that activated macrophages may play a role in the progression of pancreatic fibrosis.

A study by Saeki *et al*[19] revealed that infiltration of macrophages in AP originates mainly from peripheral blood mononuclear cells (PBMCs) due to chemokines. Our CP model was based on repetitively inducing AP, and we speculated that infiltration of macrophages

in CP was attributable to PBMCs' recruitment. MCP-1 and MIP-1α are potent C-C type chemokines that are mainly secreted by activated macrophages and fibroblasts. They recognize the C-C chemokine receptor type (CCR)-2 or CCR-3 on PBMCs and recruit macrophages to injured tissues[20,21]. Therefore, we measured MCP-1 and MIP-1α mRNA levels and found that they were up-regulated in mice with CP, which may contribute to macrophage accumulation in CP.

To obtain a deeper understanding of the role of macrophages in pancreatic fibrosis, other researchers previously stimulated PBMCs with lipopolysaccharide, and found that TGF-β1 and IL-6 were significantly elevated in culture supernatant. Moreover, further co-culture of macrophages with pancreatic stellate cells resulted in increased FN and collagen type I levels[22]. TGF-β1 is considered one of the strongest fibrosis factors[9], but the role of IL-6 in CP has not been recognized. Numerous studies have shown that IL-6 was related to fibrosis progress in the liver and lung[23,24]. Recent experiments also demonstrated that the serum level of IL-6 in CP patients was significantly increased[14].

In our present study, IL-6 levels in serum and IL-6 mRNA levels in the pancreas were also significantly increased in the progression of CP mice. These results indicated that IL-6 participates in the development of pancreatic fibrosis. To determine the source of IL-6 production, we preformed immunofluorescent double-staining of F4/80 and IL-6 to evaluate F4/80 and IL-6 expression in the pancreas and found large numbers of doubly positive cells in the pancreas of the CP group. We can thus infer that macrophage infiltration is the main source of IL-6 secretion, and an excess of IL-6 might aggravate inflammation and further accelerate pancreatic fibrogenesis.

The traditional Chinese herbal compound DCHD is composed mainly of Radix bupleuri, Radix scutellariae, Fructus aurantii immaturus, Paeonia lactiflora, Rhizomapinelliae, Rheum palmatum, Rhizoma zingiberis recens, and Fructus jujubae[25]. In the clinic, DCHD has been effective in treating the characteristics of the "shao-yang signs", such as fever, chills and rib-side fullness, and "yang-ming" signs, such as abdominal pain and fullness[15]. Therefore, DCHD is used mainly to treat acute and chronic digestive diseases, such as AP, inflammatory bowel disease, hepatitis and disorders of the gallbladder[15].

Clearly, CP, a common disease of the digestive system, is associated with the shao-yang and yang-ming signs of abdominal pain and rib-side distention. According to the traditional Chinese medical theory, many doctors consider that the mechanism underlying CP involves "liver-spleen disharmony, qi and blood stasis, and dampness-heat obstruction"[26], while the main actions of DCHD are removal of heat and toxic materials and elimination of blood stasis[27]. DCHD may be effective in treating CP. Modern medical studies have shown that petunidin and quercetin from *Radix bupleuri* exert anti-inflammatory effects and act as antioxidants[15,26,28]. Therefore, DCHD has also been used to treat patients of CP, and some related clinical symptoms such as abdominal pain, abdominal distension and loss of appetite, with significant improvement[15], but the underlying molecular mechanisms remain unclear.

In this study, the effects of DCHD on the development of pancreatic fibrosis in CP were evaluated systematically using an L-arginine-induced CP mouse model. Following DCHD administration, morphological changes indicative of CP, including pancreatic acinar cell injury, inflammatory cells infiltration, and pancreatic fibrosis were improved. This suggests that DCHD can attenuate inflammatory lesions and intervene in the progression of pancreatic fibrosis, and led us to perform further study on its underlying mechanism of action.

We next found that DCHD treatment significantly attenuated macrophage infiltration and IL-6 expression in the pancreas. Combined with our previous results, DCHD may suppress pancreatic fibrosis *via* the inhibition of macrophage infiltration, which in turn reduces the release of IL-6. In addition, MCP-1 and MIP-1α expression was also significantly decreased, suggesting that the DCHD-induced decrease in macrophage infiltration was due to a reduction in the release of macrophage-associated chemokines.

The present study suggests that macrophages play a critical role in CP and pancreatic fibrosis, and their dominant role in CP may be related to the release of cytokines, specifically IL-6. We demonstrated that macrophages are the main source of IL-6 production in CP. In addition, DCHD can ameliorate pancreatic fibrosis by inhibiting the macrophage infiltration of CP, which provides a new experimental basis for the clinical promotion of DCHD.

However, our work had certain limitations. We confirmed that the effect of macrophages on CP is related to IL-6, but the detailed mechanism of IL-6 on CP progression was not further explored. In addition, DCHD is effective in CP treatment, but its in-depth mechanism is not further studied, and these are our next steps.

ARTICLE HIGHLIGHTS

Research background

Pancreatic fibrosis is a common pathological feature characteristic of chronic pancreatitis (CP). As the necrosis-fibrosis sequence plays an important role in the underlying pathogenesis of CP, pancreatic fibrosis commonly develops after repeated inflammation. Macrophages are important inflammatory cells that can also promote fibrogenesis by interfering with the synthesis and degradation of the extracellular matrix. This has been confirmed in models of liver fibrosis and renal fibrosis, but any role of macrophages in pancreatic fibrosis has remained unclear. A traditional Chinese medicinal formula, Dachaihu decoction (DCHD), has been widely used in the clinical treatment of AP, and recently, DCHD was

used to treat CP, which significantly improved the patient's clinical symptoms, but, again, the underlying mechanism has been unclear.

Research motivation

CP is a progressive inflammatory disease characterized by irreversible injury to the pancreas leading to endocrine and exocrine dysfunctions that pose serious threats to human health, because the pathogenesis is unclear, and few treatments are available. Recent studies suggested that DCHD can significantly improve the clinical symptoms of CP patients, such as abdominal pain, abdominal distension, loss of appetite and others. However, DCHD cannot be widely used clinically because the therapeutic mechanism of action remains unclear.

Research objectives

The aim was to explore the role played by macrophages in the pathogenesis of CP to further elucidate the mechanisms of CP. In addition, they assessed the efficacy of DCHD in treating CP in animal experiments to determine the mechanism involved, providing an experimental basis for promoting the use of DCHD in clinical practice.

Research methods

KunMing mice were randomly divided into a control group, CP group, and DCHD group. In the CP and DCHD groups, mice were intraperitoneally injected with 20% L-arginine (3 g/kg twice a day, 1 d a week). Mice in the DCHD group were given DCHD (14 g/kg per day) intragastrically for 1 wk after CP induction. The animals were anesthetized and sacrificed at 2 wk, 4 wk and 6 wk after study commencement. Pancreatic morphology and the extent of fibrosis were assessed using hematoxylin and eosin and Masson staining. Serum interleukin-6 (IL-6) levels were assessed by enzyme-linked immunosorbent assay. Double immunofluorescence staining was performed to assess the co-expression of F4/80 and IL-6 in the pancreas. The mRNA levels of inflammatory factors including monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1α (MIP-1α) and IL-6 were determined by real time-polymerase chain reaction. Western blotting was used to measure fibronectin (FN) levels in the pancreas.

Research results

We found that macrophage infiltration was significantly increased in the CP group, and the IL-6 levels in serum and IL-6 mRNA levels in the pancreas were also increased in the CP group. Further, immunofluorescent double-staining of F4/80 and IL-6 revealed that macrophages were the main source of the IL-6. In addition, DCHD ameliorated pancreatic fibrosis, inhibited the pancreatic infiltration of macrophages in the CP group, and reduced the release of cytokines IL-6, MCP-1 and MIP-1α mRNA, and FN levels. However, our work had certain limitations. We confirmed that the effect of macrophages on CP is related to IL-6, but the detailed mechanism of IL-6 on CP progression was not further explored. In addition, DCHD is effective in CP treatment, but its in-depth mechanism was not studied further.

Research conclusions

The authors confirmed that macrophages are involved in the development of pancreatic fibrosis and may constitute a new therapeutic target. In addition, DCHD can ameliorate pancreatic fibrosis by inhibiting macrophage infiltration and inflammatory factor secretion in the pancreas.

ACKNOWLEDGMENTS

Abstract

AIM

To investigate the protective effect of prostaglandin E1 (PGE1) against endoplasmic reticulum (ER) stress-induced hepatocyte apoptosis, and to explore its underlying mechanisms.

METHODS

Thapsigargin (TG) was used to induce ER stress in the human hepatic cell line L02 and hepatocarcinoma-derived cell line HepG2. To evaluate the effects of PGE1 on TG-induced apoptosis, PGE1 was used an hour prior to TG treatment. Activation of unfolded protein response signaling pathways were detected by western blotting and quantitative real-time RT-PCR. Apoptotic index and cell viability of L02 cells and HepG2 cells were determined with flow cytometry and MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-

tetrazolium] assay.

RESULTS

Pretreatment with 1 μmol/L PGE1 protected against TG-induced apoptosis in both L02 cells and HepG2 cells. PGE1 enhanced the TG-induced expression of C/EBP homologous protein (CHOP), glucose-regulated protein (GRP) 78 and spliced X box-binding protein 1 at 6 h. However, it attenuated their expressions after 24 h. PGE1 alone induced protein and mRNA expressions of GRP78; PGE1 also induced protein expression of DNA damage-inducible gene 34 and inhibited the expressions of phospho-PKR-like ER kinase, phospho-eukaryotic initiation factor 2α and CHOP. Treatment with protein kinase A (PKA)-inhibitor H89 or KT5720 blocked PGE1-induced up-regulation of GRP78. Further, the cytoprotective effect of PGE1 on hepatocytes was not observed after blockade of GRP78 expression by H89 or small interfering RNA specifically targeted against human GRP78.

CONCLUSION

Our study demonstrates that PGE1 protects against ER stress-induced hepatocyte apoptosis *via* PKA pathway-dependent induction of GRP78 expression.

Key words: Hepatocytes; Endoplasmic reticulum stress; Thapsigargin; Glucose-regulated protein 78; Protein kinase A; Apoptosis

Core tip: The mechanism underlying the hepatoprotective effect of prostaglandin E1 (PGE1) remains unclear. In this study, we found that pretreatment with PGE1 protected hepatocytes against thapsigargin-induced apoptosis. PGE1 alone induced protein and mRNA expressions of glucose-regulated protein (GRP)78. Treatment with protein kinase A (PKA)-inhibitor H89, KT5720 or small interfering (si)RNA specifically targeted against human GRP78 blocked PGE1-induced up-regulation of GRP78. The hepatoprotective effect of PGE1 was lost by blocking GRP78 expression with either H89 or siRNA. Our study demonstrates for the first time that PGE1 protects against endoplasmic reticulum stress-induced hepatocyte apoptosis *via* PKA pathway-dependent induction of GRP78 expression.

INTRODUCTION

Hepatocyte apoptosis can be triggered by intra- or extracellular signals[1]. The intracellular signals for hepatocyte apoptosis are induced by DNA damage, oxidative stress, growth factor deprivation, mitochondrial dysfunction, ATP depletion and endoplasmic reticulum (ER) stress[2,3]. A complex interaction occurs among these intracellular apoptotic signaling pathways. ER stress is known to induce hepatocyte apoptosis under various pathological conditions[4]. ER stress is implicated in the pathogenesis of various liver diseases, such as obesity-associated fatty liver disease[5,6], viral hepatitis[7], alcohol-induced liver injury[8], drug-induced liver injury[9] and ischemia/reperfusion injury of the liver[10,11]. Devising a treatment strategy to protect hepatocytes from ER stress-induced apoptosis will benefit most patients with liver diseases.

ER is a multifunctional intracellular organelle responsible for the synthesis, processing and trafficking of proteins that are essential for cell growth and survival. ER also serves as a storage organelle for calcium[12]. When the homeostasis of ER is disturbed under various pathophysiological conditions, ER stress is induced and the unfolded protein response (UPR) is activated. The UPR activates three ER transmembrane transducers: inositol-requiring enzyme (IRE) 1a, PKR-like ER kinase (PERK), and activating transcription factor (ATF) 6α[12-14]. Activation of these three UPR pathways enhances the ER's protein folding *via* up-regulation of the synthesis of glucose-regulated protein (GRP) 78. UPR signals also accelerate the degradation of misfolded proteins and reduce the synthesis of new proteins. Therefore, UPR during ER stress facilitates restoration of homeostasis. However, sustained or unresolved ER stress can activate a cascade of apoptotic signals that eventually result in cell death[15,16].

In several experimental models of liver injury, prostaglandin (PG) E1 has been shown to protect against hepatocyte apoptosis[17-19]. PGE1 is also effective in the treatment of patients with fulminant hepatitis and those with primary graft non-function after liver transplantation[20,21]. Thus, PGE1 appears to protect hepatocytes against apoptosis through various mechanisms[22-24]. However, the underlying mechanism of its hepatoprotective effect is not well understood.

In two recent studies, PGE1 was shown to induce expressions of heat-shock protein (HSP) and GRP78 in animal models of liver injury caused by ischemia reperfusion and hepatectomy[25,26]. These findings suggest that modulation of UPR may mediate the hepatoprotective effects of PGE1. However, the role of PGE1 in ER stress-induced apoptosis of hepatocytes is largely unknown.

In this study, we evaluated the protective effect of PGE1 against ER stress-induced hepatocyte apoptosis in both the normal human hepatocyte cell line L02 and

the hepatocarcinoma-derived cell line HepG2[27].

MATERIALS AND METHODS

Chemical reagents

RPMI 1640 was obtained from Thermo-Fisher Biochemical Products Co. Ltd (Beijing, China). Fetal bovine serum (FBS), thapsigargin (TG), protein kinase A (PKA) inhibitor H89 and KT5720, 4-phenylbutyric acid (PBA) and PGE1 were purchased from Sigma (St. Louis, MO, United States). Antibodies against GRP78, PERK, eukaryotic translation initiation factor-2α (eIF-2α), phospho-PERK (p-PERK) and phospho-eIF2α (p-eIF2α), C/EBP homologous protein (CHOP), spliced X box-binding protein 1 (sXBP1), growth arrest and DNA damage-inducible gene 34 (GADD34) and β-actin were purchased from Santa Cruz Biotechnology (Dallas, TX, United States). Annexin V-FITC/propidium iodide (PI) apoptosis detection kit was purchased from Dojindo Laboratories (Kumamoto, Japan). Small interfering (si)RNA scramble control and validated human GRP78-siRNA were purchased from Santa Cruz Biotechnology. All other chemicals and reagents were obtained from Sigma, unless stated otherwise.

Cell culture

The human hepatocyte cell line L02 and hepatocarcinoma-derived cell line HepG2 were obtained from the cell bank of the Type Culture Collection at the Chinese Academy of Sciences (Shanghai, China). The L02 and HepG2 cells were propagated at 37 ℃ in 5% CO_2 in RPMI 1640 medium containing 10% (v/v) FBS and 100 units/mL penicillin, and were passaged every 5-7 d. The L02 and HepG2 cells were cultured until they acquired 80%-100% confluence. Thereafter, the cells were rinsed three times with 10 mL of phosphate-buffered saline (PBS) and cultured in a medium lacking FBS for 24-36 h. To evaluate the effects of PGE1 or PBA on TG-induced apoptosis, PGE1 or PBA was used an hour prior to TG treatment and, thereafter, the medium was not changed. TG and H89 were dissolved in dimethyl sulfoxide (DMSO) at concentrations of 40 μmol/L and 20 μmol/L, respectively, as stock solution. PGE1 was dissolved in ethanol at a concentration of 2.82 mmol/L as stock solution. PBA was dissolved in RPMI 1640 medium. All control conditions included corresponding vehicles at the appropriate concentrations (ethanol for PGE1 and DMSO for TG and H89).

Cell apoptosis analysis

Apoptosis was determined using the annexin V-FITC/PI apoptosis detection kit, according to the manufacturer's instructions. Briefly, 2×10^6 cells were harvested using 0.05% trypsin with 0.5% mmol/L EDTA. To analyze the whole apoptotic cell population, non-adherent cells present in the culture medium were added to the harvested cells. The cells were then washed twice with pre-chilled PBS and resuspended in 500 μL annexin binding buffer. Then, 5 μL of annexin V-FITC and 5 μL of PI were added to each sample and incubated in dark at room temperature for 10 min. Flow cytometry (Gallios; Beckman Coulter, Brea, CA, United States) was performed according to the manufacturer's specifications. The apoptotic index was calculated as the percentage of annexin V^+ cells divided by the total number of cells in the gated region.

Cell viability assay

Cell viability was assessed with MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium] method using the CellTiter 96® AQueous One Solution Cell Proliferation Assay kit (Promega Corporation, Madison, WI, United States) according to the manufacturer's instructions. In brief, early passage of L02 or HepG2 cells were plated in triplicate on 96-well plates (10000 cells/well) and cultured in modified RPMI 1640 for 24 h. Thereafter, the cells were rinsed three times in 200 μL of PBS and cultured in a medium lacking fetal calf serum. Cell viability was determined by replacing the medium with 20 μL of MTS. After incubation of the cells at 37 ℃ for 3 h, the absorbance was measured at 490 nm using a microplate reader (Bio-Rad model 680; Bio-Rad, Hercules, CA, United States). Cell viability was normalized as a percentage of control. This experiment was performed five times.

Western blotting

Cell lysates containing 40 μg of protein were resolved by SDS-PAGE using 4%-20% polyacrylamide gradient gel, and the fractioned proteins were subsequently transferred to nitrocellulose membranes. After blocking with Tris-based saline buffer containing 5% dry milk and 0.1% Tween 20 for 1 h, the membranes were blotted with the corresponding antibodies. The primary and secondary antibodies used were: rabbit anti-human GRP78 (1:500 dilution), PERK (1:1000 dilution), phospho (p)-PERK (1:500 dilution), eIF-2α (1:500 dilution), p-eIF-2α (1:250 dilution), sXBP1 (1:500 dilution), CHOP (1:1000 dilution), GADD34 (1:1000 dilution), mouse anti-human β-actin, goat anti-rabbit IgG conjugated with horseradish peroxidase (HRP), and goat anti-mouse IgG conjugated with HRP. The membranes were developed using a chemiluminescence detection system and thereafter exposed to BioMax Light Film (Kodak, Rochester, NY, United States). The band intensity for each protein was measured using ImagePro Plus analysis software (MediaCybernetics, Silver Spring, MD, United States) and the expression normalized to that of β-actin.

Quantitative real-time RT-PCR

Total RNA was isolated from L02 cells using TRIzol reagent (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's instructions. RNase-free DNase I (TaKaRa, Dalian, China) was applied before cDNA synthesis to remove any genomic contamination. A total of 1 μg RNA from each sample was used for cDNA synthesis with a reverse transcription kit (TaKaRa). Reverse transcription (final volume of 20 μL) was performed at 42 ℃ for 10 min, followed by 75 ℃ for 5 min. The real-time PCR reaction (25 μL) containing 12.5 μL of 2 × SYBR Premix Ex*Taq* II (Tli RNaseH Plus; TaKaRa), 1 μL of each 10 μmol/L primers, 2 μL of cDNA template, and 8.5 μL RNAse/DNAse-free water was performed on a CFX96 PCR system (Bio-Rad). The reaction process was as follows: denaturation at 95 ℃ for 3 min, followed by 40 cycles of amplification (95 ℃ for 10 s and 60 ℃ for 30 s), ending with a melt curve ranging from 60 ℃ to 95 ℃ with a heating rate of 0.3 ℃/15 s. All samples were run in triplicate. Relative expression of GRP78 was calculated using the delta-delta-Ct method with β-actin as the reference control.

Primers used in the PCR were: GRP78 forward, 5′-AAATAAGCCTCAGCGGTTTCTT-3′ and reverse, 5′-TCAAGTTCTTGCCGTTCAAGG-3′; β-actin forward, 5′- CGGGAAATCGTGCGTGAC-3′ and reverse, 5′-CAGGAAGGAAGGCTGGAAG-3′ (TaKaRa). Quantitative real-time PCR was performed according to the MIQE guidelines[28].

GRP78-siRNA transfection

Briefly, cell culture plates containing 6-wells were seeded with 2 × 10^5 cells/well and cultured in RPMI 1640 medium containing 10% (v/v) FBS and 100 units/mL penicillin. siRNA scramble control and validated human GRP78-siRNA were used. GRP78 inhibition was performed using a commercially available siRNA kit (Santa Cruz Biotechnology). Knock-down of the target molecule, GRP78, was monitored by western blotting and real-time PCR.

Statistical analysis

Results of cell apoptosis and cell viability are expressed as mean ± SD. One-way analysis of variance (ANOVA) with Bonferroni's post hoc analysis was performed to compare multiple groups. The Student's *t*-test was used to assess between-group differences. The level of significance was set at $P < 0.05$.

RESULTS

TG-induced ER stress and apoptosis in L02 cells and PGE1 protected L02 and HepG2 cells against ER stress-induced apoptosis

We confirmed TG-induced ER stress in L02 cells (Figure 1). At 48 h, TG (1 μmol/L) caused significant

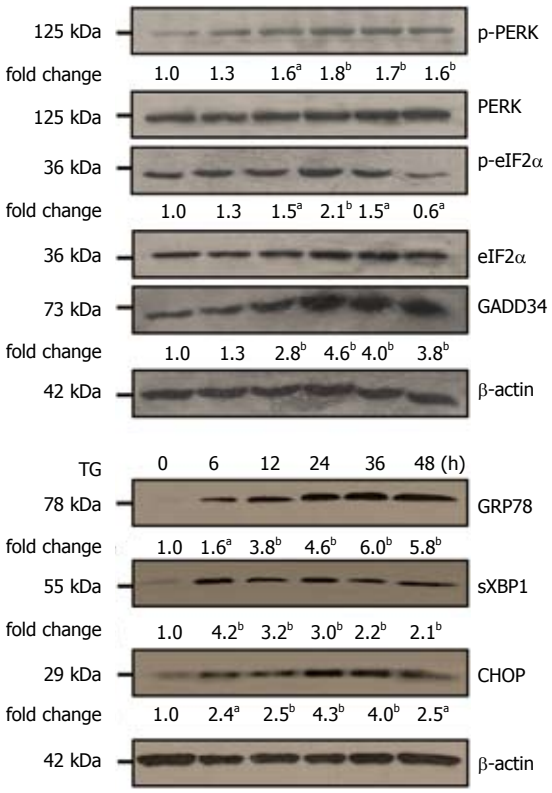

Figure 1 TG induced endoplasmic reticulum stress in L02 cells. L02 cells were treated with 1 μmol/L TG for 6, 12, 24, 36 and 48 h. Expressions of p-PERK, p-eIF2α, GADD34, GRP78, sXBP1 and CHOP were assessed by western blotting. Representative blots from three independent experiments are presented. The results of densitometric analysis are presented as a fold-change compared to that at 0 h ($^aP < 0.05$; $^bP < 0.01$). CHOP: C/EBP homologous protein; ER: Endoplasmic reticulum; GADD34: Growth arrest and DNA damage-inducible gene34; GRP78: Glucose-regulated protein 78; p-eIF2α: Phospho-eukaryotic translation initiation factor-2α; p-PERK: Phospho-PKR-like ER kinase; sXBP1: Spliced X box-binding protein1; TG: Thapsigargin.

enhancement in phosphorylation of PERK and GADD34 proteins, as compared to that observed at 6 h. Further, phosphorylation of eIF2α at 24 h was also up-regulated, as compared to that at 6 h. TG also induced a significant increase in the expressions of GRP78, CHOP and sXBP1 proteins.

We also confirmed TG-induced apoptosis in both L02 and HepG2 cells by means of flow cytometry and MTS assay. As shown in Figure 2A, the apoptotic index of L02 cells after TG treatment was significantly higher than that of control from 6 h to 48 h ($P < 0.01$). At 48 h, the apoptotic index reached 32.66%. TG also showed a dose-dependent increase in apoptotic index with increase in the concentration of TG (1 μmol/L, 2 μmol/L and 3 μmol/L; data not shown). Cell viability of both L02 and HepG2 cells significantly decreased from 24 h to 48 h after TG treatment (Figure 2B and C).

We assessed the effect of PGE1 on ER stress-induced apoptosis in L02 cells (Figure 2A). From 6 h to 48 h, 1 μmol/L PGE1 pretreatment significantly decreased TG-induced apoptotic index. At 48 h, 0.5 μmol/L and 1 μmol/L PGE1 showed dose-dependent

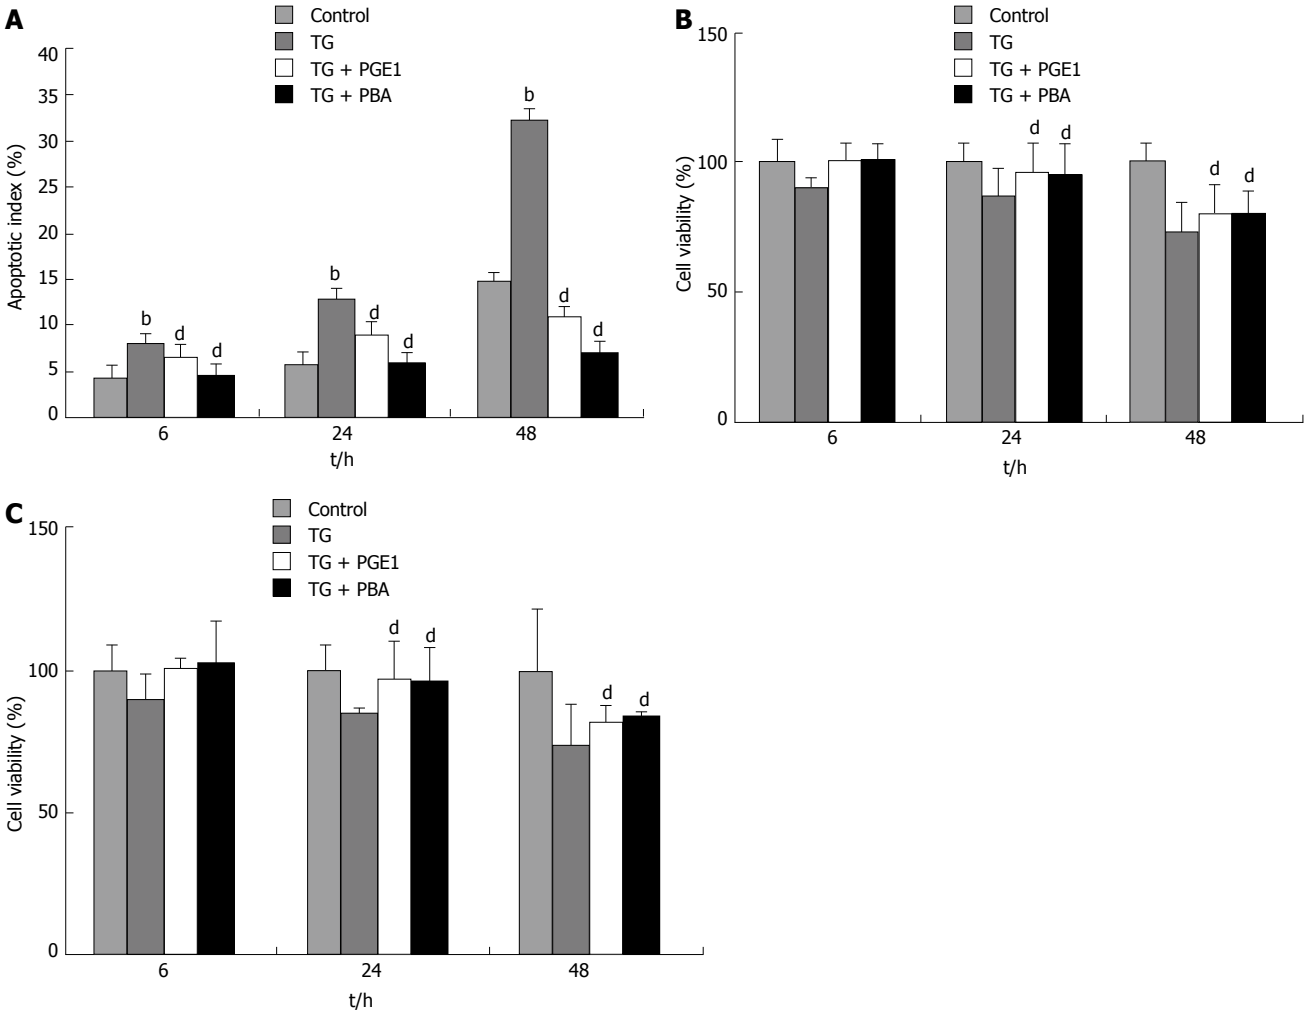

Figure 2 Prostaglandin E1 protected against thapsigargin-induced apoptosis in both L02 cells and HepG2 cells. L02 cells and HepG2 cells were pretreated with PGE1 or PBA for 1 h and treated with a final concentration of 1 μmol/L TG for 6, 24 and 48 h. A: Apoptotic index of L02 cells was determined by flow cytometry. Histograms represent mean ± SD of five separate experiments, each of which was performed in triplicate. $^{b}P < 0.01$ *vs* control at the same time point; $^{d}P < 0.01$ *vs* TG at the same time point; B and C: Cell viability of L02 cells and HepG2 cells was determined by MTS assay. The absorbance was measured at 490 nm and cell viability was normalized as a percentage of control. Histograms represent mean ± SD of five separate experiments, each of which was performed in triplicate. $^{d}P < 0.01$ *vs* TG at the same time point. MTS: [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium]; PBA: 4-phenylbutyric acid; PGE1: Prostaglandin E1; TG: Thapsigargin.

protection against TG-induced apoptosis (data not shown). PBA is a low molecular weight chemical chaperone and an ER stress inhibitor. PBA at 10 nmol/L significantly inhibited TG induced apoptosis (Figure 2A). MTS assay revealed that PGE1 significantly increased the viability of TG-treated L02 cells and HepG2 cells (Figure 2B and C). These results demonstrate the protective effect of PGE1 on ER stress-induced apoptosis in L02 cells and in HepG2 cells.

PGE1 promoted rapid recovery of ER stress

After demonstration of the cytoprotective effect of PGE1, we investigated the effects of PGE1 on UPR signals induced by TG. We selected three indicators from UPR, GRP78, CHOP and sXBP1, as GRP78 is a common downstream target of the three UPR signal pathways. CHOP is the major protein involved in apoptotic signals induced by ER stress, and sXBP1 is activated through the oligomerization of IRE1a[29]. As shown in Figure 3, 1 μmol/L PGE1 appeared to increase TG-induced GRP78, CHOP and sXBP1 expressions till 6 h post-treatment. However, from 24 h to 48 h, PGE1 suppressed TG-induced GRP78 and CHOP expressions. These results indicate that although PGE1 increased the early expression of UPR signals, it promoted the rapid recovery of ER stress.

PGE1 induced GRP78 expression via the PKA pathway

The observation that PGE1 attenuated the ER stress-induced apoptosis and promoted the rapid recovery from ER stress prompted us to investigate the effect of PGE1 on GRP78, CHOP and GADD34 expressions. GRP78 is a critical chaperone which determines the outcome of ER stress. GADD34 is involved in both recovery and resumption of protein synthesis as well as in the ER stress-induced apoptosis[14,30]. We also investigated the effects of PGE1 on phosphorylation of eIF2α and PERK, since the activation of PERK and

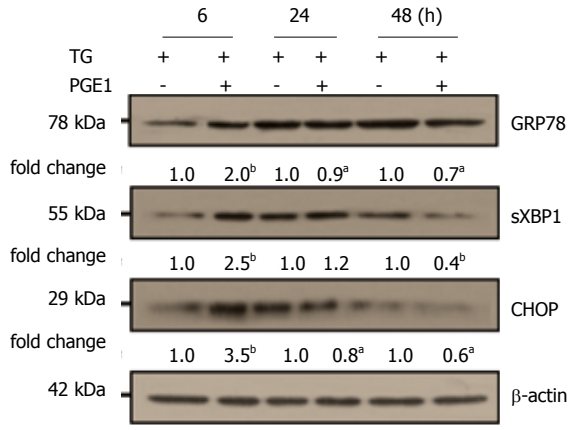

Figure 3 Prostaglandin E1 promoted rapid recovery of endoplasmic reticulum stress. L02 cells were pretreated with 1 μmol/L PGE1 for 1 h and at a final concentration of 1 μmol/L TG for 6, 24 and 48 h. Expressions of GRP78, CHOP and sXBP1) were assessed on western blotting. One representative blot each of three individual experiments is presented. The results of densitometric analysis are presented as a fold-change compared to those of TG at the same time point ($^{a}P < 0.05$, $^{b}P < 0.01$). CHOP: C/EBP homologous protein; ER: Endoplasmic reticulum; GRP78: Glucose-regulated protein 78; PGE1: Prostaglandin E1; sXBP1: Spliced X box-binding protein 1; TG: Thapsigargin.

eIF2α is known to induce CHOP and GADD34. From 3 h to 24 h after treatment with 1 μmol/L PGE1, a significant increase in GRP78 expression was observed in both L02 cells and HepG2 cells (Figure 4A and B). PGE1 also decreased CHOP expression in L02 cells and induced the expression of GADD34; however, it suppressed the expression of p-PERK and p-eIF2α proteins (Figure 4A). Results of quantitative real-time RT-PCR also demonstrated that PGE1 induced the mRNA expression of GRP78 from 3 h to 24 h (Figure 4C).

To explore the signal pathways that may mediate the effect of PGE1 on GRP78 expression, we inhibited the PKA pathway by H89 or KT5720. Treatment with 10 μmol/L of H89 or 1 μmol/L KT5720 appeared to counteract the effect of PGE1 on GRP78 expression (Figure 5A and B). These results indicate that PGE1 increased GRP78 expression *via* a PKA-dependent pathway.

PGE1 protected L02 and HepG2 cells against ER stress-induced apoptosis via PKA-dependent induction of GRP78 expression

H89 at 10 μmol/L appeared to inhibit the protective effect of PGE1 on hepatocyte apoptosis, which suggests that the cytoprotective effect of PGE1 was mediated *via* the PKA signaling pathway (Figure 5C). To further test whether the protective effect of PGE1 was dependent on the induction of GRP78 expression, we inhibited GRP78 expression by transfection with siRNA specifically targeted against human GRP78. On blocking the PGE1-induced up-regulation of GRP78 expression by siRNA (Figure 6A-C), PGE1 appeared to lose its cytoprotective effect in both L02 cells and HepG2 cells (Figure 6D-G). These findings imply that PGE1 protected against hepatocyte apoptosis *via* PKA-dependent induction of GRP78 expression.

DISCUSSION

The key findings of this study are that PGE1 protected hepatocytes from ER stress-induced apoptosis, that PGE1 enhanced the expression of GRP78 *via* the PKA pathway, and that the cytoprotective effect of PGE1 on hepatocytes was mediated *via* PKA-dependent GRP78 induction.

TG is known to induce ER stress by blocking ER Ca^{2+} uptake, which leads to depletion of ER Ca^{2+} stores[31]. PGE1 can also increase intracellular Ca^{2+} level by promoting the influx of Ca^{2+} from the external medium as well as by mobilization of Ca^{2+} from intracellular stores[32]. As intracellular Ca^{2+} level is an important factor in hepatocyte apoptosis and necrosis, cotreatment with TG and PGE1 may have modulated apoptotic signals of L02 cells, which eventually led to cell death by necrosis. Therefore, we assessed cell apoptosis and viability on flow cytometry and by MTS assay. Our results strongly suggest that PGE1 protects hepatocytes from ER stress-induced apoptosis.

PGE1 is known to have a direct vasodilator as well as an anti-platelet effect[22,33]. Several *in vivo* studies have indicated that PGE1 protects against hepatocyte apoptosis and promotes hepatocyte proliferation *via* inducing down-regulation of proinflammatory cytokine levels[24,26], suppression of tumor necrosis factor-α receptor and adhesion molecule expression[23,24], and by up-regulating cyclin C and cyclin D1 expressions[34]. PGE1 also inhibits oxidative stress and nitrosative stress-induced hepatocyte death by inhibiting production of superoxide anion, by enhancing nitric oxide synthase expression and by inhibiting nuclear factor-κB activation *in vitro*[19,35,36]. In this study, we demonstrated that PGE1 protected hepatocytes from ER stress-induced apoptosis. Our findings suggest that modulation of UPR may mediate the cytoprotective effect of PGE1 in various pathological conditions.

The mechanisms involved in ER stress-induced apoptosis are yet to be elucidated. The adaptive capacity of cells to ER stress is an important determinant of the outcomes of ER stress. Apoptosis results from sustained or strong ER stress when UPR fails to restore ER homeostasis[37,38]. In the present study, PGE1 treatment enhanced TG-induced CHOP, GRP78 and sXBP1 expressions at 6 h, and significantly attenuated TG-induced CHOP, GRP78 and sXBP1 expressions, as assessed at 48 h. These results suggest that PGE1 boosted the initial expression of UPR and promoted restoration of ER homeostasis during ER stress.

During ER stress, UPR may have been activated to restore ER homeostasis. UPR is precisely regulated by three ER stress transducers and their downstream signals. GRP78 is considered as a master regulator of response to ER stress[39,40]. GRP78 binds with all three major UPR sensors (PERK, IRE1a and ATF6) and

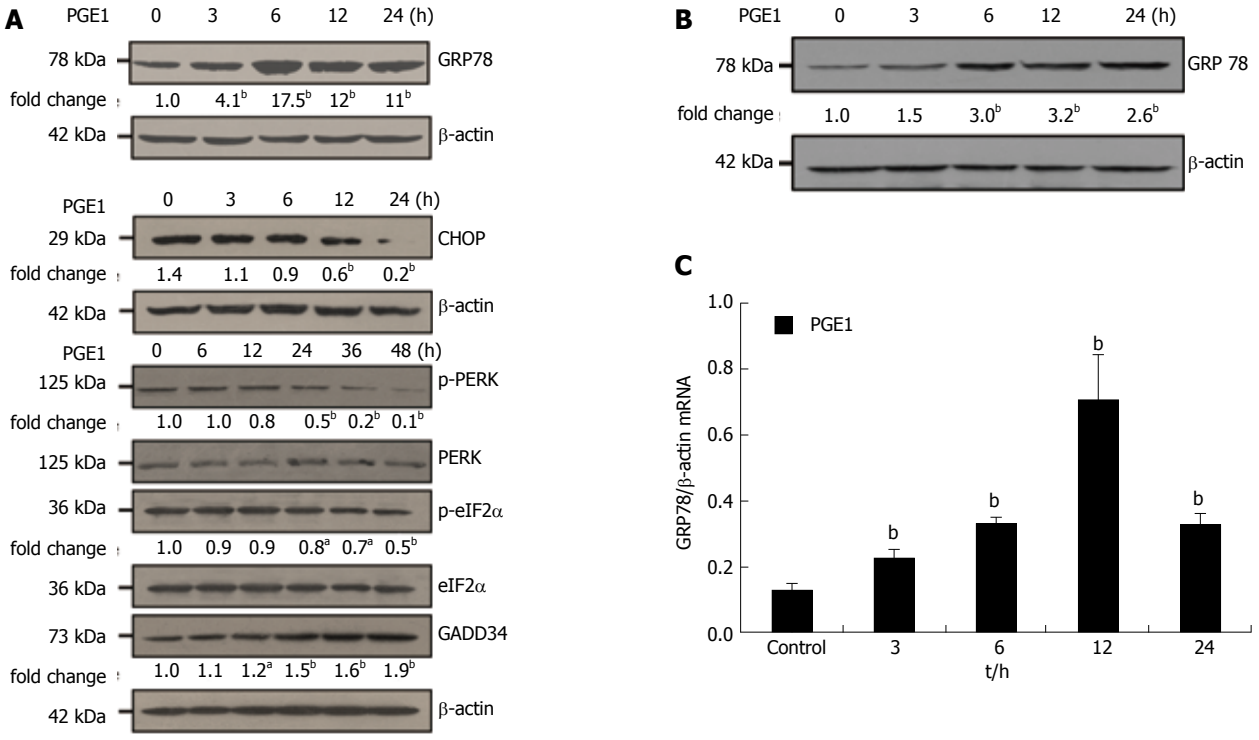

Figure 4 Prostaglandin E1 induced glucose-regulated protein 78 protein and mRNA expressions. To determine GRP78 and CHOP protein or mRNA expressions, L02 cells and HepG2 cells were treated with 1 μmol/L PGE1 for 3, 6, 12 and 24 h; for detecting GADD34 and the p-PERK and p-eIF2α, L02 cells were treated with 1 μmol/L PGE1 for 6, 12, 24, 36 and 48 h. A: Expressions of GRP78, CHOP, GADD34, p-PERK and p-eIF2α in L02 cells were assessed by western blotting. One representative blot each from the three individual experiments is presented. The results of densitometric analysis are presented as a fold-change compared to those at 0 h ($^aP < 0.05$, $^bP < 0.01$); B: Expression of GRP78 in HepG2 cells was assessed by western blotting. One representative blot each from the three individual experiments is presented. The results of densitometric analysis are presented as a fold-change compared to those at 0 h ($^bP < 0.01$); C: mRNA expression of GRP78 in L02 cells was assessed by quantitative real-time PCR (E). Histograms represent mean ± SD of three experiments ($^bP < 0.01$ *vs* those at 0 h). CHOP: C/EBP homologous protein; ER: Endoplasmic reticulum; GADD34: Growth arrest and DNA damage-inducible gene 34; GRP78: Glucose-regulated protein 78; p-eIF2α: Phospho-eukaryotic translation initiation factor-2α; PGE1: Prostaglandin E1; p-PERK: Phospho-PKR-like ER kinase; TG: Thapsigargin.

keeps them inactivated while the homeostasis of ER is maintained. During ER stress, GRP78 dissociates from PERK, ATF6 and IRE1a and binds to unfolded or misfolded proteins, promotes their proper folding or directs them to degradation. The dissociation of GRP78 from PERK, ATF6 and IRE1a, triggers the UPR response and further enhances the expression of GRP78. Increased GRP78 augments the folding capacity of the ER, inactivates the three ER sensors and promotes restoration of ER homeostasis[29].

The protective role of GRP78 against apoptosis during ER stress has been demonstrated both *in vivo* and *in vitro*[41-44]. The insulin signaling pathway has been found to promote cell proliferation and improve cell survival *via* up-regulation of GRP78 expression[45]. In this study, PGE1 significantly inhibited TG-induced apoptosis. PGE1 induced protein and mRNA expressions of GRP78. Further, inhibition of GRP78 expression *via* either H89 or siRNA hindered the protective role of PGE1 on TG-induced apoptosis. These results demonstrate that the cytoprotective effect of PGE1 on hepatocytes was mediated *via* induction of GRP78 during ER stress. The protein expression of GRP78 induced by PGE1 peaked at 6 h; however, mRNA expression of GRP78 induced by PGE1 peaked at 12 h. It is difficult to explain the difference in the time frame for attainment of peak levels of mRNA and protein expressions of GRP78. One explanation is that PGE1 regulated the GRP78 expression not only at the transcriptional level but also at the translational or posttranslational level. Whether PGE1 regulates the expression of GRP78 at the translational or posttranslational level warrants further studies.

The other important signal pathways in ER stress-induced apoptosis are mediated *via* induction of CHOP and GADD34. During UPR, phosphorylation of eIF2α *via* the PERK pathway results in inhibition of mRNA translation and general protein synthesis. However, mRNA for activating transcription factor (ATF) 4 is selectively up-regulated. Activation of ATF4 results in induction of CHOP and GADD34 expressions. GADD34 and protein phosphatase 1 were shown to promote dephosphorylation of eIF2α and allow protein synthesis[46]. However, recent studies have shown that induction of GADD34 exacerbates the disturbance of ER homeostasis and leads to cell apoptosis by increasing oxidative stress[47]. CHOP has been identified as one of the most important mediators of ER stress-induced apoptosis; it induces apoptosis through various signal pathways[48].

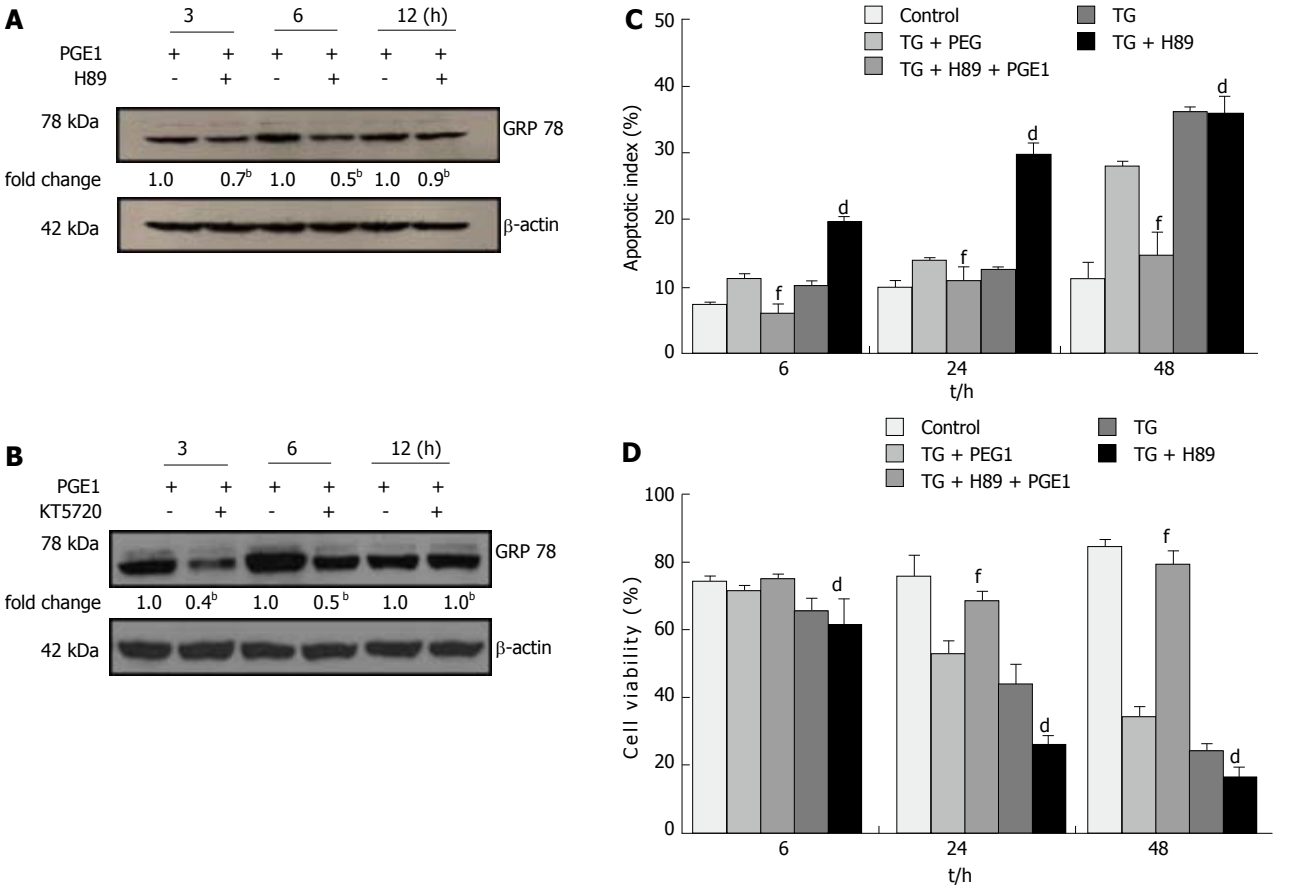

Figure 5 Prostaglandin E1 induced glucose-regulated protein 78 expression and protected L02 cells against endoplasmic reticulum stress-induced apoptosis *via* a protein kinase a-dependent pathway. A and B: L02 cells were pretreated with or without PKA inhibitor H89 (10 μmol/L) or KT5720 (1 μmol/L), and then 1 μmol/L PGE1 for 3, 6 and 12 h. The expressions of GRP78 were detected by western blotting. One representative blot each from three independent experiments is presented. The results of densitometric analysis are presented as a fold-change compared to those of PGE1 at the same time points ($^bP < 0.01$); C: L02 cells were pretreated with or without 10 μmol/L H89, and then 1 μmol/L PGE1 and a final concentration of 1 μmol/L TG for 6, 24 and 48 h. The apoptotic index was determined by flow cytometry. Histograms represent mean ± SD of five separate experiments, each of which was performed in triplicate. ($^dP < 0.01$ *vs* those of TG + PGE1 at the same time point; $^fP < 0.01$ *vs* those of TG at the same time point); D: L02 cells were pretreated with or without 10 μmol/L H89, and then 1 μmol/L PGE1 and a final concentration of 1 μmol/L TG for 6, 24 and 48 h. Cell viability of L02 cells was determined by MTS assay. Histograms represent mean ± SD of five separate experiments, each of which was performed in triplicate ($^dP < 0.01$ *vs* those of TG + PGE1 at the same time point; $^fP < 0.01$ *vs* those of TG at the same time point). GRP78: Glucose-regulated protein 78; MTS: [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium]; PGE1: Prostaglandin E1; PKA: Protein kinase A; TG: Thapsigargin.

In the current study, we had anticipated inhibition of GADD34 by PGE1. However, we observed an enhanced expression of GADD34 and significant inhibition of p-PERK, CHOP and p-eIF2α expressions in L02 cells. Our results indicate that the cytoprotective effect of PGE1 against hepatocyte apoptosis does not depend on the inhibition of GADD34. Since PGE1 lost its protective effects after inhibition of GRP78 expression in this study, it is possible that the increased expression of GADD34 in our study was the result of induction of GRP78 by PGE1 and that this represented restoration of ER homeostasis. Further study is needed to clarify the role of GADD34 in ER stress-induced apoptosis.

The biological effects of PGE result from its binding to its receptors, EP1 to EP4, and previous studies have shown that L02 cells express EP1 receptors[49]. Binding of PGE1 with its receptors stimulates production of the second messenger cyclic 3, 5 adenosine monophosphate (cAMP). cAMP may act *via* distinct intracellular signaling effectors, such as PKA and the exchange proteins activated by cAMP[50]. A previous study has shown that cAMP has PKA-independent interaction with Ca^{2+} stored in lymphocytes[51]. To test whether the hepatoprotective effect of PGE1 is mediated *via* PKA-independent interaction with Ca^{2+} stores in L02 cells, we used H89 to block the PKA pathway. The results showed that the protective effects of PGE1 were largely dependent on the PKA pathway. However, H89 inhibited GRP78 expression most effectively at 6 h, and then at 12 h the inhibitory effect was alleviated; the increased apoptotic index lasted from 6 h to 48 h. It is difficult to explain this result. One explanation is that H89 may also have inhibited other kinases in addition to PKA. H89 has been shown to inhibit at least 8 kinases beside PKA[52]. The role of PKA and other kinases in ER stress-induced apoptosis remains to be studied in the future.

It is known that GRP78 expression is regulated at the transcriptional level by ER stress. Previous

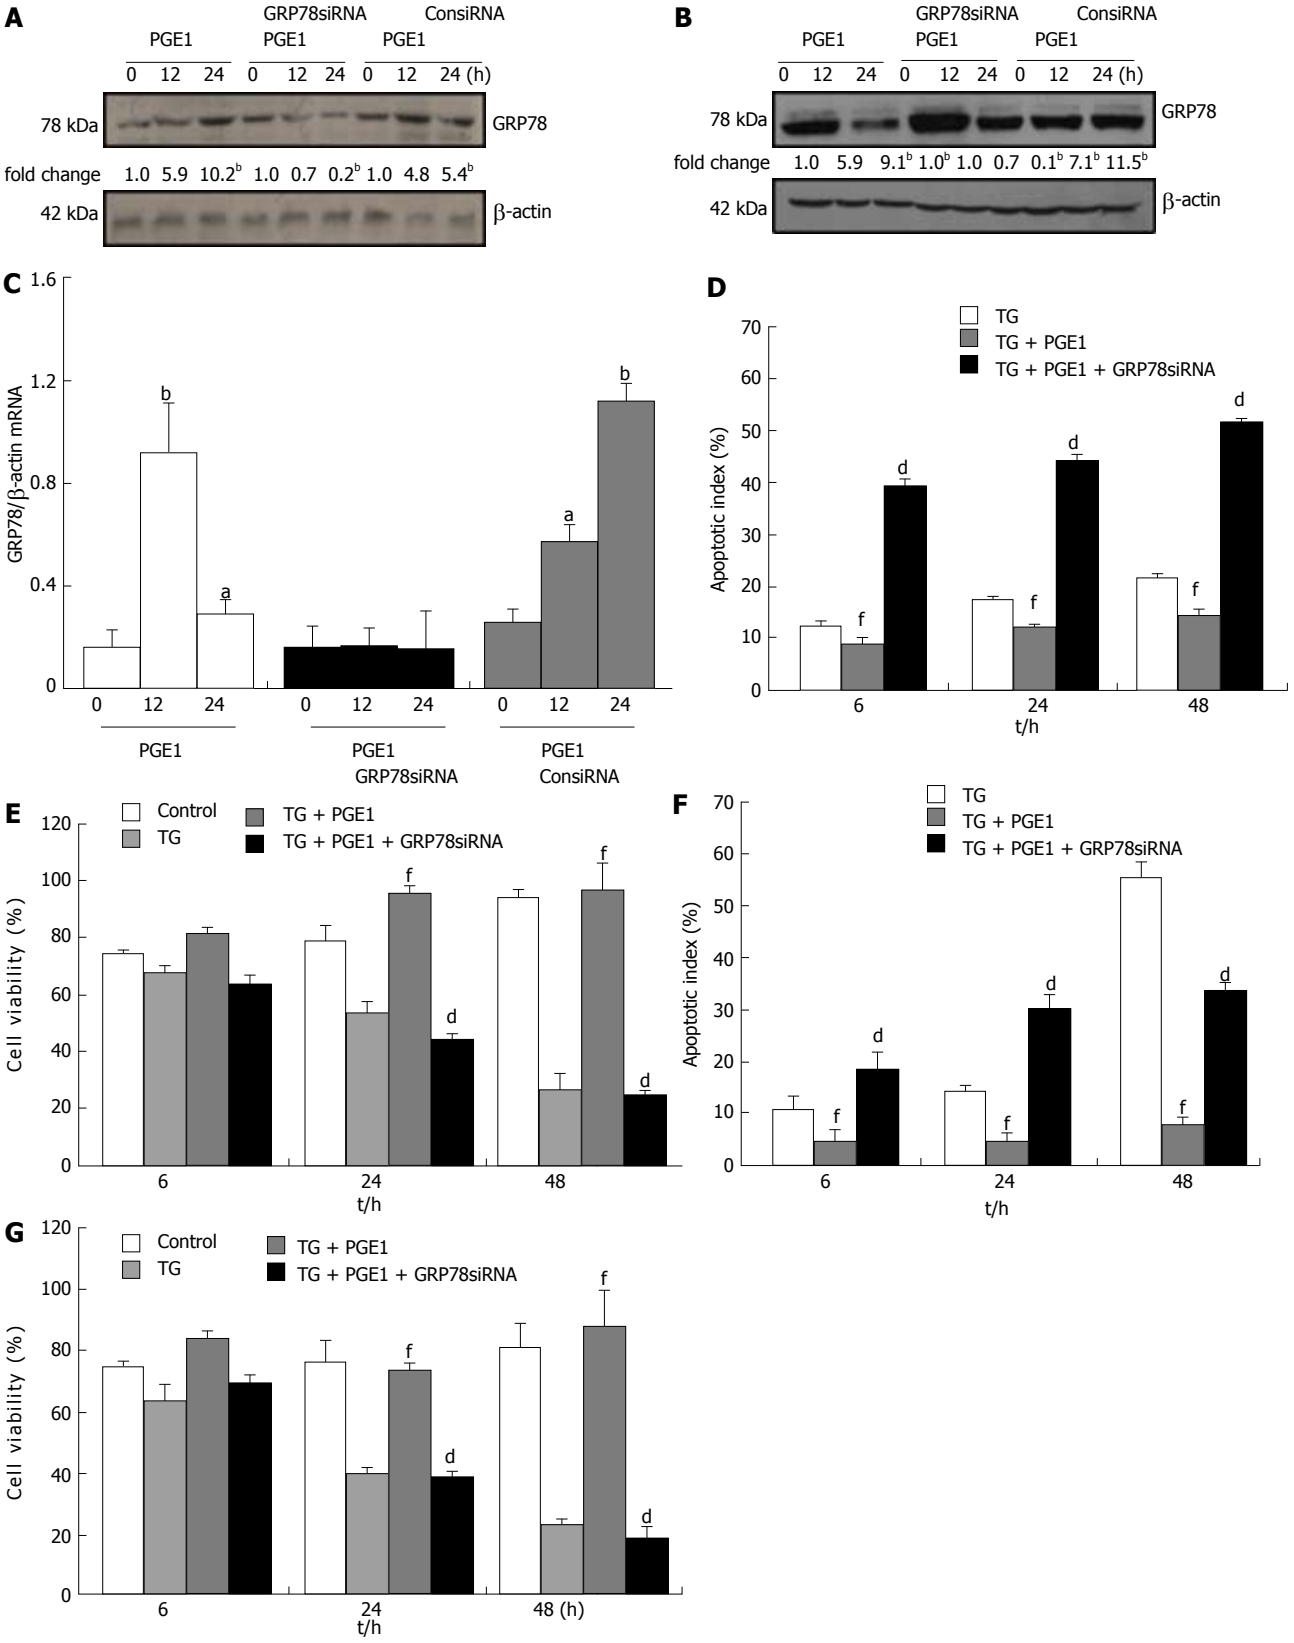

Figure 6 Prostaglandin E1 protected against endoplasmic reticulum stress-induced apoptosis *via* induction of glucose-regulated protein 78 expression in both L02 and HepG2 cells. L02 and HepG2 cells were transfected with either siRNA scramble control (ConsiRNA) or siRNA against human GRP78 (GRP78 siRNA) for 48 h. The cells were treated with 1 μmol/L PGE1 for 12 h and 24 h. A and B: Expressions of GRP78 in L02 cells and in HepG2 cells were detected by western blotting. One representative blot each from the three individual experiments is presented. The results of densitometric analysis are presented as a fold-change compared to those at 0 h ($^bP < 0.01$); C: mRNA expression of GRP78 in L02 cells was detected by real-time PCR. Histograms represent mean ± SD of three experiments ($^aP < 0.05$; $^bP < 0.01$ *vs* those at 0 h). D and F: Apoptotic indices of L02 cells and HepG2 cells were determined by flow cytometry. Histograms represent mean ± SD of five independent experiments, each of which was performed in triplicate ($^dP < 0.01$ *vs* those of TG + PGE1 at the same time point; $^fP < 0.01$ *vs* those of TG at the same time point); E and G: Cell viability of L02 cells and HepG2 cells was determined by MTS assay. Histograms represent mean ± SD of five independent experiments, each of which was performed in triplicate ($^dP < 0.01$ *vs* those of TG + PGE1 and $^fP < 0.01$ *vs* those of TG at the same time point). GRP78: Glucose-regulated protein 78; PGE1: Prostaglandin E1; MTS: [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium]; siRNA: Small interfering RNA; TG: Thapsigargin.

studies have shown that preconditioning to ER stress protects against cell death *via* induction of GRP78 or autophagy[53]. In this study, although PGE1 pretreatment significantly induced GRP78 expression and enhanced TG-induced early CHOP and sXBP1 expressions, PGE1 alone inhibited the expressions of p-PERK and p-eIF2α and CHOP. Therefore, whether PGE1 induced GRP78 expression *via* induction of ER stress is not known. In previous studies, leptin was shown to induce GRP78 expression in neuronal cells through the PI3K-mTOR pathway[54]; further, oncostatin M was also shown to induce GRP78 expression without triggering ER stress[55]. The mechanisms involved in the induction of GRP78 expression by PGE1 warrant further investigation.

In conclusion, this is the first study to demonstrate that the cytoprotective effect of PGE1 against ER stress-induced apoptosis is mediated *via* PKA-dependent induction of GRP78 expression in hepatocytes. Further studies are required for devising treatment strategies to protect hepatocytes against ER stress-induced apoptosis, which will be of much clinical relevance in the context of liver diseases.

COMMENTS

Background

Prostaglandin (PG) E1 has been shown to protect against hepatocyte apoptosis; however, the role of Prostaglandin E1 (PGE1) in endoplasmic reticulum (ER) stress-induced apoptosis of hepatocytes is largely unknown.

Research frontiers

ER stress has been implicated in the pathogenesis of various liver diseases. Understanding the mechanisms underlying ER stress-induced apoptosis and devising a treatment strategy to protect hepatocytes from ER stress-induced apoptosis will benefit most patients with liver diseases.

Innovations and breakthroughs

Pretreatment with PGE1 protected hepatocytes against thapsigargin-induced apoptosis. PGE1 alone induced protein and mRNA expressions of glucose-regulated protein (GRP) 78. Treatment with protein kinase A (PKA)-inhibitor H89, KT5720 or small interfering (si)RNA specifically targeted against human GRP78 blocked PGE1-induced up-regulation of GRP78. The hepatoprotective effect of PGE1 was lost by blocking GRP78 expression by either H89 or siRNA. Our study demonstrates, for the first time, that PGE1 protects against ER stress-induced hepatocyte apoptosis *via* PKA pathway-dependent induction of GRP78 expression.

Applications

PKA and GRP78 may be new targets for pharmacological treatment in patients with liver diseases.

Peer-review

The strengths of this study lie in the experimental design, methodology and that the authors describe the caveats and potential pitfalls in great detail. Overall, the study was well-designed and the paper is interesting and sound.

Abstract

AIM

To study the type and frequency of adverse events associated with anti-tumor necrosis factor (TNF)

therapy and evaluate for any serologic and genetic associations.

METHODS

This study was a retrospective review of patients attending the inflammatory bowel disease (IBD) centers at Cedars-Sinai IBD Center from 2005-2016. Adverse events were identified *via* chart review. IBD serologies were measured by ELISA. DNA samples were genotyped at Cedars-Sinai using Illumina Infinium Immunochipv1 array per manufacturer's protocol. SNPs underwent methodological review and were evaluated using several SNP statistic parameters to ensure optimal allele-calling. Standard and rigorous QC criteria were applied to the genetic data, which was generated using immunochip. Genetic association was assessed by logistic regression after correcting for population structure.

RESULTS

Altogether we identified 1258 IBD subjects exposed to anti-TNF agents in whom Immunochip data were available. 269/1258 patients (21%) were found to have adverse events to an anti-TNF-α agent that required the therapy to be discontinued. 25% of women compared to 17% of men experienced an adverse event. All adverse events resolved after discontinuing the anti-TNF agent. In total: *n* = 66 (5%) infusion reactions; n = 49 (4%) allergic/serum sickness reactions; *n* = 19 (1.5%) lupus-like reactions, *n* = 52 (4%) rash, *n* = 18 (1.4%) infections. In Crohn's disease, IgA ASCA (*P* = 0.04) and IgG-ASCA (*P* = 0.02) levels were also lower in patients with any adverse events, and anti-I2 level in ulcerative colitis was significantly associated with infusion reactions (*P* = 0.008). The logistic regression/human annotation and network analyses performed on the Immunochip data implicated the following five signaling pathways: JAK-STAT (Janus Kinase-signal transducer and activator of transcription), measles, IBD, cytokine-cytokine receptor interaction, and toxoplasmosis for any adverse event.

CONCLUSION

Our study shows 1 in 5 IBD patients experience an adverse event to anti-TNF therapy with novel serologic, genetic , and pathways associations.

Core tip: Tumor necrosis factor-α (TNF-α) plays a key role in the development and progression of inflammatory bowel disease (IBD). Anti-TNF therapy is highly efficacious in treating IBD patients, but many experience adverse events. Few studies have evaluated factors associated with adverse events to anti-TNF therapy. In this study, we found some genetic associations and pathways that are enriched for genes associated with the development of adverse events. Future studies will need to confirm these findings as the ability to identify subjects at high risk may help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

Genetic associations with adverse events from anti-tumor necrosis factor therapy in inflammatory bowel disease patients. *World J Gastroenterol* 2017; 23(40): 7265-7273 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7265.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7265

INTRODUCTION

Tumor necrosis factor-α (TNF-α) plays a key role in the development and progression of inflammatory bowel disease (IBD)[1-3]. While anti-TNF therapy is an effective therapeutic option for IBD patients[1,4,5], response to these agents is highly heterogeneous and a high proportion of patients either fail initial induction therapy or lose response during maintenance therapy[6-8]. Predicting response to these agents has been studied extensively by evaluating a multitude of factors including potential genetic components[7], but an important addition would be the ability to predict the development of adverse events associated with these agents including: infusion reactions; infections; rash; allergic reactions; serum sickness like reactions; and lupus-like reactions[9-11]. Minimizing the risks is important to increase patient compliance and improve response to therapy, and will also become more important as physicians struggle with decisions around where to position biologic therapies as therapeutics targeting novel mechanisms become available[12,13].

Currently, there are few studies designed to determine factors associated with adverse events to anti-TNF-α therapy. The objectives of this study were to describe the type and frequency of adverse events associated with anti-TNF-α therapy in a large cohort and evaluate for any serologic and genetic associations.

MATERIALS AND METHODS

Study population

This study was a retrospective review of patients attending the IBD centers at Cedars-Sinai IBD Center from 2005-2016. Patients included in the study were

those that had given consent, had available genotype data, carried a diagnosis of IBD (Crohn's disease, ulcerative colitis, or IBDU), and who had been treated with anti-TNF-α agents (infliximab, adalimumab, certolizumab pegol). All research-related activities were approved by the Cedars-Sinai Medical Center Institutional Review Board (IRB #3358).

Data gathering

Detailed clinical information for each patient was obtained *via* chart review. Clinical information included age at disease diagnosis, type of IBD (CD, UC, or IBDU), gender, and type of anti-TNF-α agent used. All patients were seen by gastroenterologists, experienced in managing patients with IBD treated with anti-TNF agents, at the IBD centers at Cedars-Sinai Medical Center, Los Angeles.

Adverse events

Adverse events were identified *via* chart review by evaluating the "Allergies" section and the progress notes written by the gastroenterologist. Potential adverse events include infusion reactions, serum sickness-like reactions, drug-induced lupus, rash, infections, and non-specific symptoms (arthralgias, shortness of breath, rash, *etc*). An infusion reaction was defined as any significant adverse experience that occurred during or within two hours of infusion[14]. An allergic or a serum sickness-like reaction was defined clinically as the occurrence of myalgias, arthralgias, fever, or rash within 1-14 d after reinfusion of infliximab[15].

The likelihood of a causal relationship for each adverse event was determined based on the assessment of the gastroenterologist as documented in the progress note and as evidenced by the following: time elapsed between a dose and adverse event, resolution of the adverse event when the therapy was discontinued, and return of the adverse event if the therapy was resumed[16].

Serological analysis

IBD serologies (ANCA, anti-nuclear cytoplasmic antibodies; anti-CBir1, anti-flagellin; anti-I2, anti-*Pseudomonas fluorescens*-associated sequence I2; anti-OmpC, anti-outer membrane porin C; ASCA, anti-*Saccharomyces cerevisiae* antibodies) were measured by enzyme-linked immunosorbent assay (ELISA) as previously described[17]. Results were expressed as ELISA units (EU/mL) relative to Cedars-Sinai Medical Center laboratory or a Prometheus laboratory standard derived from a pool of patient sera with well-characterized disease found to have reactivity to these antigens. All assays were performed in a blinded fashion.

Genotype data

DNA samples were genotyped at Cedars-Sinai using Illumina Infinium Immunochipv1 array per manufacturer's protocol (Illumina, San Diego, CA, United States). Average genotyping call rate for samples that passed quality control was 99.8%; average replicate concordance and average heritability rates were > 99.99% and 99.94%, respectively. Single-nucleotide polymorphisms (SNPs) underwent methodological review and were evaluated using several SNP statistic parameters to ensure optimal allele-calling[18].

Statistical analysis

χ^2 test and logistic regression were performed to identify demographic and clinical characteristics associated with development of adverse events. For continuous variables with skewed distribution (*e.g.*, serology levels), Wilcox test signed rank test was performed. SNPs association with adverse events was evaluated using PLINK. Principal components (PCs) from population stratification analysis were included in the PLINK analysis to control for potential confounding[19]. Two-sided *P*-value of 0.05 was considered statistically significant.

Genetic pathway, and network analyses

For any reaction, infusion reactions, and allergic reactions, the logistic regression/human annotation and network analysis was performed with statistically significant SNPs ($P < 0.001$). These SNPs were first annotated into corresponding genes, and the genes were further analyzed with multiple biological functional databases including human protein reference databases (http://www.hprd.org), Reactome, NCI/Nature pathway interaction database and others. The final networks were then constructed form the known interactions from any of these databases. Pathways and gene set enrichment analysis was performed with STRING (http://string-db.org/) and cytoscape (http://www.cytoscape.org).

RESULTS

Patient demographics and characteristics

1258 IBD (954 CD patients, 260 UC, 44 IBDU) patients qualified for this study. The average age of onset was 25.7 years and, and the overwhelming majority were of European ancestry.

Adverse events

A total of 269/1258 patients (21%) were found to have experienced an adverse event. The different

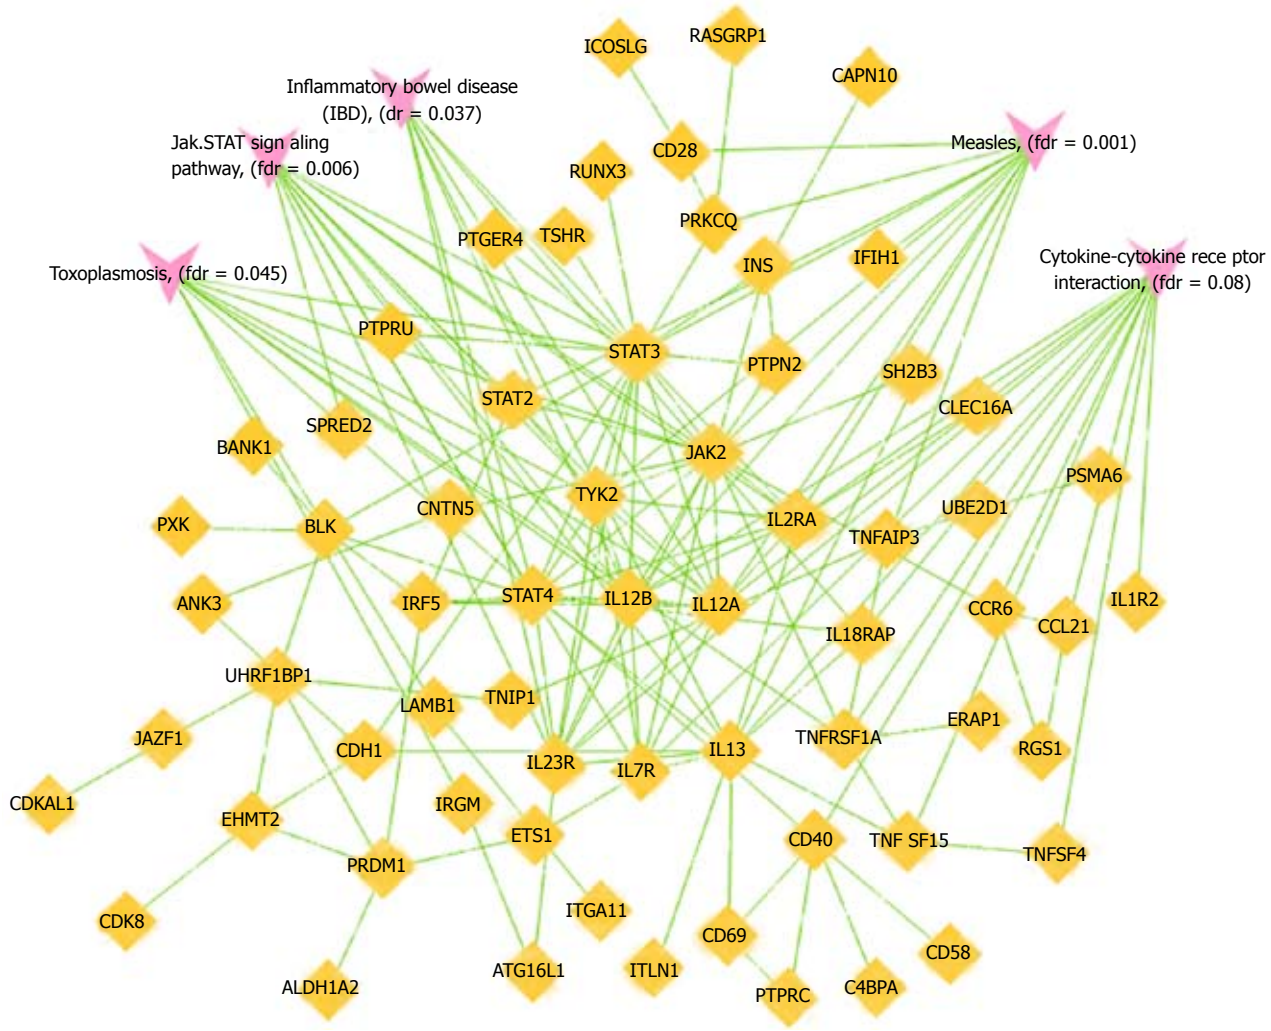

Figure 1 Network analyses of allergic reactions to anti-tumor necrosis factor agents.

types of adverse events were similar among women and men, except for lupus-like reactions and rashes, which were both more commonly seen in women (Table 1).

Serology

In CD patients we observed that IgA ASCA+/- was associated with a lower risk of developing any adverse event (OR = 0.68, *P* = 0.047), while IgG ASCA+/- and total ASCA+/- show a similar trend and borderline association respectively (OR = 0.72 and 0.70, *P* = 0.09 and 0.05, respectively). IgA ASCA (*P* = 0.04) and IgG ASCA (*P* = 0.02) levels were also lower in patients with any adverse events (Table 2). Anti-I2 level in UC was significantly associated with infusion reactions (*P* = 0.008) (Table 2). No other associations were seen with IBD-associated serologies (data not shown).

Genetic analysis

IBD-associated SNPs that achieved a nominal level of significance with adverse events are shown in Table 3. For any reaction, infusion reactions, and allergic reactions, the logistic regression/human annotation and network analyses performed on the Immunochip data implicated the following five signaling pathways: JAK-STAT (Janus Kinase-signal transducer and activator of transcription), Measles, IBD, Cytokine-cytokine receptor interaction, and Toxoplasmosis (Table 4 and Figure 1). After False Discovery Rate correction, all associations remained statistically significant except for the Cytokine-cytokine receptor interaction for infusion and allergic reactions.

DISCUSSION

In our cohort approximately 1 in 5 IBD patients experienced adverse events to anti-TNFs that eventually led to the discontinuation of the therapy in keeping with the current literature, although most studies only report the presence or not of adverse events and do not comment on whether patients had to

Table 1 Adverse events based on type of inflammatory bowel disease and gender *n* (%)

discontinue[20]. The incidence of serious lupus-like reactions requiring the discontinuation of anti-TNFs was found to be 1.1%[21], which was comparable to that seen in our population of 1.5%. To our knowledge, this is the largest study examining adverse events with anti-TNF agents.

We identified a number of genetic associations with known IBD loci including two (*HLA-DRB1* and *ERAP2* [endoplasmic reticulum aminopeptidase 2]) that are associated with a number of immune-mediated diseases as well as IBD and also, in the case of *HLA-DRB1*, with the development of extra-intestinal manifestations in IBD[22-24]. Furthermore, both are involved in peptide presentation by HLA molecules[25,26]. We also observed associations at other IBD genes including *ZNF365,* a transcription factor in maintaining genomic stability during DNA replication in the brain, heart, lung, pancreas, small intestine and colon[27,28]. Our genetic findings also implicated genes that maintain colonic wall permeability including *SPRED* (Sprouty-related EVH1 domain-containing protein) and *PARD3* (Partitioning defective 3 homolog)[29,30]. In addition, *GNA12* (Guanine nucleotide-binding protein alpha-12), a modulator of different transmembrane signaling systems, has also been implicated in the loss of barrier integrity[31]. Our pathway analyses strongly implicated

IBD: Inflammatory bowel disease.

five signaling pathways including JAK-STAT signaling pathway, Cytokine-cytokine receptor interaction pathway, Measles signaling pathway, Toxoplasmosis signaling pathway, and the IBD signaling pathway. The network analyses for allergic reactions (Figure 1) show a number of key nodes including *TYK2, BLK* and *IL13*, which have previously been shown to be associated with allergic susceptibility[32-34].

IBD serologies (ANCA, anti-CBir1, anti-I2, anti-OmpC, and ASCA) can distinguish CD from UC, risk stratify IBD patients, and also predict postoperative complications and occur as a result of an aberrant or exaggerated response to commensal flora[35]. The association with ASCA and I2 are interesting. Perhaps these markers identify patients with a predilection towards small bowel involvement. Patients with colonic disease tend to respond less to anti-TNFs or require higher doses[8,36] and, perhaps therefore, these patients are more likely to develop antibodies or reactions to anti-TNFs. Further studies will be needed to confirm these borderline associations.

There are several potential limitations of this study including, the relatively small sample size and the retrospective nature of the study (despite it being the largest of its kind to date). Additionally, we did not have information on anti-drug antibody formation as the majority of these patients developed adverse events prior to the widespread use of these parameters in clinical practice. It is also important to note that our study population was predominantly of European ancestry. While IBD is rising in non-Europeans, the highest prevalence is still seen in European ancestry populations. For this reason, and the location of Cedars-Sinai Medical Center in west Los Angeles, the majority of our patients are "European". Previous work have shown ethnic differences in genetic associations with adverse events[37], and a study similar to this one should be performed for other ethnic groups.

In conclusion, our study revealed that approximately 1 in 5 IBD patients experienced an adverse event to anti-TNF therapies that required cessation of therapy. The majority of these were infusion/allergic reactions but approximately 1 in 30 women will develop a lupus-like reaction and we also observed other serious adverse events including pancreatitis and vascultitis but these were rare. We have demonstrated some genetic associations and pathways that are enriched for genes associated with development adverse events. Future studies will need to confirm these findings as the ability to identify subjects at high risk may help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

ATRICLE HIGHLIGHTS

Research Background

Tumor necrosis factor (TNF) inhibitors are highly efficacious in treating inflammatory bowel disease (IBD). Response to these agents is highly heterogenous, and there have been a multitude of studies aimed at predicting the response to these agents. An important addition is the ability to predict the development of adverse events associated with these agents such as infusion reactions, infections, or rash. Minimizing the risk is important to increase patient compliance and improve response to therapy.

Research motivation

Recognizing the type and frequency of adverse events to anti-TNF therapy, and the potential genetic and serologic associations can help identify subjects at high risk, and may help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

Research objectives

The objectives of this study were to describe the type and frequency of adverse

events associated with anti-TNF-α therapy in a large cohort and evaluate for any serologic and genetic associations. The significance of realizing these objectives is that it can identify subjects at high risk for developing adverse events and can help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

Research methods

This study was a retrospective review, and detailed clinical information was collected *via* manual chart review. χ^2 test and logistic regression were performed to identify demographic and clinical characteristics associated with development of adverse events.

The serological data was measured by ELISA assay at Cedars-Sinai, which was performed in a blinded fashion, and analyzed with Wilcox test signed rank test.

DNA samples were genotyped at Cedars-Sinai using Illumina Infinium Immunochipv1 array per manufacturer's protocol (Illumina, San Diego, CA, United States). Average genotyping call rate for samples that passed quality control was 99.8%; average replicate concordance and average heritability rates were > 99.99% and 99.94%, respectively. Single-nucleotide polymorphisms (SNPs) underwent methodological review and were evaluated using several SNP statistic parameters to ensure optimal allele-calling. SNPs association with adverse events was evaluated using PLINK, with two-sided p-value of 0.05 was considered statistically significant.

For any reaction, infusion reactions, and allergic reactions, the logistic regression/human annotation and network analysis was performed with statistically significant SNPs ($P < 0.001$). These SNPs were first annotated into corresponding genes, and the genes were further analyzed with multiple biological functional databases. The final networks were then constructed form the known interactions from any of these databases.

The research methods described above are standard for a retrospective review analyzing genetic and serologic data.

Research results

About 1 in 5 patients were found to have adverse events to an anti-TNF-α agent that required the therapy to be discontinued. All adverse events resolved after discontinuing the anti-TNF agent. The majority of patients developed infusion reactions. In CD patients we observed that IgA ASCA +/- was associated with a lower risk of developing any adverse event. IgA ASCA and IgG ASCA levels were also lower in patients with any adverse events. Anti-I2 level in UC was significantly associated with infusion reactions. The authors identified a number of genetic associations with known IBD loci including *HLA-DRB1, ERAP2, ZNF365*. Their pathway analyses strongly implicated JAK-STAT signaling pathway, Cytokine-cytokine receptor interaction pathway, Measles signaling pathway, Toxoplasmosis signaling pathway, and the IBD signaling pathway. The network analyses for allergic reactions showed a number of key nodes including *TYK2, BLK* and *IL13*, which have previously been shown to be associated with allergic susceptibility.

They have demonstrated some novel genetic associations and pathways that are enriched for genes associated with development adverse events. Future studies should be performed to confirm our results, and incorporate other ethnic groups besides European ancestry, and include data on anti-drug antibody formation.

Research conclusions

The genetic and serologic associations found in concordance with adverse events to anti-TNF therapy. This is the first study to evaluate and describe these associations. There are potentially genetic and serologic associations with adverse events to anti-TNF therapy that can help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

Current studies describe in great detail the efficacy of anti-TNF therapy and the ability to predict response to therapy. However, current studies are lacking in evaluating the ability to predict the development of adverse events. The results from this study reveal that there indeed are genetic and serologic associations with anti-TNF therapy that can potentially be targeted to prevent or avoid these adverse events in the future. The new hypothesis proposed by this study is that there serologic and genetic associations with anti-TNF therapy.

The methods used in this study were similar to other retrospective studies analyzing genetic and serologic data. Manual chart review was performed to generate detailed clinical information; ELISA assay was performed to gather serologic data; and genetic data was generated using Illumina Infinium Immunochipv1 array. χ^2 test and logistic regression were performed to identify demographic and clinical characteristics associated with development of adverse events; serological data were analyzed with Wilcox test signed rank test; and SNPs association with adverse events were evaluated using PLINK, with two-sided *P*-value of 0.05 considered statistically significant.

The genetic and serologic associations found in concordance with adverse events to anti-TNF therapy are novel and have not been described elsewhere. This study confirmed that there are genetic and serologic associations with adverse events from anti-TNF therapy. Identifying the potential factors associated with adverse events from anti-TNF therapy can help clinicians anticipate and therefore prevent or avoid these adverse events in the future.

Abstract

AIM

To study differences of presentation, management, and prognosis of alcoholic hepatitis in Latinos compared to Caucasians.

METHODS

We retrospectively screened 876 charts of Caucasian and Latino patients who were evaluated at University of California Davis Medical Center between 1/1/2002-12/31/2014 with the diagnosis of alcoholic liver disease. We identified and collected data on 137 Caucasians and 64 Latinos who met criteria for alcoholic hepatitis, including chronic history of heavy alcohol use, at least one episode of jaundice with bilirubin ⩾ 3.0 or

coagulopathy, new onset of liver decompensation or acute liver decompensation in known cirrhosis within 12 wk of last drink.

RESULTS

The mean age at presentation of alcoholic hepatitis was not significantly different between Latinos and Caucasians. There was significant lower rate of overall substance abuse in Caucasians compared to Latinos and Latinos had a higher rate of methamphetamine abuse (12.5% *vs* 0.7%) compared to Caucasians. Latinos had a higher mean number of hospitalizations (5.3 ± 5.6 *vs* 2.7 ± 2.7, $P = 0.001$) and mean Emergency Department visits (9.5 ± 10.8 *vs* 4.5 ± 4.1, $P = 0.017$) for alcohol related issues and complications compared to Caucasians. There was significantly higher rate of complications of portal hypertension including gastrointestinal bleeding (79.7% *vs* 45.3%, $P < 0.001$), spontaneous bacterial peritonitis (26.6% *vs* 9.5%, $P = 0.003$), and encephalopathy (81.2% *vs* 55.5%, $P = 0.001$) in Latinos compared to Caucasians.

CONCLUSION

Latinos have significant higher rates of utilization of acute care services for manifestations alcoholic hepatitis and complications suggesting poor access to outpatient care.

Key words: Alcoholic hepatitis; Latino; Hispanic; Caucasian; Alcoholic liver disease

Core tip: We conducted a retrospective chart review on Caucasian and Latino patients with alcoholic hepatitis. We showed that Latinos had significantly higher rates of gastrointestinal bleeding, encephalopathy, spontaneous bacterial peritonitis, recurrence of alcoholic hepatitis, and utilization of acute care services for alcohol related issues compared to Caucasians. However, the survival rates were not significantly different between Latinos and Caucasians. Our findings suggest that Latino patients have poor access to outpatient care and management of complications of portal hypertension.

Pinon-Gutierrez R, Durbin-Johnson B, Halsted CH, Medici V. Clinical features of alcoholic hepatitis in latinos and caucasians: A single center experience. *World J Gastroenterol* 2017; 23(40): 7274-7282 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7274.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7274

INTRODUCTION

Alcoholism is estimated to cause 2.5 million deaths annually worldwide, and it represents 4% of all deaths[1]. Forty percent of all mortality from cirrhosis is attributed to alcoholic liver disease (ALD). ALD includes different clinical entities with different severity and prognosis, ranging from alcoholic fatty liver disease characterized by hepatic steatosis, to severe alcoholic hepatitis (AH), and ultimately alcoholic cirrhosis[1] with portal hypertension and its complications. Disparities exist in the incidence and severity of ALD among various racial and ethnic groups in the United States.

Ethnicity data from the National Center for Health Statistics for 1991-1997 showed greatest liver cirrhosis mortality among Latino men compared to Black and Caucasian men followed by Latina females[2]. A comprehensive discharge study of all patients with ALD in non-federal hospitals in Los Angeles County in 1999 showed that ALD accounted for 1.2% of all deaths and was most prevalent in middle aged Latino men as compared to other ethnicities[3]. A more recent study showed that the Latino population in the United States has a higher incidence and more aggressive pattern of chronic liver diseases than the Caucasian population[4]. Longevity data from a multicenter Veteran Affairs cooperative study showed that the 5-year survival from active ALD was only 28% among Latino men compared to 40% in Caucasian men[5]. Among heavy alcohol drinkers, Latinos were 9.1 times more likely to have a 2-fold elevation in AST and GGT levels when compared to Caucasians[6], and Mexican American men are more likely to be heavy binge drinkers than Caucasians and African American men or Mexican American women[7]. A recent review highlights the linkage of excessive alcohol intake and dependence among Mexicans to the presence of functional SNPs in genes that regulate both alcohol craving mechanisms in the brain and alcohol metabolism in the liver[8]. In our own experience[9], Latino patients treated at UC Davis for ALD were significantly younger than Caucasians at the time of presentation and were more likely than Caucasian patients to present with AH or cirrhosis. Despite these well documented differences, there are no ethnic-specific data on the various manifestations of ALD. AH is the most severe manifestation of ALD is characterized by an inflammatory process of the liver with neutrophilic infiltration leading to ballooning degeneration of hepatocytes, hepatocyte necrosis, steatosis and presence of Mallory bodies. AH clinic presentation is associated with jaundice, fever, hepatomegaly, liver tenderness, encephalopathy, and gastrointestinal bleeding (GIB)[1]. The goal of the present study was to determine the clinical features of AH in Latino patients compared to Caucasian patients.

MATERIALS AND METHODS

We performed a single-center retrospective chart review of 137 Caucasian patients and 64 Latino patients older than 18 years old diagnosed with AH and who were seen at the University of California Davis

Hepatology Clinic or hospitalized at the University of California Davis Medical Center in Sacramento, California between 1/1/2002-12/31/2014. Of note, it is estimated that 83% of Latinos living in the Sacramento area are Mexican Americans (http://quickfacts.census.gov/qfd/states/06/06067.html). We performed a chart review of 876 Caucasian and Latino patients with ICD9 codes for AH, alcoholic cirrhosis, ALD, and unspecified liver damage identify subjects with AH of each group. When possible, we applied the NIAAA Alcoholic Hepatitis Consortia criteria[10] with few modifications given the retrospective nature of the study: (1) chronic history of heavy alcohol use; (2) at least one episode of jaundice with bilirubin ⩾ 3 or coagulopathy with INR ⩾ 1.2 (modification); (3) new onset of liver decompensation; (4) diagnosis acute AH per ICD-9 code on known cirrhosis; and (5) within 12 wk (modification) of last drink and where no other causes of liver decompensation were identified. Otherwise, ICD9 codes for AH were applied to ensure the highest number of subjects was included in the study. We excluded patients with known active hepatitis B (positive HBsAg and Hepatitis B viral load > 20,000 IU/mL) and active hepatitis C (positive HCV Ab and HCV viral load > 615 IU/mL).

We used the demographics section of the electronic medical record and/or from history and physical examination notes to identify our research population, ethnicity, gender, and age of onset of AH. We defined the drinking patterns as follow: moderate drinking was defined as no more than four drinks per day, or 14 drinks per week for men, and no more than three drinks per day, or 7 drinks per week for women, and heavy drinking defined as 15 or more drinks per week, or four drinks in a day, for men or, more than seven drinks per week, or three drinks a day for women. We defined binge drinking as five or more drinks for male or 4 or more drinks in female in about 2 h on multiple occasions. We also gathered drinking duration occurred in our patient population. We included data pertaining to body mass index (BMI) and whether subjects had a diagnosis of metabolic syndrome and diabetes mellitus (DM). We recorded the development of complications associated with AH and/or portal hypertension including GIB, encephalopathy, spontaneous bacterial peritonitis (SBP), and presence of other infections, pancreatitis, development of acute kidney injury (AKI) and/or hepatorenal syndrome, disseminated intravascular coagulopathy (DIC), and hepatocellular carcinoma. We recorded intensive care unit (ICU) admission, length of ICU stay, development of respiratory failure, and length of hospital stay, and we determined the number of emergency room visits and hospitalizations for alcohol related morbidity.

We made the distinction of AH without known history of cirrhosis and AH with known cirrhosis and recorded the number of times a patient met our criteria for AH. To assess severity of AH, we calculated the Discriminant Function (DF) [4.6 × (Pt's PT - Control PT) + TBili]. If ⩾ 32, it is considered severe AH[11] with related increased risk of mortality[12]. We determined Glasgow score for AH, Model for End-Stage Liver Disease (MELD) score, and Child-Turcotte-Pugh class. We collected data on modality of medical treatment of severe AH (supportive care, steroids, pentoxifylline including their duration and doses). Finally, we collected survival data that included total survival days after episode of AH (total number of days since date of AH to last day to be alive or seen at the UC Davis Medical Center or clinic).

Statistical analyses

Categorical variables were compared between ethnicities using χ^2 tests, followed by examination of adjusted residuals in the case of a significant test. Continuous variables were compared between ethnicities using *t*-tests, with duration data and lab data log-transformed prior to testing. Survival was compared between ethnicities using log rank tests.

The effects of subject disease characteristics and treatment on overall survival were analyzed using Cox proportional hazards models. Analyses were conducted for all subjects and separately for each ethnicity. All analyses were adjusted for age, sex, BMI, and, for analyses in all subjects, ethnicity. Analyses were conducted using R, version 3.3.1 (R Core Team, 2016).

RESULTS

The mean age at presentation for all patients was 48.6 ± 10.4 years and was not significantly different between Latinos and Caucasians. Among men, there was a marginally significant higher proportion of male Latino subjects with AH compared to Caucasians subjects (71.9% *vs* 56.2%, $P = 0.049$). There were no significant differences between Latinos and Caucasians in BMI, presence of DM, or metabolic syndrome (Table 1). The mean duration of drinking was longer in Latinos compared to Caucasians (24.3 ± 11.0 years *vs* 20.5 ± 12.7 years, $P = 0.027$). There were no significant differences between Latinos and Caucasians regarding pattern of drinking or daily mean average number of alcoholic drinks (Table 1). Latinos and Caucasians presented different patterns of non-alcoholic substance abuse. Caucasians had significant higher rates of having no history of substance abuse (73.0% *vs* 57.8%), whereas more Latinos had a history of methamphetamine abuse (12.5% *vs* 0.7%) and a remote history of substance abuse (9.4% *vs* 4.4%) than would be expected under homogeneity of variance ($P = 0.003$) (Table 1).

Latinos had about twice the number of emergency department (ED) and hospitalizations visits due to alcohol intoxication and alcohol related issues compared to Caucasians (Figures 1 and 2). There was no significant difference in the mean length of hospital stay between Latinos (52 subjects admitted out of 64)

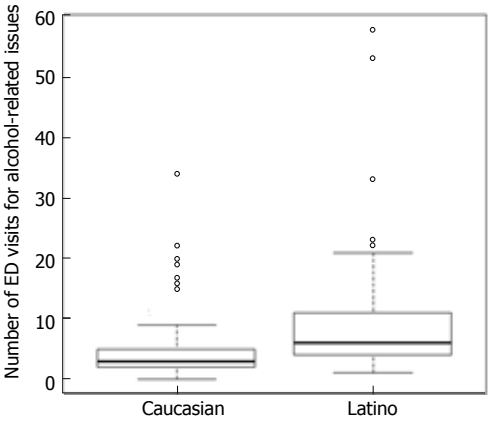

Figure 1 Emergency department visits for alcohol-related issues. There was a significant difference in the mean number of ED visits for alcohol related issues between ethnicities. Latinos had a significant higher mean number of ED visits for alcohol related issues compared to Caucasians (9.5 ± 10.8 *vs* 4.1 ± 4.1 ED visits, $P \leqslant 0.001$). ED: Emergency department.

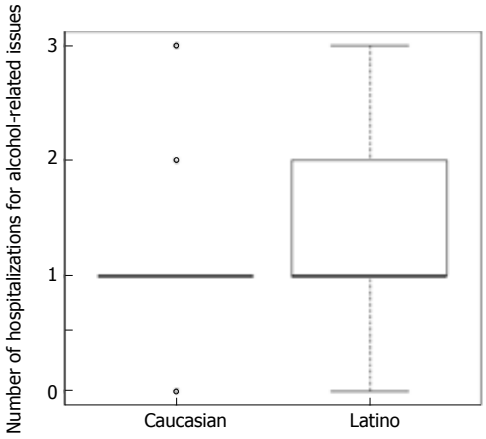

Figure 2 Hospitalizations for alcohol-related issues. There was a significant difference in the mean number of hospital admissions for alcohol related issues between ethnicities. Latinos had a higher mean number of hospital admissions for alcohol related issues compared to Caucasians (5.3 ± 5.6 *vs* 2.7 ± 2.7 admissions, $P = 0.001$).

and Caucasians (111 admitted out of 137) admitted to the hospital with AH and there was no significant difference between Latinos and Caucasians requiring ICU admission and length of ICU stay in days (Table 2).

There were no significant differences in the proportions of Latinos and Caucasians who presented with AH without history of cirrhosis (76.6% *vs* 68.6%) and with history of cirrhosis (23.4% *vs* 31.4%) ($P = 0.321$). The mean DF score of the whole group was 46.7 ± 33.9 and there was no significant difference in prevalence of severe AH, as determined by DF > 32, between Latinos and Caucasians, mean MELD score, and

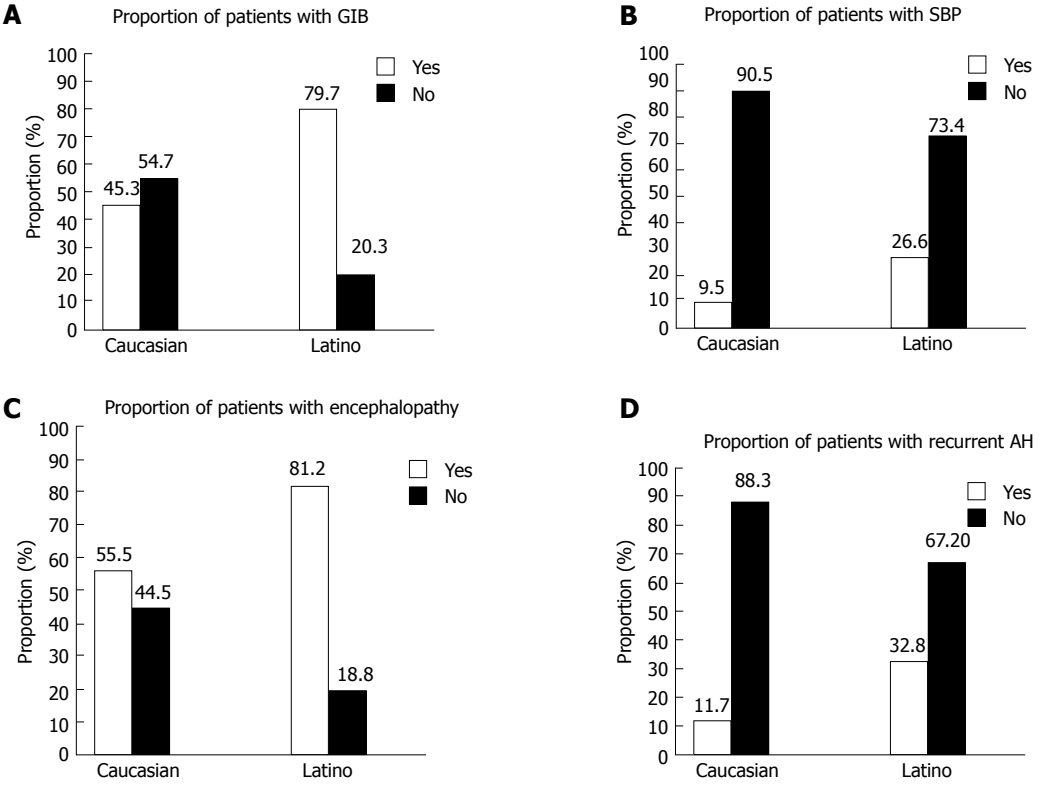

Figure 3 Clinical manifestations of alcoholic hepatitis. There was a significant difference in the proportion of patients who experienced GIB, SBP, encephalopathy, and recurrence of AH between ethnicities. A: A significant higher proportion of Latinos experienced GIB compared to Caucasians (79.7% *vs* 45.3%, $P < 0.001$); B: A significantly higher proportion of Latinos experienced SBP compared to Caucasians (26.6% *vs* 9.5%, $P = 0.003$); C: A significant higher proportion of Latinos experienced encephalopathy compared to Caucasians (81.2% *vs* 55.5%, $P = 0.001$); D: A higher proportion of Latinos had recurrent AH compared to Caucasians (32.8% *vs* 11.7%, $P = 0.005$). AH: Alcoholic hepatitis; GIB: Gastrointestinal bleeding; SBP: Spontaneous bacterial peritonitis.

111 out of the 137 Caucasians and 52 out of 64 Latino Subjects were admitted to the hospital for management of alcoholic hepatitis. The other Caucasians and Latino patients were seen in the ED or outpatient setting. ICU: Intensive care unit.

initial mean Glasgow score for AH (Table 3). Among patients who received medical treatment for severe AH (Latinos $n = 15$ and Caucasians $n = 37$), patients from both ethnicities were treated similarly with similar proportions of patients treated with steroids, pentoxyfilline or combination of both (Table 3). There was no significant difference in the Lille score after 7 d of treatment between Latinos ($n = 14$) and Caucasians ($n = 35$) (Table 3).

Latinos and Caucasians admitted with AH presented a similar rate of complications including respiratory failure, acute pancreatitis, AKI, hepatorenal syndrome, and DIC (Table 4). However Latinos had higher rates of portal hypertension complications including overall GIB (Figure 3A), SBP (Figure 3B), encephalopathy (Figure 3C), and recurrence of AH (Figure 3D) compared to Caucasians. Despite these higher rates of complications, Latinos presented a longer median survival compared to Caucasians but the difference was not significant (12.1 *vs* 4.6 years, $P = 0.055$) (Figure 4).

Table 5 shows results of Cox proportional hazards analysis of overall survival. In the analysis of all subjects, after adjusting for age, BMI, sex, and ethnicity, a higher MELD score, a Child-Turcotte-Pugh score of C, an initial Maddrey score > 32, abnormal renal function, and presence of hepatorenal syndrome were all associated with significantly higher hazards of death.

AH: Alcoholic hepatitis; MELD: Model for end stage liver disease; DF: Maddrey discriminant function is defined as DF = 4.6 x [prothrombin time (s) - control prothrombin time (s)] + (serum bilirubin in mg/dL)[11].

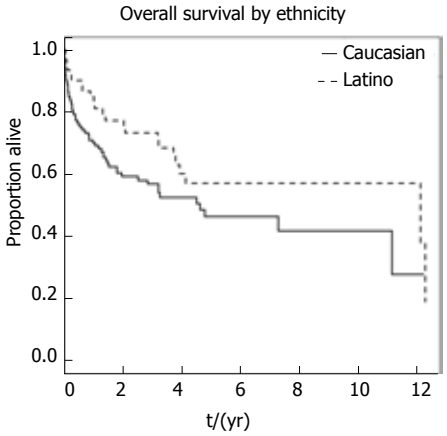

Figure 4 Survival by ethnicity. There was no significant difference in the median survival between ethnicities as shown on Kaplan-Meier Plot. The median survival in years between Latinos and Caucasians was not significantly different (12.1 yr *vs* 4.6 yr, *P* = 0.055).

In Latinos, after adjusting for age, BMI, and sex, a higher MELD score, a Child-Turcotte-Pugh score of C, an initial Glasgow score above 9, and the presence of hepatorenal syndrome were associated with significantly higher hazards of death. In Caucasian subjects, after adjusting for age, BMI, and sex, a higher MELD score, a Child-Turcotte-Pugh score of C, abnormal renal function, and presence of hepatorenal syndrome were associated with significantly higher hazards of death.

DISCUSSION

AH is an acute hepatic inflammation that usually occurs in heavy drinkers and is associated with significant morbidity and mortality in severe cases of up to 30%-50% at 6 mo[13]. Several previous studies indicated that Latino patients with ALD had earlier onset of disease and poorer prognosis compared to Caucasians[9] but specific data on ALD subtypes are lacking. The goal of the present study was to focus on a sample of Latino patients with AH followed at UC Davis Medical Center in Sacramento, California and describe any similarities and differences of AH in comparison to Caucasian patients, with the ultimate goal to identify specific needs and potential gaps in the care of this population. First, Latinos and Caucasians appeared to differ primarily in the duration of alcohol drinking, which was longer for the Latinos, and methamphetamine use, which was also more prevalent in Latinos. These findings are corroborated by previous large epidemiological studies showing that Mexican migrants in California presented a high prevalence of methamphetamine use associated with alcohol use and other psychiatric issues[14]. The two groups received similar medical treatment once admitted for severe AH. However, Latinos appear to present more frequently with manifestations of severe portal hypertension in association with more frequent utilization of the acute services but not ICU. Overall, these disparities did not seem to affect the survival of our studied Latino population. Several clinical studies

indicate that Latinos develop more severe liver diseases than other ethnicities and this has been confirmed in common conditions including ALD[9,15], non-alcoholic steatohepatitis[16], and chronic hepatitis C[17,18] or more rare diseases including primary biliary cholangitis[19]. In addition, Latinos might have an increased risk of hepatocellular carcinoma[20]. Ethnic matching between patients with alcohol-related injury or alcohol problems improved the effectiveness of the brief alcohol intervention on drinking outcomes of Latino patients, especially the foreign-born and less acculturated[21]. Our data indicate that, at least in our center, Latinos with AH are receiving similar inpatient medical management compared to Caucasians. It should be noted that only a small number of patients received treatment for severe AH during the studied period. This could be

related to the presence of contraindications to the use of steroids (for example active infections or GIB) or to the lack of proper diagnosis of severe AH by providers. The main issue regards the long term management of the complications of portal hypertension. Previous published data have shown that Latinos are more likely to visit the ED and are more often admitted through the ED for alcohol related issues[22]. Similarly, our study showed that Latinos present more frequently at the ED and are hospitalized more often compared to Caucasians for alcohol related issues, but also present more frequently severe complications of portal hypertension. This suggests a poor outpatient management of chronic complications of liver disease and inadequate access or use of outpatient clinics to receive preventive measures, including GIB prophylaxis with upper endoscopies and beta blockers, encephalopathy prophylaxis with lactulose, or prophylaxis with SBP when indicated. We did not observe any difference in survival between the two subpopulations and this may be in contradiction with the data showing worse outcome for Latinos with ALD. It is also interesting to note that the overall Latino population has better survival rate compared to Caucasians[23]. Our data reflect a small population in a highly diverse urban area but this initial data should help in identifying some of the major challenges in the care of underserved populations. Given the retrospective nature of the data collection and given the fact that is based on single center experience, we could not identify the actual background of the Latino population, which could be very heterogeneous.

This single retrospective study did not confirm previous findings that Latinos developed AH at earlier age compared to Caucasians[9]. In fact, there was no significant difference between the ages of presentation of AH between Latinos and Caucasians. Our study also suggested that there is no difference in the severity of AH at presentation and management between the ethnicities. On the other hand, this study showed Latinos had higher rates of complications associated with AH which include GIB, encephalopathy, and SBP. Latinos also had higher rates of AH recurrence. Interestingly, there was no significant difference in the overall mortality between ethnicities. In fact, Latinos may have better survival than Caucasians even though this is was not statistically significant in our study. Future research is needed to elucidate the effects of alcohol on Latinos and the predisposing factor that lead to the development of AH as well as the study of measures that can improve access to care and adequate outpatient follow-up for this underserved population.

ATRICLE HIGHLIGHTS

Research background

There are well known differences in the presentation of alcoholic liver disease (ALD) between Caucasian and Mexican-American patients. However, there are no ethnic-specific data on alcoholic hepatitis.

Research motivation

Alcoholic hepatitis is the most severe manifestation of ALD and is characterized by an inflammatory process of the liver with neutrophilic infiltration leading to ballooning degeneration of hepatocytes, hepatocyte necrosis, steatosis and presence of Mallory bodies. Alcoholic hepatitis clinic presentation is associated with jaundice, fever, hepatomegaly, liver tenderness, encephalopathy, and gastrointestinal bleeding. Ultimately, alcoholic hepatitis is characterized by a high risk of mortality. Latino and Caucasian patients with ALD and alcoholic hepatitis may have different progression and prognosis compared to other ethnicities.

Research objectives

The goal of the present study was to determine the clinical features of alcoholic hepatitis in Latino patients compared to Caucasian patients. The overarching goal is to optimize the care of patients of different ethnicities and identify their challenges when accessing medical care in the United States.

Research methods

The authors conducted a single-center retrospective chart review of 137 Caucasian patients and 64 Latino patients older than 18 years old diagnosed with alcoholic hepatitis. We collected extensive clinical data on their diagnosis, treatment, and outcome.

Research results

The major finding was a significantly higher rate of complications of portal hypertension including gastrointestinal bleeding, spontaneous bacterial peritonitis, and encephalopathy in Latino compared to Caucasian patients with alcoholic hepatitis. Despite these differences, the two ethnic groups did not present differences in survival. Future studies should prospectively confirm these findings in larger populations.

Research conclusions

According to our results, Latinos with alcoholic hepatitis presents with more severe complications of alcoholic hepatitis and appear to have limitations in access to medical treatment of long term complications of portal hypertension. Efforts should be made to ensure improved access to care and compliance.

Author contributions: All authors were equally involved in the design of the study; Chang conducted the statistical analyses; and all authors contributed equally in the interpretation of results and writing of the manuscript.

Supported by Novartis Pharmaceuticals, One Health Plaza, East Hanover, NJ 07936-1080, United States.

Institutional review board statement: We conducted a retrospective case-control study using the Truven Health Analytics MarketScan Database and the IMS Health PharMetrics Database, both commercial health insurance claims database for employer-insured beneficiaries in the United States. The databases are fully compliant with the Health Insurance Portability and Accountability Act and meet the criteria for a limited-use dataset. Since the patient and provider data included in this analysis were fully de-identified, this study was exempt from the Institutional Review Board review.

Informed consent statement: This study involved analyses of Health Insurance Portability and Accountability Act-compliant secondary databases, MarketScan and PharMetrics, thus no informed consent was feasible or necessary.

Conflict-of-interest statement: Cai is an employee of Novartis Pharmaceuticals Corporation. Broder, Chang, and Yan are employees of the Partnership for Health Analytic Research, LLC, which received funding from Novartis to conduct the researchdescribed in this manuscript. Metz is an employee of Northwestern University and was paid by Novartis to consult as a subject matter expert. Metz is Chair of the North American Neuroendocrine Tumor Society (NANETS) and also a consultant for Ipsen. Metz has received commercial research grants from Lexicon and Advanced Accelerator Applications (AAA), and is a consultant/on the advisory board for AAA.

Data sharing statement: The study statistician, Eunice Chang, conducted all statistical analysis for this study using Health Insurance Portability and Accountability Act-compliant commercial-insurance secondary databases MarketScan and PharMetrics.

Abstract

AIM

To discover unknown factors associated with carcinoid syndrome (CS) with the goal of earlier diagnosis of CS.

METHODS

In this retrospective case-control study using United States administrative claims, patients (⩾ 18 years) newly-diagnosed with gastrointestinal neuroendocrine tumors (GI NETs) without CS (controls) were exactly matched to patients with CS (cases) based on NET diagnosis date at a 3-to-1 ratio. Study index date was first CS diagnosis (controls: same distance from NET diagnosis as cases). The most observed conditions, excluding CS-associated symptoms/diagnoses, during the year before index date were assessed. Forward-stepwise logistic regression models were used to derive predictors, and were validation within another claims database.

RESULTS

In the development database, 1004 patients with GI NETs were identified; 251 (25%) had CS and 753 (75%) were controls. In the validation database, 724 patients with GI NETs were identified; 181 (25%) had CS and 543 (75%) were controls. A total of 33 common diagnoses (excluding conditions already known to be associated with CS) in the development database were entered in forward step-wise logistic regression models. In the final, validated logistic regression model, three factors prior to CS diagnosis were found consistently associated with higher risks for CS, including liver disorder [odds ratio (95%CI): 3.38 (2.07-5.51)], enlargement of lymph nodes [2.13 (1.10-4.11)], and abdominal mass [3.79 (1.87-7.69)].

CONCLUSION

GI NET patients with CS were 2-4 times as likely to have preexisting diagnoses (*i.e.*, liver disorder, enlarged lymph nodes, abdominal mass) than non-CS patients.

Key words: Carcinoid syndrome; Gastrointestinal neuroendocrine tumors; Predictive factors; Data mining

Core tip: By assessing patients with gastrointestinal neuroendocrine tumors from two independent United States claim databases, this study found that patients with carcinoid syndrome (CS) were 2-4 times as likely to have a preexisting diagnosis of a liver disorder, enlargement of lymph nodes, or abdominal mass than patients without CS.

INTRODUCTION

Neuroendocrine tumors (NETs), the most of common of which are carcinoid tumors[1], are characterized by a relatively indolent rate of growth and an ability to secrete a variety of peptide hormones. These tumors can be functional or non-functional and benign or malignant[1]. Even though NETs can develop anywhere in the body, the majority of them occur in the gastrointestinal (GI) tract (67.5%)[2]. Within the GI tract, sites of origin include the stomach, small intestine, appendix, and colorectum[2]. A 6-fold increase in the age-adjusted incidence of diagnosed NETs has been observed from 1.09 new cases per 100000 individuals in 1973 to 6.98 new cases per 100000 individuals in 2012[3,4].

One of the more common functional NET syndromes is carcinoid syndrome (CS), occurring in 8% to 35% of NET patients[5]. CS occurs when functional carcinoid tumors metastasize to the liver or outside the GI tract, and the vasoactive hormones secreted by metastases, such as serotonin, histamine, or tachykinins, are no longer metabolized and inactivated by the liver and reach the general circulation[6,7]. 5-hydroxyindoleacetic acid (5-HIAA), a product of serotonin metabolism of urinary excretion, is used as a first-line test for biochemical detection of suspected CS, in which 5-HIAA excretion is usually elevated[8]. CS includes an array of signs and symptoms. The classical manifestations of episodic flushing and diarrhea affect more than 80% of patients with CS[6]. Other signs include pellagra, wheezing, abdominal pain, telangiectasia and heart disease (usually right sided valvular regurgitation). The clinical presentation with diarrhea and/or abdominal pain dominating often leads to misdiagnosis of CS as irritable bowel disease or small bowel obstruction[9,10] especially in middle-aged perimenopausal females. Delays in the correct diagnosis are common; reports on median time from onset of symptoms to diagnosis range from 2 to 20 years[9].

Other than the typical signs associated with CS, there is limited knowledge on the existence of any other predictors that may be associated with the risk of developing CS. We conducted the current study in patients with GI NETs, the most common type of NETs, to describe factors associated with CS with the intention of assisting physicians with making an earlier diagnosis of CS.

MATERIALS AND METHODS

Data source

We conducted a matched case-control study using data from two large United States healthcare claims databases - IMS PharMetrics Plus and Truven Health Analytics MarketScan. We used IMS PharMetrics Plus as the development database to derive risk factors for CS and MarketScan databases to validate the factors for CS. We used data from 1/1/2009 to 12/31/2014 from both databases.

The PharMetrics Plus database comprises adjudicated

medical and pharmacy claims for approximately 150 million patients enrolled in United States health insurance plans, with an annual capture of 40 million. This database is representative of the United States commercially insured population for individuals under age 65 years. The MarketScan Research Database combines 2 separate databases-the Commercial Claims and Encounters database, and the Medicare Supplemental and Coordination of Benefits database. The commercial database contains the inpatient, outpatient, and outpatient prescription drug experience of about 40 million employees and their dependents, who are covered under a variety of fee-for-service and managed care health plans. The Medicare database contains the healthcare experience of about 3 million retirees with Medicare supplemental insurance paid for by employers. Both databases contain detailed cost, use, and outcomes data for inpatient and outpatient healthcare services. The medical claims are linked to outpatient prescription drug claims and person-level enrollment data through the use of unique enrollee identifiers. Both PharMetrics and MarketScan are Health Insurance Portability and Accountability Act compliant[11,12]. The study was exempt from review by an institutional review board

Study population

The study population consisted of patients who were new diagnosed with GI NETs during the identification (ID) period (1/1/2010-12/31/2014). We identified patients with at least one inpatient or two outpatient claims with International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes for any NET (209.xx.) Among these, patients who had ICD-9-CM codes for GI NET (209.0, 209.1, 209.2, 209.4, 209.5, and 209.6) as the most frequent NET codes were classified as GI NET. To ensure that patients were newly diagnosed, we excluded patients with GI NETs during the 1-year prior to the first diagnosis date. We excluded patients with pancreatic NETs and Merkel cell carcinoma at any time during the study period.

We matched patients with GI NETs without CS (controls) to patients with CS (cases) based on the diagnosis date (month and year) of the first GI NET diagnosis at a 3-to-1 ratio. For cases, the index date was the first CS diagnosis date. For controls, the index date was assigned to have the same distance from the date of first NET diagnosis as the matched case patients. All patients were required to have at least 1-year continuous enrollment prior to the index date (study baseline).

The algorithm used to identify cases was developed based on a series of analyses performed before undertaking the main study. First, we examined overall prevalence of CS and the distribution of all NET locations (*e.g.*, GI, lung, pancreas) in patients with a CS by identifying cases using a diagnosis (ICD-9-CM code 259.2) and found it did not match the expected distribution. Specifically, we found that 6% of patients with pancreatic neuroendocrine tumor (PNET) had at least two claims with a code for the CS, as did 23% of patients with GI NET. We suspected that the diagnosis code was being applied at an early point in the diagnostic process (*e.g.*, as a "rule out"). We tested the application of more stringent criteria, which required two claims with ICD-9-CM code 259.2 and either a urine 24-h 5-HIAA [Current Procedural Terminology (CPT) code: 83497] or a serum serotonin (CPT code: 84260). In addition, the tests must have been ordered in the period 3 mo before or 3 mo after the CS diagnosis. This stricter algorithm resulted in only 1% of patients with PNET and 11% of GI NET being identified as having CS. As a result, we used the 2 CS diagnosis plus testing algorithm to identify cases with CS for this study.

Patient demographic characteristics included age in years on index date, sex, and geographic region (Midwest, Northeast, South, and West). Clinical characteristics included Charlson Comorbidity Index[13,14], and number of chronic condition indicators [15].

The outcome of interest in this study was the presence of CS.

Statistical analysis

We performed descriptive analyses to assess differences between case/control cohorts and patient demographic and clinical characteristics. χ^2 tests were used for categorical variables and two sample *t*-tests were used for continuous variables.

Data mining is a process of selecting, exploring and modeling large amounts of data in order to discover unknown patterns or relationships that provide a clear and useful result[16]. We used data mining to explore unknown factors associated with CS. Specifically, using the development database (PharMetrics Plus), we assessed the top 50 most frequently observed conditions (based on CS patients) other than symptoms/diagnoses known to be associated with CS during the 1 year prior to the index date. We eliminated conditions or symptoms already known to be associated with CS, those related to screening or health maintenance, other GI cancers, and factors occurring in < 10% of both case and control groups. We began the multivariate analysis by forcing demographics and two general comorbidity measures (Charlson Comorbidity Index and number of chronic conditions) into the model. We used forward-stepwise logistic regression to estimate, for each condition in the final model, the extent to which a patient who went on to be diagnosed with CS would have greater odds of having the condition than a patient who went on to be diagnosed with NET, but not CS. In the forward selection, significant factors ($P < 0.05$) from the list of conditions referred to above were retained. Demographic or comorbidity measures were removed from the final model if they were highly

insignificant ($P \geqslant 0.1$). To validate these predictors, we re-ran the model with completely independent data from another administrative claims database (Truven MarketScan).

RESULTS

Descriptive statistics

Of the 23815 NET patients identified from the IMS PharMetrics Plus, the development database, we excluded 23310 patients who did not meet the inclusion criteria, such as enrollment, age, and definition of CS. Of the 505 patients who met the study selection criteria 251 were GI NET patients with CS (cases) (Figure 1). These 251 cases along with the 753 matched controls (GI patients without CS) were included in the final analytic sample in the development database. Case patients were slightly younger than control patients (mean ± SD: 52.8 ± 10.9 years *vs* 54.4 ± 13.3 years; $P = 0.06$). The majority of patients were in the 55-64 age range for both cohorts (37.5% in CS cohort; 34.1% in non-CS; $P = 0.04$). There were no significant differences in sex, region, and number of chronic conditions between the two cohorts (Table 1).

In the validation database 724 patients with GI NETs were identified, among whom 181 (25%) had CS and 1158 (75%) were controls (Table 1). The mean (SD) age in the CS cohort was 51.8 (9.33) years, compared to 51.7 (10.03) years in the non-CS cohort. There were no significant differences in age, sex, and region (Table 1). With this approach, we identified a total of 33 most common conditions in both CS and non-CS cohorts (Table 2) of the development database for further assessment. In both cohorts, abdominal pain (66.1% of CS cohort; 51.5% of non-CS cohort), hypertension (50.6%; 52.2%), and dyslipidemia (49.4%; 46.1%) were the most prevalent diagnoses (Table 2).

Multivariable analysis

Eight of the 33 common diagnoses tested remained significant in the forward step-wise logistic regression models and were further validated using the validation database (Table 3). In the final, validated logistic regression model, three factors were associated with higher risks for CS, including liver disorder [odds ratio (95%CI): 3.38 (2.07-5.51)], enlargement of lymph nodes [2.13 (1.10-4.11)], and abdominal mass [3.79 (1.87-7.69)] (Table 4).

DISCUSSION

By assessing patients from two independent United States claim databases, this study suggested that in patients with proven GI NETs, patients with CS were 2-4 times as likely to have a preexisting diagnosis of a liver disorder, enlargement of lymph nodes, or abdominal mass than patients without CS.

Among patients with NETs, preexisting enlarged lymph nodes, abdominal mass lesions, and a liver disorder seem to jointly indicate increasing tumor burden, which implies that tumor progression may be associated with a higher risk of developing CS. Although there is no obvious clinical explanation for these findings, we propose the following two considerations: first, patients with CS have a larger systemic tumor bulk at diagnosis than patients who do not manifest CS, implying that increasing tumor burden correlates with increasing tumor products, which in turn led to the syndrome; and second, that patients with CS have more aggressive tumors than those without CS, which leads to more rapid growth of tumor and a larger burden of disease when diagnosed. The first consideration appears less likely since patients with small strategically located tumors (*e.g.*, the ovary or lung) commonly present with CS prior to large bulky liver disease developing. On the other hand, it is well known that patients with CS have a poorer quality of life and outcome than those without CS suggesting that the latter explanation is more likely. To the best of our knowledge, this is only the second study assessing distinctions between CS and non-CS patients. The only other study we could identify in the existing literature is a recent study by Halperin and colleagues[17] that used SEER-Medicare data to assess the clinical factors that may be associated with CS specifically. They found that their CS cohort included more patients with regional and distant metastases, while their non-CS cohort included more patients with local disease; for each distinct site of tumor origin, the percentage of CS increased with tumor progression. In the aforementioned study, CS was also associated with shorter survival compared without patients without CS, further supporting the second explanation for our findings[17]. Of note, our findings extend Halperin's data in that we have now identified three specific predictors of the CS that can be used to direct physicians to specifically consider CS over a more general diagnosis of NET, and to monitor those patients more closely by 5-HIAA or serum serotonin testing In our study, we matched the CS and non-CS cohorts on duration of disease as carefully as possible, knowing that one of the limitations of using claims databases for research is that the precise diagnosis date is not the true date of tumorgenesis. Consequently the duration between the first NET diagnosis and first CS diagnosis was the best proxy for disease duration that we could use. Conditional on the reliability of this proxy, our findings suggest that patients who were eventually diagnosed with CS tended to have additional diagnoses indicating tumor advancement, compared with the non-CS patients who had the same duration of disease.

In general, early diagnosis of cancer can improve quality of life and survival[18]. Patients with CS have a significantly worse quality of life than patients with

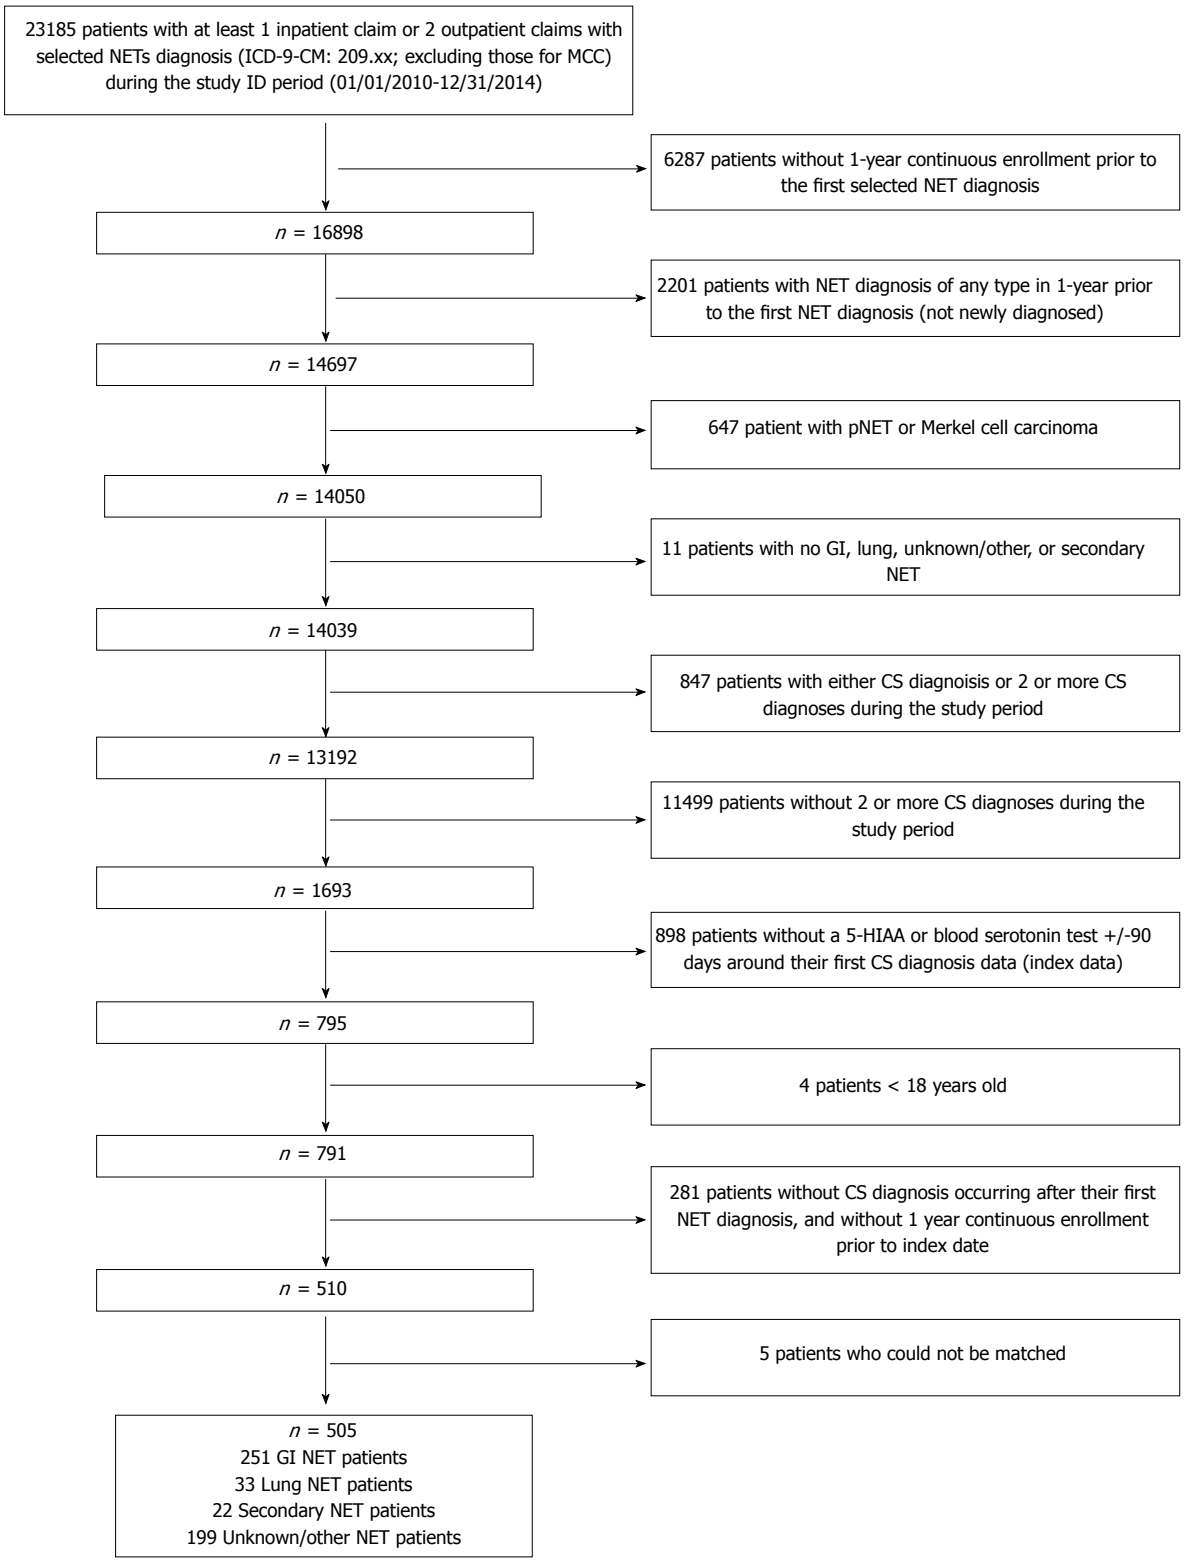

Figure 1 Patient identification. There were 23185 patients with at least one inpatient claim or two outpatient claims with selected NETs diagnosis (ICD-9-CM: 209.xx; excluding those for MCC) during the study ID period (01/01/2010-12/31/2014) in the development database. After excluding patients who were not newly diagnosed and did not have a NET diagnosis of interest; did not have 2 or more CS diagnosis during study period; did not have a 5-HIAA or blood serotonin test +/-90 days around their first CS diagnosis date (index date); were < 18 years old; did not have CS diagnosis occurring after their first NET diagnosis; could not be matched; or were not continuously enrolled in the 1 year pre-index period, there remained 505 NET patients who met the study inclusion criteria. Out of these, 251 were GI NET patients with CS. GI NETs: Gastrointestinal neuroendocrine tumors; CS: Carcinoid syndrome; 5-HIAA: 5-hydroxyindoleacetic acid.

NETs but without CS[19]. Therefore, reducing delays in diagnosis may help improve quality of life in CS. In addition, our findings indicate that the poorer quality of life among patients with CS may also be a composite result of both tumor progression and CS symptoms, as the CS patients also tended to have more advanced

tumor. Therefore, therapy for CS patients should address both symptom control as well as tumor progression to maintain quality of life.

In addition, we find it rather curious that there were no gender differences in our study. Since flushing is a common symptom of the CS, and since flushing is often confused with the hot flashes of menopause, one might have expected males with CS to be diagnosed earlier than females if the propensity is to misdiagnose CS until the disease is well established (with a known liver disorder, abdominal mass or lymphadenopathy). On the other hand, the delay in identifying CS in NET patients may simply be because flushing is not often sought out by physicians when interviewing patients. Indirectly then, these data suggest that educating physicians about the unusual manifestation of CS may help lead to an earlier diagnosis. The gender equivalence in our study may also be evidence that our algorithm for identifying CS, which required the presence of 5-HIAA or serotonin test around the diagnosis date, was reasonably specific for the condition, so that we minimized the misdiagnosed CS in our CS cohort by requiring this criterion for diagnosis.

Our study had limitations. First, GI NET and CS diagnoses were identified from healthcare claims coded for reimbursement, not research, and misclassification was possible. Errors in coding could bias our analysis. Specifically, patients with CS who have less severe symptoms may never be coded as having the syndrome. Nevertheless, health insurance claims data remain a valuable source of information as they constitute a fairly valid, large sample of patient characteristics and outcomes in a real-world setting. A strength of this study was that it was drawn from two very large underlying databases covering nearly 200 million patients enrolled in United States health insurance plans. The rate of CS among GI-NET patients in our study was higher than in some prior studies[20], and it was lower than at least one other[17]. The criteria we used to identify CS were more restrictive than the study by Halperin *et al*[17]. Current recommendations for diagnosing CS include measuring 5-HIAA[1,21]. We incorporated that recommendation into our identification algorithm, requiring two claims with an ICD-9-CM code for CS and a claim for either a urine 24-hour 5-HIAA or a serum serotonin in the period surrounding that diagnosis, whereas the prior study required two claims for CS, diarrhea, or flushing. Second, because ICD-9-CM codes may be inaccurate, we were not able to identify the specific anatomic location (*e.g.*, portion of large or small bowel) of the GI NET in our study. This could lead to confounding. For instance, small bowl NETs are more commonly associated with CS than large bowel tumors, and previous studies have suggested that hepatic and lymph node metastasis are usually present at time of small bowel NET diagnosis[22]. If our CS cohort systematically includes more small bowel patients than the non-CS cohorts, and the small bowel patients tend to be more advanced at diagnosis, this could explain why we see that CS patients were more likely to have this diagnosis. However, due to the lack of specificity of ICD-9-CM codes, we cannot confirm the anatomic section of the GI tract in which the tumor was identified. Therefore, we could not validate if small bowel NETs may present at a more advanced stage than other NETs based only on the data from a claims database. A study in a data source where the exact location of the tumor could be identified with confidence would be very useful to confirm our findings. Third, our results are reflective of a commercially-insured population, but may not be generalizable to patient populations with other insurance types.

In summary, our study suggests that a liver disorder, enlargement of lymph nodes, or an abdominal mass is associated with higher risk of a future CS diagnosis. There are two aspects with regards how this finding may be applicable to a real world clinical setting. First, CS develops insidiously, and patients who grow accustomed to their syndromic features such as flushing may not think of reporting these symptoms, even when prompted. If physicians are not aware of the presence of CS symptoms in their patients, our findings offer additional signs to prompt them to inquire specifically.

Table 2 Patients with gastrointestinal neuroendocrine tumors: Most frequent diagnoses1 in carcinoid syndrome patients, ordered by prevalence in carcinoid syndrome cohort *n* (%)

Diagnosis description	No. of patients		Difference in Rate (CS-Non-CS)	Relative Risk (CS *vs* Non-CS)
	CS cohort *n* = 251	Non-CS cohort *n* = 753		
Abdominal pain[2]	166 (66.14)	388 (51.53)	14.61%	1.28

[1]Variables found consistently significantly associated with risk of CS are bolded; [2]Liver disorder includes other specified disorders of liver (ICD-9-CM 573.8x, 573.9x). CS: Carcinoid syndrome.

Second, patients with a liver disorder, enlarged nodes, or abdominal mass may also not yet have clinically detectable CS symptoms, but may be destined to develop them in the future. In this context, our data suggest that in a patient with NET, even in the absence of typical symptoms, if one of these three findings is noted, consideration should be given to ordering a 5-HIAA or serotonin level. Although validation studies using patients' medical charts are warranted, such a practice could potentially aid physicians in speeding the diagnosis of CS.

ATRICLE HIGHLIGHTS

Research background

Functional neuroendocrine tumors (NETs) have the ability to secrete hormones that may cause carcinoid syndrome (CS), the most common symptoms of which include flushing and diarrhea. Carcinoid syndrome occurs in 8% to 35% of NET patients. Delays in diagnosis of CS are common, ranging from 2 to 20 years. Little is known about predictors that might be related the risk of developing CS.

Research motivation

Patients with CS often face delays in getting the correct diagnosis. Their symptoms, such as diarrhea, are often mistaken for other diseases, such as irritable bowel disease. Finding risk factors that are associated with CS might help physicians with making an earlier diagnosis of CS.

Research objectives

The objective was to identify risk factors that are associated with a future CS diagnosis.

Research methods

The authors conducted the study using data from two large United States health insurance claims databases. These databases contain healthcare cost, use, and outcomes data for covering nearly 200 million insured Americans. We first identified patients newly diagnosed with gastrointestinal NETs between 2010 and 2014 and then compared patients with CS to those without CS. We performed statistical analyses to identify the risk factors associated with CS from one databased and then validated the results using the other database.

Research results

The authors identified 251 patients with CS and 753 without CS in one database, and 386 patients with CS and 1158 patients without CS in the other database. There were no significant differences in age, sex, and region between patients with CS and those without CS. In both databases, we found that CS patients were 2-4 times more likely than non-CS patients to have a diagnosis of liver disorder, enlargement of lymph nodes, or abdominal mass within 1 year prior to their CS diagnosis.

Research conclusions

This study suggests that diagnosis codes of liver disorder, enlargement of lymph nodes, or an abdominal mass are associated with higher risk of a future CS diagnosis. In a patient with NETs, even in the absence of typical symptoms, if one of these three conditions is noted, consideration should be given to ordering a test for CS. Such a practice could potentially aid physicians in speeding the diagnosis of CS.

Abstract

AIM

To determine the prevalence of Epstein-Barr virus (EBV)-associated gastric carcinomas in the North Region of Portugal and to study its clinicopathological characteristics.

METHODS

We have performed a retrospective study including a total of 179 consecutive patients with gastric cancer (GC) submitted to gastrectomy during 2011 at the Portuguese Oncology Institute of Porto. Clinical and pathological data was collected from individual clinical records and inserted on a database with unique codification. Tumour tissues were collected from the institutional tumour bank. EBV was detected by *in situ* hybridization for the detection of EBV-encoded small RNAs (EBERs) and EBV latent proteins (LMP1 and LMP2A) were detected by immunohistochemistry.

RESULTS

The analysis showed that EBV-associated gastric carcinomas (EBVaGC) represents 8.4% (15/179) of all GC cases, with a significant differential distribution among histological types ($P < 0.001$): 100% (3/3) of medullary carcinomas, 100% (1/1) of adenosquamous carcinoma, 8.7% (8/92) of tubular adenocarcinomas, 8.0% (2/25) of mixed carcinomas and 2% (1/51) in poorly cohesive carcinomas. The analysis revealed a higher predominance of EBVaGC in the upper third and middle (cardia, fundus and body) of the stomach ($P = 0.041$), a significant lower number of regional lymph nodes invasion ($P = 0.025$) and a tendency for better prognosis ($P = 0.222$). EBV latent protein expression revealed that all EBVaGC cases were LMP1-negative, nevertheless 6 cases (40%) expressed LPM2A, which reveals that these cases show a distinct EBV-Latency profile (latency II-like).

CONCLUSION

EBVaGC represents 8.4% of all GC in the North Region of Portugal. The EBV-infected patients have specific clinic-pathological features that should be further explored to develop new strategies of management and treatment.

Key words: Gastric cancer; Epstein-Barr virus; Prevalencel; Epstein-Barr virus-associated gastric carcinomas

Core tip: This is the first study to report the prevalence of Epstein-Barr virus (EBV)-associated gastric carcinomas (EBVaGC) in Portugal. The EBVaGCs were found in 8.4% of all gastric cancer cases, being more frequent in upper and middle regions of the stomach and among tubular and medullary carcinomas. Patients with EBV-positive tumours also have a significant lower number of regional lymph nodes with metastasis and a tendency for a better prognosis.

Clinical and pathological characterization of Epstein-Barr virus-associated gastric carcinomas in Portugal. *World J Gastroenterol* 2017; 23(40): 7292-7302 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7292.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7292

INTRODUCTION

Gastric cancer (GC) is the fifth most common malignancy worldwide with nearly one million new cases estimated in 2012 (952000 cases) and despite the significant reduction of its incidence, GC still remains the third leading cause of death by cancer[1,2]. Portugal is one of the European countries with the higher GC incidence and mortality rates, where GC represents the fifth most common cancer with about 3000 new cases per year and with 1387 deaths in men and 898 in women[1,2].

Epstein-Barr virus (EBV) is one of the most common viruses and has been associated with several malignancies including Burkitt's Lymphoma, Hodgkin Lymphoma, post-transplant lymphoproliferative disease, a subset of T/NK cell lymphomas and nasopharyngeal carcinoma[3]. Recently, EBV has been associated with the development of GC, with several reports pointing that E BV-associated GC (EBVaGC) might account for nearly 10% of all GC cases[4,5]. The mechanisms of EBVaGC carcinogenesis are not well understood although some authors have suggested that EBV infection can represent a late event after *Helicobacter pylori* (*H. pylori*) infection[6,7].

The presence of EBV in patients with gastric carcinoma was first reported in gastric lymphoepithelioma-like carcinomas (also classified as medullary

carcinomas, gastric carcinomas with lymphoid stroma or uncommon variant), nevertheless it has been detected in different histopathological subtypes of gastric carcinoma[8,9]. The majority of GC are adenocarcinomas and are classified according to the Lauren or World Health Organization (WHO) classification system[10]. These classification systems have a reduced clinical utility and recent studies suggested a new classification based on molecular features of tumours, where EBVaGC arises as a new subtype of gastric cancer[11,12].

Despite the high incidence of both GC and EBV infection prevalence in the Portuguese population, there are no studies reporting the prevalence of EBVaGC in Portugal[2,13]. We aimed to determine the prevalence and characteristics of EBVaGC and analyse the profile of EBV latent proteins expressed in gastric tumours from the North Region of Portugal.

MATERIALS AND METHODS

Study description

We have developed a retrospective study in a cohort of 179 consecutive patients diagnosed with gastric cancer and submitted to surgery at the Portuguese Institute of Oncology of Porto (IPO Porto FG EPE) in 2011. Inclusion criteria: (1) patients with histologically confirmed gastric cancer; (2) submitted to gastrectomy (total or partial); and (3) with representative tumour blocks for adequate evaluation of EBV presence.

All tumour samples were histologically examined by a senior pathologist and classified according to the WHO classification system[10,14]. All clinical and pathological data was collected from individual clinical records and inserted on a database with unique codification. TNM-staging was performed in accordance to the UICC/AJCC system 7th edition[14]. The clinical outcome of the patients was followed from the date of surgery to either the date of death or 1st August 2016. All procedures were approved by the Ethical Committee of IPO Porto (CES IPO 80/2014).

EBV detection

The presence of EBV infection was investigated in all patients using histological sections (3 μm slides) obtained from formalin-fixed paraffin-embedded (FFPE) tissue blocks. EBV was identified using the *in situ* hybridization (ISH) for the detection of EBV-encoded small RNAs (EBERs) in FFPE tissue samples. The ISH was performed using Epstein-Barr virus Probe/Antibody ISH Kit (Leica, Newcastle upon Tyne, United Kingdom) in association with Ultra Vision Large Volume Detection System Anti-Polyvalent, HRP (THERMO SCIENTIFIC, Fremont, United States) according to the manufacturer's instructions. Detection of hybrids is achieved by enzymatic reaction using the *ImmPACT™ DAB* Peroxidase Substrate (VECTOR, Burlingame, CA, United States).

Only gastric tumours with presence of EBV infection in neoplastic cells were considered EBVaGC. For quality control, all EBV-positive cases and 10% of EBV-negative cases were retested and the results were 100% concordant. FFPE samples from a known EBV-positive post-transplant lymphoproliferative disorder (PTLD) tissue were used as positive controls and a sense probe for EBERs were used as the negative controls.

EBV latent proteins analysis

The presence of latent membrane protein 1 (LMP1) and latent membrane protein 2A (LMP2A) were evaluated with specific monoclonal antibodies in EBERs-positive gastric tissues using immunohistochemistry (IHC) (Table 1). IHC was performed using the UltraVision Large Volume Detection System Anti-Polyvalent, HRP kit (THERMO SCIENTIFIC, Fremont, United States) and the signal was detected using the *ImmPACT™ DAB* Peroxidase Substrate (VECTOR, Burlingame, CA, United States). All procedures were realized according to the manufacturer's instructions. PTLD samples with known positivity for LMP1 and LMP2A were used as positive controls. Gastric tumours were considered positive if 10% or more of the neoplastic cells were stained.

Statistical analysis

Statistical analysis was performed using the computer software IBM SPSS statistics for Macintosh, version 20.0 (IBM Corp, Armonk, NY, United States). χ^2 or Fisher Exact-test was used to compare categorical variables, with a significance level of 5%. Overall survival was defined as the time between the date of surgery to the date of last follow-up (censored) or the date of patient death (event). Cases lost to follow-up and those ending in death from any cause other than gastric cancer were regarded as censored data during the analysis of survival rates. The differences in survival times between subgroups were calculated using the log-rank test and the Kaplan-Meier method was used to calculate survival probabilities.

RESULTS

Characterization of the study population

The clinicopathological characteristics of all patients are described in (Table 2). A total of 179 patients (108 males and 71 females) with mean age of 64 ± 12 were included in this study; the majority were submitted to gastrectomy (n = 177), wherein 100 were total resections and 77 partial resections, and the remaining 2 patients were submitted to esophagogastrectomy. Regarding the tumour localisation in stomach: 26 (14.5%) were found in the upper third (cardia or fundus); 46 (25.7%) in the middle region (body); and 107 (59.8%) in lower third (antrum or pylorus).

Tumours were classified according to WHO (2010) classification system and the most common

histological type was tubular adenocarcinoma (n = 92, 51.4%) followed by poorly cohesive carcinoma (n = 51, 28.5%), mixed carcinoma (n = 25, 14%) and less frequent were mucinous adenocarcinoma (n = 5, 2.8%), papillary adenocarcinomas (n = 1, 0.6%), undifferentiated carcinoma (n = 1, 0.6%), adenosquamous carcinoma (n = 1, 0.6%) and medullary carcinomas with lymphoid stroma (n = 3, 1.7%) (Table 2). The correlation of histological type with anatomic localisation (data not shown), revealed that tubular type can be found in any stomach region, being more frequent in the lower third (56.5%) followed by upper and middle regions with 20.8% and 20.7%, respectively; poorly cohesive carcinomas were also more frequently located in the lower third (84.3%) and only 11.8% and 3.9% were in the middle and upper third, respectively; mixed adenocarcinomas were also more prevalent in lower third of the stomach with 72% of cases located in this region, with 16% in the middle and 12% in the upper region; and medullary carcinomas showed a similar distribution throughout the stomach with a percentage of 33.3% in all regions.

Regarding the characteristics of tumours, the most frequent invasion pattern was infiltrative (52.7% *vs* 46.1% expansive); the majority were poorly differentiated (54.5% *vs* 45.5% well or moderate differentiated); and lymphovascular invasion was extremely frequent (57.5% *vs* 42.5%) (Table 2). The tumour staging revealed that the majority of cases (63.8%) were at Stage III and IV and in only 6.7% of all cases presented distant metastasis.

Regarding survival analysis, the median overall survival was of 45 mo (mean 36 ± 20.5; range 1-63). Furthermore, we observed that lymph node metastasis (N), lymphovascular and perineural permeation and infiltrative tumours had a significantly reduced median overall survival (P < 0.001) (Figure 2A, B, C and D).

Characterization of EBVaGC

In our series, out of the 179 patients with GC, fifteen patients (8.4%) were positive for EBV - (Table 2). All EBV positive cases showed EBER positivity staining in > 90 of tumour cells while it was not observed in normal mucosa with or without atrophic gastric, intestinal metaplasia or in stromal cells (endothelial cells and fibroblasts) (Figure 1). In addition, one case showed EBER positivity only in the lymphocytic infiltration but not in tumour cells and therefore it was classified as EBV-negative GC.

Despite no statistical differences, it was observed that EBVaGC is more frequent in males (11.1% *vs* 4.1% in females) and among patients with more than 65 years old (10.1% *vs* 6.7% in younger patients) (Table 2). EBVaGC were not equally distributed among the stomach localisation (P = 0.087), being more often found in upper third and middle of the stomach than in the lower third; and regarding the anatomical site, it was more frequent (P = 0.041) in the body and fundus regions (40.0% and 13.0%, respectively) (Table 2).

Results have revealed statistical significant differences (P < 0.001) when comparing the distribution of EBV among different histological types according to WHO classification: EBV was detected in 8.7% (8/92) of tubular adenocarcinomas, 8.0% (2/25) of mixed carcinomas and only 2.0% (1/51) of poorly cohesive carcinomas. The results have also shown that all medullary (n = 3) and adenosquamous carcinomas (n = 1) were EBVaGC, while no EBV-positive case was identified in papillary adenocarcinomas and undifferentiated carcinomas (Table 2). The analysis of the invasion pattern of the GC, revealed that tumours with expansive patterns have a higher prevalence of EBV when compared with infiltrative patterns (13.0% *vs* 5.7%, respectively), despite not statistically significant (P = 0.237) (Table 2). No significant differences were also observed regarding the tumour differentiation and lymphovascular invasion (P > 0.050).

The results show that EBVaGCs were associated with a low number of regional lymph nodes invasion (P = 0.024) and that all cases had no evidence of distant metastasis, nevertheless there was no evidence of association with tumour stage (P = 0.289). Additionally, comparing the number of lymph nodes with metastasis between EBVaGCs and EBV negative cases, it was observed that EBVaGC cases have a significant lower number (mean difference of 3.7; 95%CI: 1.8-1.5; P < 0.001).

Table 3 resumes the individual characteristics of EBVaGC cases. Briefly, of the 15 EBVaGC cases 12 were males and 3 females with a mean age of 66 years old (range 44-82). Anatomically EBVaGCs were found in the body (n = 6), antrum (n = 4), fundus (n = 2), cardia (n = 2) and pylorus (n = 1). Regarding the histological subtypes, 8 were tubular adenocarcinoma, 3 were medullary carcinoma, 2 mixed carcinoma, 1 poorly cohesive carcinoma and 1 adenosquamous carcinoma. The invasion pattern showed that the majority of cases were expansive (n = 10/15) and regarding the differentiation, cases were equally distributed as poorly and moderately differentiated (n = 7 each). Moreover, there was no EBVaGC with distant metastasis.

The survival analysis revealed that despite not statistically significant, EBVaGC patients have a higher overall survival (41 ± 1.8 mo *vs* 46 ± 5.9 mo, P = 0.222) (Figure 3).

EBV latent proteins expression

Immunohistochemistry results revealed that all of EBVaGC cases were negative for LMP1 while 6 cases (40%) were positive for LMP2A and one case was inconclusive (Table 3). The positive cases for LPM2A expression were randomly distributed among histological subtypes: tubular adenocarcinomas (n = 2),

mixed carcinomas (n = 2), medullary carcinomas (n = 1) and adenosquamous carcinoma (n = 1) (Table 3).

DISCUSSION

Gastric carcinoma is a serious public health problem worldwide with high rates of mortality and Portugal has the highest gastric cancer mortality rates in Western European countries[2,15]. The impact of classification systems in GC clinical decisions has been reduced and more recently two studies suggested a new classification based on molecular features of gastric tumours[11,12]. In this new classification arises four new subtypes of gastric cancer: Epstein-Barr Virus positive tumours (EBVaGC); microsatellite unstable tumours; genomically stable tumours; and tumours with chromosomal instability (CIN)[11,12].

Over the past 30 years, EBV infection has been reported in gastric cancer tumours[16]. Currently, it is accepted that about 10% of all GC represents a specific subset of gastric carcinomas that are associated with EBV carcinogenesis[17]. The gold-standard method for the detection of EBV in tissues is EBER-ISH and the decision to accept one case as EBV-associated should be taken considering the presence of EBERs expression in tumour cells and its absence in the normal surrounding tissue. In our study we found that 8.4% of GC in our population are EBV-associated, based on the EBERs expression in > 90 of tumour cells and its absence in non-malignant or stromal cells. To the best of our knowledge, this is the first study reporting the prevalence of EBVaGC in the North Region of Portugal. The prevalence found in our population is in line with those reported in other studies, which have reported a prevalence ranging 2%-20%[5,8,18]. Similar data was found in other countries from Europe, including Netherlands (7.8%)[18], and Denmark (7.6%)[19] and also from Asiatic countries, such as South Korea (7.8%)[20] and Japan (8%)[21]. Geographic differences have been discussed as a possible reason for the variation of EBVaGC prevalence[8,22] and some studies suggest that EBVaGC prevalence might be inversely correlated with the background incidence of GC[4]. The fact that Portugal has a higher incidence of GC

when compared to other European countries seems to indicate that other factors apart from geography may be influencing the distribution of EBVaGC. Indeed, data from different meta-analyses have failed to show this association[8,22].

We found that EBVaGC was more frequent in males

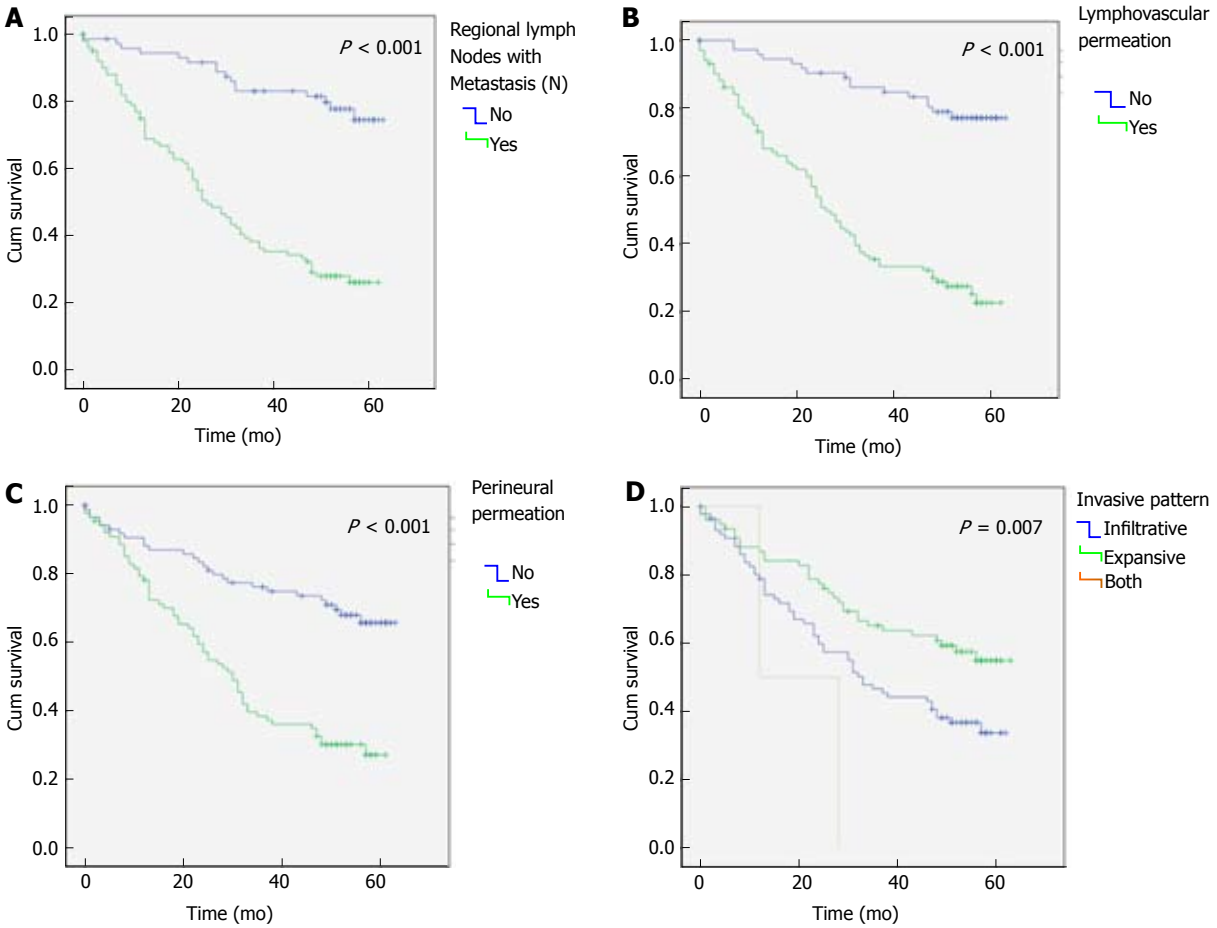

Figure 2 Kaplan-Meier survival curves for overall survival. Comparison of overall survival in gastric cancer patients considering: A: Regional lymph node metastasis; B: Lymphovascular permeation; C: Perineural permeation; and D: Invasive pattern.

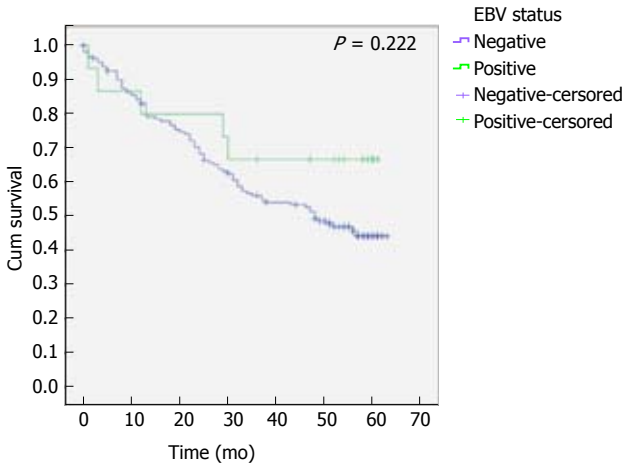

Figure 3 Comparison of overall survival in patients with Epstein-Barr virus-associated gastric carcinomas and Epstein-Barr virus-non associated gastric cancer. than in females, which is in line with several studies and suggests an association with others factors, such as life style or hormonal risks[23-25]. In contrast with other reports, we have found no association between EBV status and patients' age[8,26]. Regarding the tumour location, our study revealed a higher predominance of EBVaGC in upper third and middle of stomach and considering that *H. pylori* preferentially colonises the antral region, these results suggest a possible antagonism of EBV and *H. pylori* in gastric mucosa[27-29]. In fact, Minoura-Etoh *et al*[30] described in an *in vitro* study that reactive products from *H. pylori* seem to induce EBV reactivation from latently in infected gastric epithelial cells, which would avoid EBV transformation of gastric cells in the same areas of *H. pylori* colonization. Despite this association remains unclear, two recent studies have suggested that *H. pylori* may contribute for EBV-associated gastric carcinogenesis by recruiting to gastric tissue the inflammatory cells that are already infected by EBV in the majority of adults[7,31]. This mechanism is not well understood and further studies should be made to establish if the recruitment of EBV-infected lymphoid cells might be the explanation for the infection and subsequent transformation of gastric epithelium. In our series, all EBVaGC cases had EBV only in tumour cells and not in normal tissues, nevertheless, we have

found one case with EBV only in the lymphocytic infiltration, which we considered negative for EBV, and therefore more studies are required to understand if in such cases tumour cells will be later infected by EBV.

The association between EBV and gastric histological types remains controversial, indeed while one meta-analysis regarding EBV in gastric carcinoma has shown that EBVaGC was associated with diffuse histological type according to Lauren classification[5,8], two other meta-analyses did not find any association between EBV and histology subtypes[22,32]. Several studies demonstrated a strong EBV association with diffuse type while others have reported a similar prevalence between intestinal and diffuse types (classified in our study as poorly cohesive according to the WHO)[9,18,33,34]. Our study revealed that EBVaGC are more frequently associated with specific histologic subtypes. EBVaGC represent about 8% of tubular (intestinal type in the Lauren classification system) and mixed types while it was only found in 2% (n = 1/51) of poorly cohesive carcinomas (diffuse type in the Lauren classification system). These distinct features show that the differences in the GC histological distribution among different populations may impact on the prevalence of EBVaGC subtype, which should gather importance on the detection of EBV in GC. As expected, all medullary carcinomas, also known as gastric carcinoma with lymphoid stroma or lymphoepithelioma-like gastric carcinoma, were EBV positive[35]. In fact, EBV association with gastric cancer was first described in lymphoepithelioma-like gastric subtype and the literature shows that more than 80% of these cases are EBV-positive[5,22,36].

Some studies have revealed that EBVaGC is associated with poor or moderate differentiation of gastric cancer tissues[9,24]. In accordance with these reports, our study showed that 100% of cases were poorly or moderately differentiated and that these differentiation patterns seem to be associated with the histological types. This evidence may be a significant mark of EBVaGC tumours and may provide important information regarding the clinical approach to these tumours.

All these data support the evidence that recent studies have shown by considering EBVaGC as a distinct clinicopathological entity due to its individual features[11,12,18,37]. Interestingly, we found that EBVaGC had a significantly lower number of regional lymph nodes with metastasis and that none have a distant metastasis. Additionally, when analysing the overall survival of EBVaGC compared to all other cases it was observed that EBVaGC seems to have an improved survival, that despite not statistically significant may be explained by the low number of cases in our population. Several studies have reported a better overall survival of EBVaGC, especially in Asiatic populations suggesting that the explanation for this better overall survival could be due to the low

frequency of lymph node involvement and distant metastasis[18,23,24,38]. In Portugal, GC remains at high mortality rates due to the late diagnosis of this disease and these patients are frequently only treated with chemo/radiotherapy. In our study we have included only patients with available tissue sample from surgical procedures and therefore we had not included patients that had received only chemo/radiotherapy, therefore our findings should be applied in patients with recommendation for total or partial gastrectomy as according to the ESMO Clinical Practice Guidelines for Diagnosis, Follow-up[39]. Moreover, others factors may be influencing patients survival and this question should be explored with further large-scale studies.

To elucidate the role of EBV in the pathogenesis of gastric carcinoma several studies have focused on the study of EBV latent proteins expression in gastric tumour cells[40-42]. As expect, in our study LMP1 was not found in any of EBVaGC cases and, in fact, literature also shows that LMP1 is generally absent in EBVaGC except for the data reported in a few studies, which have detected low *albeit* detectable levels of LMP1 mRNA[41-43]. The absence of LMP1 expression in EBV positive cases suggests that LMP1 may not be needed for gastric carcinogenesis or at least not for sustaining the already established malignant tumours. Regarding LMP2A, our results demonstrated that EBV LMP2A is expressed in 40% of EBVaGC cases that is in line with previous studies[41,44]. Recent studies have pointed that LMP2A seems to have an important role contributing to malignant state in epithelial cells by inducing the genome hypermethylation through up-regulation of DNMT1 and phosphorylation of STAT3 and thus contributing for the carcinogenic potential of the cells[45]. A systematic review performed by our group has shown that EBVaGC are usually associated with a distinct latency pattern, characterized by the expression of EBERs, EBNA1, LMP2A and EBV microRNAs. Furthermore, literature also shows that EBV latency I pattern, which is characterized by the expression of EBERs, EBNA 1 and EBV microRNAs[46], has been also frequently found among EBVaGC tumours[47,48]. In line with this, our study demonstrates that the majority of our cases express EBERs with absence of LMP1 and LMP2A, however, 40% of our cases also expressed LMP2A, which does not fit into the standard EBV latency patterns. In fact, literature has described this distinct pattern as latency II-like and has also reported that lytic transcripts such as BARF0 and BARF1 can also be found within EBV-associated gastric neoplasias[44,49]. Our data reinforces that the clarification of which EBV transcripts (including lytic transcripts and EBV microRNAs) are expressed in gastric tumours assumes a great importance to understand the viral carcinogenesis in gastric cancer and may contribute for the identification of new molecular targets for treatment.

In our study, EBVaGC represents 8.4% of our population with gastric cancer and it is more frequent among tubular adenocarcinomas and medullary carcinomas rather than poorly cohesive carcinomas. EBVaGCs were more common in upper and middle regions of the stomach; were correlated with a lower number of regional lymph nodes with metastasis and with no distant metastasis. The results also revealed that EBVaGC patients seem to have an improved survival and better prognosis. These features suggest that EBVaGC is a distinct subtype of gastric cancer and that the mechanisms of carcinogenesis should be further investigated for particular therapeutic targets

COMMENTS

Background

Gastric cancer (GC) is the fifth most prevalent cancer and it remains the third most common cause of cancer-related death in the world. Epstein-Barr virus (EBV) is an oncogenic virus that has been associated with several malignancies, including B-cell lymphomas and nasopharyngeal carcinomas (NPC). Recently, EBV has been also associated with GC development with several studies suggesting that EBV-associated gastric carcinomas (EBVaGC) represent approximately 10% of all GC cases.

Research frontiers

Gastric carcinomas have been widely classified according to the Lauren or World Health Organization classification systems but these systems have a reduced clinical utility. A recent study has suggested a new classification based on molecular features of the tumours, where EBVaGC arises as a new subtype of gastric cancer. Despite the high incidence of both GC and EBV infection prevalence in the Portuguese population, there are no studies reporting the prevalence of EBVaGC in Portugal. The characterization of the EBVaGC in different populations is crucial to the development of new therapies and classification systems.

Innovations and breakthroughs

This is the first study in Portugal to characterize the EBV infection in gastric cancer. It demonstrated that EBV-associated carcinomas represent 8.4% of all gastric cancer cases and that EBVaGCs are a distinct subgroup of GC. Furthermore, it also showed that EBV displays a new latency profile in some of the EBVaGCs.

Applications

The understanding of clinical relevance and carcinogenesis of EBVaGC in different populations worldwide helps the improvement of preventive or management strategies as well as in the identification of more specific therapeutics.

Peer-review

This study showed that 8.4% of GC cases are EBV-associated being more frequent in upper and middle regions of the stomach, among tubular and medullary carcinomas, and having a lower number of regional lymph nodes invasion. Furthermore, this study confirms that EBVaGC may present a new latency-profile which may be useful to study to better characterize this GC subtype.

Abstract

AIM

To investigate whether the short-term prognosis of hepatitis B virus (HBV)-related acute-on-chronic liver failure (ACLF) could be improved by using a modified model for end-stage liver disease (MELD) including serum lactate.

METHODS

This clinical study was conducted at the First Affiliated Hospital, Fujian Medicine University, China. From 2009 to 2015, 236 patients diagnosed with HBV-related ACLF at our center were recruited for this 3-month follow-up study. Demographic data and serum lactate levels were collected from the patients. The MELD scores with or without serum lactate levels from survival and non-survival groups were recorded and compared.

RESULTS

Two hundred and thirty-six patients with HBV-ACLF were divided into two groups: survival group (S) and

non-survival group (NS). Compared with the NS group, the patients in survival the S group had a significantly lower level of serum lactate (3.11 ± 1.98 *vs* 4.67 ± 2.43, t = 5.43, P < 0.001) and MELD score (23.33 ± 5.42 *vs* 30.37 ± 6.58, t = 9.01, P = 0.023). Furthermore, serum lactate level was positively correlated with MELD score (r = 0.315, P < 0.001). Therefore, a modified MELD including serum lactate was developed by logistic regression analysis (0.314 × lactate + 0.172 × MELD - 5.923). In predicting 3-month mortality using the MELD-LAC model, the patients from the S group had significantly lower baseline scores (-0.930 ± 1.34) when compared with those from the NS group (0.771 ± 1.32, t = 9.735, P < 0.001). The area under the receiver operating characteristic curve (AUROC) was 0.859 calculated by using the MELD-LAC model, which was significantly higher than that calculated by using the lactate level (0.790) or MELD alone (0.818). When the cutoff value was set at -0.4741, the sensitivity, specificity, positive predictive value and negative predictive value for predicting short-term mortality were 91.5%, 80.10%, 94.34% and 74.62%, respectively. When the MELD-LAC scores at baseline level were set at -0.5561 and 0.6879, the corresponding mortality rates within three months were 75% and 90%, respectively.

CONCLUSION

The short-term prognosis of HBV-related ACLF was improved by using a modified MELD including serum lactate from the present 6-year clinical study.

INTRODUCTION

Hepatitis B virus (HBV) infection is a severe public health problem all over the world. The prevalence of hepatitis B is particularly high in China. HBV-related acute-on-chronic liver failure (ACLF) is a rapidly progressive disease with a high mortality rate up to 60%-75%[1]. The accurate assessment of the disease severity is critical before clinicians can make decisions on potential treatments like medication or liver transplantation (LT). The model for end-stage liver disease (MELD)[2,3] is a well-accepted model for assessing the feasibility of LT; however, the accuracy of its prediction is still unsatisfying[4]. A more objective and quantitative model with higher repeatability to predict the short-term prognosis of HBV-related ACLF is urgently needed.

Lactate (LAC) is mainly metabolized in the liver and is widely used as an important indicator of organ failure or serious bacterial infection. Hyperlactatemia normally reflects both increased production and impaired clearance in patients with liver dysfunction[5], and a higher level of LAC always indicates a worse prognosis[6]. Although several potential hypoxic and non-hypoxic mechanisms have been implicated on the persistent hyperlactatemia and the high level of LAC, the exact role of these parameters has not been specifically addressed in clinical studies[7,8]. In this study, we investigated the serum LAC level in patients with HBV-related ACLF, and developed a modified MELD including serum lactate (MELD-LAC model) to predict the short-term prognosis (three months) of HBV-related ACLF.

MATERIALS AND METHODS

Patients

Three hundred and ninety-three patients, who were diagnosed with HBV-related ACLF and admitted in our center, were included in the present clinical study between September 2009 and October 2015. The subjects were aged from 18 to 65 years. The diagnosis of ACLF was conducted according to the American Association for the Study of Liver Failure: Update 2011[9]. Three months after diagnosis, these patients were followed by telephone. The patients were divided into two groups: survival group (S group) and non-survival group (NS group), based on whether they were surviving or not three months after admission. The clinical data were collected within the first 24 h after admission, including hepatic, renal, and coagulation functions, as well as the LAC level. The onset time of hepatic encephalopathy (HE) was also noted if it happened. MELD scores were calculated as follows: MELD = 3.8 × Ln(Tbil [mg/dL]) + 11.2 × Ln(INR) + 9.6 × Ln (Cr [mg/dL]) + 6.4 × cause. Since the ACLF was due to HBV infection, the cause was counted as 1 in this study.

On admission, each patient's baseline values of serum LAC level, total bilirubin, creatinine level and

prothrombin time-international normalized ratio were measured. The serum LAC level was measured using a commercial test kit (Johnson & Johnson Inc., United States) with a normal value of 0.9-2.0 mmol/L. Total bilirubin and creatinine levels were tested using an Olympus Chemistry Analyzer (AU2700). All reagents for bilirubin and creatinine tests were purchased from Olympus Corporation (Japan). PT test and INR calculation were performed using a Stago STA Compact coagulation analyzer (Diagnotica Stago, French).

Treatment

After HBV-related ACLF was diagnosed, all the patients were treated with standard protocols, including nutritional support, hepatocyte proliferation, prevention of infection, correction of anomalies in the coagulation system and improvement of cerebral edema. In addition, plasmapheresis was also performed when it was necessary. The survival data were collected after three months.

Statistical analysis

Data analyses were performed using SPSS 17.0 software. The significance of data was tested by the Student's test or the χ^2 test. The correlation between groups was analyzed by the Pearson's product-moment correlation coefficient test. *P*-values less than 0.05 were considered statistically significant. Logistic regression analysis was used to establish the prognosis model. The accuracies of the newly developed prognosis model (MELD-LAC model), LAC and MELD scores in predicting the short-term prognosis of HBV-related ACLF patients were assessed by the area under the receiver operating characteristic (AUROC) curve.

RESULTS

Demographic data

A total of 393 serum samples from patient with HBV-related ACLF were collected, 157 of which were excluded from the present study due to the complications of hepatocellular carcinoma, kidney injury, diabetes or alcoholic liver diseases. According to the follow-up results in the 236 enrolled cases, 130 (110 males and 20 females) were recruited into the S group, and 106 (87 males and 19 females) were recruited into the NS group. The two groups had no statistical difference in gender or age, but had significant differences in TBIL, Cr, INR, LAC levels and MELD scores ($P < 0.05$ for all) (Table 1). There were 68 patients in the S group and 57 patients in the NS group who had received plasmapheresis as an additional enhanced therapy, but it did not provide any positive outcome ($P = 0.896$). No patient in this study had received LT.

Approximately 82.3% (107 of 130) of patients in the S group and 95.2% (101 of 106) of patients in the NS group were found to have elevated LAC level of more than 2 mmol/L. A significant difference was found in the above percentages between the two groups ($\chi^2 = 9.40$, $P = 0.002$). Furthermore, 13.1% of patients (17 of 130) in the S group and 59.4% (63 of 106) in NS group were found to have elevated LAC level of more than 4 mmol/L. A significant difference between the percentages of the S group and the NS group was also found ($\chi^2 = 55.999$, $P < 0.001$). The mean LAC level in the S group (3.11 mmol/L ± 1.98 mmol/L) was significantly lower than that in the NS group (4.67 mmol/L ± 2.43 mmol/L) ($P < 0.001$). No significant difference was shown in the CTP scores between the S and NS groups ($P = 0.373$), but a significant difference was shown in the MELD scores between the two groups ($P = 0.023$).

Using the Spearman analysis method, the correlations between MELD score/serum LAC levels and the mortality in three months were analyzed (Table 2). The results from Pearson's analysis also showed that both serum LAC level and MELD score had a statistically significant correlation with the short-term prognosis of HBV-related ACLF ($r = 0.315$, $P < 0.001$).

Construction of a modified MELD including serum lactate

Based on single factor analysis, both MELD score and LAC level were correlated with the 3-mo mortality of HBV-related ACLF. The forward logistic regression method was used to establish the MELD-LAC model: 0.314 × LAC + 0.172 × MELD score - 5.923 (Table 3). The patients from the S group had significantly lower baseline MELD-LAC scores (-0.930 ± 1.34) compared with those from the NS group (0.771 ± 1.32, $t = 9.735$, $P < 0.001$).

The short-term prognosis of HBV-related ACLF was improved by using the modified MELD including serum lactate from the present 6-year clinical study.

Prediction of the short-term prognosis of HBV-related ACLF by using MELD-LAC model

To predict the 3-month mortality, the LAC model alone had a very similar positive predictive value (PPV), negative predictive value (NPV), sensitivity and specificity to MELD. Interestingly, the new MELD-LAC model by combining these two independent factors had a better predicting score than these two models alone. When the cutoff value of the MELD-LAC model was set at -0.4741, based on the best Yoden index, an AUROC curve of 0.859 (Table 4) was obtained when this equation was applied to evaluate the prognosis, with a sensitivity of 91.5% and a specificity of 80.10%, which were much greater than the other two models. Comparing the AUROCs obtained from the above three models, the prognosis performances were listed as follows: MELD-LAC > MELD > LAC (Figure 1). From our analysis, the patients with an MELD-LAC score of -0.5561, -0.4741 and 0.6879 had the three-month

mortality rate of 75%, 78.86% and 90%, respectively. The PPV and NPV of MELD-LAC were 94.34% and 74.62%, which were significantly improved compared with the scores obtained from the MELD and LAC model alone.

The patients were divided into two groups, when the cutoff value of the MELD-LAC model was set at -0.4741. The first group (MELD-LAC ≥ -0.4741) included 123 patients, and 78.86% were dead after three months. The second group (MELD-LAC < -0.4741) included 113 patients, and only 11.50% died after three months. A statistically significant difference was observed between these two groups (χ^2 = 107.35, P < 0.001). When compared with MELD with a cutoff value of 25, the MELD-LAC model with a cutoff value of -0.4741 apparently achieved better prediction of short-term prognosis.

DISCUSSION

ACLF is a severe health problem with a high mortality rate[10-12]. In clinical practice, predicting the progression of this disease is the biggest challenge for clinicians. Currently, three scoring systems, namely, King's College Hospital criteria, Child-Turcotte-Pugh (CTP) score and MELD score[4,13] systems, are commonly implemented to predict the prognosis of ACLF patients; CTP score has been used traditionally to assess the prognosis of cirrhosis instead of ACLF; the MELD scoring system has been developed to assess various liver diseases, including assessing the severity of ACLF of all causes to determine the ideal timing of liver transplantation, as well as providing direct information to support medical decision making[14]. The MELD scoring system is widely considered to be better than the CTP score; however, it does have several limitations, for example, the diagnostic sensitivity and specificity of MELD are not high enough.

In the MELD scoring system, several variables associated with poor prognosis of ACLF are not considered, including HE, infections, and hemorrhage. Therefore, modification for MELD is needed to improve its outcome in clinical practice. Addition of Na+ into the MELD (MELD-Na) has been proposed and has been successfully evaluated as a better score in patients with ascites, but only for those patients with sodium levels below normal. However, such a condition is only presented in 30% of patients with decompensated cirrhosis[15].

The elevation of lactate level in ACLF situation has been reported and might be attributed to several suggested mechanisms[16,17]. First, the liver is the organ primarily responsible for LAC clearance, and the LAC clearance may be impaired in the presence of severe liver dysfunction. Second, some ACLF-related complications, *e.g.*, bacterial infection, may also raise the LAC level. Last but not least, hypovolemia-related hypoperfusion is also very likely to induce an elevation of LAC level during the early pre-resuscitative phase. In fact, some previous studies have shown that the acutely injured liver may act as a source of evaluating LAC[18]. Taken together, we suggest that the LAC level could be used as a useful marker for assessing the severity of ACLF. As a simple measure widely available in current hospital system, early measurement of serum LAC can provide important prognostic information in patients with acute variceal hemorrhage requiring ICU admission[19-21]. But to the best of our knowledge, the LAC level had never been considered as a critical biomarker for prognosis prediction of HBV-related ACLF.

Our results showed that LAC could be used as a useful tool to assess the situation of HBV-related ACLF. The evaluated LAC level was found in 82.3% of patients in the S group, but 95.2% of those in the NS group (χ^2 = 9.40, P = 0.002). The mean LAC level in the S group (3.11 mmol/L ± 1.98 mmol/L) was lower than that in the NS group (4.67 mmol/L ± 2.43 mmol/L) (P < 0.001). Further analysis showed that the baseline LAC level was related with patients' prognosis with a rational sensitivity (86.80%). The AUROC for predicting the 3 mo mortality based on the LAC model was relatively lower than that from MELD (0.79 *vs* 0.818), which is consistent with previous studies[21].

In our study, a positive correlation between the LAC and MELD scores was demonstrated, suggesting that a combination of LAC and MELD scores was very likely to increase prediction accuracy for ACLF prognosis. Therefore, we developed a modified MELD including serum lactate level to improve the short-term prognosis prediction of HBV-related ACLF by combining two parameters together (LAC and MELD). By adopting the forward logistic regression method, LAC and MELD scores were subjected to the equation, to yield a new MELD-LAC model.

The new model showed a better (AUROC = 0.859) prediction score for the prognosis of HBV-related ACLF when compared with either LAC (0.790) or MELD (0.818) alone. When the cutoff value was set at -0.4741, the MELD-LAC model had a sensitivity

MELD: Model for end-stage liver disease; LAC: The venous lactate.

of 91.50% and a specificity of 80.10% for predicting the mortality within three months. The patients were further divided into two groups according to the above cutoff value. The mortality was 78.86% in the higher score group (MELD-LAC ⩾ -0.4741) and 7.96% in the lower score group (MELD-LAC < -0.4741), showing a significant difference between these two groups (χ^2 = 107.35, P = 0.000). Under such a cutoff value setting (-0.4741), the MELD-LAC model seemed to provide a much more accurate prediction than normal MELD with a cutoff value of 25 (Table 5). According to our data, the three-month mortality rate of the patients was 75%, and 90% could be precisely predicted by the scores of MELD-LAC (-0.5561 or 0.6879) at baseline. Our results also showed no difference between the S group and NS group in CTP scores (Table 1), suggesting that CTP system is not a good tool in evaluating the outcome of HBV-related ACLF.

There are some limitations of this study. Our study indicated, for the first time, that a modified MELD including serum lactate was a better prediction model for the prognosis of HBV-related ACLF, with higher PPV and NPV. Further research is required to combine this model into the classic model or develop a more accurate prognostic model. Another limitation of this study is that the patient population came merely from a single center in this study and it was a retrospective study; further research and verification need to be done in larger multi-center studies.

Serum LAC test is a simple and mature clinical measurement in modern hospitals, and it reflects both direct liver injury and other organ dysfunction. Dynamic monitoring of LAC was able to provide a new opportunity for clinicians with more accurate disease assessment, prognosis predication and treatment guidance at the early stage of the liver disease. We concluded that the modified MELD including serum lactate is a better prediction model for the prognosis of HBV-related ACLF, with higher PPV and NPV.

Table 4 Prognostic value of the various models

model	AUROC	95%CI	Cut-off value	Sensitivity	Specificity	PPV	NPV
MELD	0.818	0.759-0.877	24.5	87.70 %	63.80%	85.85%	64.62%
LAC	0.79	0.730-0.850	2.68	86.80%	62.10%	86.79%	58.46%

COMMENTS

Background

Hepatitis B virus (HBV)-related acute-on-chronic liver failure (ACLF) is a rapidly progressive disease with a high mortality rate up to 60%-75%. The accurate assessment of disease severity is critically needed, before clinicians make decisions on potential treatments such as medication or liver transplantation (LT). The model for end-stage liver disease (MELD) score model is a well-accepted model for assessing the feasibility of LT; however, the accuracy of prediction is still unsatisfying. A more objective and quantitative model with higher repeatability to predict the short-term prognosis of HBV-related ACLF is urgently needed.

Research frontiers

In the MELD scoring system, several variables associated with poor prognosis of ACLF are not considered, including hepatic encephalopathy (HE), infections, and hemorrhage. Therefore, modification of MELD is needed to improve its outcome in clinical practice. Addition of Na+ into MELD (MELD-Na) has been proposed and has been successfully evaluated as a better score in patients with ascites, but only for those patients with sodium levels below normal. However, such a condition is only presented in 30% of patients with decompensated cirrhosis.

Innovations and breakthroughs

Lactate (LAC) is mainly metabolized in the liver and is widely used as an important indicator in organ failure or serious bacterial infection. Hyperlactatemia normally reflects both increased production and impaired clearance in patients with liver dysfunction, and a higher level of LAC always indicates a worse prognosis. Although several potential hypoxic and non-hypoxic mechanisms have been implicated on the persistent hyperlactatemia and the high level of LAC, the exact role of these parameters has not been specifically addressed in clinical studies. In the present study, they investigated the serum LAC level in patients with HBV-related ACLF, and developed a modified MELD including serum lactate (MELD-LAC model) to predict the short-term prognosis (three months) of HBV-related ACLF.

Applications

This study developed a modified MELD model including serum lactate level to improve the short-term prognosis prediction of HBV-related ACLF by combining the two parameters together (LAC and MELD).

Peer-review

The authors of this paper found that the efficacy of the short-term prognosis of HBV-related ACLF was improved by using a modified MELD including serum lactate from the present 6-year clinical study. The new model showed a better prediction score on the prognosis of HBV-related ACLF, when compared with either LAC or MELD alone.

Abstract

AIM

To examine the relationship of chronic scheduled opioid use on symptoms, healthcare utilization and employment in gastroparesis (Gp) patients.

METHODS

Patients referred to our tertiary care academic center from May 2016 to July 2017, with established diagnosis or symptoms suggestive of Gp filled out the Patient Assessment of Upper GI Symptoms, abdominal pain and demographics questionnaires, and underwent gastric emptying and blood tests. They were asked about taking pain medicines and the types, doses, and duration. We used Mann Whitney *U* test, Analysis of Variance, Student's *t* test and χ^2 tests where appropriate for data analyses.

RESULTS

Of 223 patients with delayed gastric emptying, 158 (70.9%) patients were not taking opioids (GpNO), 22 (9.9%) were taking opioids only as needed, while 43 (19.3%) were on chronic (> 1 mo) scheduled opioids (GpCO), of which 18 were taking opioids for

reasons that included gastroparesis and/or stomach pain. Median morphine equivalent use was 60 mg per day. GpCO reported higher severities of many gastrointestinal symptoms compared to GpNO including nausea (mean ± SE of mean of 4.09 ± 0.12 *vs* 3.41 ± 0.12, $P = 0.011$), retching (2.86 ± 0.25 *vs* 1.98 ± 0.14, $P = 0.003$), vomiting (2.93 ± 0.24 *vs* 2.07 ± 0.15, $P = 0.011$), early satiety (4.17 ± 0.19 *vs* 3.57 ± 0.12, $P = 0.004$), post-prandial fullness (4.14 ± 0.18 *vs* 3.63 ± 0.11, $P = 0.022$), loss of appetite (3.64 ± 0.21 *vs* 3.04 ± 0.13, $P = 0.039$), upper abdominal pain (3.86 ± 0.20 *vs* 2.93 ± 0.13, $P = 0.001$), upper abdominal discomfort (3.74 ± 0.19 *vs* 3.09 ± 0.13, $P = 0.031$), heartburn during day (2.55 ± 0.27 *vs* 1.89 ± 0.13, $P = 0.032$), heartburn on lying down (2.76 ± 0.28 *vs* 1.94 ± 0.14, $P = 0.008$), chest discomfort during day (2.42 ± 0.20 *vs* 1.83 ± 0.12, $P = 0.018$), chest discomfort at night (2.40 ± 0.23 *vs* 1.61 ± 0.13, $P = 0.003$), regurgitation/reflux during day (2.77 ± 0.25 *vs* 2.18 ± 0.13, $P = 0.040$) and bitter/acid/sour taste in the mouth (2.79 ± 0.27 *vs* 2.11 ± 0.14, $P = 0.028$). GpCO had a longer duration of nausea per day (median of 7 h *vs* 4 h for GpNO, $P = 0.037$), and a higher number of vomiting episodes per day (median of 3 *vs* 2 for GpNO, $P = 0.002$). Their abdominal pain more frequently woke them up at night (78.1% *vs* 57.3%, $P = 0.031$). They had a lower employment rate (33.3% *vs* 54.2%, $P = 0.016$) and amongst those who were employed less number of working hours per week (median of 23 *vs* 40, $P = 0.005$). They reported higher number of hospitalizations in the last 1 year (mean ± SE of mean of 2.90 ± 0.77 *vs* 1.26 ± 0.23, $P = 0.047$).

CONCLUSION

GpCO had a higher severity of many gastrointestinal symptoms, compared to GpNO. Hospitalization rates were more than 2-fold higher in GpCO than GpNO. GpCO also had lower employment rate and working hours, when compared to GpNO.

Key words: Opioid; Gastroparesis; Symptoms; Hospitalizations; Employment

Core tip: Chronic opioid use can cause gastrointestinal side effects and negatively influence the quality of life. The impact of chronic opioid use on symptoms, healthcare utilization, and employment of gastroparesis patients is not well studied. In our study, gastroparesis patients on chronic scheduled opioids had more severe gastrointestinal symptoms, less work productivity and more frequent hospitalizations compared to gastroparesis patients without opioid use. Whether opioid use is to treat a higher symptom severity from gastroparesis, or the opioid use worsens symptoms requires further study.

Chronic opioids in gastroparesis: Relationship with gastrointestinal symptoms, healthcare utilization and employment. *World J Gastroenterol* 2017; 23(40): 7310-7320 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7310.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7310

INTRODUCTION

Opioid use has become a healthcare epidemic in United States with increasing prescription rates in the recent years, and over 3% of the adults are now chronically using opioids[1-3]. In 2013, the overall cost burden from opioids in United States was estimated to be $78.5 billion[4]. A recent systematic review identified mean costs to the payer (commercial or private insurance) of $23000-$25000 per year for the opioid misusers, approximately $15000 more than the non-opioid users[5].

Patients on chronic opioids are more likely to have bowel related issues[2]. The wide array of gastrointestinal symptoms that the patients on chronic opioids may experience, including constipation (38%-63%), gastroesophageal reflux disease (33%), nausea (20%-90%), vomiting (9%-84%), bloating (24%-75%) and delayed gastric emptying are known as opioid induced bowel dysfunction[2,6-13]. The actual incidence of some of these side effects may even be higher as many patients tend to underreport their symptoms, and may self-adjust their regimen to avoid side effects[12]. Approximately 6% of the chronic opioid patients develop worsening chronic or intermittent abdominal pain (AP) even with continuous or increasing doses of opioids, a condition termed narcotic bowel syndrome[8]. The opioid-induced gastrointestinal side effects are often not anticipated while prescribing these medications, and may lead to increase healthcare utilization[9].

Despite the known gastrointestinal side effects of opioids, they are used in some patients with gastroparesis (Gp). Previous studies reported that 30%-46% of the Gp patients regularly use opioids[10,14,15]. In addition to opioids causing constipation, opioids slow gastric emptying and also can cause nausea and vomiting by activating the chemoreceptor trigger zone in the area postrema at the floor of the fourth ventricle[9,16]. Moreover, it has been shown that Gp patients on opioids may have worse outcomes with medical treatment with prokinetics agents and after gastric pacemaker placement[14].

The aim of this study was to examine the relationship of chronic opioid use on symptoms, healthcare utilization and employment in patients referred for Gp. We studied gastroparesis patients; comparing those on chronic scheduled opiates (GpCO) to gastroparesis patients

not taking opiates (GpNO).

MATERIALS AND METHODS

Patients referred to our tertiary care academic center gastroenterology motility clinic at Temple University Hospital (TUH) with established diagnosis of gastroparesis, or patients who presented with symptoms suggestive of gastroparesis from May 2016 to July 2017 (n = 303) were studied. This observational study was reviewed and approved by the TUH Intuitional Review Board. Patients are often referred to our motility clinic for persistent or refractory symptoms of gastroparesis. Subjects were recruited at the end of their regularly scheduled appointments after obtaining informed consent. Inclusion criteria were the following: (1) adults aged 18 to 80 years old; (2) symptoms suggestive of gastroparesis; and (3) delayed gastric emptying on scintigraphy.

On their initial evaluation, patients were asked to fill out a questionnaire about their clinical condition. This questionnaire contained the following: Patient Assessment of Upper Gastrointestinal Symptom (PAGI-SYM), Abdominal Pain Questionnaire, and demographic questionnaire. Patients underwent 4-h gastric emptying scintigraphy (GES)[17] if had not already recently been performed. Blood tests were obtained (see below). A retrospective review of the questionnaires, gastric emptying scintigraphy and blood tests was subsequently performed.

Questionnaires

PAGI-SYM: This validated questionnaire for upper gastrointestinal symptoms of gastroparesis, dyspepsia, and gastroesophageal reflux disease asked patients to rate the severity of 20 common gastrointestinal symptoms over the past two weeks[18]. Patients were asked to rate symptoms over the prior two weeks as none (0), very mild (1), mild (2), moderate (3), severe (4), and very severe (5). They were also asked to rate symptoms of diarrhea and constipation on the same scale. In addition, they were asked about the duration of nausea per day in the past week, number of episodes of vomiting and bowel movements in the past week. We also asked the patients about the frequency of some of their gastrointestinal symptoms over the preceding 3 mo using the Rome IV questionnaires[19].

Abdominal pain questionnaire: This questionnaire was modified from previous studies assessing the presence and severity of abdominal pain in chronic pancreatitis[20,21]. If abdominal pain was present, patients filled out the remaining portion of the questionnaire asking about the duration, location of the most severe pain, relationship of pain to meals and nocturnal awakenings as a result of the pain.

Demographics questionnaire: This questionnaire asked patients to report information such as age, gender, race/ethnicity, height, weight, smoking history, alcohol usage, employment and working hours per week if employed. It also asked about the length of diagnosis with Gp, history of diabetes, and prior abdominal surgeries. Patients were asked about taking pain medicines and the types, doses, frequency, clinical indication and total duration of pain medicine use.

Laboratory analysis

Patients underwent blood drawing including hemoglobin A1c and thyroid stimulating hormone, as hyperglycemia and hypothyroidism are risk factors for delayed gastric emptying[22,23]. We also checked serum trypsinogen level as symptoms of Gp can resemble those of chronic pancreatitis (CP)[24]. Lastly, we ordered random serum cortisol levels as opioid-induced adrenal insufficiency has been reported in the literature[25-27].

Gastric emptying scintigraphy

Gastric emptying scintigraphy was performed using a low-fat, egg white meal with imaging at 0, 1, 2, 4 h after meal ingestion[17]. Patients were instructed to stop medications that could affect gastrointestinal motility (including prokinetics) for 48 h prior to the study and to come to the Nuclear Medicine Section in the morning after fasting overnight, that is, an 8 h fast. The patients on chronic opioids were advised to gradually taper off their opioids as tolerated prior to their scheduled GES to prevent opioid withdrawal. Diabetics have their glucose checked at the beginning of the study, with appropriate treatment measures being taken if low blood sugar (hypoglycemia) or high blood sugar (hyperglycemia > 250 mg/dL) is detected. Gastric emptying scintigraphy is performed using a standard low-fat, Eggbeaters® meal to measure solid emptying. The meal consists of the equivalent of two large eggs radiolabeled with 0.5-1 mCi Tc-99m sulfur colloid served with two pieces of white bread and jelly. Patients are given 120 mL water. Following ingestion of the meal, imaging is performed at 0, 1, 2 and 4 h with the patient standing upright for measuring gastric emptying of Tc-labeled solids. Gastric emptying is analyzed as percent of radioactivity retained in the stomach over time using the geometric center of the decay-corrected anterior and posterior counts for each time point. Gastric retention of Tc-99m > 60% at 2 h. and/or > 10% at 4 h is considered delayed gastric emptying of solids.

Statistical analysis

We used Kolmogorov-Smirnov test to determine the normal distribution of continuous variables; Student's t-test was used for variables with normal distribution, while Mann Whitney U Test was used for variables with skewed distribution and symptoms assessed on ordinal scale. These results are expressed as mean ± SE of mean, or median with interquartile range as

appropriate. χ^2 test was used for categorical data, with results expressed as percentages[28]. A two-tailed *P* value less than 0.05 was considered as statistically significant while comparing chronic opioid using Gp patients to non-opioid users; no adjustment for multiple comparisons was made. Analysis of Variance (ANOVA) was used for comparison of multiple groups, followed by Students; *t*-test with *p* value adjusted with Bonferroni correction for multiple comparisons. Unanswered questions were excluded from the analyses. Gp patients who were using opioids as needed (*n* = 22) were not included in the analyses. Statistical review of the study was performed by an epidemiologist/statistician of our department.

RESULTS

Patients

Of 303 patients referred for symptoms suggestive of gastroparesis in 15 mo, 80 patients had normal gastric emptying tests and were excluded from the analyses. Of the remaining 223 patients, the majority (*n* = 196, 87.9%) had previously been diagnosed with Gp. More than half (52%) of the Gp patients came from outside the catchment area of TUH that we defined as more than 50 miles from our center. The most frequent type of Gp was idiopathic Gp (*n* = 122; 54.7%), followed by diabetic Gp (*n* = 62, 27.8%), post-surgical Gp (*n* = 20; 9.0%), and atypical Gp (*n* = 19; 8.5%) (Table 1). The median age of these patients was 44 years (interquartile range of 32 to 56 years), and 80.7% were females. Amongst 210 patients who reported their race, the most common races were Whites (79.4), African Americans (7.6%) and Hispanics (6.7%). Over two third of patients with Gp (*n* = 158, 70.9%) were not taking opioids, 22 (9.9%) were taking opioids only as needed, while 43 (19.3%) were on chronic scheduled opioids (Table 1).

Gastroparesis patients on chronic scheduled opioids

Amongst the 43 patients on chronic scheduled opioids, 6 (14%) were taking opioids exclusively for Gp and/or stomach pain, while another 12 (27.9%) were taking opioids for reasons that included Gp and/or stomach pain. Other frequent causes of opioid use included back pain (*n* = 27, 62.8%), leg pain (*n* = 10), arthritis (5), fibromyalgia (4), Reflux Sympathetic Dystrophy (3), and neuropathy (2). Nearly one fourth of these patients (*n* =10, 23.3%) were taking more than 1 opioid. The opioids used chronically included oxycodone (18 patients), fentanyl (9), methadone (5), morphine (5), tramadol (5), hydromorphone (4), hydrocodone (3), and oxymorphone (2). Median duration of narcotic use was 2 years (interquartile range of 0.6-6.5 years). Median oral morphine equivalent dose for GpCO was 60 mg/d, with interquartile range of 22.5 mg to 112.5 mg per day.

Patients with diabetic gastroparesis were more likely to be on chronic scheduled opioids (24.2 % *vs* 18.9%), or as needed opioids (14.5% *vs* 4.9%), when compared to the patients with idiopathic gastroparesis who were more likely to be non-opioid users (76.2% *vs* 61.3%), *P* = 0.039. Thirty-three Gp patients on chronic opioids were able to recall the duration of their Gp symptoms as well as chronic opioid use. Out of these, about 1 in every 4 GpCO (27.3%) stated that they started using opioids chronically before their symptoms of Gp started. For another 21.2% of GpCO, the duration of opioid use was the same as the duration of their Gp symptoms. For 51.5% of GpCO, the Gp symptoms started before the use of chronic opioids. Of note however, we had to rely on patients' recall for the duration of their opioids use, and patients reported drug ingestion histories can often be inaccurate[29].

GpCO and GpNO did not have any statistically significant difference in their age, duration of symptoms, gender, body mass index, racial distribution, history of diabetes, and past surgeries on esophagus and stomach (Table 2). GpCO were more likely to be active smokers (31.7% *vs* 13.0%, *P* = 0.004). There was a trend towards higher prior and/or current alcohol use in GpNO compared to GpCO (37.4 % *vs* 23.8% respectively, *P* = 0.100), as well as current alcohol use (20.0% *vs* 7.3% respectively; *P* = 0.057).

Laboratory studies

GpCO were also more likely to have low trypsinogen levels compared to GpNO (23.1% *vs* 4.2% respectively, *P* = 0.004). However, only about half of these patients had their trypsinogen levels drawn (Table 2). Among GpCO, 16.2% had low random serum cortisol levels, *vs* 10.4% among GpNO, *P* = 0.345 (Table 2). We did not confirm the diagnosis of adrenal insufficiency by checking adrenocorticotrophic hormone or by performing stimulation test; this requires further study to determine the actual incidence of adrenal insufficiency in chronic opioid using Gp patients. There was no statistically significant difference in the other laboratory tests, including hemoglobin A1c, thyroid stimulating hormone.

Gastric emptying scintigraphy

On gastric emptying tests, there was no difference between GpCO and GpNO at 2 h (median of 62% *vs* 66%, normal $\leqslant$ 60%) and 4 h (median of 22% *vs* 24%, normal $\leqslant$ 10%) (*P* > 0.05) (Table 2). Amongst GpCO 11 patients (25.6%) had severe delays in gastric emptying (> 35% retention at 4 h), compared to 30 patients (19%) in GpNO (*P* = 0.341).

Opioids did not seem to have a dose-related effect on the delay in gastric emptying, as we did not find any difference in the four quartiles of GpCO based on morphine equivalents per day by comparing the gastric emptying results of these groups using ANOVA (Table 3). We also calculated Pearson correlation coefficient

Table 1 Patients with gastroparesis referred to a tertiary care center between May 2016 and July 2017

Classification	Total	Chronic scheduled opioids	PRN opioids	No opioids
Idiopathic	122	23	6	93
Diabetic	62	15	9	38
Post-surgical[1]	20	2	5	13
Atypical[2]	19	3	2	14
Total	223	43	22	158

[1]Post-surgical gastroparesis consisted of patients with history of duodenal-jejunostomy, esophagectomy, fundoplication, gastric sleeve, gastric banding, gastric bypass, hiatal hernia repair, and vagotomy with pyloroplasty. [2]Atypical gastroparesis consisted of gastroparesis patients with history of Bulimia, Complex Regional Pain Syndrome, Ehlers Danlos Syndrome, Lupus, Parkinson's Disease, Reflux Sympathetic Dystrophy, Scleroderma and Sjogren's Syndrome.

between opioid dose and delay in gastric emptying, and there was no significant correlation between morphine equivalents per day and gastric retention at 2 h ($r < 0.01$, $P = 0.988$) or 4 h ($r = 0.19$, $P = 0.356$).

Of note, 14 patients on chronic scheduled opioids were still taking opioids at the time of their GES, which may have resulted in the delay in their gastric emptying. However, when we compared these patients to GpCO who were able to taper off the opioids prior to the study, there was no difference in gastric retention at 2 h (median of 60% *vs* 70% respectively, $P = 0.461$) and 4 h (16% *vs* 20%, $P = 0.718$).

GI Symptoms

GpCO had higher symptom severities of many GI symptoms including nausea, retching, vomiting, early satiety, post-prandial fullness, loss of appetite, upper abdominal pain, upper abdominal discomfort, heartburn during day, heartburn on lying down, chest discomfort during day, chest discomfort at night, regurgitation/reflux during day, and bitter/acid/sour taste in the mouth compared to GpNO ($P < 0.05$) (Table 4). The severity of constipation was not statistically different between the two groups (2.92 ± 0.30 in GpCO, compared to 2.63 ± 0.14 in GpNO, $P = 0.296$). On PAGI-SYM questionnaire, the total symptom severity score in GpCO was also higher than GpNO (Table 4).

As stated previously the median morphine equivalent use in GpCO was 60 mg per day. When we compared GpCO taking more than 60 mg morphine equivalents per day to GpCO taking 60 mg per day or less, the patients taking more than 60 mg per day reported more severe heartburn during the day (3.30 ± 0.45 *vs* 2.0 ± 0.21, $P = 0.023$). There was also a trend towards more severe heartburn in recumbent position (3.30 ± 0.46 *vs* 2.30 ± 0.38, $P = 0.116$), and bitter, acid or sour taste in the mouth (3.50 ± 0.44 *vs* 2.30 ± 0.36, $P = 0.058$) amongst GpCO taking more than 60 mg morphine equivalents per day (results not shown).

When we compared GpCO with severe delay in gastric emptying (> 35% at 4 h) with GpCO with mild to moderate delay in gastric emptying, there was no difference in symptom severity on PAGI-SYM questionnaire, and we did not notice any differences in the impact of gastroparesis on their employment and healthcare utilization (results not shown).

GpCO had a longer duration of nausea per day in the past week (median of 7 h *vs* 4 h in GpNO, $P = 0.037$), as well as higher number of vomiting episodes per day (median of 3 *vs* 1 in GpNO, $P = 0.002$) but there was no statistically significant difference in the number bowel movements in the past week (Table 5).

AP was frequently present in GpCO and GpNO (84.1% and 85.2% respectively, $P = 0.861$). Epigastrium was the most common location of the most severe AP in GpNO (44.2%); while GpCO most commonly had their most severe AP in periumbilical area (41.7%) followed by epigastric area (38.9%), $P = 0.863$. AP got worse with meal intake in majority of patients (76.5% in GpCO *vs* 80.0% in GpNO, $P = 0.508$). There was no difference in the overall duration of AP (median of 2 years in GpCO *vs* 1.5 years in GpNO, $P = 0.526$). AP more frequently woke up GpCO at night compared to GpNO (78.1% *vs* 57.3%, $P = 0.031$).

Nausea and vomiting were more frequent in GpCO in the past 3 mo (Table 6); 92.5% of GpCO had nausea interfering with their activities at least once a week or more frequently *vs* 76% amongst GpNO ($P = 0.021$).

Employment

The employment rate was lower in GpCO compared to GpNO (33.3% *vs* 54.2%, $P = 0.016$). The average number of working hours per week in GpCO (who were employed) was also lower than GpNO (median of 23 h *vs* 40 h respectively, $P = 0.005$).

It is plausible that a higher severity of abdominal pain in GpCO compared to GpNO was affecting employment. However, when we studied only those patients who had moderate to very severe abdominal pain as one of the symptoms from gastroparesis, GpCO still had a lower rate of employment (35.9% *vs* 54.5%, $P = 0.037$), and lower number of working hours per week (median of 20 h *vs* 40 h, $P = 0.003$), compared to GpNO. In GpCO on more than 60 mg morphine equivalents per day, there was a trend towards less working hours per week compared to GpCO on 60 mg or less morphine equivalents per day (median of 17.5 h *vs* 26 h, $P = 0.071$).

Health care utilization

There were higher number of hospital admissions for GpCO in the past year compared to GpNO (2.90 ± 0.77 *vs* 1.26 ± 0.23, $P = 0.047$) (Table 7). There was a trend towards a higher number of emergency room

Table 2 Gastroparesis patients: Demographics, employment, social history, laboratory tests and gastric emptying test in chronic opioid using gastroparesis patients, and patients with no opioid use

visits in the past year in GpCO compared to GpNO (5.13 ± 1.46 *vs* 3.74 ± 0.65) but this did not reach statistical significance ($P = 0.468$).

DISCUSSION

Our study shows that chronic opioid use is present in nearly one fifth of the gastroparesis patients referred for evaluation and treatment of their gastroparesis. Use of chronic opioids in these gastroparesis patients was associated with a higher severity of many gastrointestinal symptoms, especially the symptoms often attributable to gastroparesis. In addition, patients on chronic opioids had decreased work productivity, and more frequent hospitalizations.

The prevalence of chronic scheduled opioid use in our study (19.2%) is less than 30%-46% reported in other studies[10,14,15]. It is plausible that many of our patients on opioids as needed were also taking opioids at least once a day, and including these patients gives a much higher prevalence of opioid use (29.1%). A significantly higher proportion of the Gp patients use opioids compared to the general adult population, which is estimated to be 3%[30].

Our study shows that Gp patients on chronic scheduled opioids have a higher severity of many upper gastrointestinal symptoms especially in those symptoms often attributable to gastroparesis. A higher frequency of upper gastrointestinal symptoms in patients taking opioids for chronic non-cancer pain (CNCP) has previously been reported[2]. Females have been shown to have a 60% greater chance of experiencing nausea and vomiting after receiving opioid therapy, which is noteworthy as majority of patients who suffer from Gp are females[12]. The female preponderance in our study is consistent with the previous literature that shows a higher prevalence of Gp and other functional gastrointestinal disorders in females[31]. The most common types of Gp in our population (idiopathic and diabetic) were also similar

Table 4 Symptom Severity as assessed with Patient Assessment of Upper Gastrointestinal Symptoms questionnaire; comparison between gastroparesis patients on chronic opioids and patients with no opioid use

GI symptom	GpCO (n = 43)	GpNO (n = 158)	P value
Nausea	4.09 ± 0.12	3.41 ± 0.12	0.011

to previous studies on Gp[10,31].

In our study, the higher prevalence of opioid use in patients with diabetic gastroparesis compared to patients with idiopathic gastroparesis is possibly related to other co-morbidities, as both diabetic and idiopathic gastroparesis patients were equally likely to have abdominal pain as one of their symptoms of Gp, and there was no statistically significant difference in the severity of their abdominal pain or discomfort on PAGI-SYM questionnaire (results not shown). GpCO with diabetes more frequently reported using opioids for leg pain and/or neuropathy (33.3%) *vs* GpCO with idiopathic gastroparesis (21.7%), though the difference was not significant (P > 0.05).

The prevalence of abdominal pain in our study groups (> 80%) is towards the higher end of the reported prevalence of abdominal pain in Gp (42%-89%)[15]. Epigastrium was the most common location of the most severe AP, and majority of the patients with AP experienced post-prandial worsening of pain, similar to a previous study performed at our center on a different cohort of Gp patients[32]. Every 3 in 4 GpCO in our study woke up at night from AP, higher than about 1 in 2 of our GpNO patients and significantly higher than the reported 1 in 4 patients on opioids for CNCP reported by Tuteja *et al*[2]. It is possible that the abdominal pain may be the reason these patients were taking opioids. Alternatively, there could be enhanced pain perception in disabling narcotic bowel syndrome.

In this cohort, GpCO did not have increased severity of constipation, which is historically one of

Table 6 Frequency of symptoms in the past 3 mo using Rome IV questionnaire: comparison between gastroparesis patients with chronic scheduled opioid use and patients with no opioid use (percentage of patients with symptoms once a week or more often)

Symptom	GpCO	GpNO	*P* value
Post-prandial fullness interfering with activities	81.6% (31/38)	78.7% (118/150)	0.692
Unable to finish regular sized meal due to fullness	84.6% (33/39)	79.1% (117/148)	0.438
Epigastric pain/burning interfering with activities	75.0% (30/40)	66.9% (103/154)	0.324
Nausea interfering with activities	92.5% (37/40)	76.0% (117/154)	0.021
Vomiting	70.7% (29/41)	50.6% (78/154)	0.022
Bloating or stomach distension	72.5% (29/40)	68.8% (106/154)	0.653
Belching interfering with activities	62.5% (25/40)	51.3% (79/154)	0.206

GpCO: Gastroparesis patients on chronic opioids; GpNO: Gastroparesis patients not on opioids.

the most commonly reported symptoms of opioid induced bowel dysfunction[2]. Fentanyl was the second most commonly used opioid in GpCO, and a randomized cross over trial showed a lower prevalence of constipation in patients taking transdermal fentanyl compared to sustained release oral morphine[7]. Even though our questionnaire did not ask specifically about usage of stool softeners or laxatives, some of these patients had stool softeners (n = 4), stimulant laxatives (2) and osmotic laxative (1) listed on their medication list, and it is plausible that many other patients were on these over-the-counter medications as well, as these medications are often taken prophylactically in patients on chronic opioids[6,33]. Future studies can look into the prevalence of laxative use in opioid using gastroparesis patients. Our finding of higher severity of many gastrointestinal symptoms in GpCO compared to opioid-naïve Gp patients, despite no statistically significant difference in the 2 and 4 h retention in gastric emptying tests between the two groups is not novel, as Karamanolis et al showed that the symptom pattern in Gp is not determined by the severity of delay in gastric emptying[34].

Patients with Gp may have symptoms that mimic clinical manifestations of CP. In fact, Chowdhury *et al*[24] reported that 44% of small duct CP patients may have concomitant Gp. While the prevalence of CP in the general population is only 41.76 per 100000[35], the prevalence of CP in patients with Gp is not known. In our study, GpCO (7%) were more likely to have a history of CP compared to GpNO (1.3%). In addition, nearly one fourth (23.1%) of GpCO who had their trypsinogen levels checked had low levels, compared to < 5% in GpNO, suggesting some of our Gp patients using opioids chronically possibly had severe calcific CP with associated Gp, which might have been causing them abdominal pain. While the sensitivity of serum trypsinogen level in diagnosing CP was only 28%, the specificity was 100% in a study by Pezzilli *et al*[36].

Gp patients have been reported to have the longest length of hospital stay (5 d) amongst the functional gastrointestinal disorders[31]. Recent studies suggest increasing hospitalization due to Gp over the past 20 years[37-39]. A Nationwide Inpatient Sample Study reported 17220 admissions from Gp in 2012, a more than 400% increase compared to 1997[39]. Some authors suggest that the increasing hospitalization due to Gp comes from better recognition of this disorder[40]. Our study suggests a higher number of hospitalizations in GpCO than in Gp patients not taking opiates.

Our finding that GpCO are more likely to be unemployed and work less is consistent with the multi-national questionnaire based study showing that the chronic use of opiates negatively influences the quality of life[41]. We found a higher prevalence of current smoking in GpCO, and a study by Young-Wolff *et al*[42] suggested a higher likelihood of opioid use disorder in current smokers *vs* non-smokers.

Our study has some limitations. Whether opioid use is to manage a higher severity of Gp symptoms, or is responsible for the higher severity of symptoms is unclear as we do not have symptoms of patients prior to starting opioids. Increased opioid use in Gp patients with moderate to severe abdominal pain has previously been reported[15], however nausea, vomiting and retching are frequently reported side effects of opioids and it is plausible that the opioid use itself explains the higher severity of these symptoms amongst GpCO in our study. Secondly, these patients were generally referred from community settings and over half of these patients were referred from outside the catchment area of our tertiary care center, with GpCO and GpNO equally likely to be referred from outside the catchment area. This was a questionnaire based study. Some of the questions were not answered by all the patients, and some patients did not go for the laboratory tests that we requested. These missed questions and laboratory tests were excluded from analyses, however their number were relatively small in most cases, and likely did not to affect the results. Lastly, since this is a questionnaire based study, there is a potential of recall bias as well. This would likely apply both to patients taking and those not taking opioid analgesics.

In conclusion, chronic regular opioid use is present in a significant number (19.3%) of gastroparesis patients. These patients have a higher severity of many gastrointestinal symptoms including those of Gp. They have decreased work productivity compared to non-opioid using Gp patients. Whether opioid use is to

Table 7 Comparison of healthcare utilization between chronic opioid using gastroparesis patients and patients with no opioid use

	GpCO (n = 43)	GpNO (n = 158)	P value
ER visits in last 1 yr from Gp	5.13 ± 1.46	3.74 ± 0.65	0.468

treat a higher symptom severity from Gp, or opioid use itself worsens symptoms in patients with Gp requires further study.

ARTICLE HIGHLIGHTS

Research frontiers

Despite the gastrointestinal side effects associated with opioid use, they are used in some patients with gastroparesis. The relationship of opioid use to the gastrointestinal symptoms, healthcare utilization and employment is not known.

Research motivation

As opioid use had become a healthcare epidemic in United States, studies on opioid use in gastroparesis would be useful for clinicians and researchers.

Research objectives

This objective was to study the relationship of chronic scheduled opioid use to gastrointestinal symptoms, healthcare utilization and employment in gastroparesis patients.

Research methods

The authors used Mann Whitney *U* Test, Student's *t*-test, Analysis of Variance, and χ^2 test as appropriate for data analysis.

Research results

This study shows higher severity of many gastrointestinal symptoms, and more frequent hospitalizations in gastroparesis patients on chronic scheduled opioids, compared to gastroparesis patients not using opioids. Chronic opioid using patients also reported their work being effected more frequently by their gastrointestinal symptoms. The prevalence of chronic pancreatitis is also higher in opioid using gastroparesis patients.

Research conclusions

This study confirmed the hypothesis that chronic opioid use in gastroparesis is related with more severe gastrointestinal symptoms, and hospitalizations. Whether opioid use is to manage a higher severity of gastroparesis symptoms, or is responsible for the higher severity of symptoms is not clear as we did not have symptoms of patients prior to starting opioids. In clinical practice, this study implicates that the opioids may need to be used with caution in gastroparesis patients.

Research perspectives

Opioid use is quite prevalent in patients with gastroparesis. Opioid-using gastroparesis patients have more severe gastrointestinal symptoms. These opioid-using patients are more frequently hospitalized, compared to the patients without opioid use. They also more commonly report their employment being affected due to their gastrointestinal symptoms. Patients with gastroparesis may have chronic pancreatitis, possibly contributing to their gastrointestinal symptoms.

Future studies can look into the trends of laxative-use in opioid-using gastroparesis patients. The noticeable prevalence of chronic pancreatitis in gastroparesis patients in this study can be further confirmed in studies with larger sample size. This study found more frequent hospitalizations in gastroparesis patients; future studies to evaluate opioid use during hospitalizations in gastroparesis patients will add useful information to the current literature on gastroparesis.

Future research can look into opioid use in gastroparesis through different perspectives, this could be not only in the tertiary care centers, but also in smaller community settings so that the results more accurately reflect the generalized population. Moreover, bigger databases using diagnosis codes and medication-lists can be used to get a larger sample size.

Abstract

AIM

To investigate the impact of medication beliefs, illness perceptions and quality of life on medication adherence in people with decompensated cirrhosis.

METHODS

One hundred adults with decompensated cirrhosis completed a structured questionnaire when they attended for routine outpatient hepatology review. Measures of self-reported medication adherence (Morisky Medication Adherence Scale), beliefs surrounding medications (Beliefs about Medicines Questionnaire), perceptions of illness and medicines (Brief Illness Perception Questionnaire), and quality of life (Chronic Liver Disease Questionnaire) were examined. Clinical data were obtained *via* patient history and review of medical records. Least absolute shrinkage and selection operator and stepwise backwards regression techniques were used to construct the multivariable logistic regression model. Statistical significance was set at alpha = 0.05.

RESULTS

Medication adherence was "High" in 42% of participants, "Medium" in 37%, and "Low" in 21%. Compared to patients with "High" adherence, those with "Medium" or "Low" adherence were more likely to report difficulty affording their medications (P < 0.001), lower perception of treatment helpfulness (P = 0.003) and stronger medication concerns relative to medication necessity beliefs (P = 0.003). People with "Low" adherence also experienced greater symptom burden and poorer quality of life, including more frequent abdominal pain (P = 0.023), shortness of breath (P = 0.030), and emotional disturbances (P = 0.050). Multivariable analysis identified having stronger medication concerns relative to necessity beliefs (Necessity-Concerns Differential $\leqslant$ 5, OR = 3.66, 95%CI: 1.18-11.40) and more frequent shortness of breath (shortness of breath score $\leqslant$ 3, OR = 3.87, 95%CI: 1.22-12.25) as independent predictors of "Low" adherence.

CONCLUSION

The association between "Low" adherence and patients having strong concerns or doubting the necessity or helpfulness of their medications should be explored further given the clinical relevance.

Key words: Medication adherence; Medication beliefs; Illness perceptions; Quality of life; Liver cirrhosis

Core tip: Medication non-adherence is common in people with decompensated cirrhosis but the impact that patients' medication beliefs and illness perceptions have on adherence is under-recognised. Clinician engagment with non-adherent patients should include open discussion of medications and liver disease. Acknowledgement of patient concerns surrounding their medicines, with positive reinforcement of medication necessity in terms of disease management may improve adherence behaviour and patients' quality of life.

Medication beliefs predict medication adherence in ambulatory patients with decompensated cirrhosis. *World J Gastroenterol* 2017; 23(40): 7321-7331 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7321.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7321

INTRODUCTION

People with decompensated cirrhosis require intensive inpatient and outpatient management, experience poor quality of life (QoL), and have a median survival of approximately two years. While liver transplantation is a viable treatment for end-stage liver disease, this is not an option for many patients. A complex regimen of medications is usually prescribed to manage complications of portal hypertension and liver insufficiency, however medication mismanagement and non-adherence is relatively common among patients with decompensated cirrhosis.

Medication adherence is defined by the World Health Organisation (WHO) as "the extent to which a person's behaviour - taking medication, following a diet, and/or executing lifestyle changes - corresponds with agreed recommendations from a health care provider"[1]. Similar to other chronic diseases where approximately 50% of patients are thought to be non-adherent, up to 70% of patients with cirrhosis identify

as having "Low" or "Medium" levels of medication adherence[2].

Non-adherence with medications has been associated with increased mortality in diabetes, coronary heart disease and heart failure[3,4]. It has been estimated that between 22% and 37% of 30-d readmissions among patients with decompensated cirrhosis may be potentially preventable with improved management of pharmacotherapy[5,6]. For example, non-adherence with lactulose, a non-absorbable disaccharide syrup used in the treatment of hepatic encephalopathy (HE), is reported to be as high as 69%[7], and has been associated with approximately 36% of potentially preventable 30-d readmissions[6]. Intentional non-adherence due to adverse effects (diarrhoea, flatulence and abdominal pain)[7] or misunderstanding of the indication[6] carries a 3-fold risk of HE recurrence[8]; a substantial, potentially preventable burden on patients, carers and the healthcare system[9]. The one-year survival probability following an episode of overt HE is 42%[10], and persisting cognitive impairment or covert HE[11] may in turn lead to unintentional non-adherence with other medications.

Non-adherence and mismanagement of diuretic therapy, which is prescribed in the management of abdominal ascites, peripheral oedema or pleural complications, contributes to 55% of potentially preventable 30-d readmissions in people with decompensated cirrhosis[6]. While prevalence has not been reported in cirrhosis, 30%-66% of patients prescribed loop diuretics in the management of heart failure are non-adherent with therapy[12,13]. Incorrect use of diuretics in cirrhosis can lead to severe electrolyte disturbances and renal impairment, and may contribute to a requirement for recurrent large volume paracentesis. Bacterial infections in people with decompensated cirrhosis are common and often precipitate further deterioration. Spontaneous bacterial peritonitis (SBP) carries a mortality rate of 31.5% at one month and 66.2% at one year[14], with a one-year recurrence rate of 61% without prophylaxis[15]. Prophylaxis with antibiotic therapy considerably reduces SBP recurrence, development of hepatorenal syndrome, and improves probability of one year survival[15], however adherence with long-term antibiotics is known to be low in other patient groups[16,17].

The WHO has identified non-adherence as an international priority in the prevention of patient harm and optimisation of limited health resources[1]. However, medication adherence is a complex health behaviour that is the result of numerous interacting dynamic variables including health literacy, self-efficacy, psychological perceptions of medicines and disease, quality of life, and other internal and external barriers[1]. Previous studies in liver disease patients have identified that side effects and changes to routine are the most commonly cited reasons for non-adherence[7,18]. Illness perceptions have been shown to influence patients' confidence to self-manage alcoholic liver disease and limit self-efficacy[19], while self-perceived disease stigma can affect medical-care seeking behaviours and impact on QoL[20]. However there is limited information available about how perceptions and beliefs surrounding medications and liver disease affect adherence behaviours in people with decompensated cirrhosis. Identifying potentially-modifiable factors that influence adherence behaviour is important, as strategies to support adherence can be tailored to individual patients' needs.

The aim of this study was to: (1) investigate medication non-adherence in a cohort of ambulatory patients with decompensated cirrhosis; and (2) to identify the effect of patients' medication beliefs, illness perceptions, quality of life and clinical and demographic factors on medication non-adherence.

MATERIALS AND METHODS

A convenience sample of adult patients with cirrhosis who had experienced a decompensating event (abdominal ascites, spontaneous bacterial peritonitis, hepatic hydrothorax, encephalopathy or variceal bleeding) within the preceding two years were invited to participate when they attended routine outpatient follow-up at the Princess Alexandra Hospital in Brisbane, Australia, between February and October 2016. Patients were excluded if they were less than 18 years of age, unable to provide informed consent, undergoing transplant workup, or receiving intensive management by the palliative care team.

A structured questionnaire was used to obtain measures of medication adherence, quality of life, medication beliefs and illness perceptions. Questionnaires were completed independently by the patient or with the assistance of a carer, family member, or study coordinator, according to patient preference. Clinical data was collected from patients and/or their medical records, including standard biochemical and serological assays and liver imaging to confirm the diagnosis of cirrhosis and decompensation history. Socio-demographic items included patient-reported individual-based measures of education level and employment status, and residential area-based measures (Index for Relative Socioeconomic Disadvantage[21] and the Accessibility/Remoteness Index of Australia[22] for classification of remoteness of residence).

Medication adherence

Self-reported medication adherence was examined using the 8-Question Morisky Medication Adherence Scale (MMAS-8) which contains seven questions with yes/no alternatives, and one question which features a 5-point Likert scale. The scores from completed

questionnaires are categorised into "High" (score = 8), "Medium" (score 6 to < 8) and "Low" (score < 6) adherence groups[23-25].

Medication beliefs

The Beliefs about Medications Questionnaires (BMQ-General and BMQ-Specific) were used to elicit patients' beliefs about medications. Participants responded to eighteen statements across four domains using a 5-point Likert scale, from "strongly disagree" (score = 1) to "strongly agree" (score = 5). The BMQ-General contains 4 items that examine beliefs about Overuse of medicines by doctors, and 4 items about medication Harms. The BMQ-Specific contains 5 items in the Necessity domain and 5 items in the Concerns domain, which elicit patients' respective necessity and concern beliefs about the medicines prescribed for their liver disease. Scores derived from the Concerns domain can be subtracted from the Necessity domain to give a Necessity-Concerns Differential (N-C differential)[26].

Illness perceptions

The Brief Illness Perceptions Questionnaire (Brief-IPQ) was used to examine the strength of patients' perceptions about liver cirrhosis. The Brief-IPQ contains eight items, including identity (severity of symptoms) and consequences of disease on daily life, personal control and treatment control over disease, timeline for disease duration, self-perceived coherence or understanding of the disease, in addition to concerns and emotional representation that are caused by the disease. Patients self-measure each item on a scale from 0 to 10, where one end of the scale represents a benign perception and the other represents a threatening perception of illness[27].

Quality of life

The Chronic Liver Disease Questionnaire (CLDQ) was chosen to measure health related quality of life as it comprises specific domains relevant to the study population[28]. The full CLDQ contains 29 items across six domains; however responses to the twenty-ninth item have been excluded from analysis due to inapplicability to the majority of study participants. The twenty-ninth item pertains to worry about the availability of a liver if the patient requires a liver transplant; however patients being actively assessed for liver transplant were excluded from the study.

The shortened CLDQ used for the present study therefore contained eight questions related to Emotional Function, five questions within the domains of Systemic Symptoms and Fatigue, three questions within the domains of Abdominal Symptoms and daily Activity, and four items related to Worry. Individual item scores range from 1 to 7 and domain scores are calculated by averaging item scores within each domain. Higher scores represent better perceived health-related quality of life.

Data analysis: Statistical review of the study was performed by a biomedical statistician. Data was analysed using IBM® SPSS© Version 20.0. Where a question was missed within a validated tool, but at least 85% of the tool had otherwise been correctly completed, the missing value was imputed based on the mean or median response to that question, according to data skew. Imputation was required for a single value for two participants: one Brief IPQ-timeline (imputed median score 10) and one CLDQ-anxiety (imputed mean value 4).

Continuous and normally-distributed variables are presented as mean ± SD. Differences between groups were analysed by one-way ANOVA. Non-normally distributed data are presented as median (range) and have been analysed using the Kruskal-Wallis *H* test. Categorical data are presented as proportional percent and analysed using Pearson's chi-squared (χ^2), Fisher's Exact test or Linear-by-Linear Associated test for trend as denoted. Statistical significance was set at alpha = 0.05.

The relationship between "Low" medication adherence and patients' clinical, demographic and self-reported medication beliefs, illness perceptions and QoL were determined by calculating the odds ratio (OR) and 95%CI. Continuous variables were systematically assessed to identify optimal cut-points. Least absolute shrinkage and selection operator and stepwise backwards regression techniques were used to construct the final multivariable logistic regression model. Both methodologies identified the same significant factors for inclusion in the final model. The Hosmer-Lemeshow test was used to assess goodness-of-fit. Interactions between individual variables were not found to be statistically significant.

RESULTS

Demographic and clinical

One-hundred and thirty-four eligible patients were invited to participate in the study (Figure 1). Fourteen patients declined. Five patients indicated that they did not take medicines for their liver disease and thus did not complete essential components of the questionnaires. Of these five patients, three were unaware that their current pharmacotherapy included treatment for hepatic decompensation events, and two had ceased their therapy without medical advice. An additional fifteen patients incompletely filled out the questionnaires for other reasons.

Of the 100 patients who completed the questionnaire tools, the majority (65.0%) were male and the mean age was 58.4 ± 10.2 years. Primary disease aetiology was alcoholic liver disease (ALD) in 49 patients, hepatitis C (HCV) in 35, non-alcoholic fatty liver disease in 9, primary sclerosing cholangitis in two, hepatitis B in one, autoimmune hepatitis in one, drug-induced liver injury in one, alpha-1-antitrypsin

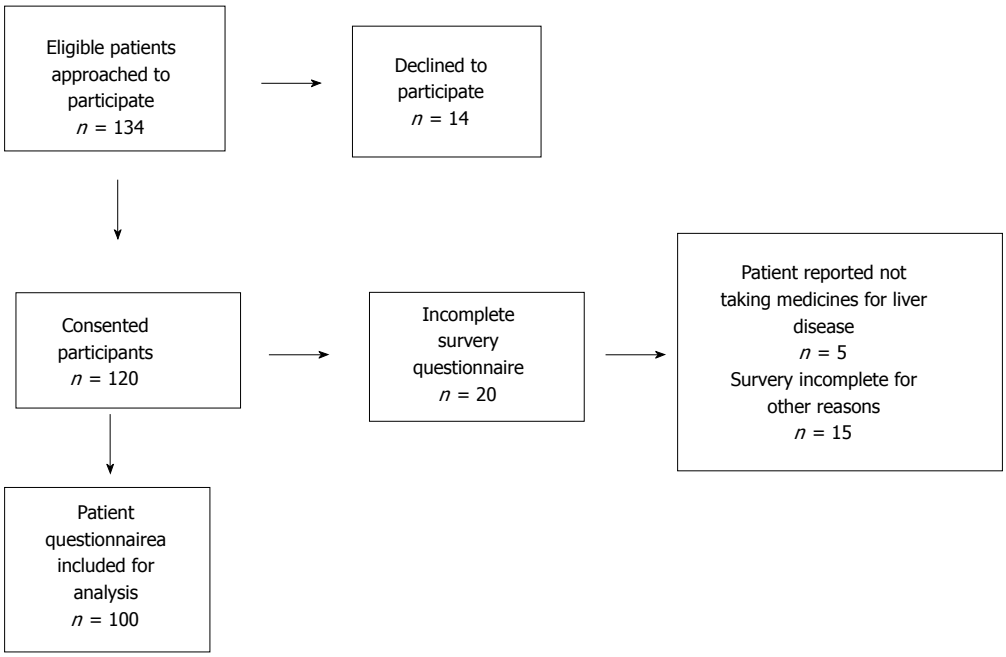

Figure 1 Participant recruitment flow diagram.

deficiency in one and unknown in one. Of the 51 patients who were not considered to have ALD, alcohol was a documented cofactor in 21 patients (41.2%).

Forty-two participants (42%) were categorised as having "High" medication adherence, 37% with "Medium" adherence, and 21% with "Low" adherence. Demographic and clinical characteristics of patients, and their association with medication adherence, are presented in Table 1. Male gender (P = 0.015) and inability to afford medications (P < 0.001) were associated with lower levels of medication adherence. Self-reported ability to afford medicines could not be predicted by employment status, relative sociodemographic disadvantage, or other sociodemographic factors (P > 0.05).

Medication beliefs

Compared to "Low" adherence, there was a non-significant increase in the strength of Necessity beliefs in "High" and "Medium" adherence groups, and a non-significant increase in the strength of Concerns, Harms and Overuse beliefs from "High" to "Low" adherence groups. Compared to patients with "Medium" and "High" medication adherence, patients with "Low" medication adherence reported a lower mean Necessity-Concerns Differential (P = 0.003; Table 2). Three patients had a negative Necessity-Concerns Differential and eight patients had a differential of zero, indicating that their Concerns about their liver disease medicines outweighed or were equal to the perceived Necessity of therapy respectively.

Patients were more likely to have a lower Necessity-Concerns Differential if they were male (6.6 ± 4.3 *vs* 8.5 ± 5.2, P = 0.046), reported inability to afford medications (4.8 ± 4.6 *vs* 7.8 ± 4.5, P = 0.011) or had fewer comorbidities (Pearson's r = 0.263, P = 0.008). Medication beliefs measured using the BMQ scales were not related to age, disease severity, education, sociodemographic status or other clinical and demographic variables.

Illness perceptions

Overall, participants had generally high levels of concern about their liver disease, felt they did not have much personal control over it, and perceived that it would persist for a long duration of time (Table 3). Patients with "Low" medication adherence reported lower perception of how much treatment could help their liver disease (treatment control, P = 0.003) and a lower self-perceived understanding of their liver disease (coherence, P = 0.014).

Patients with HCV reported experiencing more severe symptoms (identity score 6.5 ± 2.4 *vs* 4.9 ± 3.1, P = 0.009), greater impact of disease on daily life (consequences score 6.9 ± 2.4 *vs* 5.5 ± 3.3, P = 0.019) and perceived that their disease would persist for a shorter duration of time (timeline median score 8 [range 0-10] *vs* 10 [range 2-10], P = 0.010) compared to patients who did not have HCV. Female patients reported greater emotional impact of disease (emotional representation score 5.8 ± 3.3 *vs* 4.3 ± 3.4, P = 0.041) while patients with higher levels of education (completed high school, formal trade qualification, university degree *etc.*) perceived greater impact of disease on daily life (consequences score 6.7 ± 2.8 *vs* 5.3 ± 3.2, P = 0.024) compared to patients educated up to middle school. There was a negative correlation between the total Brief-IPQ and CLDQ scores (r = -0.707, P < 0.001), indicating that stronger threatening perceptions of illness are associated with

Table 1 Demographic and clinical factors in patients with high, medium and low medication adherence *n* (%)

Demographic and clinical variables		All patients	Medication adherence ranking			*P* value

	Low–moderate disadvantage	68 (68.0)	26 (68.9)	30 (81.1)	12 (57.1)	

Normally distributed data presented as mean ± SD and analysed using one-way ANOVA. Categorical data presented as proportional percent (%) of column (adherence ranking) and analysed using Pearson's χ^2 or Fisher's Exact test unless otherwise noted. [1]Analysed using the Linear-by-Linear Exact Association test for trend; [2]Excluding 6 patients for whom data was not available (*n* = 40 High adherers, *n* = 33 Medium adherers and *n* = 21 Low adherers); [3]Excluding 8 patients for whom data was not available (*n* = 41 High adherers, *n* = 30 Medium adherers and *n* = 21 Low adherers); [4]Excluding 5 patients for whom data was not available (*n* = 41 High adherers, n = 33 Medium adherers and *n* = 21 Low adherers). *P*-values represent "Employed" *vs* "Unemployed" (data not shown), and "Government Welfare" *vs* "Not receiving Government Welfare" (data not shown) respectively. Two patients reported concurrent part-time employment and Government Welfare support and are represented twice. "Employed" includes full-time, part-time, casual and self-employment. "Government Welfare" includes disability support, aged pension, carer's pension, total permanent disability, Newstart allowance. Six patients reported no active income (living off savings or financially supported by family). ALD: Alcoholic liver disease; HCV: Hepatitis C virus ARIA: Accessibility/Remoteness Index of Australia; IRSD: Index for relative socioeconomic disadvantage.

Table 2 Responses to the beliefs about medications questionnaires in patients with high, medium and low medication adherence

Medication beliefs domains	All patients (*n* = 100)	Medication adherence ranking			*P* value
		High (*n* = 42)	Medium (*n* = 37)	Low (*n* = 21)	
Necessity	19.3 ± 3.8	19.6 ± 3.1	19.9 ± 4.1	17.6 ± 4.0	0.064
Concerns	12.0 ± 3.6	11.2 ± 3.3	12.2 ± 3.3	13.3 ± 4.2	0.074
Necessity-Concerns Differential	7.3 ± 4.7	8.4 ± 4.8	7.6 ± 4.2	4.3 ± 4.2	0.003
Harms	8.3 ± 2.5	7.9 ± 2.8	8.3 ± 2.0	8.8 ± 2.7	0.405
Overuse	10.3 ± 3.1	9.5 ± 3.0	10.7 ± 3.0	11.3 ± 2.9	0.053

Data presented as mean ± SD and analysed using one-way ANOVA. Higher scores indicate stronger medication beliefs within a given domain. Harms and Overuse scores range from 5 to 20. Necessity and Concerns scores range from 5 to 25. The Necessity-Concerns Differential (score range 0 to 20) is calculated by subtracting individual patients' Concern scores from their Necessity scores.

lower quality of life.

Quality of life

The greatest overall health-related QoL impacts reported by patients were in the domains of Fatigue and Worry. Impact of QoL on medication adherence is presented in Table 4. "Low" medication adherence was associated with lower QoL in terms of shortness of breath that impacted on daily activity (*P* = 0.030), greater emotional disturbances (*P* = 0.050), particularly irritability (*P* = 0.017) and mood swings (*P* = 0.031), and greater frequency of abdominal and bodily pain (*P* = 0.023 and *P* = 0.037, respectively). Patients with moderate or large ascites at the time of review reported greater impact of abdominal bloating (CLDQ-abdominal bloating score 3.47 ± 2.04 *vs* 4.69 ± 1.88, *P* = 0.014) and those with a history of HE reported more frequent irritability (CLDQ-irritability score 4.31 ± 1.57 *vs* 5.04 ± 1.72, *P* = 0.029), but these did not translate into an effect on medication

Table 3 Illness perceptions in patients with high, medium and low medication adherence

Brief illness perception questionnaire items	All patients (n = 100)	Medication adherence ranking			P value
		High (n = 42)	Medium (n = 37)	Low (n = 21)	
Consequences How much does your liver disease affect your life? 0 = No affect; 10 = Severely affects my life	6.0 ± 3.1	6.1 ± 3.0	6.0 ± 3.1	5.7 ± 3.2	0.846
Timeline How long do you think your liver disease will continue? 0 = Very short time; 10 = Forever	10.0 (0-10)	10 (3-10)	10 (0-10)	10 (3-10)	0.962
Personal Control How much control do you feel you have over your liver disease? 0 = Absolutely no control; 10 = Extreme amount of control	4.8 ± 3.0	4.6 ± 3.2	4.8 ± 2.9	5.0 ± 2.8	0.893
Treatment Control How much do you think your treatment can help your liver disease? 0 = Not at all; 10 = Extremely helpful	8.0 (0-10)	8 (2-10)	10 (4-10)	7 (0-10)	0.003
Identity How much do you experience symptoms from your liver disease? 0 = No symptoms; 10 = Many severe symptoms	5.5 ± 3.0	5.6 ± 3.0	5.5 ± 3.0	5.2 ± 2.9	0.905
Concern How concerned are you about your liver disease? 0 = Not at all; 10 = Extremely concerned	8.0 (0-10)	8 (0-10)	9 (0-10)	8 (0-10)	0.416
Coherence How well do you feel you understand your liver disease? 0 = Don't understand at all; 10 = Understand very clearly	8.0 (0-10)	8 (3-10)	8 (0-10)	7 (2-9)	0.014
Emotional Representation How much does your liver disease affect you emotionally? 0 = Not at all; 10 = Extremely affected emotionally	4.9 ± 3.4	4.7 ± 3.2	5.1 ± 3.9	4.7 ± 3.1	0.874

Normally distributed data presented as mean ± SD and analysed using one-way ANOVA. Non-normally distributed data presented as median group score and (range) and analysed using the Kruskal-Wallis H Test.

adherence.

Patients who reported feeling hassled about sticking to their treatment plan (n = 10) and those that stated they did not take their medicines the preceding day (n = 9) reported lower overall QoL (average CLDQ score 2.96 ± 1.08 *vs* 4.30 ± 1.17, P = 0.001 and 2.97 ± 0.78 *vs* 4.28 ± 1.20, P = 0.002 respectively), especially within the domains of Activity, Emotion and Fatigue. Feeling hassled about sticking to the treatment plan was particularly associated with increased irritability (CLDQ-irritability score 3.50 ± 2.01 *vs* 4.81 ± 1.60, P = 0.019) and mood swings (CLDQ-mood swings score 3.33 ± 1.32 *vs* 4.81 ± 1.66, P = 0.003 respectively).

Factors associated with low medication adherence

Bivariate analysis indicated that patients with Necessity-Concerns Differential ⩽ 5, Brief Illness Perception Questionnaire "treatment control" score ⩽ 8 and "coherence" score ⩽ 8, or CLDQ score ⩽ 3 in the items of bodily pain, abdominal pain, shortness of breath or irritability, had higher odds of reporting "Low" medication adherence (Table 5). However, when included in the regression model having a Necessity-Concerns Differential ⩽ 5 (OR = 3.66, 95%CI: 1.18-11.40), Brief IPQ-coherence score ⩽ 8 (OR = 8.15, 95%CI: 0.98-67.78) or a CLDQ-shortness of breath score ⩽ 3 (OR = 3.87, 95%CI: 1.22-12.25) were the only independent predictors of "Low" medication adherence.

DISCUSSION

In our study, self-reported medication non-adherence in ambulatory patients with decompensated cirrhosis was prevalent, with over one-fifth of patients categorised with "Low" adherence and more than one-third categorised with "Medium" adherence. We have identified that lower levels of medication adherence in this group are associated with stronger patient Concerns about their medication relative to their belief in its Necessity, lower self-perceived understanding of liver disease, and lower QoL.

The relationship between medication beliefs and medication adherence behaviour has been explored in numerous chronic diseases, including asthma, cardiovascular disease and mental health disorders[29]. Perceptions of illness have also been shown to influence medication adherence in asthma, diabetes, hypertension and heart failure[30], though the impact of the different illness perception items on adherence appears to differ between diseases. In the present study, people with decompensated cirrhosis were more likely to have "Low" medication adherence if they had a lower Necessity-Concerns Differential, poorer self-perceived understanding of their hepatic disease (coherence), and had lower perceptions of the benefits of treatment for their hepatic disease (treatment control). It can therefore be inferred that decompensated cirrhosis patients who have a

Table 4 Health-related quality of life in patients with high, medium and low medication adherence

Quality of life domains	All patients (n = 100)	Medication adherence ranking			P value
		High (n = 42)	Medium (n = 37)	Low (n = 21)	
Abdominal symptoms	4.7 ± 1.5	4.6 ± 1.4	5.1 ± 1.4	4.2 ± 1.6	0.063

Dry mouth	3.9 ± 2.0	4.0 ± 2.0	3.9 ± 2.0	3.7 ± 1.9	0.833
Itching	4.5 ± 2.1	4.2 ± 2.2	4.6 ± 2.0	5.0 ± 2.1	0.392
Worry	3.9 ± 1.8	4.1 ± 1.8	3.8 ± 2.0	3.6 ± 1.6	0.491
Worry about impact of liver disease has on family/friends	3.9 ± 2.1	4.0 ± 2.0	3.9 ± 2.2	3.7 ± 2.2	0.876
Worried that symptoms will develop into major problems	3.7 ± 2.1	4.0 ± 2.1	3.6 ± 2.2	3.1 ± 2.0	0.357
Worry about condition getting worse	3.9 ± 2.0	4.1 ± 2.0	3.7 ± 2.1	3.6 ± 2.0	0.569
Worry about never feeling any better	4.2 ± 2.2	4.5 ± 2.2	4.2 ± 2.3	3.8 ± 1.8	0.436

Normally distributed data presented as mean ± SD and analysed using one-way ANOVA. Item scores range from 1 to 7 where a lower score indicates lower quality of life (*i.e.*, more frequent symptoms). Domain scores (range from 1 to 7) are calculated averages of items within the domain.

weaker belief in the necessity or helpfulness of their medications, and those who do not understand the consequences of cirrhosis, are less likely to perceive a need to take their medications and may therefore exhibit non-adherent behaviour.

Interestingly, perceptions of symptom frequency/severity (identity), concerns and consequences of disease on daily life were not associated with adherence behaviour. This was further confirmed using the CLDQ which identified that adherence was not influenced by the domains of Activity, Fatigue, Worry, Systemic or Abdominal Symptoms. This may be explained by changes to patients' priorities in the terminal stages of illness which may affect their decisions for self-care. For example, people with palliative diseases such as cancer and end-stage heart failure may exhibit non-adherent behaviour in an attempt to maintain control, reduce adverse events, or in response to social or financial circumstances[31-33]. Similar issues may affect people with decompensated cirrhosis, as this is a palliative condition for patients who are ineligible for transplantation. Most patients in the present study were aware of the incurable nature of their disease as evidenced by responses to the timeline item. The presence of hepatocellular carcinoma, considered to be an "imminently terminal" occurrence in people with decompensated cirrhosis who are ineligible for liver transplant, was not associated with adherence, which indicates that perceptions of palliation alone may not strongly influence adherence behaviour in this group.

Notably, people with HCV perceived that their liver disease would last for a shorter duration of time compared to people with other aetiologies of cirrhosis, possibly related to availability of new HCV direct-acting antiviral therapies. Unfortunately, this may be the result of false hope in this group as it is possible that many patients with HCV cirrhosis will have persisting complications despite a HCV "cure". People with HCV also perceived greater impact of symptom frequency/severity (identity) and consequences of disease on their daily lives compared to other aetiologies, but this was not associated with adherence behaviour. Where improved control over debilitating symptoms may be an incentive for better adherence for some

Table 5 Crude and multivariable predictors of low medication adherence in patients with decompensated cirrhosis

		Crude		[1]Multivariable		*P* value
		OR	95%CI	OR	95%CI	
Age ⩾ 60 yr		1.20	0.46-3.16	1.79	0.56-5.70	0.325
Gender, male		1.10	0.40-3.04	0.74	0.21-2.58	0.639

CLDQ-irritability (15)	QoL score ⩽ 3	3.12	1.08-9.04	1.70	0.47-6.11	0.416
CLDQ-mood swings (19)	QoL score ⩽ 3	2.09	0.75-5.82	0.93	0.24-3.58	0.917

[1]Odds ratio adjusted for N-C Differential ⩽ 5, Brief IPQ-treatment control score ⩽ 8, Brief IPQ-coherence score ⩽ 8 and CLDQ-shortness of breath score ⩽ 3 (indicative of experiencing the symptom "all the time", "most of the time" or "a good bit of the time") in the multivariable logistic regression model.

patients, others could perceive side effects of therapy to outweigh benefits. This may be evidenced by the increased likelihood for "Low" adherence in patients who had stronger Concerns (*i.e.,* side effects) relative to Necessity (*i.e.,* benefits) beliefs, and those with less understanding about cirrhosis (coherence) and the role of medicines in disease and symptom management (treatment control). Alternatively, studies in other chronic diseases with a heavy symptom burden like decompensated cirrhosis, such as asthma and heart failure, have suggested that many patients with good adherence report a more benign perception of illness identity, concerns and consequences[34,35]. This may be attributed to improved disease control or fewer episodes of exacerbation because of good adherence with treatment, and may partially explain the heterogeneity of responses to these Brief-IPQ items among people with decompensated cirrhosis.

A previous investigation by Polis *et al*[18] in cirrhosis patients has identified that medication adherence, defined as "never missing medications", was associated with having less abdominal symptoms and increased emotional well-being[18]. Similarly, we have identified that decompensated patients with "Low" medication adherence reported more frequent emotional disturbances, greater abdominal and bodily pain, and activity-limiting shortness of breath. Rather than a cause, these symptoms are postulated to be an effect of non-adherence. Conversely, irritability and mood swings were associated with patients reporting they felt "hassled about sticking to their treatment plan" and failure to take medications the day preceding the survey. Irritability and mood swings are thus postulated to impact on adherence in this group. While emotional disturbances are often associated with hepatic encephalopathy, irritability and mood swings were not necessarily more common in people with a history of HE, and these symptoms were not found to relate to non-adherence in patients prescribed lactulose. While the effect of adverse drug events experienced by individual patients on medication adherence was not specifically explored, the BMQ items designed to capture negative beliefs potentially related to adverse effects were not strongly related to nonadherence. Interestingly, disease severity measured using the Child-Turcotte Pugh classification was not related to QoL at either the domain or item level. This is contrary to other studies in cirrhosis patients[36,37], however by the nature of this study we aimed to recruit patients with a diverse decompensation history, which may explain the heterogeneity of responses to the CLDQ.

Strengths and limitations

The single study site, the General Hepatology Clinic at the Princess Alexandra Hospital, is one of the largest hepatology centres in Australia. The Clinic delivers ambulatory care to a substantial proportion of south-east Queensland hepatology patients, in addition to regional, remote and interstate patients who travel to access specialist services. Despite the broad representation of people with chronic liver diseases at our site, an element of selection bias may exist in the present study due to recruitment constraints. If two or more eligible patients were scheduled for hepatology review simultaneously (parallel hepatology clinics), patients who were taking more medicines for decompensation events were selectively approached. Thus, the patients included may represent the more severe end of the disease spectrum. Furthermore, participants could only be recruited if they were scheduled to attend clinic on a day the principal researcher (KH) was present and as such a convenience sample of patients was recruited.

As far as we are aware, this is the first study to use the BMQ and Brief-IPQ to measure beliefs and perceptions about medications and illness in people with decompensated cirrhosis. While these tools have not been previously validated in this cohort, our findings are comparable with studies in other chronic diseases. Non-equal questioning methodology (due

to patients' preference, need for carer/family member involvement, researcher assistance and feasibility) may have introduced an element of bias, however this was difficult to avoid given the study group of interest often requires assistance completing complex tasks and reflects a "real-world" clinic setting. To minimise potential bias, the study coordinator read survey questions aloud verbatim and did not actively seek additional information beyond what patients volunteered.

In conclusion, a large proportion of ambulatory patients with decompensated cirrhosis are non-adherent with prescribed medications. The association between "Low" medication adherence and patients having strong concerns or doubting the necessity of their medications should be explored further given the potential clinical relevance. Interventions that promote positive reinforcement of the value and necessity of medications in addition to education about disease and medication management tailored to individual patient needs may improve adherence.

COMMENTS

Background

Non-adherence and medication-mismanagement in people with decompensated cirrhosis have been associated with substantial potentially-preventable harm. The current study describes the relationship between patients' self-reported adherence and medication beliefs, illness perceptions and quality of life. The study was conducted in a cohort of patients receiving ambulatory care at a large tertiary government hospital.

Research frontiers

Existing data on medication-nonadherence behaviour in people with decompensated cirrhosis is largely qualitative. The present study intended to quantitatively measure these variables using validated tools, to correlate potentially-modifiable beliefs, perceptions and quality of life with medication adherence.

Innovations and breakthroughs

In this study, the authors have identified that patients with lower levels of medication adherence were more likely to have lower perception of treatment helpfulness, higher concerns relative to necessity beliefs surrounding their medicines, and poorer quality of life.

Applications

The authors findings have important implications for evolving clinical practice, as medication-management and disease education interventions can be developed to target these potentially-modifiable patient variables.

Terminology

Levels of adherence (High, Medium and Low) were assessed using a validated adherence tool, the Morisky Medication Adherence Scale-8 (MMAS-8). Patients' beliefs and perceptions towards their medicines were elicited using previously validated questionnaires (Beliefs about Medicines Questionnaire and Brief Illness Perception Questionnaire), which have been correlated with adherence behaviour. Quality of Life was measured using the Chronic Liver Disease Questionnaire.

Peer-review

This is a very interesting article dealing with the adherence to therapy by decompensated cirrhotic patients.

Abstract

Hypertriglyceridemic pancreatitis (HTGP) accounts for up to 10% of acute pancreatitis presentations in non-pregnant individuals and is the third most common cause of acute pancreatitis after alcohol and gallstones. There are a number of retrospective studies and case reports that have suggested a role for apheresis and insulin infusion in the acute inpatient setting. We report a case of HTGP in a male with hyperlipoproteinemia type Ⅲ who was treated successfully with insulin and apheresis on the initial inpatient presentation followed by bi-monthly outpatient maintenance apheresis sessions for the prevention of recurrent HTGP. We also reviewed the literature for the different inpatient and outpatient management modalities of HTGP. Given that there are no guidelines or randomized clinical trials that evaluate the outpatient management of HTGP, this case report may provide insight into a possible role for outpatient apheresis maintenance therapy.

INTRODUCTION

Hypertriglyceridemic pancreatitis (HTGP) accounts for up to 10% of acute pancreatitis presentations in non-pregnant individuals and is the third most common cause of acute pancreatitis after alcohol and gallstones[1,2]. Both genetic and secondary causes of lipoprotein metabolism have been implicated in HTGP. A serum triglyceride (TG) level of 10 g/L or greater is associated with acute pancreatitis. The risk of HTGP is approximately 5% with TG levels above 10 g/L and 10% to 20% with TG > 20 g/L[3]. The 2013 American College of Gastroenterology (ACG) guidelines in managing acute pancreatitis recommend obtaining a triglyceride level on all patients with acute pancreatitis without a known history of alcoholism or gallstones. While the ACG guidelines extensively explore the management of pancreatitis in general, there is a lack of data on the specific management of HTGP[4]. A number of retrospective studies and case reports in the past decade have suggested a role for insulin infusion with or without apheresis as an approach to rapidly lowering TG levels in an attempt to treat HTGP[1,5-18]. There are no randomized clinical trials evaluating the benefit of insulin infusion or apheresis in managing HTGP. Furthermore, there is a lack of characterization of post-discharge course and outpatient management of HTGP[19,20]. To our knowledge, there is only one case report of two patients with HTGP in 1996 who were managed with monthly plasmapheresis as maintenance therapy to prevent HTGP recurrence[21]. We report a case of HTGP in a male with hyperlipoproteinemia type Ⅲ who was treated successfully with insulin and apheresis followed by bi-monthly maintenance apheresis sessions post-discharge as prevention of recurrent HTGP. This case report may provide insight into a possible role for outpatient apheresis maintenance therapy.

CASE REPORT

A 40-year-old Caucasian male with a past medical history significant for hyperlipoproteinemia type Ⅲ (on atorvastatin 80 mg daily, fenofibrate 200 mg daily and omega-3 polyunsaturated fatty acids), coronary artery disease status post 3-vessel coronary artery bypass graft, peripheral vascular disease, hypertension, diabetes mellitus (DM) type 2, and one reported episode of acute pancreatitis in the past presented with epigastric pain, nausea and decreased oral intake over 3 d. Physical exam was remarkable for tachycardia to 100 beats/min, localized epigastric tenderness, and xanthomas with striae palmaris. Labs were remarkable for mildly elevated lipase of 334 U/L (reference range 114-286 U/L) and TG levels of 45.3 g/L (reference range 0-149). Abdominal CT scan showed moderate fat stranding around the pancreas and stable pseudocyst. He was started on insulin drip at a rate of 1 unit/h. TG levels trended down after 3 d of insulin infusion to 9.57 g/L. The patient, however, continued to have severe abdominal pain and inability to tolerate oral intake. After 3 d of inpatient stay, patient received his first session of apheresis. After 24 h of apheresis, patient improved symptomatically and was able to tolerate oral intake. Triglyceride levels trended down to 4.61 g/L after 24 h of apheresis and were 6.75 g/L on the day of discharge.

Given that the patient had a complicated cardiac history and that this was his second HTGP presentation in one year, a decision was made to have the patient undergo maintenance apheresis sessions bi-monthly as an outpatient to prevent recurrent pancreatitis and cardiac complications. Patient was discharged on home cardiac medications which consisted of hydrochlorothiazide 12.5 mg daily, Plavix 75 mg daily, aspirin 325 mg daily, metoprolol tartrate 50 mg BID, atorvastatin 80 mg daily, fenofibrate 200 mg and omega-3 polyunsaturated fatty acids. Twelve mo post-discharge course was remarkable for a total of three admissions due to recurrent pancreatitis with one admission attributed to poor adherence to apheresis, fat-free diet and lipid lowering medications. His TG levels mostly remained otherwise successfully below 15 g/L. Repeat abdominal CT scans over 12 mo demonstrated resolution of previous pseudocyst and absence of local complications (Figure 1).

DISCUSSION

Patients with HTGP present with symptoms typical of

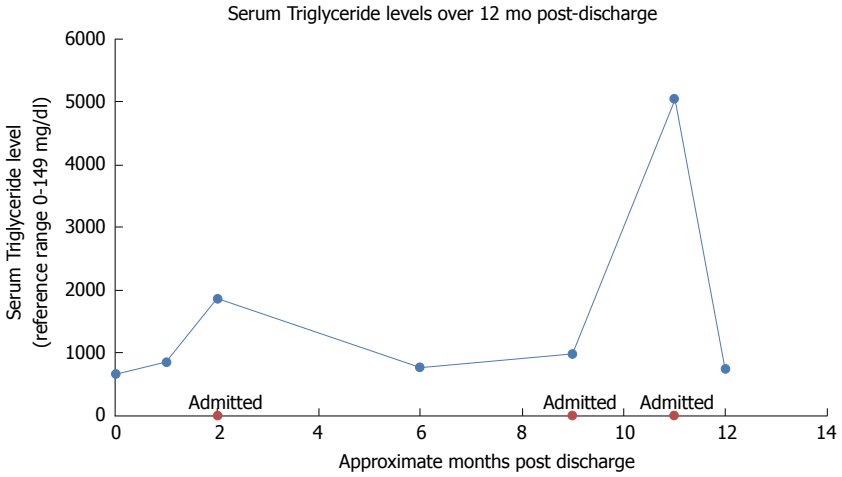

Figure 1 Serum triglyceride levels over 12 mo post-discharge. Hospital admissions are highlighted in red.

acute pancreatitis[1]. Specific features of HTGP that can help identify the etiology include xanthomas on extensor surfaces of arms and legs, lipemia retinalis and hepatosplenomegaly[22]. Lactescent serum is found in 45% of patients with mean Hypertriglyceridemia (HTG) level of 4537[2]. A serum TG level of 10 g/L or greater is associated with acute pancreatitis. The risk of HTGP is approximately 5% with TG levels above 10 g/L and 10% to 20% with TG > 20 g/L[23]. HTG by itself is not toxic to the pancreas, however, the breakdown of TG into free fatty acids (FFA) by pancreatic lipase causes lipotoxicity during acute pancreatitis, leading to a systemic inflammatory response[22]. Primary HTG that includes Frederick's phenotype Ⅰ-Ⅴ is associated with HTGP. Our patient was diagnosed with hyperlipoproteinemia type Ⅲ, an autosomal recessive trait, characterized by presence of Apo E2/E2[24]. Apo E ligand clears chylomicrons and Very low-density lipoprotein (VLDL) remnants from the circulation. Thus, this disorder leads to accumulation of VLDL and chylomicrons leading to HTG. Secondary HTG is caused by DM, alcoholism, hypothyroidism, pregnancy, and certain medications such as thiazides, beta blockers, corticosteroids, isotretinoin, immunosuppressants and antipsychotics[1].

A number of retrospective studies and case reports in the past decade suggested a role for insulin infusion with or without apheresis as an approach to rapidly lower TG levels in an attempt to treat HTGP[1,5-18]. There are no randomized clinical trials evaluating the benefit of insulin infusion, heparin or apheresis in managing HTGP to date. However, lowering of TG levels to below 5 g/L has been shown to advance clinical improvement in HTGP[25]. Apheresis is used to lower triglyceride level > 10 g/L and improve signs of severe inflammation such as hypocalcemia and lactic acidosis. One study reported (average TG of 14.06 g/L) a 41% decrease in TGs after one session of plasma exchange[18]. To our knowledge, there is only one case report of two patients with severe HTGP in 1996 who were managed with monthly plasmapheresis maintenance therapy[21]. Their 32-38 mo course was remarkable for only one episode of acute pancreatitis in one patient, suggesting a beneficial role for maintenance plasmapharesis[21].

With regard to anticoagulation during apheresis, studies have shown that citrate as opposed to heparin is associated with decreased mortality[18]. Intravenous insulin has been shown to be more effective than subcutaneous insulin in managing HTGP[26]. Insulin increases lipoprotein lipase which in turn accelerates chylomicron and VLDL metabolism to glycerol and FFA. It also inhibits lipase in adipocytes. Heparin is controversial in efficacy when used alone. It is thought to stimulate the release of endothelial lipoprotein lipase into the circulation, but the mechanism of lowering TG remains unclear[27].

Lipid lowering agents are indicated in the management of HTGP[25]. However, this is further complicated by the association between statin therapy and the development of acute pancreatitis. A series of case-control studies in Taiwan demonstrated that individuals using a statin therapy for the first time are more likely to develop an episode acute pancreatitis when compared to individuals who are not on statin therapy. These studies included Simvastatin (OR = 1.3, 95%CI: 1.02-1.73), Atrovastatin (OR = 1.67, 95%CI: 1.18-2.38), and Rosuvastatin (OR = 3.21, 95%CI: 1.70-6.06)[28-31]. Table 1 provides a summary of HTGP management strategies.

In summary, we presented a case of HTGP in a male with hyperlipoproteinemia type Ⅲ who was treated successfully with insulin and apheresis followed by outpatient bi-monthly maintenance apheresis sessions with a 12 mo post-discharge course remarkable for total of three admissions due to recurrent pancreatitis but with TG levels mostly remaining successfully below 15 g/L and repeat abdominal imaging demonstrating resolution of previous pseudocyst and absence of local

Table 1 Summary of hypertriglyceridemic pancreatitis management strategies

Management strategy	Description	Indication	Outcomes	Case report/Ref.
Diet restriction	Absolute restriction of fat intake	HTG, Primary prevention	Effective when combined with lipid lowering agents[15]	Tsuang *et al*[15], 2009
Lipid lowering agents	Fibrates (gemfibrozil 600 mg twice daily), niacin, N-3 fatty acids, statins	First line in HTG Adjuvant therapy in HTGP	Triglyceride level lowered about 60% by fibrates, about 50% by niacin, about 45% by omega-3 fatty acids[15]	Tsuang *et al*[15], 2009
Apheresis	Therapeutic Plasma Exchange which is removal of plasma and replacement with colloid solution (albumin, plasma). Citrate is used as an anticoagulant. Goal is TGH < 500	HTGP without contraindication to Apheresis such as inability to obtain central access or hemodynamic instability	Appears to be effective based on multiple case reports and case series. about 41% decrease in HTG levels. Apheresis within 48 h associated with better outcomes[16]	Furuya *et al*[16], 2002
Insulin	Intravenous regular insulin drip (0.1 to 0.3 units/kg/h). Goal is TGH < 500. Used alone or in combination with apheresis and/or heparin	Apheresis unavailable unable to tolerate apheresis hyperglycemia > 500	Intravenous insulin is more effective than subcutaneous[17] Effective in lowering triglyceride levels	Berger *et al*[17], 2001
Heparin	Combined with insulin. Subcutaneous heparin 500 units BID in 2 case reports	Controversial in HTGP	Controversial. Associated with increased mortality when compared to citrate (both combined with apheresis)[18].	Gubensek *et al*[18], 2014
Periodic apheresis	Described in 2 patients as monthly apheresis in 1996	Recurrence prevention especially in noncompliant patients	Reported success in one case report (2 patients in 1996)[21].	Piolot *et al*[21], 1996

HTGP: Hypertriglyceridemic pancreatitis; HTG: Hypertriglyceridemia; BID: Bis in die; TGH: Triacylglycerol hadrolase.

complications. This may suggest a beneficial role for outpatient apheresis as maintenance therapy in HTGP patients.

COMMENTS

Case characteristics

A 40-year-old Caucasian male with a past medical history significant for hyperlipoproteinemia type Ⅲ (on atorvastatin 80 mg daily, fenofibrate 200 mg daily and omega-3 polyunsaturated fatty acids), coronary artery disease status post 3-vessel coronary artery bypass graft, peripheral vascular disease, hypertension, diabetes mellitus type 2, and one reported episode of acute pancreatitis in the past presented with epigastric pain, nausea and decreased oral intake over 3 d.

Clinical diagnosis

Physical exam was remarkable for tachycardia to 100 beats/min, localized epigastric tenderness, and xanthomas with striae palmaris.

Differential diagnosis

Acute pancreatitis, gastritis, peptic ulcer disease, gastroenteritis, gastroesophageal reflux disease.

Laboratory diagnosis

Labs were remarkable for mildly elevated lipase of 334 U/L (reference range 114-286 U/L) and triglyceride levels of 45.3 g/L (reference range 0-149 g/L).

Imaging diagnosis

Abdominal CT scan showed moderate fat stranding around the pancreas and stable pseudocyst.

Treatment

Insulin, apheresis, atorvastatin 80 mg daily, fenofibrate 200 mg and omega-3 polyunsaturated fatty acids.

Related reports

There are a number of case reports in the literature that have demonstrated a benefit from apheresis and insulin therapy in the inpatient management of hypertriglyceridemic pancreatitis (HTGP). There is only one case report that have suggested a role for outpatient apheresis as a maintenance therapy.

Term explanation

HTGP is acute pancreatitis caused by high levels of serum triglycerides. Apheresis is the process of removal and separation of blood components and replacement with colloid solution (albumin, plasma).

Experiences and lessons

Multiple studies have demonstrated a role for apheresis in the acute management of HTGP. This case report suggests a role for outpatient apheresis in preventing recurrent attacks of HTGP.

Peer-review

This is a nice case report on a timely topic: hypertriglyceridemia-induced acute pancreatitis and role for outpatient apheresis maintenance therapy. This manuscript is generally of interest. The authors provided the complete review of this issue. The manuscript provides the updated evidence to the readers. It can be accepted for publication.

Abstract

We report a case involving a rescued low birth weight infant (LBWI) with acute liver failure. Case: The patient was 1594 g and $32^{3/7}$ gestational wk at birth. At the age of 11 d, she developed acute liver failure due to gestational alloimmune liver disease. Exchange transfusion and high-dose gamma globulin therapy were initiated, and body weight increased with enteral nutrition. Exchange transfusion was performed a total of 33 times prior to living donor liver transplantation (LDLT). Her liver dysfunction could not be treated by medications alone. At 55 d old and a body weight of 2946 g, she underwent LDLT using an S2 monosegment graft from her mother. Three years have passed with no reports of intellectual disability or liver dysfunction. LBWIs with acute liver failure may be rescued by LDLT

after body weight has increased to over 2500 g.

Key words: Liver transplantation; Acute liver failure; Low birth weight infant; Transplantable body weight; Monosegment graft

Rescue case of low birth weight infant with acute hepatic failure. *World J Gastroenterol* 2017; 23(40): 7337-7342 Available from: URL: http://www.wjgnet.com/1007-9327/full/v23/i40/7337.htm DOI: http://dx.doi.org/10.3748/wjg.v23.i40.7337

INTRODUCTION

Neonatal acute hepatic failure is a rare but serious disease[1]. Reports have indicated that the cause of neonatal acute hepatic failure is most frequently gestational alloimmune liver disease (GALD), but in rare cases, it can be metabolic disorder, viral infection, or mitochondrial disorder, among other possibilities[2]. The initial treatment for neonatal acute liver failure is apheresis and medication while the cause of hepatic failure is determined. If hepatic recovery has not been achieved with medication alone, liver transplantation is indicated[1,3]. However, the living donor liver transplantation (LDLT) procedure for neonatal recipients is challenging due to the size mismatch between the liver graft and the body of the recipient. Moreover, management during the perioperative period is also challenging[4]. LDLT is particularly difficult for low birth weight infants (LBWIs) for the reasons discussed above. In such cases, LDLT can result in recovery if the body weight of the infant can be increased by nutritional management[5]. However, few reports have discussed LDLT for neonatal recipients with low body weights[6]. Herein, we report a case involving a rescued LBWI with acute liver failure and discuss the limitation of body weight as an indicator for neonatal LDLT.

CASE REPORT

The patient was born at $32^{3/7}$ gestational wk because of fetal distress. Her birth weight was 1594 g (Figures 1 and 2). Immediately after birth, hypoglycemia and hypotension appeared. A daily administration of hydrocortisone and continuous administration of dopamine hydrochloride were started at the age of 1 day. At the age of 11 d, coagulation dysfunction and an elevated serum ferritin level due to acute liver failure were observed (ferritin 2865 ng/mL, total bilirubin 12.5 mg/dL, PT-INR 4.57). The patient's older sister was highly suspected of GALD by clinical course and pathological findings and underwent LDLT at 13 d of age. GALD was highly suspected in this case after excluding the possibility of metabolic disorder or infectious disease. The patient did not undergo magnetic resonance imaging or salivary grand biopsy for GALD diagnosis. We explained the high recurrence rate of GALD in siblings to her parents; however, the parents gave birth to a baby in another hospital without informing us. Starting at 11 d of age, exchange transfusion and medication therapy using high-dose gamma globulin and deferoxamine were initiated. The patient's body weight had been gradually increased with enteral nutrition using commercially available nutrients, administered 8 times per day *via* a gastric tube. She then recovered from hypotension, and the continuous administration of dopamine hydrochloride was finished. Exchange transfusion was performed a total of 33 times prior to LDLT. The patient was transported to our hospital at 44 d of age; at that time, her body weight was 2525 g. We speculated that her target body weight for LDLT would be over 2500 g based on the estimated graft volume. Computed tomography scan revealed a markedly atrophied liver (resected liver was 78 g). Laboratory data showed repeated coagulopathy and hyperbilirubinemia with daily exchange transfusion and a pediatric end-stage liver disease (PELD) score of 15.8 (T-bil 5.09 mg/dL, PT-INR 1.91, Albumin 3.4 g/dL). A liver biopsy revealed a marked loss of hepatocytes. The remaining hepatocytes were multinucleated, and there was widespread fibrosis around Glisson's sheath and in the parenchymal area (F3-4) (Figure 2F and G). Thus, her liver dysfunction could not be successfully treated *via* medications alone, and she was judged to be indicated for liver transplantation at that time. We tried to perform LDLT at 45 d of age, but before LDLT, she went into shock following hemothorax due to failure of catheter insertion with injury of the right subcla*via*n artery. After the recovery period, she underwent LDLT at 55 d of age using an S2 monosegment graft from her mother (107 g, graft-recipient weight ratio (GRWR) 3.6%; Figure 2 A). The body weight of the patient at LDLT was 2946 g. At the time of LDLT, the PELD score of the patient was 21.9 (T-bil 13.74 mg/dL, PT-INR

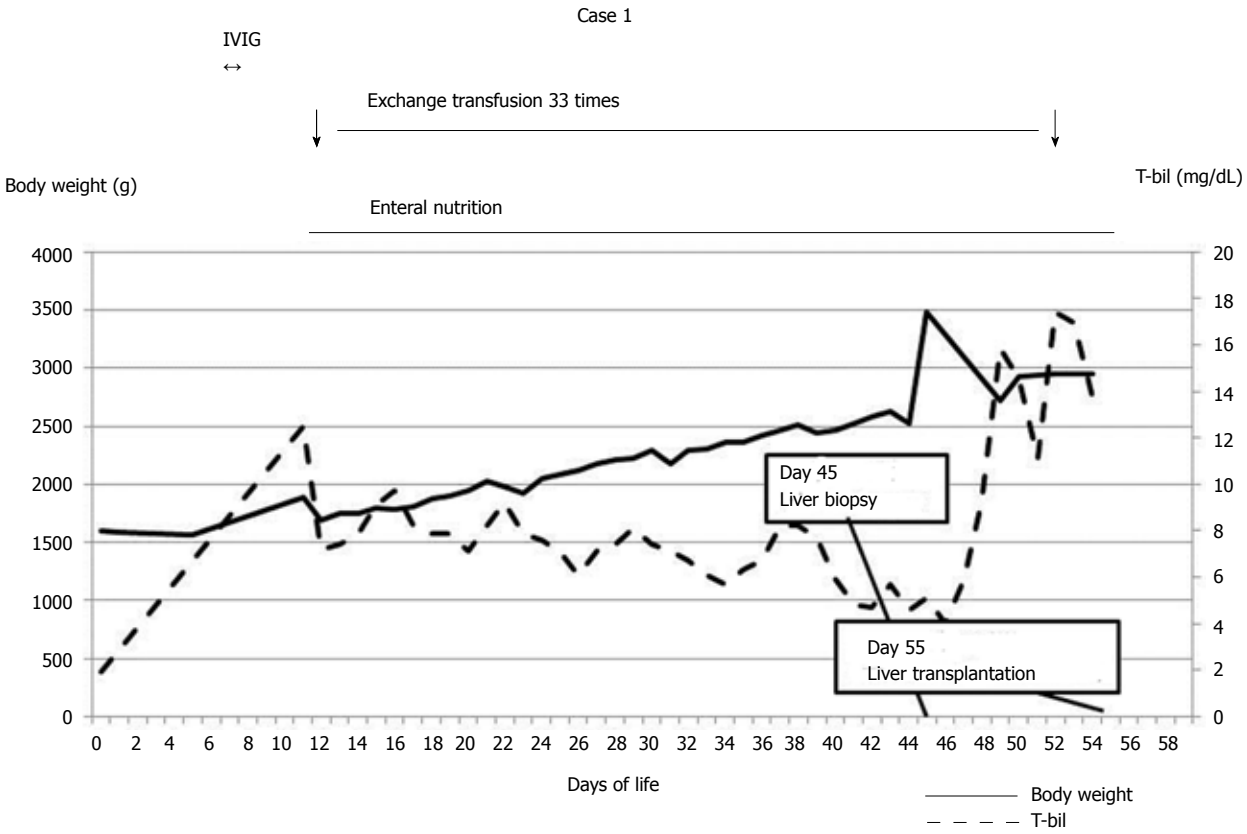

Figure 1 The preoperative treatment and changes in body weight and total bilirubin. The patient was able to gain weight due to the use of internal medication and enteral nutrition.

2.12, Albumin 3.7 g/dL). The operation duration was 13 h and 37 min and bleeding was 700 mL [238 mL/recipient body weight (kg)]. A transverse incision was created, and the liver was resected with temporary bypass of the portal vein. The resected liver was 78 g (Figure 2E). The recipient's right hepatic artery (2.0 mm) was anastomosed to the graft's left hepatic artery (2.5 mm) *via* a dorsal position of the portal vein anastomosis using a microsurgical technique. The graft-to-recipient distance ratio (GRDR) was 2.4 (58/24). Biliary reconstruction was performed using a Roux-en-Y hepaticojejunostomy. The abdominal wound could not be closed because respiratory failure occurred due to abdominal compartment syndrome (Figure2B and C). Intraoperative water balance was +1645 mL [558 mL/recipient body weight (kg)]. After LDLT, continuous hemodiafiltration (CHDF) had been performed for systemic edema, removing water as long as blood pressure and portal vein flow remained steady. Respiratory failure due to abdominal compartment syndrome and lung edema gradually improved. Thus, on postoperative day (POD) 5, the abdominal skin of the patient was closed without closing the abdominal fascia (Figure 2D). Tacrolimus and methylprednisolone were used as the standard postoperative immunosuppression therapy regimen. Acute rejection occurred on POD 17, so steroid pulse therapy was initiated. After steroid pulse therapy, liver enzyme, PT-INR and T-bil were nearly normalized. Respiratory failure due to large-for-size graft syndrome had been prolonged; however, it gradually improved, and she was extubated on POD 81. Cytomegalovirus infection and catheter infection occurred several times and were treated using antivirus or antibiotic drugs. The patient showed difficulty eating sufficient meals and required habilitation to eating. She was discharged on POD 225. Vessel complications did not occur. Three years have passed since LDLT, with no reports of intellectual disability or liver dysfunction.

DISCUSSION

Liver transplantation for a small recipient

We rescued a case involving an LBWI with acute liver failure; however, few reports to date describe such a case (Table 1). To our knowledge, the lightest LDLT recipient had a body weight of 2.4 kg at the time of LDLT[7], and the youngest LDLT recipient in Japan was 9 d of age[8-10]. For deceased donor liver transplantation, the smallest reported recipient was 2 kg, and the youngest was 7 d of age[11]. No consensus has been reached regarding the safe lower limit of body weight for small recipients. A recent UNOS database analysis of infants weighting less than 5 kg revealed one-year patient and graft survival rates of 77.7% and 66.1%, respectively[12]. A recent Japanese

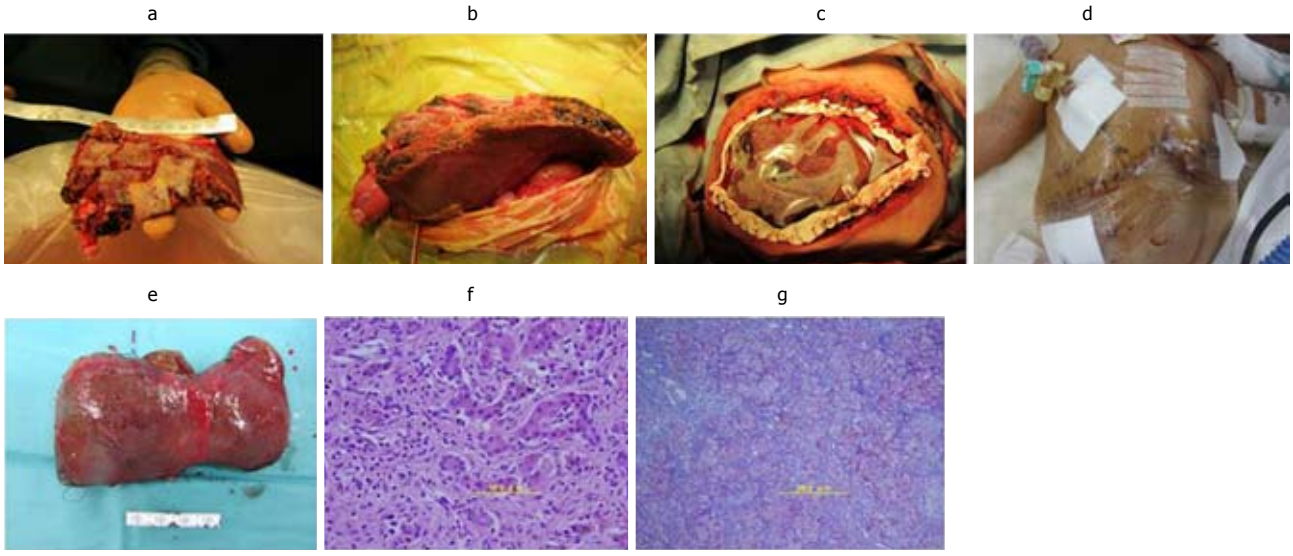

Figure 2 Images. A: The S2 monosegment graft (107 g) on the back table; B: An image obtained after reperfusion, the graft was too large to close the abdominal fascia; C: The abdominal fascia could not be closed at the time of living donor liver transplantation (LDLT), excess water was removed by continuous hemodiafiltration after LDLT; D: Secondary skin closure was performed on postoperative day 5; E: The resected liver was 78 g; F: Hematoxylin and eosin staining revealed a marked lack of hepatocytes and the presence of multinucleated hepatocytes; G: Azan staining revealed widespread fibrosis around Glisson's sheath and the parenchymal area (F3-4).

Table 1 Problems and management for low birth weight infant with acute liver failure

	Problems	Management
Pre-LT	Low body weight	Enteral nutrition targeting to over 2500 g
	Liver failure	Apheresis (exchange transfusion, plasmapheresis)
	Donor	Informed consent
LT	Large-for-size graft syndrome	Monosegment graft
	Hepatic artery reconstruction	Brunch patch, dorsal approach
	Abdominal compartment syndrome	Skin closure
		Open management→secondary skin closure
Post-LT	Fluid overload	Aggressive water removal using CHDF
	Respiratory failure	

CHDF: Continuous hemodiafiltration.

study reported an improved survival rate of 90.1% in an infant recipient within 3 mo[7]. Recipients who were within 3 mo of age also showed a higher rate of biliary complications[7]. However, our case did not have biliary complications. The problems we experienced in the described case were related to the following: (1) large-for-size graft syndrome[4]; (2) the transplantable body weight of the recipient; and (3) vessel reconstruction difficulties[13]. Challenges in managing transplantation for LBWIs with acute liver failure are nearly always due to the low body weight and fragility of the recipient.

The lower limit of the recipient's body weight for living donor liver transplantation

In liver transplantation, the transplantable body weight of a neonatal recipient is limited by graft size. If the GRWR is greater than 4.0%, the risk of abdominal compartment syndrome and insufficient blood supply in relation to a large-for-size graft are increased; the recipient abdomen cannot be closed, or massive hepatocyte necrosis may occur in the transplanted graft[8,10,14,15]. In pediatric LDLT, particularly in cases for which the recipient's body weight is less than 6 kg, monosegment grafts or hyper-reduced left lateral grafts have been transplanted[4]. A total of 268 pediatric patients underwent LDLT 275 times between May 2001 and December 2015 at Jichi Medical University Hospital. These transplantation procedures involved 196 left lateral segment grafts, with a median graft weight of 230 g (range, 138-382 g). Monosegment grafts were transplanted in 13 cases (including 9, 3, and 1 cases involving S2, reduced S2, and S3 monosegment grafts, respectively); in these cases, the median graft weight was 124 g (range, 93-180 g). A hyper-reduced left lateral segment graft was transplanted in 1 case, and the graft volume was 172 g. The smallest graft that we have transplanted was 93 g, and the median GRWR was 3.6% (2.4%-4.2%). A previous study reported hyper-reduced left lateral segment graft weights of 72-189 g,

with most graft weights being 100-150 g[7]. The lower limit of the smallest graft volume from a living donor is approximately 100 g[10]. Given this graft weight, transplantable recipient body weights of 2500 g or more will result in a GRWR of 4.0% or less. Based on this estimation, 2500 g is a reasonable body weight for such recipients.

The specific peritransplant management of living donor liver transplantation for low birth weight infant

In our experience, the body weights of the described patient were increased by enteral nutrition and became greater than 2500 g at 44 d of age. Another case of increased body weight by enteral nutrition was reported, and the body weight increased to greater than 2500 g at 41 d of age[5]. Despite the existence of acute liver failure, the body weights of the patients increased to over 2500 g *via* enteral nutrition while exchange transfusions were performed. Thus, in cases of acute liver failure, body weight may be increased with enteral nutrition if appropriate medication therapy that includes apheresis, such as exchange transfusion or plasmapheresis, is performed.

At times, it is impossible to close the abdominal fascia of the recipient during LDLT due to abdominal compartment syndrome. In this case, the abdominal fascia could not be closed during LDLT; instead, the case required secondary skin closure. In cases involving pediatric LDLT patients, apheresis and dialysis are reportedly effective[16]. Aggressive water removal using CHDF was required in this case. Thus, even if LDLT for an LBWI with acute liver failure is successfully performed after an increase in body weight, circulation and respiratory management are challenging due to volume overload. Under these circumstances, aggressive water removal using CHDF and secondary abdominal closure approaches are useful and important tools for successful postoperative management.

Hepatic arterial reconstruction during living donor liver transplantation

Vessel reconstruction in cases similar to the described case is difficult due to the high GRDR between the hepatic vein and the portal vein bifurcation and to diameter mismatch for the hepatic artery between the graft and the recipient[13]. Hepatic artery reconstruction by the dorsal approach of portal vein anastomosis has been reported to help reduce the risk of hepatic artery complications among small recipients if the GRDR is over 2.4[13]. At times, the hepatic arteries of such recipients are thin. The hepatic artery of this case was not thin; however, the GRDR was 2.4, and the hepatic artery was anastomosed by a dorsal approach. In our experience of 13 cases of LDLT using monosegment grafts, the thinnest artery among the recipients was 1.2 mm, with 3 cases involving hepatic arteries of less than 1.5 mm. The graft-to-recipient diameter ratio was 0.67: 1.67. In addition, the dorsal position was selected for hepatic artery anastomotic approaches in 7 cases (53.8%), and the branch patch technique was selected in 5 cases (38.5%). Hepatic artery complications after LDLT occurred in 3 cases, although interventional radiology was sufficient for achieving recovery in all 3 cases.

We rescued a case of LBWI with acute liver failure by performing LDLT. In cases involving LBWIs with acute liver failure, infants may be rescued by LDLT after their body weights have been increased to over 2500 g *via* repeated exchange transfusions and enteral nutrition.

COMMENTS

Case characteristics

The patient was 1594 g, $32^{3/7}$ gestational wk at birth and immediately after birth, hypoglycemia and hypotension appeared.

Clinical diagnosis

At the age of 11 d, coagulation dysfunction and an elevated serum ferritin level due to acute liver failure were observed.

Differential diagnosis

The case was highly suspected of gestational alloimmune liver disease and differential diagnosis was metabolic disorder, infectious disease and Neimann-Pick disease type C.

Laboratory diagnosis

Laboratory data showed repeated coagulopathy and hyperbilirubinemia with daily exchange transfusion and a pediatric end-stage liver disease score of 15.8.

Imaging diagnosis

Computed tomography scan revealed a markedly atrophied liver.

Pathological diagnosis

A liver biopsy revealed a marked loss of hepatocytes and the remaining hepatocytes were multinucleated, and there was widespread fibrosis around Glisson's sheath and in the parenchymal area (F3-4).

Treatment

The case underwent living donor liver transplantation at 55 d of age using an S2 monosegment graft from her mother (107 g).

Related reports

Kasahara M *et al* and Mizuta K *et al* reported the living donor liver transplantation for small recipient (*Exp Clin Transplant* 2014; 12 Suppl 1:1-4, *Am J Transplant* 2010; 10: 2547-2552).

Term explanation

Low birth weight infant (LBWI) is defined as a birth weight of a infant of 2499 g or less regarding of gestational age.

Experiences and lessons

In cases involving LBWI with acute liver failure, infants may be rescued by living donor liver transplantation after their body weights have been increased to over 2500 g.

Peer-review

The authors presented an interesting case with LBWIs (1594g, 323/7 wk) with acute liver failure.

Abstract

S-Adenosyl-L-methionine (SAM) is a cofactor serving as a methyl donor in numerous enzymatic reactions. It has been reported that SAM has the potential to modify antioxidant-enzymes, glutathione-biosynthesis and methionine adenosyltransferases-1/2 in hepatitis C virus -expressing cells at millimolar concentrations. The efficacy of SAM at micromolar concentrations and the underlying mechanisms remain to be demonstrated.

Core tip: *S*-Adenosyl-L-methionine (SAM) serves as a cofactor for enzymes that transfer its methyl group to nucleophilic functionalities of various biomolecules including DNA and RNA. Exogenous SAM has been shown to be a useful pharmacological agent in liver-associated diseases. SAM is a labile species, undergoes spontaneous decomposition in biological samples, and its oral bioavailability is only about 2%. Lozano-Sepulveda and colleagues observed that SAM modulates antioxidant enzymes, restores glutathione synthesis, and switches MAT1/MAT2 turnover in hepatitis C virus (HCV) expressing cells. The authors suggested that this may be a likely mechanism by which HCV expression is diminished by SAM. This SAM concentration range was chosen on the basis of cell viability experiments and is up to 1000 times higher than physiological intracellular. Other groups have used SAM in the concentration range 0 - 1000 nmol/L. The efficacy of SAM, its pharmacological effects towards

HCV and possibly adverse effects beyond cell viability need to be elaborated in further studies using SAM concentrations much lower than 1 mmol/L.

TO THE EDITOR

S-Adenosyl-L-methionine (SAM) is the common cofactor of methylating enzymes, the methyl transferases. These enzymes catalyze the transfer of the methyl group of SAM to various nucleophilic functionalities of low-molecular-mass and high-molecular-mass biomolecules. Catechol amines, DNA, RNA, and proteins are well-investigated substrates of methyl transferases. SAM deficiency is associated with many different pathogenic conditions including liver diseases, depression and inherited methylation disorders. SAM supplementation in such diseases is a therapeutic means[1-5]. Lozano-Sepulveda and colleagues recently reported in the *World Journal of Gastroenterology* that SAM decreased hepatitis C virus (HCV) -RNA levels by 50% to 70% and induced a synergistic antiviral effect with standard IFN treatment[6]. The authors found that SAM modulated several antioxidant enzymes (*e.g.,* superoxide dismutase-1 and -2, thioredoxin), restored glutathione (GSH) synthesis, and switched methionine adenosyltransferase (MAT) turnover in HCV-expressing cells. The study by Lozano-Sepulveda and colleagues adds to the pleiotropic effects of SAM. However, this study by Lozano-Sepulveda and colleagues suffers from a major limitation, namely the use of very high SAM concentrations (range, 1 - 5 mmol/L)[6]. The choice of this SAM concentration range appears arbitrary. Another study limitation is that no SAM concentration/dose-response experiments have been performed.

SAM is a physiological substance and is widely distributed in extracellular and intracellular compartments of the human body[7-11]. The concentration of SAM in plasma of healthy subjects is of the order of 150 nmol/L, seemingly independent of the concentration of total homocysteine[7]. The intracellular SAM concentration in human lymphocytes has been reported to be about 5 nmol/10^6 cells; in mouse liver the SAM content was determined to be 0.5 nmol/mg protein[7]. The latter values are close to those reported by others using different analytical methods[12]. In freshly isolated human erythrocytes the concentration of SAM is of the order of 4 μmol/L[13]. This value agrees with more recently reported median SAM concentrations in erythrocytes of diabetic (3.8 μmol/L) and non-diabetic (3.5 μmol/L) male and female subjects[14].

The pharmacokinetics of SAM has been frequently investigated in animals as well as in healthy and diseased humans[15-17]. The oral bioavailability of SAM is of the order of 1% - 4%. Ingestion of 1000 mg SAM as tosylate disulfate salt resulted in maximum plasma SAM concentrations of about 2.5 μmol/L in men and women[3]. Intravenous injection of 1000 mg SAM resulted in maximum plasma SAM concentrations of about 211 μmol/L[15]. Another study found that oral administration of 10 mg SAM/kg body weight did not result in significant increases in systemic SAM concentration[16]. Thus, the SAM concentration range used in the Lozano-Sepulveda's study[6] is almost 1000-fold higher than physiological and pharmacologically used SAM concentrations (0-1000 nmol/L), and even 5 - 25 times higher than plasma SAM concentrations from intravenously injected SAM.

Use of very high SAM concentrations in *in vitro* experiments, even if not toxic[6], may lead to entirely different or contradictory results than the use of physiological and pharmacological SAM concentrations[18]. Oral administration of radiolabeled SAM (*i.e.,* [*methyl*-^{14}C]SAM) in mice resulted in radioactivity accumulation in the liver due to authentic [*methyl*-^{14}C]SAM and [*methyl*-^{14}C]phosphatidylcholine. The latter was found to be about 8 (after 60 min) and 25 (after 240 min) times higher concentrated than [*methyl*-^{14}C]SAM[16]. In aqueous solution, SAM is unstable and decomposes spontaneously to its components including *S*-methylthioadenosine, adenosine, adenine, and homoserine lactone[19]. Above pH 6, SAM is chemically very labile. Its inherent reactivity towards nucleophilic functionalities of biomolecules such as DNA and proteins is about 1000 times higher than that of methylated folates[19]. These observations suggest that SAM does not only function as an universal cofactor in methyltransferases-catalyzed reactions, but also undergoes both spontaneous methylation reactions with various biomolecules and decomposition to species such as *S*-methylthioadenosine and homoserine lactone[19]. Possibly, SAM decomposes to additional substances with not yet known biological activities, albeit not necessarily acutely cell toxic. The decrease in total glutathione concentration in the HCV-expressing cells upon incubation with SAM at 1 mmol/L for 1 and 2 h seen by Lozano-Sepulveda *et al*[6] may be an indication of a (spontaneous) reaction of SAM with reduced glutathione (GSH) to form *S*-methyl-glutathione which cannot be detected by the Ellman's method. At least in rat kidney proximal tubules, *S*-methyl-glutathione is rapidly degraded by gamma-glutamyl-transpeptidase[20]. Measurement of oxidized glutathione, *i.e.,* glutathione disulfide (GSSG), is a much more suitable and direct approach to assess oxidative stress. Yet, no GSSG data

were reported in the paper[6]. It is worth mentioning that SAM (at 4 mmol/L) can also inhibit thioredoxin-mediated protein disulfide reductase activity[20]. This and further reports[22] are supportive of the chemical lability of SAM that makes it a spontaneous unselective methylating agent. Spontaneous decomposition of SAM considerably contributes to *S*-adenosyl-homocysteine which is a potent inhibitor of methyltransferases including protein arginine methyltransferases[23].

Lozano-Sepulveda and colleagues reported in their article interesting results and proposed possible mechanisms for the explanation of the effects exerted by SAM in HCV-expressing cells seen in their study[6]. Yet, the SAM concentrations used in the study are difficult to be reached within cells even by intravenous injection of SAM salts. The high chemical reactivity of the *S*-methyl group of SAM towards biomolecules and its spontaneous decomposition is likely to bear potential adverse effects. The efficacy and the safety of SAM, especially its pharmacological effects towards HCV, need to be elaborated in further studies taken into consideration the pharmacokinetics of SAM. Use of SAM at mmol/L-concentrations may raise unrealizable expectations.
