Abstract

Coronavirus disease 2019 (COVID-19) can be considered a systemic disease with a specific tropism for the vascular system, in which the alterations of the microcirculation have an important pathogenetic role. The lungs are the main organ involved in COVID-19, and severe progressive respiratory failure is the leading cause of death in the affected patients; however, many other organs can be involved with variable clinical manifestations. Concerning abdominal manifestations, the gastrointestinal tract and the hepatobiliary system are mainly affected, although the pancreas, urinary tract and spleen may also be involved. The most common gastrointestinal symptoms are loss of appetite, followed by nausea and vomiting, diarrhea and abdominal pain. Gastrointestinal imaging findings include bowel wall thickening, sometimes associated with hyperemia and mesenteric thickening, fluid-filled segments of the large bowel and rarely intestinal pneumatosis and ischemia. Hepatic involvement manifests as an increase in the enzymatic levels of alanine aminotransferase, aspartate aminotransferase, serum bilirubin and γ-glutamyl transferase with clinical manifestations in most cases mild and transient. The most frequent radiological features are hepatic steatosis, biliary sludge and gallstones. Edematous acute pancreatitis, kidney infarct and acute kidney injury from acute tubular necrosis have been described more rarely in COVID-19. Lastly, splenic involvement is characterized by splenomegaly and by the development of solitary or multifocal splenic infarcts with classic wedge-

shaped or even rounded morphology, with irregular or smooth profiles. In summary, the abdominal radiological findings of COVID-19 are nonspecific and with poor pathological correlation reported in the literature. Ultrasound and particularly computed tomography with multiphasic acquisition are the diagnostic methods mainly utilized in COVID-19 patients with abdominal clinical symptoms and signs. Although radiological signs are not specific of abdominal and gastrointestinal involvement, the diagnostic imaging modalities and in particular computed tomography are helpful for the clinician in the management, evaluation of the severity and evolution of the COVID-19 patients.

Key Words: COVID-19; SARS-CoV-2; Abdominal findings; Gastrointestinal findings; Computed tomography; Ultrasound

Core Tip: Coronavirus disease 2019 (COVID-19) pulmonary involvement has been extensively reported in the literature. Nowadays, a series of published data highlight how COVID-19 is a systemic disease affecting many other organs. Abdominal and gastrointestinal clinical manifestations have been more recently investigated with imaging modalities such as ultrasound and computed tomography. The aim of this review is to report the most common imaging features of abdominal and gastrointestinal involvement and the possible role of ultrasound and particularly computed tomography in the management, evaluation of the severity and evolution of COVID-19 patients.

INTRODUCTION

Severe acute respiratory syndrome by severe acute respiratory syndrome corona-virus 2 (SARS-CoV-2) was first recognized in December 2019 in Wuhan (Hubei province, China), but its origin is still unknown and debated. Since then, the disease spread worldwide, leading the World Health Organization to declare a global pandemic on March 11, 2020[1]. More than 21 million confirmed cases of coronavirus disease 2019 (COVID-19) have been reported on all continents except Antarctica, and the incidence is steadily increasing[2]. In all territories affected by the COVID-19 pandemic, the diagnostic tests, the workload of the intensive care units and the initiation of mitigation strategies, such as the restriction of interpersonal contacts, have been established and increased over time[3]. Men seem to be disproportionately more commonly affected by a SARS-CoV-2 infection, and the hospital mortality rate among males is significantly higher than female patients[4]. Main vehicles of transmission of SARS-CoV-2 disease are respiratory droplets being released during coughing, sneezing or conversation between subjects and accumulate on surfaces causing an indirect contamination[5].

SARS-CoV-2 pathogenic agent of this pandemic disease belongs to the Coronaviridae family. Coronaviruses are nonsegmented enveloped RNA viruses with a single-strand linear positive-sense RNA[6]. They are routinely present among animals as well as humans. They are the most common cause of colds, particularly in cats and dogs[7]. Although the origin of the new mutant strain SARS-CoV-2 remains uncertain, it is likely that it originated in a wet market in Wuhan, where animals of all kinds are slaughtered in poor sanitary conditions and their meats are sometimes eaten raw[8].

Six types of coronaviruses causing human disease have been identified: Four of them cause mild respiratory symptoms, whereas the other two, Middle East respiratory syndrome coronavirus and SARS-CoV-1, have previously resulted in epidemics with high mortality rates[9]. SARS-CoV-2 has 80% genomic compatibility

with SARS-CoV-1 and uses the same angiotensin-converting enzyme 2 (ACE2) receptor to enter cells. In fact, ACE2 is an integral membrane protein that seems to be the host cell receptor for SARS-CoV-2, which appears significantly increased in COVID-19 positive patients[10]. ACE2 positive endothelial cells from patients with COVID-19 show significant changes in their morphology, disruption of the intercellular junctions, cell swelling and loss of contact with the basement membrane [11]. The presence of the SARS-CoV-2 virus within endothelial cells suggests that direct viral effect as well as perivascular inflammation may contribute to endothelial damage[11]. This underlines the importance of microcirculation alterations in the pathogenesis and subsequent manifestations at the systemic level[11,12].

Pulmonary involvement in the COVID-19 pandemic is the most known and largely studied because progressive severe respiratory failure represents the leading cause of death in affected patients. Pathological samples of peripheral lung of patients who died from COVID-19 showed a histological pattern of diffuse alveolar damage with perivascular infiltration of T cells[13]. Pulmonary parenchymal tissue also showed typical vascular findings, represented by severe endothelial lesions with the presence of intracellular viruses and interrupted cell membranes[14].

Histological analysis of pulmonary vessels in affected patients showed diffuse thrombosis with microangiopathy; alveolar capillary microthrombi seem to be nine times more frequent as well as the amount of new vessel growth was reported to be 2.7 times higher in patients with COVID-19 in respect to those affected by influenza virus disease[15]. Therefore, three distinctive angiocentric characteristics of COVID-19 were found in the lung: (1) severe endothelial injury associated with the intracellular SARS-CoV-2 virus and rupture of endothelial cell membranes; (2) diffuse vascular thrombosis with microangiopathy and occlusion of the alveolar capillaries; and (3) significant growth of new vessels through an intussusceptive angiogenesis mechanism [13]. Although COVID-19 typically manifests as a respiratory illness and most of the literature described pulmonary signs and symptoms, this disease can affect other anatomical districts and structures, whose clinical manifestations are relatively poorly known. A whole series of signs and symptoms related to systemic manifestations are known to have a certain relevance. In particular, it has been reported that 57% of patients with low severity COVID-19 disease could have reported abdominal discomfort alone or in combination with pulmonary symptomatology[16]. The abdominal clinical manifestations have been related to the gastrointestinal tract and the hepato-biliary-pancreatic system, whereas urinary tract and spleen involvement have been less frequently reported[17].

Our review was aimed to report the current abdominal and gastrointestinal imaging features in COVID-19 patients as well as to define the role of the diagnostic imaging modalities in the abdominal manifestations.

GASTROINTESTINAL TRACT

Abdominal and gastrointestinal signs and symptoms in COVID-19 are being increasingly reported[18]. Indeed, on January 19, 2020, the first known patient of COVID-19 in Washington, United States reported a history of nausea and vomiting in addition to respiratory symptoms[19]. In the literature, it has been reported that series of COVID-19 patients presenting to the emergency room with abdominal pain but without the typical respiratory symptoms of SARS-CoV-2; therefore, the abdominal radiologist was the first to suggest COVID-19 infection because of the typical findings in the lung lower lobes on computed tomography (CT) scans of the abdomen, such as peripheral and subpleural ground-glass opacities[18,20,21] (Figure 1). In this context, some authors have proposed additional CT of the whole chest as part of a CT imaging pathway of acute abdominal pain during the COVID-19 pandemic; this did not get approval because in these patients it was enough just to review the pulmonary bases on abdominal CT scans[22].

Patients with primarily mild gastrointestinal symptoms may not be identified as COVID-19 patients, with serious consequences for themselves and their contacts[18]; in this setting the most common gastrointestinal symptom is loss of appetite, followed by nausea and vomiting, while diarrhea and abdominal pain are the presenting symptoms in only a small percentage of cases[18].

In a retrospective study by Han *et al*[16], patients with gastrointestinal symptoms compared with patients with only respiratory symptoms, tended to have a longer course between symptom onset and viral clearance and took longer to report for medical care, a finding observed in other studies[23]; this suggests that in these

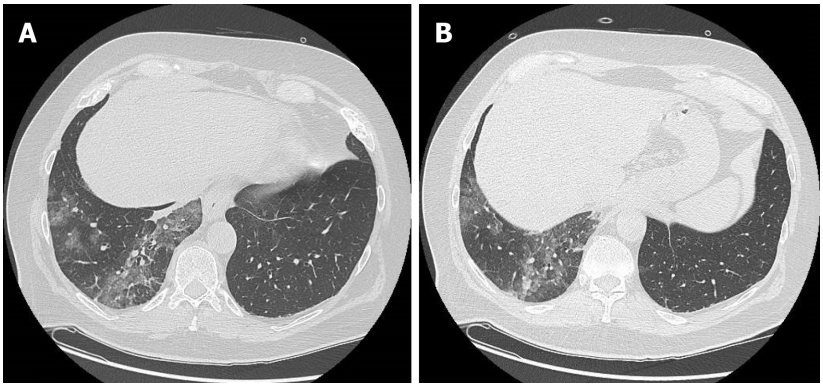

Figure 1 A 63-year-old man who presented to the emergency room for abdominal pain and no significant alterations on abdominal computed tomography. A: Computed tomography scan with pulmonary window at the level of lung inferior lobes (included in the volume acquisition) shows the presence of ground-glass opacities and crazy-paving pattern in the right side; B: Computed tomography scan with pulmonary window at lower levels of lung inferior lobes always exhibited ground-glass opacities and crazy-paving pattern in the right side.

patients the COVID-19 involvement was not initially recognized leading to delayed diagnosis[24]. Moreover, SARS-CoV-2 has been identified in stool samples of a proportion of infected patients[16]; viral replication in both small and large intestine was confirmed by the result of electron microscopy of autopsy biopsy specimen[24, 25]. In particular, an autoptic study on the small intestine of two COVID-19 patients showed endothelitis of the submucosa vessels with mononuclear cell infiltrates within the intima along the lumen of many vessels, besides the evidence of direct viral infection of endothelial cells[11].

The inflammatory response in the gut due to active viral replication is also supported by the evidence of elevated fecal calprotectin concentrations in COVID-19 patients with diarrhea when compared with COVID-19 patients without diarrhea[26].

The radiological alterations of the gastrointestinal system in COVID-19 patients are represented by nonspecific thickening of various regions of the small and large bowel wall[27,28] (Figures 2 and 3), sometimes associated with hyperemia and mesenteric thickening[28] (Figure 4). Goldberg-Stein *et al*[29] retrospectively reported that the most common gastrointestinal symptom in 141 COVID-19 patients was the abdominal pain, present in 73.8% of patients with negative abdominal CT findings and in 53.8% of patients with positive abdominal CT findings; in this series the most commonly reported CT finding was represented by segmental wall thickening of the gastrointestinal tract[29]. In addition, 64% of patients with no positive CT abdominal findings but gastrointestinal symptoms showed suggestive features for COVID-19 pneumonia at the lung bases[29]. This suggests that abdominal symptoms may be present in COVID-19 patients without correlative CT abdominal findings; in fact, in patients with pneumonia it was hypothesized that the abdominal and back pain may be secondary to pleural irritation[30,31].

Tirumani *et al*[32], instead, in a retrospective study identified the incidence of abdominal findings in COVID-19 patients with and without abdominal symptoms and concluded that bowel abnormalities are the most common finding in the abdomen in patients with COVID-19, often without abdominal symptoms and especially regardless of the severity of lung involvement[32]. The most common CT abdominal findings are a fluid-filled colon with no wall thickening (Figures 5 and 6), severe colitis (characterized by a thickened and edematous wall with fat stranding), gastritis and small bowel pneumatosis with portal venous gas[32].

Other minor manifestations are also reported. In a case report, Noda *et al*[33] described a COVID-19 healthy teenager who initially presented with abdominal discomfort. The patient underwent CT scan that demonstrated only isolated mesenteric adenopathy and adjacent fat stranding associated to ground-glass opacities and solid consolidation as well as interlobular septal thickening at lung bases[33]. This case highlights how abdominal findings in COVID-19 patients are not specific and should be suspected given the continued emergence of new manifestations of the disease.

Bhayana *et al*[34] retrospectively analyzed 42 abdominal CT scans performed in COVID-19 patients for abdominal pain or septic status. Colorectal and small bowel wall thickening (defined as single-wall thickness greater than 3 mm in distended intestine and greater than 5 mm in collapsed intestine) were found in 12 out of 42

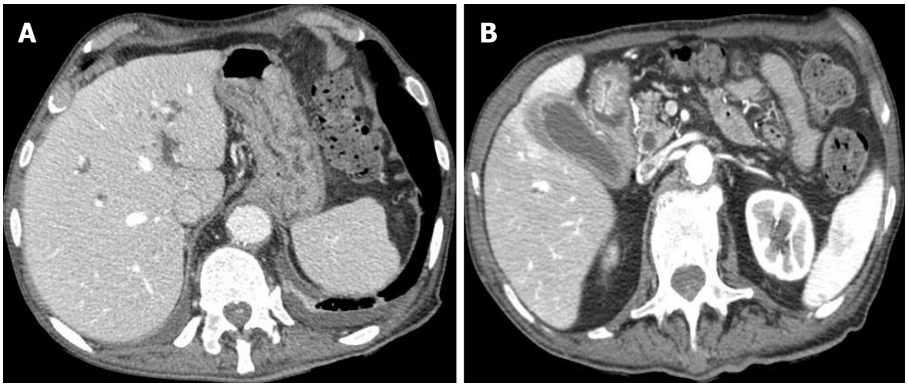

Figure 2 An 83-year-old woman with epigastric pain. A: Abdominal contrast-enhanced portal-venous phase computed tomography showed diffuse thickening of the submucosa of the gastric walls and intrahepatic biliary dilatation; B: Abdominal contrast-enhanced portal-venous phase computed tomography also depicts thickening of the submucosa of the pyloric region and signs of cholecystitis.

Figure 3 A 68-year-old woman with abdominal pain. Abdominal contrast-enhanced portal-venous phase computed tomography image showed circumferential thickening of the submucosa of the right colon that appeared hypodense, in the absence of both significant contrast-enhancement and perivisceral fat stranding.

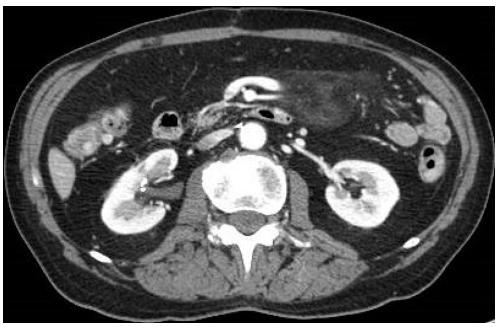

Figure 4 A 74-year-old man with abdominal pain. Abdominal contrast-enhanced portal-venous phase computed tomography image showed well-circumscribed hyperattenuation of the fat surrounding the mesenteric vessels.

abdominal CT, whereas pneumatosis associated to gas in the portal vein and fluid-filled colon (defined as homogeneous, low-attenuation colonic content) were identified in 4 and 18 out of 42 cases, respectively. The remaining 8 patients did not exhibit CT alterations of the gastrointestinal tract[34]. The 4 cases of pneumatosis and portal vein gas underwent exploratory laparotomy; 2 cases had necrotic bowel at surgery with a yellow discoloration of the small bowel in contrast with the usual black or purple color of a necrotic bowel. One patient also underwent a bowel resection demonstrating ischemic enteritis with patchy necrosis and submucosal arterioles containing fibrin thrombi[34].

Bowel ischemia has also been described in COVID-19 patients, particularly in those admitted to the intensive care unit[35], constituting a life-threatening clinical

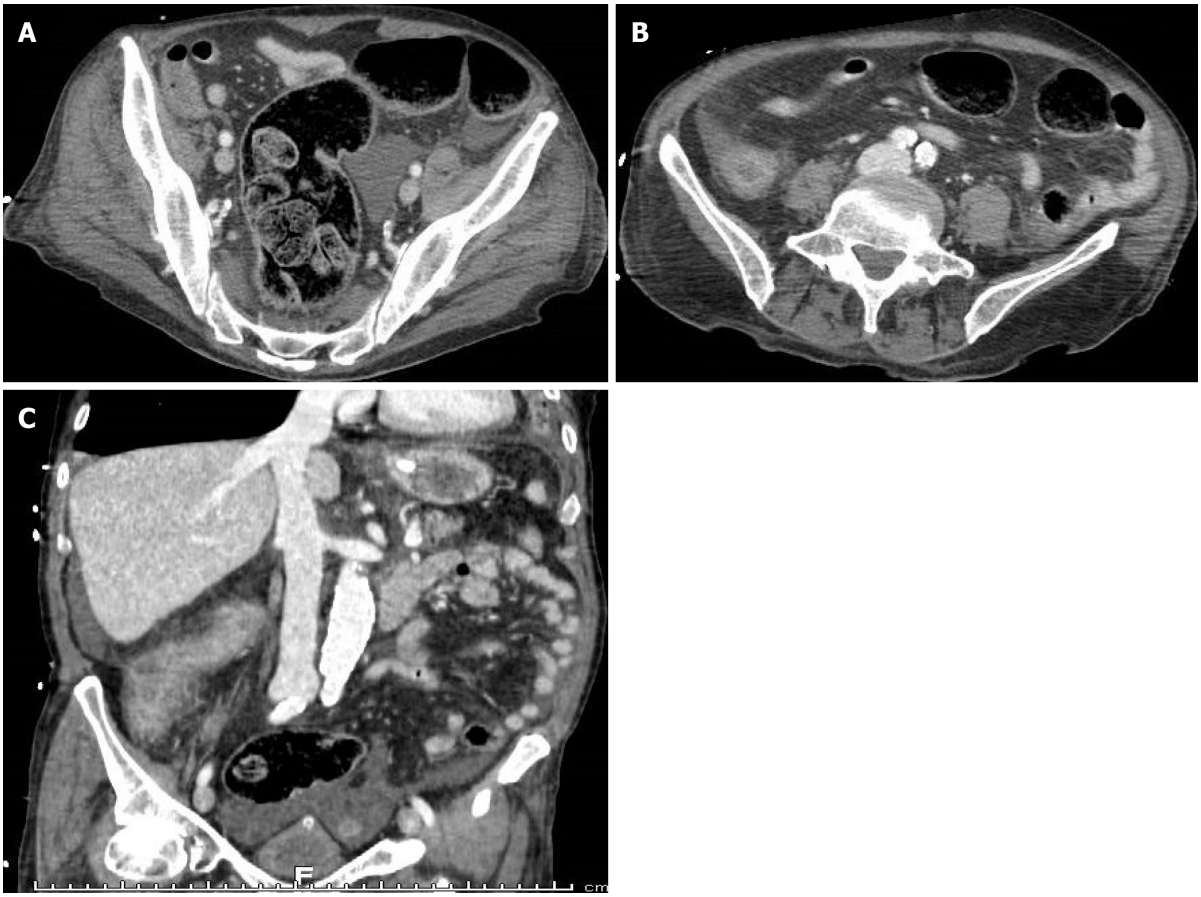

Figure 5 A 73-year-old woman with abdominal pain. A: Contrast-enhanced portal-venous phase computed tomography image of the lower abdomen demonstrated gas distension of the sigma-rectum with evidence of multiple stools inside the lumen; free effusion was also appreciable around the colon; B: Contrast-enhanced portal-venous phase computed tomography image of the abdomen showed distention of the left bowel and hyperemic thickened walls (particularly affecting the mucosa) of the right colon with perivisceral fat suffusion; C: Coronal multiplanar reconstruction from contrast-enhanced computed tomography well demonstrated these findings.

Figure 6 A 69-year-old woman with diarrhea. Contrast-enhanced portal-venous phase computed tomography image of the abdomen showed evidence of fluid-filled distension of the large bowel, particularly of the sigma and rectum, without evidence of parietal thickening. Free effusion was also present in the abdomen and between the intestinal loops with associated diffuse imbibition of the subcutaneous soft tissues.

emergency[9]. It is well known that the hypercoagulable state induced by COVID-19 results in micro- and macrovascular complications[36]. The microvascular complications are detected in the early stages of the disease, while the macrovascular ones are more typically observed in severely ill patients[37]. Anyway, thromboembolic disease within the mesenteric vascular system is not frequently identified on CT imaging[35].

Revzin *et al*[38] divided the COVID-19 related bowel ischemia into early, intermediate and late presentations[38]. On CT images the early phase shows contracted gasless bowel that may transform into dilated gas-filled bowel with a paper-thin bowel wall in the intermediate phase. The CT findings of the late phase

include intestinal wall pneumatosis, absence of mucosal enhancement and luminal dilatation. It is important to note that these phases reflect those of a classic intestinal ischemia regardless of etiology[39] and that the presence of pneumatosis intestinalis suggests bowel ischemia[36], but its presence must be interpreted with caution because it may be secondary to mechanical ventilation in patients with severe COVID-19[40] (Figure 7).

Actually, the exact pathological mechanism of intestinal ischemic disorders is not clearly known. In a letter to the editor, Parry *et al*[41] reported four possible mechanisms that work alone or in varying combination: coagulation disorder, elevated levels of von Willebrand Factor, expression of ACE2 on enterocytes of the small bowel and shock/hemodynamic compromise associated with COVID-19 pneumonia[41].

COVID-19 patients may be in a state of hypercoagulability induced by a systemic inflammatory state, endothelial activation, hypoxia and immobilization. These could lead to mesenteric microvascular thrombosis without involvement of the large mesenteric vessels, resulting in a condition of thrombosis in situ rather than an embolic event[41].

Elevated levels of von Willebrand factor have been reported in severe COVID-19 patients[42]. von Willebrand factor is released from endothelium in response to damage caused by SARS-CoV-2 and consequent endothelium dysfunction and vascular thrombosis[43].

Regarding the last two points, the enterocytes express ACE2, the target receptor for SARS-CoV-2 with intestinal tropism and direct bowel damage. Lastly, shock or hemodynamic compromise, which is commonly associated with severe COVID-19 pneumonia, may lead to a non-occlusive mesenteric ischemia[42].

LIVER, BILIARY TRACT AND PANCREAS

The liver is the second most frequently injured organ after the lung in COVID-19[44]. The mechanism of liver damage is probably due to a series of events that can occur simultaneously. Direct cytopathic effect of SARS-CoV-2, indirect damage from systemic inflammation, drug hepatotoxicity[44] and hypoxic alterations related to ventilation have been mainly described[45]. SARS-CoV-2 causes direct liver damage because the ACE2 receptor is widely expressed in the liver, more on cholangiocytes than on hepatocytes[46]. The virus alters the barrier and bile acid transport functions of cholangiocytes through the dysregulation of genes involved in tight junction formation and bile acid transport[47]. Drugs commonly used during SARS-CoV-2 infection causing liver toxicity include remdesivir, tocilizumab, chloroquine, hydroxychloroquine and azithromycin[48]. The immune-mediated cytokine storm also participates in the damage; in fact, we have a marked activation of inflammatory markers, including abnormal levels of C-reactive protein, lymphocytes, neutrophils and cytokines, in particular interleukin-6. The control of cytokine dysregulation at an early stage could be useful to slow down the progression of the disease[45]. In addition, respiratory-induced hypoxia can cause elevated serum aminotransferase concentrations, a laboratory marker of liver injury[49]. The combination of these events determines a generalized coagulopathy state that determines an alteration of the microcirculation with microthrombosis within the hepatic sinusoids[20]. As a support to this etiopathogenetic theory, liver autopsy results by Medeiros *et al*[50] show periportal necrosis, lymphocytic infiltration of the sinusoids, dense infiltration of the gate by abnormally small lymphocytes, central venous thrombosis and cirrhotic alterations with fibrosis in a retrospective series of 316 patients[50].

Liver injury usually manifests as an increase in enzyme levels. Current literature data show that 14.8%-53.0% of COVID-19 patients have abnormal levels of alanine aminotransferase and aspartate aminotransferase and a slight increase in serum bilirubin levels during the course of the disease[16]. Phipps *et al*[51] found that an alanine aminotransferase spike was significantly associated with clinical outcome[51]. In respect to mild to moderate or no liver injury, patients with severe liver injury have a higher rate of intubation and renal replacement therapy. Additionally, approximately 50% of COVID-19 patients had increased levels of γ-glutamyl transferase[52].

To the best of our knowledge, hepatic manifestations of COVID-19 were in most cases mild and transient. Despite this, there is an ever increasing number of subjects with severe hepatic manifestations that are very often associated with the pulmonary ones[53].

For the management of COVID-19 patients with liver injury, the American Association for the Study of Liver Diseases provides recommendations, highlighting

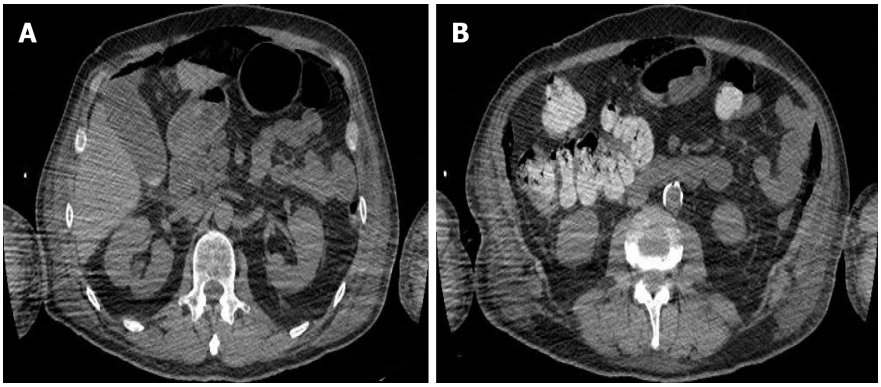

Figure 7 A 65-year-old man with abdominal pain and severe pulmonary involvement. A: Unenhanced computed tomography scan of the upper abdomen showed signs of pneumoperitoneum secondary to mechanical ventilation and cholelithiasis; B: The presence of gas within the peritoneal cavity was also appreciable at lower levels of the abdomen on unenhanced computed tomography scan.

that there are no contraindications to the use of drugs such as remdesivir, tocilizumab, chloroquine, hydroxychloroquine and azithromycin unless alanine aminotransferase or aspartate aminotransferase are no more than five times the upper normal limit[48].

A systematic review and meta-analysis of international data on the hepatic manifestations of COVID-19 was performed by The American Gastroenterological Association Institute[54]. Among COVID-19 patients with liver injury, more than 60% of patients had mild hepatic injury (1 time upper normal limit to 5 times upper normal limit)[51]. It should be noted that previous liver disease and underlying liver function may have influenced the results. In fact, some patients may have abnormal liver function prior to SARS-CoV-2 infection, such as nonalcoholic fatty liver disease or chronic hepatitis B[55]. Moreover, there is a higher prevalence of hepatic steatosis that is probably due to the known association between infection and obesity[50].

Hepatic steatosis is a very frequent and nonspecific finding of COVID-19 patients, which has been identified with both ultrasound (US) and CT. The findings of hepatic steatosis are the same as those found in non-COVID-19 patients. On US we can observe the typical "bright liver" that is characterized by an increase in echogenicity compared to the renal cortex or spleen (in the case of renal pathology), loss of physiological hyperechogenicity of the portal branches walls and posterior attenuation of the ultrasonic beam with failure to visualize the diaphragm (Figure 8). On the other hand, diffuse liver hypodensity is the typical sign on CT scans. In the presence of a slight steatosis a hepatic attenuation of less than 10 HU compared to the density of the spleen is observed, whereas in moderate/severe forms hepatic attenuation is less than 40 HU compared to the spleen[56] (Figure 9).

Ji *et al*[57] found that COVID-19 patients with nonalcoholic fatty liver disease were more likely to have liver damage and disease progression than patients without nonalcoholic fatty liver disease[57]. Singh *et al*[58] studied the impact of pre-existing liver disease on outcomes in a large cohort of COVID-19 patients and found that the risk of hospitalization and death in patients with pre-existing liver disease was significantly higher[58].

Further, in 54% of patients with COVID-19, biliary sludge and gallstones were found and were closely related to an increase in cholestasis indexes[59], values that appear to be markedly increased in comparison with the incidence in the general population (about 10%-20%)[38]. US is considered the gold standard for detecting gallstones. It allows the evaluation of macro- and microlithiasis, sludge and cholesterol deposits as well as the structural evaluation of the gallbladder[60]. The cholesterol deposition along the gallbladder walls appears as hyperechogenic spots with the typical "comet sign" whereas the biliary sludge as sediment in the declivous portion of the gallbladder lumen[60] (Figure 10). Although the role of CT in the evaluation of biliary lithiasis is marginal compared to US in the normal patient, this technique easily allows the visualization of hyperdense calcium stones and hypodense cholesterol stones in COVID-19 patients because US is not easily performed in the most compromised patients[61].

Pancreatic involvement has also been described in COVID-19 patients. As for other districts, the pathogenetic mechanism is not yet clear and could be the result of direct (cytopathic effect of the virus) or indirect (immune-mediated storm) mechanisms[62].

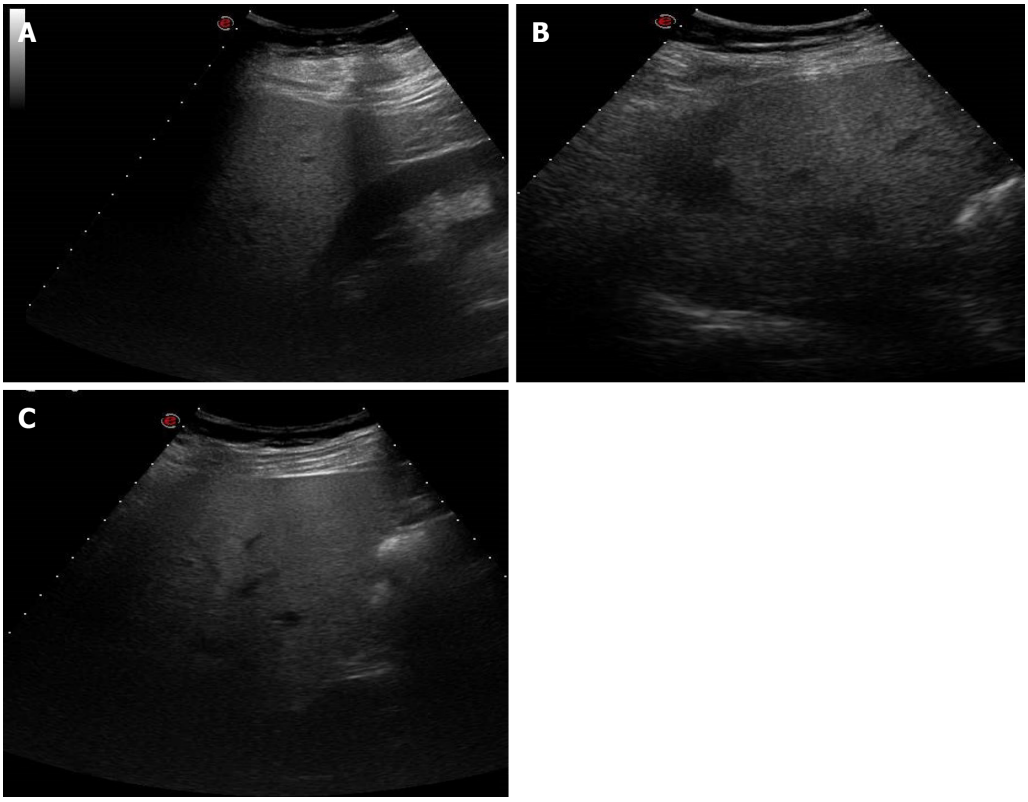

Figure 8 A 38-year-old man with abdominal discomfort. A: Abdominal ultrasound image demonstrated hepatic steatosis as an increase in echogenicity compared to the renal cortex; B: Abdominal ultrasound image demonstrated hepatic steatosis as loss of physiological hyperechogenicity of the wall of the portal branches; C: Abdominal ultrasound image demonstrated hepatic steatosis as posterior attenuation of the ultrasonic beam with failure to visualize the diaphragm.

Figure 9 A 46-year-old woman with abdominal discomfort. Unenhanced computed tomography image showed increased liver hypodensity compared to the spleen, with attenuation value less than 40 HU.

The presence of the ACE2 receptor on the cells of the pancreatic islets and exocrine glands allows the penetration of the virus thus determining the manifestations. In a series of 52 patients with COVID-19 pneumonia by Wang *et al*[63], 17% of them had pancreatic injury with elevated blood glucose levels. These results show potential mild pancreatic injury patterns in patients with COVID-19 pneumonia with no severe pancreatitis as a common manifestation[63]. However, some cases of pancreatitis have been reported in the literature[64]; in 64 patients with severe COVID-19 Liu *et al*[62] reported that 17.9% and 16.4% had increased amylase and lipase levels, respectively [62]. Thirteen out of 64 patients were examined with CT scans; of these only 5 patients showed radiological pancreatic alterations. It is worth underlining that most of these cases have been reported in moderate or severe disease. This seemingly suggests that the pathophysiology of pancreatitis could be based on the systemic inflammatory response rather than a direct histopathological effect[62].

Figure 10 A 46-year-old woman with right hypochondrium pain. Abdominal ultrasound showed an enlarged gallbladder containing deposit of biliary sludge in the infundibular region.

The radiological signs of pancreatitis in COVID-19 patients were the same as we find in classic acute pancreatitis: Focal or diffuse parenchymal enlargement and density changes due to edema with indistinct pancreatic margins and stranding of retroperitoneal fat[65] (Figure 11). More rarely, necrotic-hemorrhagic forms of pancreatitis have been described[65]. The presence of gas (emphysematous pancreatitis) and the presence of calcifications as a sign of acute on chronic pancreatitis have also been reported[66].

URINARY TRACT

There is increasing evidence that acute kidney injury (AKI) develops commonly in COVID-19 patients[67] because it affects approximately 20%-40% of patients admitted to the hospital and particularly to the intensive care unit in Europe and in the United States[68,69]. COVID-19 patients developing AKI, in conjunction with respiratory symptoms, have a poor prognosis, with a 35% reported mortality[70].

Possible causes of COVID-19-related AKI include dehydration, hypoperfusion from myocardial dysfunction, immune response dysregulation (cytokine storm) or direct kidney endothelial damage by SARS-CoV-2[69], which manifests clinically and pathologically by the development of acute tubular necrosis, interstitial inflammation, podocytopathy, microangiopathy and collapsing glomerulopathy[69].

In a postmortem renal histopathological analysis of 26 COVID-19 patients, Su *et al* [71] reported a histopathological finding of acute tubular necrosis due to endothelial damage causing microvascular lumen occlusion. The authors hypothesized that their results had been dependent on the possible kidney cells' infections with SARS-CoV-2 [71].

In this setting the imaging modality of choice is US. It is a bedside examination that can show increased cortical echogenicity or heterogeneity and loss of corticomedullary differentiation in patients with COVID-19 and AKI[72]. In cases of renal infarction, heterogeneity and hypoperfusion of the renal parenchyma and wedge-shaped areas of decreased perfusion and/or enhancement may be visualized on US and contrast-enhanced CT and may be multifocal, involving both kidneys[72] (Figure 12). It is important to note that if renal function is impaired, the use of iodinated contrast material is not recommended, thus making US the imaging modality of choice in the evaluation of COVID-19 patients with suspected renal vascular injury.

In a retrospective study, Hectors *et al*[73] found that cortex-to-aorta enhancement index (*i.e.* the ratio of renal cortical density to aorta density on contrast-enhanced CT) at the time of COVID-19 diagnosis was significantly reduced in patients who ultimately developed AKI. The authors suggest that reduced renal perfusion in COVID-19 precedes full-fledged AKI[73].

In another retrospective study, Huang *et al*[74] highlighted the usefulness of non-contrast CT on the assessment of renal impairment associated with COVID-19, featuring as perinephric fat stranding (PFS) and decreased renal parenchymal density. PFS corresponds to the thickening of perinephric bridging septa, which are fibrous lamellae that divide the perinephric space into multiple compartments, limiting the distribution of fluids, such as urine, pus and blood[75]. In this study, patients with PFS

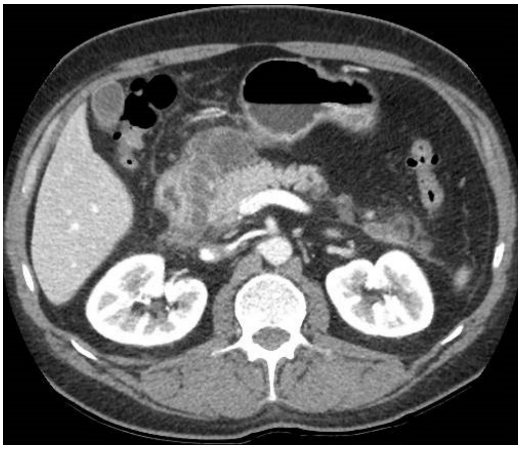

Figure 11 A 60-year-old man with abdominal pain and increased amylase and lipase levels. Abdominal contrast-enhanced portal-venous phase computed tomography image showed fluid collections at the level of the pancreatic head and isthmic region and thickening of the left anterior pararenal fascia and perivisceral fat.

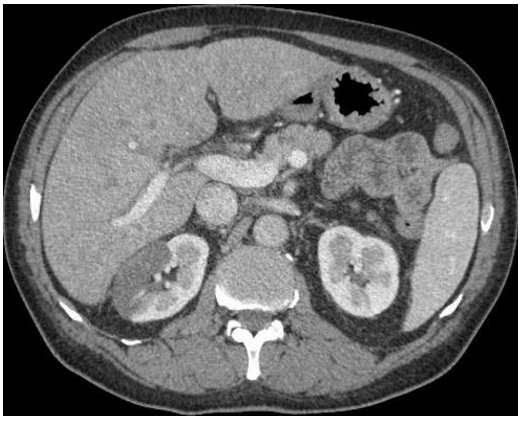

Figure 12 A 69-year-old man with hematuria and right abdominal pain. Abdominal contrast-enhanced portal-venous phase computed tomography image depicted wedge-shaped parenchymal defects that involved both the renal cortex and medulla with extension to the capsular surface, suggesting a renal infarct.

showed elevated serum creatinine levels, higher than that of the group of COVID-19 patients without PFS. Always in this study renal parenchymal attenuation in COVID-19 patients decreased. Moreover, patients with PFS showed a greater attenuation decrease, whereas patients without PFS presented a smaller decrease[75]. Therefore, the authors propose the use of PFS and renal parenchymal attenuation on non-contrast CT as a qualitative indicator for detecting renal damage associated with COVID-19.

Currently, no report has demonstrated the association between COVID-19 and urolithiasis[76], despite the nonsteroidal anti-inflammatory drugs (commonly used in stone-related colic pain) increase ACE2. This might increase the risk of developing severe and fatal COVID-19[77]. Nevertheless, the United States Food and Drug Administration recently announced that there was not enough scientific evidence connecting the use nonsteroidal anti-inflammatory drugs with worsening COVID-19 symptoms[78].

SPLEEN

Splenic injury is commonly encountered in COVID-19 patients. Red pulp cells and endothelial cells of blood vessels show an abundance of ACE2 receptors on their surfaces, so COVID-19 can directly target macrophages and dendritic cells in the spleen[79]. Autopsies in patients who died from COVID-19 exhibited splenic parenchymal congestion, hemorrhage and lack of lymphoid follicles with splenic parenchymal atrophy[79].

Splenic injuries are characterized by splenomegaly and by the development of either solitary or multifocal splenic infarcts[79]. On US examination splenic infarcts are hypoechoic compared to the remaining splenic parenchyma, although in the acute phases they may appear isoechoic and therefore difficult to identify. The morphology of the infarcts can vary as they may be classically wedge-shaped but also rounded, with irregular or smooth profiles. Over time, phenomena of contraction and scarring can develop, and in this case, they will appear as a hyperechoic region with retraction of the splenic capsule. In case of liquefaction, the area may be rounded and anechoic (splenic pseudocyst)[80]. CT is often considered the imaging method of choice, with the best visualization of infarcts during the portal-venous phase, to avoid confusing the heterogeneous improvement normally seen during the arterial phase. The CT imaging characteristics may vary with the stage of the infarct. In the hyperacute phase, there are areas of greater mottled attenuation, which represent areas of a hemorrhagic infarction typically with a wedge-shaped morphology and peripheral localization[81]. In the chronic phase, splenic infarcts may no longer be seen, or more commonly they may undergo fibrotic contraction with consequent loss of volume of the splenic parenchyma (Figure 13). As mentioned for the US, if the infarct liquefies, a cystic lesion can be left with central fluid density[81].

RADIOLOGICAL COMMENTS

As pointed out by the data of the most recent literature, COVID-19 is a systemic disease and not just a pulmonary disease, with a specific tropism for the vascular system. In fact, many other organs besides the lung can be involved by SARS-CoV-2 and thus the clinical manifestations can be variable. The gastrointestinal tract and hepato-biliary system are mainly affected, although the pancreas, urinary tract and spleen may also be involved.

The abdominal radiological findings are nonspecific and with poor pathological correlation reported in the literature. The correct use of imaging modalities in the management of these patients can be extremely helpful for the clinicians. US and particularly CT with multiphasic acquisition are the diagnostic methods mainly utilized in the COVID-19 patients with abdominal clinical symptoms and signs.

Although US can be quickly performed at the bedside and in intensive care units, this diagnostic modality is not always able to provide us reliable information in critically ill, unprepared and uncooperative patients. It also has the problem of exposing healthcare personnel to a consistent risk of infection and this limits its routine use in this setting. On the basis of the published data, US is mainly used for the hepatobiliary system, kidney and spleen evaluation, less for the pancreas and almost not utilized for gastrointestinal system assessment.

CT plays a pivotal role in identifying the signs of abdominal involvement, particularly for the gastrointestinal system, and is extremely useful for the evaluation of the vascular and parenchymal structures. Thanks to this method we can establish the severity and the evolution of the disease in COVID-19 patients. CT study should be performed at the baseline and after iodinated contrast medium injection in the various phases, paying attention to the arterial phase for ischemic lesions of the intestine and kidneys, in the portal-venous phase for wall thickening in colitis or for signs of acute pancreatitis or splenic infarcts and in the late phase for the evaluation of renal nephritis or ischemia.

Actually, magnetic resonance imaging has no defined role, and no significant experience is reported to our best knowledge. This is probably due to the fact that COVID-19 patients have difficulty undergoing magnetic resonance examination and the serious problems of management of these patients.

What is desirable in the future is that the abdominal and gastrointestinal manifestations identified by imaging may have a pathological correspondence in order to further clarify the etiopathogenetic mechanisms of the damage caused by COVID-19. Furthermore, larger series of COVID-19 patients studied with imaging methods could help us to identify the most characteristic signs of abdominal and gastrointestinal involvement. In this setting, magnetic resonance imaging could be particularly useful for the evaluation of the hepato- biliary system, pancreas and kidney.

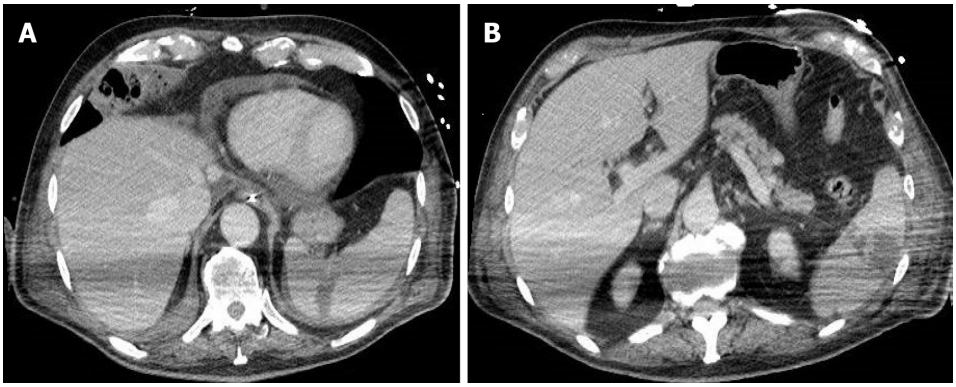

Figure 13 A 77-year-old man with abdominal tenderness. A: Contrast-enhanced portal-venous phase computed tomography image of the abdomen demonstrated a wedge-shaped low-attenuation area at the level of the spleen, typical of infarction. Pericardial effusion was also present; B: A further rounded low-attenuation area with peripheral localization was present in a lower portion of the spleen on contrast-enhanced portal-venous phase computed tomography scan.

CONCLUSION

Although radiological signs are not specific of abdominal and gastrointestinal involvement, the diagnostic imaging modalities and in particular CT are helpful for the clinician in the management, evaluation of the severity and evolution of COVID-19 patients.

Abstract

The severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2) that causes coronavirus disease-2019 (COVID-19) has provoked a global pandemic, mainly affecting the respiratory tract; however, a percentage of infected individuals can develop gastrointestinal (GI) symptoms. Some studies describe the development of GI symptoms and how they affect the progression of COVID-19. In this review, we summarize the main mechanisms associated with gut damage during infection by SARS-CoV-2 as well as other organs such as the liver and pancreas. Not only are host factors associated with severe COVID-19 but intestinal microbiota dysbiosis is also observed in patients with severe disease.

Key Words: SARS-CoV-2; Gastrointestinal symptoms; COVID-19; Gastrointestinal system

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Coronavirus disease-2019 (COVID-19) affects not only the respiratory systems but also gastrointestinal (GI) system and function of others organs. Until now, the mechanism of infection that severe acute respiratory syndrome, coronavirus 2 uses is not fully known. GI symptoms are rare but had great relevance in the severity of disease. We summarize the main known mechanisms that are associated with intestinal

INTRODUCTION

Coronaviruses are a family of viruses that cause illnesses such as the common cold, severe acute respiratory syndrome, coronavirus 2 (SARS-CoV-2), and Middle East respiratory syndrome (MERS)[1]. SARS-CoV-2 is the etiologic agent of coronavirus disease 2019 (COVID-19), designated as a pandemic by the World Health Organization on March 11, 2020. Up to January 1st, 2021, COVID-19 has caused globally over 85 million cases[2]. The impact that COVID-19 has had worldwide on health and the economy has been devastating since the number of deaths continues, partly because neither we fully understand the disease nor its transmission. Moreover, there are increasing long-term complications and sequelae after COVID-19 in some people[3,4].

The respiratory tract is the main entry route reported, and the transmission mechanism is *via* large droplets containing a high enough viral load. The virus is not motile by itself and depends on its rotational diffusivity to align its proteins (organized in hollow spikes called "peplomers") to its targets during the infection process[5]. Infected people in most cases do not develop symptoms (asymptomatic) or have mild symptoms such as fever, dry cough, fatigue, sore throat and/or headache, conjunctivitis, nausea, vomiting, skin rashes, and dysgeusia; which appear 2-14 d after being exposed to the virus[6]. It has been reported that the survival time of SARS-CoV-2 in aerosol form is 4 h, as the virus becomes inactive at 60°C. Propagation of the droplets in the air depends on the ventilation systems of the area where an infected person is spreading the virus while breathing without using personal protection equipment[7].

Additionally, gastrointestinal (GI) symptoms such as diarrhea, nausea, and vomiting have been reported[8], yet this seems to affect only about 1%–3.8% of the studied patients[9]. Nevertheless, the exact molecular mechanism with which SARS-CoV-2 produces GI damage is still unknown. Therefore, this review aims to describe the effect that SARS-CoV-2 produces in the GI tract.

MECHANISM ASSOCIATED WITH COVID-19 INFECTION IN THE GI SYSTEM

SARS-CoV-2 clinical manifestations include GI effects; however, there is insufficient research on the mechanisms that allow digestive colonization by a respiratory virus. With over 80% resemblance between SARS and SARS-CoV-2[8], several studies have shown tropism for the GI tract, as SARS-CoV-2 RNA was detected in stool specimens from COVID-19 patients with diarrhea, suggesting that it can be transmitted by the fecal-oral route[10].

The viral nucleocapsid protein of SARS-CoV-2 has been found in the GI lumen in the esophagus, stomach, duodenum, and the rectal glandular epithelial cells, suggesting this receptor as the entry point of the SARS-CoV-2 virus in the intestinal tract[10-12]. Also, the expression of angiotensin-converting enzyme 2 (ACE2) protein on glandular cells of gastric, duodenal, rectal epithelia (abundantly expression), and esophageal mucosa (less expression) was demonstrated, supporting the entry of SARS-CoV-2 into the host cells by immunofluorescent technique[13].

ACE2 is a receptor member of the angiotensin-converting enzyme (ACE) family of dipeptidyl-carboxypeptidase and is highly homologous to ACE1, which plays an important role in SARS-CoV-2 infection, through a high-affinity attachment to ACE2

receptors in human cells[11]. The primary function of ACE2 is the conversion of angiotensin (Ang) 1 to Ang 1-9 and Ang 2 into Ang 1-7. ACE receptors participate in cell proliferation and hypertrophy, inflammatory response, blood pressure, and fluid balance. Specifically, ACE2 has an important role in regulating cardiovascular, renal, and reproductive functions[10]. Besides its high expression in type II alveolar cells (AT2) in the lungs, the GI tract also expresses ACE2 receptor, particularly in the esophageal epithelium, glandular gastric mucosa, enterocytes, and colonocytes. ACE2 is present in the cytoplasm of the epithelial cells of the stomach and intestine and the cilia of glandular epithelial cells[10-12].

Recent studies have shown that SARS-CoV-2 may cause digestive symptoms by direct viral invasion of target cells and by inflammatory injury. The viral infection process involves a series of steps: (1) A direct cytopathic effect; (2) Downregulation of ACE2 expression with an increase of metalloproteinase action; and (3) Dysregulation of the immune system, with over secretion of proinflammatory cytokines[14]. Plasmatic and lymphocytic infiltration with interstitial edema[10]. Figure 1 includes more details about this process.

In general, all coronaviruses encode a surface glycoprotein and spike protein that binds to host cell receptors ACE2 and allows virus entry. The spike (S) protein of SARS-CoV-2 has a high affinity for human ACE2, which is the main entrance into the cell[12]. Furin is an enzyme that can be found on the small bowel, acting as a serine-protease that can divide the viral S-protein into two fragments: S1 and S2, allowing them to interact with ACE2. The separation of the S-spike into S1 and S2 is essential for the attachment of the virion to both the ACE receptor and the cell membrane[15]. S-protein proteases, such as cathepsins, expose the fusion domain to the endosome by acid-dependent proteolytic cleavage. Successful virus entry also requires a cellular serine protease, transmembrane protease serine 2 (TMPRSS2)[16]. TMPRSS2 cleaves the S protein of SARS-CoV-2 on the cell membrane, a process that is critical for the fusion of the viral and cell membranes. Importantly, both ACE2 and TMPRSS2 become highly expressed in the ileum and colon[16-18]. Hoffmann *et al*[19] demonstrated that inhibition of the TMPSSR (the serine protease responsible for splitting the S-spike) blocks the infection of cells by SARS-CoV-2.

After viral entry, RNA translates, and viral proteins become synthesized to form new virions released in the GI tract[13]. Thus, leading the CD4+ T cells to reach the small intestine, causing diarrhea and immune damage[12]. ACE2 participates in regulating intestinal inflammation and diarrhea by being a key enzyme in the renin-angiotensin system. It has been shown that loss of ACE2 leads to Ang 2 accumulation. Moreover, the plasma of COVID-19 patients with severe disease presents higher levels of interleukin (IL)-7, IL-10, granulocyte colony-stimulating factor, and recombinant human interferon-induced protein-10, monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1A (MIP1A), and tumor necrosis factor alpha (TNF-α)[18]. The local inflammation could debilitate the epithelial barrier, and these inflammatory changes can be part of cell damage induced by viral replication and spreading [20]. This inflammation process disturbs the gut microbiota promoting the polarization of Th17 in the small intestine, promoting the recruitment of other immune cells such as neutrophils, and inducing intestinal immune damage, diarrhea, and other GI symptoms. Also, intestinal damage and gut microbiota alteration can affect the gut-liver axis by contamination of the liver with host and microbial metabolites through the portal vein[12].

A study by Xiao *et al*[13] showed that among 73 hospitalized patients, 53.42% tested positive for SARS-CoV-2 in the stool. The duration of positive stool results ranged from 1 to 12 d, and 23.29% of patients continued to have positive results in stool after being negative in respiratory samples and presenting positive staining for ACE2 receptor and viral nucleocapsid protein in stomach, duodenum, and rectum biopsies. Raising the question if COVID-19 can be transmitted by the fecal-oral route or transmitted by aerosols generated by toilet fumes has been shown with SARS-CoV-2 [21,22]. A study conducted by Zhang *et al*[23] showed that 39.6% of 140 confirmed COVID-19 patients presented GI symptoms among the most common clinical manifestations[23]. Another study reported that 10.1% of 138 confirmed COVID-19 patients, presented diarrhea and nausea[24], furthermore, a recent report showed that 11.4% of 651 patients showed GI symptoms associated with a more severe presentation of the disease[25]. Nonetheless, patients with SARS and MERS have reported more GI symptoms than COVID-19 patients[26]. There has been a high concern in how COVID-19 can affect the body with pre-existing diseases, inflammatory bowel diseases (IBD), such as Crohn disease and ulcerative colitis.

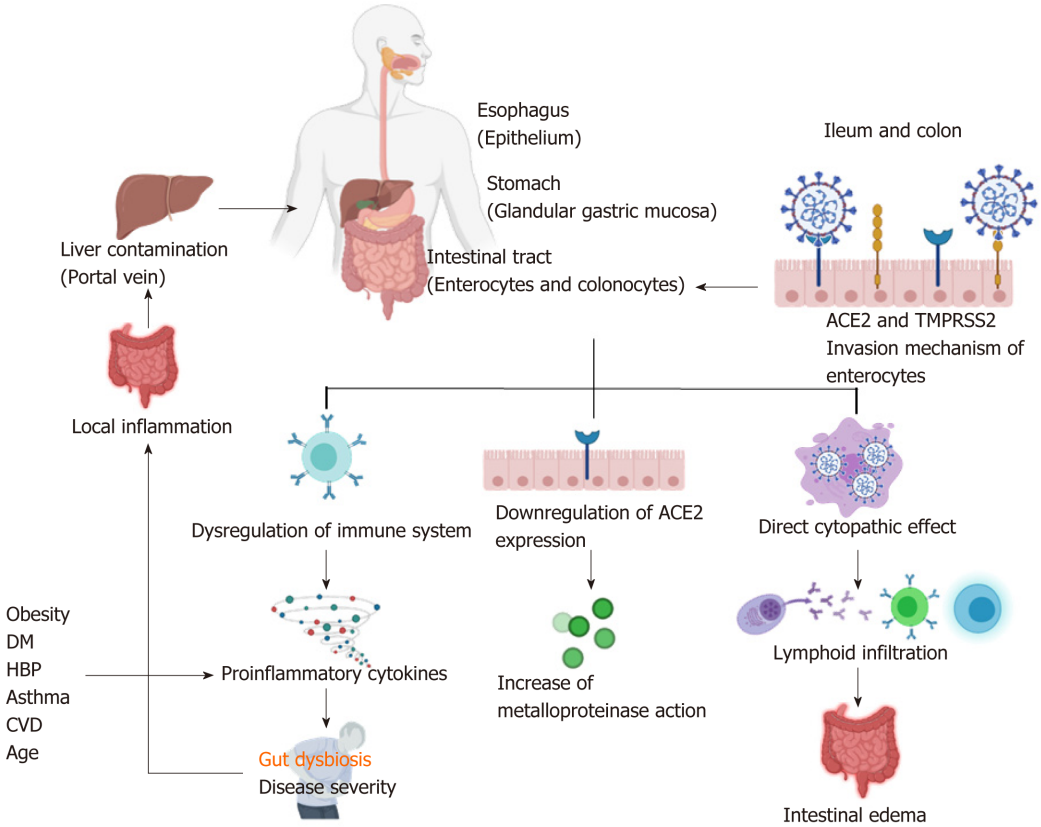

Figure 1 Mechanisms of severe acute respiratory syndrome-coronavirus-2 gastrointestinal infection. The same receptors mediate infections of the gastrointestinal system as in the respiratory system. This situation could begin at the intestinal tract by enterocyte invasion, which possesses angiotensin-converting enzyme 2 (ACE2) and transmembrane protease serine 2 receptors recognized by severe acute respiratory syndrome-coronavirus-2. Once in cells, the virus can induce cell death-mediated dysregulation of the immune system by downregulation of ACE2 receptor expression and a direct cytopathic effect. All three mechanisms induce immune dysregulation and increase the inflammation mechanism. Some risk factors that accelerate immune inflammation are obesity, diabetes mellitus, high blood pressure, asthma, cardiovascular disease, and advanced age. Moreover, the virus could enter the liver by the portal vein and induce hepatic failure. ACE2: Angiotensin-converting enzyme 2; TMPRSS2: Transmembrane protease serine 2; DM: Diabetes mellitus; HPB: High blood pressure; CVD: Cardiovascular disease.

A study showed that immunosuppressors modulate the cytokine inflammatory response, thus preventing a more severe manifestation of COVID-19[27]. Also, GI symptoms derived from drug side effects of antibacterials (macrolides, fluoroquinolones, or cephalosporin) and antivirals (chloroquine phosphate, lopinavir, and remdesivir) administered during illness[12].

COVID-19 patients with preexisting comorbidities such as hypertension, asthma, diabetes, cardiovascular problems, and old age, have a higher susceptibility to inflammation. Recent studies have shown that the severity of the clinical course of COVID-19 is related to inflammation and higher levels of proinflammatory cytokines[14]. Studies show that SARS-CoV-2 rapidly activates T cells and induces the release of several inflammatory cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin 1 (IL-1), IL-6, monocyte chemoattractant protein-1, and interferon-gamma (IFN-γ). GM-CSF activates CD14+ cells, CD16+ cells, and monocytes, increasing inflammatory cytokine levels, stepping up the inflammatory cascade. This intense immune response causes tissue damage[28]. T cells from peripheral blood in COVID-19 infection present high cytotoxic activity with more cytotoxic granules, granulysin, and perforin, which shows that activated T cells could speed up systemic inflammation[29]. Also, ACE2 expressing cells release proinflammatory cytokines such as MCP-1, tumor growth factor (TGF-1), TNF-α, IL-1, and IL-6 [12].

Recently, COVID-19 intestinal pathogenesis mechanisms have been proposed since SARS-CoV-2 also might interfere with tryptophan absorption. Tryptophan stimulates the mTOR pathway for the production of antimicrobial peptides that maintain gut microbiota homeostasis. This process requires intestinal ACE2 to regulate the expression of neutral amino acid transporters. Tryptophan is absorbed by factors of

the B0AT1/ACE2 transport pathway on the lumen surface of intestinal epithelial cells. When there is not enough niacin or tryptophan intake, there is a high risk of developing pellagra, which eventually develops into colitis. As SARS-CoV-2 infection competes for available ACE2 receptors, it causes tryptophan deficiency and lower production of antimicrobial peptides[16]. COVID-19 murine models showed a deficiency of ACE2 receptors in the colon, which increase susceptibility to inflammation and colitis development due to decreased antimicrobial peptides and the alteration of gut microbiota, finalizing with diarrhea[12,29]. However, this mechanism needs to be proven in humans.

COVID-19 RELATED DAMAGE TO INTESTINAL MICROBIOTA

The human gut microbiota comprises 10^{14} resident microorganisms which include bacteria, *archae*, viruses, and fungi and has a key role in health through its protective function by regulating various host physiological functions, including dietary digestion, and imparting protective immunity against pathogens[30]. The defense mechanism of microbiota induces alpha-defensin, secretory IgA, and some other AMPs (antimicrobial peptides)[31], affecting innate lymphoid cells, but mainly they affect the innate and adaptive immune system by influencing epithelial or macrophage cell receptors, such as toll-like receptors (TLRs) or NOD-like receptors (NLRs). TLRs are involved in normal mucosal immune system development of the intestine, decreasing inflammatory responses and promoting immunological tolerance to the normal microbiota components. NLRs participate in the adjustment of the IL-18 level, the immune response, dysbiosis, and intestinal hyperplasia[32].

Healthy gut microbiota, primarily dominated by *Bifidobacterium* spp., *Faecalibacterium* spp., *Ruminococcus* spp., *and Prevotella* spp. Whom`s alterations in the balance between gut microbiota and the immune system, sometimes collectively called "gut dysbiosis" are associated with infections, inflammations, allergies, colorectal cancer, and autoimmune disease[30]. Studies have suggested that "gut-dysbiosis" might contribute to GI symptoms by SARS-CoV-2 infection, *i.e.*, *Bacteroides dorei, Bacteroides thetaiotaomicron, Bacteroides massiliensis*, and *Bacteroides ovatus*, can downregulate the expression of ACE2 during the hospitalization of COVID-19 patients[33].

Microbial dysbiosis with decreased levels of *Lactobacillus* and *Bifidobacterium* and the abundance of *Clostridium hathewayi, Clostridium ramosum*, and *Coprobacillus* positively correlated with the severity of the disease[33]. A study in a Chinese population reported that intestinal infection by SARS-CoV-2 can induce the production of proinflammatory factors such as IL-18. IL-18 is a proinflammatory cytokine produced by multiple enteric cells, including intestinal epithelial cells, immune cells, and the enteric nervous system, is shown increased in the serum of COVID-19 patients. IL-18 levels seem to correlate with an abundance of *Peptostreptococcus*, *Fusobacterium*, and *Citrobacter*, indicating changes in gut microbiota[34].

Obesity presents changes in microbiota, dysregulation of cytokine profiles, and higher levels of ACE2 in adipocytes[35]. As the opposite, an adequate fiber intake and whole grains diet improves intestinal microbiome composition, reduces intestinal inflammation markers like CRP, IL-6, and TNF-α[36]. Besides the colon and intestines, the liver is another organ the SARS-CoV-2 could affect[29].

LIVER INJURY IN COVID-19 PATIENTS

The few reports regarding liver damage by COVID-19 come from autopsies carried out in different hospital centers. The incidence of liver damage in patients with COVID 19 ranges from 14% to 53%[37]. Patients with elevated liver function tests were more likely to have a moderate-high degree fever, and these elevations were significantly more prevalent in male patients (68.67% *vs* 38.36%). It is important to mention that it is difficult to define how COVID-19 generates liver damage since patients at the time of hospitalization usually have chronic diseases such as non-alcoholic hepatic steatosis, which increases the progression of the disease, hepatitis C such as those reported by Schmit[20,38]. Among the biochemical indicators, there have been reports of elevated aminotransferases approximately on the tenth day of hospitalization[39].

Patient biopsies reveal the presence of hepatocyte mitosis with acidophilic bodies, moderate inflammation, and ballon degeneration. In the SARS virus epidemic in 2003, a study reported the elevation of aminotransferases in a range of 300-400, and prominent mitoses, which refers to what researchers have published in various studies

from these pandemics. The authors assumed that the prominent mitosis was likely due to a hyperproliferative state and cell cycle arrest[40].

Some researchers hypothesized that the direct action of the virus on liver cells causes centrilobular, periportal necrosis without significant inflammation compatible with acute liver damage. Also, the authors report that development of cholestasis and a great reactive biliary proliferation as consequences of the virus are to be expected. They further consider the possibility that the virus enters the liver through the portal vein[38]. The definitive mechanism by which liver injury occurs in COVID-19 patients remains unclear. There are multiple theories of the pathophysiology of the viral infection that could explain this phenomenon: (1) ACE2-mediated direct viral infection of hepatocytes; (2) Critically-ill status and immune-mediated injury; or (3) Drug hepatotoxicity[11] (Figure 2).

Liver damage by COVID-19 can be clarified thanks to the severe inflammatory response and cytotoxicity of the active replication with ACE2 receptors expressed in the liver, especially in cholangiocytes and epithelial cells of the bile duct, which is why the liver is also considered a target organ for SARS-CoV2 infection[41].

Fiel *et al*[42] found this elevation associated with pharmacological treatment with lopinavir/ritonavir. However, a review demonstrated that aminotransferases are only significantly elevated in severe COVID-19 cases. Drug toxicity has served as one mechanism for COVID-19-associated liver injury, damage that is secondary and does not make them susceptible to viral infection. However, little is known about the incidence of hepatotoxicity of various drugs used in COVID-19. Understandably, efforts are currently made regarding this concern. These efforts will prove important in developing a reasonable intervention and reducing the harmful effects of drug-induced hepatotoxicity for patients[29].

SARS-COV-2 AND THE PANCREAS

Expressed in the pancreas is the angiotensin converting enzyme 2 specifically in the exocrine glands, and islets[43] therefore, it is susceptible to SARS-CoV-2 infection. In a cohort of 121 patients with COVID-19 in China, 10% had increased lipase levels but only 4% showed pancreas enlargement or dilatation in computerized tomography (CT) scans[44].

In another cohort of 71 patients in the United States, 12% had increased lipase levels but only 3% exceeded three times the upper normal limit. None of the patients had abnormal pancreas images in CT scans[45]. In a cohort of 83 patients with COVID-19 in the United States, 16.8% had increased lipase levels (three times the upper limit). Researchers have associated high lipase levels with admission to the intensive care unit and intubation after a multivariable-adjusted model[46]. In a retrospective pooled analysis, the pooled prevalence of hyperlipasemia was 12% and the pooled odds ratio for severe COVID-19 was 3.143[47]. The ACE2 receptor is also highly expressed in pancreatic islet cells[43]; therefore, SARS-CoV-2 infection can theoretically cause islet damage resulting in acute diabetes, which associates to patients with pancreatic injury and high blood sugar. Mechanisms by which pancreatic injury could occur include the direct cytopathic effects of SARS-CoV-2 or indirect systemic inflammatory and immune-mediated cell responses, resulting in organ damage or secondary enzyme abnormalities. Antipyretics, which most of the patients in this study took before admission, could also cause drug-related pancreatic injury[48]. However, more information to understand the role of pancreatic injury in patients with COVID-19 is needed.

TREATMENTS OF GI SYMPTOMS

At the current stage of the COVID-19 pandemic, several vaccines are in their last stages of authorization for emergency use[49,50]. While full distribution will continue as a challenge, hopes of major population immunity are coming close. Yet, until we have a more resistant population, respiratory complications will continue as the major symptom reported during a COVID-19 infection. Interestingly, other lesser-known indicators that manifest, such as those of the GI which include vomiting, nausea, and diarrhea[12,51]. Many studies have shown that vomiting and nausea can be present in upwards of 30% and 15% of patients[12]. Interestingly enough, in a pediatric setting, one reported case showed patients with no-respiratory affliction who were all COVID-19 positive; all presented GI alterations. Several showed gastroenteritis, another

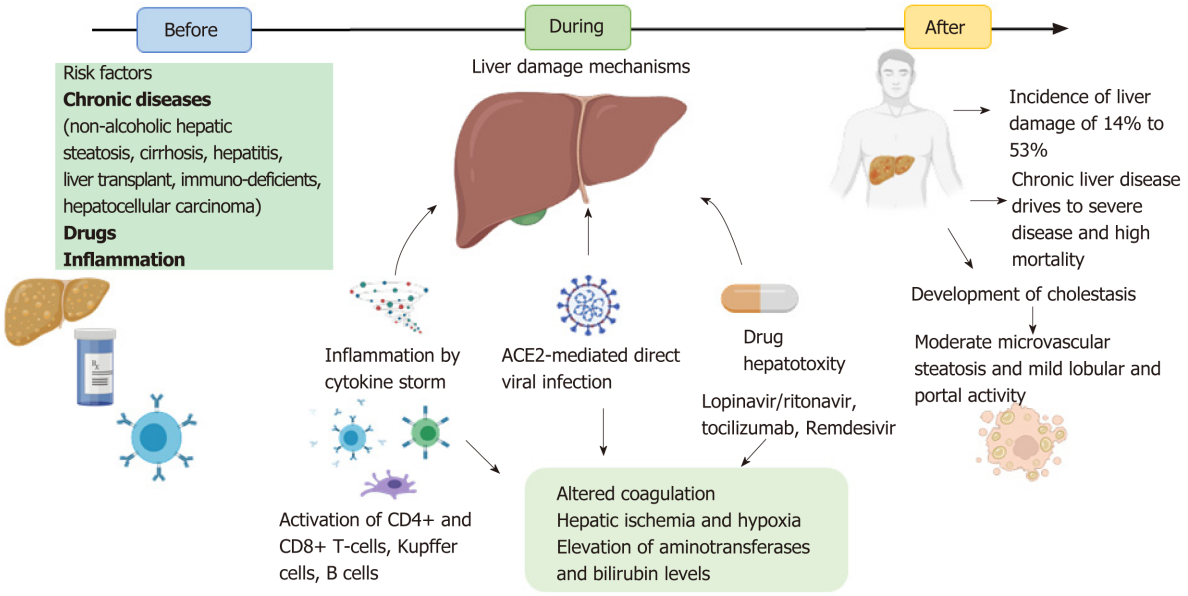

Figure 2 Proposed process of liver damage. Before severe acute respiratory syndrome-coronavirus-2 infection, there are risk factors considered that could be poor prognostic factors, such as chronic diseases, the use of drugs that affect the liver and the inflammation process. The virus can infect the liver through the portal vein. There are three proposed mechanisms of liver damage: inflammation induced by cytokine storm and activation of hepatic immunity, angiotensin-converting enzyme 2-mediated direct viral infection of hepatocytes, epithelial cells, and cholangiocytes, and drug hepatotoxicity mediated by some antivirals employed for coronavirus disease-2019 (COVID-19) treatment. The three mechanisms culminate in altered coagulation, hepatic ischemia, and elevation of aminotransferases and bilirubin levels. Following this, the incidence of liver damage derived from COVID-19 is up to 53%, which could develop cholestasis and reach high mortality risk. ACE2: Angiotensin-converting enzyme 2.

patient appendicitis, and yet another, hydronephrosis[52]. As more data becomes available, GI manifestations such as loss of appetite seem to be direct signs of COVID-19. Counter to the GI manifestations brought about by COVID-19, several drugs used to combat the effects of the virus have secondary side effects. Drugs like remdesivir, hydroxychloroquine, favipiravir, ivermectin, and azithromycin can induce side effects such as vomiting, nausea, elevated liver enzymes, weight loss, abdominal pain, and others[53]. The Table 1 display wide information.

In addition, COVID-19 patients can present a hyper-inflammatory state, with systemic response and cytokine storm mediated by IL-6, IL-8, and TNF-α, which can induce platelet activation and thrombosis, also presenting endothelial dysfunction due to direct virus damage and inflammation[54]. Heparin is used in COVID-19 patients as prophylactic therapy to prevent thrombosis. However, heparin-induced-thrombocytopenia (HIT) after administering low doses may not be enough to counteract the hypercoagulable state, leading to coagulation problems in these patients[55]. Heparin treatment, by a direct interaction between heparin and platelets, induces platelet clumping or sequestration. This event occurs within the first 48-72 h after starting treatment and generates mild and transient thrombocytopenia[56]. In some cases, thrombosis could be associated with HIT after heparin cessation[57].

In the GI system, the intestinal microbiota plays a crucial role in the correct balance and maintenance. If unbalanced component processing becomes inefficient, direct damage to the intestinal mucosa results in more accessible routes for viral infection[12,58]. Studies have confirmed that probiotics can assist in this treatment; both bifidobacterium and lactic acid can help induce antibody production[12]. It is important to mention that patients with severe GI symptoms require a nutritional risk assessment, as it becomes a predictor of outcome both in the long term and the short term[59].

COVID-19 individuals presenting irritable bowel disease are of particular interest since this condition warrants the use of immunosuppressants and steroids. Interestingly, vedolizumab and ustekinumab do not increase the risk of COVID-19, hence patients can continue its use safely. Yet, thiopurines, anti-tumor necrosis factor (anti-TNF) agents, and JAK inhibitors may continue to present a risk. In mild cases, 5-ASA and budesonide use are reasonable[53]. We should take special consideration to outweigh the benefit against the risk for each case. Also, unless emergent, patients should defer all surgical procedures until pandemic conditions rescind[60]. We should

Table 1 Side effects of most common drugs during coronavirus disease-2019 treatment

Pharmacological intervention	Mechanism of action	Adverse effects	Ref.
Hydroxychloroquine	Elevated endosomal pH; Disruption of lysosome-endosome fusion. Inhibition of cell-virus fusion when interacting with N-terminal domain of the SARS-CoV-2 peak	Q-T segment prolongation; Gastrointestinal Adverse Effects	[62-64]
Chloroquine	Inhibits RNA-dependent polymerases, decreases endosomal iron release required for DNA replication, and inhibits glycosylation of viral envelope glycoproteins	Gastrointestinal adverse effects; visual and extrapyramidal disturbances; Arrhythmogenic cardiotoxicity	[65-67]
Remdesivir	Transcription Inhibitor	Caution in patients with severe renal impairment [estimated glomerular filtration rate (eGFR) < 30 mL/min/1.73] or severe liver disease	[68]
Lopinavir/Ritonavir	Lopinavir binds to the viral protease and prevents the cleavage of the Gag-Pol polyprotein, resulting in the production of non-infectious immature viral particles. Ritonavir increases the plasma concentration of lopinavir by inhibiting the metabolism of cytochrome P450 3A (CYP3A)	Gastrointestinal adverse effects	[64, 65,68-72]
Ribavirin	Interferes with RNA polymerase and viral protein synthesis	Hemolytic anemia; Leukopenia; Teratogenic	[68]
Interferon	Degradation of viral RNA; Alteration of RNA transcription; Inhibition of protein synthesis and apoptosis	Worsening psychiatric conditions, cytopenia, and uncontrolled seizures	[68]
Cortocosteroids, dexametasone	Inhibitor of the inflammatory process	Impair the immune response; Bacterial pneumonia risk; Hyperglycemia; Osteoporosis; Hypertension	[68-70]
Azithromycin	Bacteriostatic antibiotics; Anti-inflammatory effects Immunomodulatory effects	QTc with the risk of arrhythmias	[71, 73]
Heparin	Antiplatelet	Risk GI symptoms; Bleeding; Heparin-induced thrombocytopenia	[74]
Favipiravir	Competitive inhibitor of RNA-dependent RNA polymerase	GI adverse effects; liver injury	[75, 76]

SARS-CoV-2: Severe acute respiratory syndrome-coronavirus-2; GI: Gastrointestinal.

consider patients with Crohn's disease for colectomy with end ileostomy. An important aspect to take into consideration is comorbidities, such as diabetes and hypertension, which are exacerbators of damage in COVID-19. As expected, comorbidities become paramount in symptom management, because of the high risk they represent[60,61].

CONCLUSION

By now, we know that GI symptoms in COVID-19 disease such as diarrhea are related to gut microbiota alterations that alter profile cytokines, either by SARS-Cov-2 ACE2 alterations or as a secondary effect of antibiotic and antiviral drugs employed in treatment. However, additional research is needed for the hepatic and pancreatic manifestations that aggravates the patient´s situation, and a deeper understanding of the sequelae after symptoms of the disease. Until now, the knowledge that we have mainly involves the host; however, we must not ignore the pathogenicity of the virus and the recent variants that are currently circulating since these could in the future serve to explain in greater detail the mechanisms involved in the intestinal damage or with the presentation of GI symptoms that can accompany COVID-19 respiratory disease.

Abstract

Adult pancreatoblastoma is an exceptionally rare malignant tumour of the pancreas that mimics other solid cellular neoplasms of the pancreas, which may pose diagnostic difficulties. Because of its rarity, little is known about its clinical and pathologic features. This article reviews the clinical and pathologic features of pancreatoblastoma in adults including differential diagnosis, treatment, and follow-up. Although pancreatoblastoma commonly occurs in childhood, there have now been more than 70 adult pancreatoblastomas described in the literature. There is a slight male predominance. There are no symptoms unique to pancreatoblastomas and adult patients are frequently symptomatic. The most common presenting symptom is abdominal pain. Grossly, the tumours are often large and well-circumscribed. Microscopically, pancreatoblastomas are composed of neoplastic cells with predominantly acinar differentiation and characteristic squamoid nests. These tumours are positive for trypsin, chymotrypsin, lipase, and BCL10. Loss of heterozygosity on chromosome 11p is the most common molecular alteration in pancreatoblastomas. Adult pancreatoblastomas are aggressive tumours with frequent local invasion, recurrence, and distant metastasis. Treatment consists of surgical resection. Chemotherapy and radiotherapy may have a role in the treatment of recurrent, residual, unresectable, and metastatic disease. It is important to distinguish pancreatoblastomas from morphological mimics such as acinar cell carcinomas, solid pseudopapillary neoplasms, and pancreatic neuroendocrine neoplasms.

Key Words: Pancreas; Adult pancreatoblastoma; Pancreatic cancer; Solid pancreatic mass; Non-ductal pancreatic tumours

INTRODUCTION

Pancreatoblastoma is a malignant epithelial neoplasm of the pancreas composed of cells with predominantly acinar differentiation and characteristic squamoid nests. Neuroendocrine, ductal and less commonly, mesenchymal differentiation can be seen but are often less extensive[1-3]. Less than 1% of pancreatic neoplasms are pancreatoblastomas[4,5]. Pancreatoblastoma commonly occurs in childhood, accounting for 25% of pancreatic neoplasms occurring in the first decade of life, with a mean age of approximately 4 years[1].

Adult pancreatoblastoma is extremely rare. Hence, little is known about its clinical and pathologic features. Furthermore, pre-operative diagnosis can be quite challenging because of the considerable overlap with other cellular neoplasms of the pancreas.

This article provides an up-to-date review of the clinical and pathologic features of pancreatoblastoma in adults, including cytology, molecular pathology, differential diagnosis, treatment, and follow-up.

EPIDEMIOLOGY

Adult pancreatoblastomas are exceptionally rare. To date, only 74 adult pancreatoblastomas have been reported in the literature, mostly in the form of isolated case reports and small series[6-10]. The mean age at diagnosis is 41 years (range, 18-78 years). There is a slight male predilection, with a male-to-female ratio of 1.2:1.

AETIOLOGY

The aetiology is unknown. Although most tumours are sporadic[11-15], few adult pancreatoblastomas have been described in the setting of familial adenomatous polyposis (FAP)[8,9]. Rare cases in children have been associated with Beckwith-Wiedemann syndrome[16,17].

CLINICAL PRESENTATION

Most patients are symptomatic, with very few cases discovered incidentally during routine examination and imaging[4,10,11]. There are no symptoms unique to pancreatoblastomas. The most common presenting symptom is abdominal pain[2]. Other clinical features include abdominal mass, weight loss, nausea, jaundice, and diarrhoea [6,14,15,18,19]. Rarely, patients may present with upper gastrointestinal bleeding[12].

Most adult pancreatoblastomas arise in the head of the pancreas. Of the 74 adult pancreatoblastomas described in the literature, localization data were available in 69 cases. The head of the pancreas was involved in 52.1% of cases (36 patients); the tail in 30.4% of cases (21 patients); the body in 14.5% of cases (10 patients); the body and tail in 1.5% of cases (1 patient); and the ampulla of vater in 1.5% of cases (1 patient).

Elevated serum levels of CA19-9[14,15] as well as corticotropin releasing hormone secretion[20] rarely occurs in adult pancreatoblastomas. Serum alpha fetoprotein

(AFP) is elevated in some pancreatoblastomas[4,7,13,21,22]. In addition, AFP may be detected immunohistochemically in tumours associated with elevated serum levels of AFP[3,4,22]. Serum AFP is frequently elevated in children[4,10,13] with levels often in excess of 1000 μg/L[3]. In contrast, AFP is not consistently elevated in adults[2,7,10,13]. When present, elevated serum AFP has been used as a marker of tumour recurrence or disease progression because AFP levels should decrease or normalize with successful treatment[7,13,21].

It is important to note that elevated AFP is not specific for pancreatoblastoma in a patient with a pancreatic mass. Pancreatic ductal adenocarcinomas[23] and pancreatic acinar cell carcinomas[24,25] have been associated with elevated serum AFP. Furthermore, AFP is widely used as a tumour marker for hepatocellular carcinoma (HCC). However, the limitations of AFP in detecting HCC includes the poor sensitivity in detecting small tumours and elevated levels of AFP in patients with chronic liver disease without HCC. To overcome this limitation, the *Lens culinaris* agglutinin-reactive AFP (AFP-L3) has been found to be highly specific and useful not only for early detection of HCC but also for predicting the risk of development of HCC in patients with chronic liver disease[26,27]. However, AFP-L3 or other isoforms of AFP are yet to be extensively studied in pancreatoblastomas.

Malignant behaviour is prominent in adult pancreatoblastomas. Approximately 59% of adult patients with pancreatoblastoma develop metastases at the time of diagnosis or afterwards in the course of the disease. The liver is the most common site of metastasis[2,12,15,28] followed by lymph nodes[4,5,29], and lung[4,5,7,15]. Chest wall[5], breast[15], bone[30], and brain metastases[31] are extremely rare. Tumours can invade adjacent structures such as the duodenum, spleen, common bile duct, portal vein, and superior mesenteric vessels[2,4,7,19,29].

IMAGING

There are no significant differences in the imaging findings of adult and paediatric patients[2,32]. Pancreatoblastomas are large well-defined heterogenous masses with low to intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Enhancement is a common feature on contrast-enhanced computed tomography images and may be present on magnetic resonance imaging. Calcifications when present may be rim-like or clustered[19,33]. On ultrasound, pancreatoblastomas are well-demarcated solid masses inseparable from the pancreas with mixed echogenicity[33].

CYTOLOGY

Fine needle aspiration specimens are composed of cellular singly dispersed and/or clustered polygonal cells. The cells have round to oval nuclei with fine chromatin pattern, small indistinct nucleoli, and moderate amounts of amphophilic or eosinophilic cytoplasm[3,9]. Squamoid nests or corpuscles are best appreciated in cell block preparations. They are composed of plump epithelioid cells with abundant cytoplasm [7,9].

PATHOLOGY

Grossly, the tumours are solitary, solid, well-circumscribed, and often encapsulated. Pancreatoblastomas are usually large, averaging 8 cm in diameter (range, 1.8–30 cm)[2,3,6]. On cut section, the tumours have yellow to tan fleshy lobules separated by dense fibrous bands. Foci of haemorrhage and necrosis may be present. Rarely, pancreatoblastomas may undergo cystic change or show gross extension into the adjacent peripancreatic soft tissue[4].

Microscopically, pancreatoblastomas are composed of cellular well-delineated lobules separated by dense fibrous bands, often imparting a geographic low power appearance (Figure 1A). The dense fibrous bands between the lobules are composed of spindled cells with varying amounts of collagen (Figure 1B). Tumours predominantly show acinar differentiation; however, ductal, neuroendocrine and less commonly, mesenchymal differentiation may be present[1-3]. Solid areas with sheets of cells often alternate with areas with acinar differentiation. The acinar units comprise small cells

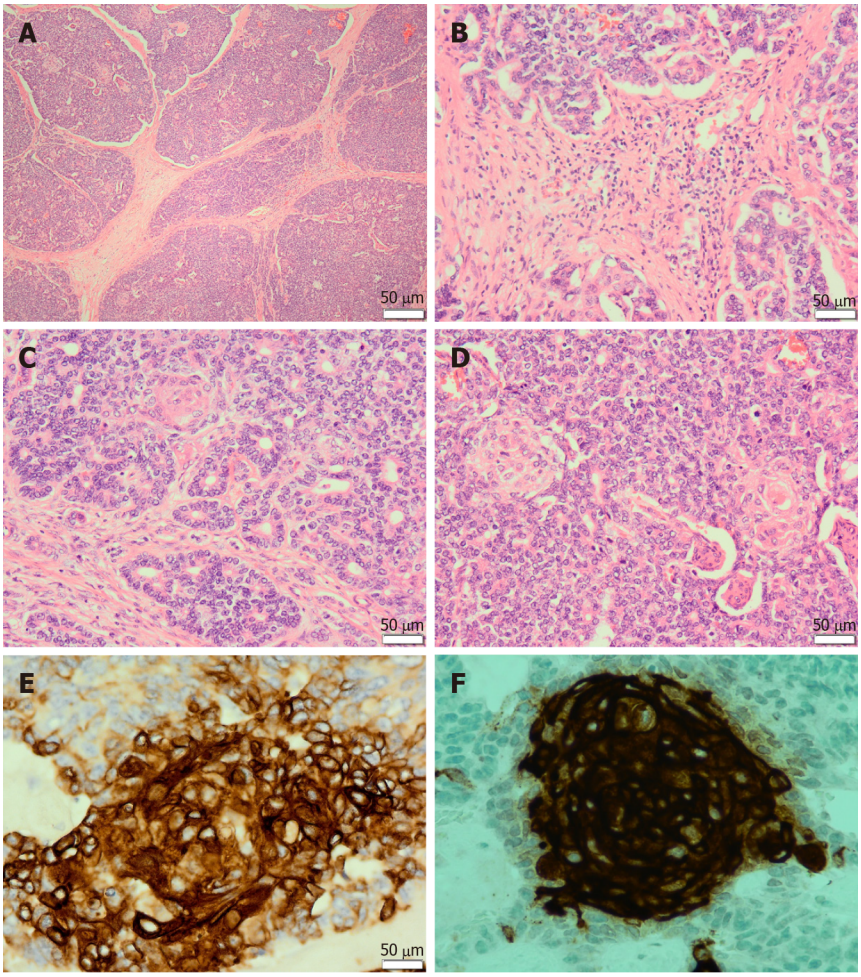

Figure 1 Pancreatoblastoma. A: The tumour is composed of lobules separated by dense fibrous bands, imparting a geographic low power appearance [Haematoxylin and Eosin (H&E) staining, 40 ×]; B: The dense fibrous bands between the lobules are composed of spindled cells with varying amounts of collagen (H&E staining, 200 ×); C: The tumour predominantly shows acinar differentiation. The acinar units are composed of neoplastic cells arranged around central lumina (H&E staining, 200 ×); D: The tumour shows characteristic squamoid nests. Squamoid nests are large islands of plump epithelioid cells with abundant eosinophilic cytoplasm (H&E staining, 200 ×); E: The squamoid nests are immunoreactive for AE1/AE3 (400 ×); F: The tumour shows immunolabeling for CD10 limited to the squamoid nests (400 ×).

with granular cytoplasm arranged around central lumina (Figure 1C). The cells have round to oval nuclei with single prominent nucleoli[1,3,4].

The defining histological feature of pancreatoblastoma is the squamoid nests. Squamoid nests vary from large islands of plump epithelioid cells to whorled nests of spindled cells showing mild to frank keratinization. The cells of the squamoid nests are often distinct from surrounding acinar cells. They are larger than surrounding cells with abundant eosinophilic to clear cytoplasm and without cytological atypia (Figure 1D). The amount of squamoid nests can vary both within and between tumours.

Pancreatoblastomas typically express trypsin, chymotrypsin, lipase, and BCL10. The granules are periodic acid-Schiff (PAS)-positive and resistant to diastase (PASD)[3,4]. Focal expression of chromogranin A and synaptophysin may be present. Squamoid nests may be positive for EMA, AE1/AE3 (Figure 1E) or CD10 (Figure 1F). In addition, patchy nuclear and cytoplasmic expression of β-catenin may be seen.

The staging of pancreatoblastoma follows the TNM classification of carcinoma of the exocrine pancreas[3].

MOLECULAR PATHOLOGY

Loss of heterozygosity on chromosome 11p is the most common molecular alteration in pancreatoblastomas, occurring in 86% of cases. Molecular alterations in the adenomatous polyposis coli (APC)/β-catenin signalling pathway have also been

identified in 67% of pancreatoblastomas, including biallelic inactivation of the *APC* gene and activating mutations of CTNNB1 (β-catenin) gene. Biallelic inactivation of the *APC* gene has been identified in a patient with pancreatoblastoma arising in the setting of FAP[8]. Interestingly, aberrations in the APC/β-catenin pathway have been implicated in the development of hepatoblastoma, a tumour associated with Beckwith-Wiedemann syndrome[8,34].

Recent RNA sequencing studies have identified molecular aberrations in the fibroblast growth factor receptor (FGFR) signalling pathway. These include somatic FGFR1 mutation, *FGFR2* gene rearrangement, and a high mRNA expression of fibroblast growth factor (FGF) receptors 1, 3 and 4 as well as of their ligands, FGF3 and FGF4[18].

The most frequent recurrent molecular alterations identified in pancreatic ductal adenocarcinomas, including mutations in *KRAS*, *TP53*, and *CDKN2A/p16* genes, are typically lacking in pancreatoblastomas, suggesting that pancreatoblastomas are genetically distinct from pancreatic ductal adenocarcinomas[8]. Loss of SMAD4/DPC4 expression is rare in pancreatoblastomas[8,35].

DIFFERENTIAL DIAGNOSIS

Pancreatoblastomas are distinct from the more common pancreatic ductal adenocarcinoma, and it is generally easy to differentiate them on the basis of morphology. The differential diagnosis of pancreatoblastoma includes solid cellular neoplasms of the pancreas such as acinar cell carcinomas, solid pseudopapillary neoplasms, and pancreatic neuroendocrine neoplasms (PanNENs).

There are a number of clinical and morphological similarities between acinar cell carcinomas and pancreatoblastomas. Acinar cell carcinomas are rare, accounting for 1%-2% of pancreatic neoplasms in adults and about 15% in children[1]. Acinar cell carcinomas have a poor prognosis, with a mean survival of 18-24 mo and a 3-year survival rate of 26%[36,37]. Both acinar cell carcinomas and pancreatoblastomas present with non-specific clinical symptoms such as abdominal pain, abdominal mass, and weight loss. In addition, both tumours are cellular neoplasms with acinar differentiation. Neoplastic cells are often polarized around central lumina. The cells contain PASD-positive cytoplasmic granules. Furthermore, acinar cell carcinomas and pancreatoblastomas are typically immunoreactive for trypsin, chymotrypsin, lipase, and BCL10. However, the distinguishing feature is the characteristic squamoid nests seen in pancreatoblastomas.

Solid pseudopapillary neoplasm of the pancreas is a low-grade malignant neoplasm characterized by cells with solid and pseudopapillary growth patterns. Approximately 1%-2% of pancreatic neoplasms are solid pseudopapillary neoplasms, and they frequently occur in girls and young women[3]. Microscopically, solid pseudopapillary neoplasms are composed of poorly cohesive monomorphic epithelial cells arranged around hyalinized fibrovascular stalks, forming solid and pseudopapillary structures. The nuclei frequently show indentations, clefts, and grooves. Typically, these tumours contain scattered PASD-positive hyaline globules, foamy histiocytes, cholesterol clefts, and foreign body giant cells[1]. Solid pseudopapillary neoplasms are positive for nuclear and/or cytoplasmic β-catenin, CD56, CD10, vimentin, and cyclin D1. Unlike pancreatoblastomas, the prognosis of solid pseudopapillary neoplasm of the pancreas is excellent.

PanNENs constitute about 2%-5% of pancreatic neoplasms[3]. They are architecturally diverse and can be confused with pancreatoblastomas. In addition, pancreatoblastomas can focally express neuroendocrine markers. In contrast, pancreatic neuroendocrine tumours are composed of cells with amphophilic to eosinophilic cytoplasm and the nuclei have characteristic salt and pepper chromatin. Typically, pancreatic neuroendocrine tumours strongly express synaptophysin, chromogranin A, and CD56. Features that favour a diagnosis of pancreatoblastoma include predominant acinar differentiation, squamoid nests, PASD-positive cytoplasmic granules, and expression of trypsin, chymotrypsin, lipase, and BCL10.

OUTCOME

There are no established treatment guidelines for pancreatoblastoma. Treatment consists of surgical resection with a variable combination of chemotherapy, radiotherapy, or targeted therapy (Table 1).

RT: Radiotherapy; GKRS: Gamma knife radiosurgery; DOD: Died of disease; AWD: Alive with disease; DFUD: Died from unrelated disease; NED: No evidence of disease; NA: Not available.

Of the 74 cases of adult pancreatoblastomas described in the literature, outcome data were available in 57 cases. The mean follow-up time was 36 mo (range, 0.8-348 mo). Forty-two percent (24 cases) of patients died of the disease at a mean interval of 27 mo (range, 0.8-143.7 mo); 4% (2 cases) of patients died from unrelated causes (cerebral haemorrhage and pulmonary artery embolus); 16% (9 cases) of patients were alive with disease; and 38% (22 cases) of patients had no evidence of disease (Table 1).

Although long-term survival has been observed in some adults, the prognosis of pancreatoblastoma in children may be more favourable than in adults[1,4,13,14]. Poor prognostic factors include the presence of metastases and unresectable disease[3]. Chemotherapy and radiotherapy may have a role in the treatment of recurrent, residual, unresectable and metastatic disease[3,38]. Because of the tendency for

recurrence and metastasis, long-term follow-up is advised for these patients[38].

CONCLUSION

In summary, adult pancreatoblastomas are extremely rare. Although these tumours typically occur in children, pancreatoblastomas should be considered in the differential diagnosis of solid pancreatic tumours in adults. An appreciation of distinctive squamoid nests, predominant acinar differentiation, and expression of trypsin, chymotrypsin, lipase, and BCL10 are important for the accurate diagnosis of pancreatoblastomas. These tumours are aggressive with frequent local invasion, recurrence, and distant metastasis. They must be distinguished from morphological mimics. There is a need for further research to better understand the molecular drivers of pancreatoblastomas, identify druggable molecular targets, and, most importantly, improve patient care.

Abstract

Hepatitis B virus (HBV) is the leading cause of chronic viral hepatitis. Annually, almost two million children younger than 5 years acquire the infection, mostly through vertical or horizontal transmission in early life. Vertical transmission of HBV is a high efficacy phenomenon ranging, in the absence of any preventive interventions, from 70% to 90% for hepatitis e antigen positive mothers and from 10% to 40% for hepatitis e antigen-negative mothers. Maternal viraemia is a preeminent risk factor for vertical transmission of HBV. Maternal screening is the first step to prevent vertical transmission of HBV. Hepatitis B passive and active immunoprophylaxis at birth together with antiviral treatment of highly viraemic mothers are the key strategies for global elimination of HBV infection. Strategies are needed to promote implementation of birth-dose vaccination and hepatitis B immunoglobulins in low- and middle-income countries where the prevalence of the infection is at the highest.

Key Words: Hepatitis B; Vertical transmission; Hepatitis B vaccine; Hepatitis B immune globulin; Neonatal immunoprophylaxis; Tenofovir alafenamide fumarate

INTRODUCTION

Hepatitis B virus (HBV) is the leading cause of chronic viral hepatitis and a major cause of acute and chronic liver disease and associated morbidity and mortality worldwide[1]. According to the latest estimation, in 2016 there were 291 million people chronically infected with HBV in the world corresponding to a global prevalence of 3.9%. Annually, almost two million children younger than 5 years acquire the infection. The highest prevalence has been reported in Africa and in the Western Pacific area. In these regions the coverage with the birth vaccination dose is at the lowest, mostly through vertical transmission in early life[1]. Vertical transmission or infections acquired during early infancy are still responsible for most chronic HBV infections in adults, especially in the areas with high prevalence of the infection[2,3]. Hepatitis B passive and active immunoprophylaxis at birth together with antiviral treatment of highly viraemic mothers are the key strategies for global of HBV infection [4]. According to latest World Health Organization (WHO) estimates, the relative amount of children under 5 years of age chronically infected with HBV dropped to under 1% in 2019, down from around 5% in the pre-vaccine era[5]. In 2019, coverage of three doses of the vaccine reached 85% worldwide compared to around 30% in 2000. However, coverage of the hepatitis B vaccine birth dose remains uneven. Global coverage of the HBV birth dose is 43%, while coverage in the WHO African Region is only 6%[5].

Breast-feeding does not entail any additional risk of transmission in infants who receive a correct immunoprophylaxis[6]. The aim of the present narrative review is to summarise the knowledge on prevention of vertical transmission of HBV infection.

VERTICAL TRANSMISSION OF HBV: DEFINITION, TIMING AND TRANSMISSION RATE

Vertical transmission of HBV is defined as transmission occurring during pregnancy and in the perinatal period from the HBV-infected mother to the foetus or to the child, resulting in positivity at 6-12 mo of life of the hepatitis B surface antigen (HBsAg) or HBV DNA in infants[7]. Overall, vertical transmission of HBV is a high efficacy phenomenon ranging, in the absence of any preventive interventions, from 70% to 90% for hepatitis e antigen (HBeAg) positive mothers and from 10% to 40% for HBeAg-negative mothers. The high success rate of immunoprophylaxis provided to newborns in reducing the incidence of HBV transmission suggests that most vertical transmissions occur at or near the time of birth. Intrauterine infections take place in < 15% of pregnancies.

RISK FACTORS FOR VERTICAL TRANSMISSION OF HBV

Maternal viraemia, identified through the detection of HBV DNA or through the positivity of its surrogate markers HBsAg and HBeAg, is a preeminent risk factor for vertical transmission of HBV. HBeAg-positive mothers and mothers with high circulating concentrations of HBV DNA (> 10^6 IU/mL) have the highest risk of transmission[8,9]. All the conditions leading to maternal-foetal microtransfusions with HBV-infected maternal blood increase the risk of vertical transmission. Microtrans-

fusions could occur intrauterine, during labour, or at delivery. Placental leakages due to threatened preterm delivery or abortion, amniocentesis or chorionic villus sampling, and prolonged uterine contractions could be associated with maternal microtransfusions. The exposure of the neonate to the maternal HBV-infected cervical secretions and blood is possible during labour and delivery.

Mode of delivery

The mode of delivery has been examined as a potential risk factor for vertical transmission of HBV, but the resulting evidence is conflicting. In a large study from China, the effect of Caesarean section delivery on vertical transmission of HBV was evaluated in 1409 infants born to 1401 HBsAg-positive mothers of whom 61.5% (863 of 1401) had detectable levels of HBV DNA. All the children enrolled completed appropriate immunization against HBV. A lower vertical transmission rate was observed among infants in the group delivered by elective Caesarean section (1.4%) compared with that of those in the vaginal delivery group (3.4%). In the multivariate analysis, elective Caesarean section was beneficial for vertical transmission prevention only in mothers with maternal HBV DNA levels > 200000 IU/mL. In line with this study, two recent systematic reviews with meta-analysis showed that Caesarean section reduced the risk of vertical transmission in infants of HBeAg-positive mothers who did not receive antiviral therapy during pregnancy[10]. Other previous studies had contradictory results regarding the benefit of elective Caesarean section. Overall, there is no robust evidence to support Caesarean section as the mode of choice for the prevention of HBV transmission. The possible beneficial effect of Caesarean section should be weighed against the efficacy of the other well recognised practices for prevention of transmission, (*i.e.* antiviral therapy during pregnancy and passive and active immunoprophylaxis at birth). Thus far, regardless of viraemia, the mode of delivery of mothers with chronic HBV infection should follow the usual obstetric indications and is not influenced by the presence of the infection.

Amniocentesis and other obstetric procedures

Invasive diagnostic procedures during pregnancy, such as amniocentesis, occur before the timing for immunoprophylaxis and may favour the mixing of maternal and foetal blood. Different studies[11-15] conducted before the routine use of HBV viral load testing did not demonstrate an augmented risk for *in utero* infection after amniocentesis in women with chronic infection. In a recent study enrolling 642 consecutive Chinese infants born to HBsAg positive mothers without antiviral exposure and who completed appropriate immunization, 63 infants with amniocentesis were compared with 198 matched infants selected from the remaining 579 infants without amniocentesis. There was a significantly higher vertical transmission rate in infants with amniocentesis than in those without amniocentesis if the maternal HBV DNA levels were ≥ 2×10^6 IU/mL (50% *vs* 4.5%, respectively, $P = 0.006$). On the basis of this result, adequate counselling is advised for HBV-infected women who may necessitate invasive testing (*e.g.*, amniocentesis or chorionic villus sampling) including the possible increased risk for maternal-foetal transmission with HBV viral load ≥ 2×10^6 IU/mL[16].

All the procedures that break the skin and mucosal barrier including foetal scalp electrodes and blood sampling and vigorous suctioning of the newborn's airway at birth should be avoided. The risk of traumatizing the foetal skin is lower with vacuum extraction and forceps, and its use should follow obstetric indications.

Breastfeeding

We identified three major questions concerning breastfeeding and vertical transmission of HBV: (1) Does breastfeeding increase the risk of vertical transmission of HBV? (2) Does breastfeeding interfere with the immune response to vaccine? and (3) Is breastfeeding from HBV-infected mothers on antiviral treatment contraindicated? The role of breastfeeding in the transmission of hepatitis B has been discussed for many years. Examination of relevant studies indicates that there is no evidence that breastfeeding poses any additional risk to infants of HBV carrier mothers[17-19]. The risk of vertical transmission of HBV through breastfeeding is negligible if infants born to HBV-positive mothers who receive the hepatitis B immunoglobulins (HBIG)/hepatitis B vaccine at birth, and the benefits of breastfeeding outweigh any potential risk of infection. HBV infection should not be considered a contraindication to breastfeeding of infants who receive the HBIG and HBV vaccine[20]. Data are insufficient to say whether it is safe or not for the HBV-positive mother to breastfeed if her nipples are cracked and bleeding. Breastfeeding should be temporarily stopped to avoid any

potential exposure to blood, and once nipples are no longer cracked or bleeding, the HBV-positive mother may fully resume breastfeeding.

Wang *et al*[21] have showed that breastfeeding does not interfere with the immune response to the HBV vaccine. A total of 230 babies with HBV immunoprophylaxis at birth were followed up for 1 year in order to measure rates of anti-HBs antibodies at different ages. There were no significant differences in the incidence of immunoprophylaxis failure between breast-fed and formula-fed babies[21]. For mothers who received antivirals during pregnancy, the safety of continuing these drugs after delivery during breastfeeding has been and is a matter of concern and discussion. Although the risk of *in utero* exposure to drugs is likely higher than for infants through breast milk, antivirals are recommended for use during pregnancy but many experts remain concerned about long-term consequences of prolonged antiviral agent exposure in the neonate and of its possible impact on growth and development. However, breastfeeding is advantageous on many issues, especially in low-income countries where formula feeding is not widely available. Furthermore, in human-immunodeficiency setting, antiretroviral treatment could continue during the breast-feeding period in infected women. Only a small quantity of oral nucleoside analogues is secreted in breast milk[22], and the effect on bone growth of exposed children is not significantly different after a follow-up period[23]. In women treated with tenofovir, presence of the drug in breast milk has been reported, but its oral bioavailability is limited, and thus infants are exposed to only small concentrations. Current recommendations by the European Association for the Study of Liver Disease stated that breastfeeding is not contraindicated in HBV-positive mothers on tenofovir-based treatment or prophylaxis.

PREVENTION OF VERTICAL TRANSMISSION OF HBV: MANAGEMENT STRATEGIES DURING PREGNANCY

Maternal screening

The first step to prevent vertical transmission of HBV is to test all pregnant women in the first trimester in order to identify the best management strategy for mothers and the correct immunoprophylaxis schedule for future newborns[24]. In case of positive HBsAg, it is necessary to perform further investigations (hepatitis B core antibody, HBeAg, hepatitis B e antibody, serum aminotransferase levels, quantification of serum HBV DNA, liver imaging) to determine the woman's hepatitis B phase and therefore the possible requirement for treatment during or after pregnancy[25]. In HBsAg negative women with an increased risk of infection (infected partners, infected family members, at risk habits) the evaluation of maternal serological status should also be repeated when entering the hospital at the time of delivery.

In recent years there is a growing interest in new biomarkers of HBV infection, such as covalently-closed circular DNA (cccDNA), hepatitis B core-related antigen, and circulating HBV RNA. cccDNA is a key factor for the persistence of infection and represents a specific marker of replication[26] and was shown to persist in the liver, serum, and peripheral mononuclear cells[27].

Hepatitis B vaccination during pregnancy

Vaccination against HBV during pregnancy is safe and effective[28,29]. There is agreement that pregnant women who are not immune or infected with HBV, whether or not at high risk for HBV infection (as defined by having > one sex partner during the previous 6 mo, a current diagnosis of a sexually transmitted disease, having had an HBsAg-positive sex partner or a recent or current injection drug use), should be vaccinated[16,25]. Following the vaccination, maternal antibodies are passively transferred across the placenta to newborns, although without the active vaccination at birth, its titres rapidly wane over time[28]. Pregnant women can be considered HBV-immune when anti-HBs levels are higher than 10 mIU/mL. Sheffield *et al*[30] have shown that an accelerated vaccination schedule at 0, 1, and 4 mo in high-risk pregnant women is effective and well tolerated.

Hepatitis B immunoglobulin during pregnancy

The rationale behind the possible use of HBIG and/or of antiviral treatment during pregnancy is that up to 10% of infants born to HBV-infected mothers still have HBV infection despite receiving HBIG and HBV vaccine at birth. This suggests that additional interventions during the pre-birth phase could be favourable to decrease

the transmission rate.

HBIG is a purified solution of human immunoglobulin that could be administered to the mother, newborn, or both. When HBIG is administered to pregnant women, the antibodies passively diffuse across the placenta to the foetus. The maternal-foetal diffusion is maximal during the third trimester of pregnancy. Several studies have explored the efficacy of the administration of HBIG to HBV-infected pregnant women [31-34]. Unfortunately, the studies are quite heterogeneous in term of HBIG doses and routes of administration and of definitions of maternal and neonatal infection. A recent Cochrane review found varying effects of maternal antenatal HBIG in preventing vertical transmission of HBV. This review selected 36 trials originated from China including 6044 pregnant women who were HBsAg, HBeAg, or HBV DNA positive. Most of the trials (30/36; 83%) assessed HBIG 200 IU at 28, 32, and 36 wk of pregnancy. Serological signs of hepatitis B infection of the newborns were reported as HBsAg, HBeAg, and HBV DNA positive results at end of follow-up. Although, overall HBIG seemed to impact the HBsAg and HBV DNA status of the newborn, due to low quality evidence found in the review, the authors concluded for the uncertainty of the effect of benefit of antenatal HBIG administration to the HBV-infected mothers on newborn outcomes as compared with no intervention[35].

Antiviral treatment during pregnancy

The use of nucleoside or nucleotide analogues (lamivudine, telbivudine, or tenofovir [36-38]) during the last trimester of pregnancy in highly viraemic, HBeAg positive mothers, in combination with standard infant immune-prophylaxis, has been shown to be effective in further reducing the vertical transmission of HBV[36,37].

Antiviral treatment should be considered based on HBV DNA quantification, and it has been generally suggested in pregnant women with HBV DNA levels of more than 2×10^5 IU/mL. The appropriate time to start and stop antiretroviral drug in pregnant women is still debated. The aim of therapy is to reduce HBV DNA levels below the threshold of transmission or immunoprophylaxis failure at the time of delivery, and for this reason treatment is mainly started around 28 wk to 32 wk of gestation. Earlier may be beneficial and has been suggested for prevention of early placental infection and intrauterine transmission[39]. When the treatment is started only to prevent vertical transmission, it could be discontinued as early as at delivery or, as suggested by the major international societies, prolonged until 12 wk after delivery. While small amounts of drugs are usually present in breast milk, there is a potential risk of maternal hepatitis flare following the end of treatment, most of which are asymptomatic. However, there is no additional benefit in the aspect of hepatitis flare prevention in women who carry on treatment to 4 wk postpartum[40]. Close check of transaminase levels is needed after the end of treatment. Lamivudine[41], telbivudine [42], and tenofovir disoproxil fumarate[43] are the antiretroviral drugs that are considered safe to use during pregnancy. Telbivudine and lamivudine could significantly reduce transmission in infants compared with cases with no treatment, but both drugs have a low genetic barrier to resistance barrier. Therefore, tenofovir disoproxil fumarate is the treatment of choice for HBV-positive mothers because of its potent antiviral activity and high genetic barrier to resistance. Tenofovir alafenamide fumarate is a prodrug of tenofovir that can be administered at a lower dose compared with tenofovir disoproxil fumarate, as its active metabolite could be delivered to the target organs with lower circulating drug levels. The efficacy and safety of tenofovir alafenamide fumarate in HBV-infected pregnant women need to be evaluated before recommending it for use.

Treatment guidelines differ mainly with regard to the type of treatment, the threshold viraemia level, and timing for starting antiviral treatment. Consistency across the different guidelines seems a desirable and achievable target in order to standardise the global approach to mothers with HBV infection and antenatal prevention of vertical transmission.

Indications for treatment including which drug, the threshold of HBV DNA level, when to start, and when to stop treatment, as recommended by the main international scientific societies are summarised in Table 1[44]. Despite the different indications provided by the current guidelines, all societies agree to start antiviral treatment when HBV DNA levels are higher than 2×10^5 IU/mL, regardless of maternal serological status (HBeAg positive or negative).

In 2018, a large, double-blinded randomised placebo-controlled trial of tenofovir disoproxil fumarate given from 28 wk of gestational age to 8 wk postpartum to HBeAg-positive pregnant women with a mean HBV DNA of 10^8 IU/mL in Thailand, plus birth-dose vaccination and HBIG, did not find a significantly lower vertical transmission rate beyond the low rate already achieved in the comparison group that

Table 1 Recommendations for antiviral treatment in pregnant women with chronic hepatitis B virus infection

Societies	Antivirals	HBV-DNA level	When to start treatment	When to stop treatment
American Association for the Study of Liver Diseases[25]	Tenofovir disoproxil fumarate	> 2×10^5 IU/mL	28-32 wk	At birth to 3 mo
European Association for the Study of the Liver[24]	Tenofovir disoproxil fumarate	> 2×10^5 IU/mL	24-28 wk	Up to 12 wk after delivery
Asian Pacific Association for the Study of the Liver[70]	Tenofovir disoproxil fumarate, telbivudine	> 10^{6-7} IU/mL	28-32 wk	At delivery
Chinese Medical Association[71]	Tenofovir disoproxil fumarate, telbivudine, lamivudine	> 2×10^6 IU/mL	24-28 wk	At delivery
National Institute for Health and Care Excellence[72]	Tenofovir disoproxil fumarate	> 10^7 IU/mL	3rd trimester	4-12 wk after birth

HBV: Hepatitis B virus.

was given infant HBIG and HBV vaccination initiated at birth[45]. The study confirmed a significant drop at delivery of HBV DNA for the pregnant women treated with tenofovir. However, all infants received HBV vaccine and immunoglobulin at a mean time of 1.2 and 1.3 h after delivery, and the vertical transmission rate with the administration of HBIG and vaccine in the placebo group was low (2% instead of the expected 12%). Furthermore, mothers with signs of HBV-related liver disease (alanine aminotransferase > 30 IU/L) were excluded and both the tenofovir and the placebo groups consisted of mothers with low viral loads at baseline, possibly impacting the results of the study.

PREVENTION OF VERTICAL TRANSMISSION OF HBV: MANAGEMENT STRATEGIES AT BIRTH

Neonatal immunoprophylaxis: The birth vaccine dose

Post-exposure combined immunoprophylaxis through early administration of the first dose of vaccine and of HBIG is the most effective weapon to prevent vertical transmission of HBV. Without any preventative measures, the risk of vertical transmission for HBeAg-positive and HBeAg negative mothers ranges from 70% to 90% and from 10% to 40%, respectively[46]. The administration of HBV vaccine within 12 h of birth, followed by at least two more doses of vaccine within 6-12 mo[47], is 90%-95% effective in preventing vertical transmission[48,49]. If the administration of HBV vaccine is delayed until 48 h after birth, it would cause significant reduction in neonatal immunoprophylaxis efficacy. The recommendation by the WHO is to provide the first dose of hepatitis B vaccine as soon as possible after birth, preferably within 24 h[50], even in areas where HBV is of low endemicity. The combined approach with hepatitis B vaccine and HBIG at birth is not affordable in most of the endemic low and middle income countries. In these countries, considering the limited resources and the lack of access of HBIG, the WHO identifies HBV vaccination within 24 h of birth as the minimum intervention level and the main strategy to prevent infection[51]. In 2016 the coverage for the three-dose series of hepatitis B vaccine in infancy was estimated to be 84% (compared with 1% in 1990), and birth-dose coverage was estimated to be 39%.

Neonatal immunoprophylaxis: The combined vaccine and hepatitis B immunoglobulin approach

In addition to the HBV vaccination, providing a dose of HBIG at birth to the vaccinated infants can further reduce the risk of transmission, especially in highly viraemic mothers, to less than 5%[52-54]. This was first demonstrated by Wong and collaborators[55] in 1984 in a prospective study enrolling 189 infants who were randomly assigned to receive (1) vaccine at birth and at 1, 2, and 6 mo with seven monthly HBIG injections (100 IU); (2) the same vaccine schedule but only one HBIG injection at birth; (3) only the vaccine, at months 0, 1, 2, and 6; and (4) placebos for both vaccine and HBIG. In all three treatment groups, development of the persistent carrier state was significantly less frequent than in the placebo group (2.9%, 6.8%, 21%, and

73.2%, respectively). Vaccination alone was associated with a remarkable protection toward vertical transmission but was significantly less protective than vaccination plus multiple HBIG injections.

HBIG are obtained from plasma donors with high levels of anti-HBs antibodies. Standard immunoglobulins are not indicated for prevention of vertical transmission of HBV because they contain too low antibody titres against HBV. Timely administration of HBIG and hepatitis B vaccine is critical for interrupting vertical transmission[47]. The Centers for Disease Control and Prevention recommends that the birth dose of HBIG and hepatitis B vaccine be given within 12 h after birth through intra-muscular injection but in an anatomic site different from that of the vaccine[47,56,57]. The earlier the administration of HBIG, the higher is the efficacy of the intervention that is unlikely to exceed the 7th day of birth. After administration of HBV vaccination combined with HBIG, infection can still occur in 2%-10% of HBeAg-positive or highly viraemic mothers[8,45,58]. Failure of the vaccine and immune-prophylaxis regimen or transplacental or intrauterine infection could account for this[8,9,59]. HBeAg-positive mothers and mothers with high circulating levels of HBV DNA (> 10^6 IU/mL) have the highest risk of transmission[8,9]. The dose of HBIG generally used in infants is between 100 and 200 IU, corresponding to 30-40 IU/kg. It is important to note that the availability of HBIG in many countries, especially in those with low and middle income, that also have the higher endemicity is still low. The need for refrigerated storage, short shelf life, and low cost of the product should be addressed in order to make the use of HBIG feasible in all the different settings[60].

Specific indications for immunoprophylaxis according to the HBsAg status of the mother and the weight of the child

According to the Advisory Committee on Immunization Practice of the Center for Disease Control (ACIP-CDC) and the Committee on Infection Diseases of the American Academy of Pediatrics, the choice of the post-exposure immunoprophylaxis schedule is based on the mother's antigenic status (HBsAg) and the birth weight of the child (higher or lower than 2000 g)[47,61,62].

Infants born to HBsAg positive mothers

All newborns born to a mother with HBsAg must receive the birth dose of vaccine and HBIG within 12 h of birth regardless of the birth weight. The completion of HBV vaccine is different according to the birth weight. According to the ACIP-CDC, newborns of mothers with HBsAg test not available during pregnancy but with highly suggestive evidence of HBV infection (presence of HBV DNA, HBeAg-positive, or mother known to be chronically infected with HBV) must be considered as born to HBsAg positive mothers[47].

Infants born to women with unknow HBsAg status

Women with unknown HBsAg status at the time of delivery must be tested as soon as possible. In the meantime, newborns must receive the birth dose of the hepatitis B vaccine within 12 h of birth, regardless of birth weight. If the mother is positive, HBIG should be administered as soon as possible within 7 d of birth. If the mother is negative, the vaccination scheme should be completed as scheduled. In children weighing less than 2000 g, considering the potential reduced immunogenicity of the HBV vaccine in these children, it is recommended to administer HBIG within 12 h of birth even if the maternal status is still unknown. The vaccination schedule should be completed as indicated for HBsAg positive mothers[47].

Infants born to HBsAg negative mothers

The WHO Strategic Advisory Groups of Experts recommends that infants receive the HBV vaccine at birth, preferably within 24 h, but administration up to 7 d after birth followed by two or three additional doses can still be effective[63]. In the case of newborns weighing less than 2000 g, the first dose should be administered after 1 mo of life or at the discharge if this occurs earlier.

Completion of HBV vaccine series after the birth dose

The birth HBV vaccine dose should be followed by completion of a vaccine series. A study from the United States enrolling 17951 mother-infant pairs showed that the number of HBV vaccine doses was associated with risk of infant infection[64]. Overall, vertical HBV infection occurred among 1% of infants who received HBV vaccine and HBIG. Infection was detected in 6.7% (3 of 45 infants) of infants who received < three vaccine doses, compared with 1.1% (97 of 9207 infants) of infants who received ≥ three

doses. The ACIP recommends immunoprophylaxis consisting of hepatitis B vaccine and HBIG within 12 h of birth, followed by completion of an HBV vaccine series.

According to the indications from WHO, if the birth weight is more than 2000 g, the vaccination schedule must be completed with two or three more doses[60], starting within the 2nd month of life and administering the final dose after the 24th week of life (164 d). In case of birth weight less than 2000 g, the birth dose should not be considered as part of the vaccination schedule but three additional doses of vaccine will be required for a total of four, starting when the child has reached 1 mo of age[65, 66]. This recommendation is provided because some studies showed that seroconversion rates may decrease among infants with a birth weight < 2000 g after administration of hepatitis B vaccine at birth. However, within the 1st month of age, all medically stable preterm newborns, regardless of their initial birth weight or gestational age, are as likely to respond to HBV immunization as term and larger infants.

Testing infants for anti-HBs and HBsAg

Newborns to HBsAg positive mother should be tested after 1-2 mo from the final vaccine dose and normally at the age of 9-12 mo, through the evaluation of HBsAg and anti-HBs[67,68]. Test should not be executed before 9 mo of age to avoid detection of passive anti-HBs from HBIG administered at birth and to maximise the probability of detecting late HBV infection. Detection of anti-core antibodies is not recommended in infants born to HBsAg positive mothers because can be passively acquired and detected up to the age of 24 mo[47]. HBsAg negative and vaccinated children with anti-HBs titre greater than or equal to 10 mUI/mL have an adequate protection. If anti-HBs titres < 10 mIU/mL, a fourth additional dose should be administered and the test must be repeated after 1-2 mo. In case of persistence of anti-HBs < 10 mIU/mL after four vaccine doses, two additional doses for a total of six may be administered. The test should be repeated 1-2 mo after the sixth dose. In case of non-response, no further doses are expected[69].

CONCLUSION

Vertical transmission of HBV is the leading mode of acquisition of the infection worldwide. Prevention of vertical transmission is possible in the majority of cases through the correct administration of the birth dose of HBV vaccine and HBIG to the neonate. Strategies are needed to promote implementation of birth-dose vaccination and HBIG in low- and middle-income countries where the prevalence of the infection is at the highest. Breastfeeding should be encouraged as long as the infant receives immunoprophylaxis at birth. Further studies on the use of antivirals (tenofovir alafenamide and tenofovir disoproxil fumarate) during pregnancy are required to increase prevention of HBV infection and their effectiveness in preventing vertical HBV infection when used together with to early active and passive immunoprophylaxis.

Abstract

Endoscopic ultrasound tissue acquisition, in the form of both fine needle aspiration (EUS-FNA) and fine needle biopsy (EUS-FNB), is utilized for pancreatic mass lesions, subepithelial lesions, and lymph node biopsy. Both procedures are safe and yield high diagnostic value. Despite its high diagnostic yield, EUS-FNA has potential limitations associated with cytological aspirations, including inability to determine histologic architecture, and a small quantitative sample for further immunohistochemical staining. EUS-FNB, with its larger core biopsy needle, was designed to overcome these potential limitations. However, it remains unclear which technique should be used and for which lesions. Comparative trials are plagued by heterogeneity at every stage of comparison; including variable needles used, and different definitions of endpoints, which therefore limit generalizability. Thus, we present a review of prospective trials, systematic reviews, and meta-analyses on studies examining EUS-FNA *vs* EUS-FNB. Prospective comparative trials of EUS-FNA *vs* EUS-FNB primarily focus on pancreatic mass lesions, and yield conflicting results in terms of demonstrating the superiority of one method. However, consistent among trials is the potential for diagnosis with fewer passes, and a larger quantity of sample achieved for next generation sequencing. With regard to subepithelial lesions and lymph node biopsy, fewer prospective trials exist, and larger prospective studies are necessary. Based on the available literature, we would recommend EUS-FNB for peri-hepatic lymph nodes.

Key Words: Endoscopic ultrasound fine needle aspiration; Endoscopic ultrasound fine needle biopsy; Pancreatic lesions; Subepithelial lesions; Lymph node biopsy

Core Tip: Endoscopic ultrasound fine needle aspiration (EUS-FNA) and fine needle biopsy (EUS-FNB) provide two methods for endoscopic ultrasound tissue acquisition for pancreatic mass lesions, subepithelial lesions, and lymph node biopsy. Both methods are safe and provide high diagnostic yield. Prospective comparative trials of EUS-FNA *vs* EUS-FNB primarily focus on pancreatic lesions. EUS-FNB provides diagnostic accuracy with fewer needle passes, and may provide higher diagnostic yield for peri-hepatic lymph nodes.

INTRODUCTION

As medical and surgical therapeutics continue to evolve, there is a renewed emphasis on timely diagnosis of various illnesses. This mantra certainly holds true in gastrointestinal (GI) diseases, including pancreatic malignancies and GI tumors, where early and specific diagnosis guides management and impacts morbidity and mortality [1]. While cross-sectional imaging can characterize lesions, a tissue diagnosis is often required for a definitive diagnosis prior to therapy[2-5]. Endoscopic ultrasound tissue acquisition (EUS-TA) has improved the ability for tissue diagnosis using a minimally invasive technique. The two modalities for EUS-TA, endoscopic ultrasound fine needle aspiration (EUS-FNA) and endoscopic ultrasound fine needle biopsy (EUS-FNB) vary in technique and utility. Common indications for EUS-TA include the diagnosis and staging of pancreaticobiliary and luminal GI malignancy, and assessing lymphadenopathy associated with luminal GI and lung cancers[6]. Additionally, EUS-TA aids in the evaluation of potentially neoplastic GI subepithelial lesions[6]. Comparative studies on the diagnostic ability of EUS-FNA and EUS-FNB have yielded conflicting results. Here we review prospective comparative data on EUS-FNA *vs* EUS-FNB for pancreatic masses, subepithelial lesions, and lymph node biopsy (Table 1-3).

EUS-FNA

EUS-FNA was first introduced in 1992. It is often combined with rapid onsite evaluation (ROSE) to improve diagnostic ability[7,8]. EUS-FNA is now standard of care for sampling pancreatic solid masses, subepithelial lesions, and lymph nodes, among others. The European Society of Gastroenterology and American Society of Gastroenterology recommend EUS-FNA as first line for diagnosing pancreatic lesions [9-11].

Marked variability exists in EUS-FNA equipment and technique. Several different needle sizes are available including 19 G, 20 G, 22 G, and 25 G. Additionally, variability exists in aspiration technique, including the use of negative pressure suction (used with either a 5 mL or 10 mL syringe) or slow stylet pull. The aspirate from EUS-FNA is often sufficient for cytology and adequate for diagnosis, with diagnostic accuracy ranging from 77% to 95% for pancreatic masses[9,10]. Given its minimally invasive technique and small needle size, EUS-FNA has low rates of morbidity[12].

However, several limitations exist for EUS-FNA which obtains a cytological specimen. EUS-FNA is limited by an inability to obtain histological architecture, and the inability to perform immunohistochemical analysis and molecular profiling. This is of particular importance as certain neoplasms, such as stromal cell tumors and lymphomas, may be difficult to diagnose without histologic samples, as their tissue architecture and morphology are essential for accurate pathologic assessment and histochemical studies[9,13-17]. Furthermore, with the increased attention on personalized or precision medicine in oncology, a sufficient tissue sample to perform next generation sequencing is required. Current National Comprehensive Cancer Network guidelines recommend germline testing for any patient with confirmed pancreatic

cancer using comprehensive gene panels for hereditary cancer syndromes, as well as tumor/somatic gene profiling for patients with locally advanced or metastatic disease to identify mutations that may benefit from anti-cancer therapy. Testing on tumor tissue is preferred; however, cell-free DNA testing can also be considered[18]. There is uncertainty whether EUS-FNA will be able to routinely provide adequate material for these studies[6].

EUS-FNB

In an attempt to overcome the limitations of EUS-FNA, EUS-FNB was first introduced in the early 2000s to obtain tissue specimens as opposed to aspiration-based cytology. With the goal of evaluating tissue core, EUS-FNB provided novel needles for improved diagnostic accuracy.

Nagula *et al*[49], 2018)	RCT	46	Variable, variable Procore	All lymph nodes	92.9% *vs* 94.4% (NS)	N/A	2 *vs* 2 (NS)	
de Moura *et al*[52], 2020)	Retrospective study of prospectively collected data	209	Variable, variable	All lymph nodes	N/A	78.8% *vs* 83.2% (NS)	N/A	For peri-hepatic lesions, EUS-FNB was significantly more accurate

EUS-FNA: Endoscopic ultrasound fine needle aspiration; EUS-FNB: Endoscopic ultrasound fine needle biopsy; RCT: Randomized controlled trial; N/A: Not applicable; NS: Not significant.

Early models of EUS-FNB utilized Trucut needle biopsy, with a tissue penetrating stylet within an outer cannula. The 19 G Trucut FNB proved more accurate than EUS-FNA for diagnosing lymphomas and stromal tumors, but was limited by mechanical failure when attempting to biopsy pancreatic head masses and duodenal lesions due to the torqued echoendoscope and mechanical friction[16,19]. Newer models, including EchoTip HD ProCore™ (Wilson-Cook Medical Inc., Winston-Salem, NC, United States) is available in 19-25 G, and provides two cutting surfaces, a tip and reverse bevel, to further preserve histological architecture[1]. The reverse or opposing cutting bevel design of the EUS-FNB needle allows for the biopsy of core histopathologic tissue. This

aspect has the potential advantage of improving diagnostic performance, but also allowing a wide range of follow-up testing[20]. Immunohistochemistry, which is required for the diagnosis of autoimmune pancreatitis, lymphoma, and metastasis, can be performed on the tissue core. Furthermore, molecular analysis, which is now standard of care for pancreatic malignancies, can also be performed. Other needles, including SharkCore™ (Medtronic Inc., Sunnyvale, CA, United States) and Acquire™ (Boston Scientific, Malborough, MA, United States), (Figure 1) may achieve even higher diagnostic accuracy[21,22].

Studies have demonstrated high diagnostic yields of core specimens with EUS-FNB with fewer needle passes[23-25]. The potential concern for increased bleeding when using EUS-FNB is offset by the fewer passes required for diagnosis.

EUS-FNA *VS* EUS-FNB: OVERVIEW

Several comparative trials have evaluated EUS-FNA *vs* EUS-FNB. Interpreting the conflicting data is challenging, as trials are plagued by heterogeneity in every stage of comparison. Reported outcomes as well as definition of those outcomes vary between studies. For example, inconsistent use of the term "diagnostic accuracy" and "diagnostic adequacy" creates confusion. Furthermore, heterogeneity exists within equipment use (needle size), and technique (suction *vs* slow pull; specified number of passes). Additionally, designing strong randomized trials is limited by the inability to blind endosonographers, and sometimes cytopathologists, to the type of needle used [26-57].

METHODS

In compiling this review article, we performed a literature search utilizing PUBMED, EMBASE, and Google Scholar for comparative trials of EUS-FNA *vs* EUS-FNB for pancreatic mass lesions, subepithelial lesions, and lymph nodes. A total of 77 articles were identified. Trials were excluded if they were retrospective (n = 26), if they did not directly compare EUS-FNA and EUS-FNB (n = 18), or if they were incomplete manuscripts (n = 6). Any study performed on a variety of mass lesions without subcategories for the aforementioned groups was also excluded (n = 4).

PANCREATIC LESIONS

Pancreatic adenocarcinoma is characterized by a poor prognosis, with a 5-year survival rate of 5%-6%[27]. Pancreatic adenocarcinoma may be difficult to differentiate from other pancreatic mass lesions based on cross-sectional imaging and abdominal ultrasound[2-5]. The reported sensitivity of EUS in the detection of pancreatic cancer is between 94% and 100%[28]. Compared to computed tomography (CT), EUS can detect up to 14% of pancreatic tumors that were not visualized on CT, especially tumors smaller than 20 mm[11]. As such, EUS is currently the standard method for tissue diagnosis of pancreatic masses[11].

Tissue sampling of pancreatic mass lesions by EUS is vital in diagnosis. Several sampling approaches are possible depending on the location of the pancreatic mass lesion. A trans-duodenal approach may be optimal for lesions in the pancreatic head, while the transgastric approach is more appropriate for lesions in the pancreatic body and tail. Bang *et al*[29] proposed an algorithm for needle selection based on anatomical site; a 25 G needle for the trans-duodenal approach and a 22 G or 25 G for all other punctures.

Comparative trials of EUS-FNA *vs* EUS-FNB for pancreatic mass lesions focus mostly on safety, diagnostic accuracy, sample adequacy for diagnosis and further testing (Table 1).

Randomized controlled trials of pancreatic masses with EUS-FNA or EUS-FNB

Bang *et al*[9] performed the earliest randomized controlled trial (RCT) comparing EUS-FNA and EUS-FNB. The study randomized 56 patients to receive either EUS-FNA 22 G or EUS-FNB 22 G ProCore for pancreatic mass lesions, with the primary outcome being the number of passes required to establish a diagnosis with ROSE. They found no significant difference in the median number of passes required to establish on-site

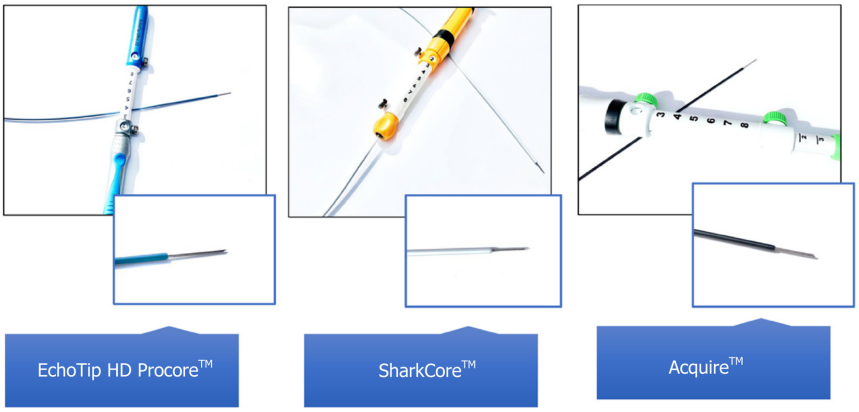

Figure 1 Fine needle biopsy needles.

diagnosis, and overall similar rates of diagnosis were achieved within 3 passes (100% EUS-FNA, 89% EUS-FNB). Incomplete diagnosis by EUS-FNB was due to diagnostic failure in two patients, and technical failure in 1 patient. Procedural complications among the two techniques were similar (one patient with post-procedural abdominal pain in the EUS-FNA cohort, and one patient with pancreatitis in the EUS-FNB cohort). With regard to secondary outcomes, EUS-FNA had a higher proportion of samples with histologic core tissue present (100% *vs* 88.3%, not-significant) but EUS-FNB had a higher percentage of histologic core tissue optimal for histochemical testing.

It is noteworthy that their technique varied from subsequent trials in several respects, and perhaps limited the study's generalizability. First, ROSE was carried out for all specimens, thereby possibly preferentially inflating the diagnostic ability of EUS-FNA. Additionally, they utilized an earlier model of FNB, the 22 G Echotip ProCore™ devise. Lastly, they utilized fewer needle movements for the EUS-FNB cohort (only 4 movements to and fro).

A subsequent larger RCT by Aadam *et al*[30] similarly showed no difference in diagnostic yield or specimen adequacy between EUS-FNA and EUS-FNB in patients with pancreatic lesions.

A 2018 RCT by Tian *et al*[31] of 36 patients similarly showed no superiority in diagnostic accuracy between EUS-FNA and EUS-FNB; although they did find a difference in the number of passes needed to make a diagnosis. Similar to Bang *et al*[9], patients were randomized to either EUS-FNA or EUS-FNB ProCore for solid pancreatic masses, although ROSE was not performed on any of the specimens. For the primary outcome of diagnostic yield, the authors found identical results (83%). However, among their secondary outcomes, EUS-FNB required fewer passes to make a diagnosis (1.11 *vs* 1.83, $P < 0.05$). It is noteworthy that a smaller percentage of their cohort were diagnosed with pancreatic adenocarcinoma (66.7%) compared to other trials. There were no complications in either cohort in their study.

Similar findings were also demonstrated in a larger, more recent RCT performed by Chen *et al*[32]. The authors randomized 235 patients with pancreatic mass lesions to EUS-FNA + ROSE (n = 120) *vs* EUS-FNB (22 G or 25 G Fork-tip needle, n = 115). For the primary outcome of diagnostic accuracy, the authors found no difference (92.2% *vs* 93.3%, respectively). However, among the secondary outcomes, EUS-FNB was associated with fewer needle passes to make a diagnosis compared to EUS-FNA + ROSE (2.3 *vs* 3.0) and decreased procedure time (19.3 min *vs* 22.7 min). There were no adverse events in the EUS-FNB cohort, and three adverse events in the EUS-FNA cohort (2 pancreatitis, 1 bleeding).

Crossover trials

In contradistinction to the aforementioned articles, in several trials patients underwent both EUS-FNA and EUS-FNB in a crossover study design, thereby allowing direct comparison between specimen procurement in the same patients and providing an internal control. Hedenstrom *et al*[33] randomized 68 patients with a pancreatic mass to receive either EUS-FNA (25 G) followed by EUS-FNB (22 G), 1 pass each, or vice versa. A reverse bevel EUS-FNB 22 G needle was used (Wilson-Cook Medical) and further passes were performed by alternating the two needles. They utilized similar

suction (10 cc) and fanning techniques for both EUS-FNA and EUS-FNB. ROSE was carried out for the majority of both EUS-FNA and EUS-FNB samples. The primary outcome of diagnostic accuracy was not significantly different between the two methods of tissue acquisition. No adverse events were recorded.

Utilizing a newer model of EUS-FNB Fork tip (SharkCore™ FNB Needle), Oppong *et al*[34] randomized 108 patients with pancreatic mass lesions to EUS-FNA and then EUS-FNB, 3 passes each, or vice versa. The primary endpoint was diagnostic performance for malignancy (malignant yes/no), compared to a gold standard of unequivocal malignant pathology obtained by EUS sampling, surgical resection, or alternative biopsy. For non-operated patients, clinical and radiological disease progression consistent with malignancy at 6-mo follow-up was required. The authors found increased sensitivity for the diagnosis of malignancy with EUS-FNB compared to EUS-FNA (82% *vs* 71%). The study was unique in that it also assessed procedural time and pathology viewing time, both of which were significantly shorter for EUS-FNB (710 s *vs* 759 s, $P = 0.001$; 188 s *vs* 332 s, $P < 0.001$, respectively). The authors performed a cost-analysis and found no significant difference; however, they analyzed only materials used and did not factor in operational/labor time. The authors reported four serious adverse events (2 cholangitis, 1 pancreatitis, 1 abdominal pain), but did not specify which cohorts the patients belonged to.

Other studies have utilized alternative endpoints to diagnostic accuracy or adequacy. As discussed previously, obtaining a diagnosis for pancreatic adenocarcinoma may still require further testing for personalized medicine, and therefore additional tissue may be required. Kandel *et al*[35] performed a RCT of 50 consecutive patients to assess adequacy for genomic profiling. In their study, they randomized patients to EUS-FNA followed by EUS-FNB (or vice versa) in a randomized order. They also utilized the SharkCore™ FNB needle. The first pass with each needle was used for histology, and subsequent passes were used to collect DNA. They found that EUS-FNB yielded significantly higher mean DNA concentrations compared to EUS-FNA (5.930 μg/mL *vs* 3.365 μg/mL, $P = 0.01$).

These findings have unclear clinical significance, since despite the quantitative difference in DNA acquired, both acquisition techniques yielded sufficient DNA for next generation sequencing (approximately 10 ng/μL). Furthermore, it is noteworthy that the EUS-FNA utilized a smaller needle (25 G) compared to both EUS-FNB needles (19 G or 22 G). This was likely done to maximize diagnostic accuracy, which was similar in both cohorts (100% final diagnosis in both), but may come at the expense of the DNA quantity acquired.

Systematic reviews and meta-analyses

Several systematic reviews and meta-analyses have attempted to summarize the conflicting data on pancreatic lesions. However, heterogeneity in the studies included and outcomes measured further perpetuate the confusion.

In 2017, Wang *et al*[26] performed a meta-analysis on 8 RCTs to determine diagnostic accuracy. Significant variability existed within needle size and suction technique between the trials. For diagnostic accuracy, they found no significant difference between EUS-FNA (84%) and EUS-FNB (88%, OR 0.72; 95%CI: 0.49-1.07). Among the 5 trials that reported specimen adequacy, and the four trials reporting the number of needle passes required, EUS-FNB demonstrated superiority (OR 0.57, 95%CI: 0.37-0.89; and OR 0.86, 95%CI: 0.45-1.26, respectively). Among the five studies that reported adverse events, the rates were low and not significantly different between the two groups (2/313 in the EUS-FNA group, and 4/311 in the EUS-FNB group), and specific complications were not mentioned.

One year later, in 2018, Li *et al*[27] performed a meta-analysis with the same 8 RCTs, and included an additional 3 RCTs, and yielded different results. They found that EUS-FNB had significantly better specimen adequacy (OR 1.83, 95%CI: 1.27-2.64), and higher diagnostic accuracy (OR 1.62, 95%CI: 1.17-2.26) than EUS-FNA, again with fewer needle passes (MD -0.69, 95%CI: -1.18 to -0.2). There was no difference in complications or technical success.

However, a larger 2019 meta-analysis by Facciorusso *et al*[20] of 27 RCTs found different results. They evaluated diagnostic accuracy, and found no significance difference between needle type (EUS-FNA or EUS-FNB) or needle size. The authors summarized the adverse events as rare among their studies; however, most studies did not itemize the etiology of the adverse events. The only studies that specifically reported bleeding episodes, all reported bleeding in the EUS-FNA cohort. Of note, the authors performed a network meta-analysis technique, thereby utilizing both direct RCT (EUS-FNA *vs* EUS-FNB) as well as indirect evidence (RCT of EUS-FNA *vs* EUS-FNA, or EUS-FNB *vs* EUS-FNB) and then extrapolated the data. Only 14 of the 27 trials

included were actually EUS-FNA *vs* EUS-FNB. As such, their results should be interpreted with caution.

Summary of pancreatic mass studies

Conflicting data exist among prospective studies evaluating the superiority of different EUS-TA techniques. Taken together, both methods provide overall high, and comparable, diagnostic accuracy and specimen adequacy for diagnosis. Adverse events, including bleeding, are rare in both techniques, with pancreatitis being the most common adverse event. Multiple trials have demonstrated that fewer passes are required for EUS-FNB compared to EUS-FNA. The ramifications of this, with the resulting decreased procedural time and likely fewer adverse events, may prove beneficial when applied broadly, but larger trials are required for further elucidation. Additionally, clinical benefit from the increased quantity of tissue obtained remains unclear, if standardized testing and next generation sequencing can be performed on all samples.

SUBEPITHELIAL LESIONS

Subepithelial lesions (SELs) of the GI tract are tumors that originate from the muscularis mucosa, submucosa, or muscularis propria[36]. Initial management of SELs focuses on proper diagnosis and determination of malignant potential, to guide further resection recommendations. EUS is the most accurate imaging method for evaluating SELs of the GI tract[37-39], because it can delineate the individual histologic layers and likely site of tumor origin. Certain SELs have a distinct endoscopic appearance, such as lipomas, duplication cysts, and ectopic pancreas, and endoscopic appearance may be considered diagnostic[36]. However, endoscopic appearance alone is not sufficient for diagnosis in many cases, such as hypoechoic and heterogeneous lesions from the submucosal and muscularis propria, and tissue acquisition is often required. Standard biopsy forceps and jumbo biopsy forceps (bite on bite technique) have low diagnostic yield[40,41].

EUS-FNA is the most widely used method for obtaining SEL tissue arising from the submucosal and muscularis propria layer[36]. However, the diagnostic accuracy of EUS-FNA is variable, ranging from 34% to 93%[39,42]. Additionally, the amount of cytological material obtained by EUS-FNA is often insufficient for the immunohistochemical staining required to differentiate different SELs[43].

Comparative trials

There are few prospective comparison trials of EUS-FNA and EUS-FNB focused solely on SELs, although several larger prospective trials contained cohorts of SELs (Table 2). We excluded trials that did not perform subgroup analysis on this SEL subgroup in isolation[30,44-46].

The first RCT focused solely on SELs was performed by Kim *et al*[47] in 2014. The authors randomized 22 patients with GI SELs of all types to either EUS-FNA (n = 10) or EUS-FNB (n = 12, ProCore). The patients did not receive both methods of tissue acquisition. The cohort was comprised of mostly gastric SELs (17/22), and mainly arising from the muscularis propria (20/22). The needle size was dependent on tumor diameter at the time of EUS, with a 22 G needle used if the tumor was estimated to be < 30 mm, and 19 G used if the tumor was > 30 mm. The authors utilized the unique endpoint of the number of passes required to obtain macroscopically optimal core samples. Since ROSE was not carried out at all sites, the endoscopist immediately inspected the material for the presence of tissue core, defined as whitish pieces of tissue with apparent bulk. If present, no further passes were obtained. However, if absent, the endoscopist proceeded with an additional pass with a maximum of 3 passes. If the sample still did not contain macroscopic tissue core, the number of passes was recorded at 4, and the patient crossed over to the other cohort. The authors found that the median number of needle passes required to obtain macroscopically optimal core sampled by EUS-FNB was significantly lower than that by EUS-FNA (2 *vs* 4, P = 0.025). Despite being macroscopically defined as optimal core samples, the core samples were suboptimal for microscopic analysis in three cases. Overall, the rates of obtaining macroscopically and histologically optimal core samples with EUS-FNB (92% and 75%, respectively) were superior to EUS-FNA (30% and 20%, respectively). No technical difficulties were encountered, and one patient in the entire cohort developed post-procedural bleeding which was managed conservatively. A limitation of the study design was lack of blinding of the endoscopist who assessed the primary

endpoint.

A follow-up study by Iwai *et al*[43] in 2017, focused solely on gastric SELs arising from the muscularis propria and randomized 24 patients to receive either EUS-FNA followed by EUS-FNB or vice versa. The two needles were used alternatively to puncture the same lesion with a total of four punctures per session. Similar to Kim *et al*[47], needle size was dependent on tumor size on EUS, and the ProCore needle was used for all EUS-FNB. The primary outcome was diagnostic yield. The authors found that the rate of correct diagnosis on immunohistochemical staining tended to be higher for EUS-FNB (91.3%) than for EUS-FNA (73.9%, P = 0.120), although this failed to reach statistical significance. When sub-characterized by tumor size, they found that EUS-FNB had significantly higher rates of positive histology among tumors 21-30 mm. The study was limited by sample size and was underpowered, as several of their findings trended towards significance.

A larger 2018 RCT performed by Hedenstrom *et al*[48] similarly found superiority of EUS-FNB to EUS-FNA for SELs, utilizing the reverse bevel ProCore EUS-FNB needle. The study randomized 70 patients with GI SELs to dual sampling with EUS-FNA and EUS-FNB in an alternating fashion until the yield was regarded as satisfactory by the cytotechnician, with a maximum of six passes. Similar to Iwai *et al*[43], in the absence of ROSE, gross examination was performed by the endoscopist. The cohort consisted of mostly gastric SELs (66/70). The study found significantly higher overall diagnostic accuracy for EUS-FNB than EUS-FNA (83% *vs* 49%, P < 0.001). A trend of lower sensitivity of EUS-FNA for extramural lesions compared to intramural lesions was also observed, a trend that did not exist for EUS-FNB. The authors hypothesized that this may be related to increased mobility of extramural lesions, preferentially affecting EUS-FNA diagnostic accuracy. The characterization of intramural and extramural was based on appearance at EUS. The authors reported few adverse events.

These findings are in contrast to Nagula *et al*[49] who found in the SELs cohort (n = 18) that there was no significant difference in diagnostic yield between EUS-FNB ProCore and EUS-FNB (EUS-FNB 75% *vs* EUS-FNA 83.3%, P = 0.754).

LYMPH NODES

Lymphadenopathy may arise from many different etiologies, ranging from benign inflammatory or infectious, to malignant etiologies. Evaluation of lymphadenopathy must include tissue sampling, as lymph node size has demonstrated poor specificity for differentiating malignant from benign lymphadenopathy[50,51]. Clarifying the malignant potential of lymphadenopathy is essential for clinical management[52].

The modality for sampling lymph nodes depends on anatomic location. For mediastinal lymph node sampling, EUS-TA is safer and less invasive compared to alternative techniques[10]. Additionally, for abdominal lymph nodes, EUS-sampling is successful in 92% of patients[53].

EUS-TA for lymph nodes is typically performed with EUS-FNA. However, the sensitivity of EUS-FNA for providing material for cytological evaluation is suboptimal, with reported rates of 88%-96%[54]. The suboptimal results are often attributed to damaged lymph node architecture[51,54]. This limitation of EUS-FNA is important in the evaluation of lymphadenopathy of unknown etiology, where the differential diagnosis includes lymphoma, metastasis, mycobacterial infection, and sarcoidosis, and core biopsy with preservation of lymph node architecture is particularly important for diagnostic purposes[53,55,56].

Comparative trials

We found no published prospective RCTs of EUS-FNA *vs* EUS-FNB for only lymph node biopsy. In the large RCT by Nagula *et al*[49] mentioned above, the subgroup of lymph node biopsies (n = 46) found no difference between EUS-FNA and EUS-FNB Procore in diagnostic yield (92.9% *vs* 94.4%) or number of passes needed to make a diagnosis (median 2, P = 0.43) (Table 3).

De Moura *et al*[52] performed a prospective study comparing EUS-FNA *vs* EUS-FNB exclusively for lymph node diagnosis. The authors performed an analysis on a prospectively collected database of 209 patients undergoing either EUS-FNA (n = 108) or EUS-FNB (n = 101) to evaluate lymph nodes. No predefined protocol was used in the study, and as such several different EUS-FNB needles were used including Acquire, SharkCore, and ProCore. The cohort consisted mostly of peri-hepatic lymph nodes (60%) followed by peri-pancreatic (10.4%) and mediastinal (10.4%), and were mostly accessed *via* a transgastric approach (45%). The pathology of most specimens

was benign (61%). Their primary outcome was diagnostic yield from cytological and histological analysis with and without immunohistochemical staining.

Overall, the authors found similar diagnostic accuracy between EUS-FNA and EUS-FNB (78.8% *vs* 83.2%, $P = 0.423$). However, the specificity for EUS-FNB demonstrated significant superiority (100% *vs* 93.62%, $P = 0.01$). In the subgroup analysis, EUS-FNB showed significantly higher sensitivity and specificity for abdominal lymph nodes. The diagnostic accuracy tended to be greater in the EUS-FNB cohort, but this failed to reach statistical significance. Following further analysis of lymph node location, EUS-FNB was associated with significantly higher sensitivity, specificity, and overall diagnostic accuracy for peri-hepatic lesions (88.9% *vs* 70.5%, $P = 0.038$).

Taken together, the study forms an important backdrop for further research, and argues for consideration of EUS-FNB over EUS-FNA for lymph node biopsy, specifically for peri-hepatic lesions.

UTILIZING BOTH TECHNIQUES

Additional studies have assessed the additive benefit of sampling lesions with both EUS-FNA and EUS-FNB. One such study by Hedenstrom *et al*[33] found that EUS-FNA/FNB compared to EUS-FNA alone had a higher diagnostic sensitivity for pancreatic tumors (89% *vs* 69%, $P = 0.02$), but not for pancreatic adenocarcinoma. However, compared to the diagnostic accuracy of EUS-FNB in isolation, Keswani *et al*[57] found no additional diagnostic accuracy by including EUS-FNA for pancreatic adenocarcinoma.

CONCLUSION

Endoscopic ultrasound tissue acquisition is routinely utilized in the evaluation of pancreatic mass lesions, subepithelial lesions, and lymph node biopsies. Ongoing confusion surrounds the ideal modality for EUS-TA, whether by EUS-FNA or EUS-FNB. While more robust comparative clinical trials exist for pancreatic lesions compared to subepithelial lesions and lymph nodes, the data continue to be mixed. Randomized controlled trials with homogenous populations and homogenous sampling protocols are needed in order to truly understand which needle is superior.

Based on the literature reviewed in this article, the authors conclude the following: EUS-FNA and EUS-FNB both provide high diagnostic accuracy, with low technical failure and adverse events, and thus either needle can be utilized for EUS-TA of pancreatic lesions, subepithelial lesions, and lymph nodes. In our experience we prefer FNB with a new generation needle as it allows us fewer passes of the needle, allows us to forgo ROSE which adds significant time and resources to a procedure, and gives a sample suitable for molecular testing. When increased quantity of DNA is desired for next generation sequencing, the utilization of EUS-FNB should be considered. For extramural subepithelial lesions, the utilization of EUS-FNB should be considered. Despite the dearth of prospective literature, we would recommend EUS-FNB for lymph node biopsy, specifically for peri-hepatic nodes.

Abstract

BACKGROUND

Norcantharidin (NCTD) is suitable for the treatment of primary liver cancer, especially early and middle primary liver cancer. This compound can reduce tumors and improve immune function. However, the side effects of NCTD have limited its application. There is a marked need to reduce the side effects and increase the efficacy of NCTD.

AIM

To develop a nanomaterial carrier, NCTD-loaded metal-organic framework IRMOF-3 coated with a temperature-sensitive gel (NCTD-IRMOF-3-Gel), aiming to improve the anticancer activity of NCTD and reduce the drug dose.

METHODS

NCTD-IRMOF-3-Gel was obtained by a coordination reaction. The apparent characteristics and *in vitro* release of NCTD-IRMOF-3-Gel were investigated. Cell cytotoxicity assays, flow cytometry, and apoptosis experiments in mouse hepatoma (Hepa1-6) cells were used to determine the anti-liver cancer activity of NCTD-IRMOF-3-Gel in *in vitro* models.

RESULTS

The particle size of NCTD-IRMOF-3-Gel was 50-100 nm, and the particle size distribution was uniform. The release curve showed that NCTD-IRMOF-3-Gel had an obvious sustained-release effect. The cytotoxicity assays showed that the free drug NCTD and NCTD-IRMOF-3-Gel treatments markedly inhibited Hepa1-6 cell proliferation, and the inhibition rate increased with increasing drug concentration. By flow cytometry, NCTD-IRMOF-3-Gel was observed to block the Hepa1-6 cell cycle in the S and G2/M phases, and the thermosensitive gel

nanoparticles may inhibit cell proliferation by inducing cell cycle arrest. Apoptosis experiments showed that NCTD-IRMOF-3-Gel induced the apoptosis of Hepa1-6 cells.

CONCLUSION

Our results indicated that the NCTD-IRMOF-3-Gel may be beneficial for liver cancer disease treatment.

Key Words: Norcantharidin; Metal-organic frameworks; IRMOF-3; Temperature-sensitive gel; Drug delivery; Liver cancer

Core Tip: Norcantharidin (NCTD) is suitable for the treatment of primary liver cancer, especially early and middle primary liver cancer. However, the side effects of NCTD have limited its application. Therefore, we established a liver-targeting therapy in which NCTD is loaded into IRMOF-3 coated with a thermosensitive gel, which can be efficiently delivered to liver cancer cells and slowly released. The results demonstrate that this thermosensitive gel-encapsulated IRMOF-3 has great advantages as an antitumor drug carrier and provides some ideas for passive targeting therapy of tumors.

INTRODUCTION

Liver cancer has the characteristics of a high incidence, poor prognosis, and high mortality. The latest World Health Organization data show that the global incidence rate of liver cancer is ranked fifth among malignant tumors, and the incidence rate is ranked third. China is a country with a high incidence of liver cancer and hepatitis B[1,2]. At present, surgical resection[3,4], drug chemotherapy[5,6], nanotechnology[7], and interventional therapy[8] are the main treatment methods for liver or other cancers. Among many chemotherapeutic drugs, norcantharidin (NCTD) has strong antitumor activity and can inhibit a variety of tumors including gastrointestinal cancer[9], malignant lymphoma[10], lung cancer[11], and liver cancer[12].

NCTD was synthesized by removing the 1,2-methyl group from cantharidin, which was extracted from the cantharides of Coleoptera. Compared with cantharidin, NCTD exhibits not only significantly improved anticancer effect but also a great reduction in renal toxicity and strong irritation to the urinary system[13]. The clinical use of NCTD is mainly based on tablets and injections, and this drug has unique advantages in the treatment of cancer. However, the side effects of NCTD have limited its application [14]. First, compared to cantharidin, the toxicity of NCTD is reduced to a large extent but still has a certain degree of urinary system toxicity, and organ toxicity occurs with large doses or long-term use, so there is a strict limit on the maximum dosage of NCTD in the clinic[15]. Second, NCTD is rapidly distributed in various tissues after absorption when administered to mice by gavage. The concentration of NCTD peaks in liver and cancer tissues 15 min after administration. However, this concentration significantly decreases 6 h after administration. Most NCTD is excreted through the kidney within 24 h, with little accumulation in the body. The elimination speed of NCTD from the body is fast, which reduces the compliance of patients with medication[16]. In addition, NCTD is widely distributed in the body after oral administration, and is less distributed in the liver tissue due to its fast elimination speed, which not only reduces its efficacy but also increases the toxicity to other organs[17]. Third, most NCTD injections used in the clinic are sodium salt, with a pH value of approximately 9.0, which makes it highly irritating[18].

In recent years, a large number of studies have been carried out to reduce the side effects and increase the efficacy of NCTD[19-22]. This project aimed to develop a multifunctional metal-organic framework (IRMOF-3) that can play an important role in drug carrying and delivery. Because of the special topological structure of IRMOF-3, drugs can be loaded into the spatial structure to the maximum extent, and it plays great role in controlled release[23-26]. However, when NCTD-IRMOF-3 enters the body, burst release is caused due to endocytosis or gastrointestinal absorption. Therefore, we established a liver-targeting therapy in which NCTD is loaded into IRMOF-3 coated with a thermosensitive gel (NCTD-IRMOF-3-Gel), which can be efficiently delivered to liver cancer cells and slowly released. In this study, NCTD-IRMOF-3-Gel was prepared, and the *in vitro* targeting behavior was explored. It was shown that the combination of IRMOF-3 and the thermosensitive gel could decrease the toxicity and increase the bioavailability of NCTD, representing an effective method for the chemotherapy of liver cancer. This study lays a foundation for the liver-targeting ability of NCTD-IRMOF-3-Gel. The results demonstrate that this thermosensitive gel-encapsulated IRMOF-3 has great advantages as an antitumor drug carrier and provides some ideas for passive targeting therapy of tumors.

MATERIALS AND METHODS

Materials

All of the chemicals used were of analytical grade. N,N-Dimethylformamide (DMF), dichloromethane (CH_2Cl_2) (both Tianjin Fuyu Fine Chemical Co., Ltd., Tianjin, China), zinc acetate dihydrate ($Zn(OAc)_2.2H_2O$) (Kaitong Chemical Industry Co. Ltd., Tianjin, China), and 2-amino-terephthalic acid (NH_2-BDC, $C_8H_7NO_4$) (Henghua Technology Co., Ltd., Jinan, China) were used to prepare nanosized IRMOF-3.

Preparation of NCTD-IRMOF-3-Gel

First, $Zn(OAc)_2.2H_2O$ (4 mmol) and NH_2-BDC (1 mmol) were completely dissolved in 10 mL and 15 mL DMF, respectively. Then the zinc salt solution was quickly poured into the ligand solution at room temperature (25 °C) to form a milky white precipitate. After magnetic stirring for 1 min and centrifugation for 5 min (12000 r/min), the supernatant was removed and the precipitate was obtained. The deposit was washed three times with DMF (removing unreacted raw materials) and soaked for 3 d with CH_2Cl_2 (removing DMF), with the solvent replaced once per day. Next, the deposit was centrifugally filtered and dried under natural conditions. Then, the samples were activated under vacuum for 12 h at 100 °C, and IRMOF-3 was obtained. For the encapsulation studies, 30 mg NCTD and 10 mg nanoIRMOF-3 were accurately weighed in a 5 mL volumetric flask, and 80% alcohol solution was added. The suspension was stirred for 72 h at room temperature. NCTD-loaded nanoIRMOF-3 (NCTD-IRMOF-3) was then collected by centrifugation and vacuum-dried at room temperature. NCTD-IRMOF-3 (15 mg) was accurately weighed, 3 mL freeze-dried protective agent (4% mannitol and 2% poloxamer) was added, and the mixture was fully dissolved. A small amount of supernatant was collected, frozen in a vial at -40 °C for 24 h, and then frozen in a vacuum freeze dryer for 30 h to obtain the freeze-dried product. NCTD-IRMOF-3 was then dispersed into a thermosensitive gel solution at room temperature to form a dispersion of nanoparticles. When the NCTD-IRMOF-3 nanoparticle dispersion was injected into the body or heated to 37 °C, the NCTD-IRMOF-3-Gel gel could be formed.

Characterization

Physical characterization was performed by powder X-ray diffraction (PXRD) analysis (Phillips Xpert Pro MPD diffractometer with Cu Kα radiation λ = 1.5418 nm at 40 kV and 50 mA). Scanning electron microscopy (SEM) images were obtained using a Quanta 200F (FEI Sirion SEM), confirming the regular shape and nanosize of the particles. Nitrogen adsorption/desorption isotherms and pore size distributions were measured using an MFA-140 system (Beijing Builder Electronic Technology Co., Ltd., Beijing, China). The particle size distribution was measured by a Zetasizer Nano-ZS90 Laser particle size analyzer (Malvern Instruments Co., Ltd., Malvern, United Kingdom).

NCTD release assay

In vitro studies of the release of NCTD from NCTD, NCTD-IRMOF-3, and NCTD-

IRMOF-3-Gel were carried out using dialysis bags (Sigma, St. Louis, MO, United States) soaked in double-distilled water for 12 h. Freeze-dried NCTD, NCTD-IRMOF-3, and NCTD-IRMOF-3-Gel suspensions were added into a dialysis bag, which then was placed in 50 mL phosphate-buffered saline (pH 5.0) to maintain sink conditions and shaken at 100 rpm in a constant-temperature shaker (SHAB; Donglian Electric Technique Co. Ltd., Harbin, China) at 37 °C. Subsequently, 2 mL release medium was withdrawn at regular intervals, and fresh release medium was added to maintain a constant volume. Every trial was repeated three times. The samples were analyzed using high-performance liquid chromatography, and the control experiments were similarly performed using the same proportions to investigate drug release.

In vitro examination

MTT assay for cytotoxicity detection: The mouse hepatoma (Hepa1-6) cell line (Beijing Boyu Kangtai International Biological Technology Co., Ltd., Beijing, China) used in this experiment was maintained in Roswell Park Memorial Institute-1640 medium (HyClone; Thermo Fisher Scientific, Inc., Waltham, MA, United States) supplemented with 10% heat-inactivated fetal calf serum (Sijiqing Tianhang Biological Science and Technology Co., Ltd., Hangzhou, China), 105 U/L penicillin G, and 100 mg/L streptomycin in a CO_2 incubator at 5% CO_2 and 37 °C.

The cells were plated in 96-well cell culture plates, and different concentrations of NCTD (0-80 μg/mL) were added to the complete cell culture medium. Then, 10 concentrations of NCTD-IRMOF-3 and NCTD-IRMOF-3-Gel were prepared (0-80 μg/mL). After 24, 48, 72, and 96 h of incubation, chemosensitivity was evaluated using thiazolyl blue tetrazolium bromide (MTT reagent, 98%; Wuhan Baodu DE Co., Ltd., Wuhan, China) in complete cell culture medium (5 μg/mL). Then, 20 μL MTT reagent was added to each well and incubated for 4 h, and the mitochondrial aldehyde dehydrogenase from the viable cells subsequently reduced the yellow, water-soluble MTT reagent to water-insoluble blue formazan crystals, which were dissolved by adding 150 μL dimethyl sulfoxide to each well. The absorbance of the dissolved formazan blue dye was measured at 490 nm using a BioTex microplate reader (American Power Instruments Co., Ltd., Wilmington, MA, United States), and the cell viability calculations were performed.

Flow cytometry assay of the effects on the Hepa1-6 cell cycle: The cells were placed in 6-well cell plates and cultured for 24 h in a CO_2 incubator at 5% CO_2 and 37 °C. Then, NCTD-IRMOF-3-Gel at different concentrations (10-40 μg/mL) was added to each well and incubated in an incubator for 24 h. The cells were digested with trypsin (Shanghai Beyotime Biotechnology Co., Ltd., Shanghai, China) and centrifuged at 1500 rpm for 5 min. The supernatant was removed from the solution and washed twice with phosphate-buffered saline (PBS). Then the precooled 75% ethanol solution was added to each well and fixed at 4 °C for 12 h. The solution was centrifuged at 1500 rpm for 5 min to remove the supernatant and resuspended in PBS. Finally, the prepared solution (including 0.5 mL of PBS, 25 μL propidium iodide staining solution and 10 μL ribozyme A) was added to each well and incubated at 37 °C for 30 min. The cells were filtered using a 35 μm cell filter and detected by flow cytometry (Becton, Dickinson and Company, Franklin Lakes, NJ, United States).

Apoptosis experiment: Apoptosis was detected by Annexin V-FITC/PI double staining. K562 cells in the logarithmic growth phase were inoculated into 24-well culture plates at 1×10^5/well. NCTD-IRMOF-3-Gel, NCTD-IRMOF-3 and NCTD were added at two different concentrations (25 μg/mL and 50 μg/mL). After 48 h, the cells were washed with PBS three times, and 1 μL propidium iodide and 5 μL Annexin V-FITC (Shanghai Beyotime Biotechnology Co., Ltd., Shanghai, China) were added. The cells were incubated in the dark for 10 min and washed once with PBS. Then, 400 μL PBS was added to each tube. Apoptosis was detected by flow cytometry, and the apoptosis rate was calculated.

Statistical analyses

Statistical analyses were performed using analysis of variance with SPSS 24.0 software (version 24.0.0; Chicago, IL, United States). Statistical differences were defined as $^aP < 0.05$ and $^bP < 0.01$. The data are presented as the mean ± SD.

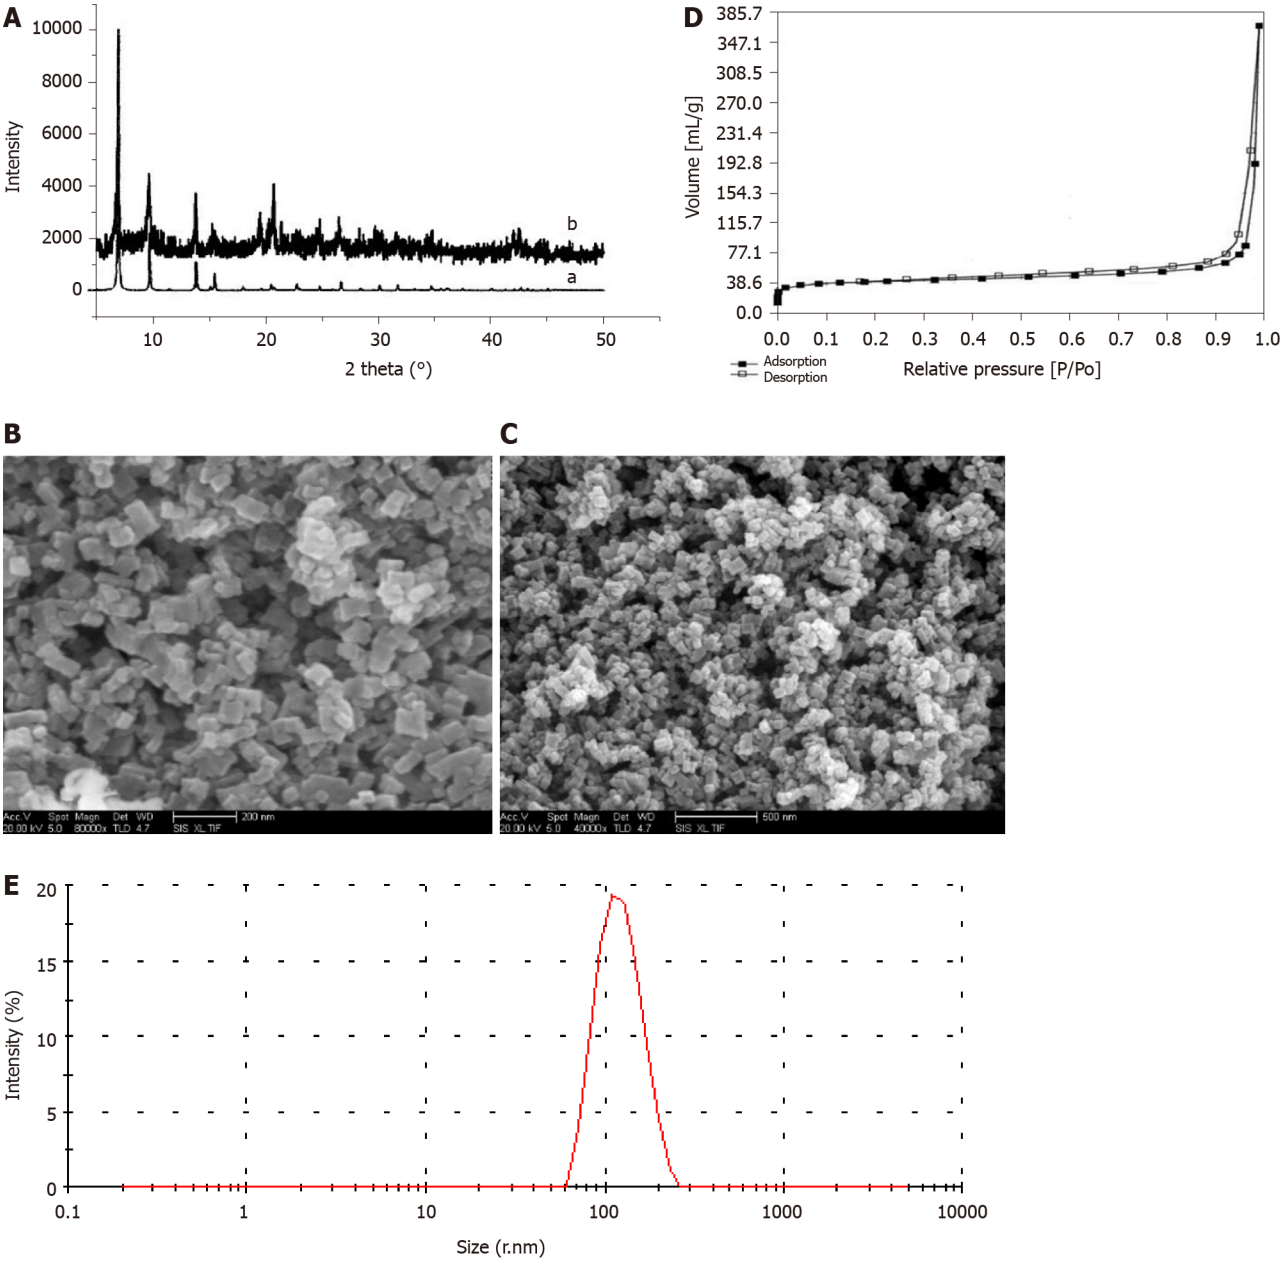

Figure 1 Structure and morphology of IRMOF-3 and norcantharidin-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel. A: X-ray diffraction (XRD) spectra of IRMOF-3. Note: XRD patterns of synthetic IRMOF-3 (b) and standard IRMOF-3 (a). XRD patterns of the sample show the same peaks as those of the standard, confirming the high purity of IRMOF-3. The peak patterns of the sample account for the rough appearance of the nanosized particles; B: Scanning electron microscopy (SEM) images of the morphology of IRMOF-3. SEM images of the morphology of IRMOF-3. The particles show a regular square, uniform distribution and a size of 50-100 nm. The single-particle surface is rough, indicating the existence of pores; C: SEM images of the morphology of norcantharidin (NCTD)-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel). SEM images of the morphology of NCTD-IRMOF-3-Gel showing the same size as that of IRMOF-3; D: Nitrogen adsorption–desorption isotherms of IRMOF-3. Nitrogen adsorption–desorption isotherms. A hysteresis loop phenomenon appears under relatively high pressure, indicating the existence of channels in the sample; E: Particle size distribution of NCTD-IRMOF-3-Gel. The particle size distribution of NCTD-IRMOF-3-Gel indicated that the average particle size was 100 nm.

RESULTS

Structure and morphology

The PXRD patterns shown in Figure 1A illustrate that the IRMOF-3 materials possessed three well-resolved peaks, similar to the standard patterns. The SEM images of IRMOF-3 and NCTD-IRMOF-3-Gel are presented in Figure 1B and Figure 1C which show that the sample consisted of square particles (50-100 nm). The single-particle surface was rough, indicating the existence of pores. SEM images show that the morphology of NCTD-IRMOF-3-Gel had similar size features as those of IRMOF-3. The nitrogen gas (N_2) adsorption–desorption isotherms of IRMOF-3 are shown in Figure 1D. The hysteresis loop phenomenon appeared in the range of relatively high

pressure, indicating the existence of channels in the sample (Figure 1D). The particle size distribution of NCTD-IRMOF-3-Gel indicated that the average particle size was 100 nm (Figure 1E).

NCTD release assay

In the simulated pH 5.0 environment of tumor cells, the drug release data were fitted by a zero-order dynamics equation, first-order kinetic equation, Higuchi equation and Weibull model. The NCTD regression equation obtained is shown in Table 1. The resulting correlation coefficients of the drug release kinetics show that the drug release conforms to the Weibull equation, and the R^2 value is 0.9508.

As shown in Figure 2, the release of NCTD is very fast and is completely finished at 5 h. However, the drug release of NCTD-IRMOF-3 was slower than that of NCTD. The first half of the drug release curve of NCTD was steep and showed a sudden release within 0.6 h. The reason was that the free drug molecules adsorbed on the surface of the nanoparticles diffused rapidly into the medium. Then the curve of NCTD-IRMOF-3 showed a steady slowly release process because the drug in the pores was slowly released. Approximately 5 h were necessary for 50% NCTD release from NCTD-IRMOF-3. After 36 h, the release rate was more than 70%, and the release was basically complete. The release rate of NCTD-IRMOF-3-Gel nanoparticles at 0.3 h was lower than that of the other formulations because NCTD was released gradually with the slow dissolution of poloxamer. After 10 h, the release rate was approximately 50%; after 36 h, the release rate was more than 65%.

In vitro examination

MTT assay: In contrast to that of NCTD- and NCTD-IRMOF-3-treated cells, the inhibition of Hepa1-6 cells treated with NCTD-IRMOF-3-Gel increased in a dose-dependent manner (Figure 3). When the half-maximal inhibitory concentration (IC_{50}) values of each group at different time periods were compared, it was found that these values were 30.59 μg/mL, 93.74 μg/mL, and 112.3 μg/mL with NCTD, NCTD-IRMOF-3, and NCTD-IRMOF-3-Gel, respectively. The inhibitory effects of NCTD-IRMOF-3-Gel on Hepa1-6 cells were stronger than those of NCTD and NCTD-IRMOF-3 and showed a certain sustained-release effect.

Flow cytometry assay of the effects on the Hepa1-6 cell cycle: Figure 4 and Table 2 show that the percentage of the total number of cells in S phase and G2/M phase increased significantly with increasing NCTD-IRMOF-3-Gel concentration, while the proportion of cells in G0/G1 phase decreased significantly. This result indicates that NCTD-IRMOF-3-Gel can block the cell cycle in the S and G2/M phases, and thermosensitive gel nanoparticles may inhibit cell proliferation by inducing cell cycle arrest.

Apoptosis experiment

It can be seen from the figure that the apoptosis rates of NCTD-IRMOF-3-Gel at the high concentration (C) and low concentration (F) were 32.11 μg/mL and 65.60 μg/mL, respectively. Compared with that in the NCTD control group, the apoptosis rate in the NCTD-IRMOF-3-Gel group was highest, which indicated that NCTD-IRMOF-3-Gel could induce the apoptosis of Hepa1-6 cells (Figures 5 and 6).

DISCUSSION

In recent years, with the wide application of medical polymer materials and increased clinical utilization[27,28], research on sustained-release and controlled-release preparations has increased and has become an important research direction. As a new type of drug formulation, sustained- and controlled-release preparations can increase efficacies and reduce side effects compared with traditional drugs. The thermosensitive gel has a hydrophilic three-dimensional network structure, which can be loaded in the liquid state to control drug release. In addition, thermosensitive gel has a stronger affinity, longer retention time and less stimulation in medically relevant locations than traditional gel, especially in mucosal tissue. This type of gel is suitable for all kinds of drug carriers and has now become a research hotspot in pharmaceutics [29,30].

The aim of this project was to prepare NCTD-IRMOF-3-Gel by using the porous material metal-organic framework IRMOF-3 as a drug carrier and NCTD as a model drug. Loading the drug and drug carrier within the thermosensitive gel not only delayed the action time of the drug but also compensated for sudden drug release

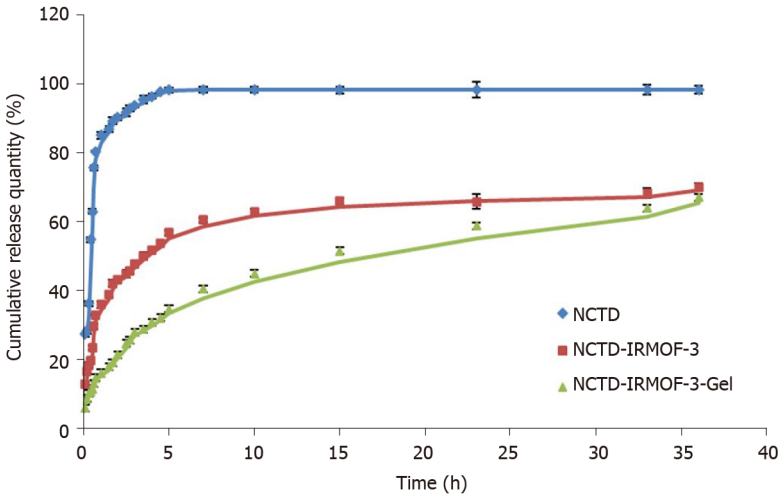

Figure 2 *In vitro* release curves of norcantharidin (NCTD) (blue line), NCTD-loaded metal-organic framework IRMOF-3 (red line), and NCTD-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (green line). After approximately 5 h, 90% of norcantharidin (NCTD) was found in the release medium, while only 50% of NCTD was released from NCTD-loaded metal-organic framework IRMOF-3 (NCTD-IRMOF-3), and 30% of NCTD was released from NCTD-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel). Every trial was repeated three times. All values are shown as the mean ± SD.

from the metal-organic framework carrier. The XRD pattern of the IRMOFs is consistent with that of the standard materials and the peak pattern is rough, which suggest that IRMOFs are nanoparticles with rough surfaces and high purity. The SEM images of the morphology of IRMOF-3 and NCTD-IRMOF-3-Gel showed that the IRMOFs were square and regular nanoparticles containing pores. NCTD-IRMOF-3-Gel was prepared using a poloxamer thermosensitive gel as the carrier, and its morphology did not change. This result shows that the thermosensitive gel has no effect on the original metal-organic framework structure, solves the problem of sudden drug release, and can reduce the toxicity caused by sudden drug release.

The Brunauer–Emmett–Teller surface areas and micropore volume of NCTD-IRMOF-3-Gel were determined using N_2 adsorption isotherms, which showed that it was a microporous material. The N_2 adsorption method is commonly used to

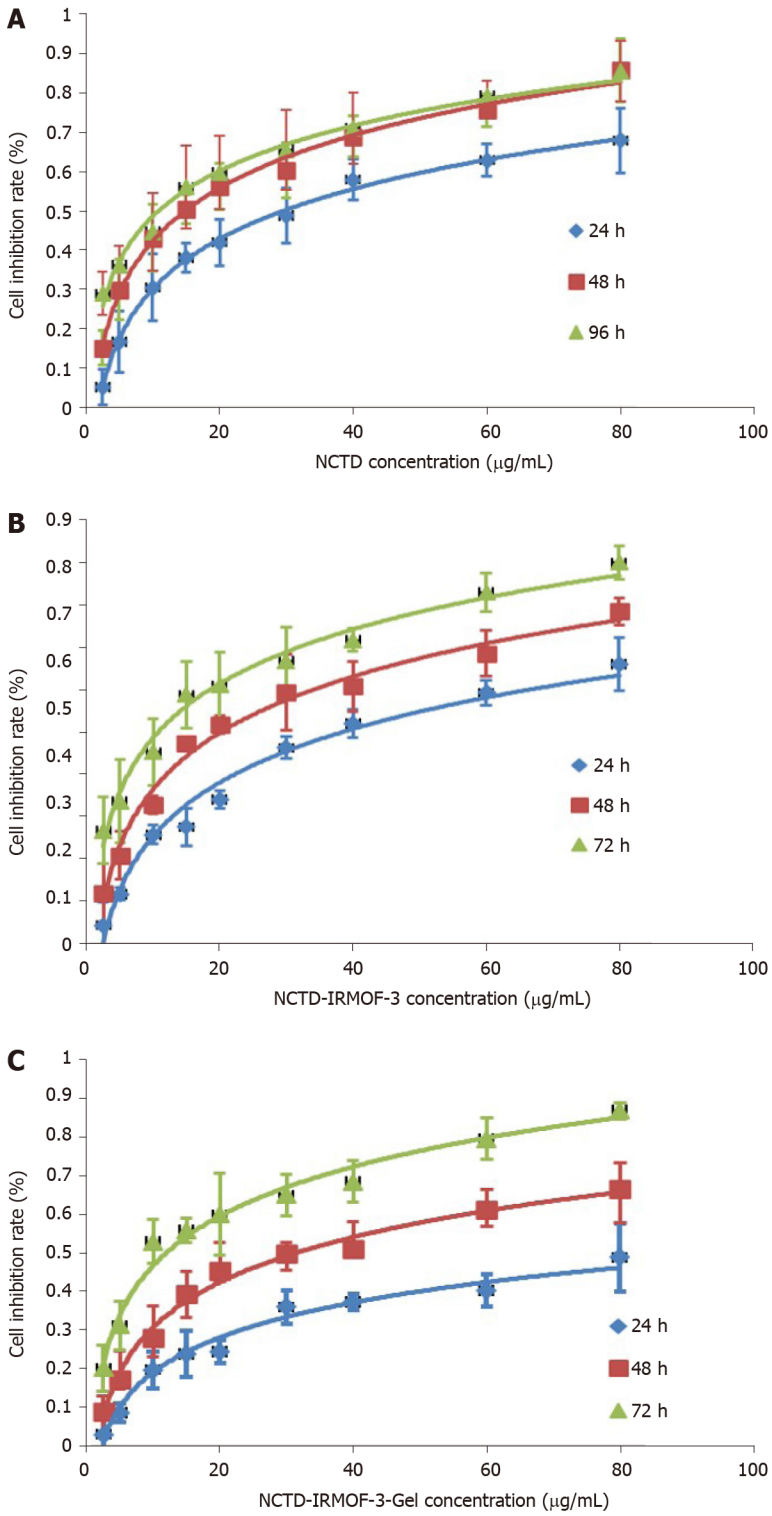

Figure 3 Comparison of the cytotoxicities of norcantharidin (NCTD), NCTD-loaded metal-organic framework IRMOF-3, and NCTD-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel. The inhibitory effect of norcantharidin (NCTD)-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel) (C) on Hepa1-6 cells was stronger than that of NCTD (A) and NCTD-loaded metal-organic framework IRMOF-3 (NCTD-IRMOF-3) (B) and showed a certain sustained-release effect.

determine the specific surface area and pore size of nanomaterials. The determination principle of N_2 adsorption is that the surface pores of porous materials will adsorb nitrogen at liquid nitrogen temperatures. The flat areas in the low-pressure section were caused by the nanopores. The N_2 adsorption quantity increased suddenly, which generated a hysteresis loop, indicating the existence of micropores, and this phenomenon was caused by capillary condensation. After zeta potential analysis of the particle size distribution, NCTD-IRMOF-3-Gel was shown to have a particle size of approximately 100 nm and good dispersibility.

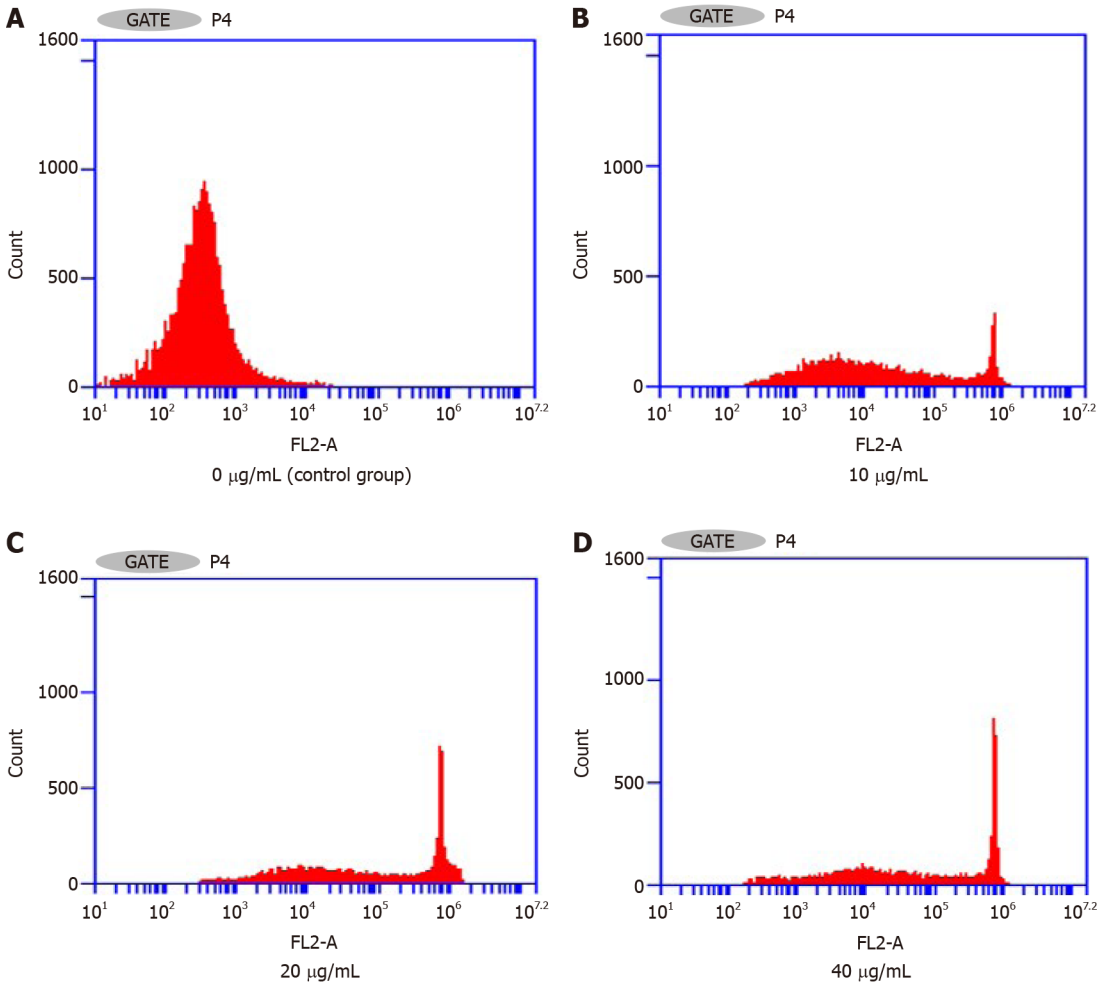

Figure 4 Effects of norcantharidin-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel on the cell cycle. The percentage of total cells in S and G2/M phases increased significantly with increasing norcantharidin (NCTD)-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel) concentration, and the proportion of cells in G0/G1 phase decreased significantly. A: Control group; B: 10 μg/mL; C: 20 μg/mL; D: 40 μg/mL. G1 phase: DNA presynthetic phase, where mitosis is complete before DNA replication begins; G2 phase: DNA synthesis replication phase, where DNA replication is complete before mitosis begins; M phase: Cell division phase; S phase: DNA synthesis replication phase.

The kinetics of *in vitro* drug release can effectively determine the profile of *in vitro* drug release and predict the conditions of *in vivo* drug release. From the drug release curve, NCTD was released quickly, with basically complete release at 5 h. NCTD-IRMOF-3 nanoparticles released NCTD more slowly than free NCTD treatment and showed sudden release within 0.6 h. After 36 h, the release rate was more than 70%, and the release was basically completed. NCTD-IRMOF-3-Gel nanoparticles showed a significantly slower release trend, and the degree of release at 0.3 h was lower than that in the other groups, which was due to the gradual release of NCTD with the slow dissolution of poloxamer. After 36 h, the release rate reached more than 65%. We speculated that NCTD-IRMOF-3-Gel nanoparticles had a certain sustained-release effect and could effectively improve the drug release process.

The MTT assay demonstrated the cytotoxicity of the NCTD-IRMOF-3-Gel nanoparticles. At the same concentration, the inhibition rate of each group of drugs acting on Hepa1-6 cells increased with the extension of time. The inhibition rate of the free drug group was slightly lower than that of the nanoparticle group, but it still had a killing effect on the cells. Compared with that of NCTD-IRMOF-3-Gel, the inhibition rate of NCTD-IRMOF-3 was slightly low, indicating that the thermosensitive gel-coated nanoparticles had a better inhibitory effect on cells. The inhibition rate of the nanoparticle group was low at 24 h and gradually increased after 48 h to the level of inhibition of the free drug, indicating that the drug-loaded nanoparticle-thermosensitive gel group presented an obvious sustained-release effect. Meanwhile, the cell cycle study using flow cytometry showed that NCTD-IRMOF-3-Gel could block the S phase and G2/M phase of the cell cycle, and thermosensitive gel-suspended nanoparticles may inhibit cell proliferation by blocking the cell cycle. The apoptosis

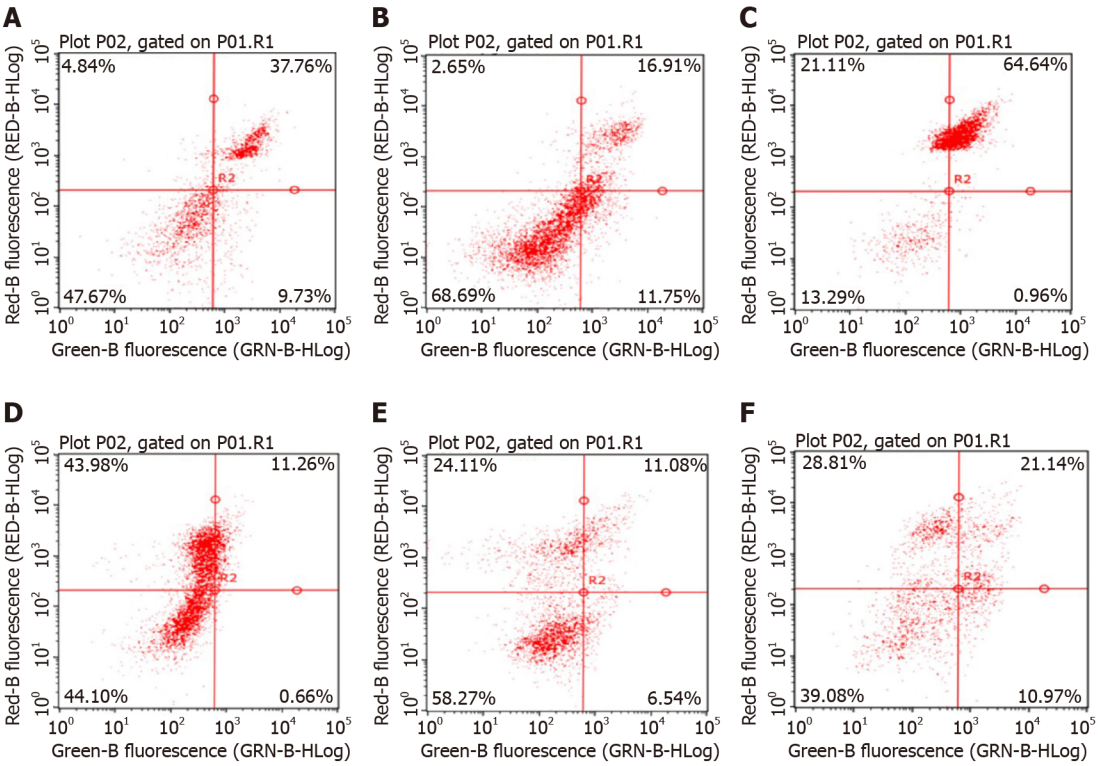

Figure 5 Apoptosis rates of Hepa1-6 cells after 48 h. Apoptosis rates of norcantharidin (NCTD)-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel) at the high concentration (C) and low concentration (F) were 32.11 μg/mL and 65.60 μg/mL, respectively. Compared with the NCTD control group, the apoptosis rate in the NCTD-IRMOF-3-Gel group was highest, which indicated that NCTD-IRMOF-3-Gel could induce the apoptosis of Hepa1-6 cells. A: 50 μg/mL NCTD-IRMOF-3; B: 50 μg/mL NCTD; C: 50 μg/mL NCTD-IRMOF-3-Gel; D: 25 μg/mL NCTD-IRMOF-3; E: 25 μg/mL NCTD; F: 25 μg/mL NCTD-IRMOF-3-Gel.

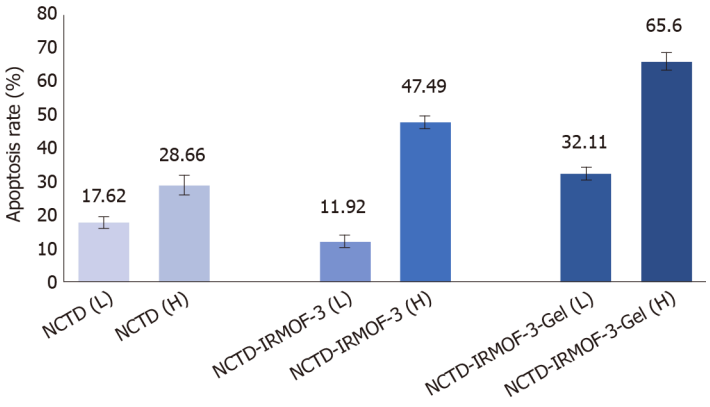

Figure 6 Apoptosis rates of norcantharidin (NCTD), NCTD-loaded metal-organic framework IRMOF-3, and NCTD-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel. Compared with the norcantharidin (NCTD) control group, the apoptosis rate in the NCTD-loaded metal-organic framework IRMOF-3 coated with temperature-sensitive gel (NCTD-IRMOF-3-Gel) group was highest, which indicated that NCTD-IRMOF-3-Gel can induce the apoptosis of Hepa1-6 cells.

rates of NCTD-IRMOF-3-Gel at high concentrations and low concentrations were determined, which indicated that NCTD-IRMOF-3-Gel could induce the apoptosis of Hepa1-6 cells.

CONCLUSION

Based on the results of this study, NCTD-loaded IRMOF-3 nanoparticles incorporated into a thermosensitive gel appeared to be a useful tool for cancer treatment because of the enhanced inhibition rate of cancer cells and controlled release of drugs from these

nanocarriers. Our future studies will focus on elucidating the activity of the drug delivery system and its effects on the mechanism of action of the encapsulated anticancer drug.

ARTICLE HIGHLIGHTS

Research background

Norcantharidin (NCTD) is suitable for the treatment of primary liver cancer, especially early and middle primary liver cancer. As a new type of drug formulation, sustained- and controlled-release preparations can increase the efficacy and reduce the side effects compared with traditional drugs. Metal-organic frameworks (MOFs) have potential applications in drug carriers. The thermosensitive gel has a hydrophilic three-dimensional network structure, which can be loaded in the liquid state to control drug release.

Research motivation

The side effects of NCTD have limited its application in liver cancer, which has prompted the development of sustained- and controlled-release preparations.

Research objectives

This study established a liver-targeting therapy in which NCTD is loaded into IRMOF-3 coated with a thermosensitive gel (NCTD-IRMOF-3-Gel), which can be efficiently delivered to liver cancer cells and slowly released.

Research methods

NCTD-loaded IRMOF-3 coated with a temperature-sensitive gel (NCTD-IRMOF-3-Gel) was obtained by a coordination reaction. The apparent characteristics and *in vitro* release of NCTD-IRMOF-3-Gel were investigated. Cell cytotoxicity assays, flow cytometry and apoptosis experiments on mouse hepatoma (Hepa1-6.) cells were used to determine the anti-liver cancer activity of NCTD-IRMOF-3-Gel in *in vitro* models.

Research results

The particle size of NCTD-IRMOF-3-Gel was 50-100 nm, and the particle size distribution was uniform. The release curve showed that NCTD-IRMOF-3-Gel had an obvious sustained-release effect. The cytotoxicity assays showed that the free drug NCTD and NCTD-IRMOF-3-Gel treatments markedly inhibited Hepa1-6 cell proliferation, and with increasing drug concentrations, the inhibition rate increased. By flow cytometry, NCTD-IRMOF-3-Gel was observed to block the Hepa1-6 cell cycle in the S and G2/M phases, and the thermosensitive gel nanoparticles may inhibit cell proliferation by inducing cell cycle arrest. Apoptosis experiments showed that NCTD-IRMOF-3-Gel induced the apoptosis of Hepa1-6 cells.

Research conclusions

NCTD-loaded IRMOF-3 nanoparticles incorporated into a thermosensitive gel appeared to be a useful tool for cancer treatment because of the enhanced inhibition rate of cancer cells and controlled release of drugs from these nanocarriers.

Research perspectives

Thermosensitive gel-encapsulated IRMOF-3 has great advantages as an antitumor drug carrier and provides some ideas for passive targeting therapy of tumors.

Abstract

BACKGROUND

Ubiquitin-specific protease 15 (USP15) is an important member of the ubiquitin-specific protease family, the largest deubiquitinase subfamily, whose expression is dysregulated in many types of cancer. However, the biological function and the underlying mechanisms of USP15 in gastric cancer (GC) progression have not been elucidated.

AIM

To explore the biological role and underlying mechanisms of USP15 in GC progression.

METHODS

Bioinformatics databases and western blot analysis were utilized to determine the expression of USP15 in GC. Immunohistochemistry was performed to evaluate the correlation between USP15 expression and clinicopathological characteristics of patients with GC. A loss- and gain-of-function experiment was used to investigate the biological effects of USP15 on GC carcinogenesis. RNA sequencing, immunofluorescence, and western blotting were performed to explore the potential mechanism by which USP15 exerts its oncogenic functions.

RESULTS

USP15 was up-regulated in GC tissue and cell lines. The expression level of USP15 was positively correlated with clinical characteristics (tumor size, depth of invasion, lymph node involvement, tumor-node-metastasis stage, perineural invasion, and vascular invasion), and was related to poor prognosis. USP15

knockdown significantly inhibited cell proliferation, invasion and epithelial-mesenchymal transition (EMT) of GC *in vitro*, while overexpression of USP15 promoted these processes. Knockdown of USP15 inhibited tumor growth *in vivo*. Mechanistically, RNA sequencing analysis showed that USP15 regulated the Wnt signaling pathway in GC. Western blotting confirmed that USP15 silencing led to significant down-regulation of β-catenin and Wnt/β-catenin downstream genes (c-myc and cyclin D1), while overexpression of USP15 yielded an opposite result and USP15 mutation had no change. Immunofluorescence indicated that USP15 promoted nuclear translocation of β-catenin, suggesting activation of the Wnt/β-catenin signaling pathway, which may be the critical mechanism promoting GC progression. Finally, rescue experiments showed that the effect of USP15 on gastric cancer progression was dependent on Wnt/β-catenin pathway.

CONCLUSION

USP15 promotes cell proliferation, invasion and EMT progression of GC *via* regulating the Wnt/β-catenin pathway, which suggests that USP15 is a novel potential therapeutic target for GC.

Key Words: Ubiquitin-specific protease 15; Gastric cancer; Wnt/β-catenin; Cell proliferation; Cell invasion; Epithelial-mesenchymal transition

INTRODUCTION

Gastric cancer (GC) has a high incidence worldwide and is one of the main causes of cancer-related deaths, especially in China[1,2]. Although there have been great advances in surgical procedures and targeted chemotherapy in recent years, the results are still not satisfactory and the survival rate is low, with median overall survival (OS) less than 12 mo[3-5]. Therefore, identifying novel potential targets for GC diagnosis and therapy and elucidating the underlying mechanisms of disease progression are essential for the prevention and treatment of GC.

In recent years, increasing evidence has shown that ubiquitin-specific proteases (USPs), the largest deubiquitinase subfamily, plays an important role in GC. For example, USP14[6], USP42[7], and USP44[8] are upregulated in GC and can be used as independent prognostic markers in GC patients. USP15, one of the most important members of the USP family, has been found to have some amplifications in many tumors. The N terminus of the protein encoding USP15 includes a ubiquitin-specific protease (DUSP) domain and two ubiquitin-like (UBL) domains, which can specifically remove the substrate protein by monoubiquitination and polyubiquitination modification[9]. The active site of the USP15 protein is located at Cys-269, and mutation of Cys269 to Ser (USP15 C269S) can inhibit enzyme activity[10]. Previous studies have reported that USP15 is upregulated in the liver and pancreatic cancer, and is associated with poor prognosis[11,12]. Mechanistically, USP15 can activate the transforming growth factor β (TGF-β) signaling pathway and promote the progression of advanced malignant glioma by combining the SMAD-specific E3 ubiquitin protein ligase 2

complex and deubiquitinating and thus stabilizing the TGF b type I receptor[13]. In addition, USP15 can negatively regulate the function of p53 through affecting de-ubiquitination and stabilizing MDM2. Interestingly, inhibiting the activity of USP15 can induce tumor apoptosis and improve the antitumor T-cell response[14]. However, the role of USP15 in GC and its potential mechanisms have not been identified.

The Wnt/β-catenin signaling pathway is involved in many cellular processes such as tumor growth, differentiation and invasion, and tumorigenesis[15]. It is often activated in many types of cancer, and the nuclear accumulation of β-catenin is an important sign of Wnt signaling activation[16]. The activation of β-catenin can activate many oncogenes including c-myc and cyclin D1, and regulate cell proliferation, cell cycle progression and apoptosis during tumorigenesis[17-19]. However, the mechanisms of Wnt/β-catenin activation in GC have not been fully elucidated.

We found that USP15 was upregulated in GC cells and tissues, and was associated with a poor prognosis in GC patients. USP15 promoted cell proliferation, invasion, and epithelial-mesenchymal transition (EMT) of GC cells *in vitro* and tumor growth *in vivo*. Mechanistic studies showed that USP15 functioned as a tumor promoter in GC by regulating the Wnt/β-catenin signaling pathway. Thus, USP15 is expected to be a novel potential target for GC therapy.

MATERIALS AND METHODS

Tissue samples

Paraffin-embedded GC samples, including cancerous tissues (n = 115) and adjacent tissues (n = 30), from May 2011 and May 2013, were obtained from the First Affiliated Hospital of Nanchang University (Nanchang, China). The clinicopathological characteristics of these patients are shown in Table 1. The fresh GC tissues (n = 8) and corresponding adjacent noncancerous tissues were stored in liquid nitrogen until use. This study obtained ethical approval from the Human Research Ethics Committee of the First Affiliated Hospital of Nanchang University.

Cell lines and culture

Human GC cell lines (SGC-7901, HGC-27, MKN-45, MGC-803, BGC-823, and AGS) and the human immortalized gastric epithelial cell line (GES-1) were purchased from the Beijing Beina Chuanglian Institute of Biotechnology (Beijing, China). The cells were cultured in (RPMI-1640) or Dulbecco's modified Eagle's medium with 10% fetal bovine serum (FBS; HyClone, Logan, UT, United States) in an incubator with 5% CO_2 at 37 °C.

Immunohistochemistry

Immunostaining of USP15 proteins in 115 clinical GC samples followed previously described methods[20]. A primary antibody against USP15 (1:100, #66310; Cell Signaling Technology, Danvers, MA, United States) was used to detect the expression of USP15. All staining scores were evaluated blindly by two pathologists based on staining intensity and positive staining ratio. The grading standard of immunohistochemistry was carried out as previously described [20].

Cell Counting Kit-8 assay and colony formation assay

At 48 h after transfection, 2000 GC cells per well were seeded into a 96-well plate for the Cell Counting Kit-8 (CCK-8) assay and 1000 GC cells per well were seeded into a 6-well plate for the colony formation assay as previously described[21].

Wound healing assay

At 48 h after transfection, 5 × 10^5 GC cells per well were seeded into a 6-well plate, and the cells were starved for 24 h until complete fusion. Straight lines were drawn with a sterile 10-μL pipette tip to form wounds. Then the cells were carefully washed with phosphate-buffered saline (PBS) and cultured in serum-free medium. Images were captured at 0, 24, and 48 h to assess wound closure.

Transwell assay

The transwell assay was performed *via* using 8-μm transwell chambers (Merck KGaA, Darmstadt, Germany) with or without 60 μL Matrigel gel (BD Biosciences, Hercules, CA, United States), and then the chambers were put in each well of a 24-well plate. Cells of each group (5 × 10^4) were placed in 200 μL serum-free medium for 48 h after transfection, and subsequently transferred to the upper compartment of the above

chambers. The lower chamber contained RPMI-1640 with 10% FBS. After 36 h of incubation, the cells that had migrated or invaded to the bottom side of the chamber were fixed with methanol, and then stained with crystal violet.

Immunofluorescence

We dipped the coverslip into the culture medium to allow the cells to attach and grow, and then washed the cells three times with PBS. At room temperature, the cells were fixed on a coverslip with 4% tetraformaldehyde for 20 min, and then were washed again three times with PBS. After a 10 min incubation with 0.5% Triton X-100, the cells were blocked in 5% bovine serum albumin for 2 h and then were incubated with anti-β-catenin antibody (1:200 dilution; Cell Signaling Technology) at 4 °C. After washing three times with PBS, cells were incubated with secondary antibody (1:50 dilution, ab150077; Abcam, Cambridge, MA, United States) for 1 h at room temperature. The coverslips were subsequently washed three times with PBS and then were stained with 4′,6-diamidino-2-phenylindole (DAPI). Fluorescence images were captured *via*

laser confocal microscopy.

Western blotting

Western blotting was performed following as previously described[22]. The following primary antibodies were used: USP15 (1:2000, #66310; Cell Signaling Technology), E-cadherin (1:1000, ab1416; Abcam), N-cadherin (1:1000, ab18203; Abcam), vimentin (1:1500, ab8978; Abcam), c-Myc (1:1500, #5605; Cell Signaling Technology), β-catenin (1:2000, #8480; Cell Signaling Technology), cyclin D1 (1:1000, #2978; Cell Signaling Technology), and GAPDH (1:2000, #60004-1-Ig; Proteintech, Rosemont, IL, United States).

Plasmid construction and cell transfection

To knock down the expression of USP15, three different small interfering RNAs (siRNAs) and a negative control (NC) were designed as followed: USP15-Homo-249, 5′-GGAACACCUUAUUGAUGAATT-3′; USP15-Homo-1150, 5′-GCAGAUGGAAGGC-CAGAUATT-3′; USP15-HoMo-1382, 5′-CCAAACCUAUGCAGUACAATT-3′; and a NC siRNA, 5′-UUCUCCGAACGUGUCACGUTT-3′. USP15 overexpression plasmid (USP15: NM_006313.2) and USP15 mutated plasmid (USP15-C269S) were based on pcDNA3.1 plasmid. The above siRNA and plasmid were synthesized by GenePharma (Suzhou, China). Cells were grown to 50%–60% confluency and transfected using TurboFect transfection reagent (R0532; Thermo Scientific Scientific, Waltham, MA, United States).

RNA sequencing analysis

The isolated USP15 knockdown and control BGC-823 cells were used for cDNA amplification and RNA sequencing (RNA-seq) library preparation. RNA-seq was performed by Beijing Novel Bioinformatics Co. Ltd. (Beijing, China). Genes with a false discovery rate < 5% and a fold change > 2.0 that met the established threshold criteria were considered to be significantly differentially expressed.

Nude mouse tumor cell xenograft assay

Short hairpin RNAs (shRNAs) targeting USP15 or scramble shRNAs were subcloned into the lentiviral expression vector (Jikai Co. Shanghai, China). BGC□823 cells transfected with LV-shUSP15 or LV-scramble shRNA was stably expressed and screened by puromycin. The stably expressed strain was amplified and inoculated at a rate of 5×10^6 cells per animal into 5- to 6-wk-old BALB/c-nu mice. Tumor volume was measured every 3 d and calculated according to the formula: volume (mm^3) = (length × $width^2$)/2. Mice were sacrificed after 28 d and xenograft tumors were measured and weighed. Proteins were extracted from tumors and USP15 and β-catenin expression was detected by western blotting.

Statistical analyses

We statistically analyzed the data using SPSS version 26.0 software (Chicago, IL, United States). The relationship between clinical characteristics and USP15 expression was evaluated by the χ^2 test. The Kaplan–Meier method was performed to determine the OS curve of all enrolled GC patients. Student's *t*-test was used to determine the mean difference between two groups. $P < 0.05$ was considered statistically significant.

RESULTS

USP15 is upregulated in GC cells and tissues and is associated with a poor prognosis in patients with GC

First, an online database, cBioPortal for Cancer Genomics (http://www.cbioportal.org/)[23], showed that USP15 was amplified in many types of tumor including GC (Figure 1A). TIMER (https://cistrome.shinyapps.io/timer/)[24] and UALCAN database (http://ualcan.path.uab.edu/)[25], based on The Cancer Genome Atlas (TCGA) database, indicated that the mRNA levels of USP15 in GC tissues were higher than those in normal tissues (Figure 1B and C). To confirm the protein expression level of USP15 in GC, western blotting was conducted on GC cell lines and tissues. Most GC cell lines expressed a higher level of USP15 than the gastric epithelial cell line GES-1 (Figure 1D). USP15 was elevated in most of the eight pairs of clinical GC tissues and their adjacent normal tissues (Figure 1E).

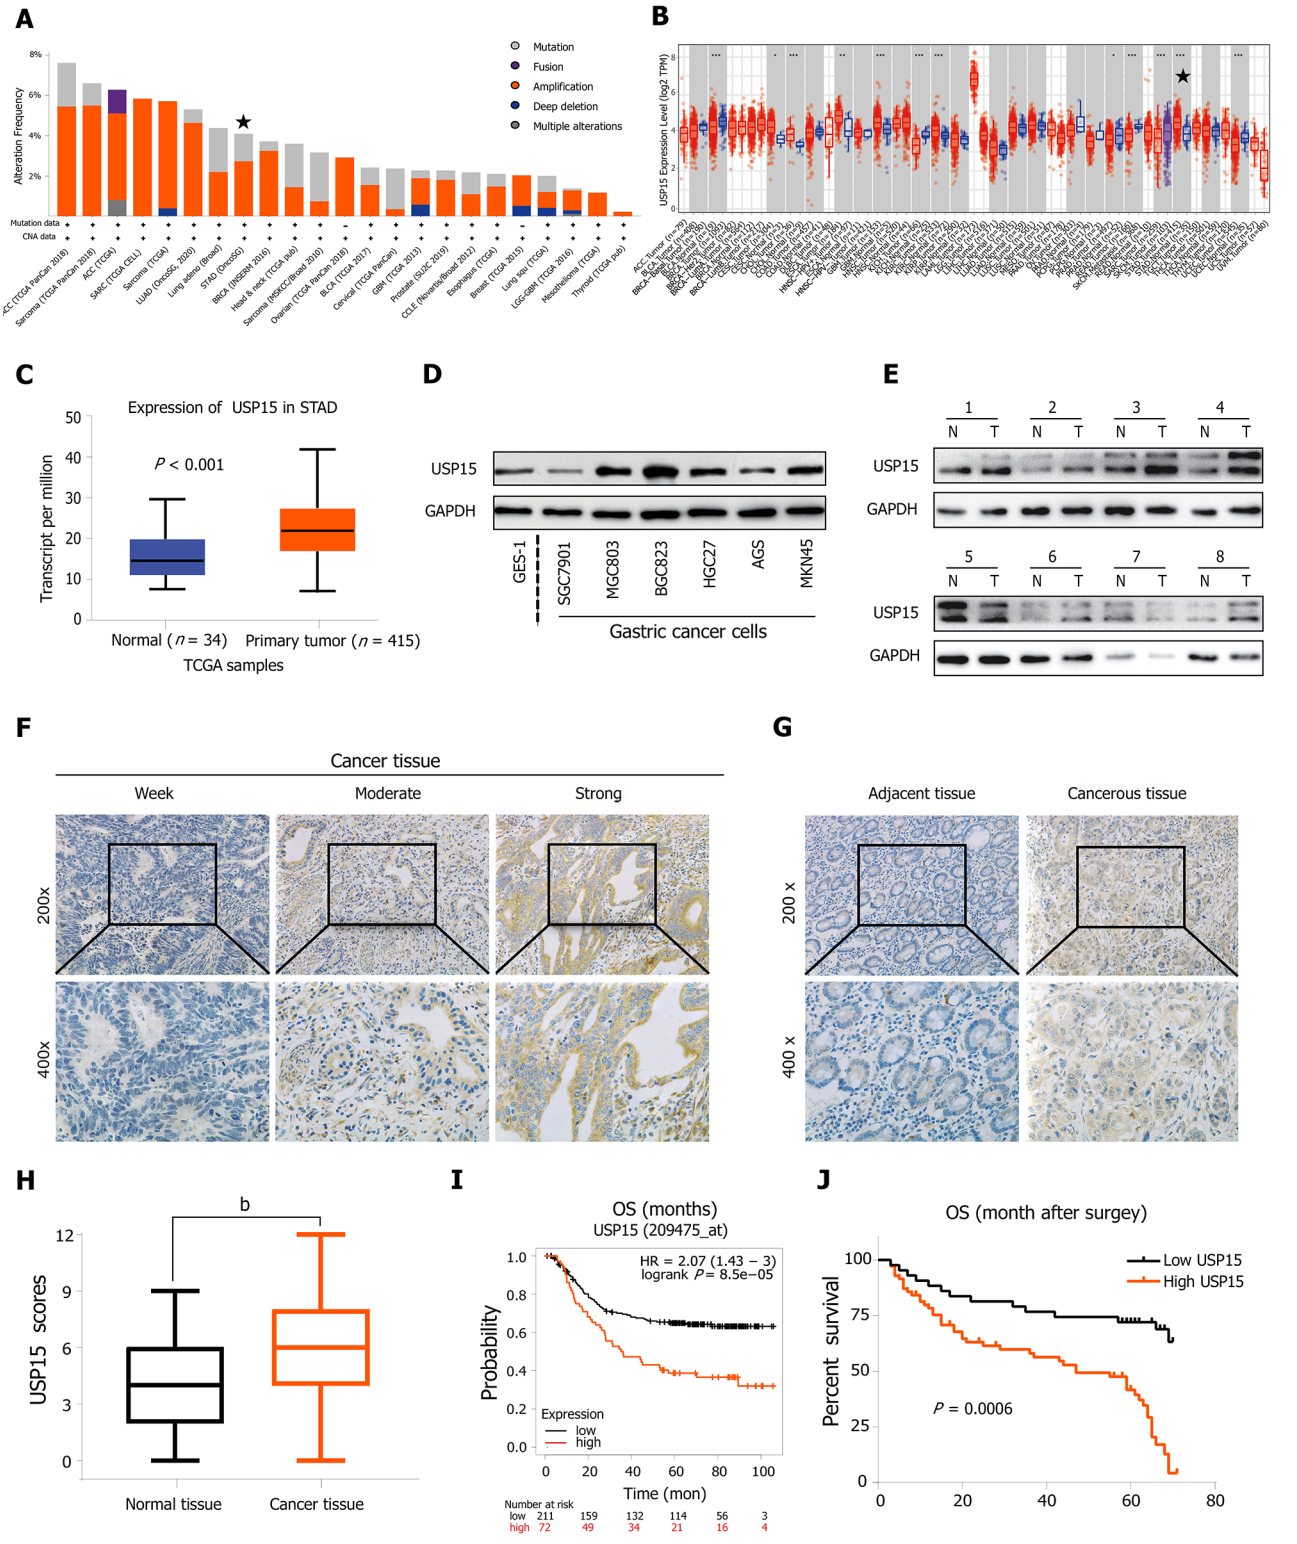

Figure 1 Ubiquitin-specific protease 15 is upregulated in gastric cancer cells and tissues, and is associated with a poor prognosis in gastric cancer patients. A: Frequency of ubiquitin-specific protease 15 (USP15) in various cancers, including gastric cancer (GC). The data were derived from the cBioPortal for Cancer Genomics; B, C: USP15 mRNA expression level of cancer tissue and normal tissue in GC. Analysis of The Cancer Genome Atlas data from TIMER and UALCAN databases; D: Protein expression of USP15 in GES-1 cell line and GC cell lines; E: Protein expression of USP15 in GC tissue and adjacent noncancerous tissues (n = 8); F, G: Representative images of immunohistochemical staining of USP15 in human GC tissues and adjacent noncancerous tissues; H: USP15 staining scores of GC and normal tissues; I: Correlation between USP15 expression level and overall survival (OS) in GC patients obtained from Kaplan–Meier Plotter databases (209475_at, HR = 2.07 (1.43-3), log rank $P = 8.5e^{-05}$); J: Kaplan–Meier curve stratified by USP15 expression in 115 GC patients (log-rank test, P = 0.0006). $^{b}P < 0.01$, data were expressed as the mean ± standard error of the mean.

As USP15 was found to be upregulated in GC, we confirmed its clinical significance *via* using immunohistochemistry. The staining of USP15 protein ranged from weak to strong and located in the cytoplasm (Figure 1F), which showed that USP15 was markedly increased in GC tissue sections, whereas USP15 staining was weak or negative in noncancerous tissue sections (Figure 1G). The staining scores of USP15 in adjacent tissues were significantly lower than those in GC tissues, which were considered significantly different (Figure 1H).

Subsequently, we evaluated the correlation between the staining score of USP15 and the clinicopathological characteristics of patients. There was no significant difference among patient gender, age, differentiation, and USP15 expression; however, tumor size (P = 0.004), tumor-node-metastasis (TNM) stage (P = 0.015), depth of invasion (P = 0.009), lymph node involvement (LNI) (P = 0.002), perineural invasion (P = 0.021), and vascular invasion (P = 0.001) were significantly associated with USP15 expression in GC. Consistent with the results obtained from Kaplan–Meier Plotter Database Analysis[26] (http://kmplot.com/analysis/) , the Kaplan–Meier curve stratified by USP15 expression in these 115 GC patients showed that patients with lower USP15 expression had longer OS (Figure 1I and J).

Knockdown of USP15 inhibits cell proliferation, invasion, and EMT progression of GC in vitro

As shown above, BGC-823 and MKN-45 cells had high expression of USP15. siRNA-mediated knockdown of USP15 expression in BGC-823 and MKN-45 cells was used to detect the function of USP15 *in vitro*. Western blotting was used to confirm the silencing efficiency of USP15 in GC cells (Figure 2A). The results of CCK-8 and colony formation assays showed that the proliferation rate and colony formation ability were markedly decreased in the USP15-siRNA-1/2 group compared to the NC group (Figure 2B and C). Based on correlation of USP15 expression and lymph node status, perineural and vascular invasion, wound healing and transwell assays were used to evaluate the role of USP15 in tumor cell migration and invasion. As shown in Figure 2D and Figure 2E, USP15 silencing suppressed GC cell migration and invasion. In addition, knockdown of USP15 upregulated E-cadherin and downregulated N-cadherin and vimentin (Figure 2F).

USP15 overexpression promotes cell proliferation, invasion, and EMT progression in GC

We explored the cellular behavioral changes caused by overexpression of USP15. A stably transfected cell line with USP15 overexpression plasmid, USP15 mutant plasmid (USP15-C269S), and a NC (empty-vector) cell line were established in SGC7901 cells. Western blotting confirmed the transfection efficiency (Figure 3A). Compared with the empty vector group, proliferation of the USP15 group was significantly enhanced, while the USP15-C269S group had no changes (Figure 3B and C). Overexpression of USP15 promoted GC cell migration and invasion, while USP15-C269S did not (Figure 3D and E). Western blotting analysis showed that overexpression of USP15 upregulated vimentin and N-cadherin but downregulated E-cadherin (Figure 3F). Collectively, these data demonstrated that USP15 overexpression promoted GC proliferation, invasion, and EMT progression.

USP15 regulates the Wnt/β-catenin pathway in GC cells

To explore the potential molecular mechanism responsible for the effects of USP15 on GC progression, the whole transcriptome profiles of BGC-823 cells with USP15 knockdown or NC were analyzed by RNA-seq. The transfection efficiency was confirmed by western blotting (Figure 4A). The most differentially expressed genes (DEGs) (29829) were displayed on the heat map (Figure 4B). Among the 2343 significant DEGs (adjusted $P < 0.05$), transcripts of 1134 genes were upregulated and transcripts of 1209 were downregulated in USP15 knockdown groups compared to the control groups (Figure 4C). Gene Ontology enrichment analyses showed that the difference in Wnt signaling pathway was the most obvious (Figure 4D) among the enriched pathways.

As one of the most classic Wnt signaling pathways, the Wnt/β-catenin pathway has been involved in multiple physiological processes of GC progression. To confirm the role of the Wnt/β-catenin signaling pathway in the malignant biological behavior in GC mediated by USP15, western blotting was performed to investigate expression of β-catenin and Wnt/β-catenin downstream genes (including c-myc and cyclin D1). USP15 knockdown resulted in downregulation of the protein level of β-catenin, c-Myc and cyclin D1, while USP15 overexpression yielded opposite results and there was no

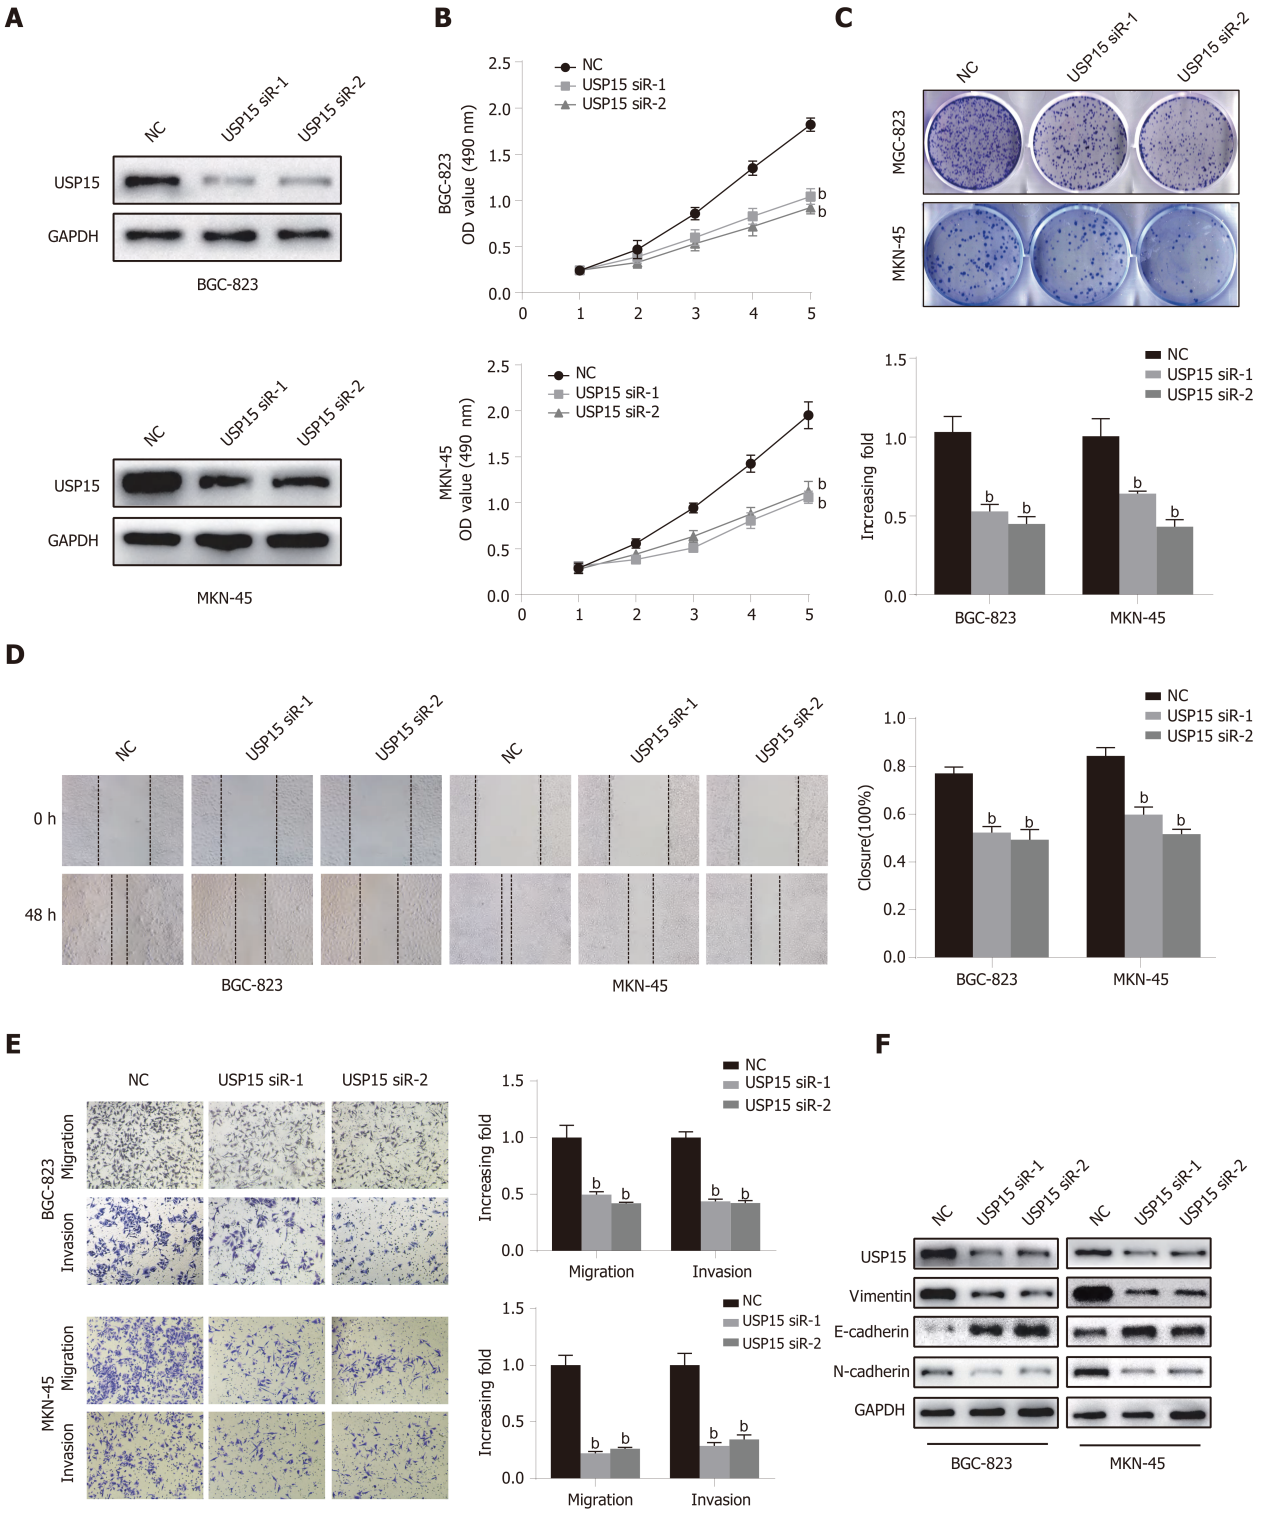

Figure 2 Knockdown of ubiquitin-specific protease 15 inhibits cell proliferation, invasion, and epithelial-mesenchymal transition progression of gastric cancer *in vitro*. A: BGC-823 and MKN-45 cells were transfected with ubiquitin-specific protease 15 (USP15) small interfering RNA or negative control for 48 h, and the efficiency was detected by Western blotting; B and C: Cell Counting Kit-8 assay and colony formation assay evaluated cell proliferation ability; D and E: Wound healing assay and transwell assays evaluated migration and invasion; F: Western blotting detected epithelial-mesenchymal transition markers (E-cadherin, vimentin, and N-cadherin). $^{b}P < 0.01$, data were expressed as mean ± standard error of the mean.

change in USP15 C269S group (Figure 4E). In addition, immunofluorescence assay showed that USP15 knockdown significantly reduced nuclear β-catenin accumulation compared with the control groups, while USP15 overexpression yielded opposite results, and there was no change in the USP15 C269S group (Figure 4F).

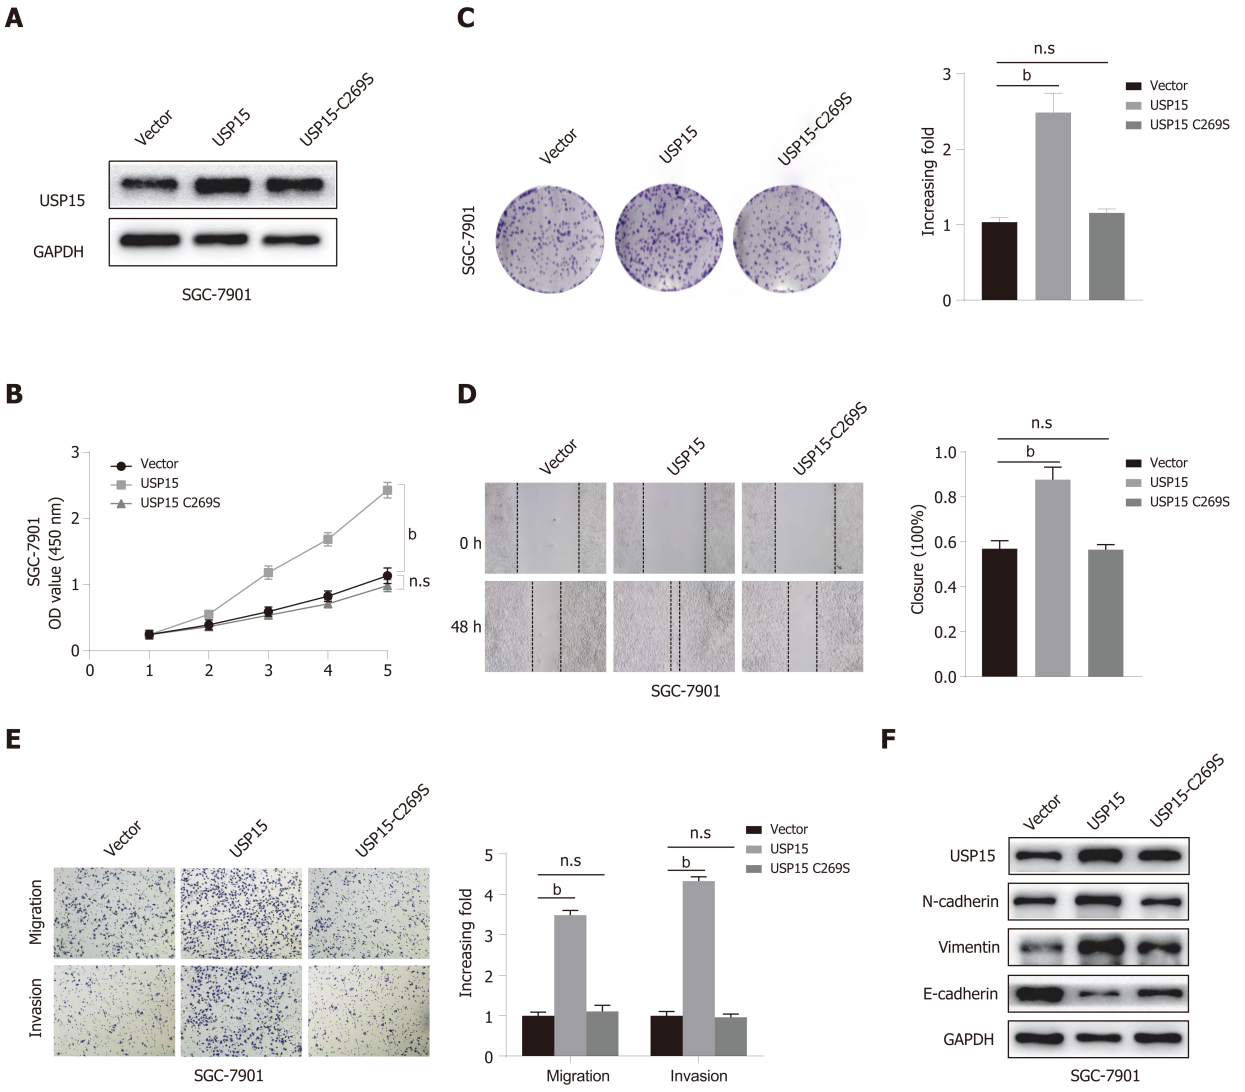

Figure 3 Overexpression of ubiquitin-specific protease 15 promotes proliferation, invasion, and epithelial–mesenchymal transition of gastric cancer cells. A: SGC-7901 cells were transfected with ubiquitin-specific protease 15 (USP15) overexpression plasmid, USP15-C269S plasmid (USP15 mutant) or empty vector for 48 h, and the efficiency was detected by Western blotting; B, C: Cell Counting Kit-8 assay and colony formation assay evaluated cell proliferation ability; D, E: Wound healing assay and transwell assay evaluated migration and invasion; F: Western blotting detected epithelial–mesenchymal transition markers (E-cadherin, vimentin, and N-cadherin). $^{b}P < 0.01$, data are expressed as the mean ± standard error of the mean. n.s: Not significant.

Lithium chloride partly reversed the effects of USP15 knockdown on GC progression

To further clarify whether the function of USP15 in GC was mediated by the Wnt/β-catenin pathway, we performed a rescue experiment using lithium chloride (LiCl) (Wnt/β-catenin pathway activator). The cell proliferation ability of BGC-823 and MKN-45 cells transfected with USP15 siRNA-1 was significantly elevated after treatment with LiCl compared to the untreated group (Figure 5A and B). Furthermore, the inhibition of invasion by USP15 knockdown can also be partly reversed by LiCl (Figure 5C). In addition, LiCl-treatment induced upregulation of β-catenin, c-myc, and cyclin D1 (Figure 5D). The above findings suggest that the function of USP15 on GC progression is dependent on Wnt/β-catenin pathway.

USP15 knockdown inhibits tumor growth in vivo

We investigated the function of USP15 *in vivo*. BGC-823 cells transfected with LV-shUSP15 or LV-scramble shRNA were subcutaneously injected into nude mice to establish a xenograft mouse model. After the mice were sacrificed on day 29, we obtained tumor images (Figure 6A). Compared with the scramble shRNA group, USP15 knockdown reduced tumor volume and weight (Figure 6B and C). In addition, USP15 knockdown significantly reduced the protein levels of β-catenin, c-myc, and cyclin D1 in tumor tissue of nude mouse, consistent with the *in vitro* results

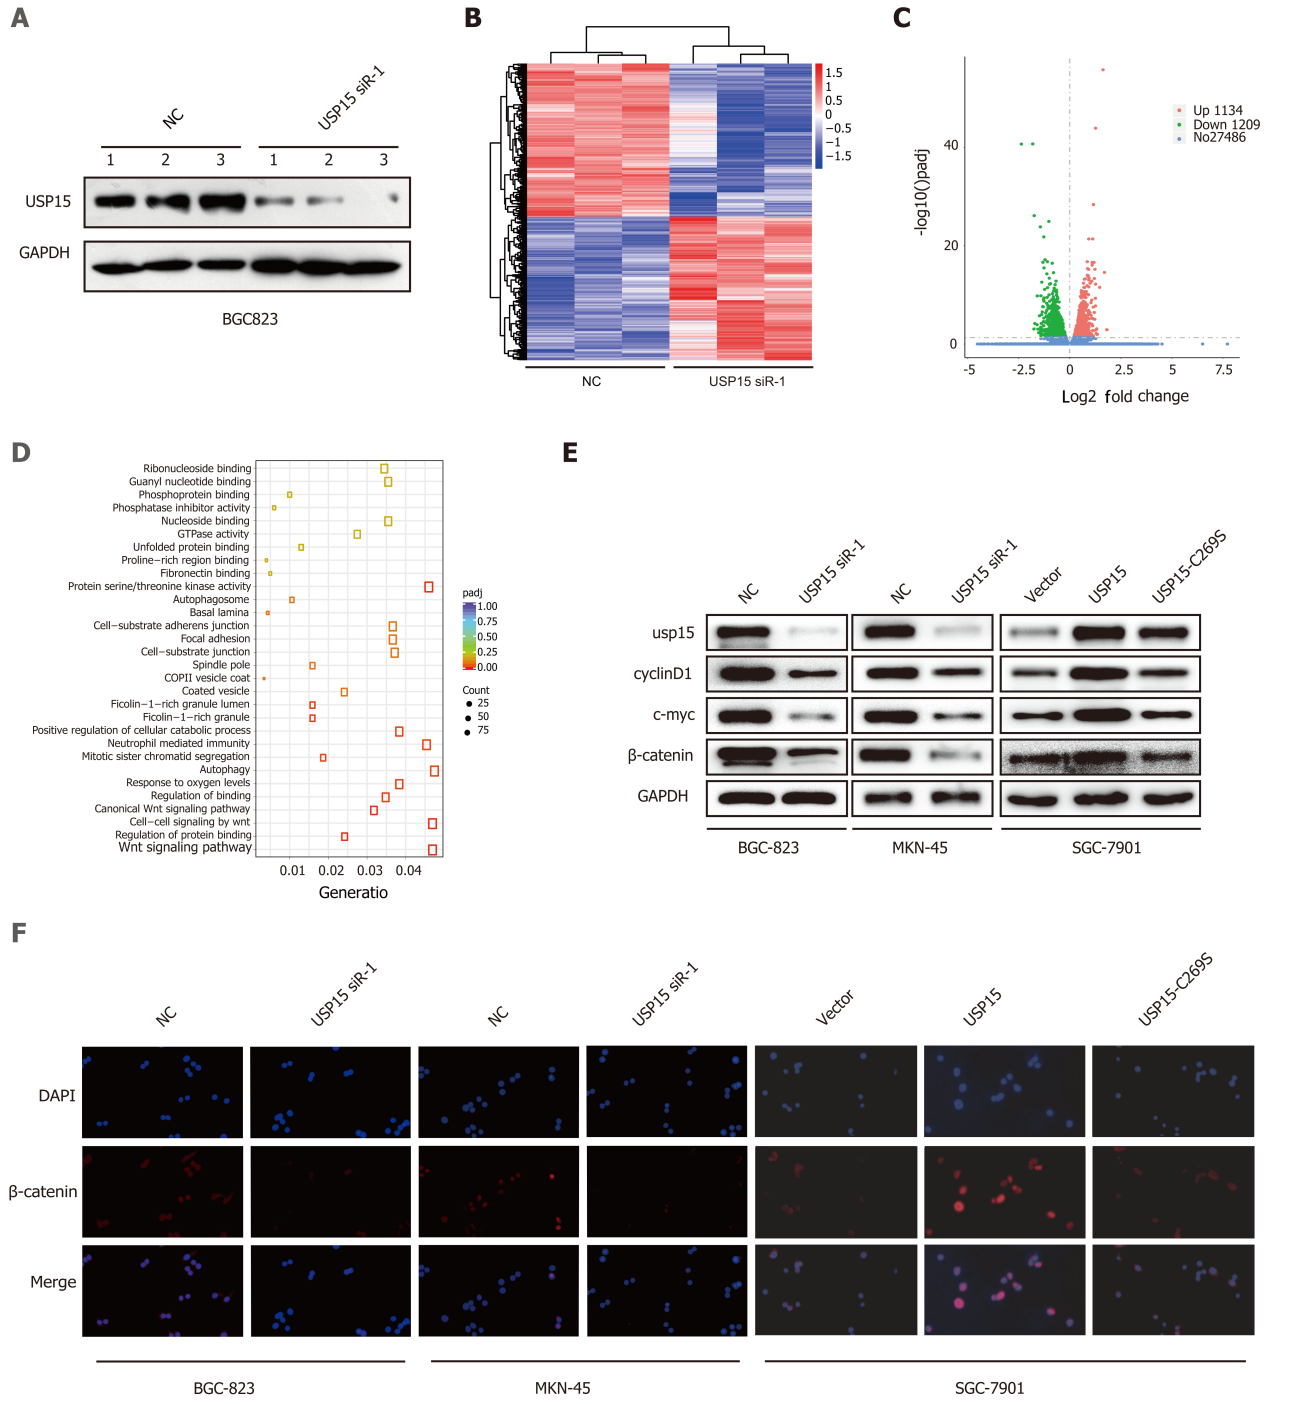

Figure 4 Ubiquitin-specific protease 15 regulates the Wnt/β-catenin pathway in gastric cancer. A: Western blotting confirmed the transfection efficiency of ubiquitin-specific protease 15 (USP15) knockdown in BGC-823 cell lines before RNA sequencing analysis; B: Heat map and hierarchical clustering based on the most differentially expressed genes (5739); C: Volcano plot illustrated differentially regulated gene expression. 1134 upregulated genes (red) and 1209 downregulated genes (green); D: Gene Ontology enrichment analyses of targets associated with USP15 for biological process, cellular component, and molecular function (top 10 most significantly affected categories are shown); E: Expression levels of USP15, β-catenin, c-Myc, and cyclin D1 in BGC-823 and MKN-45 cell lines transfected with USP15 knockdown or SGC-7901 cell lines transfected with USP15 overexpression; F: Immunofluorescence staining of β-catenin in BGC-823 and MKN-45 cell lines transfected with USP15 knockdown. Blue: DAPI; Red: β-catenin. Bar = 50 μm.

(Figure 6D).

DISCUSSION

In recent years, an increasing number of USP proteins have been reported to be critical to human cancers. For example, high expression of USP28 is related to the OS of patients with non-small cell lung cancer[27], while the expression of USP22 and USP11

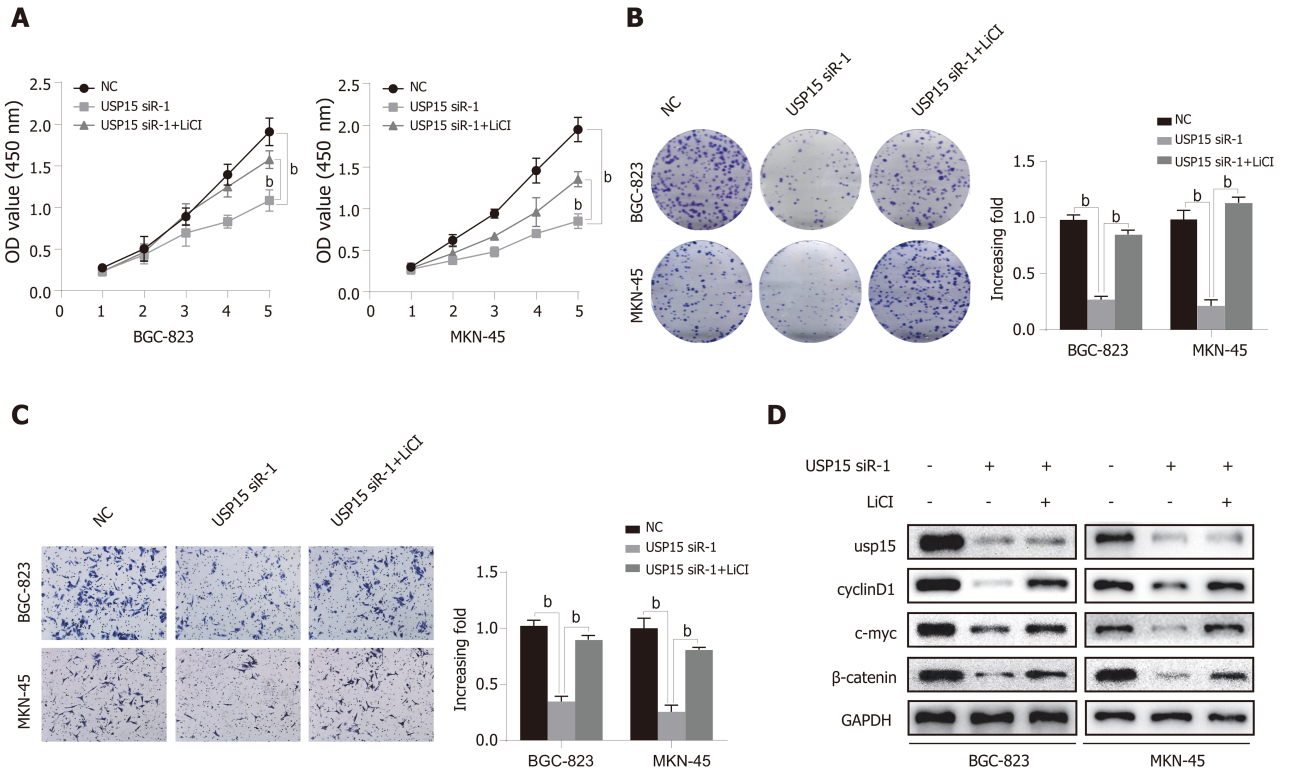

Figure 5 Lithium chloride partly reverses the effects of ubiquitin-specific protease 15 knockdown on gastric cancer progression. BGC-823 and MKN-45 cells transfected with ubiquitin-specific protease 15 (USP15) small interfering RNA-1 or negative control were incubated with or without lithium chloride (LiCl) (20 mmol/L). A, B: The Cell Counting Kit-8 (CCK-8) assay and colony formation assay evaluated cell proliferation ability; C: Transwell assays evaluated cell invasion ability; D: Western blotting detected the protein expression of β-catenin, c-Myc, and cyclin D1. $^{b}P < 0.01$, data are expressed as the mean ± standard error of the mean.

is related to the poor prognosis of breast cancer[28,29]. Two recent studies have shown that USP15 is upregulated in liver cancer and pancreatic ductal cell carcinoma[11,12]. In this study, IHC analyses showed that the high expression of USP15 was closely related to the depth of invasion, LNI, TNM stage, which indicated that USP15 acted as an oncogene, thereby promoting GC invasion, metastasis, and progression. In addition, the high expression of USP15 was related to the poor survival rate of GC patients, suggesting that USP15 is very important in the pathogenesis and development of GC, and could be used as a prognostic biomarker.

Similar to previous results[11,12], our study confirmed that USP15 was significantly associated with tumor cell proliferation *in vitro*. In addition, we also found that USP15 could participate in the tumor growth *in vivo*. Subsequently, we further found that USP15 can significantly promote the migration and invasion of GC cells *in vitro*. Migration and invasion, as the basic characteristics of malignant tumors, are the main reasons for the short survival time of cancer patients[30,31]. Mounting evidence has shown that tumor cells after EMT has high motility and aggressiveness, among which E-cadherin, N-cadherin, and vimentin are important molecular markers[32]. In addition, the epithelial marker E-cadherin is downregulated, while the mesenchymal markers vimentin and N-cadherin are upregulated during EMT[32]. As shown in our results, knockdown of USP15 resulted in upregulation of E-cadherin and downregulation of N-cadherin and vimentin, while overexpression of USP15 had the opposite effects, suggesting that USP15 can induce EMT in GC cells. The above findings indicated that USP15 may promote cell proliferation, migration, invasion and EMT process to become an oncogene of GC.

USP15 was related to a variety of cell signaling events, including transforming growth factor β (TGF-β)[13,33], constitutive photomorphogenesis 9 (COP9) signaling body[34], p53 signaling pathway[14], and nuclear factor kappa B (NF-kB)[35]. For example, USP15 promotes the stabilization of TGF-β receptor and its downstream signal transducers, thereby resulting in enhanced TGF-β signaling[13,36]. USP15 can protect the constituent subunits of cullin-RING ubiquitin ligase from self-ubiquitination and degradation *via* a stable cooperation with COP9-signalosome[34,37]. USP15 can stabilize MDM2 and negatively regulate the protein level of p53, and inactivation of USP15 can induce tumor apoptosis and improve the antitumor T-cell

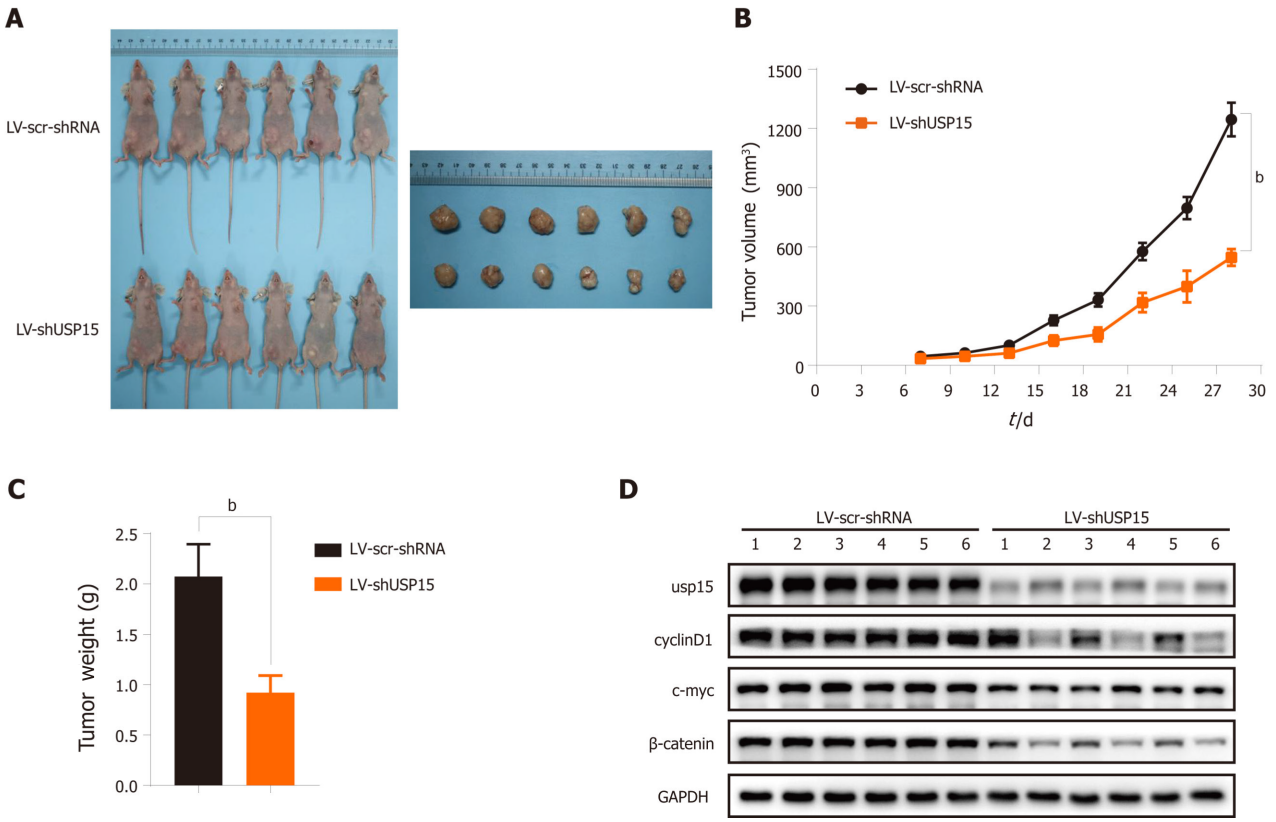

Figure 6 Ubiquitin-specific protease 15 silencing inhibits tumor growth *in vivo*. A: Cervical dislocation was used to sacrifice nude mice on day 29 and representative images of xenograft mouse samples were obtained (n = 6); B: Tumor volume was measured every 3 d and a growth curve was drawn; C: Tumor weight was measured when mice were sacrificed; D: Western blotting detected the protein expression of ubiquitin-specific protease 15, β-catenin, c-Myc, and cyclin D1 in tumor samples of two groups. $^{b}P < 0.01$, data are expressed as the mean ± standard error of the mean. USP15: Ubiquitin-specific protease 15.

response[14]. Another recent study showed that USP15 can effectively activate NF-κB by maintaining the stability of TAB2/3 differentially[38]. In our study, GO enrichment analysis based on RNA-Seq indicated that USP15 regulated the Wnt/β-catenin signaling pathway in GC. Previous studies have shown that abnormal activation of the Wnt/β-catenin pathway could promote the malignant progression of a variety of cancers, including GC[39,40]. Increased nuclear expression of β-catenin is an important sign of Wnt/β-catenin signaling pathway activation, which mainly depends on the transport of cytoplasmic β-catenin to the nucleus[39,40]. In our study, knockdown of USP15 significantly reduced the nuclear expression of β-catenin and downregulation of Wnt/β-catenin downstream genes in GC cells, while USP15 overexpression yielded opposite results, and there was no change in the USP15 C269S group (USP15 mutant), indicating that USP15 acted as a Wnt/β-catenin pathway activator. A rescue experiment by using LiCl (a Wnt/β-catenin pathway activator) showed that the effect of USP15 on GC progression was dependent on Wnt/β-catenin pathway. All of these findings suggest that USP15 contributes to GC progression by regulating the Wnt/β-catenin signaling pathway.

To the best of our knowledge, this study is the first to explore the clinical significance and molecular function of USP15 in GC. However, our research had some limitations. This was a retrospective study that included a small number of GC patients from a single center in our hospital, so there may have been a degree of bias. In the future, a large multicenter study should be conducted to verify our results. In addition, although GeneMANIA[41], a protein interaction bioinformatics website, predicts that USP15 can interact with some upstream proteins (CTNNB1, NUSAP1) of the Wnt/β-catenin pathway, the specific molecular mechanism problems need to be resolved in future research.

CONCLUSION

In conclusion, the results presented in our study demonstrated that USP15 was

upregulated in GC cells and tissues, and was associated with a poor prognosis in patients with GC. Furthermore, USP15 promoted cell proliferation, invasion, and EMT progression *via* the Wnt/β-catenin signaling pathway *in vitro* and promoted the growth of GC cells *in vivo*. All of our findings shed light on USP15 as a novel promising therapeutic target for understanding the pathogenesis of GC, providing new insights into the development of novel strategies for diagnosis and treatment from the bench to clinic.

ARTICLE HIGHLIGHTS

Research background

Ubiquitin-specific protease 15 (USP15) is an important member of the ubiquitin-specific protease (USP) family, whose expression is dysregulated in many types of cancer. However, the function role and the underlying mechanism of USP15 in gastric cancer (GC) progression have not yet been elucidated.

Research motivation

To explore the underlying mechanisms of GC development and discover biomarkers for the treatment of GC.

Research objectives

To investigate the role and potential mechanism of USP15 in GC.

Research methods

Bioinformatics databases and western blot analysis were utilized to determine the expression of USP15 in GC. Immunohistochemistry was performed to evaluate the correlation between expression of USP15 and clinicopathological characteristics of GC patients. A loss- and gain-of-function experiment was used to investigate the biological effects of USP15 on GC carcinogenesis. RNA sequencing analysis, immunofluorescence, and western blotting were performed to explore the potential mechanism by which USP15 exerted its oncogenic functions.

Research results

USP15 was upregulated in GC tissue and cell lines. The expression level of USP15 was positively correlated with clinical characteristics (tumor size, depth of invasion, lymph node involvement (LNI), tumor-node-metastasis (TNM) stage, perineural invasion, and vascular invasion), and was related to poor prognosis. USP15 knockdown significantly inhibited cell proliferation, invasion and epithelial-mesenchymal transition of GC *in vitro*, while overexpression of USP15 promoted these processes. Knockdown of USP15 inhibited tumor growth *in vivo*. Mechanistically, RNA-seq analysis showed that USP15 regulated the Wnt signaling pathway in GC. Western blotting confirmed that USP15 silencing led to significant downregulation of β-catenin and Wnt/β-catenin downstream genes (c-myc and cyclin D1), while overexpression of USP15 yielded the opposite results and USP15 mutation showed no change. Immunofluorescence indicated that USP15 promoted the nuclear translocation of β-catenin, suggesting activation of the Wnt/β-catenin signaling pathway, which may be the critical mechanism promoting GC progression. Finally, rescue experiments showed that the effects of USP15 on gastric cancer progression were dependent on the Wnt/β-catenin pathway.

Research conclusions

USP15 promotes cell proliferation, invasion, and EMT progression of GC *via* regulating the Wnt/β-catenin pathway.

Research perspectives

USP15 is expected to be a novel potential therapeutic target for GC.

Abstract

BACKGROUND

Prophylactic drains have been used to remove intraperitoneal collections and detect complications early in open surgery. In the last decades, minimally invasive gastric cancer surgery has been performed worldwide. However, reports on routine prophylactic abdominal drainage after totally laparoscopic distal gastrectomy are few.

AIM

To evaluate the feasibility performing totally laparoscopic distal gastrectomy without prophylactic drains in selected patients.

METHODS

Data of patients with distal gastric cancer who underwent totally laparoscopic distal gastrectomy with and without prophylactic drainage at China National Cancer Center/Cancer Hospital from February 2018 to August 2019 were reviewed. The outcomes between patients with and without prophylactic drainage were compared.

RESULTS

A total of 457 patients who underwent surgery for gastric cancer were identified. Of these, 125 patients who underwent totally laparoscopic distal gastrectomy were included. After propensity score matching, data of 42 pairs were extracted. The incidence of concurrent illness was higher in the drain group (42.9% *vs* 31.0%, $P = 0.258$). The overall postoperative complication rates were 19.5% and 10.6% in

the drain (n = 76) and no-drain groups (n = 49), respectively; there were no significant differences between the two groups (P > 0.05). The difference between the two groups based on the need for percutaneous catheter drainage was also not significant (9.8% *vs* 6.4%, P = 0.700). However, patients with a larger body mass index (≥ 29 kg/m^2) were prone to postoperative complications (P = 0.042). In addition, the number of days from surgery until the first flatus (4.33 ± 1.24 d *vs* 3.57 ± 1.85 d, P = 0.029) was greater in the drain group.

CONCLUSION

Omitting prophylactic drainage may reduce surgery time and result in faster recovery. Routine prophylactic drains are not necessary in selected patients. A prophylactic drain may be useful in high-risk patients.

Key Words: Gastric cancer; Prophylactic drainage; Totally laparoscopic gastrectomy; Enhanced recovery after surgery; Minimally invasive surgery; Early gastric cancer

Core Tip: We reviewed the outcomes of 125 consecutive patients with distal gastric cancer who underwent totally laparoscopic distal gastrectomy with and without prophylactic drainage at China National Cancer Center/Cancer Hospital from February 2018 to August 2019. We found that performing totally laparoscopic gastrectomy without prophylactic drains in selected patients is possible. It significantly improved postoperative comfort and did not increase the risk of postoperative complications.

INTRODUCTION

In the last decade, gastric cancer has been one of the most frequently occurring malignancies worldwide, with about one million new cases of gastric cancer in 2017. It is the fifth most common malignancy and the third highest malignant tumor, with an estimated 783000 deaths[1]. In China, there were approximately 677000 new gastric cancer cases in 2015. This accounted for half of the new gastric cancer cases worldwide [2].

In 1994, Kitano *et al*[3] reported the first case of laparoscopic assisted distal gastrectomy (LADG) with D2 lymphadenectomy[3]. A recent multi-center clinical study in South Korea also confirmed that the operation was safe and effective[4]. With the development of surgical instruments and technology, early minimally invasive gastric cancer surgery has been widely performed worldwide. Meanwhile, the interim results of a class 01 clinical trial led by China's Southern Hospital showed that the efficacy of laparoscopic surgery for advanced distal gastric cancer was comparable to that of open surgery[5].

The development of laparoscopic gastric cancer surgery has led to its emergence as a treatment modality for distal gastric cancer. Compared with laparoscopic assisted surgery, totally laparoscopic distal gastrectomy (TLDG) is an intra-cavitary anastomosis, which does not require an auxiliary small incision. The reconstruction of TLDG anastomosis is safer, regardless of tumor location, with a lower incidence of incision problems than LADG. Moreover, it can be performed more effectively in obese patients[6,7].

Prophylactic drains have been used to remove intraperitoneal collections and detect complications early. However, numerous trials have failed to demonstrate a reduction in postoperative complications by routine drainage in gastrointestinal surgery[8]. Several studies performed after open gastrectomy or LADG concluded that the prophylactic use of drains did not significantly improve postoperative outcomes.

because the analysis used anonymous clinical data that were obtained after each patient agreed to treatment by written consent.

However, there are few studies on routine prophylactic drainage after TLDG.

In the current retrospective study, we compared the outcomes of patients who underwent TLDG with and without drainage to clarify the value of routine prophylactic drainage in uncomplicated TLDG procedures for distal gastric cancer.

MATERIALS AND METHODS

Patients

We reviewed the outcomes of 457 consecutive patients with distal gastric cancer who underwent TLDG with and without prophylactic drainage at China National Cancer Center/Cancer Hospital from February 2018 to August 2019. Among them, 145 patients who underwent proximal gastrectomy or total gastrectomy, 159 patients who underwent laparoscopic assisted surgery, 23 who underwent open gastrectomy (including four cases converted from laparoscopic surgery), and five who underwent simultaneous surgery for other diseases such as choledocholithiasis (n = 1), ovarian tumor (n = 1), and pancreatic tail (n = 3) were excluded. Finally, a total of 125 patients were included in this study. They were assigned to a drain or no-drain group according to their operation records. The drain group comprised 76 patients who underwent TLDG with routine prophylactic drainage, and the no-drain group comprised 49 patients who underwent TLDG without routine prophylactic drainage (Figure 1).

Totally laparoscopic distal gastrectomy

The extent of gastrectomy and lymph node dissection were determined based on the Japanese gastric cancer treatment guidelines[9]. The surgeon was on the left side of the patient to finish laparoscopic ligation and division, and the first assistant was positioned on the opposite side. A cameraman stood between the patient' s legs. A five-port system (*i.e.*, two 5 mm and three 12 mm ports) was used for each totally laparoscopic distal gastrectomy. Ten-millimeter flexible laparoscopes were used, with CO_2 pressure maintained at 13-15 mmHg.

The operator was on the left side of the patient to perform Billroth-I reconstruction using a modified delta-shaped anastomosis[10] or overlap anastomosis[8]. Billroth-II or Roux-en-Y reconstruction was performed on the right side of the patients.

Postoperative management

Patients in both groups were administered prophylactic antibiotics 30 min before surgery. The decision of whether to use a prophylactic drain was made by the surgeon. Oral intake of water was initiated on the first day after surgery. A soft diet was initiated after the patient could tolerate liquid meals, and postoperative upper gastrointestinal contrast confirmed the absence of anastomotic leakage.

Outcome assessment

The clinical, operative, and pathological variables were compared between the two groups based on the information obtained from our prospectively collected surgical database. Early postoperative complications (occurring on postoperative days 0-30) were graded using the Clavien–Dindo classification. Early postoperative complications requiring medical, radiological, or surgical interventions (grade 2 or higher) were regarded as events. The risk for the occurrence of postoperative complications was also assessed.

Statistical analyses

All values are expressed as the mean ± SD. The χ^2 test and Student's t test were used to compare the categorical and continuous variables, respectively. For categorical data, the chi-squared test or Fisher's exact test was performed. A P value of < 0.05 was considered significant. Statistical analyses were performed using Statistic Package for Social Science. 20.

Propensity score matching

Multiple factor logistic regression models were used to calculate the propensity score for each patient to balance the following covariates: Age, sex, body mass index (BMI), abdominal operation history, smoking history, drinking history, concurrent illness, American Society of Anesthesiologists classification, operation time, estimated blood loss, primary tumor stage, regional lymph node stage, tumor size, and number of

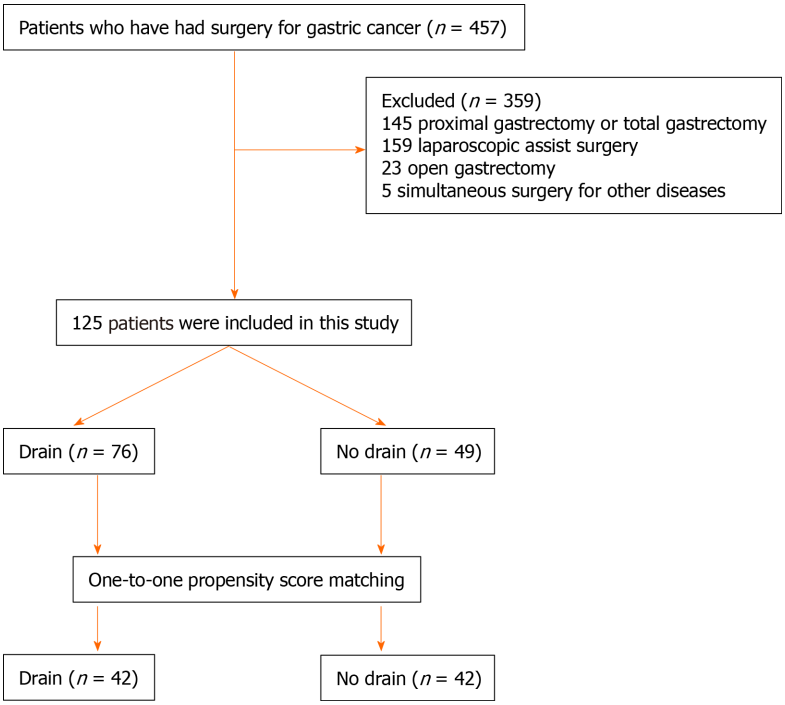

Figure 1 Flow chart of the patients assessed in this study.

retrieved lymph nodes. We imposed a caliper width of 0.1 of the standard deviation of the logistic propensity score.

RESULTS

Patient characteristics

Table 1 shows the clinical characteristics of patients undergoing TLDG with or without a prophylactic drain. No significant differences were observed in patient sex, age, BMI, American Society of Anesthesiologists classification, abdominal operation history, smoking history, drinking history, concurrent illness primary tumor stage, or regional lymph node stage between the two groups after propensity score matching (PSM).

Operative findings

The operative outcomes are summarized in Table 2. The drain group had a longer operating time than the no-drain group (198.4 ± 41.0 min *vs* 164.0 ± 37.0 min, $P < 0.001$). Mean estimated blood loss and intraoperative blood transfusion were similar between the two groups. There were no significant differences between the two groups in terms of the number of retrieved lymph nodes and tumor size ($P > 0.05$). After PSM, no significant differences were noted in operating time between the drain and no-drain groups.

Recovery

The recovery outcomes are listed in Table 3. The number of days from surgery to the initiation of soft diet (5.34 ± 2.27 d *vs* 4.17 ± 2.13 d, $P = 0.036$) and to first flatus (4.29 ± 1.45 d *vs* 3.55 ± 1.83 d, $P = 0.041$) were greater in the drain group. There were no significant differences in the time to ambulation or length of postoperative hospital stay (8.15 ± 2.9 d *vs* 6.77 ± 2.3 d, $P = 0.219$) between the two groups. Postoperative C-reactive protein levels (8.24 ± 4.47 mg/L *vs* 8.67 ± 5.97 mg/L, $P > 0.05$) and postoperative maximum body temperature (Tmax) (37.6 ± 0.6 ℃ *vs* 37.5 ± 0.4 ℃, $P > 0.05$) were similar between the two groups. After PSM, only the number of days from surgery to first flatus (4.33 ± 1.24 d *vs* 3.57 ± 1.85 d, $P = 0.029$) was greater in the drain group.

Short-time outcomes

Postoperative patient complications are listed in Table 4. No mortality was recorded in

either group. The overall postoperative complication rates were 15.8% and 10.2% in the drain and no-drain groups, respectively ($P > 0.05$). No anastomotic bleeding, anastomotic leakage, lymph leakage, ileus, or pancreatic fistula occurred in either group. Clavien-Dindo grade 3 complications included duodenal stump leakage ($n = 2$), anastomotic leakage ($n = 2$), intra-abdominal abscess ($n = 2$), and intra-abdominal bleeding ($n = 1$) in the drainage group. The need for percutaneous catheter drainage (PCD) was not significantly different between the groups (9.8% *vs* 6.4%, $P = 0.700$). After PSM, no significant differences were noted in the complications between the drain and no-drain groups.

Risk assessment for the occurrence of postoperative complication

Postoperative complication risk factors are listed in Table 5. Between the two groups,

PCD: Percutaneous catheter drainage.

no significant differences were observed in most variables. However, the patients with a larger BMI had a higher possibility of postoperative complications (27.44 ± 3.92 *vs* 24.25 ± 3.53, $P = 0.01$). In addition, we identified that patients with a BMI ≥ 29 kg/m^2 were prone to postoperative complications ($P = 0.042$). A prophylactic drain may be useful in patients with a higher risk, larger BMI, or more concurrent illness. Prophylactic drains was not an independent risk factor for postoperative complications.

DISCUSSION

Since 2015, totally laparoscopic surgery has been widely used in clinical practice, although there are few reports on whether totally laparoscopic surgery requires prophylactic drains[10,11]. Most studies on prophylactic drains were based on open gastrectomy. Cochrane review included four single-institution, randomized controlled trials that sought to evaluate the role of prophylactic drain placement in gastric resection for gastric cancer[12-14]. In this study, we reviewed the clinicopathological data of patients with gastric cancer during the past 2 years and found that routine prophylactic drains were not necessary in selected patients. To minimize the risk of confounding variables, PSM was used. Routine prophylactic drains are not necessary in all patients. A prophylactic drain may be useful in patients at higher risk.

Table 5 Risk assessment for the occurrence of postoperative complication

Variable	Postoperative complications (+) (*n* = 17)	Postoperative complications (-) (*n* = 108)	*P* value
Sex			0.584
Male	13	74	
Female	4	34

Prophylactic drains have been used to enhance early detection of complications, prevent collection of fluid, reduce morbidity and mortality, and decrease the duration of hospital stay[15,16]. The present study results showed that there was no significant difference between the two groups in terms of postoperative hospital stay. The length of the postoperative hospital stay in the no-drain group was shorter than that in the drain group (7.93 ± 4.98 d *vs* 6.81 ± 5.50 d, $P > 0.05$). Among the 17 patients who experienced postoperative complications, there was also no significant difference between the two groups in terms of postoperative hospital stay. This result was different from that of Hirahara *et al*[10] study. In addition, omitting prophylactic drainage significantly improved the postoperative comfort of patients due to an earlier flatus (4.33 ± 1.24 d *vs* 3.57 ± 1.85 d, $P < 0.05$).

Moreover, the application of prophylactic drains did not reduce the incidence of complications, and the rate of complications was even higher in the drain group. However, there was no statistically significant difference between the two groups (19.0% *vs* 9.5%, $P > 0.05$). Through risk assessment, we identified that patients with a BMI ≥ 29 kg/m^2 are prone to postoperative complications ($P = 0.042$). More visceral fat may make surgery more difficult. Thus, prophylactic drain is recommended for patients with a BMI > 29 kg/m^2.

For patients with mild symptoms, administration of broad-spectrum antibiotics may be a good conservative management strategy. However, patients with severe symptoms need PCD. In the current study, postoperative complications were recognized in approximately 15% of patients. Two cases of duodenal stump leakage and two cases of intra-abdominal abscess occurred in the drain group, all of which required PCD. In the no-drain group, two cases of intra-abdominal abscess and one case of pleural effusion needed PCD. There was no significant difference between the two groups. Prophylactic drains do not alter the rates of secondary drainage procedures. Thus, omitting prophylactic drains during gastric cancer surgery did not increase the risk of PCD postoperatively. Similarly, in a study by Lee *et al*[16], omitting prophylactic drains did not increase the risk of PCD postoperatively, while male sex, older age, and longer operative time were identified as independent risk factors for postoperative PCD in patients without prophylactic drains.

CONCLUSION

In conclusion, omitting the use of prophylactic drains in selected patients during surgery for gastric cancer is feasible. It can significantly improve the postoperative comfort of patients and does not increase the risk of postoperative complications.

ARTICLE HIGHLIGHTS

Research background

Prophylactic drains have been used to remove intraperitoneal collections and detect complications early in open surgery. In the last decades, minimally invasive gastric cancer surgery has been performed worldwide. However, reports on routine prophylactic abdominal drainage after totally laparoscopic distal gastrectomy are few.

Research motivation

To evaluate the feasibility of performing totally laparoscopic distal gastrectomy without prophylactic drains in selected patients.

Research objectives

To evaluate the feasibility of performing totally laparoscopic distal gastrectomy without prophylactic drains in selected patients.

Research methods

Data of patients with distal gastric cancer who underwent totally laparoscopic distal gastrectomy with and without prophylactic drainage at China National Cancer

Center/Cancer Hospital from February 2018 to August 2019 were reviewed.

Research results

After PSM, data of 42 pairs were extracted. The incidence of concurrent illness was higher in the drain group (42.9% *vs* 31.0%, P = 0.258). The overall postoperative complication rates were 19.5% and 10.6% in the drain (n = 76) and no-drain groups (n = 49), respectively; there were no significant differences between the two groups (P > 0.05). The difference between the two groups based on the need for percutaneous catheter drainage was also not significant (9.8% *vs* 6.4%, P = 0.700). However, patients with a larger body mass index (≥ 29 kg/m^2) were prone to postoperative complications (P = 0.042). In addition, the number of days from surgery until the first flatus (4.33 ± 1.24 d *vs* 3.57 ± 1.85 d, P = 0.029) was greater in the drain group.

Research conclusions

Omitting prophylactic drainage may reduce surgery time and result in faster recovery. Routine prophylactic drains are not necessary in selected patients. A prophylactic drain may be useful in high-risk patients.

Research perspectives

Omitting the use of prophylactic drains can significantly improve the postoperative comfort of patients and does not increase the risk of postoperative complications.

Abstract

The coronavirus disease 2019 (COVID-19) pandemic has greatly impacted health systems. Many guidelines on chronic liver diseases have been released to optimize the use of medical resources and patient management. However, most of these guidelines have been established through expert consensus because the existing data do not provide strong evidence for developing effective recommendations. As Wilson disease (WD) is a rare chronic liver disease, the impact of COVID-19 on the clinical status of patients with WD is unclear. The present study showed a marked shortage of medical resources for clinically managing patients with WD during the pandemic. Although patients with WD who consistently took anticopper therapy showed no significant differences in hepatic and extrahepatic markers before and after the pandemic, their complication incidences, especially the infection incidence, were significantly increased during the study period. Therefore, patients with WD should be encouraged to adhere to anticopper therapy and be closely monitored to prevent infections and other complications. The present study provides a clinical basis for further managing WD during the pandemic.

Core Tip: The coronavirus disease 2019 (COVID-19) pandemic has had a long-lasting impact on the quality of care for patients with cirrhosis. Although many guidelines have been released for the rational use of medical resources, few clinical data are available to support these guidelines. The clinical features of patients with Wilson disease during the COVID-19 pandemic remain unclear. We compared the clinical features of patients with Wilson disease before and after the pandemic to clarify the impact of COVID-19 on these patients and provide a basis for their clinical management.

URL: https://www.wjgnet.com/1007-9327/full/v27/i26/4248.htm
DOI: https://dx.doi.org/10.3748/wjg.v27.i26.4248

TO THE EDITOR

Many countries have enforced social distancing and strict stay-at-home strategies to reduce the spread of coronavirus disease 2019 (COVID-19). However, these measures often negatively affect patients with other diseases[1,2]. Many guidelines on chronic liver diseases have been released to optimize the use of medical resources and patient management[3]. Most of these guidelines have been established through expert consensus because the existing data do not provide strong evidence for developing effective recommendations.

Given the high copper deposition in the livers of patients with Wilson disease (WD), these patients often develop liver injury and cirrhosis. Because WD has clinical features that are distinct from those of liver diseases caused by other etiologies and medical resources have been in short supply during the pandemic, the clinical features of patients with WD should be examined to improve their management. Therefore, we conducted a before–after study to investigate the clinical features of these patients before and during COVID-19.

We reviewed the medical records of patients with WD who were hospitalized for routine office visits or emergency visits at the First Affiliated Hospital of Guangdong Pharmaceutical University from 1 January 2018 to 3 September 2020. In China, the diagnostic criteria for WD are similar to those of the diagnostic scoring system for WD. During the COVID-19 pandemic, the number of WD inpatient visits dropped from 198 to 95, indicating a 52.02% decrease from the number of WD inpatient visits during the same period in 2019. These data indicate that the ongoing pandemic has led to a marked shortage of medical resources for clinically managing patients with WD. Medical data on 68 patients with WD who were hospitalized at our hospital during and before the pandemic were analyzed. All of these patients underwent anticopper therapy during the pandemic. Most of them (83.82%) had developed cirrhosis before the pandemic, and none had COVID-19.

The hepatic and extrahepatic status of patients who consistently used anticopper therapy during the pandemic did not significantly deteriorate (Table 1). However, owing to lifestyle changes and delayed screening for complications during the pandemic, the complication incidence increased significantly in these patients during the study period (23.53% *vs* 11.76%, $P = 0.021$). Notably, most complications (22/24) occurred in patients with WD-associated cirrhosis. Among the complications, infections were the most prevalent (11.8% *vs* 1.5%, $P = 0.016$). Although the community mitigation measures for COVID-19 are thought to reduce the incidence of respiratory infections in the general population[4], our data showed that the incidence of respiratory infections in patients with WD increased during the pandemic (7.4% *vs* 0%, $P = 0.063$).

Following the COVID-19 outbreak, the Chinese government implemented strong strict measures, and most citizens, except those involved in essential services, were ordered to stay at home. These measures helped keep the pandemic under control in China. However, the lockdown and movement restrictions often led to reduced physical activity, prolonged sedentary behaviors, imbalanced nutritional intake, poor mental health and delayed routine follow-up visits in these patients[5]. These changes were associated with cirrhosis-associated immune dysfunction and accounted for the

high infection risk[6].

In conclusion, the hepatic and extrahepatic status of patients with WD who adhered strictly to their anticopper therapy during the COVID-19 pandemic did not significantly worsen, but the complication incidence — especially the infection incidence — increased significantly. Therefore, patients with WD should be encouraged to adhere

to anticopper therapy and be closely monitored to prevent infections and other complications.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Intrahepatic cholangiocarcinoma (iCCA) is a subgroup of cholangiocarcinoma that accounts for about 10%-20% of the total cases. Infection with hepatitis B virus (HBV) is one of the most important predisposing factors leading to the formation of iCCA. It has been recently estimated based on abundant epidemiological data that the association between HBV infection and iCCA is strong with an odds ratio of about 4.5. The HBV-associated mechanisms that lead to iCCA are under intense investigation. The diagnosis of iCCA in the context of chronic liver disease is challenging and often requires histological confirmation to distinguish from hepatocellular carcinoma. It is currently unclear whether antiviral treatment for HBV can decrease the incidence of iCCA. In terms of management, surgical resection remains the mainstay of treatment. There is a need for effective treatment modalities beyond resection in both first- and second-line treatment. In this review, we summarize the epidemiological evidence that links the two entities, discuss the pathogenesis of HBV-associated iCCA, and present the available data on the diagnosis and management of this cancer.

both in terms of epidemiology and pathogenesis. Moreover, the potential for the development of the combined hepatocellular-cholangiocarcinoma form poses additional difficulties in the successful management of iCCA. Herein, we discuss the available epidemiological data, present the current knowledge on the pathogenesis of HBV-associated iCCA, and review all of the available information on the diagnosis and management of this aggressive cancer.

INTRODUCTION

A 61-year-old woman with compensated liver cirrhosis due to chronic hepatitis B (CHB) presented to the outpatient clinic of our hospital for her semi-annual evaluation. She had started antiviral treatment with entecavir (0.5 mg per day) approximately 2 years prior. Her family history is significant for hepatocellular carcinoma (HCC), as her twin brother also suffered from liver cirrhosis due to CHB. On physical examination, no signs of liver decompensation were detected. Her liver synthetic function and alpha fetoprotein (aFP) value were completely normal. However, a small (1.8 cm) liver nodule with arterial enhancement was discovered in the left hepatic lobe during magnetic resonance imaging (MRI) (Figure 1). Hence, the patient underwent left hepatectomy without complications. Surprisingly, histological examination of the surgical specimen revealed a definite intrahepatic cholangiocarcinoma (CCA) (Figure 2).

This case vignette highlights the possible association between hepatitis B virus (HBV) infection and intrahepatic CCA (iCCA). iCCA is a subgroup of CCA that accounts for about 10%-20% of the total cases and classically arises above the second-order bile ducts[1]. iCCA was recently recognized as a distinct entity opposed to the extrahepatic type of CCA (eCCA)[2]. Several predisposing factors that contribute to the development of CCA have been described. A recent meta-analysis clearly showed that the degree to which these risk factors are associated with the development of this cancer significantly differ according to the tumor location[3]. Specifically for HBV infection, the odds ratio (OR) for the development of CCA is much greater for iCCA than for eCCA (4.57 *vs* 2.11). In view of these findings, several questions regarding this association arise such as how accurately can we distinguish between HCC and iCCA; what are the mechanisms that lead to the formation of iCCA; is there is a specific role for HBV in iCCA; and finally, can antiviral treatment against HBV reduce the incidence of iCCA. In this review, we summarize the epidemiological evidence that links the two entities, discuss the pathogenesis of HBV-associated iCCA, and present the available data on the diagnosis and management of this aggressive cancer.

EPIDEMIOLOGICAL STUDIES OF HBV-ASSOCIATED ICCA

To identify relevant epidemiological studies from geographically diverse regions, a comprehensive literature search of PubMed was conducted up to December 2020 without language restrictions. Studies were eligible for inclusion if they met the following criteria: were case-control or cohort study design, reported outcomes for the association between HBV infection and iCCA, and provided risk estimates with 95% confidence intervals (CIs) or sufficient data to calculate them. The following Medical Subject Headings were included: "intrahepatic cholangiocarcinoma" and "HBV." Reference lists of the retrieved articles were also manually searched to identify additional studies.

The literature search identified a total of 417 references, of which 20 case-control[4-23] and 2 cohort studies[24,25] fulfilled the inclusion criteria (Table 1). The population of the included epidemiological studies originated not only from geographical regions of high or intermediate prevalence of cholangiocarcinoma (*i.e.* Thailand, South Korea,

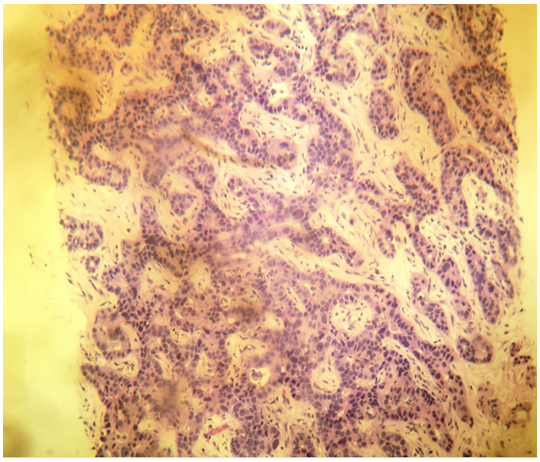

Figure 2 Histological findings typical of cholangiocarcinoma.

Twenty case-control studies were included (seven from Mainland China[9-12,14,15,18], six from the United States[4,5,8,13,19,21], three from South Korea[7,17,20], two from Taiwan area of China[6,16] and one each from Japan[22] and Italy[23]), involving 14899 patients and 681258 cases. Notably, only 4 of the 20 retrieved studies were published in the last 5 years. Population-based controls were employed in 3 studies from the United States[4,13,21] and 1 from Mainland China[9] and the Taiwan area of China[6], whereas the remaining 15 studies were hospital-based. HBV infection status was defined by the presence of hepatitis B surface antigen (HBsAg) in 15 studies[5,7,8,10-12,14-20,22,23] and by international classification of diseases-9 coding in 5 studies[4,6,9,13,21]. Seropositivity of hepatitis B core antibody (HBcAb) was assessed in five studies[10-12,14,19]. All of the included case-control studies reported adjustments for age and gender. Fourteen studies showed a statistically significant association between HBV infection and risk of iCCA (range of individual OR = 2.23-12.9)[4-7,9-18], whereas the rest of the studies (n = 6) did not[8,19-23]. These six studies were concluded prior to 2002 in geographically different areas. Geographical variations in iCCA incidence may be explained by differences in environmental and genetic risk factors. Moreover,

observational studies are difficult to control for confounders, which could present an important risk factor and influence the prognostic value of HBV infection in iCCA.

Two large-scale cohort studies with a total of 1937215 participants evaluating the correlation between HBV infection and iCCA were identified (Table 1). A retrospective cohort study from Japan involved 154814 blood donors with a median follow-up period of 7.6 years and reported an iCCA incidence rate of 0.88 per 100000 person-years[24]. Compared with individuals negative for both HBsAg and hepatitis C virus antibody (anti-HCV), those who tested positive for HBsAg had a significantly higher risk of iCCA (hazard ratio [HR] = 8.56; 95%CI: 1.33-52.20). The latter study from Taiwan area of China included a cohort of 1782401 pregnant women with a median follow-up of 6.91 years and reported 18 cases of iCCA[25]. Women seropositive for HBsAg had significantly increased incidence rates of iCCA (0.43 per 100000 person-years) than HBsAg-negative women (0.09 per 100000 person-years) with an age-adjusted hazard ratio HR = 4.80; 95%CI: 1.88-12.20.

Occult HBV infection (OBI), which is defined by the detection of HBV DNA in the serum and liver tissue of HBsAg-negative individuals with or without serological markers of previous viral exposure[28], is an emerging risk factor for iCCA. HBV maintains its pro-oncogenic properties in patients with OBI[29]. Indeed, epidemiological and molecular studies have indicated that OBI represents an important risk factor for the development of cirrhosis and HCC[30,31]. Relevant evidence from pathological studies, investigating the presence of HBV DNA, genes, and proteins in iCCA tissue specimens, also suggests a possible etiological role of OBI in iCCA[32-34]. A case-control study of 183 cryptogenic iCCA patients and 549 healthy individuals confirmed that HBsAg seroclearance does not signify eradication of HBV and may not entirely prevent the development of iCCA in Chinese patients[32]. Pollicino *et al*[33] investigated the presence of HBV DNA in liver tissue specimens from 47 HBsAg-negative patients with iCCA and 41 paired non-tumor liver tissues. A high prevalence of OBI in iCCA patients, along with the presence of both free viral genomes and integrated HBV DNA in the tumor tissue, suggested an involvement of HBV in the carcinogenesis of iCCA not only in overt but also in occult infection[33].

To date, there are limited data on the relationship between iCCA and HBV genotype. Barusrux *et al*[35] investigated the prevalence of HBV and HCV infection among 295 CCA patients in northeast Thailand[35]. In this study, HBV genotypes C (73.3%) and B (26.7%) were detected, in line with the HBV genotype distribution in Thailand[36]. In a cohort of 11 cases of iCCA in the eastern United States, liver specimens were examined for HBV DNA and HCV RNA and the genotypes observed represented the dominant genotype (genotype A) in this area[37]. Currently, there is no sufficient evidence to support an etiological association between specific HBV genotypes and iCCA.

Meta-analyses of HBV-associated iCCA

To address the inconsistent results reported in previous epidemiological studies, an overview of the most comprehensive meta-analyses exploring the association between HBV infection and iCCA is provided (Table 2). A total of six systematic reviews and meta-analyses were retrieved[3,38-42], two of which focused on the risk factors of iCCA alone[41,42]. The remaining studies assessed HBV infection as a sole factor or among other risk factors for both iCCA and eCCA[3,38-40]. Of these, two meta-analyses were published in 2020 (one from the United Kingdom[3] and the other from China[38]), one in 2016 from China[39] and three in 2012 (two from China[40,42] and one from the United States[41]). In four meta-analyses, the population of the primary epidemiological studies originated from both Eastern and Western countries[3,40-42], whereas the remaining two meta-analyses included studies only from Asia[38,39]. The period of data collection among these primary studies ranged from 1987 to 2014.

All of the included meta-analyses suggested that HBV infection was significantly associated with an increased risk of iCCA (range of pooled OR = 3.17-5.98)[3,38-42]. A moderate to severe degree of statistical heterogeneity was noted across the primary epidemiological studies, as assessed by Cochran's Q and I^2 statistic (Table 2). Publication bias was identified in two meta-analyses[38,42].

To the best of our knowledge, the most up-to-date systematic review and meta-analysis were performed by Clements *et al*[3] in 2020. A total of 13 risk factors, including HBV, were evaluated for iCCA and eCCA. Eighteen case-control studies were included to study the association between HBV and iCCA. The pooled risk estimate (OR = 4.57; 95%CI: 3.43-6.09) showed a statistically significant increased risk of iCCA with HBV infection. Furthermore, meta-regression analysis indicated that in Eastern countries, HBV conferred a greater risk of iCCA than in Western countries. Similar geographical differences for the association of HBV with iCCA have been

Table 2 Summary of meta-analyses evaluating hepatitis B virus infection as a risk factor for intrahepatic cholangiocarcinoma

Ref.	Number of included studies	Data collection period	Regions	Cases	Controls	Pooled OR (95%CI) for HBV infection	Heterogeneity	Publication bias
Clements *et al*[3], 2020	Case-control = 18	1991-2014	Eastern = 12. Western = 6	14825	681181	4.57 (3.43-6.09)	I^2 = 83% Q = 100.88 (P < 0.001)	Funnel plot: Symmetrical. No bias
Tan *et al*[38], 2020	Case-control = 6	1998-2013	Eastern = 6	3623	13597	5.98 (4.08-8.76)	I^2 = 69% Q = 16.01 (P = 0.07)	Funnel plot: Relatively symmetrical. Moderate bias
Zhang *et al* [39], 2016	Case-control = 11	1991-2013	Eastern = 11	4966	17752	3.18 (2.35-4.30)	I^2 = 84% Q: P < 0.001	Begg's test: P = 0.75, Egger's test: P = 0.42. No bias
Li *et al*[40], 2012	Case-control = 11. Cohort = 2	1991-2008	Eastern = 10. Western = 3	2402. NA	96266. NA	3.42 (2.46-4.74)	I^2 = 75% Q = 48.37 (P < 0.001)	Funnel plot: Symmetrical Begg's test: P = 0.70, Egger's test: P = 0.26. No bias
Palmer *et al* [41], 2012	Case-control = 8	1991-2008	Eastern = 5. Western = 3	2753	291756	5.54 (3.19-9.63)	I^2 = 86.3% Q = 51.2 (P < 0.001)	Funnel plot: Symmetrical. No bias
Zhou *et al* [42], 2012	Case-control = 12. Cohort: = 2	1987-2009	Eastern = 11. Western = 3	2362. NA	96452. NA	3.17 (1.88-5.34)	I^2 = 81% Q: P < 0.001	Funnel plot: Asymmetry. Moderate bias

Statistical heterogeneity was assessed by the Cochran's Q statistic and I^2 statistic. Significant heterogeneity is considered if Q: P < 0.10 or I^2 > 60%. Publication bias was evaluated using the Begg's funnel plot and Egger's test with P < 0.10 as an indication of publication bias. CI: Confidence interval; HBV: Hepatitis B virus; ICC: Intrahepatic cholangiocarcinoma; NA: Not applicable; OR: Odds ratio.

reported by Li *et al*[40], however Palmer and Patel[41] did not reveal any significant difference between Eastern and Western populations.

PATHOGENESIS OF HBV-ASSOCIATED ICCA

Cholangiocarcinoma is a multifactorial heterogeneous disease of diverse predisposing factors. However, regardless of underlying etiology, chronic inflammation seems to be a common denominator of most risk factors for CCA as they are usually associated with inflammation or cholestasis. Chronic inflammation leads to increased production of a multitude of inflammatory mediators such as interleukin-6 (IL-6), tumor necrosis factor (TNF), cyclooxygenase-2, and Wnt, resulting in an "activated" environment favoring successive mutations of tumor suppressor genes, and other oncogenes. Other mediators found to be upregulated in CCA include transforming growth factor beta (TGF-β), vascular endothelial growth factor, hepatocyte growth factor, and several microRNAs[43]. Most of those changes promote angiogenesis and cell proliferation.

In particular, liver cirrhosis regardless of etiology represents an inflammatory process that is clearly associated with the development of iCCA. Several population-based studies have confirmed cirrhosis as an important risk factor not only for HCC but also for iCCA[44]. A meta-analysis found that cirrhosis causes iCCA with an OR as high as 22[41]. Furthermore, a retrospective analysis of United States-based Surveillance, Epidemiology, and End Results found that cirrhosis is associated with both iCCA (OR 8.26) and eCCA (OR 3.83)[4]. As chronic infection with HBV and HCV account for most cases of cirrhosis globally, it is not surprising that a definite association between viral hepatitis infection and iCCA has been observed. A large metanalysis produced an OR for iCCA of 3.17 and 3.42 for HBV and HCV, respectively [42]. A distinct phenotype of viral hepatitis-related iCCA that more frequently affects younger males and is characterized by mass-forming tumors with cholangiolar differentiation, higher aFP, lower carbohydrate antigen (CA) 19-9 levels and higher N-cadherin expression has been suggested[12,45,46]. Such tumors are more commonly associated with cirrhosis or elevated prothrombin time. Recent studies have suggested that HBV-associated iCCA displays infrequent nodal metastases and confers better a prognosis, whereas patients with CCA associated with HCV may fare worse[47,48]. In addition, viral hepatitis-associated CCA more frequently expresses programmed death-ligand 1 (PD-L1), which in theory may be exploited for the development of immunotherapy strategies[49].

Inflammation is a multifactorial and diffuse process. It involves multiple pathways acting through diverse mechanisms in an environment conducive of proliferation and oncogene mutations leading to malignant transformation. As a result, there has been no single molecular alteration characteristic of CCA. IL-6, a strong proinflammatory cytokine has a pleiotropic role, by increasing cell proliferation through activation of the Janus kinase-signal transducer and activator of transcription pathway; it also promotes expression of antiapoptotic myeloid leukemia cell differentiation protein and the activation of both the Akt and mitogen-activated protein kinase kinase (MEK)-extracellular signal-related kinase (ERK) pathways, which results in strong proliferative and anti-apoptotic effects[50-52]. In such an activated environment, increased DNA instability may lead to critical genetic alterations of the excited cells, and also increases the probability of mutations of important genes such as tumor suppressor gene p53 and the MYC proto-oncogene, among others[53]. The DNA instability is at least partially attributable to the effect of TNF-α, which among others, causes the upregulation of activation-induced cytidine deaminase, an enzyme that can create DNA mutations by converting cytosine to uracil.

In addition to the inflammatory changes caused in the liver tissues by the continuous presence of the virus, it seems that hepatitis viral components may act as oncogenes and promote oncogenicity *per se*. In particular, hepatitis B x (HBx) protein has been implicated in carcinogenesis. Experiments with transgenic mice have demonstrated that its expression enhances IL-6-dependent proinflammatory effects and causes malignant transformation towards both HCC and CCA[54].

The presence of HBV genes in the genome of CCA has been described. Although the exact effect on tumorigenesis is unknown, the observed proximity of the insertion sites to the gene encoding the tumor suppression p53 is intriguing. Wang *et al*[55] using *in situ* hybridization demonstrated the presence of HBV genes in 33 of 40 iCCA cases tested; the most common gene found was again HBx[55]. In a study by Pollicino *et al* [33] employing a PCR technique, incorporation of HBV genes in patients with iCCA and no overt viral infection was detected in tumor or non-tumorous liver cells in 29 of the 47 examined cases, suggesting the importance of occult viral infection in the development of CCA. Most cases involved the HBx gene.

Expression of the culprit HBx gene may be documented by immunohistochemistry in about 70% of patients with iCCA and correlates with peripheral tumors and higher aFP levels, but the exact percentage obviously depends on the epidemiology of the tested population[56]. Co-expression of HBx and HCV core proteins in transgenic zebra fish livers induces fibrosis and iCCA[57], and is associated with activation of the phosphorylated Smad3L oncogenic pathway with consequent phosphorylation and activation of MEK-ERK proteins. Bile duct proliferation, fibrosis, and iCCA were markedly reduced by knockdown of TGF-β, suggesting the important role of this mediator. Semaphorine 3B is a recently identified tumor suppressor gene encoded on chromosome 3p21.3 and is connected to p53 activity. Silencing of the locus due to gene or promoter hypermethylation or loss of homozygosity was detected in several CCA tumor cells, and as expected, was associated with the downregulation of mRNA transcripts[43].

These dysregulations result in a broad variety of somatic mutations that have been recently identified using next-generation sequencing, some of which impair the function of known oncogenes. Almost any gene implicated in carcinogenesis is abnormal in CCA, attesting to the heterogeneity of the disease and the lack of a pathognomonic driver mutation[58]. Thus, KRAS mutations may affect 20% of CCA. Mutations of isocitrate dehydrogenase 1 (IDH1) and IDH2 genes occur in approximate 20% of iCCA. IDH1 and IDH2 genes encode for enzymes active in the citric acid cycle (Krebbs cycle), and their loss of function mutations results in accumulation of an abnormal oncometabolite R-2-hydroxyglutarate which interferes with the function of several pathways and causes epigenetic DNA changes. Other alterations of iCCA include fibroblast growth factor receptor 2 (FGFR2) mutations. Translocation or amplification of the FGFR2 locus is found in 19% of 122 iCCA patients[59]. Tumors of such patients tend to be of the mass-forming type and compared to non-FGFR2 altered tumors, they secrete less mucus and are more commonly associated with HBV infection.

Although some of these alterations appear to be important for the malignant behavior of the tumor, they may not represent the initiating transforming event, which should be sought earlier in the pathogenesis of iCCA. There is enough evidence to suspect that chronic, overt or occult, infection with hepatitis virus may trigger the transformation of infected cells in the context of a conducive, inflammatory environment. Of the various HBV genes, evidence suggests that HBx plays the most crucial role. HBx protein promotes cell cycle progression, inactivates negative growth

regulators, and binds to and inhibits expression of the p53 tumor suppressor gene, other tumor suppressor genes, and senescence-related factors[60]. It appears that some of these actions are mediated through overexpression of telomerase (hTERT) mainly by interfering with its promoter. Thus, the importance of HBx was demonstrated in an experiment involving HCC cell lines, whereby transfection with HBx resulted in the overexpression of hTERT a factor important for the non-senescence of transformed cells[61]. Using current sequencing technology, it appears that the integration of viral sequences to human DNA tends to aggregate in the vicinity of the telomerase gene, although other sites of viral gene insertion of unclear significance have been observed [62]. Interestingly, HBV gene insertions (hepatitis B S and/or C gene fragments) have also been noted in the normal hepatocytes of patients, albeit at reduced frequency. The capacity of HBx gene insertion to directly promote the expression of TERT was demonstrated in a direct transfection experiment in CCA cell lines; HBx gene resulted in cis-activation of TERT mRNA transcription[46]. Figure 3 summarizes the potential pathological mechanisms that lead to carcinogenesis in patients with hepatitis B.

It can be concluded that mounting evidence supports the theory that chronic, overt, or latent infection with HBV has direct causative effects on the development not only of HCC but also of iCCA, perhaps by acting on a common progenitor cell. The effect of certain viral genes, such as HBx, seems to have direct oncogenic capacity beyond the genetic instability produced by the chronic inflammation, perhaps aided by the latter. These observations support the epidemiologic data linking CHB to the development of iCCA and call for further studies to fully reveal the intricate interaction of the virus with the cellular mechanisms leading to carcinogenesis.

CLINICAL PRESENTATION

Patients with iCCA usually present with unspecific symptoms such as abdominal pain, malaise, night sweats, and cachexia[63]. Jaundice is usually a sign of advanced disease. In particular, patients with HBV-associated iCCA can be diagnosed before they develop any symptoms, due to the fact that they undergo annual or semi-annual surveillance for HCC, which enables iCCA diagnosis at a relatively early stage[64].

DIAGNOSIS

Imaging techniques

Imaging modalities, such as computed tomography (CT), MRI, and fluorodeoxy-glucose positron emission tomography (FDG-PET) can be of great value in the management of iCCA in terms not only of diagnosis but also of staging, follow-up, and assessment of treatment response.

CT scan serves as the standard imaging method for the preoperative assessment of iCCA. It provides a comprehensive evaluation of the primary tumor, the relationship between the primary tumor and adjacent structures such as the hepatic artery or portal vein, and the whole abdomen surveillance for potential metastases[65]. On both contrast-enhanced CT and MRI scans, iCCA usually presents as a mass with irregular borders, peripheral rim enhancement on the arterial phase with progressive homogeneous contrast agent uptake until the delayed or stable uptake during late dynamic phases[66,67]. However, smaller tumors are less likely to demonstrate these characteristics and may be hard to distinguish from HCC, especially in the context of chronic liver diseases.

The utility of FDG-PET for iCCA diagnosis and management is still controversial. Although mass-forming iCCA can be detected with a reported sensitivity of 85% to 95%, it cannot be used for the diagnosis of iCCA as it is not specific enough[68]. However, it could prove useful in detecting distal, unexpected metastases. In fact, a recent meta-analysis suggested that it can bring changes to the management of a substantial portion of iCCA patients[69]. Therefore, it could be considered an option prior to surgical resection (SR) to rule out distant metastatic foci.

Serum markers

Tumor markers in serum are not specific for iCCA, but may be of diagnostic value in some cases. Widely used tumor markers such as CA 19-9 and carcinoembryonic antigen have significant overlap with other cholestatic diseases and low sensitivity for early stage disease, consequently limiting their use[70]. However, high values of these

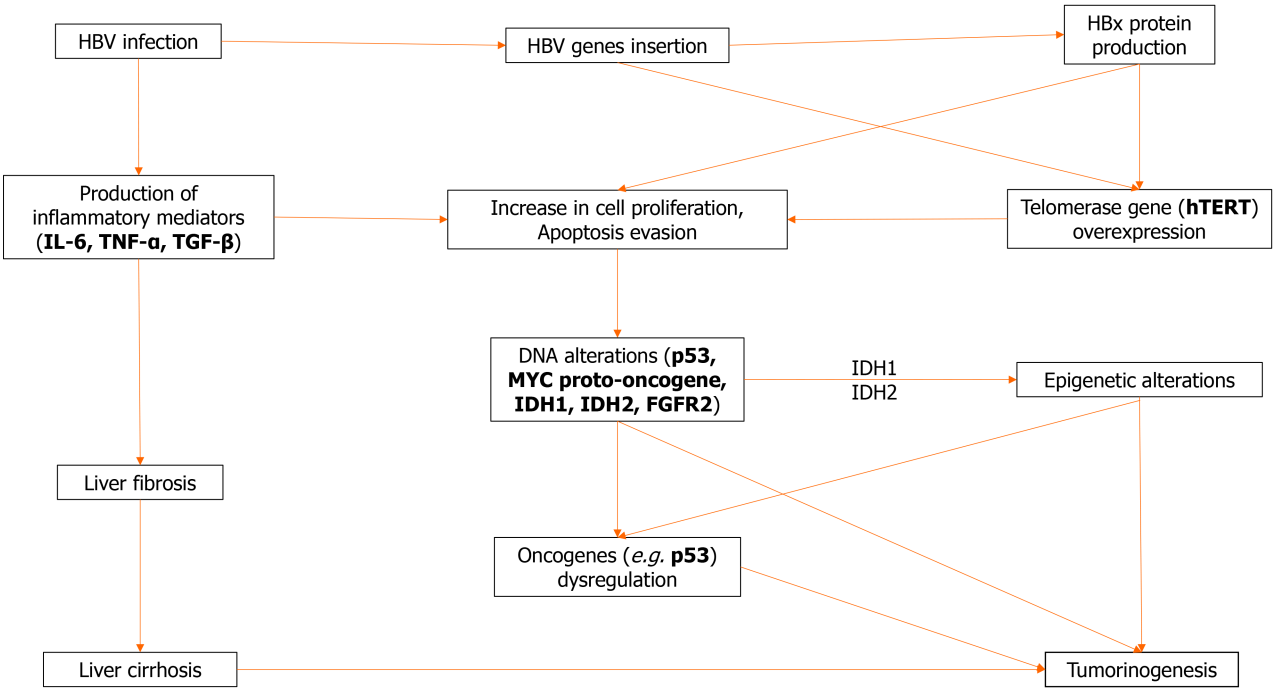

Figure 3 Pathological mechanisms that lead to tumorigenesis in patients with hepatitis B virus infection. FGFR: Fibroblast growth factor receptor; HBV: Hepatitis B virus; IDH: Isocitrate dehydrogenase; IL-6: Interleukin 6; TGF-β: Transforming growth factor β; TNF-α: Tumor necrosis factor α.

markers have been connected with a deterioration in overall survival (OS)[71,72]. As a result, high (> 500 ng/mL) levels of CA 19-9 in the absence of jaundice are considered a relative contraindication for resection of iCCA[73].

However, in cases of HBV-associated iCCA, these markers tend to be even less sensitive[48]. Instead, it has been suggested that such patients tend to have higher levels of aFP, a serum marker widely used for HCC diagnosis, probably because of the fact that both malignancies originate from hepatic progenitor cells, which have the ability to produce aFP[16,46,74,75].

Histological diagnosis

Pathological diagnosis is recommended for all patients who will undergo systemic chemotherapy or radiation therapy, or take part in a therapeutic clinical trial[68,76]. It should be noted that although a positive result demonstrates the presence of the tumor, a negative result does not exclude it because of the potential sampling errors. In such cases, repeat sampling is often required to confirm the correct diagnosis[77].

According to the World Health Organization (WHO) classification for biliary tract cancer[78], iCCA can be further classified to two main subtypes according to the level or size of the affected duct; large duct type, which resembles eCCA and small duct type, which shares etiological, pathogenetic, and imaging characteristics with HCC and usually develops on a background of chronic liver disease (such as chronic viral hepatitis and cirrhosis)[58]. Small bile duct iCCA presents as a tubular or acinar adenocarcinoma with nodular growth invading the liver parenchyma, and with no or minimal mucin production[79-81]. Characteristic findings of small bile duct iCCA are IDH1 and IDH2 mutations or FGFR2 fusions or translocations[80-82]. In HBV-associated iCCA, there are data indicating the presence of hyperactivated programmed cell death protein 1/PD-L1 signaling and increased expression of N-cadherin and HBx protein[45,49,56]. It remains to be seen if these diagnostic characteristics can also serve as potential therapeutic targets.

Staging

iCCA is mainly staged according to the 8th edition of the American Joint Committee on Cancer (AJCC) TNM system (Tables 3 and 4). Despite providing some meaningful contribution to the patient's prognostication, it does have some rather important limitations. First, although the tumor size was introduced for the first time in the latest AJCC Cancer Staging Manual, the only discriminating size cut-off used is the one of < 5 cm encompassing all T1 tumors. However, there are some data indicating that patients with very small (< 2 cm) tumors have potentially better outcomes in terms of

Table 3 American Joint Committee on Cancer staging classification for intrahepatic cholangiocarcinoma (8th edition, 2017)

Staging classification	
T1a	Solitary tumor ≤ 5 cm without vascular invasion
T1b	Solitary tumor > 5 cm without vascular invasion
T2	Solitary tumor with vascular invasion, or multiple tumors with or without vascular invasion
T3	Tumor perforating the visceral peritoneum
T4	Tumor involving the local extrahepatic structures by direct invasion
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis present
M0	No distant metastasis
M1	Distant metastasis present

Table 4 American Joint Committee on Cancer staging classification for intrahepatic cholangiocarcinoma (8th edition, 2017)

Stage	T	N	M
Ia	T1a	N0	M0
Ib	T1b	N0	M0
II	T2	N0	M0
IIIa	T3	N0	M0
IIIb	T4	N0	M0
	Any T	N1	M0
IV	Any T	Any N	M1

survival, rendering them eligible for different therapeutic modalities[83]. In addition, the latest TNM system fails to include parameters such as performance status (PS) or the severity of liver function impairment. Both of these limitations are clearly extremely important for assessing the prognosis of patients with HBV-associated iCCA, as very small tumors can be detected during surveillance programs and may also have advanced parenchymal liver disease.

THE CASE OF COMBINED HCC AND CHOLANGIOCARCINOMA

Combined HCC-CCA (cHCC-CCA) is a rare type of primary liver cancer (PLC), which has been defined as a distinct carcinoma displaying features of both hepatocytic and cholangiocytic differentiation[84]. Since the first description of this entity in 1949[85], significant terminology changes have been introduced. The 2010 WHO classification system distinguishes a classical form of cHCC-CCA and three variants with stem/progenitor cell features including typical, intermediate cell, and cholangiolocellular subtypes[86]. However, molecular advancements throughout the years have challenged the validity of stemness; thus, the term "typical subtype" has been abandoned; cholangiolocellular carcinoma is currently considered to be a subtype of iCCA, but it can still be within the spectrum of cHCC-CCA only if an HCC component is also involved and is currently addressed as "cholangiolocarcinoma"; PLCs consisting exclusively of intermediate cells are specified as intermediate cell carcinomas, while the role of intermediate cells in cHCC-CCA is still debated[84,87,88].

Large series have reported that cHCC-CCA represents 0.77%-5.8% of all PLCs[89,90]. Viral hepatitis (HBV, HCV), alcohol abuse, and cirrhosis have been associated with this cancer. Notably, cirrhosis and HBV infection are more commonly related with cHCC-CCA than iCCA, although with lower rates compared to HCC[91-94]. Most patients are aged between 50 and 60 years, with comparative studies claiming presentation in a younger age than iCCA[91,95], while others have not managed to point out significant age differences[92,93]. Male predominance is well documented

(65%-80%)[89,90,95,96] and tends to be more notable opposed to iCCA patients[92]. Studies focusing on HBV-related cHCC-CCA present an even greater male to female ratio that reaches 9:1[97,98].

Imaging features may resemble patterns of HCC, CCA, or both, therefore rendering radiological modalities insufficient to ensure definite diagnosis. Arterial phase hyperenhancement and portal/delayed phase hypoenhancement (washout) are characteristic findings of HCC in CT, MRI, and contrast-enhanced ultrasound; however, they could also be displayed by cHCC-CCA lesions and lead to misdiagnosis [93,99]. Similarly, cHCC-CCA tumors can mimic CCA by displaying gradual enhancement and peripheral irregular rim-like contour. According to Wang *et al*[92], in the former case the presence of lymphadenopathy, elevation of CA 19-9 and/or biliary dilation are in favor of cHCC-CCA, whereas the presence of pseudocapsule and well-defined margin are more suggestive of HCC. In the latter case when cHCC-CCA resembles features of CCA, the presence of simultaneous cirrhosis, HBsAg positivity, pseudocapsule and/or portal vein thrombosis should raise suspicion of cHCC-CCA. Furthermore, concurrent elevation of both aFP and CA 19-9 or discordance between tumor markers and imaging features (*i.e.* radiological hallmarks of HCC accompanied by increased CA 19-9 or lesions resembling CCA with raised aFP) should prompt consideration of cHCC-CCA diagnosis[100,101]. Histopathological examination of biopsies or surgical specimens based on routine stains ultimately establishes the correct diagnosis. Immunohistochemical markers can provide additional information, but are of secondary importance[84].

Complete excision with negative margins and sufficient residual liver volume is the goal of treatment[102]. In a large series of 390 HBV-related cHCC-CCA, the median OS after SR was 20 mo and negative prognostic factors included male gender, number of tumors ≥ 2, major thrombus, gamma-glutamyl transferase (GGT) > 60 IU/L, and CA 19-9 levels[98]. In a recent systematic review, data analyses of 14 studies showed that patients with cHCC-CCA, HCC, and CCA undergoing SR had 5-year survival rates of 32.7%, 47.5%, and 30.3% respectively[96]. Similar outcomes have been published about liver transplantation (LT): HCC patients achieve considerably greater survival rates than cHCC-CCA and CCA subgroups[95,103]. The role of locoregional treatment and systematic chemotherapy in the management of cHCC-CCA remains uncertain. A retrospective analysis of 50 patients with unresectable cHCC-CCA undergoing transarterial chemoembolization (TACE) demonstrated that better response rates could be attained when careful selection is applied (*i.e.* hypovascular tumors respond poorly due to inability of chemotherapeutic agents to reach target)[94]. Limited data about chemotherapy are available; however, it is noteworthy to mention the results of two recent multicenter studies using platinum-based regimens, which were associated with favorable outcomes compared to sorafenib monotherapy[104] and could be potentially effective when used together with gemcitabine as first-line treatment for advanced, unresectable cHCC-CCA[105].

TREATMENT OF ICCA

SR

SR is the treatment of choice for all iCCA patients, since it is the only established therapy capable of achieving a possible cure[68,76]. Conventional surgical aim of a SR should be complete tumor resection with negative microscopic (R0) margins while preserving adequate liver volume to avoid post-operative liver failure[73].

The eligibility of a patient for curative surgery should always be determined by a multidisciplinary board on a case-by-case basis. Given the poor prognosis of patients who have multifocal disease or clinically evident lymph node metastasis, SR should be precluded for these patients[106,107]. Regarding macroscopic vascular invasion, although it should generally be considered a contraindication, there are some data from specialized centers supporting that major vascular resection is not associated with worse perioperative or oncologic outcomes[108]. Obviously, as with HCC[109], liver function should be assessed in patients with underlying liver cirrhosis. Restrictions for resection are recommended in cases where liver function is significantly impaired and/or the patient's PS is poor.

As aforementioned, patients with HBV-associated iCCA are often diagnosed at a relatively early stage. This is probably the reason why the proportion of iCCA patients who undergo curative resection is significantly higher for HBV-positive than HBV-negative patients[110]. HBV infection has been identified by many studies as an independent factor associated with favorable outcomes, suggesting that better

prognosis of HBV associated iCCA may be perhaps explained by less aggressive biological nature[111-115]. In fact, a meta-analysis showed that lymph node metastasis occurred less commonly in HBV-associated iCCA than iCCA of other etiology (OR = 0.39)[48]. In a large single-center retrospective study from China that included 1333 iCCA patients (608 HBsAg-positive and 725 HBsAg-negative) the median post-operative survival was 19 mo for HBsAg(+) compared to 12 mo for HBsAg(-) patients ($P < 0.001$)[116]. Factors that have been associated with better outcomes for patients with HBV-associated iCCA include tumor diameter < 5 cm, better tumor differentiation, lower serum levels of aFP or CA 19-9 and absence of vascular invasion, lymph node metastasis, extrahepatic metastasis or TP53 mutation[113,117,118].

Adjuvant chemotherapy

Until a few years ago, the role of adjuvant chemotherapy in the setting of iCCA was not well defined because of a complete lack of data from randomized trials. However, a meta-analysis of retrospective cohorts indicated that administration of chemotherapy in the adjuvant setting provides a survival benefit to patients with iCCA[119]. This contrasted with the randomized PRODIGE 12[120] trial (gemcitabine and oxaliplatin [GEMOX] *vs* surveillance for patients with resected biliary tract cancer) which failed to produce statistically significant results. On the other hand, the BILCAP trial (capecitabine *vs* observation for patients with resected biliary tract cancer)[121], showed a benefit in terms of recurrence-free survival in the intention-to-treat analysis (HR = 0.75, $P < 0.05$) and also in terms of OS in the pre-planned sensitivity analysis (HR = 0.75, $P < 0.05$), both in the first 24 mo from randomization. However, no statistically significant benefit was observed in the intention-to-treat OS analysis of the whole population or the iCCA subgroup. Based on these partial benefits, the American Society of Clinical Oncology published a new guideline recommending that all patients undergoing SR of any biliary tract tumors should be offered adjuvant capecitabine chemotherapy for 6 mo[122]. More information is expected in the foreseeable future from the ACTICCA-1 study (NCT02170090), a phase III trial investigating the clinical performance of the GEMOX combination compared to capecitabine in the adjuvant setting.

Antiviral treatment

There are not much data concerning the role of antiviral treatment in the management of HBV-associated iCCA. However, one retrospective study demonstrated that antiviral treatment, even when initiated post-operatively, can provide a significant benefit to the patients compared to patients with high (> 2000 IU/mL) HBV-DNA levels who are left untreated (5-year recurrence rate 70.5% *vs* 86.5%, $P < 0.001$ and 5-year OS rate 43% *vs* 20.5%, $P < 0.001$ respectively)[123].

In 2017, a large-scale retrospective study from Taiwan area of China that was based on data from the National Health Insurance Research Database showed that treatment with nucleos(t)ide analogues (NA) is an independent factor for the development of HBV-associated iCCA (HR 0.44, $P = 0.004$)[124]. In the population treated with NA, the 5-year cumulative incidence of iCCA was lower compared to the NA-untreated group (0.17% *vs* 0.39%, $P = 0.005$), stating that treatment with NA could contribute in preventing HBV-associated iCCA, in a similar way as it contributes to reducing the risk of HBV-associated HCC.

LT

LT for iCCA is still a controversial issue. In the era of organ shortage, iCCA was traditionally considered a contraindication for LT, as both the OS and disease-free survival were disappointing. It should be noted that most of this information came from small, retrospective studies with much heterogeneity in transplant protocols. In certain studies, the 5-year OS rate ranged between 30% to 60%[125-128].

Studies focusing on favorable groups of patients who could potentially derive significant benefit from LT have been reported. In a multicenter retrospective study from Spain[129], a subgroup of patients ($n = 8$) with "very early" iCCA (single tumor, < 2 cm) was highlighted. The 5-year OS in this subgroup was 73% compared to 35% for the patients with single tumors > 2 cm or multinodular tumors ($n = 21$). Another international, multicenter study showed similar results, as the actuarial survival rate for "very early" iCCA was 65%[83]. A recent meta-analysis confirmed the results of such efforts (5-year pooled OS rate 71% *vs* 48% for advanced iCCA), stating that a solitary < 2 cm iCCA in a background of cirrhosis should not preclude consideration of LT[130]. It should be noted though, that the application of LT for cirrhotic patients, with "very early" iCCA unresectable due to impaired liver function still requires

validation by a prospective study. Such a study (NCT02878473) is currently recruiting patients and is expected to provide primary results by 2026.

Another interesting subgroup of iCCA patients, who could substantially benefit from LT, are those with locally advanced, unresectable (due to tumor size, location, or multifocality) disease with a durable response or stability after neoadjuvant chemotherapy[131]. In fact, in an interim analysis of a small series of patients (n = 6), with large, unresectable iCCA subjected to LT after an at least 6-mo disease stability under neoadjuvant chemotherapy with gemcitabine-based regimens, the 5-year survival was 83%, although, of note, 5-year recurrence rate was 50%[132].

In light of this information, a recent consensus approved by the International Liver Transplant Society recommends that patients with "very early" iCCA may benefit from upfront LT, whereas those with advanced, unresectable iCCA in a non-cirrhotic state may become LT candidates if the disease remains stable after neoadjuvant therapy[133].

MANAGEMENT OF UNRESECTABLE DISEASE

Unfortunately, many patients with iCCA present with advanced disease that is not amenable to surgery. When assessing a patient with unresectable iCCA, the medical team managing his care should first take into consideration the patient's PS, as determined by the Eastern Cooperative Oncology Group PS (ECOG-PS) scale. Patients with ECOG-PS > 2 are unlikely to benefit from any treatment and should be managed with best supportive care. After that, the stage of the disease and the molecular profile of the tumor should be assessed in order to decide the most suitable therapeutic approach for each patient.

Systemic chemotherapy

Systemic chemotherapy is generally recommended for patients with ECOG-PS 0-1[68]. The combination of gemcitabine and cisplatin (GEMCIS) is used as the first-line therapeutic regimen in patients with advanced iCCA[105,134]. In the ABC-02 trial (n = 410, all biliary tract cancers) the researchers observed a statistically significant difference in OS and in progression-free survival (11.7 mo *vs* 8.1 mo and 8 mo *vs* 5 mo, respectively) in favor of the GEMCIS combination compared to gemcitabine alone. The GEMOX combination may be used instead in patients with renal function impairment [76]. Additional combinations of chemotherapeutic agents are being investigated in the first-line setting, including more intensive, triple chemotherapy combinations like GEMCIS with nab-paclitaxel[135]. Acelarin is a NA which can achieve greater intracellular concentrations than gemcitabine and its efficacy in combination with cisplatin is currently being investigated in a phase III study as opposed to GEMCIS (NCT04163900).

After disease progression under first-line chemotherapy with GEMCIS, the next best choice is probably the combination of folinic acid, fluorouracil and oxaliplatin (FOLFOX). In the phase III ABC-06 trial, 162 patients who had already signs of disease progression under GEMCIS administration, were randomly assigned to active symptom control alone or concomitant FOLFOX[136]. In this study, differences in 6- and 12-mo survival (35% *vs* 50.6% and 11.4% *vs* 25.9%, respectively) were considered clinically important, although there was no significant difference in the median OS between the two arms (5.3 mo *vs* 6.2 mo).

A recent multicenter study used clinical and pathological data in addition to information from RNA sequencing in order to identify distinct subtypes of iCCA that might have favorable response to specific treatments. In the subtype that was associated with hepatitis B and C, an *in vivo* sensitivity to gemcitabine was observed. This was attributed to a higher expression of gemcitabine-response genes (SLC28A1 and SLC29A1)[137]. However, these findings should be confirmed in large clinical studies prior to establishing a recommendation for patients with hepatitis B.

Locoregional treatments

Locoregional therapies have implicit appeal as a treatment option for iCCA, as it is a PLC and often the disease burden is either completely or largely confined to the liver [138]. The most widely used types of locoregional therapeutic regimens in iCCA are TACE, radiofrequency ablation (RFA) and microwave ablation (MWA) and transarterial radioembolization (TARE) with Yttrium^{90} (Y-90). The possible role of these modalities in the management of iCCA has mainly been investigated by retrospective studies in various settings. Consequently, the results of the studies are difficult to

interpret, due to the high heterogeneity in terms of patient population (chemotherapy naïve or not) and type of treatment.

TACE is the most widely used treatment modality for patients with intermediate stage HCC not eligible for curative treatments. The rationale for TACE is based on the hypervascular nature of HCC that enables both strong cytotoxic and ischemic effects following the intra-arterial infusion of a cytotoxic agent and the selective embolization of the blood vessels feeding the tumor. However, iCCA rarely appears hypervascular on CT or MRI studies[68]. Despite that, a retrospective study showed that TACE (n = 72) could be beneficial in terms of OS to patients with unresectable iCCA when compared to supportive care (n = 83, OS = 12.2 *vs* 3.3 mo, respectively)[139]. However, in another multiinstitutional retrospective study of 188 patients with advanced-stage iCCA, TACE did not seem to have any significant benefit when compared to other arterial-based therapeutic interventions[138]. The efficacy of TACE has also been investigated in the adjuvant setting by a prospective study of 553 consecutive patients (122 TACE *vs* 431 non-TACE)[140]. Although in the whole cohort, the 5-year OS rates between groups were significantly different (38.4% *vs* 29.7) after 1:1 propensity score matching no significant differences were observed regarding OS or 5-year recurrence rate. Nevertheless, a recent systematic review and meta-analysis concluded that TACE in the adjuvant setting can actually prolong both the OS and the relapse-free survival [141]. A small, prospective study from China included 42 either HBsAg(+) or HBcAb(+) patients with iCCA who had received SR with curative intent and evaluated the prognostic impact of postoperative TACE[118]. TACE was performed in 9 patients who had demonstrated early recurrence of the tumor within 12 mo from the surgery. The OS of the patients in the TACE (n = 9) group was significantly prolonged (1-year, 88.9%; 3-year, 77.8%; 5-year, 66.7%) as compared to the non-TACE (n = 33) group (1-year, 63.6%; 3-year, 30.8%; 5-year, 13%), implying that TACE could have a role in the management of patients with HBV-associated iCCA when performed in the adjuvant setting.

A theoretical advantage of ablative therapies like RFA and MWA when compared to TACE, is that they are safe and effective for the local control of hepatic malignancies in patients considered unsuitable for SR without regard to the tumor's vascular profile [142,143]. The efficacy of ablative therapies in the management of unresectable iCCA has been mostly studied in small-scale, retrospective studies. RFA and MWA seem to be helpful for smaller tumors (< 3 cm), but lose part of their effectiveness when it comes to bigger or irregularly shaped tumors resulting in higher recurrence rates[144, 145]. This issue may be overcome by using stereotactic RFA, which combines pre-interventional three-dimensional imaging, computerized three-dimensional planning of electrode positions, and guided electrode placement at arbitrary angulations and orientations[146,147]. In a systematic review and meta-analysis regarding the efficacy of ablative therapies in the management of unresectable iCCA the pooled 1-, 3-, and 5-year OS rates were 76%, 33% and 16%, respectively[148]. It should be noted though, that this systematic review analyzed studies that included cases with various disease stages, such as recurrent or inoperable disease, thus resulting in a high degree of heterogeneity. To our knowledge, there are no published studies regarding the use of ablative therapies in the context of HBV-associated ICCA. It is obvious that in order to extract safer conclusions regarding the role of ablative therapies in the management of iCCA and HBV-associated iCCA in particular, well-designed prospective studies are needed.

In a systematic review and pooled analysis assessing the efficacy of Y-90 in the management of unresectable iCCA, the median OS was 15.5 mo, but the study highlighted the need for prospective studies on this subject[149]. In the MISPHEC study, a phase II single-arm trial where 41 patients were treated with Y-90 and GEMCIS, the results were rather promising, as median OS was 22 mo and 9 patients (22%) were even downstaged to surgery[150]. A phase III randomized trial investigating the efficacy of Y-90 with GEMCIS compared to GEMCIS alone is currently ongoing (NCT02807181). Unfortunately, there are no published studies regarding the use of TARE in the treatment of HBV-associated iCCA.

Genome-targeted therapies

As our knowledge broadens regarding the DNA alterations and the molecular pathways that are involved in the pathogenesis of HBV-associated iCCA, more possible therapeutic targets are going to arise, until we reach a point where the treatment of each patient will be personalized. As mentioned earlier, some of the most common findings in the genome of viral hepatitis-associated iCCA, include IDH1, IDH2 and FGFR2 mutations. The efficacy of ivosidenib, a targeted inhibitor of IDH1 and IDH2, was investigated in the phase III ClarIDHy trial involving 185 patients with

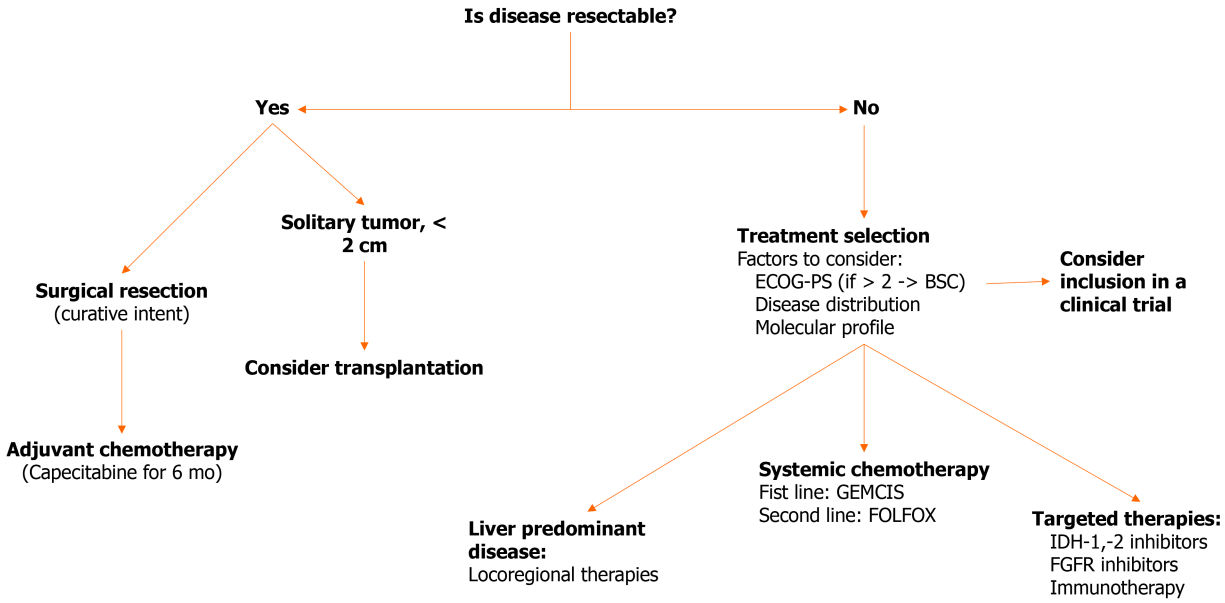

Figure 4 Therapeutic algorithm for hepatitis B virus-associated intrahepatic cholangiocarcinoma. BSC: Best supportive care; ECOG-PS: Eastern Cooperative Oncology Group-Performance Status; FGFR: Fibroblast growth factor receptor; FOLFOX: Folinic acid, Fluorouracil and Oxaliplatin combination; GEMCIS: Gemcitabine and cisplatin combination; IDH: Isocitrate dehydrogenase.

chemotherapy-refractory, IDH1 mutant CCA who were randomly assigned to ivosidenib or placebo[151]. The study managed to prove the clinical benefit of targeting IDH1 mutations in such tumors, as progression-free survival was significantly improved, compared to the placebo arm (HR = 0.37, $P < 0.0001$). Inhibitors of FGFR have been tested mostly in smaller, open-label, phase II trials showing some promising results in the treatment of chemotherapy refractory CCA with FGFR alterations[152-154]. In April 2020, the U.S. Food and Drug Administration approved pemigatinib, an FGFR inhibitor for the treatment of adults with previously treated, unresectable locally advanced or metastatic CCA with FGFR2 fusion or other rearrangement. Some additional FGFR inhibitors are currently being evaluated in the first-line setting, such as pemigatinb in the FIGHT-302 study (NCT03656536) and BGJ398 (oral infigratinib) in the PROOF study (NCT03773302).

Immunotherapy

The clinical data regarding immunotherapy in the management of CCA are limited. Although there is a lot of merit to the idea of a therapeutic approach that targets the immune checkpoint hyperactivation, which is common especially in HBV-associated iCCA, to date, the results from clinical trials are not promising. Pembrolizumab monotherapy provided antitumor activity in just 6% of patients with advanced biliary cancer enrolled in the KEYNOTE-158 study, with median progression-free survival of 2 mo[155]. Possibly, these therapeutic agents can provide better results when administered in combination with chemotherapy. There is an ongoing, phase II, single-arm trial assessing the efficacy of GEMCIS with pembrolizumab in patients with advanced biliary cancer (NCT03260712). Other studies have investigated the possible benefit of immune checkpoint inhibitors combined with locoregional therapeutic regimens (NCT02821754, NCT04299581).

Figure 4 presents a therapeutic algorithm that encompasses all the above described treatment modalities for iCCA.

CONCLUSION

Increasing data during the last 5 years have strengthened the association between the infection with HBV and the development of iCCA. The epidemiological data unveiling this association are from both Eastern and Western countries and this linkage has been confirmed by multiple meta-analyses. In addition, the pathogenetic pathways through which HBV leads to the development of iCCA have been recently the targets of intense investigation. Furthermore, the diagnosis of iCCA in the setting of chronic liver

disease is frequently challenging and often requires histological examination. Nonetheless, certain aspects of this association still remain ill-defined.

In terms of management, the need for effective treatment modalities beyond SR is critical both in the first and the second line treatment. The evolution of personalized approaches through the recognition of specific therapeutic targets will improve the effectiveness of our treatment approaches. It is also likely that the results of ongoing studies in the field of immunotherapy will allow the use of this promising treatment in patients with iCCA, as well. Furthermore, it is currently unclear whether antiviral treatment for HBV can decrease the incidence of iCCA. Large, well-designed studies should address this important question. Focused research on these aspects of the management of HBV-associated iCCA in the future will enhance our ability to manage successfully this dreadful cancer.

ACKNOWLEDGEMENTS

The authors want to thank Drs. Dimitrios Bekiaropoulos, Vasiliki Georgopoulou and Evangelia Katsiki for their help and encouragement in the process of preparing this work.

Abstract

Over the past decades, the treatment of inflammatory bowel diseases (IBD) has become more targeted, anticipating the use of immune-modifying therapies at an earlier stage. This top-down approach has been correlated with favorable short and long-term outcomes, but it has also brought with it concerns regarding potential infectious complications. This large IBD population treated with immune-modifying therapies, especially if combined, has an increased risk of severe infections, including opportunistic infections that are sustained by viral, bacterial, parasitic, and fungal agents. Viral infections have emerged as a focal safety concern in patients with IBD, representing a challenge for the clinician: they are often difficult to diagnose and are associated with significant morbidity and mortality. The first step is to improve effective preventive strategies, such as applying vaccination protocols, adopt adequate prophylaxis and educate patients about potential risk factors. Since viral infections in immunosuppressed patients may present atypical signs and symptoms, the challenges for the gastroenterologist are to suspect, recognize and diagnose such complications. Appropriate treatment of common viral infections allows us to minimize their impact on disease outcomes and patients' lives. This practical review supports this standard of care to improve knowledge in this subject area.

Key Words: Inflammatory bowel diseases; Viral infections; Opportunistic infections; Standard of care; Crohn's disease; Ulcerative colitis

Core Tip: The inflammatory bowel disease population treated with immune-modifying therapies is at increased risk of severe infections, including opportunistic infections sustained by viral agents. Of these opportunistic infections, 40% are due to viral pathogens, including hepatitis A virus, hepatitis C virus, hepatitis B virus, human papillomavirus, influenza virus, human immunodeficiency virus, herpes simplex virus, cytomegalovirus, varicella zoster virus, Epstein-Barr virus, and severe acute respiratory syndrome coronavirus 2 (causing coronavirus disease 19). A challenge for the gastroenterologist is to adopt preventive measures, recognize and treat common viral infections to minimize their impact on disease outcomes and patients' lives. This practical review supports this standard of care, aiming to bridge the gap of knowledge in this subject area.

INTRODUCTION

Inflammatory bowel diseases (IBD), including Crohn's disease (CD) and ulcerative colitis (UC) are lifetime conditions characterized by a relapsing and remitting clinical course. The complete pathogenic mechanisms of IBD are unknown. The major hypothesis is that the diseases occur when genetically vulnerable individuals meet unknown environmental triggers that exacerbate an inappropriate immune response against gut microbiota[1]. Curative therapies for IBD are not available yet. Medical treatment aims to guarantee long-lasting disease remission, thus avoiding complications and improving patient quality of life.

Drugs currently available for the management of IBD are mesalazine (5-ASA), locally active steroids, systemic steroids, thiopurines such as azathioprine (AZA) and mercaptopurine (MP), methotrexate (MTX), and biological therapies [Tumor necrosis factor-alpha inhibitors (anti-TNF) and other monoclonal antibodies targeting interleukin 12 (IL-12), IL-23, and cellular adhesion molecule ligands a4 integrin and a4b7 integrin][2].

Over the past decades, IBD treatment has become more targeted, anticipating the use of immune-modifying therapies at an earlier stage[3,4]. This has been correlated with favorable prognosis such as a reduction in surgery, hospitalization, and use of steroids[5-10], but it has also brought with it concerns about potential infectious complications.

IBD patients treated with immune-modifying therapies have an increased risk of developing severe infections, including opportunistic infections sustained by viral, bacterial, parasitic, and fungal agents[11-16], that are associated with hospital admission, use of intravenous antimicrobials, disability and death. The incidence of serious infections is not well defined, ranging from 10 to 100 events per 1000 patient-years[13,17-19]. Opportunistic infections are caused by ordinarily nonpathogenic organisms that can take advantage of an impaired immune system. According to the European Crohn's and Colitis Organization (ECCO) consensus guidelines on the prevention, diagnosis and management of opportunistic infections in IBD[20], updated in 2014[12], IBD patients treated with immune-modifying agents, especially in combination, those with malnutrition, comorbidities and a history of severe infections should be considered at risk for opportunistic infections. In an era of intensifying immune-modifying therapies, infective complications have emerged as a focal safety concern in patients with IBD. Today's challenge for gastroenterologists is to adopt preventative strategies, suspect, recognize, and treat appropriately IBD infectious complications to minimize their impact on disease outcomes and patients' lives. In particular, viral infections represent demanding problems for the clinician, as they are often difficult to diagnose and are associated with significant morbidity. This review intends to outline the most relevant viral infections in IBD, focusing on the careful

screening and monitoring before and during the use of immune-modifying therapies, timing of vaccinations, opportunity for primary or secondary prophylaxis and indications for therapy. A summary of recommendations for the prevention and management of viral infections in IBD are shown in Table 1.

VIRAL INFECTION IN IBD

Risk factors

A population-based study of patients with IBD[18] found that of opportunistic infections, 40% were due to viral pathogens. A recent prospective observational study [21] estimated that the incidence rate of systemic viral infections in patients with IBD was 2 per 1000 person-years, three-fold higher compared to the general population. Age is an independent risk factor for opportunistic infections in IBD[22], but for viral infections, the highest incidence rates are observed in patients under the age of 35 years[21]. In elderly patients, infections sustained by viral pathogens are rare compared with the younger population[23], except for influenza[24], herpes zoster reactivation (shingles)[25], and viral gastroenteritis[26]. Viral infections may also be triggered by disease activity and the resulting defective mucosal immunity, especially cytomegalovirus (CMV) colitis[27,28], and Epstein-Barr virus (EBV) systemic reactivation[29]. Finally, viral infections may arise as adverse events attributable to the immune-modifier action of IBD drugs. The direct correlation between a specific immunomodulator or biologic drug and viral infections has not been established. A retrospective analysis found that AZA/6MP-treated patients are at risk of developing opportunistic viral infections, such as herpes simplex (HSV), varicella-zoster (VZV), CMV, and EBV[11]. In a prospective cohort of outpatients with IBD, it was reported that exposure to thiopurines was associated with an increased incidence of cutaneous herpes flares and warts[30]. The incidence of zoster is increased in patients with IBD [31-33] and exposure to immunomodulators, in particular corticosteroids or combination therapy with thiopurines and anti-TNF agents, raises the risk[18,34]. During a 5-year follow-up, combination therapy (anti-TNF + thiopurine) was associated with an increased risk of opportunistic viral infections compared to anti-TNF monotherapy (1.3% *vs* 0.7%); no difference was found compared to thiopurine monotherapy (1.1%). Conversely, anti-TNF monotherapy was associated with a decreased risk of opportunistic viral infection compared to thiopurine monotherapy, suggesting that thiopurines drive the risk of opportunistic viral infections under combination therapy. These observations seem to agree with the AZA/6MP mechanism of action which primarily suppresses T lymphocytes activity that is involved in the prevention of viral infections.

With regard to corticosteroids, it is difficult to conclude their benefit and risk as they have many selection biases, as they are likely to be given to patients with severe disease, and there is heterogeneity in the type, dose and duration of their use. There are data suggesting that doses of prednisolone above 20 mg are associated with increased risk of bacterial and viral infections in IBD[35]. In patients with IBD exposed to thiopurines and anti-TNF agents, the increase in mortality from infection is negligible[17,36], instead, some studies have reported increased mortality in patients exposed to corticosteroids[34,37]. Case series recorded thiopurine-associated fatal infections, mainly in young patients. These infections include severe forms of varicella [38] and primary EBV or CMV infections complicated by hemophagocytic lymphohistiocytosis[39,40].

General approach

In immunocompromised patients, fever is sometimes the only manifestation of severe infection[41]. The approach in febrile patients must include exploration of their history and accurate physical examination. It is essential to recognize any symptoms or signs that can help identify the site of infection. Evaluation tests should include complete blood cell counts, C-reactive protein, serum procalcitonin (PCT), urine analysis and culture, VZV serology in patients without a reliable history of varicella immunization, hepatitis B virus (HBV) and hepatitis C virus (HCV), EBV and human immunodeficiency virus (HIV) serologies, stool examinations and strongyloidiasis serology (for returning travelers) and chest X-ray[12]. In the case of severe illness or when unusual pathogens are suspected, an infectious disease specialist should be involved.

In patients with respiratory symptoms (dyspnea, cough, purulent sputum, hemoptysis, pleuritic chest pain) or focal chest signs, a chest X-ray or chest ultrasound should be performed, and oxygen saturation determined. For patients with abnormal

Table 1 Summary of recommendations for the prevention and management of viral infections in inflammatory bowel disease

Infection	Screening prior to IM	Vaccination	Prophylaxis	Diagnosis	Therapy
HAV	IgG anti-HAV	Inactivated HAV vaccine; (2 doses, 0-6 mo)	-	IgG anti-HAV	Supportive
HCV	Ab anti-HCV; If positive HCV-RNA	-	-	Anti-HCV Ab; if positive HCV-RNA	DAA[62]
HBV	HBsAg, anti-HBs, anti-HBc;If positive HBV-DNA	Accelerated double-dose; (0, 1, 2 mo); If no response, re-vaccination; (0, 1, 2 mo) at a double-dose	In HBsAg+ (or antiHBc+); Entecavir 0.5 mg/d;Tenofovir, start 2 wk prior to IM	Exacerbation: ↑ AST/ALT; 100-fold rise HBV DNA	Entecavir 0.5-1 mg/daily; Tenofovir
HPV	Cervical smear test	bi/quadri/nine-valent;Women: 9-26 yr, Men: 11-23 yr	-	Cervical smear test	-
Influenza	-	Inactivated non-live trivalent	-	RT-PCR	Single neuraminidase inhibitor
HIV	HIV p24 Ag and Ab	-	-	Acute infection: RT-PCR	ART[99]
HSV	History of herpes lesions	-	Frequent/severe recurrence:acy-, valacy-, famci-clovir	Viral culture, H&E, RT-PCR	acyclovir, valacyclovir, and famciclovir
CMV	In steroid refractory patients	-	-	CMV inclusions in H&E + IHC followed by tissue RT- PCR	IV ganciclovir 5-7.5 mg/kg twice daily for 2 wk
VZV	VZV IgG/IgM	VZV vaccine: 4-3 wk before IM; HZ vaccine (recombinant): 2 doses, 0-3/6 mo	After exposure: VZV-Ig	RT-PCR on skin lesions	IV or PO acyclovir, valacyclovir, and famciclovir
EBV	EBV IgG/IgM	-	-	IgM VCA + and IgG EBNA -	-
SARS-CoV2	Recommended (test based on availability)	Recommended; mRNA-based; adenoviral vector	-	nasopharyngeal swabs; PCR-SARS-CoV-2	-

IM: Immune-modifier; DAA: Direct-acting antiviral; RT-PCR: Real-time polymerase chain reaction; IV: Intra-venous; PO: Per-os; HAV: Hepatitis A virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HPV: Human papillomavirus; HIV: Human immunodeficiency virus; HSV: Herpes simplex virus; CMV: Cytomegalovirus; VZV: Varicella zoster virus; EBV: Epstein-Barr virus; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

oxygen saturation rates, computed tomography is required[42]. When a radiological and clinical picture of pneumonia is detected, an etiological diagnosis may be achieved by performing hemocultures, sputum cultures, nasopharyngeal swabbing for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) or influenza virus real-time polymerase chain reaction (RT-PCR), Legionella and pneumococcal urinary antigen or, in specific situations by bronchoalveolar lavage.

The persistence or relapses of gastrointestinal symptoms (diarrhea, rectal bleeding, abdominal pain and weight loss) may be due to exacerbation of the underlying IBD or enteric infections. As a first approach, a potential enteric infection should be ruled out. In this regard, stool cultures with examination for parasites and *Clostridium difficile* toxin testing are necessary[43]. Recently, different multiplex molecular assays (FilmArray Gastrointestinal GI Panel and Luminex xTAG Gastrointestinal Pathogen Panel, GPP) have been developed for the rapid identification of pathogens responsible for causing diarrheal illness, included Adenovirus F 40/41, Astrovirus, Norovirus GI/GII, Rotavirus A, and Sapovirus (I,II, IV, and V). Their adoption in clinical practice can improve the diagnostic efficiency of GI pathogens[44]. If stool microbiological analyses are negative, colonoscopy or recto-sigmoidoscopy with biopsies should be performed. HSV, and especially CMV, may be responsible for severe IBD relapses.

A lumbar puncture should be considered, under neurological advice, in patients with meningeal signs or encephalopathy, with strain culture or serology of cerebro-spinal fluid (CSF). CSF cultures are essential for the detection of bacterial pathogens. PCR of CSF is the gold standard for CMV, HSV, VZV, *Toxoplasma gondii* and John Cunningham virus (JCV) diagnosis. Magnetic resonance imaging should be performed for patients with mass forming lesions or encephalopathy and may be effective for diagnosing progressive multifocal leukoencephalopathy due to JCV, reported in the past for patients treated with natalizumab[45].

Dermatological manifestations of viral infections are mainly caused by HSV and VZV. The diagnosis of these conditions is usually based on clinical manifestations. Yet virological analysis can be performed directly on a recent lesion by PCR.

Diagnostic approaches for IBD patients with infectious symptoms are shown in Table 2.

IBD patients should follow all age-appropriate vaccinations as recommended by the Advisory Committee on Immunization Practices[46]. It is also important to respect the optimal timing of vaccination with regard to initiation of immunosuppressive therapy, as the use of immunosuppressive agents can lead to decreased immunogenicity of the vaccination[47,48].

In the case of minor infection (rhinitis, upper respiratory tract infection, *etc*.) with no risk of disseminated disease or rapid worsening, it is unnecessary to withdraw immunomodulators. However, in the case of risk for disseminated or uncontrolled disease (shingles, viral pneumonia, encephalitis), high-grade fever and infection with a well-known mortality risk, withdrawal of immunomodulators are best advised at the peak of infection, and the decision to resume immunomodulator treatment is on a case-by-case basis and a multidisciplinary approach[49].

VIRAL DISEASES

Hepatitis A virus

Hepatitis A virus (HAV) is responsible for hepatitis A infection, which is usually a mild, self-limited disease that does not become chronic. It is transmitted by the fecal-oral route, and poor hygienic and socioeconomic conditions promote this infection[50,51]. Infection confers lifelong immunity and is preventable *via* vaccination. The onset of symptoms is sudden, with malaise, asthenia, nausea, vomiting, and pain in the upper abdominal quadrants. No specific disease manifestations in immunocompromised hosts have been described. The most relevant biochemical alteration is the increase in transaminases (often > 1000 IU/dL) and, generally, precedes the increase in bilirubin (typically ≤ 10 mg/dL). The presence of IgM anti-HAV antibodies allows the etiological diagnosis. The American College of Gastroenterology and the Korean Association for the Study of Intestinal Diseases recommend a test for HAV (IgG anti-HAV antibodies) in patients with IBD. In those who are negative, vaccination should be recommended[52,53]. On the other hand, ECCO guidelines suggest vaccination only in high-risk subjects and those traveling to endemic areas[12]. Inactivated hepatitis A vaccines should be preferred[54], as they have high, long-lasting immunogenicity with few side effects[55]. Since immunosuppressive therapy can lower the seroconversion rate[56], optimal timing for HAV vaccination is at IBD diagnosis or before starting immunosuppressive therapy, even if administration is acceptable during maintenance therapy. The vaccine should be administered in 2 doses with an interval of 6 mo.

HCV

The global HCV prevalence is estimated at 2.5%, ranging from 2.9% in Africa and 1.3% in the Americas[57]. In Europe it is estimated that 0.2-2% of the population is infected with HCV. The prevalence of HCV in patients with IBD is comparable to that in the general population[58-61]. HCV is typically transmitted parenterally. Acute HCV infection is often asymptomatic and chronic HCV infection develops in about 85% of all cases. Among patients with chronic HCV infection, 20% develop liver cirrhosis within 20 years of disease duration, with a high rate of incidence of hepatocellular carcinoma. General measures to reduce or prevent HCV infection are appropriate since vaccination and prophylactic treatment are not available. The ECCO guidelines suggest performing HCV screening before starting treatment with immune-modifying drugs for IBD. Testing should be performed by searching for anti-HCV antibodies and, if antibodies are positive, by identification of HCV-RNA[62,63]. Management of HCV in this population is important as immunosuppression may precipitate HCV-associated liver damage[64] and immunomodulators may result in cumulative liver toxicity[65,66]. If infection is confirmed, patients should be treated according to the HCV clinical practice guidelines[64], possibly before starting biologics or immunomodulator therapy. However, the timing strategy for treating HCV-infected IBD subjects could depend on several factors, including the IBD activity and patient's comorbidities. If HCV-infected patients with IBD cannot delay their immune-modifying therapy, their liver function should be monitored closely. There are no data to suggest that biologics are associated with reactivation or exacerbation of the course

Table 2 Diagnostic approach to inflammatory bowel disease patients with infectious symptoms

Symptoms cluster	Potential viral pathogens	Diagnostic work up
Fever	VZV, HBV, HCV, EBV, HIV, SARS-CoV-2	Medical history, physical examination
		Blood cell counts, PCR, PCT
		VZV, HBV, HCV, EBV and HIV Ab
		Hemocultures
		Urine analysis and culture
		Stool examinations
		Strongyloidiasis serology
		Chest X-ray
		Infectious disease specialist consult
Respiratory	Influenza, SARS-CoV-2 (Bilateral interstitial infiltrates)	Chest X-ray or US
		SaO_2% < range → CT
		Pneumonia:
		Sputum cultures
		NPS for SARS-CoV-2/influenza virus Legionella and pneumococcal U-Ag
		Bronchoalveolar lavage
Gastrointestinal	HSV, CMV, EBV, Adenovirus, Astrovirus, Norovirus, Rotavirus, Sapovirus	Rule out potential enteric infection:
		Stool cultures
		Examination for parasites
		C. difficile toxin testing
		Multiplex molecular assays
Central nervous system	CMV, HSV, VZV, JC virus	Neurological advice
		CSF cultures and PCR
		MRI
Cutaneous	HSV, VZV	Dermatological consult
		PCR on recent lesion

CRP: C-reactive protein; PCT: Procalcitonin; US: Ultrasound; CT: Computed tomography; NPS: Nasopharyngeal swab; U-Ag: Urinary antigen; CSF: Cerebrospinal fluid; PCR: Polymerase chain reaction; MRI: Magnetic resonance imaging; HAV: Hepatitis A virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HPV: Human papillomavirus; HIV: Human immunodeficiency virus; HSV: Herpes simplex virus; CMV: Cytomegalovirus; VZV: Varicella zoster virus; EBV: Epstein-Barr virus; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; JC: John Cunningham virus; *C. difficile*: *Clostridium difficile*.

of HCV and the safety profile of anti-TNF-α agents in HCV patients is good, even if there seems to be variances in the hepatotoxic profile between different biologics[59,66,67].

HBV

HBV is carried globally by 248 million people. HBsAg seroprevalence is 3.61% and it varies by country and region, from 2% in areas with low prevalence (UK, Canada, Western Europe, *etc.*), 2%-7% in those with moderate prevalence (South Korea, Mediterranean countries, Japan, Central Asia, Middle East, and parts of South America), and more than 8% in countries of the African region, which have the highest endemicity[68,69]. The prevalence of HBV in patients with IBD is similar to that in the general population[61,70]. HBV can manifest as acute and chronic infection. In the acute phase, the infection can manifest as jaundiced or non-jaundiced hepatitis (high levels of HBV DNA are associated with increased transaminases, with varying degrees of bilirubin elevation) and in more severe cases as fulminant hepatitis. The chronic phase has various patterns of expression, from asymptomatic carrier to the sequence chronic hepatitis, liver cirrhosis and related hepatocellular carcinoma. Patients with

IBD should be assessed for HBV infection (HBsAg, anti-HBs, anti-HBc) or immunization status. Anti-core antibodies could represent the only indicator in patients with HIV or HCV co-infections[71]. In patients diagnosed with HBV infection, HBeAg, anti-HBe, and HBV DNA should also be assessed[12] and then referred to a specialist for diagnosis of the phase of HBV infection. Vaccination of seronegative (anti-HBs -, anti-HBc -) patients is recommended. Patients with IBD on immunosuppression demonstrated a significantly reduced response to the standard vaccination (rHBAg 20 μg single dose at 0, 1 and 6 mo) as compared with the general population[72] (64% adequate immune response and 40% effective immune response)[73]. Receiving an accelerated double-dose at 0, 1, 2 mo followed by revaccination (0, 1, and 2 mo) at a double-dose if no adequate response is achieved has demonstrated better efficacy than the standard schedule[74,75]. Serology testing 1 to 2 mo after administration of the last dose are required to assess the need for revaccination and check-ups for anti-HBs yearly or every 2 years seems to be good practice[12,76]. A single booster dose should be given to immunocompromised patients who lose seroprotection[77].

The risk of viral reactivation in HBV is increased in patients who are receiving immune-modifying therapy and are HBsAg-positive or HBsAg-negative plus anti-HBc positive[64], in a manner that is proportional to the level of immunosuppression achieved[65,78]. Liver dysfunction has been described in retrospective studies in 25%-36% of HBsAg-positive patients with IBD receiving immunosuppressive agents; HBV reactivations have been associated with hepatic decompensation in a considerable proportion of cases[79,80]. Recognized risk factors were treatment with 2 or more immunomodulators for a long period of time, presence of HBV DNA and avoidance of antiviral prophylaxis. TNF-α and related cytokines are important in regulating hepatitis B replication and anti-TNF treatments confer a high risk of HBV reactivation [81,82].

Exacerbation of HBV infection is recognized by an increase in transaminases associated with high levels of serum HBV DNA (100-fold rise compared to baseline) in patients with chronic hepatitis B. HBsAg positive patients should receive prophylactic antiviral treatment with nucleotide/nucleoside analogues with a high barrier to resistance (*i.e.* entecavir or tenofovir), best started 2 wk prior to the introduction of immunomodulators or a biologic and continued for 12 mo after their withdrawal.

Relapse of past HBV infection is detected based on reverse seroreversion from HBsAg-negativity to HBsAg-positivity, or on the detection of serum HBV DNA in patients who are HBsAg-negative plus anti-HBc-positive. Relapse of occult HBV has been described in IBD and rheumatology patients treated with anti-TNF and corticosteroids or DMARDs[83,84], but this rarely occurs[59,79]. The preventive approach in patients with HBsAg negative and anti-HBc positive varies among the published guidelines. The American Gastroenterological Association suggest antiviral prophylaxis for patients treated with anti-TNF-α or with corticosteroids[85]. The ECCO, according to the European Association for the Study of the Liver, recommends active monitoring of AST/ALT levels and the virus markers (HBsAg and/or HBV DNA) every 1-3 mo with antiviral therapy once HBV DNA or seroreversion is detected (preemptive therapy strategy)[12,64].

Human papillomavirus

Human papillomavirus (HPV) is a sexually transmitted infection. There are approximately 40 serotypes of HPV classified into low-risk serotypes and high-risk serotypes, which are associated with cervical and anal squamous cell carcinoma[86]. HPV also causes cutaneous warts. There are reports of an increased frequency of HPV-related anogenital warts in patients receiving AZA[30], but not anti-TNF[87]. IBD has not been associated with the development of cervical cancer; however, patients with CD who smoke, are younger at diagnosis, and those who use thiopurines or methotrexate combined with corticosteroids might be more at risk[88,89]. Other immunosuppressive medications, in particular anti-TNF therapy, seem not to have an increased risk. However, the quality of evidence is poor, physician awareness and prevention by lifestyle counseling, HPV vaccination and screening are warranted[90]. There are three types of HPV vaccine: bivalent, Cervarix, comprising 16, 18 serotypes, quadrivalent, Silagard, and Gardasil, with 6, 11, 16, 18 serotypes, and nine-valent, Gardasil 9, with 6, 11, 16, 18, 31, 33, 45, 52, 58 serotypes. As the HPV vaccines do not contain live viruses, they may be administered to an immunosuppressed patient with an excellent safety profile and immunogenicity[91]. The vaccine is indicated for women aged 9 to 26 years, preferably before the first sexual intercourse but also after initiation of sexual activity. Male patients should be vaccinated at the age of 11 to 12 years, and catch-up for those aged 13 to 21 years. Of note, cervical screening recommendations are similar for vaccinated and nonvaccinated women. In IBD patients, a cervical smear test should

be performed initially at the time of diagnosis, and if normal then annually[12]. Different studies have shown an unsatisfactory cervical cancer screening rate and inadequate HPV vaccine coverage among IBD patients[92-94] advising that better cooperation between patients and physicians is required to improve education on preventive measures. Management of abnormal findings at cervical smears includes colposcopic examination with biopsy/brushing, and eventually conization.

Influenza virus

There are two types of influenza virus: type A and type B, which cause seasonal epidemics of acute respiratory illness. IBD patients have an increased risk of influenza compared with those without IBD with a higher rate of hospitalization, often with bacterial pneumonia superinfection[95,96]. Patients requiring hospitalization for possible influenza infection should be tested. The gold standard for diagnosis of influenza is RT-PCR testing in specimens from different respiratory sites[97]. In the outpatient setting, diagnosis is made with a high likelihood by clinical criteria alone. Inactivated non-live trivalent influenza vaccination is recommended annually in the fall and spring for IBD patients and their household contacts to prevent influenza virus infection. Live attenuated influenza vaccine is not recommended for patients on immunomodulators[12]. IBD patients treated with anti-TNF alone or combined with thiopurine, may have a reduction in the influenza seroprotection rate after inactivated non-live trivalent influenza vaccination[98-100]; however, it is sufficient to warrant annual influenza vaccination. Antiviral treatment (single neuraminidase inhibitor; either oral oseltamivir, inhaled zanamivir, or intravenous peramivir) should be started as soon as possible for patients with documented or suspected influenza, who are taking immunomodulator therapy, especially if older than 65 years[97].

HIV

HIV belongs to the human retrovirus family. HIV infection causes a wide range of clinical consequences varying from asymptomatic to severe opportunistic diseases due to immunosuppression, including infections and malignancies, which are characterized by acquired immunodeficiency syndrome (AIDS). HIV infection is usually transmitted through sexual intercourse, exposure to infected blood, or perinatal transmission. Antiretroviral therapy (ART) effectively suppresses viral replication so that an almost normal immune status can be regained, leading to dramatic reductions in morbidity and mortality. For most individuals, an ART regimen consists of a dual nucleoside combination plus a third agent from a different class[101]. Patients with IBD and HIV infection have shown controversial data concerning the remission hypothesis of IBD due to CD4 count depletion caused by HIV[102]. A recent multicenter retrospective cohort study suggested that HIV infection might attenuate the IBD course as HIV-infected patients need fewer immunosuppressants and biologics to control the disease[103]. In a previous analysis, over a median follow-up of 8.4 years, HIV status was the only risk factor independently associated with a lower probability of IBD relapse[104]. However, evidence of the interrelation between HIV and IBD remains poorly understood. The diagnosis of IBD in HIV infection can be complex because of possible symptom overlap[105]. The differential diagnosis includes a multitude of etiologies from protozoic, fungal, viral, and bacterial pathogens (HSV, AIDS-related CMV gastrointestinal disease[106-108], Salmonella, Shigella, Campylobacter, *Mycobacterium tuberculosis*, Histoplasma or Cryptococcus) to malignancy (lymphoma or Kaposi's sarcoma[109]) to medications (ART-associated diarrhea[110,111]). The entity known as AIDS enteropathy can be diagnosed once other causes of diarrhea are investigated and excluded[112]. It is expected that all cases of IBD in HIV infection require biopsy confirmation by an expert gastrointestinal pathologist. All IBD patients undergoing immunomodulator or biological therapy should receive testing for HIV infection (HIV p24 antigen and antibody testing, with PCR if acute infection is suspected) to exclude unknown infection. Experiences in treating individuals with HIV infection with anti-TNF therapies are limited. It is possible to prescribe with a reasonable ratio of benefits to risks if the patients have a low HIV viral load and are not severely immunosuppressed (>350 CD4 cells/μL), keeping them closely monitored[103,113-115].

HSV

HSV type 1 (HSV-1) and HSV type 2 (HSV-2) are common infections worldwide. HSV-1 is implicated in most cases of orofacial herpes lesions ("cold sores"), while HSV-2 causes most cases of recurrent genital herpes[116]. After primary infection, HSV establishes chronic infection in neural ganglia and reactivates on mucosa and skin;

infection is lifelong. Especially in immunocompromised hosts, HSV infection may cause severe manifestations, including encephalitis, meningitis[117], hepatitis[118], respiratory tract infections[119,120], esophagitis[121-123] and proctitis[124-126]. Within the treatment regimens for IBD, corticosteroids and azathioprine have been related to skin or genital herpetic flares[30,127]. Extended HSV colitis associated with IBD exacerbations are largely reported[128-132]. The testing approach depends upon the site of the disease (mucocutaneous, ocular, neurologic or visceral). HSV can be diagnosed, either by isolating the virus in a culture of the affected tissue or by histopathological examination showing nucleated ground-glass herpes inclusions in the cells. HSV PCR is an alternative, but more sensitive method to confirm HSV infection. Before starting with immunosuppressive drugs, previous history of HSV infection should be investigated, but serological screening is unnecessary[12]. Frequent and severe recurrence of HSV disease can be prevented by therapy with oral acyclovir (400-800 mg twice or thrice daily), valacyclovir (500 mg daily) or famciclovir (500 mg twice daily).

CMV

With a worldwide prevalence of over 80%[133], CMV causes in most subjects asymptomatic or mononucleosis-like syndrome during primary infections, persisting lifelong in a latent form in different organs, including the gut[134]. Especially in immunocompromised patients, CMV can reactivate, causing tissue-invasive end-organ damage, mainly in the brain, lung, retina and digestive tract. CMV colitis in IBD patients should be considered. Seroprevalence (CMV IgG) in IBD patients is comparable to that in the general population[135,136]. On the contrary, identification of CMV viral DNA in the mucosa was reported, from limited data, to be more prevalent in patients with IBD than in healthy controls[137,138]. CMV tissue reactivation is rare in CD flares, whereas it is frequent in UC[139]. Characteristics that increase the risk of CMV reactivations in IBD and develop colitis flare include female sex, pancolitis[140,141], advanced age[142], and disease duration less than 60 mo. Immunomodulator therapy with azathioprine[140,143] and steroids[142,144] is a recognized trigger factor, while on chronic anti-TNF, the data is conflicting[145-148]. Screening for subclinical CMV infection in IBD patients is not required unless the patient is steroid-refractory[12]. Patients with CMV infection and severe acute colitis, in fact, show a higher probability of steroid resistance[135,136,149] and enhanced risk for colectomy[150,151] than non-infected patients. Colonic CMV infection can be diagnosed by hematoxylin and eosin (H&E) or immunohistochemical staining (IHC) histology, serology assay, polymerase chain reaction (PCR) for CMV DNA in peripheral blood or tissue (from targeted biopsies taken from the ulcer base), and CMV antigenemia (pp65)[152]. The gold standard for diagnosing CMV overinfection is the identification of CMV inclusions (typically basophilic intranuclear inclusions) or positive CMV-specific immunohistochemistry staining on histopathology[153], eventually followed by tissue-direct PCR for viral load quantification. CMV infection cannot be excluded based on a negative whole-blood PCR result[154]. In patients who are steroid-dependent or refractory[155] and those with high CMV viral load in colonic tissue[156], antiviral therapy is recommended. Several agents are available for CMV infection, including ganciclovir, valganciclovir and foscarnet. The most used antiviral agent is intravenous ganciclovir at a dose of 5-7.5 mg/kg twice daily for 2 wk [152]. ECCO guidelines allow a course of intravenous ganciclovir 5 mg/kg twice for 3-5 days, followed by oral valganciclovir at 900 mg *per os* twice daily for 2-3 wk[12]. Foscarnet (for 2-3 wk) is an alternative in case of resistance or intolerance (hematologic or renal toxicity). Overall, there is a lack of knowledge to give recommendations on managing immunosuppressant medications during or after treatment of CMV colitis. Inducing remission with anti-TNF and tapering off the steroids while continuing intravenous ganciclovir may be an acceptable strategy[152].

VZV

VZV causes varicella (chickenpox) during its primary infection, and after decades of latency in sensory ganglia, it maintains the potential for reactivation as herpes zoster (shingles). Primary infection is generally a mild-moderate disease in most children. However, it can be life-threatening in adults (especially during pregnancy) and immunocompromised patients, potentially leading to severe complications such as central nervous system involvement, pneumonia, secondary bacterial infections, and death[157]. At diagnosis, all IBD patients (unless those with documented vaccination history) should be tested for VZV IgG serology[158]. Corticosteroids, thiopurines, methotrexate, and anti-TNF in monotherapy or even more in combination, are recognized risk factors for varicella infection[159,160]. The literature describes 23 cases

of varicella in IBD patients receiving immunosuppressants and the fatality rate is reported to be 22%[161]. Diagnosis is based on clinical signs (fever and typical vesicular lesions in different stages of development on the face, trunk, and extremities), or real-time PCR on samples taken from skin lesions in an immunocompromised host or in the evaluation of atypical lesions[162]. In immunocompromised hosts with active varicella lesions, antiviral therapy is recommended in order to reduce the severity of symptoms and the risk of serious complications. Oral valacyclovir (1 g 3 times daily) may be considered in patients with mild disease followed closely. For most patients, initial therapy with intravenous acyclovir (10 mg/kg every 8 h) is suggested, with the possibility of switching to oral antiviral after defervescence in the absence of visceral involvement. The treatment duration is 7-10 days, and it has to be continued until all lesions have crusted. After significant exposure, primary prophylaxis with VZV immune globulin within 10 days is indicated in IBD patients receiving immunosuppressive therapy since they are ineligible for varicella vaccine prophylaxis[163]. From a prevention perspective, as the VZV vaccine is a live vaccine, its administration (2 doses, 1 mo apart) should be carried out at least 4-3 wk before starting immunosuppressive therapy[12,52] or 3-6 mo after stopping it.

IBD patients are also at increased risk of developing herpes zoster (HZ). Due to diffuse concurrent use of immunosuppressant agents, clinical manifestations are often more severe, and the risk of complications such as post-herpetic neuralgia, central nervous system and ocular involvement are enhanced[164,165]. Corticosteroids and thiopurines (especially in combination with anti-TNF medication) are known risk factors linked to HZ infection[32,33,166]. Recently tofacitinib has also been observed to be related in a dose-dependent manner to HZ, with additional risk conferred by older age, diabetes mellitus, corticosteroids therapy and prior anti-TNF failure[167,168]. The diagnosis of HZ is usually based on the clinical presentation (unilateral, usually painful vesicular-papular eruption with a defined dermatomal distribution). However, since immunocompromised subjects may have an atypical presentation (hemorrhagic skin lesions affecting multiple dermatomes), real-time PCR may confirm the diagnosis. Antiviral therapy must be started in IBD patients with HZ, even after 72 h from presentation. Patients with disseminated HZ should be hospitalized for intravenous acyclovir therapy (10 mg/kg every 8 h). On the other hand, oral therapy is usually sufficient for the initial treatment of uncomplicated HZ. Regimen options last 7 days and include valacyclovir (1 g 3 times daily), famciclovir (500 mg 3 times daily) and acyclovir (800 mg 5 times daily). Two types of zoster vaccine are available: the first one is a live attenuated vaccine, which is contraindicated in patients receiving moderate or high-dose immunosuppressive therapy and recently a new recombinant glycoprotein E vaccine has become available. The vaccine is administered twice, at 0 and 2-6 mo. Recombinant vaccine has been proven to be highly effective in reducing HZ risk and postherpetic neuralgia among adult subjects[169]; thus, the ACIP recommends it for use in immunocompetent adults aged ≥ 50 years[170]. There are insufficient data to make recommendations regarding zoster vaccination in immunosuppressed patients, but initial evidence suggests good safety and immunogenic profile in this subgroup of patients[171-173]. Therefore, it seems to be an acceptable strategy, to propose recombinant vaccine in patients with uncontrolled severe disease activity, history of shingles, a scheduled therapy with tofacitinib, treated with azathioprine and aged > 40 years, and to all patients aged > 50 years[161].

EBV

EBV is a ubiquitous herpesvirus with a seroprevalence >90% worldwide. It is responsible for infectious mononucleosis (IM), and after primary infection persists asymptomatically lifelong in latently-infected circulating B-lymphocytes[174]. EBV infection is associated with different types of malignancies, including B cell lymphomas, T cell lymphomas, Hodgkin lymphoma and nasopharyngeal carcinomas [175-177]. The incidence rate of lymphoproliferative disorders is much higher in IBD patients than in the general population. The relationship between immunosuppressive drugs (in particular, evidence seems to suggest that thiopurines have specific additional risks[178,179]) and EBV infection may be implicated in the pathogenesis of this disease[180,181]. In addition, severe EBV diseases such as fatal infectious mononucleosis and hemophagocytic lymphohistiocytosis occur when primary infection develops in immunosuppressed patients[182-184]. Therefore, it seems relevant to determine EBV serology status by testing EBV IgG before starting immunomodulator therapy. In EBV seronegative patients, anti-TNF monotherapy should be preferred over thiopurines[12]. The diagnosis of acute EBV infection is made in the presence of IgM VCA and the absence of IgG EBNA antibodies. When primary infection is recognized, immunomodulator therapy should be reduced or discontinued

if possible. Advice from a hematologist/oncologist is required when lymphoproliferative disease is suspected.

SARS-CoV-2 (coronavirus disease 19)

On March 11th, 2020 the World Health Organization declared coronavirus disease 19 (COVID-19) a global pandemic, marking one of the most intense passages in recent history. The range of symptomatic infection goes from mild to critical; >80% of cases are not severe[185], but morbidity and mortality are not negligible. Current evidence shows that the IBD population does not have an increased prevalence of SARS-CoV-2 infection[186-188] and immunomodulators, biologics, or Janus Kinase inhibitors do not represent a risk factor for SARS-CoV-2 infection and more severe COVID- 19[189,190]. On the other hand, in several studies of IBD patients with COVID-19, a trend towards an adverse outcome with concomitant corticosteroids was reported[191]. COVID-19 may occur early with gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal pain, and diarrhea)[192] simulating IBD manifestations. For that reason, patients with a suspected IBD flare should be tested to exclude SARS-CoV-2 infection, especially before initiation of biologics[193]. When IBD patients are diagnosed with COVID-19, in its current state, several consensuses and expert opinions propose discontinuation of thiopurines, methotrexate, and JAK inhibitors and extend the interval of administration for biological drugs until nasopharyngeal swab PCR-SARS-CoV-2 tests results are negative or 3 after days of no fever and clinical improvement [194,195]. Since IBD patients were ruled out of the SARS-CoV-2 vaccine clinical trials, questions regarding the safety and effectiveness in patients with IBD are currently unanswered. As the COVID-19 vaccines available use mRNA-based technology (Pfizer/Biontech, ModeRNA) or non-replicating adenoviral vectors expressing the spike protein (AstraZeneca/Oxford, J&J, Sinovac, Sputnik V) the International Organization for the Study of Inflammatory Bowel Disease (IOIBD) recommends vaccinating all patients with IBD as soon as they are able to receive the vaccine, regardless of immune-modifying therapies[196]. The exception is for any live-attenuated virus vaccines or replication-competent viral vector vaccines that may come to market. Even The British Society of Gastroenterology agrees, strongly supporting SARS-CoV-2 vaccination in patients with IBD, underlining that the critical concerns in patients taking immunosuppressive drugs are more related to the risk of suboptimal immunization rather than the vaccine safety profile[197].

CONCLUSION

Due to the alterations in the immune response and the growing adoption of immunomodulators and biologics, IBD patients represent a population exposed to opportunistic infections. The risk of infections is also aggravated by an insufficient immunization status as too frequently observed in patients with IBD. In this field, gastroenterologists should be aware of viral infections that may complicate the IBD course, as they are often challenging to diagnose and treat. Moreover, excess hospitalizations due to viral infections and their related costs, contribute to the human and financial burden of IBD. Prevention is the most important step; a careful workup aimed at avoiding viral infectious disease is essential. Anamnestic and serological screening should be performed in all patients before starting immunosuppressive therapy. In addition, assessing and completing the vaccination status in IBD patients, ideally before immunosuppressive therapy, is the new standard of care. It is also important to provide prophylaxis when indicated to avoid the occurrence of potentially preventable infection. Continued vigilance and a high degree of suspicion is required to monitor for viral infection during maintenance therapy. Even if a direct correlation between a specific immunosuppressant drug and viral infection is not established, special attention must be paid to patients receiving corticosteroids, thiopurines, or combination therapy with thiopurines and anti-TNF agents as they are more prone to contracting opportunistic viral infections, in particular HSV, VZV, CMV, and EBV. It seems prudent to minimize the use of systemic steroids, think of alternatives to steroids and, if used, taper to the lowest possible dose quickly. As a matter of course, long-term steroids are contraindicated to avoid the risk of viral infection. Early diagnosis and appropriate treatment are necessary to prevent potentially severe complications that could precipitate the disease course if infective complications occur. Multidisciplinary cooperation between the gastroenterologist, infectious disease specialist and primary care physicians is the best way to optimize the care provided to IBD patients. The most significant gaps in knowledge in this area

are related to the difficulty in stratifying high-risk patients who may benefit from personalized preventive or therapeutic interventions. Prospective randomized controlled trials focused on IBD patients who are diagnosed with viral infection should be planned.

Abstract

Despite rapid advances in modern medical technology and significant improvements in survival rates of many cancers, pancreatic cancer is still a highly lethal gastrointestinal cancer with a low 5-year survival rate and difficulty in early detection. At present, the incidence and mortality of pancreatic cancer are increasing year by year worldwide, no matter in the United States, Europe, Japan, or China. Globally, the incidence of pancreatic cancer is projected to increase to 18.6 per 100000 in 2050, with the average annual growth of 1.1%, meaning that pancreatic cancer will pose a significant public health burden. Due to the special anatomical location of the pancreas, the development of pancreatic cancer is usually diagnosed at a late stage with obvious clinical symptoms. Therefore, a comprehensive understanding of the risk factors for pancreatic cancer is of great clinical significance for effective prevention of pancreatic cancer. In this paper, the epidemiological characteristics, developmental trends, and risk factors of pancreatic cancer are reviewed and analyzed in detail.

Core Tip: Pancreatic cancer is still a highly lethal gastrointestinal cancer with a low 5-year survival rate and difficulty in early detection. A comprehensive understanding of the risk factors for pancreatic cancer is of great clinical significance for effective prevention of pancreatic cancer. In this review, the latest epidemiology, future trends, and various risk factors of pancreatic cancer are analyzed and summarized, which will provide more guidance and suggestions for the prevention and control of this malignancy.

INTRODUCTION

The pancreas is an about 15-cm-long, spongy, tube-shaped organ located in the upper abdomen between the stomach and spine[1]. A normal healthy pancreas consists of acinar cells secreting digestive enzyme, ductal cells secreting bicarbonate, centroacinar cells that are the transitional region between acinar and ductal cells, endocrine islets secreting hormone, and relatively inactive stellate cells[2]. Pancreatic cancer occurs when abnormal DNA mutations in the pancreas cause pancreatic cells to uncontrollably grow and divide, forming tumors[3]. Pancreatic cancer is characterized as a fatal disease and one of the most aggressive and lethal malignancies[4,5]. By the time of diagnosis, pancreatic cancer often presents at an advanced stage, and has often spread to other parts of the body. Clinically, pancreatic cancer is the general term for malignant tumor formed in the epithelial cells of glandular structures in the pancreatic ductal cells, referred to as adenocarcinoma[6], and pancreatic ductal adenocarcinoma (PDAC) accounts for more than 90% of pancreatic cancers[7]. Due to the poor survival outcomes, PDAC is the seventh leading cause of global cancer death despite being the 10th most common cancer[8]. Other less common exocrine pancreatic cancers include adenosquamous carcinoma, squamous cell carcinoma, giant cell carcinoma, acinar cell carcinoma, and small cell carcinoma. At present, pancreatic cancer remains a devastating disease whose prognosis has remained largely unchanged over the last two decades[9]. Improvement in patient outcomes will depend on clear knowledge of epidemiology, reasonable prevention, and scientific regulation of early detection[4]. Therefore, it is necessary to understand the epidemiological characteristics, development trends, and risk factors of pancreatic cancer in detail, which will eventually establish rational prevention approaches for clinical benefit.

EPIDEMIOLOGY OF PANCREATIC CANCER

Assessing the latest epidemiologic trends in pancreatic cancer is necessary because it is of great importance for preventive measures and clinical care[10]. Therefore, we present a review of the latest epidemiology of pancreatic cancer.

Pancreatic cancer ranks consistently last among all cancers in terms of prognostic outcomes for patients and is predicted to become the second leading cause of cancer death in some regions[11]. A study including 84275 patients with at least 5 years of follow-up showed that actual 5-year survival rate in patients rose from 0.9% in 1975 to 4.2% in 2011 for all stages of pancreatic cancer, while in surgically resected patients, it increased from 1.5% to 17.4%[12]. In non-resected patients, the actual 5-year survival rate was 0.8% in 1975 and 0.9% in 2011, meaning that it remained roughly the same

between 1975 and 2011[12]. The 5-year relative survival rate of pancreatic cancer was 7.2% in China and the lowest level in all cancers[13]. Cancer Stat Facts showed that the 5-year survival rate at the time of diagnosis is approximately 10% in the United States based on data from Surveillance, Epidemiology, and End Results Program 18 between 2010 and 2016[14]. Pancreatic cancer has a poor 5-year survival rate, ranging from 2% to 9%, with little difference between high-income countries and low-income and middle-income countries[11,15]. Therefore, the 5-year survival rate of pancreatic cancer varies globally in different regions and countries, but does not exceed 10%. And it is predicted that patients with nonoperative pancreatic cancer have a lower 5-year survival rate.

According to Cancer Statistics 2021, the American Cancer Society reported approximately 60430 new cases and 48220 deaths for pancreatic cancer in the United States, ranking third after lung and bronchus cancer and colorectal cancer[16]. In the 28 countries of the European Union (EU), it was estimated that approximately 111500 people (55000 in males and 56500 in females) will die from pancreatic cancer by 2025, and the number of recorded deaths from the cancer in 2010 will increase by almost 50% (45% in men and 49% in women), and it has been projected that pancreatic cancer may become the third leading cause of cancer death in the EU after lung and colorectal cancers[17]. Global Cancer Statistics 2018 showed that the incidence and mortality of pancreatic cancer were 458918 and 432242 in 2018 in the world, respectively, and deaths account for about 94.2% of new cases[18]. Pancreatic cancer remains the seventh leading cause of cancer death globally, and Global Cancer Statistics 2020 showed that, globally, a total of 495773 new cases and 466003 related deaths were reported for pancreatic cancer in 2020, with almost as many mortality as incidence [19]. The systematic analysis for the 2017 Global Burden of Disease Study showed that the number of incident cases and deaths from pancreatic cancer in both genders increased 2.3-fold from 195000 incident cases and 196000 deaths in 1990 to 448000 incident cases and 441000 deaths in 2017 globally[15]. These reports indicate a gradual increase in the number of incident cases and deaths from pancreatic cancer.

Average age-standardized rates (ASRs) of pancreatic cancer incidence and mortality vary widely across regions of the world[19]. The ASR of the incidence was highest in Eastern Europe, with 9.9 per 100000, followed by Western Europe (9.8), Northern America (9.3), Southern Europe (8.4), Northern Europe (8.3), Australia/New Zealand (7.9), Micronesia/Polynesia (7.7), and Western and Eastern Asia (7.0)[19]. The ASR of the mortality was highest in Western Europe, with 7.4 per 100000, followed by Northern America (6.9), Northern Europe (6.7), Australia/New Zealand (6.7), Southern Europe (8.4), Eastern Europe (5.6), Eastern Asia (4.8), and Western Asia (4.4) [19]. The human development index (HDI) is a composite index that measures three dimensions: Life expectancy, education period, and access to essential sources for a suitable and reasonable life[20]. The ASRs of pancreatic cancer incidence and mortality in regions with a very high HDI were significantly higher than medium or low HDI regions[19]. The low ASRs of the incidence and mortality were found mainly in South-Central Asia (1.5 per 100000, 0.9 per 100000), Eastern Africa (2.0, 1.7), Middle Africa (2.0, 1.2), Western Africa (2.2, 1.8), Melanesia (2.9, 1.7), and South-Eastern Asia (2.9, 1.8), all of which are medium or low HDI regions[19]. The top six countries for pancreatic cancer incidence were Hungary (ASR, 11.2), Uruguay (ASR, 10.7), Japan (ASR, 9.9), Slovakia (ASR, 9.6), Czechia (ASR, 9.5), and Austria (ASR, 9.0), with 9.0 and greater per 100000, and a total of 21 countries, including the United States (ASR, 8.2), had an ASR of the incidence between 8.1 and 8.9 per 100000, as shown in Figure 1A [21]. The ASR of pancreatic cancer mortality was highest in Hungary and Uruguay, both at 10.2 per 100000, and a total of 26 countries, not including the United States (ASR, 6.6), had an ASR of the incidence between 7.2 and 8.6 per 100000, as shown in Figure 1B[21]. The proportion of estimated new cases for pancreatic cancer in China was relatively high in East China (9.4 per 100000), Northeast (9.4), Northwest (6.8), and North China (5.3), and was comparatively low in Central China (5.2), Southwest (4.3), and South China (3.6), having obvious regional characteristics[13]. Age-standardized rates of pancreatic cancer were 3-fold to 4-fold higher in higher HDI countries, compared with lower HDI countries[18]. The higher incidence and mortality rates of pancreatic cancer were reported in countries and regions with higher levels of HDI and Gross Domestic Product (GDP) per capita, and the coefficients of determination (R^2) of HDI and GPD per capita were high for the incidence and mortality[22]. The higher incidence and mortality rates of pancreatic cancer in countries with higher HDI indicates the importance that paying more attention and implementing appropriate programme to reduce risk factors acts as an effective measure to control the incidence and mortality of the cancer[23].

TRENDS OF PANCREATIC CANCER

Over the two decades from 2001 to 2020, the estimated new cases and deaths of pancreatic cancer have been increasing year by year in the United States, and the same trend has been observed among men and women, as shown in Figure 2. Using statistical models for analysis, in the United States, age-adjusted rates of new cases for pancreatic cancer remained stable from 2008 to 2017, and age-adjusted rates of death increased by an average of 0.3% each year from 2009 to 2018[14]. Prediction of pancreatic cancer incidence burden from the 28 member states of the EU and other selected countries around the world showed that in 2025, 2030, 2035, and 2040, the incidence will be 557688, 639030, 726740, and 815276, respectively, with growth rates of 21.5%, 39.2%, 58.4%, and 77.7%[24]. The incidence and mortality of pancreatic cancer in Africa will increase by 18327 and 17744 in 2040, respectively, with growth rates of 114.1% and 114.8%, the rates of which will be highest in the world, followed by Latin America and the Caribbean (incidence: + 99.3%; mortality: 101.0%)[25]. However, in 2040, the growth rates of the incidence and mortality in Europe will be

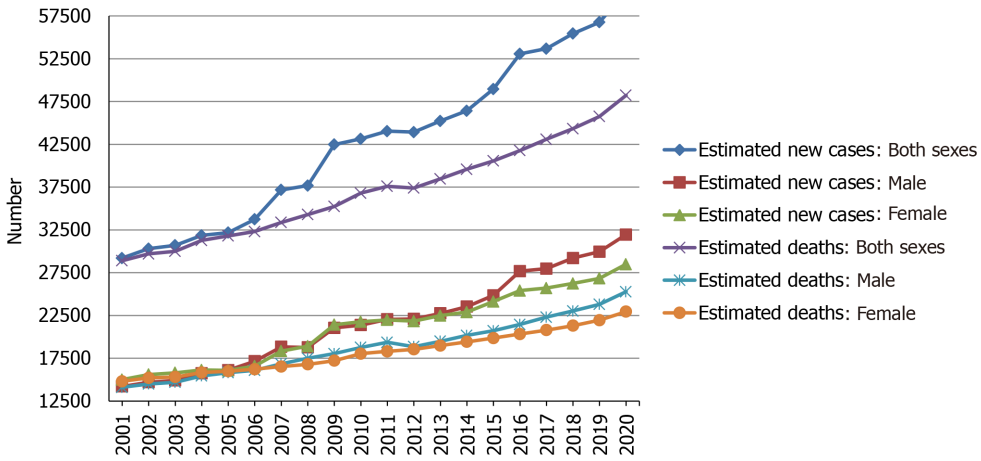

Figure 2 Estimated new cases and deaths from 2001 to 2020 in the United States. The data is from Cancer Statistics that the American Cancer Society estimates the numbers of new cancer cases and deaths in the United States from 2001 to 2020[16,28-47].

lowest at 29.3% and 31.6%, respectively[25]. Based on China and India, both countries in Asia with more than one billion population, the incidence and mortality in Asia will increase by 190532 and 182127 in 2040, respectively, which will be the largest increase in terms of number[25]. In addition, standardized mortality rate of pancreatic cancer increased from 1.30 per 100000 to 3.32 per 100000 over 1991-2014 and might reach the peak in the ensuing 5 years in China, and the mortality rate was higher among elderly people and in urban and northeast/eastern regions than among young people and in rural and middle/western regions[26]. The incidence of pancreatic cancer was 12.1 per 100000 in 2010 and is predicted to increase to 15.1 and 18.6 per 100000 in 2030 and 2050, respectively, with an average annual growth of 1.1%[27]. In the age-stratified analysis, the over 65 years group will have the highest projected incidence (31.9 per 100000) in 2050, and the incidence is projected to increase gradually in the sex-stratified analysis, with an average annual growth of 1.3% in males and 0.9% in females[27].

The number of years of life lost (YLL) is a measure of premature mortality, taking into account simultaneously the number of deaths and life expectancy at age of death, and projection of YLL due to premature mortality (*i.e.*, time-based approach) provides a comprehensive outlook of the fatal burden at a population level[27]. Due to premature death in individuals with pancreatic cancer, the total YLL was 5604 years in 2010 and is projected to increase to 9784 in 2030 and 14247 in 2050, with an average annual growth of 2.1%[27]. In the age-stratified analysis, the 40-64 years group will have the highest projected YLL (7588 years) in 2050, and the YLL is projected to increase gradually in the sex-stratified analysis, with an average annual growth of 2.1% in males and 2.2% in females[27].

In conclusion, pancreatic cancer, like other cancers such as lung, liver, and stomach cancer, will cause a huge economic burden to all countries and related populations in the next 20 years, especially China having a huge population, which is still a developing country. In order to reverse these trends and improve the prognosis of patients with pancreatic cancer, the most simple, direct, and effective way is to understand the risk factors affecting the occurrence and development of pancreatic cancer in detail, which provides comprehensive and reasonable guidance and suggestions for the prevention of pancreatic cancer, and offers reliable and feasible ideas for the early screening of pancreatic cancer.

CAUSES AND RISK FACTORS OF PANCREATIC CANCER

Pancreatic intraepithelial neoplasias (PanINs) are noninvasive epithelial proliferations in smaller pancreatic ducts, which progress from PanIN-1 (low-grade) to PanIN-2 (intermediate-grade) to PanIN-3 (high-grade)[48]. The differentiation of normal epithelium into PanIN-1/PanIN-2 and then into PanIN-3/invasive pancreatic cancer requires a considerable period of development, while the development process before high-grade PanIN-3 and invasive pancreatic cancer is the golden stage of preventing pancreatic cancer through effective interventions. Therefore, a thorough and compre-

hensive understanding of pancreatic cancer risk factors is of great practical significance for the prevention of pancreatic cancer. The exact cause of pancreatic cancer is unknown, but many non-modifiable and modifiable risk factors are associated with development of pancreatic cancer. Non-modifiable risk factors include age, gender, ethnicity, ABO blood group, microbiota, diabetes mellitus (DM), and family history and genetic susceptibility, while modifiable risk factors include smoking, alcohol drinking, dietary factors, pancreatitis, obesity, infection, and socioeconomic status and insurance. The influence of these factors on the occurrence, progression, and invasion of pancreatic cancer is analyzed and summarized as follows.

NON-MODIFIABLE RISK FACTORS

Age

Both 89.4% of new cases of pancreatic cancer and 92.6% of deaths occur in patients over 55 years of age in the United States, the new cases are most frequently diagnosed among people 65-74 years of age with a median age at diagnosis of 70 years, and the percent of deaths is also highest among people of the same age group with a median age at death of 72 years[14]. The proportions at 40-64 years and over 65 years of age were 47.9% and 48.6% in diagnosed patients with pancreatic cancer in China[49]. The mortality rates of patients aged under 30, 30-44, 45-59, 60-74, and 75 and above among males are 0.1, 1.4, 10.1, 19.3, and 14.6 per 100000 in China, respectively[50], meaning that male pancreatic cancer population over 60 years of age has a higher mortality rate. The reference does not provide the mortality rates of pancreatic cancer in the five broad age groups in women and both sexes[50]. Worldwide, it is extremely rare for pancreatic cancer to be diagnosed before the age of 30, so it is typically a disease of the elderly. The risk factor also determines the need for screening and early detection of pancreatic cancer among the population over a certain age.

Gender

In the United States, the new cases of pancreatic cancer is 31950 among males and 28480 among females in 2020, and the deaths is 25270 among males and 22950 among females[16]. In China, the age-standardized respective incidence and mortality rate are 52.2 and 45.6 per 100000 among men in 2015, and 37.9 and 33.8 per 100000 among women[50]. On a global scale, the new cases are 243033 among men and 215885 among women in 2018, and the deaths are 226910 among men and 205332 among women[18]. The global respective incidence and mortality rates are 5.5 and 5.1 per 100000 among men in 2018, and 4.0 and 3.8 per 100000 among women[18]. Globally, the respective cumulative risk of developing pancreatic cancer and dying from it from birth to 74 years is 0.65% and 0.59% among males in 2018, and 0.45% and 0.41% among females [18]. The ratio of male to female for estimated new cases and deaths increased in the United States from 2001 to 2020, as shown in Figure 3. Thus, the worldwide incidence and mortality of pancreatic cancer are higher among males than females.

ABO blood group

The ABO antigens were first described by Landsteiner as erythrocyte antigens in 1900 [51]. The antigens of ABO blood group are glycoproteins that are expressed on red blood cells and various epithelial cells, including the urothelium and gastrointestinal mucosa[52]. The phenotypic A and B antigens are terminal carbohydrates synthesized by the addition of monosaccharides catalyzed by a series of specific glycosyltransferases, and the phenotype O is characterized by deficiency of A and B glycosyltransferases[52]. There is growing evidence that ABO blood group may also be associated with carcinogenesis or progression of pancreatic cancer. A consortia-based evaluation and replication study showed that non-O blood group was associated with an increased risk of pancreatic cancer compared with blood group O[53]. A register-based cohort study showed that blood group A was associated with an increased risk of pancreatic cancer[54]. There was a significantly higher risk for developing pancreatic cancer in Chinese patients with the A or AB blood types than for those with type O [55]. El Jellas *et al*[56] reported that the prevalence of blood type A and subtype A1 was highest among the unresected cases, the unresected cases had the lowest frequency of blood group O, and patients with blood group O survived longer than non-O patients in the group of unresected cases. A study at Shanghai Pancreatic Cancer Institute showed that Chinese Han population with blood type A were more likely to develop pancreatic cancer, but people with blood type B were less likely to develop pancreatic neuroendocrine tumors and other types of pancreatic masses, compared with those

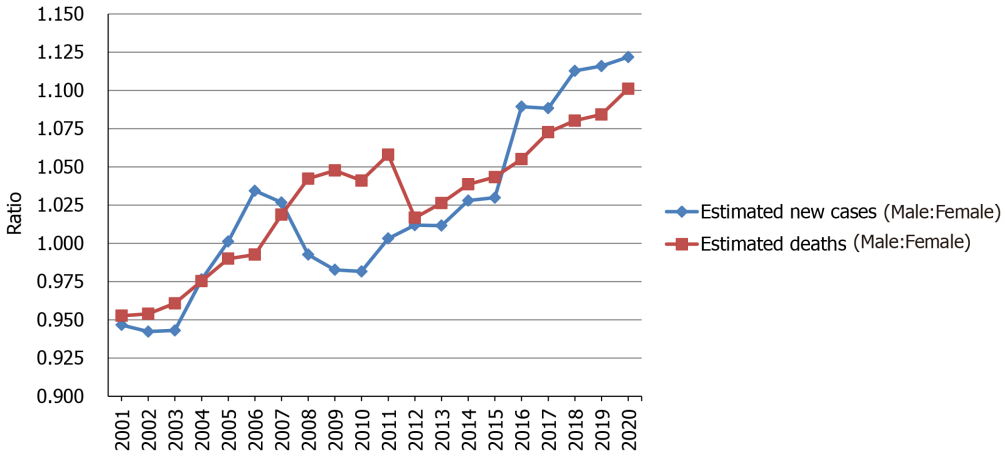

Figure 3 Ratio of male to female for estimated new cases and deaths from 2001 to 2020 in the United States. The data is from Cancer Statistics that the American Cancer Society estimates the numbers of new cancer cases and deaths in the United States from 2001 to 2020[16,28-47].

with blood type O[57]. Hofmann *et al*[51] reported that patients with blood type O had more often well-differentiated PDAC compared with blood type non-O, and they elucidated the novel interaction between blood type immunoglobulin M isoagglutinins and PDAC O-GalNAc glycoproteins, which may contribute to the pathogenesis and progression of pancreatic cancer. Accordingly, the risk for people with blood type O to develop pancreatic cancer is lower than those with other blood types. In addition, the ABO allele that determines blood type A has two major subtypes, namely, A1 and A2, and the association of A1 but not A2 with pancreatic cancer could therefore suggest that the activity of blood type A glycosyltransferase plays a role in carcinogenesis[56]. The study showed that the A2 subtype has a single base deletion near the carboxyl terminal, and introducing the single base deletion into the expression construct of A1 transferase cDNA significantly reduced the activity of A transferase in DNA-transfected HeLa cells[58]. Therefore, clarifying the etiological mechanism between the risk of pancreatic cancer and ABO blood type may provide a new perspective for the treatment of this disease.

Ethnicity

The burden of exocrine pancreatic disease, including pancreatic cancer, pancreatitis, and pancreatic cyst, differs among various ethnicities, and African-Americans and certain indigenous populations are at the greatest risk of developing these diseases [59]. Huang *et al*[60] observed that African-Americans, Native Americans, and Japanese-Americans had higher rates of developing pancreatic cancer, but no difference between Latino- and European-Americans, and found that African-Americans had a 20% greater risk of pancreatic cancer than European-Americans even after adjusting for known risk factors. In the studies including few minority patients, the neutrophil-to-lymphocyte ratio (NLR) is associated with a reduced overall survival in pancreatic cancer patients, and NLR > 5 was significantly associated with a worse overall survival compared with NLR ≤ 5[61]. Patients with an NLR ≤ 5 were also more likely to develop locally advanced disease than metastatic cancers and primary tumor located in the head or neck of the pancreas, while patients with an NLR > 5 were more likely to have liver metastases and albumin < 3.4 g/dL, suggesting that elevated NLR is an independent marker for poor prognosis and a potentially valuable factor[61]. Patients with an NLR ≤ 5 were more likely to be non-Hispanic Black, while patients with an NLR > 5 were more likely to be non-Hispanic White or Hispanic[61], suggesting that there are different predispositions and outcomes for pancreatic cancer between non-Hispanic Black and non-Hispanic White or Hispanic. Gad *et al*[62] found that the incidence of pancreatic cancer among Asian-Americans, especially malignancies of the body and tail of the pancreas, as well as the mortality based on the incidence, was overall on the rise in an epidemiological study, without respect to age, sex, or stage subgroup. Amaral *et al*[63] also emphasized the importance of the influence of ethnicity on somatic mutations in Brazilian patients with PDAC. To elucidate the reasons for the racial differences in the incidence of pancreatic cancer may help us improve the understanding and prevention of this disease.

Microbiota

Oral microbiota: Several epidemiological studies have found the direct relationship between oral bacteria and pancreatic cancer[64]. Farrell *et al*[65] reported that the levels of two bacteria biomarkers (*Neisseria elongate* and *Streptococcus mitis*) were lower in patients with pancreatic cancer than in healthy controls, and found that the combination of the two bacteria biomarkers distinguished pancreatic cancer patients from healthy subjects with an area under the curve value of 0.90, sensitivity of 96.4%, and specificity of 82.1%. Torres *et al*[66] found that the ratio of *Leptotrichia* to *Porphyromonas* in the saliva of pancreatic cancer patients was significantly higher than that in healthy individuals or those with other disease. Fan *et al*[67] found that *Porphyromonas gingivalis* and *Aggregatibacter actinomycetemcomitans* were associated with a higher risk of pancreatic cancer, and phylum Fusobacteria and its genus *Leptotrichia* were associated with a decreased risk of this cancer. Olson *et al*[68] reported that the mean relative proportions of Firmicutes and related taxa were higher in patients with pancreatic cancer, while the mean relative proportions of Proteobacteria and related taxa were higher in controls.

Gut microbiota: Studies have confirmed that gut microbiota is associated with recognized risk factors for pancreatic cancer, such as obesity and type II diabetes, suggesting the relationship between gut bacteria and pancreatic cancer[64]. In recent decades, multiple and highly complex effects of gut microbiota on pancreatic cancer have been identified as potential risk factors for the development and progression of this tumor[69]. A prospective study, for the first time, analyzed gut microbial profile in Chinese pancreatic cancer cohorts by MiSeq sequencing, revealing a significant decline in gut microbial diversity and a unique microbial profile in pancreatic cancer, due in part to the decline in alpha diversity[70]. Additionally, the microbial profile changed in pancreatic cancer, with an increase in certain pathogens and lipopolysaccharides (LPS)-producing bacteria and a decrease in probiotics and butyrate-producing bacteria [70]. LPS might play a pro-inflammatory pro-tumor role by activating the nuclear factor-κappa B (NF-κB) pathway, producing proinflammatory cytokines [tumor necrosis factor alpha (TNF-α), interleukin (IL)-6, and IL-1] and leading to liver inflammatory and oxidative damage[71]. After LPS treatment, Ras activity in cells prepared from acinar-Ras mice was greatly elevated and maintained at a high level for a long time, and severe chronic pancreatitis and PanIN lesions were induced in acinar-Ras mice, accompanied by sustained elevated Ras activity, whereas there was no observed effects in control mice, suggesting that LPS treatments led to fibrosis and PanIN formation in the presence of oncogenic Ras[72]. Therefore, LPS may have a greater pathological impact on patients carrying cells expressing oncogenic RAS, which may explain individual differences in response to infection, suggesting the association between chronic bacterial infectious diseases and colon and pancreatic cancers[72]. As a member of the RAS family of GTP-binding proteins, KRAS mediates a wide variety of cellular functions including proliferation, differentiation, and survival[73], and the prevalence of oncogenic *KRAS* mutation in PDAC ranges from 88% to 100%[74]. Consistent with a central pathogenic role of the $KRAS^{G12D}$ mutation, mice engineered with pancreas-specific expression of this activated *KRAS* allele sustain classical PanIN lesions that can progress to PDAC in the appropriate tumor suppressor background [73]. Thomas *et al*[75] found that the proportion of poorly differentiated PDAC in the microbiota-intact mice was higher than that in microbiota-depleted mice (89.75 *vs* 34.8%, respectively), demonstrated that the intestinal microbiota accelerated pancreatic carcinogenesis in the $KRAS^{G12D}/PTEN^{lox/+}$ mice model of pancreatic cancer, and considered that the intestinal microbiota had a long-distance role on PDAC progression. In addition, based on crucial genera associated with pancreatic cancer, gut microbial markers might achieve an excellent classification capacity between pancreatic cancer and healthy controls, suggesting that the specific alterations of gut microbiota might become non-invasive biomarkers for pancreatic cancer diagnosis[70].

Pancreatic microbiota: A number of different bacterial taxa are found in pancreatic tissue contents, including those known to inhabit the oral cavity, which suggest that the pancreas is not a sterile organ[76]. The relative abundance of bacterial taxa at the genus level in the pancreas has a substantial between-person variability, and bacterial composition of the pancreatic duct, head, and tail as well as the duodenum was highly similar in the same individuals[76]. The study showed that the community composition of the microbiota in the human pancreas failed to discriminate between normal and disease states, and that the acquisition of pancreatic bacteria is not a physiologic process, even under conditions of intestinal inflammation[75]. Del Castillo *et al*[76] found that the presence and relative abundance of *Lactobacillus* were lower in

pancreatic tissue of cancer subjects and the relative abundance of periodontal-related pathogens was higher in cancer subjects, when compared with noncancer subjects. Pushalkar *et al*[77] found that the bacteria (*Enterococcus faecalis* and *Escherichia coli*) could migrate into the pancreas, confirmed that the abundance of intrapancreatic bacteria in both mice and patients with PDAC was markedly greater compared with normal pancreas by 16S rRNA fluorescence *in situ* hybridization and qPCR analysis, and consider that the bacteria promote the progression of pancreatic oncogenesis in both preinvasive and invasive models[77]. Maekawa *et al*[78] mainly detected *Enterococcus* and *Enterobacter* species in bile, demonstrating that *Enterococcus* and *Enterobacter* can survive in pancreatic juice and/or bile, and found that 29 of 36 pancreatic juice samples were positive for bacterial DNA[78]. *Enterococcus faecalis* was also found in pancreatic tissue from patients with chronic pancreatitis and pancreatic cancer, and serum antibodies to capsular polysaccharide of *Enterococcus faecalis* were elevated in patients with chronic pancreatitis[78]. They demonstrated that *Enterococcus faecalis* is involved in the progression of chronic pancreatitis using the model mice with caerulein-induced chronic pancreatitis, which may ultimately result in the development of pancreatic cancer[78].

In addition, Pushalkar *et al*[77] also found that the microbiome regulates immunogenicity in PDAC and programs tumor-associated macrophages *via* Toll-like receptor signaling to induce immune tolerance, and bacterial communities are distinct between early and advanced PDAC. Geller *et al*[79] demonstrated that bacteria are a component of the PDAC tumor microenvironment, and estimated that bacteria colonized PDAC samples had an average of one bacterium per 146 human cells. Their results indicated that PDACs contain bacteria that can potentially modulate tumor sensitivity to gemcitabine, and they considered that the bacteria play a critical role in mediating resistance to chemotherapy[79]. By studying colon cancer models, they found that bacteria can metabolize the chemotherapeutic drug gemcitabine (2′,2′-difluorodeoxycytidine) into its inactive form (2′,2′-difluorodeoxyuridine), which depends on the expression of a long isoform of bacterial cytidine deaminase, seen primarily in γ-proteobacteria[79].

The above various microorganisms have different influences on the occurrence, development, and invasion of pancreatic cancer in different ways. Therefore, the study on the influence of microorganisms on pancreatic cancer will provide more new insights to reveal its etiology. And studying the effects of microorganisms on pancreatic cancer has the potential to be used as a target for the regulation of disease progression and treatment.

Family history and genetic susceptibility

Hereditary pancreatic cancer includes inherited cancer syndromes with a recognized known germline mutation associated with an increased risk of pancreatic cancer and familial pancreatic cancer with two or more cases of pancreatic cancer in their families [80]. Pancreatic cancer associated with hereditary syndromes or familial pancreatic cancer accounts for about 10% of cases[81]. Family history of pancreatic cancer was associated with an increased pancreatic cancer risk when compared with cancer-free family history, with the risk being greater when ≥ 2 first-degree relatives suffered pancreatic cancer and among current smokers[82]. Members of familial pancreatic cancer kindreds having at least one first-degree relative affected by pancreatic cancer had a 9-fold increased risk of developing pancreatic cancer, whereas members of sporadic pancreatic cancer kindreds having a first-degree relative with pancreatic cancer did not have an increased risk[83]. Risk was higher among members of familial pancreatic cancer kindreds with a young-onset patient (< 50 years) in the kindred than those without a young-onset case in the kindred[84].

Genetic mutations associated with an increased risk of pancreatic cancer include *STK11/LKB1*, *CDKN2A (p16)*, *BRCA1/2*, *PRSS1/SPINK1/CFTR*, mismatch repair genes (*MLH1/MSH6/MSH2/PMS2*), *ATM*, and *PALB2* (a new pancreatic cancer susceptibility gene)[85]. And pancreatic cancer is also found to be associated with these familial cancer syndromes for which genetic mutations correspond, such as Peutz-Jeghers syndrome (*STK11/LKB1*), familial atypical multiple mole melanoma (*CDKN2A*), hereditary breast cancer ovarian cancer syndrome (*BRCA1/2*), and hereditary non-polyposis colorectal carcinoma syndrome (*MLH1/MSH6/MSH2/PMS2*)[25,85].

A study from Mayo Clinic showed that the aggregate prevalence was 36/302 (11.9%) for all cases with any positive PDAC family history[86]. Seven PDAC-associated genes (*ATM*, *BRCA1*, *BRCA2*, *CDKN2A*, *MSH2*, *PALB2*, and *PMS2*) and four genes with no known PDAC association (*BARD1*, *CHEK2*, *MUTYH/MUY*, and *NBN*) were identified as pathogenic variants in the study[86]. Kindreds with at least one pair

of first-degree relatives who were affected by PDAC were considered FPC, and kindreds with at least two affected blood relatives that did not meet the FPC definition were considered "familial non-FPC"[86]. Thirty-six (12%) patients carried at least one pathogenic variant in one of 11 genes, and the probabilities of carriers with pathogenic variant among FPC patients and familial non-FPC patients were 14% and 9%, respectively[86]. Pathogenic variants (n) identified in PDAC patients were *BRCA2* (11), *ATM* (8), *CDKN2A* (4), *CHEK2* (4), *MUTYH/MYH* (3 heterozygotes, not biallelic), *BRCA1* (2), and 1 each in *BARD1*, *MSH2*, *NBN*, *PALB2*, and *PMS2*[86]. Regardless of FPC status, multiple susceptibility gene testing may be necessary in PDAC patients with a family history of pancreatic cancer, which will provide genetic risk counseling for families[86]. Therefore, the study of the family characteristics and genetic features of pancreatic cancer is of great clinical significance in identifying the susceptible population of pancreatic cancer, screening the high-risk individuals of pancreatic cancer, and early diagnosis of pancreatic cancer.

Diabetes mellitus

In comparison with patients without diabetes, those who were recently diagnosed with diabetes had an nearly 7-fold increase in risk of developing pancreatic cancer [87]. Either hyperglycaemia or diabetes is found among as many as 80% of patients, both of which can be detected in the presymptomatic phase, and on the contrary, older patients with new-onset diabetes have about an 8-fold higher risk of developing pancreatic cancer than the general population, suggesting a "dual causality" between diabetes and PDAC[88], in that both long-standing type 2 DM (T2DM) is a risk factor of developing PDAC and PDAC is assumed to be a cause of diabetes in many cases [89]. A multiethnic cohort study also showed that recent-onset diabetes is a manifestation of pancreatic cancer and long-standing diabetes is a risk factor of developing this cancer[90]. At present, the prevalence of diabetes in China is on the rise and has the largest diabetes epidemic worldwide, and in 2013, the estimated total prevalence was 10.9% for diabetes and 35.7% for prediabetes among adults in China, indicating the importance of diabetes as a public health problem in China[91]. In 2011-2012, the prevalence of diabetes was estimated from 12% to 14% among US adults, and participants who were non-Hispanic black, non-Hispanic Asian, and Hispanic had a higher prevalence[92]. The global spread of this enormous medical burden further highlights the necessity to better understand the pathophysiological relationship between T2DM and pancreatic cancer.

A growing body of epidemiological and experimental evidence shows that chronic hyperinsulinaemia increases the risk of cancers of the colon and endometrium, and probably other tumours (such as pancreas and kidney)[93]. Hyperinsulinemia, especially intrapancreatic, due to obesity and insulin resistance in patients with prediabetes or early T2DM may believably conduce to the observed increased risk of developing PDAC[89]. The high level of islet hormones in blood directly reaches groups of acinar and ductal cells and acts on insulin-like growth factor-1 (IGF-1) receptors to promote survival and proliferation of acinar and ductal cells[89]. The characteristics of T2DM patients and the overwhelming majority of obese individuals are insulin resistance with ensuing hyperinsulinemia and high levels of IGF-1, which can act as potent growth-promoting factors[94]. In addition, Butler *et al*[95] reported that replication of pancreatic duct cells in lean subjects with T2DM had a 4-fold increase compared with lean non-diabetic controls, suggesting that the increased risk of pancreatitis and pancreatic cancer in T2DM is driven by replication of chronically increased pancreatic duct cell replication[95].

The desmoplastic response attribute to production and proliferation of extracellular matrix proteins in tumor-associated fibroblasts, activating pancreatic stellate cells (PaSC)[94]. Yang *et al*[96] reported that progression of high-fat diet-induced PDAC in mice is associated with hyperglycemia, hyperinsulinemia, and PaSC activation, and found that the pancreas from patients with T2DM showed substantial collagen deposition and activated PaSC in islet and peri-islet exocrine pancreas compared with normal control[96]. Both quiescent and activated PaSC coexpress insulin and IGF-1 receptors, the expression of which was modulated by both insulin and glucose[96]. Insulin induces rapid tyrosine autophosphorylation of insulin/IGF-1 receptors at specific kinase domain activation loop sites, activates Akt/mTOR/p70S6K signaling, and inactivates FoxO1, a transcription factor suppressing cell growth[96]. In activated PaSC, insulin promotes cell proliferation and production of extracellular matrix proteins, and specific inhibition of mTORC1 and mTORC2 can abolish the above effects, suggesting that increased local glucose and insulin concentrations are associated with obesity and T2DM promotes PaSC growth and fibrosing responses [96]. In premalignant H6c7-kras cells, hyperglycemia increases secretion and signaling

of transforming growth factor beta1 (TGF-β1) and induces properties of cancer stem cells depending on TGF-β1-signaling, suggesting that hyperglycemia promotes pancreatic ductal epithelial cells to acquire the properties of mesenchymal and cancer-stem cells by activating TGF-β signaling[97]. Li *et al* found that patients with A blood type who also had DM had a greater odds of having pancreatic cancer, and further research is needed to confirm the results and to identify the mechanisms by which A blood type and DM jointly contribute to the risk of pancreatic cancer progression and development[55].

There are many mechanisms that explain the effect of DM on pancreatic cancer and the relationship between the two. However, in order to reveal the real relationship between diabetes and pancreatic cancer, it still needs to be further studied to provide new strategies for the prevention of pancreatic cancer.

MODIFIABLE RISK FACTORS

Smoking

Epidemiological studies have shown that many causative factors are associated with pancreatic cancer, and cigarette smoking has the strongest positive association with the risk of developing the cancer[98]. Due to smoking, the estimated prevalence was about 30% in many parts of the world and the risk of pancreatic cancer was doubled in smokers, whereas the population-attributable risk caused by smoking is about 25% for pancreatic cancer, meaning that the overall burden of this cancer would be reduced if smoking was completely eliminated[99]. Patients with pancreatic cancer who smoked prior to diagnosis had an about 40% increased hazard for death compared with those who never smoked[100]. And long-term smoking portended worse outcomes for current smokers, but former smokers experienced outcomes similar to those who had never smoked, suggesting that quitting smoking can have potential beneficial effects [100]. A large European case-control study confirmed that current smokers had a 72% increased risk of developing pancreatic cancer compared with never-smokers, and the study also endorsed that around 16% of all pancreatic cancer diagnoses could be avoided through tobacco preventive measures in terms of attributable risk[101]. And analysis of dose-response relationships confirmed that higher smoking intensity, longer smoking duration, and increased cumulative dose levels were associated with a further increased risk of pancreatic cancer, whereas smoking cessation led to a gradual decline in the risk of pancreatic cancer[101]. Smoking also notably increases the risk of developing pancreatic cancer in individuals with a family history of this cancer[82]. These studies suggest that smoking cessation has a potential benefit to improve survival for patients with pancreatic cancer and helpfully prevent pancreatic cancer in those at risk.

As an avoidable risk factor, smoking is of particular concern, and elucidating the mechanisms involved would significantly reduce the number of PDAC cases diagnosed each year[102]. Smoking-induced inflammation was accompanied by enhanced activation of PaSC and elevated levels of serum retinoic acid-binding protein 4, suggesting increased bioavailability of retinoic acid that is conducive to differentiation of myeloid-derived suppressor cells to tumor-associated macrophages and dendritic cells[103]. And smoking exposure also leads to partial suppression of the immune system in the early progression of pancreatic cancer[103]. In xenografts of patient-derived pancreatic cancer, nicotine intervention promoted growth and metastasis of tumor, and it was confirmed that nicotine reduced survival by enhancing paracrine HGF-MET signaling in the pancreatic cancer microenvironment[104]. In addition, nicotine induced dedifferentiation of acinar cells by activating AKT-ERK-MYC signaling, thereby inhibiting the activity of *Gata6* promoter and losing GATA6 protein, and subsequently causing loss of acinar differentiation and over-activation of oncogenic K-Ras[105]. And metformin could inhibit nicotine-induced carcinogenesis of the pancreas and tumor growth by up-regulating GATA6 expression and promoting programmed differentiation of acinar cell[105]. Benzo(a)pyrenes, polycyclic aromatic hydrocarbons, and tobacco-specific nitrosamines are several carcinogens identified in tobacco smoke, most of which play a genotoxic role by formation of DNA adducts and generation of reactive oxygen species, leading to mutations in vital genes such as *K-Ras* and *p53*[106]. Nicotine and other carcinogenic components in tobacco smoke can directly promote growth of tumor cells, change cross-talk between tumor and stromal cells within the tumor microenvironment, and enhance infiltration of myeloid-derived suppressor cells[100]. Therefore, the study and elucidation of carcinogenic mechanism of carcinogens in tobacco smoke will contribute to the treatment and prevention of

pancreatic cancer caused by related factors.

Alcohol drinking

East Asians have a high proportion in inefficient metabolism of acetaldehyde, so alcohol drinking may play a more important role in the developing pancreatic cancer among East Asians[107]. According to many studies, there is no doubt that the risk of pancreatic cancer is associated with high alcohol consumption (more than three drinks per day), but no association was found with low-to-moderate alcohol consumption [25]. A population-based study demonstrated that heavy alcohol consumption and binge drinking increased estimated risk of developing pancreatic cancer among males but not among females[108]. It may also be the reason why pancreatic cancer has a higher incidence and mortality in men than in women. And the study also suggested that either binge or consistent heavy alcohol consumption persistently increased the risk of developing pancreatic cancer regardless of the temporal proximity between alcohol consumption and diagnosis of pancreatic cancer[108]. A large prospective study suggested that baseline and lifetime alcohol consumption was positively associated with the risk of developing pancreatic cancer, and the estimated risk for beer and spirits/liquors was more apparent than wine[109]. Alcohol plays an independent role in promoting PDAC associated with fibrosis formed by a stellate cell-independent mechanism and further boosts formation of PanIN lesion and induction of M2 macrophages in the context of chronic pancreatitis[110]. This is an important finding, namely, M2 macrophages suppress the directed immune mechanisms of cancer and block the recruitment of T cells into the tumor, further promoting cancer progression[111]. Mice that expressed mutant *K-ras* gene developed early and advanced forms of the most common pancreatic cancer in humans[112]. Specific mutations in the *K-ras* oncogene may be more commonly found in alcohol consumers with pancreatic cancer, and may be initiators or terminators of pancreas cancer associated with heavy alcohol consumption[108]. Additionally, alcohol might promote the development of cancer by inducing oxidative stress and lipid peroxidation, and alcohol abuse may also accelerate the progression of tumor by boosting pancreatic inflammation[112].

Two NAD-dependent enzymes, namely, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), are mainly involved in alcohol metabolism in human[113]. In the body, alcohol is first converted into acetaldehyde by ADH oxidation, and acetaldehyde is then converted into non-toxic acetate by ALDH oxidation for excretion[113]. In the human liver, there are two kind of ALDHs, including ALDH1 (cytosolic) and ALDH2 (mitochondrial), and only mitochondrial ALDH2 oxidizes acetaldehyde to acetate at physiological concentrations[114]. The variant *ALDH2*2* allele can significantly decrease ALDH2 enzyme activity and affect alcohol response, which is a striking genetic polymorphism[113].

In many East Asian countries, the *ALDH2*2* allele associated with reduced enzyme activity is found in 30%-50% of the population, resulting in the inefficient metabolism of the carcinogenic acetaldehyde generated from alcohol metabolism[107]. Thus, acetaldehyde accumulates in *ALDH2*2* carriers, even after a moderate intake of ethanol (0.5 g/kg)[115], also leading to a higher risk of developing alcohol-related cancers in individuals carrying the *ALDH2*2* allele. Kanda *et al*[116] found that the impact of alcohol on pancreatic cancer risk was associated with rapid production or high accumulation of acetaldehyde, indicating that acetaldehyde may play a substantial role in the potential mechanism of pancreatic cancer[116]. This can also provide guidance and help to prevent pancreatic cancer for people of different groups and races.

Dietary factors

In general, diets high in fruits, vegetables, and other plant-based foods can reduce the risk of developing pancreatic cancer, while dietary patterns rich in meat and animal products can increase the risk of the cancer[107]. Intake of meat, especially red meat, cooked meat at high temperature, and meat-associated heterocyclic amines, and overall mutagenic activity may induce the development of exocrine pancreatic cancer [117]. Foods are often heat processed and may contain advanced glycation end products (AGEs) that can be formed by a nonenzymatic reaction between reducing sugars and free amino groups on proteins, peptides, and amino acids[118]. When the carbonyl group of reducing sugar like glucose or its oxidation or lipid peroxidation products react with the ε-amino group of lysine or the guanidino group of arginine, AGEs can be formed, including imidazolones, pentosidine, pyrraline, and N^{ε}-(carboxymethyl)lysine (CML)[118]. AGEs accumulate in sera and tissues during the ageing

process because of glycolytic and oxidative reactions, reduced activity of the detoxification systems, cigarette smoking, and consumption of high-temperature-processed foods[8]. Excessively high concentrations of AGEs in human tissue and circulation accelerate oxidative stress and inflammation, which may play a pathogenic role[118]. Exogenous AGEs, in particular those derived from the diet, have been claimed to contribute to several disease processes, including cancer in general and, specifically PDAC[8]. CML is frequently used as a marker for AGEs in general[119]. Jiao *et al*[120] proposed a novel mechanism that consumption of heat-treated red meat can cause chronic inflammation and subsequently lead to pancreatic cancer, and considered that consumption of dietary CML-AGE was associated with a modest increase in risk of pancreatic cancer for men, which might partly explain the positive correlation between red meat and pancreatic cancer. A model experiment showed that AGEs markedly accelerated the development of pancreatic cancer and inhibition of AGE prevented the tumor-promoting effect of diabetes[8]. Therefore, exogenous AGEs from processed/grilled/baked foods may be involved in the genesis and development of pancreatic cancer.

Many nutrients and phytochemicals in fruits and vegetables have antioxidant, antimutagenic, and anti-carcinogenic properties, especially for water-soluble vitamins [121]. Additionally, isothiocyanates found in cruciferous vegetables powerfully induce the detoxification enzymes, and assist in the removal of potential carcinogens[121]. Higher intake of fruit and vegetables is associated with a reduced risk of pancreatic cancer[122], and cruciferous vegetable intake might be inversely associated with pancreatic cancer risk[123]. A meta-analysis of epidemiological studies showed that high intake of dietary fiber was associated with a risk reduction of pancreatic cancer [124]. A European Prospective Investigation Into Cancer-Norfolk study showed that high-fiber diet altered a positive correlation between red/processed meats and the PDAC development but not those with lower fiber intake, and fiber intake made few alteration for the PDAC risk in past and current smokers[125]. This study showed that fiber intake may be beneficial for those with high meat intake, but the findings do not suggest that high fiber intake can protect against the PDAC development[125]. Therefore, further prospective cohort studies are needed to investigate the effect of fiber intake on the development and progression of pancreatic cancer. A low-fat dietary intervention was associated with a reduced incidence of pancreatic cancer in overweight or obese women in the Women's Health Initiative Dietary Modification trial[126]. Therefore, it is of great significance for the prevention of pancreatic cancer by adjusting the diet of pancreatic cancer susceptible population. And it is worth further investigating how both diet and lifestyle may work together to promote or inhibit pancreatic cancer.

Pancreatitis

The majority of burden in exocrine pancreatic disease arises from acute pancreatitis, chronic pancreatitis, and pancreatic cancer[127]. Acute pancreatitis, an inflammatory disease of exocrine pancreas, is associated with injury and necrosis of tissue[128]. It has been reported that acute pancreatitis may be an early symptom of pancreatic cancer[129]. A nationwide matched-cohort study in Denmark showed that patients hospitalized with acute pancreatitis had an increased risk of developing pancreatic cancer compared with age- and gender-matched controls in the general population [130]. Rijkers *et al*[131] found that patients who suffered a first incident of acute pancreatitis and had no further progression to chronic pancreatitis had a 0.4% risk of developing pancreatic cancer, but the risk of pancreatic cancer increased 9-fold for those who progressed to chronic pancreatitis, suggesting that screening for pancreatic cancer after a first incident of acute pancreatitis, especially in patients who had further progression to chronic pancreatitis, could potentially result in more curable resections and improved survival[131]. The risk of pancreatic cancer increased markedly after an initial diagnosis of acute pancreatitis, regardless of its type, and gradually decreases with passage of time[132]. An increase in the number of recurrent episodes of acute pancreatitis was associated with an increased risk of developing pancreatic cancer [132].

Patients who have an episode of acute pancreatitis are 20%-30% more likely to have one or more relapse, and approximately 10% of the relapsing cases progress to chronic pancreatitis[133]. Chronic pancreatitis is a progressive inflammatory disease, and causes pancreatic parenchyma to be replaced by fibrous tissue, resulting in a loss of acinar and islet cells[134]. Chronic pancreatitis may cause mild or asymptomatic debilitating pain, attack(s) of acute pancreatitis, endocrine and/or exocrine deficiency, local and/or systemic complications, and pancreatic cancer[135]. In recent decades, there is accumulating evidence that longstanding pre-existing chronic pancreatitis is a

strong risk factor of developing pancreatic cancer[25]. Low body mass index and pancreatic exocrine insufficiency in patients with chronic pancreatitis define a high-risk population with latent PDAC[136]. In comparison with the general population, patients with chronic pancreatitis had a significantly increased risk of pancreatic cancer, especially those with an older age at onset and a > 60 pack-year smoking history[137]. Five years after diagnosis, the risk of pancreatic cancer increased nearly 8-fold in patients with chronic pancreatitis, but the association diminishes with long-term follow-up[138]. The same risk trend was observed in patients with recurrent acute pancreatitis and chronic pancreatitis, suggesting the need for close follow-up in the first few years after diagnosis of these two types of pancreatitis to avoid neglect of pancreatic cancer. Patients who need surgery to treat chronic pancreatitis have a very high risk of developing pancreatic cancer, and early surgical intervention can play a role in preventing the progression of chronic pancreatitis to pancreatic cancer[139]. Chronic pancreatitis patients with *de novo* postoperative diabetes have a high suspicion index of developing pancreatic cancer after surgery[139].

Patients with early-onset pancreatitis caused by genetic factors appear to have a higher risk of developing pancreatic cancer[140]. Mutations of susceptibility genes in chronic pancreatitis can determine hereditary pancreatitis, idiopathic chronic pancreatitis, and cystic fibrosis, and Cazacu *et al*[140] found that mutations of cystic fibrosis transmembrane conductance regulator (*CFTR*) genes modestly increase the risk of pancreatic cancer in a meta-analysis. A total of 50080 patients were diagnosed with pancreatic cancer, of which 14.8% (7420 cases) were diagnosed with idiopathic pancreatitis prior to the diagnosis of cancer[141]. After pancreatitis diagnosis, six risk factors significantly associated with pancreatic cancer diagnosis included age between 40 and 90 years, African-American race, male sex, smoking, obesity, and DM, suggesting that it may be warranted to screen patients older than 40 years with unclear etiology of pancreatitis, especially for African-Americans and male population[141].

The study of the promoting effect of pancreatitis on the development of pancreatic cancer is beneficial to the early detection of pancreatic cancer, and can provide more guidance for the prevention of pancreatic cancer. However, in order to better understand the promoting role of pancreatitis on pancreatic cancer, more studies are needed to clarify the mechanism of pancreatitis in the development of pancreatic cancer.

Obesity

Obesity has been more and more recognized as a strong but modifiable risk factor for pancreatic cancer[142]. Relevant studies have confirmed that obesity is associated with an increased incidence of pancreatic cancer and potentially worse outcomes of this cancer[142]. A cohort study with pooled analysis found that central obesity was associated with increased mortality of pancreatic cancer, independent of body mass index, and also suggested that being overweight or obese during early adulthood may have a significant impact on the mortality risk of pancreatic cancer later in life[143]. A nationwide study including 1.79 million Israeli adolescents showed that obesity (≥ 95th percentile) was associated with an increased risk of pancreatic cancer later in life among both men and women compared with normal weight (5th to- < 85th percentile)[144].

There have been two biological mechanisms that were proposed to explain the underlying association between obesity and risk of pancreatic cancer, including inflammation and hormonal misbalance[142]. Many human cancers result directly from chronic inflammation, and inflammation has emerged to be a key mediator of pancreatic cancer development[145]. Changes in the fibro-inflammatory microenvironment are the major feature of obesity-associated pancreatic tumors[146]. Obesity is a pro-inflammatory condition, and both hypertrophied adipocytes and immune cells (primarily lymphocytes and macrophages) residing in adipose tissue contribute to increased circulating levels of pro-inflammatory cytokines like TNF-α, IL-6, leptin, and adiponectin[147]. The imbalance between these finely regulated pro-inflammatory and anti-inflammatory bioactive molecules leads to changes in tissue microenvironment, which further have influence on cell proliferation, apoptosis, cell invasion, and angiogenesis[148]. For example, Hertzer *et al*[149] reported that conditional *KRAS*^{G12D} mice with a high fat, high calorie diet exhibited significantly increased inflammation in the peri-pancreatic fat accompanied by elevated levels of several inflammatory cytokines, such as IL6, IL13, and IFN-γ, suggesting that obesity-associated inflammation in peri-pancreatic fat may accelerate pancreatic neoplasia in the model mice[149].

Obesity is also often associated with insulin resistance and T2DM, along with raised levels of insulin and IGF-1[142]. Insulin resistance is a hallmark of T2DM, in which

insulin fails to trigger adequate glucose uptake, resulting in accumulation of glucose in bloodstream and raised levels of insulin[150]. Hyperglycemia can enhance the availability of nutrients to cancer cells which metabolize glucose through the Warburg effect[151]. Islet adaptation enhances hormone production, processing, and secretion in the setting of obesity[146]. Even moderate overall and abdominal obesity and weight gain during adulthood were independently associated with an increased risk of developing hyperinsulinemia in non-diabetic middle-aged men[152]. Hyperinsulinemia causes a rise of IGF-1 which activates PI3K/MAPK/mTOR pathways after binding with its receptor, or the IGF receptor[148]. Overactivation of these pathways can activate the Ras/ERK pathway, leading to an increase in cell division, and IGF-1 activating PI3K/AKT/mTOR pathways promotes proliferation and inhibits apoptosis [142].

The mutation of oncogenic KRAS is the major event in pancreatic cancer and permanently activates KRAS protein, and then the protein serves on a molecular switch to activate various signaling pathways and transcription factors in cells, inducing cell proliferation, migration, transformation, and survival[153]. In comparison with lean KC mice, the pancreas of obese KC mice showed an increase in activation of KRAS downstream pathways, including MAPK and PI3K/AKT/mTORC1[154]. Chung *et al*[146] found that β-cell aberrantly expressed peptide hormone cholecystokinin in response to obesity and showed that islet cholecystokinin promoted oncogenic KRAS-driven tumorigenesis in pancreatic duct.

Infection

Helicobacter pylori (*H. pylori*) found mainly in the stomach is a Gram-negative microaerophilic pathogen that chronically infects as much as half the world's population[155]. *H. pylori* infection is associated with a variety of malignancies, such as gastric cancer, premalignant lesions of the stomach (atrophic gastritis and intestinal metaplasia), gastric lymphoma, pancreatic cancer, colorectal cancer, and laryngeal cancer[156]. With an estimated prevalence between 25% and 50% in Westernized countries, *H. pylori* could result in 4% to 25% of all cases with pancreatic cancer in these countries[157]. *H. pylori* infection is closely, *albeit* weakly, associated with the development of pancreatic cancer, and the association is prominent in Europe and East Asia, but less so in North America[158]. Cytotoxin-associated antigen A (CagA), a 120-145-kDa protein, was for the first time described as a virulence factor of *H. pylori* related to peptic ulcers[159]. A risk of pancreatic cancer increased in individuals with seropositivity for CagA-negative *H. pylori*, whereas the risk decreased in individuals with seropositivity for CagA-positive *H. pylori*[160]. CagA-negative strains of *H. pylori* might be a causative factor of pancreatic cancer[161]. Xiao *et al*[158] reported that CagA-positive *H. pylori* strains appear not to be associated with pancreatic cancer.

The net effects of *H. pylori* colonization in the gastric antrum are paracrine disinhibition of antral G-cell function, hypergastrinemia, and hyperacidity[162]. The risk of pancreatic cancer is increased by long-term conditions of excess gastric/duodenal acidity[162]. Gastric acid drives pancreatic bicarbonate secretion and, a consequence of hyperchlorhydria and suppressed somatostatin increases bicarbonate output from the pancreas in *H. pylori* carriers[162]. Low-level, prolonged generating of secretin or pancreatic bicarbonate increases the activity and turnover rate of ductular epithelial cell to sufficiently enhance the carcinogenic effect of environmental or endogenous N-nitroso carcinogens[162]. Asymptomatic *H. pylori* colonization, non-ulcer dyspepsia, or duodenal ulcers, and exposure to N-nitroso carcinogens *via* dietary or other routes in individuals would increase the risk of developing pancreatic cancer by increasing basal secretors or pancreatic bicarbonate[162]. CagA injected into gastric parietal cells through the interaction of *H. pylori* with integrin results in the activation of extracellular regulated protein kinases (ERK1/2) to further mobilize NF-κB p50 homodimers into the nucleus, leading to the inhibition of gastric H,K-adenosine triphosphatase (H,K-ATPase) α subunit transcription and the repression of gastric acid secretion[163]. Seropositivity of CagA-positive *H. pylori* was shown to protect against pancreatic cancer when compared to CagA-negative *H. pylori*, suggesting that differential modification of CagA-negative *vs* CagA-positive strains of *H. pylori* on chronic gastric acidity may be involved in modulating the risk of pancreatic cancer[160].

Socioeconomic status and insurance

In contrast with the traditional biomedical model, the bio-psycho-social-medical model highlights the significant role of socioeconomic status in health care services, including insurance status, marital status, and poverty level[164]. A study suggested that African-Americans, and in some cases Hispanics, had lower rates of surgery, less accessed to aggressive stage specific treatment, and underwent surgery at low volume

hospitals and/or by lower volume surgeons, which might contribute to the differences in outcomes[165]. In addition, underinsured or uninsured patients also tended to receive less aggressive treatment[165]. A study of a total of 83902 patients with pancreatic cancer showed that patients with lower socioeconomic status were less likely to undergo surgical resection among patients with localized/regional pancreatic cancer[166]. Among patients with localized/regional pancreatic cancer who underwent surgical resection, patients with higher socioeconomic status have better overall survival, and patients with lower socioeconomic status have worse pancreatic cancer-specific survival compared with patients with higher socioeconomic status[166]. These findings suggest that racial differences in treatment and outcomes might be attributable to socioeconomic, insurance, and geographic factors[165]. The study of pancreatic cancer cases from the National Cancer Database from 2004 to 2015 showed that private insurance was associated with more treatment and better survival, higher education was associated with earlier treatment, and treatment was less and delayed among African-Americans despite later diagnosis[167]. After adjusting for socioeconomic status, African-Americans had about the same rate of survival overall at integrated facilities and the survival was improved, suggesting that higher socioeconomic status was associated with better treatment and survival[167]. A pan-cancer analysis showed that socioeconomic status was strongly associated with 1-mo postoperative mortality in primary solid tumors, and the risk of dying was high within 1-mo after surgery in socioeconomically disadvantaged people[164]. And underserved populations around the world often face similar barriers to cancer treatment, largely reflecting inequalities in social factors[165]. Therefore, socioeconomic status plays an extremely important role in the prevention and prognosis of pancreatic cancer, and the formulation of policies targeting low socioeconomic status patients may improve the low 5-year survival rate of pancreatic cancer.

CONCLUSION

Over the next 10 years to 20 years, an increase in pancreatic cancer is inevitable. At the same time, in the face of the characteristics of high mortality and difficult early diagnosis of pancreatic cancer, early prevention of pancreatic cancer through understanding the risk factors for pancreatic cancer is an economical and effective means, which is to prevent pancreatic cancer in advance. In view of the non-modifiable factors affecting pancreatic cancer, we may screen the susceptible population to pancreatic cancer, and provide reliable screening strategies and reasonable diagnostic ideas for the early diagnosis of pancreatic cancer. By studying the modifiable risk factors that affect pancreatic cancer, we may provide earlier interventions to prevent pancreatic cancer so that it can be possibly blocked in its early stages of canceration, thus significantly reducing the incidence of pancreatic cancer. Globally, a comprehensive prevention and control strategy for pancreatic cancer should include effective tobacco-control policy, recommendations for healthier lifestyles, and enlarging coverage of screening, education and vaccination programmes to better improve public awareness of the need to take precautions.

Abstract

Pancreatic cancer is a challenging malignancy with limited treatment options and poor life expectancy. The only curative option is surgical resection, but only 15%-20% of patients are resectable at presentation because more than 50% of patients has distant metastasis at diagnosis and the rest of them has locally advanced pancreatic cancer (LAPC). The standard of care first line treatment for LAPC patients is chemotherapy with or without radiation therapy. Recent developments in minimally invasive ablative techniques may add to the treatment armamentarium of LAPC. There are increasing number of studies evaluating these novel ablative techniques, including radiofrequency ablation, microwave ablation, cryoablation and irreversible electroporation. Most studies which included pancreatic tumor ablation, demonstrated improved overall survival in LAPC patients. However, the exact protocols are yet to set up to which stage of the treatment algorithm ablative techniques can be added and in what kind of treatment combinations. Patients with metastatic pancreatic cancer has dismal prognosis with 5-year survival is only 3%. The most common metastatic site is the liver as 90% of pancreatic cancer patients develop liver metastasis. Chemotherapy is the primary treatment option for patients with metastatic pancreatic cancer. However, when the tumor is not responding to chemotherapy or severe drug toxicity develops, locoregional liver-directed therapies can provide an opportunity to control intrahepatic disease progression and improve survival in selected patients. During the last decade new therapeutic options arose with the advancement of minimally invasive technologies to treat pancreatic cancer patients. These new therapies have been a topic of increasing interest due to the severe prognostic implications of locally advanced and metastatic pancreatic

INTRODUCTION

Pancreatic cancer carries an extremely poor prognosis with the 5-year survival is around 8% and goes down to 3% in patients with metastatic disease[1]. Although the overall cancer-survival statistics are improving, pancreatic cancer is an exception with no major therapeutic advancement in the last 30 years since the introduction of pancreaticoduodenectomy[2].

As the survival statistics of other malignancies are improving, it is expected that pancreatic cancer becomes the second leading cause of cancer-related death by 2030[3].

The only curative option of pancreatic cancer is complete surgical resection. However, only 15%-20% of patients have potentially resectable disease at presentation [4] approximately 30% patients are unresectable due to locally advanced pancreatic cancer (LAPC)[5] and approximately 50% of patients have stage IV pancreatic cancer with distant metastasis at diagnosis[1]. The most common metastatic site is the liver as 90% of pancreatic cancer patients develop liver metastasis[6].

During the last decade new therapeutic options arose with the advancement of minimally invasive technologies. This review summarizes new ablative options for patients with LAPC and percutaneous liver-directed therapies for patients with liver-dominant metastatic disease. The term pancreatic cancer includes a histologically heterogenous group. This article focuses only on pancreatic ductal adenocarcinoma, as the most common malignancy of the pancreas, accounting for 85%-95% of cases[4,5].

MINIMALLY INVASIVE TREATMENTS OF LAPC

Non-metastatic LAPC comprises 30% of all newly diagnosed pancreatic cancer cases [7]. Patients with LAPC are not surgical candidates because of unresectable involvement of adjacent vessels like the portal vein, celiac or superior mesenteric artery or their major branches. Current standard-of-care therapy of LAPC is chemotherapy with or without radiation therapy. Adjuvant chemotherapy can downstage 20% of LAPC patients to be potentially resectable. Downstaged, surgically resected patients had a significantly improved survival (35.3 mo) compared to those who did not became surgical candidate after chemotherapy (16.2 mo)[8].

Patients with LAPC who do not became surgical candidate, may benefit from image-guided local ablation therapies, either percutaneously or during intraoperative open approach. The ablation technologies used in patients with LAPC include heat-based ablations, like radiofrequency ablation (RFA), microwave ablation (MWA) and

cryoablation and the new non-thermal ablation technique, irreversible electroporation (IRE).

RFA of LAPC

RFA is the most widely used heat-based ablative method which utilizes high frequency alternating electric current that causes cell death by heating the tissue through rapid electron vibration generating frictional heat[9]. This method of heat generation means that RFA is heavily dependent on conductivity which has close correlation to the water content of the tissue[9,10]. This is one of the disadvantages of RFA because as the tissue adjacent to the electrode heats up, it becomes desiccated and then acts as an "insulating sleeve" around the ablation probe hindering electron flow and further heat generation, thus limiting the ablation zone size[9]. Another major factor which limits the extent of the ablation zone is the cooling effect of flowing blood which works as a "heat sink"[11].

RFA treatment of the primary pancreatic cancer usually performed during open laparotomy. The studies where pancreatic RFA was used during open laparotomy are listed in Table 1. The initial publication by Matsui *et al*[12] included 20 patients and demonstrated that RFA is feasible in pancreatic cancer. This milestone publication was followed by multiple studies using RFA in pancreatic cancer with different endpoints. Wu *et al*[13] studied the pain relief effect of RFA and reported 50% pain reduction after pancreas cancer RFA. Girelli *et al*[14] also reported significantly reduced pain score in 69% of symptomatic patients. Several studies evaluated overall survival following RFA of pancreatic cancer and reported overall survival from 14.7 mo up to 33 mo[15,16]. The largest study[16] included 107 patients and divided patients into 2 arms: 47 patients underwent RFA as a first-line treatment and 60 patients received neoadjuvant therapy first followed by RFA. All patients received standard of care post-RFA treatment which included systemic chemotherapy and/or radiation and 29 patients also received intra-arterial chemotherapy which consisted of injection of epirubicin and cisplatin into the celiac artery in every 4 wk until disease progression. Median overall survival was 14.7 mo in the RFA group and 25.6 mo in the neoadjuvant treatment + RFA group. They also reported that 32 patients treated with the triple combination of RFA, radiation therapy, and intraarterial chemotherapy had an even longer median survival of 34 mo.

There is only one publication reporting data of percutaneous RFA of the pancreas tumor[17]. The authors analyzed data of 23 patients who underwent ultrasonography (US)-guided percutaneous RFA. There was no severe adverse event reported, which may be explained by the fact that in all patients the tumor located in the pancreatic tail or body and none in the head of the pancreas. Follow-up imaging showed good response to RFA, however, the median overall survival or pancreatic progression-free survival was not reported.

While RFA of pancreatic cancer has proven survival benefit, it also comes with a high morbidity risk of up to 40%[14] and mortality rate of up to 25%[13]. The most frequent major complications are portal vein stenosis (15%) and heat-injury of the duodenum (8%)[14]. The reported most common cause of death is massive gastrointestinal hemorrhage[13]. Girelli *et al*[18] reported that avoiding temperatures to exceed 90 °C during ablation and preserving surrounding tissue from overheating can reduce complications.

Despite the reported potential survival benefit of RFA, it remains unclear when RFA is best incorporated into the first line standard of care systemic chemotherapy/chemoradiation treatment protocol; should RFA performed before or after the standard of care systemic therapy? Does its potential high complication rates worth its benefit?

MWA of LAPC

MWA is another heat-based ablation technology which appears to have several advantages over RFA. Microwave generates heat using electromagnetic radiation-induced rotation of dipole molecules, such as water[19]. MWA is more powerful than RFA and generates higher temperatures in a shorter time. This leads to larger ablation zones and less heat-sink effect from the adjacent blood vessels[20]. MWA can be effective in tissues with high impedance, such as charred desiccated tissue, what is a weakness of RFA[20].

The available data on the usage of MWA in LAPC is very limited[21-24]; only 4 studies have been published with limited follow-up and survival data included (Table 2). The largest series of 20 patients reported 100% technical success without major complications and only 9.8% minor complications. However, 3-mo follow-up imaging was available in 10 patients (50%) only and no overall survival was reported

Ierardi *et al*[22], 2018	5	N/A	Percutaneous	US	No

US: Ultrasound; CT: Computed tomography.

[24]. In the study of Lygidakis *et al*[23] 15 patients were included with large pancreatic tumors (average tumor size of 6 cm) and only partial ablation was achieved in all patients. No major complications were reported. The longest follow-up was 22 mo; survival data of the group was not published. Carrafiello *et al*[21] reported of 10 patients with LAPC who underwent MWA; 5 during open surgery, and 5 percutaneously. Two major complications were reported, one pancreatic pseudocyst requiring drainage and one arterial pseudoaneurysm. The 1-year survival rate was 80%. Ierardi reported 100% technical success in 5 patients without major complications and 60% partial response and 40% progressive disease at 1 mo follow-up[22].

In our experience of 2 patients with pancreatic tail cancer, MWA was very effective without major complications; in one patient the ablation was complete (Figure 1), in the other patient the tumor recurred in the pancreatic tail 17 mo after ablation. Besides the recurrence, the MWA was also complicated with a development of an asymptomatic pancreatic pseudocyst which required no treatment. The local recurrence was first treated with stereotactic body radiation therapy which provided local control with stable disease for approximately a year, then the patient underwent repeat MWA of the enlarging pancreatic recurrence and a new solitary liver metastasis 32 mo after the initial ablation. There was no evidence of recurrence at the latest follow-up 6 mo after the second MWA.

Cryoablation of LAPC

During cryoablation intra- and extracellular ice crystals causing damage to the cell membrane, that will lead to cell death due to dehydration and osmotic pressure changes[25]. The cooling mechanism of the cryoablation probe based on the Joule-Thomson effect as high pressure argon gas is circulated *via* tiny tubes inside the probe with sudden expansion of the gas in a chamber in the ablation probe tip. The probe tip reaches temperatures as low as -160 C. The major advantage of cryoablation over other ablation technologies is that ice is visible on US, computed tomography (CT) and magnetic resonance imaging, therefore, the size of the iceball can be monitored during the ablation to prevent inadvertent damage to adjacent tissues. The other advantage is the analgesic property of cold during cryoablation which is associated with reduced intra- and postprocedural pain[26,27]. The heat sink effect of adjacent vessels can negatively influence the size of the ablation zone in cryoablation, but this effect is not as pronounced compared to RFA[28]. One of the potential major complications of cryoablation is cryoshock which occur in 0.3 to 2.0% of patients[29,30] and is charac-

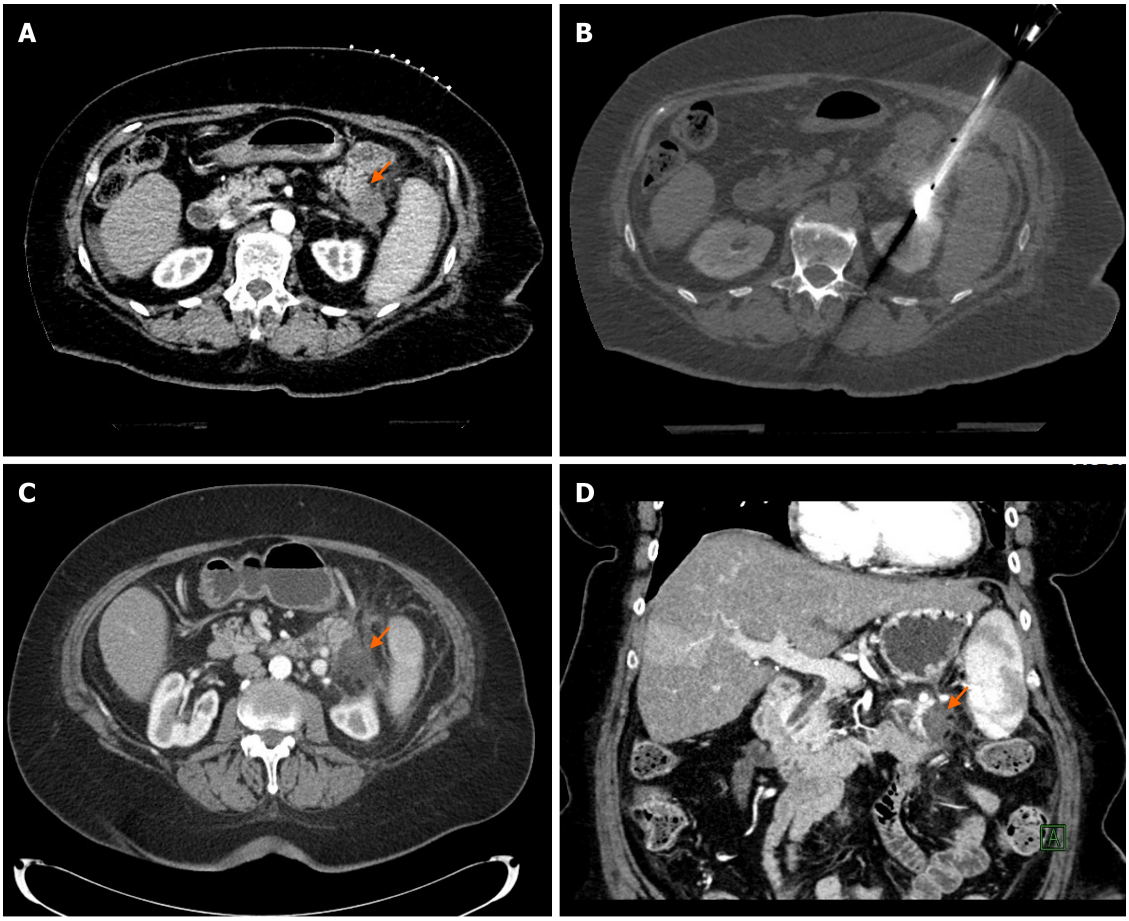

Figure 1 Percutaneous computed tomography-guided microwave ablation of a pancreatic tail adenocarcinoma. A: 72-year-old patient presented with a 1.9 cm biopsy-proven pancreatic adenocarcinoma in the tail of the pancreas as it shown on this contrast-enhanced computed tomography (CT) image (orange arrow); B: The patient was not surgical candidate due to comorbidities and underwent percutaneous CT-guided microwave ablation (MWA) of the pancreatic tumor. CT image shows the microwave antenna in place in the pancreatic tail tumor; C and D: Axial and coronal contrast-enhanced CT images 6 wk after the MWA show good radiological response with an avascular area in the tail of the pancreas corresponding to the ablation zone (orange arrows). Patient developed peritoneal metastases 4 mo later and died 13 mo after the MWA treatment.

terized by multiorgan failure and disseminated intravascular coagulation[31]. Cryoshock was observed most often in large volume liver ablations[32].

Similar to MWA, the available data on cryoablation of pancreatic cancer is very limited. There is no data regarding the effect of cryoablation in patients with LAPC. There are 3 papers which reported pancreatic cryoablation, but two of them included patients with stage 4 pancreatic cancer[33,34] the third study used combination of cryoablation with radioactive iodine-125 treatment[35]. Song *et al*[33] compared gastrojejunal bypass surgery alone *vs* bypass surgery with pancreatic tumor cryoablation in 118 patients with advanced pancreatic cancer. Cryoablation was performed in 42 patients. There were no differences between the patient characteristics and postoperative mortality; however, the 1-year survival rate was superior in the cryoablation group (4.8% *vs* 2.6%). The reason for the poor overall survival rate is the inclusion of patients with distant metastases.

Niu *et al*[34] compared 4 groups of patients with metastatic pancreatic cancer who underwent cryotherapy alone (36 patients), immunotherapy alone (17 patients), chemotherapy alone (22 patients) or cryoimmunotherapy (31 patients). Cryotherapy was used to treat both the primary tumor and the metastatic sites. Median overall survival (OS) was significantly higher in the cryoimmunotherapy (13 mo) group compared to cryotherapy (7 mo), immunotherapy (5 mo) and chemotherapy (3.5 mo) groups. There was no major complication.

Xu *et al*[36] reported outcomes of 49 patients of whom 38 underwent a combination therapy of cryoablation and iodine-125 seed implantation for LAPC. Both laparotomic and percutaneous approach were used in this study. Complete response was seen in 20.4% of patients, partial response in 38.8%, stable disease in 30.6% and progressive disease in 10.2%. The median OS was 16.2 mo, and the 12-mo and 24-mo survival was 63.1% and 22.8%, respectively. Six patients (12.2%) developed acute pancreatitis, in

one case it was considered as severe.

Given the promising results with cryoablation, further studies are warranted in patients with LAPC.

IRE of LAPC

Irreversible electroporation is a novel ablation technology[36], which, unlike RFA, MWA, and cryoablation, is non-thermal. IRE delivers high-voltage electrical current (1500 to 3000 V) between the IRE ablation probes which creates nanoscale defects in the cell membranes[37-39]. The cells within the ablation zone lose the ability to maintain homeostasis which results in apoptotic cell death with narrow zone of transition[36-38]. Since this is a non-thermal ablation, its efficacy is independent of thermal conductivity of the tissues and not influenced by the "heat-sink" effect of adjacent vessels[36,39]. The ablation zone is very predictable and easy to monitor using US or CT[39]. The high voltage delivered by IRE may cause muscular contraction and cardiac arrhythmia. Therefore, IRE must be performed under general anesthesia with complete neuromuscular blockade and electrocardiogram synchronization. Patients with pacemakers may not be a candidate for IRE[40].

The main advantage of IRE is the controlled apoptosis of the cells without harming the adjacent collagen matrix and proteins, thus saving scaffolds of blood vessels and bile ducts[41-44]. As IRE leads to apoptotic cell death it enhances antigen presentation to immunocompetent cells which may improve immunological response locally and at abscopal metastatic sites. Irreversible nanopore formation at the ablation site and reversible nanopore formation in the vicinity of the ablation zone can lead to higher intracellular concentration of chemotherapeutic agents in the damaged cancer cells[45, 46]. The disadvantage of IRE is that it requires placements of multiple ablation probes because the high electric currents delivered between the probes. The probes have to be parallel to each other and at the same tissue depth which adds complexity to the probe placements and increases procedure time.

IRE most commonly performed intraoperatively during open laparotomy (Table 3, Figure 2). Although, some surgeons use palpation and visual guidance for ablation probe placements, most commonly intraoperative US is used to precise identification of the tumor extent and visualization of major arteries inside the tumor to maximize ablation success and minimize bleeding complications.

Several studies described survival benefit for patients who underwent IRE (Table 3) [47-50]. Huang *et al*[47] found that median OS was significantly extended to 22.6 mo. The authors analyzed data of 70 patients who were treated with IRE for LAPC. All patients received neoadjuvant chemotherapy with either a gemcitabine-based or TS-1 (tegafur, gimeracil, and oteracil) chemotherapy based on the patient's age and performance status. Local recurrence rate was only 8.6% at 28 mo follow-up. Disease progression was noted in 25 patients (36%) at distant sites, mostly in the liver (12 patients). Both median OS (28.7 mo *vs* 19.1 mo) and progression-free survival (PFS, 26.4 mo *vs* 13.2 mo) were significantly longer in patients who received TS-1 adjuvant therapy compared to patients with gemcitabine-based adjuvant therapy. Patient selection bias could play a role in the excellent survival results because patients with larger than 4 cm pancreatic tumor were excluded.

Martin *et al*[48] analyzed data of 200 patients and so far this is the largest study on IRE of the pancreas. All patients received chemo- or chemoradiation therapy before the IRE (the chemotherapy was either gemcitabine- or FOLFIRINOX-based). In 50 patients IRE was used only for surgical margin extension and in 150 patients IRE was used without resection. In the resection + IRE group 75% of patients had body and neck tumors, while in the IRE group most patients (63%) had pancreatic head tumors. There was no significant difference in median OS between the two groups, however, the median OS was slightly longer in patients who received resection + IRE (28.3 mo *vs* 23.2 mo). The median OS and PFS for the entire group were 24.9 mo and 12.4 mo, respectively.

There were several studies which could not demonstrate survival benefit of IRE over standard of care chemotherapy with reported 9.3 mo median OS[51-54]. However, these are relatively early studies with potential biases (patient selection, different chemotherapeutic protocols, lack of experience) that may have influenced the outcomes. Although survival benefit of IRE was not proved compared to a matching control group, Lambert *et al*[54] recommended IRE in cases where unresectability was noted during laparotomy.

IRE can also be performed with laparoscopic approach using endoscopic or laparoscopic US guidance, but there are only 9 cases reported when laparoscopic technique was used[47,55,56]. In the study of Huang *et al*[47] 5 out of the 70 patients underwent laparoscopic ablation and their survival and complication results were not

Table 3 Studies evaluating intraoperative irreversible electroporation of pancreatic cancer

Author	Patients	Median OS(mo)	Guidancemodality	Major adverse events
Paiella *et al*[53], 2015	10	7.5	US	20%

He *et al*[49], 2020	167	16	US	N/A

[1]Survival probability at 3-year.
[2]Survival probability at 2-year. US: Ultrasound.

significantly different compared to the laparotomy group. Stillström *et al*[56] used an advanced stereotactic navigation system to perform laparoscopic IRE in 3 patients. The technical success rate was 100% and a prospective, randomized trial is planned. Tartaglia *et al*[55] reported a single case of laparoscopic IRE, where operators used laparoscopic ultrasound for guidance. The procedure was uneventful, and the 6-mo follow-up positron emission tomography-CT showed no fluorodeoxyglucose-uptake in the treated region.

In our experience probe placement-related bleeding is almost always seen due to the requirements of multiple probe placements and due to the rich blood supply of the upper gastrointestinal tract and porta hepatis. The IRE probe placements often performed *via* transgastric or transduodenal approach. During the open procedure the bleeding complications can be easily managed; in case of arterial bleed most of the times 5-10 min of manual compression is sufficient. Surgical vascular ligation is also readily available if needed. The other major advantage of open IRE over percutaneous IRE is the ability to sample and analyze suspicious lymph nodes with frozen section during the surgery and to detect obscure peritoneal metastases which are not seen on prior imaging. This reduces the chance to perform IRE on patients who have stage IV disease and unlikely would have benefit from the pancreatic ablation. Laparotomy is unavoidable anyway in a large number of LAPC patients since pancreatic head and neck tumors often cause gastric outlet obstruction. In these cases, IRE can be performed at the same time as the gastrojejunal bypass procedure.

Major adverse events of open IRE were reported in a wide range, from 4% to 53%. These can be laparotomy-related or IRE-related complications. Kluger *et al*[52] evaluated IRE-related and surgery related adverse events and found that 44% of grade 3-4 adverse events were IRE-related and 56% related to the surgical procedure. Authors concluded that IRE should not be considered as a minimally invasive treatment due to its high adverse event rate. Several authors did not describe whether they used imaging guidance during the IRE for probe placement and to monitor the ablation zone. Lack of imaging guidance may explain the high morbidity rates. Lambert *et al*[54] also included patients who underwent percutaneous IRE, but the percutaneous arm was closed after two patients due to high complication rate; one patient developed cholangitis, liver abscess, and biliary peritonitis resulting in surgical revision and antibiotic treatment, the other patient developed pancreatic fistula treated with stoma bag and antibiotics.

The most common IRE-related serious adverse events are pancreatic abscess formation, pancreatic fistula, gastrointestinal bleeding, and duodenal ulceration[47,48,57].

Percutaneous IRE is most commonly performed with CT guidance. CT-guided IRE requires administration of intravenous contrast to best visualize the tumor and its relationship to adjacent major vessels. US-guided percutaneous IRE has been reported [58-60] and US-guidance may be feasible in patients with low body mass index and without overlying gas-filled stomach and bowel loops, but in most patients

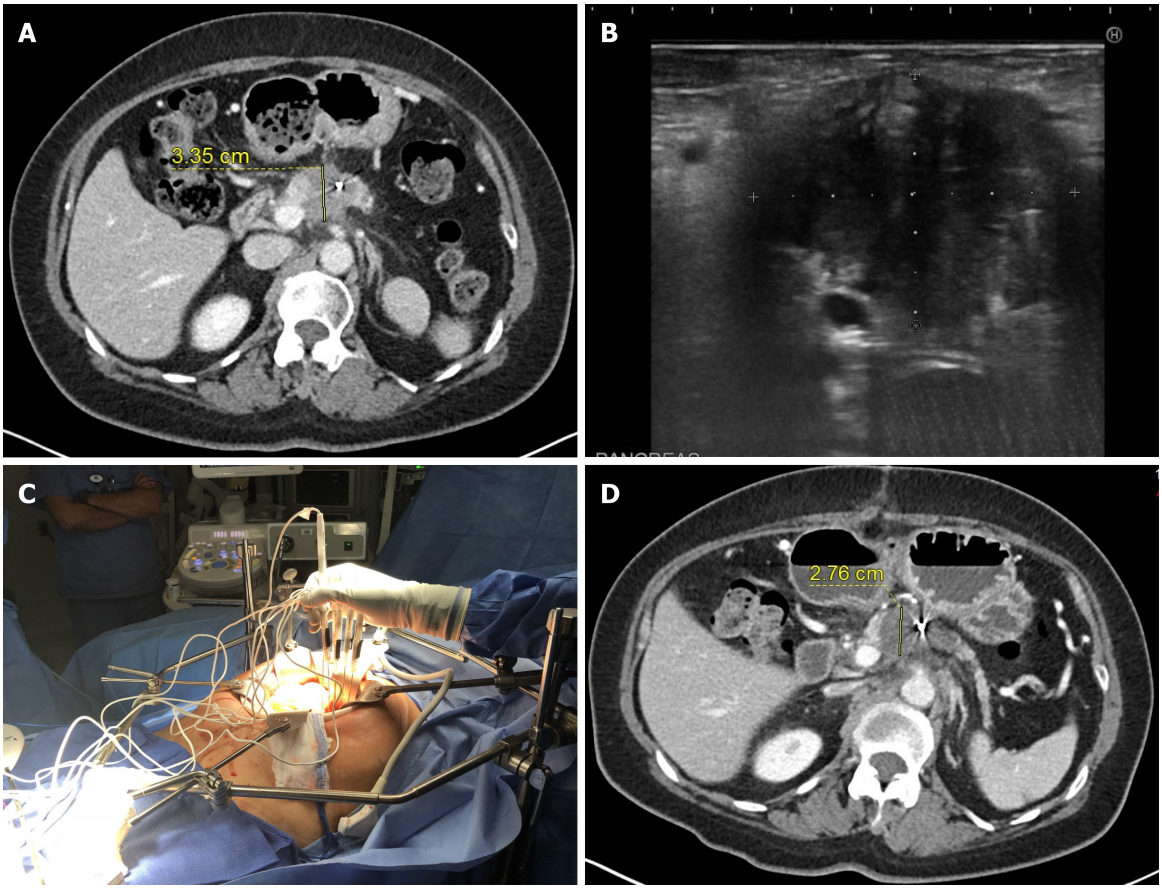

Figure 2 Intraoperative irreversible electroporation of a pancreatic adenocarcinoma. A: Pre-operative contrast-enhanced computed tomography image shows a hypodense mass in the head of the pancreas. A hyperdense fiducial marker, which was placed for prior radiation therapy, is also visible in the mass; B: Intraoperative ultrasound image shows 4 Í 3.2 cm hypoechoic mass in the pancreas; C: Intraoperative photo shows the patient with upper median laparotomy with ablation probes are placed directly into the pancreatic tumor, using ultrasound guidance; D: Follow-up imaging 1 mo after the irreversible electroporation (IRE) showed an avascular ablation zone covering the previously seen pancreatic tumor. The CA19-9 tumor marker decreased from 959 U/mL to 76 U/mL 1 mo after the ablation. The patient is still alive 31 mo after the IRE ablation.

percutaneous US is not suitable to guide pancreatic IRE ablation. The percutaneous approach is less invasive, and the hospital stay is shorter compared to open IRE, however, the management of procedural bleeding complications can be challenging and there are limitations to detect peritoneal and nodal metastases. The median OS of the percutaneous IRE studies is ranging from 10 to 19.8 mo. The longest overall survival was recently reported by Ma *et al*[51] The authors evaluated LAPC patients treated with gemcitabine plus IRE (33 patients) and gemcitabine alone (35 patients). The median OS of 19.8 mo in the combination therapy group indicates that including IRE into the treatment protocol provides significant survival benefit over gemcitabine alone (9.3 mo).

Narayanan *et al*[61] performed CT-guided percutaneous IRE in 50 LAPC patients. Nine of the 50 patients underwent a second IRE due to evidence of residual tumor. Three patients were downstaged and underwent surgical resection: pathologic examination showed negative margins in all the 3 patients with complete (1 patient) or partial (2 patients) tumor necrosis. Median OS was 14.2 mo. Most common major adverse event was abdominal pain in 7 patients. Ruarus *et al*[62] also published outcome of 50 patients who underwent CT-guided percutaneous IRE. This study included 16 patients who did not received neoadjuvant chemotherapy (FOLFIRINOX, gemcitabine, or capecitabine and oxaliplatin combination). For all patients, the median OS from IRE was 10 mo. Interestingly, the median OS was slightly longer in the patient group that received no chemotherapy, compared to those who did (11 mo *vs* 9 mo). Uni- and multivariate analysis revealed large tumor size, baseline CA19-9 Level higher than 2000 U/mL, and less than 50% reduction of CA19-9 at 3 mo follow-up as prognostic factors for poor survival.

A recent systematic review[63] compared open and percutaneous IRE. The mortality and morbidity rates were significantly higher in the open IRE group, meanwhile the median OS was found to be superior compared to the percutaneous approach. The

authors concluded that the treatment plan needs to be tailored individually.

There is a big difference between major centers in the rate of reported major adverse events ranging from 0% to 42%[58,62,64,65]. Belfiore *et al*[64] and Zhang *et al*[58] treated 20 and 21 patients, respectively, without any serious adverse events. On the other hand, most studies reported 20% or higher major adverse events after percutaneous IRE (Table 4).

Some patients may require special attention before IRE. Patients with pacemakers may not be a candidate for IRE. Metal stents and surgical clips may also contraindicate IRE. Månsson *et al*[66] reported a case of a patient with implanted metallic biliary stent who underwent IRE for the tumor in the head of the pancreas and developed severe late complications (persistent pain, abscess formation, diarrhea, peritonitis) within 8 wk of the procedure, that ended in emergency laparotomy and subsequent right hemicolectomy (for severe diarrhea). Martin *et al*[67] strongly recommends removal of metal biliary stents before IRE procedures. The metal stent can be removed endoscopically and replaced with a plastic stent or can be removed surgically with hepaticojejunostomy creation at the same laparotomy for open IRE. Dunki-Jacobs *et al*[68] demonstrated significant energy deflection during IRE in the presence of a metal stent which can lead to high current conditions, incomplete ablation, and possible thermal injury to adjacent organs. On the other hand, Melenhorst *et al*[69] successfully used IRE to treat a patient with hilar cholangiocarcinoma who had metallic stent in place. In our practice we haven't experience increased rate of complications of IRE in patients with metal stent in place (Kis *et al* unpublished data). At this point, the relationships between metal stent and IRE complications are not fully understood.

The non-thermal nature of IRE and its ability to preserve the structural integrity of blood vessels and bile ducts made IRE the preferred ablation modality in the pancreas. There are several ongoing clinical studies investigating the role of IRE in pancreatic cancer patients and to identify potential combination treatments which could improve survival (Table 5).

MINIMALLY INVASIVE TREATMENTS OF PANCREATIC CANCER LIVER METASTASES

At the time of diagnosis 53% of patients have distant metastases from pancreatic cancer and the 5-year survival of patients with metastatic disease is only 3%[1]. Liver is the most common site of metastasis with approximately 90% of patients develop hepatic metastasis[6]. In very selected cases of oligometastatic liver disease surgery can be considered[70-72], but the majority of patients are unresectable[73]. Chemotherapy is the only treatment option for most patients with metastatic pancreatic cancer[74]. The ACCORD11 trial reported 11.1 mo survival in metastatic pancreatic cancer patients treated with FOLFIRINOX, but the treatment had significant grade 3 and 4 toxicities including neutropenia (45.7%), thrombocytopenia (9.1%), diarrhea (12.7%), sensory neuropathies (9.0%), and fever (5.4%)[6]. For unresectable patients with liver-dominant metastatic disease liver-directed therapies may offer survival benefit and can provide chemotherapy holiday.

Percutaneous liver ablation

Percutaneous liver ablation is a widely used technique to treat primary and secondary malignancies in the liver[75]. The results of thermal ablations that covers the entire metastatic lesion is comparable to the results of surgical resection[76]. Studies evaluating percutaneous liver ablation in metastatic pancreatic cancer are summarized in Table 6.

Park *et al*[77] published a retrospective study of 34 patients who underwent liver RFA for metastatic pancreatic cancer. Median OS was 14 mo. Tumor size of less than 2 cm and well differentiated histology were predictive factors of longer survival. Second ablation due to new or recurrent metastasis was performed in 18 patients (58.1%), and in 16 of them the hepatic disease was controlled with the repeated ablation. Nine and one patient underwent a third and fourth ablation session, respectively.

Hua *et al*[78] performed a retrospective analysis of 102 pancreatic cancer patients who underwent RFA of liver metastases. Median OS was 11.4 mo. Univariate analysis showed that tumors in the head of the pancreas, tumor size between 3 and 5 cm and neutrophil-lymphocyte ratio > 2.5 were associated with worse prognosis. Recently Lee *et al*[79] published a retrospective study of 60 patients who underwent liver RFA for metachronous pancreatic cancer metastases and compared survival to a group of 66 patients who received systemic therapy. The median OS was significantly longer in the

RFA group (12 mo) compared to the systemic therapy group (9.1 mo).

Although MWA and cryoablation is widely used in liver malignancies, there are no dedicated reports to date on pancreatic cancer metastases. Since MWA has several advantages over RFA it can be assumed that MWA is at least as effective as RFA ablating pancreatic cancer liver metastases. Bailey *et al*[80] published a study which included 20 metastatic pancreatic cancer patients who underwent any kind of liver directed treatment. In this study 10 patients had MWA of liver metastasis, but no survival or complication data was reported. During last 10 years we performed MWA of pancreatic liver metastasis in only 2 patients despite we are a high-volume ablation center and using almost exclusively MWA for liver metastases (Figure 3). Our practice reflects the recommendations of Ghidini *et al*[81] who reviewed the available data of surgical hepatic metastasectomy and ablative techniques for metastatic pancreatic cancer. They concluded that despite the advancements in both fields, neither surgery nor ablation improved overall survival significantly during the last decade. Therefore, metastasectomy and ablation of liver metastasis are not recommended routinely for stage IV pancreatic cancer patients.

Transarterial chemoembolization of pancreatic cancer liver metastases

All trans-arterial embolization therapies for liver tumors are predicated upon the fact that the liver has dual blood supply and while the normal liver receives approximately 80% of the blood from the portal vein and 20% from the hepatic artery, the blood supply of tumors are almost exclusively is from the hepatic artery. Therefore, by embolizing the tumor feeding hepatic arteries, tumor ischemia can be achieved with minimal hypoxic damage to the normal liver parenchyma.

During transarterial chemoembolization (TACE) the embolic agent is delivered simultaneously with a chemotherapeutic agent. Direct intra-arterial administration of chemotherapy increases concentration in the target area and decreases systemic toxicities of the drug. Embolization reduces intra-tumoral blood flow, therefore prolongs the dwell time of chemotherapy within the tumor and further decreases the systemic side effects of the drug.

TACE is a well-studied intraarterial therapy in the management of hepatocellular carcinoma and colon cancer, but there is limited data on TACE in metastatic pancreatic cancer (Table 7). In the largest series Vogl *et al*[82] analyzed the data of 112 patients with metastatic pancreatic cancer who underwent TACE using a combination of mitomycin C, cisplatin, and gemcitabine, followed by iodized oil and 50 μm embolization microspheres until stasis. Median OS was 19.2 mo with an impressive 5-year survival rate of 50%. Azizi *et al*[83] retrospectively analyzed the data of 32 patients who were treated with TACE, using the same technique as Vogl *et al*[82]. The median OS was 16 mo. Sun *et al*[84] reported a very promising 23 mo median OS of the 27 patients who underwent TACE for metastatic pancreatic cancer. The authors found that TACE prolongs survival and improves quality of life.

Transarterial radioembolization of pancreatic cancer liver metastases

During transarterial radioembolization (TARE) treatment Yttrium-90 (Y90) containing microspheres are delivered into the arteries feeding the liver metastases (Figure 4). Y90 is a pure β-emitting isotope with a physical half-life of 64.2 h[85]. It has a high energy

IRE: Irreversible electroporation; LAPC: Locally advanced pancreatic cancer.

radiation with average β-emission is 0.9367 MeV, with a mean tissue penetration of 2.5 mm and maximum tissue penetration of 11 mm[86,87], allowing delivery of high radiation doses to hepatic tumors with a "cross-fire" mechanism between the Y90 microspheres, while limiting the radiation dose to the surrounding liver parenchyma [88]. The antitumoral effect of Y90 is thought to be secondary to irreversible damage to tumor epithelial, stromal, and endothelial cells[89]. The absorbed dose of Y90 microspheres in the liver may be heterogeneous as it depends on hemodynamics and intratumoral vessel density[90]. The injected microspheres implant mostly in the terminal arterioles of tumors[88] in a 3: 1 to 20: 1 ratio compared to normal liver, with a preferential deposition in the tumor periphery[91]. There are currently two type of Food and Drug Administration-approved microspheres on the market: a glass (TeraSphere, Boston Scientific, Marlborogh, MA) and a resin (SIR-Spheres, Sirtex Medical Pty. Ltd, St Leonards, Australia) based microspheres. The two types of Y90 microspheres differ in several physical parameters. The most important difference is the approximately 50 times higher radioactivity/beads in glass microspheres compared to resin.

OS: Overall survival; TACE: Transarterial chemoembolization; cTACE: Conventional transarterial chemoembolization.

TARE is generally better tolerated by patients than TACE. TARE was associated with better quality-of-life scores compared to TACE in patients with hepatocellular carcinoma[92]. Similarly, fewer side effects were reported after TARE compared to TACE in patients with intrahepatic cholangiocarcinoma and liver-dominant metastatic breast cancer patients[93-95].

Three workgroups published studies that evaluated the safety and efficacy of TARE in liver-dominant metastatic pancreatic cancer (Table 8)[96-100]. Michl *et al*[96] published a retrospective study of 19 patients treated with Y90-labelled resin microspheres. Six (31%) grade 3 or higher toxicity was reported. Overall survival was 9 mo. Kim *et al*[98] also used Y90-labelled resin microspheres in 33 patients and reported 8.1 mo median OS. Grade 3 adverse events were noted in 2 patients. Very recently we reported our experience of Y90 TARE using Y90-labelled glass microspheres in 26 patients with liver dominant metastatic pancreatic cancer[100]. Median OS was 7 mo and 3 patients (11.5%) had grade 3 clinical toxicity in this study. We found that longer hepatic progression free survival was associated with younger age (< 65 years) and decreased or stable CA19-9 tumor marker level following TARE treatment.

There was no head-to-head comparison between TACE and TARE, but it appears that TACE resulted in better OS in patients with metastatic pancreatic cancer. The reason for this difference is unknown.

CONCLUSION

The introduction of minimally invasive technologies in cancer care opened new therapeutic options for patients with malignancies beyond surgery, chemotherapy and radiation treatment. Interventional oncology is becoming the fourth pillar of cancer care besides the classic trio of medical oncology, surgery and radiation oncology. The data presented above demonstrates only modest improvement in overall survival of patients with LAPC and patients with metastatic pancreatic cancer, but still this is a significant step forward in the treatment of a disease which has dismal prognosis. In the current medical practice these new minimally invasive treatments are used mostly as salvage therapies, when a patient has no other option. This approach introduces a selection bias into the studies and may mask the real potential of these novel treatment modalities. Despite the selection bias, they have one obvious advantage, the low mortality and morbidity rates of image guided-procedures compared to surgery,

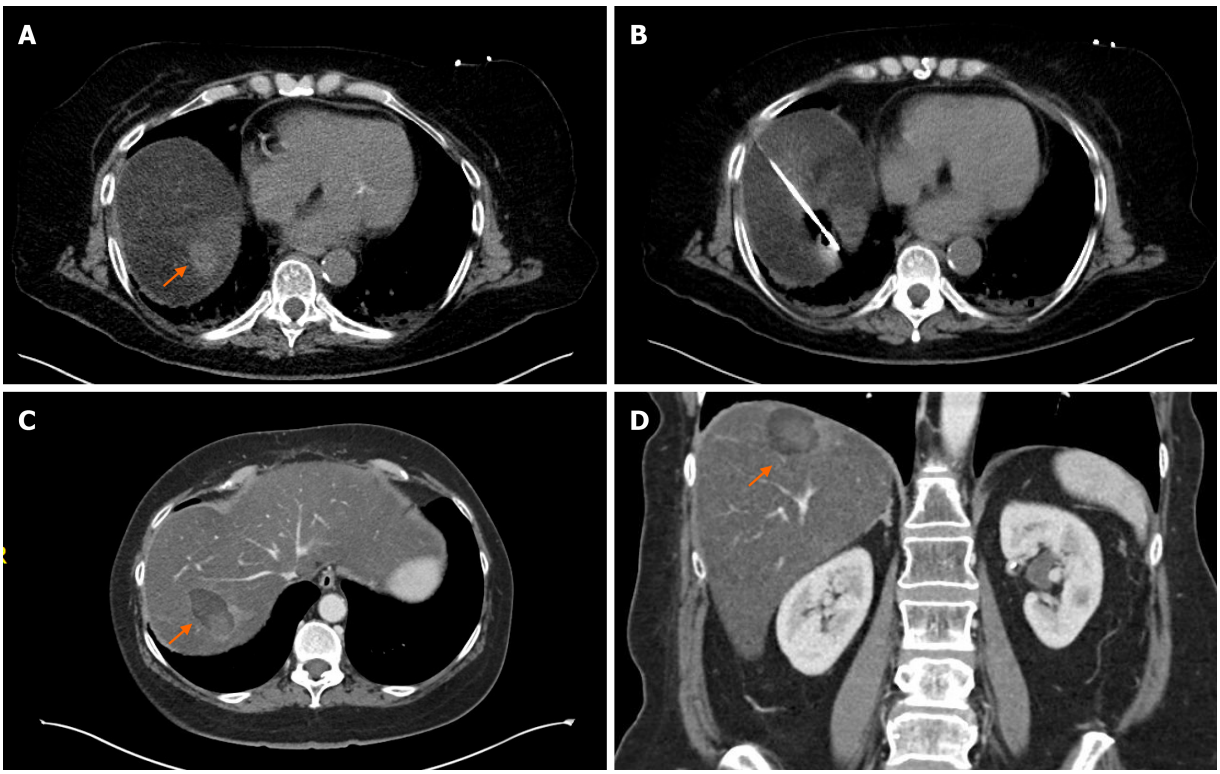

Figure 3 Percutaneous computed tomography-guided microwave ablation of a solitary pancreatic adenocarcinoma liver metastasis. A: 62-year-old female presented with a 2 cm solitary liver metastasis (orange arrow), 9 mo after the surgical resection of the primary tumor from the pancreatic head; B: Intraprocedural image shows the microwave antenna in the liver metastasis; C and D: Axial and coronal contrast-enhanced computed tomography images 1 mo after the ablation demonstrates a 4.3 Í 2.7 cm hypodense ablation zone (orange arrows). There was no evidence of residual or new metastases in the liver. Patient is currently on systemic therapy 2 mo after the ablation without evidence of disease.

radiation therapy and even to chemotherapy. Interventional oncology has many tools in its armamentarium to manage patients with primary and secondary pancreatic cancer; however, most of the new treatment options are in the experimental phase and only performed by large-volume centers.

We are in an era of a paradigm shift from conventional oncology to immuno-oncology which could promote the concurrent use of ablative technologies together with immune therapies[45,101-104]. It has been found that ablation of solid tumors triggers a tumor-specific immune response which can be beneficial in combination with immune checkpoint inhibitors or other immune modulator agents. Future studies are needed to define the specific role of interventional oncology in every stages of pancreatic cancer with special attention on the immunological effect of ablative techniques.

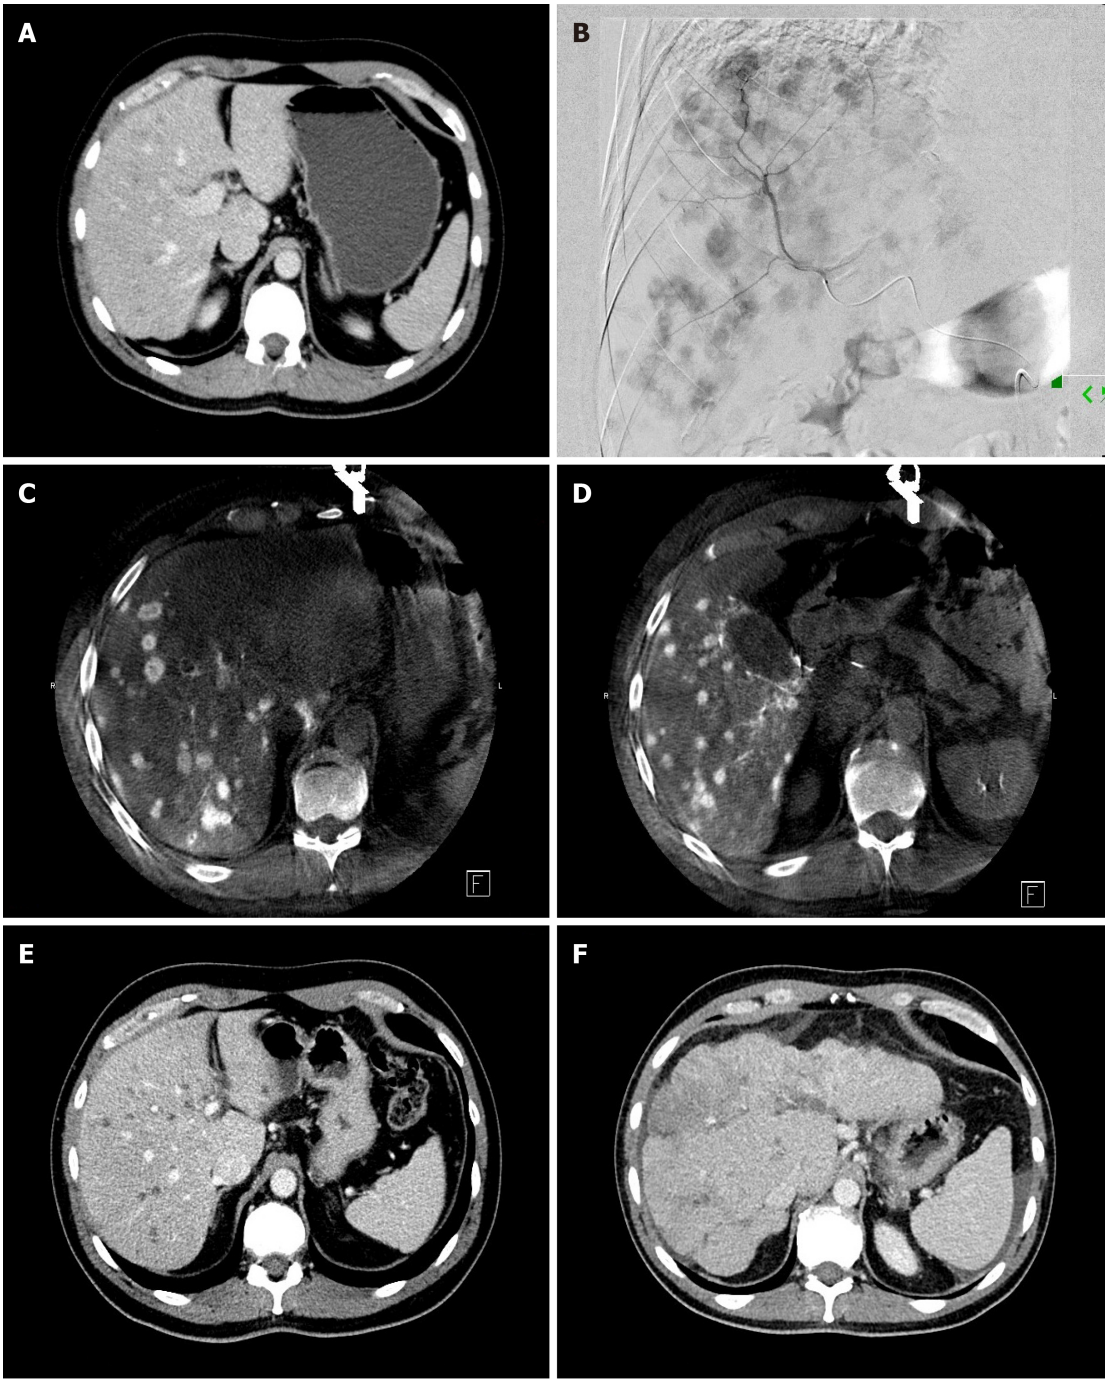

Figure 4 Transarterial radioembolization of pancreatic adenocarcinoma liver metastases. A: Pre-treatment contrast-enhanced computed tomography (CT) image of a 45-year-old man with pancreatic cancer demonstrates bilobar multifocal mildly hypodense liver metastases; B: Hepatic angiogram with contrast injection into the anterior division of the right hepatic artery shows multifocal arterially enhancing liver metastases; C and D: Intra-procedural cone-beam CT images of the liver during selective contrast injection into right hepatic artery shows multifocal arterially enhancing liver metastases; E: Contrast-enhanced CT image 1 mo after bilobar transarterial radioembolization (TARE) shows hypodense, "burnt out" liver metastases. The patient CA19-9 Level decreased from 882 U/mL pre-procedure to 56 U/mL. One year after the initial TARE new liver lesions appeared and his CA19-9 increased to 530 U/mL. He underwent a second round of bilobar TARE, and his CA19-9 Level decreased to 233 U/mL; F: Contrast-enhanced CT image 18 mo after the initial TARE shows shrunken liver with lobulated, nodular borders consistent with TARE-induced pseudocirrhosis. The patient died 22 mo after the initial TARE due to extrahepatic and hepatic progression of his disease.

Abstract

Chronic pancreatitis (CP) is a progressive condition caused by several factors and characterised by pancreatic fibrosis and dysfunction. However, CP is difficult to diagnose at an early stage. Various advanced methods including endoscopic ultrasound based elastography and confocal laser endomicroscopy have been used to diagnose early CP, although no unified diagnostic standards have been established. In the past, the diagnosis was mainly based on imaging, and no comprehensive evaluations were performed. This review describes and compares the advantages and limitations of the traditional and latest diagnostic modalities and suggests guidelines for the standardisation of the methods used to diagnose early CP.

Key Words: Chronic pancreatitis; Pancreatic fibrosis; Early diagnosis; Ultrasound endoscopy; Endosonography; Elastography; Confocal laser endomicroscopy

Core Tip: Chronic pancreatitis (CP) is a progressive disease that is difficult to diagnose at an early stage. This review evaluates the characteristics, strengths, and limitations of modalities for the diagnosis of early CP. This paper will be of interest to the readership

because the information presented here highlights multiple novel strategies, such as elastography and confocal laser endomicroscopy, some of which require further research and development to improve the diagnostic efficiency. This review will be highly beneficial for researchers and clinicians focusing on the management of this condition.

INTRODUCTION

Chronic pancreatitis (CP) is a multifactorial inflammatory syndrome characterised by recurring epigastric pain and progressive fibrosis that eventually leads to pancreatic atrophy and calcification, ductal distortion, and exocrine and endocrine dysfunction[1,2]. In early pancreatitis, clinical features of the disease are mild and non-specific[3,4]. The global incidence of CP is 10 per 100000 persons per year, and significantly more men than women are affected. In Japan, the overall prevalence of early CP is 4.2 per 100000 persons, and the annual incidence is 1.0 per 100000 persons[5-7]. Several classifications and diagnostic recommendations for CP have recently been proposed[3,4,8-10]. For advanced or end-stage CP, morphologic changes characteristic of fibrosis, duct dilation, calcifications, or atrophy can be detected with imaging modalities and functional failures can be evaluated through functional tests. However, there is no universally accepted diagnostic method for CP[4]. Furthermore, due to a lack of specific clinical presentation or morphologic features, diagnosing CP at an early stage is challenging[11]. Thus, it is critical to combine what is known about the aetiology, risk factors, clinical symptoms, imaging features, and pancreatic function test results to paint a clinical picture[12]. In this review, we compare different diagnostic modalities including several recently developed testing approaches such as endoscopic ultrasound (EUS)-elastography and EUS-guided needle-based confocal laser endomicroscopy (nCLE). We also suggest the development of standardised guidelines for the early diagnosis of CP, which will resolve the challenge of diagnosing early CP.

AETIOLOGY AND CLINICAL PRESENTATION

CP is a fibro-inflammatory disease with various aetiologies that is typically diagnosed using the TIGAR-O criteria[13] (Table 1) and M-ANNHEIM classification system[9]. These international classification systems incorporate common aetiological risks including alcohol and nicotine consumption, genetic mutations and polymorphisms, metabolic disorders, ductal obstruction, immunological factors, and idiopathic pancreatitis[14-16]. Among these factors, alcohol abuse is the most common aetiology of CP and is diagnosed in 42%-77% of patients with CP[17,18]. A prospective study reported that lifestyle-related factors such as alcoholism or smoking are closely associated with the occurrence and progression of CP[19,20]. Ethanol and nicotine are associated with oxidative stress, which activates quiescent pancreatic stellate cells that play an essential role in the inflammatory response and pathological progression of CP, eventually leading to irreversible pancreatic parenchyma damage and fibrosis[21-25]. Chronic alcohol consumption is also thought to increase gut permeability and decrease the phagocytic capacity of Kupffer cells, rendering them unable to detoxify circulating endotoxins; thus, heavy drinkers (> 80 g alcohol/d or more than 5 drinks/d) are susceptible to pancreatic diseases[26,27]. The revised TIGAR-O criteria[13] are used as a grading system for alcohol and nicotine consumption and are preferred to the exposure assessment (Table 1). Furthermore, genetic mutations are usually associated with CP onset, and different genotypes may lead to different effects and disease outcomes. A large Chinese cohort study focusing on four CP-associated genes (*SPINK1*, *PRSS1*, *CTRC*, and *CFTR*) found that patients with gene mutations had earlier disease onset than patients without. The study also found that genetic mu-

AIP Type 1—IgG4-related disease
AIP Type 2
Recurrent acute pancreatitis (RAP) and severe acute pancreatitis (SAP)
Acute pancreatitis (single episode, including date of event if available)

AP aetiology—Extra-pancreatic (excluding alcoholic, HTG, hypercalcaemia, genetic)
Biliary pancreatitis
Post-ERCP
Traumatic
Undetermined or not otherwise specified
Recurrent acute pancreatitis (number of episodes, frequency, and dates of events if available)
Obstructive
Pancreas divisum
Ampullary stenosis
Main duct pancreatic stones
Widespread pancreatic calcifications
Main pancreatic duct strictures
Localized mass causing duct obstruction

From the short form of TIGAR-O version 2 risk/aetiology checklist (2019)[13]. AP: Acute pancreatitis; CKD: Chronic kidney disease; HTG: Hypertriglyceridemia; ERCP: Endoscopic retrograde cholangiopancreatography.

tations were most common in patients with idiopathic chronic pancreatitis (ICP) than in patients with alcoholic chronic pancreatitis (ACP) or smoking-associated chronic pancreatitis (SCP)[28]. Patients with inherited *PRSS1* mutations have reportedly presented with specific imaging features including pancreatic atrophy, calcification, and main pan-creatic duct (MPD) dilatation, which have been termed the PRSS1 imaging triad[29]. Patients with *CFTR* gene mutations have presented with pancreatic atrophy.

An early diagnosis of CP is challenging due to nonspecific clinical presentation. Recurrent abdominal pain with radiation to the back is the most common symptom, with Wilcox *et al*[30] reporting that constant, mild pain with intermittent episodes of severe pain is described by 45% of patients. A history of acute pancreatitis (AP), especially recurrent AP, is a significant risk factor for early CP[4]. However, in some patients, CP is asymptomatic during the early stage, and steatorrhea or diabetes secondary to exocrine/endocrine dysfunction may be the first clinical manifestation of CP without pain[31]. If patients with CP are not diagnosed at an early stage, they have a higher risk of progressing to advanced or end-stage CP, which is characterised by multiple complications including severe pain, pancreatic insufficiency (endocrine or exocrine), metabolic bone disease, and pancreatic ductal adenocarcinoma (PDAC)[19,32,33]. It is currently accepted that an early or suggestive CP diagnosis can be made when three or more of the following clinical features are present: Abnormal serum or urine pancreatic enzyme concentrations; recurring upper abdominal pain; continuous heavy alcohol consumption (> 80 g alcohol/d); family history of hereditary CP or known sporadic high-risk mutations; and abnormal exocrine function (Table 2)[1,4,33,34]. Genetically mediated pancreatitis is likely in a young patient with clinical features of CP but without a history of risk factors such as smoking or alcohol consumption. However, early CP cannot be diagnosed using clinical manifestations alone.

IMAGING MODALITIES

The progression from normal pancreatic status to severe inflammation is typically subtle during which the patient experiences few specific symptoms. Thus, the majority of CP diagnoses are based on imaging features[1,4]. Imaging and radiographical evaluations of a patient with suspected CP should progress from a non-invasive approach to an invasive approach.

Ultrasound and computed tomography

Ultrasound (US) and computed tomography (CT) are recommended by various guidelines as the first-line non-invasive imaging approaches for evaluating patients with suspected CP[10,12]. Intraductal pancreatic calcification and parenchymal atrophy are

Table 2 Comparisons of diagnostic modalities

Modality	Diagnostic standards	Sensitivity	Specificity
Aetiology	TIGAR-O classification (version 2)[13].	-	-
Clinical presentation	Three or more of the following features: Abnormal serum or urine pancreatic enzyme concentrations; continuous heavy alcohol consumption (> 80 g alcohol/day or more than 5 drinks/day), family history of hereditary chronic pancreatitis, or known sporadic high-risk mutations; recurring epigastric abdominal pain; and abnormal exocrine function. Genetic pancreatitis should be suspected in young patients with clinical presentations but without a history of risk factors.	-	-
TA-US	Irregular main pancreatic duct with a diameter > 3 mm, hyperechoic pancreatic duct wall, or lobularity with stranding.	69% (95%CI: 54-80)	94%(95%CI: 90-100)
CT	Two or more of the following features: MPD within 2-4 mm; mild organ enlargement; irregular main pancreatic duct with ≥ 3 pathological side branches; pseudocysts ≤ 10 mm; and heterogeneous parenchyma.	75% (95%CI: 66-83)	91%(95%CI: 81-96)
MRI/MRCP	Two or more of the following features: MPD 2-4 mm; mild organ enlargement; irregular main pancreatic duct with ≥ 3 pathological side branches; pseudocysts ≤ 10 mm; and heterogeneous parenchyma.	Single-parametric: 77%; Multi-parametric: 91%	Single-parametric: 83%; Multi-parametric: 86%
ERCP	More than three pathological side branches plus a normal MPD.	82% (95% CI: 76-87)	94% (95% CI: 87-98)
EUS	More than two of the following seven criteria, including at least one of criteria 1-4: (1) Stranding; (2) Hyperechoic foci without shadowing; (3) Lobularity with honeycombing; (4) Lobularity without honeycombing; (5) Cysts; (6) Dilated side branches; (7) Hyperechoic main pancreatic duct margin.	61% (non-fibrosis); 84% (for fibrosis)	75% (non-fibrosis); 100% (for fibrosis)
EUS-EG	A strain ratio of > 10 or a mean strain histogram value of < 50 was associated with malignancy.The mean value can be used to diagnose mild or higher-grade fibrosis.	76.4%	91.7%
FE-1	Moderate EPI can be diagnosed based on an abnormal FE-1 level of < 200 μg/g, which has a high false-positive rate.	76.5%; 45.0% (mild ductal changes and insufficiency)	86.0%
ePFT	Peak bicarbonate concentration of < 80 mmol/L is considered abnormal and correlated with early fibrosis.	86% (95%CI: 67-100)	67% (95%CI: 13-100)
FNA	Ruling out malignancy and staging of CP. CEA testing: Cut-off value of 192 ng/mL. Molecular analysis: *KRAS* and *GNAS* mutations.	85% (pancreatic cancer)	98% (pancreatic cancer)
nCLE	A complementary modality for detecting subtle changes in early CP and helpful for distinguishing malignancies.	94.3% (cystic lesions); 90.3% (PDAC)	98.1% (cystic lesions); 89.5% (PDAC)

considered the most specific and reliable sonographic signs of CP. However, the value of transabdominal US (TA-US) may be limited by the retroperitoneal location of the pancreas, which increases the sound wave distance to the pancreas, and by several other factors including bowel gas, obesity, and individual variations. Nevertheless, advances in US technology have significantly improved the diagnostic value of the modern abdominal US. A prospective observational cohort study reported a sensitivity of 0.69 (95%CI: 0.54-0.80) and specificity of 0.97 (95%CI: 0.90-1.0) for the detection of CP using TA-US[35]. The following US signs have been proposed for the diagnosis of early or suspected CP: An irregular main pancreatic duct > 3 mm; an hyperechoic pancreatic duct wall; or lobularity with stranding (Table 2)[1]. In addition also criteria of size, shape and mobility should also be taken into account[36,37].

CT is believed to be the best initial imaging modality for the diagnosis of CP, and some guidelines have suggested that all patients with suspected CP should undergo a baseline CT scan[10,12,38]. Ductal changes such as dilation, strictures, and contour irregularity and parenchymal or intraductal calcification, which have been deemed to constitute an independent pathophysiological process involved in the development of CP, can be identified on CT. Furthermore, baseline CT can be useful to rule out other intra-abdominal diseases, including pancreatic and upper gastrointestinal cancers,

which may present with similar symptoms of epigastric pain, weight loss, and maldigestion[38]. In addition, CT can also be used to monitor the progression of pancreatitis and its subsequent complications, such as pseudocysts and biliary obstruction. A systematic meta-analysis reported a sensitivity of 75% (95%CI: 66-83) and specificity of 91% (95%CI: 81-96) for the detection of CP using CT[39]. However, the value of CT is limited for patients with early CP as the parenchymal and ductal changes are subtle. Furthermore, both US and CT have high rates of false negatives due to their limitations. It has been recommended that the quantity, size, and location of pancreatic calcification need to be demonstrated for accurate and comprehensive fibrosis assessments[40,41]. A dilated main pancreatic duct (2-4 mm), mild organ enlargement, pseudocysts, and pathological side branches are considered to be the diagnostic signs of early CP on CT (Table 2)[1,4,33,34].

Magnetic resonance imaging

Patients with suspected pancreatitis should also undergo magnetic resonance imaging (MRI) prior to other evaluations using invasive investigations to rule out carcinoma [10]. MRI and MR cholangiopancreatography (MRCP) are recommended, especially in patients without specific changes detected on CT. MRI and MRCP are superior to CT for the identification of mild CP. For example, morphological changes such as duct dilatation and strictures and pathological side branches that are typical early CP signs are more easily detected on MRI than on CT. Furthermore, new MRI techniques have been applied to quantitatively evaluate the severity of pancreatic fibrosis and pancreatic exocrine dysfunction, including diffusion-weighted imaging (DWI), MR elastography, and T1-mapping of the pancreatic parenchyma[38,41-43]. A retrospective analysis conducted by Tirkes *et al*[44] proposed that T1-weighted MR signaling in the pancreas had a high sensitivity (77%, $P < 0.0001$) and specificity (83%, $P < 0.0001$) for detecting parenchymal abnormalities related to exocrine dysfunction and could be helpful for the assessment of suspected early CP. Another study showed that multiparametric mapping MRI (a combination of T1, T2, and apparent diffusion coefficient values) yielded a higher accuracy for the detection of CP than any sole component (sensitivity: 91.54%; specificity: 85.81%; $P < 0.001$)[45]. If a patient has a high probability of having CP but shows negative results on MRI or MRCP, secretin-stimulating MRCP (part of the exocrine function test) should be performed[38]. However, MRCP does not always detect subtle pancreatic changes, especially when compared to endoscopic retrograde cholangiopancreatography (ERCP), which can be used to diagnose early CP based on the criteria of more than three pathological side branches and a normal main pancreatic duct (MPD) with a specificity of 94%. However, ERCP is not readily available everywhere, and it is operator-dependent and challenging to conduct[46]. The revised Cambridge classification system[47] recommends the following MRCP criteria for the diagnosis and evaluation of early CP: MPD of 2-4 mm; pseudocysts ≤ 10 mm; and irregular MPD with ≥ 3 pathological side branches (Table 2)[1,35].

Endoscopic ultrasound

Endoscopic ultrasound (EUS) has been reported to be the most sensitive modality for detecting fibrosis in patients with CP[4]. EUS is also superior to non-invasive imaging tools in diagnosing parenchymal and ductal changes, especially during the early stage of the disease. Therefore, when CT and MRI show negative results in patients who are suspected of having CP, EUS should be performed[38]. The majority of the EUS diagnostic criteria are based on the Rosemont classification system published in 2009 [48], which attempted to define each EUS criterion precisely to achieve excellent interobserver agreement. Based on the Rosemont classification system, EUS can be used to detect subtle changes in the structure of the pancreatic parenchyma and ducts even before traditional imaging and functional testing. EUS can also be used to treat pancreatitis-related symptoms or complications such as peripancreatic fluid and pseudocyst drainage[49,50]. Standard EUS findings include changes in the parenchyma (hyperechoic foci with or without shadowing, lobularity with or without honeycombing, pseudocysts, and hyperechoic stranding) and ducts (MPD irregularity, dilated side branches, hyperechoic main pancreatic duct wall, MPD dilation (3 mm at the head, 2 mm in the body, or 1 mm at the tail], and MPD stones)[48]. When more than two of the following pancreatic features are found on EUS, including at least one of the first three criteria, the patient is diagnosed with early CP: Lobularity with or without honeycombing, hyperechoic foci without shadowing, stranding, cysts, dilated side branches, and hyperechoic main pancreatic duct margins (Table 2)[1,34].

EUS findings such as hyperechoic foci and strands, parenchymal lobularity, and a hyperechoic ductal wall are considered to be signs of pancreatic fibrosis[51]. A study conducted in 2016 using a quantitative receiver operating characteristic (ROC) curve analysis to evaluate the accuracy of EUS features revealed that four or more standard EUS features achieved the best balance of sensitivity (61%; 95%CI: 46.8-73.5) and specificity (75%; 95%CI: 42.8-94.2) (AUC = 0.68) for predicting abnormal pancreatic histopathology alterations of non-calcific pancreatitis. Nevertheless, the Spearman rank correlation coefficient (*r*) calculated in the study demonstrated a poor correlation between standard EUS features and histopathology ($r = 0.24$, $P < 0.05$), suggesting that EUS is not an independent diagnostic modality for early CP, and that other influencing factors, such as age, sex, BMI, and environmental exposure, should also be included in the diagnostic algorithm[52]. However, a different retrospective study reported that the sensitivity (84%; 95%CI: 69-100) and specificity (100%; 95%CI: 40-100) of the detection of fibrosis using EUS becomes superior as the disease progresses[53,54]. A significant advantage of EUS is its ability to image the side branches and mild contortions of the MPD in normal individuals, especially in elderly individuals. Side branches exceeding 1 mm are considered abnormal. However, by the same token, there is potential for over-diagnosis of early CP especially in elderly individuals due to the very high sensitivity. Therefore, there is potential of over-diagnosis of early CP (Figure 1) by EUS and it should be performed and interpreted in the right clinical setting. Contrast-enhanced EUS with secretin stimulation and quantitative elastography are needed to improve the diagnostic accuracy for mild or suspected CP[55].

Elastography

Fibrosis in CP generally results in increased stiffness of the pancreatic parenchyma or ducts, which can be qualitatively or quantitatively evaluated based on strain or shear wave speed using elastography[56,57]. Together, EUS and elastography have been used to quantitatively measure the severity of pathological changes in CP, including parenchymal fibrosis[58]. EUS elastography (EUS-EG) involves the compression of a target tissue with an echo-endoscopic probe. The resulting strain on the tissue depends on its hardness or softness and can be compared with that of normal surrounding tissue using a three-colour system: Red, soft tissue; green, average hardness; and blue, hard tissue[59]. The quantitative analysis is based on a strain ratio (SR) calculation. Tissue stiffness is measured in a target lesion (region of interest ROI A) and a normal reference area (ROI B), which can be located either in the surrounding normal parenchyma or the wall of the gastrointestinal tract, and the SR is calculated as the quotient A/B[60]. Specific software is used to differentiate between lesions and normal tissues based on the negative correlation between SR and tissue elasticity. Strain histogram analysis is another quantitative elastography method, involving the calculation of the average hue histogram value over several compression cycles. The mean value of the strain histogram reflects the global stiffness or elasticity of a focal lesion based on the selected ROI calculation. Standard deviation (SD) and other parameters can also be used to further describe the hue distribution within the ROI [61]. Previous studies have reported that the evaluation based on the SR and histogram obtained by quantitative EUS-EG can be used as a supplementary approach for assessing the severity of parenchymal fibrosis and making a differential diagnosis of pancreatic masses[2,4,56,57,62]. A prospective study revealed a strong linear correlation between the number of EUS criteria for CP (according to the Rosemont classification system) and the SR ($r = 0.813$; $P < 0.0001$). Additionally, the area under the ROC curve was 0.949 (95%CI: 0.916-0.982), indicating outstanding diagnostic accuracy (91.1%, $P < 0.0001$) based on a cut-off SR of 2.25[63]. Itoh *et al*[64] used quantitative EUS-EG to diagnose the grade of pancreatic fibrosis and proposed that the pancreatic fibrosis grade is significantly correlated with histogram parameters, especially the mean histogram value ($r = -0.75$). When the mean value was used to diagnose mild or higher-grade fibrosis, the area under the ROC curve exceeded 0.9 (95%CI: 0.82-0.98) with a sensitivity of 76.4% and specificity of 91.7% (Table 2). An SR > 10 or a mean strain histogram value < 50 has been associated with malignancy, suggesting that EUS elastography is a useful supplementary modality to rule out malignant lesions of the pancreas due to its high negative predictive value[65]. A correlation between elasticity and EUS criteria has also been reported when elastography evaluations are based on the shear wave, which enriches the elastography approach for CP diagnosis[66-69]. As elastography is able to efficiently and accurately assess pancreatic fibrosis, combining EUS and elastography can greatly enhance the accuracy of detecting subtle or mild changes in patients with early or higher-grade CP.

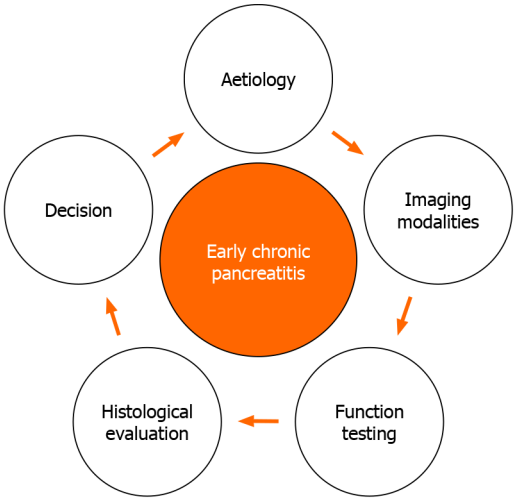

Figure 1 Outline of comprehensive diagnosis of early chronic pancreatitis.

PANCREATIC FUNCTION TESTING

Exocrine pancreatic insufficiency (EPI) is a common complication of CP mainly caused by the impairment of the production and secretion of enzymes in the pancreas. Symptoms of EPI include maldigestion of nutrients, unexpected weight loss, and steatorrhea due to fat maldigestion[32]. Pancreatic function testing (PFT) is recommended for the diagnosis of CP, especially in patients with non-specific and inconclusive morphological or imaging features of the disease[33,38]. PFT includes direct tests, which collect and analyse pancreatic secretions after a hormone stimulus, and indirect tests, which assess pancreatic function *via* faecal elastase-1(FE-1) or a breath test.

Direct PFT is conducted by determining the pancreas enzyme output after stimulation with cholecystokinin (CCK). The combination of secretin-stimulated MRI (s-MRI) and EUS-based PFT allows for the assessment of the bicarbonate concentration in the pancreatic juices as well as an improved morphological analysis[70]. S-MRI is considered to be a safe and non-invasive technique that enhances the visualisation of the ductal system by stimulating the bicarbonate-rich fluid filling the MPD and its side branches. EPI is diagnosed when the bicarbonate concentration is < 80 mmol/L after secretin stimulation[71]. Following intravenous secretin (0.2-0.3 μg/kg within 1-2 min) administration, an increase in hyperintense fluid content is observed in the small intestine 10-13 min thereafter. During the post-secretin stimulation stage, the MPD has a larger diameter and can be more easily evaluated, and pancreatic ductal compliance, which is associated with ductal stiffness or calcification, can be assessed. Healthy, nonfibrotic pancreatic parenchyma and ducts without strictures or calcification have an elastic capacity for accommodating pancreatic juice fluid without dilatation, and the diameter will not increase by more than 1 mm from the baseline value after secretin stimulation[10,23,72]. Exocrine pancreatic function can be quantitatively and semi-quantitatively evaluated by assessing the production and excretion of bicarbonate from pancreatic glands[10,73]. Thus, s-MRI can be applied to diagnose early or mild CP based on its superior ability to detect early pathological changes, such as the presence of side branches and an enlarged or restricted MPD, compared to CT or standard MRI. Several studies have reported significant differences between patients with a normal pancreas and early pancreatitis using s-MRI and correlations between s-MRI findings and the histopathological features of CP[74-76]. Similarly, EUS can be used in the endoscopic pancreatic function test (ePFT), which has been reported to have a sensitivity of 86% (95%CI: 67-100) and specificity of 67% (95%CI: 13-100) for the diagnosis of early fibrosis[53]. A retrospective study reported that a peak bicarbonate concentration of < 80 mmol/L on ePFT is considered abnormal and proposed a correlation between the peak bicarbonate concentration and fibrosis score (r = -0.57; P = 0.016). However, other studies have also claimed that the specificity and concordance for CP diagnosis were more accurate in a shortened ePFT with the use of a lower cut-off value; more prospective studies are required for further validation of the ePFT (Table 2)[77,78].

Although direct PFT is generally considered to be the gold standard for EPI, indirect PFT is useful for screening patients with risk factors for CP, as it is non-invasive and convenient. Indirect PFT can be performed using faecal chymotrypsin or FE-1 assays, 72-h faecal fat measurement, bentiromide (NBT-PABA) tests, and fluorescein dilaurate tests. FE-1 assessment is the most commonly used PFT method as it is stable throughout the intestinal tract. Furthermore, EPI can be diagnosed based on an abnormal FE-1 level (< 200 μg/g), though this diagnostic method is limited by a high false-positive rate (Table 2)[79]. FE-1 has also been reported to correlate with pancreatic duct changes, with a sensitivity of 76.5% and a specificity of 86% ($P < 0.05$) for moderate to severe changes at a cut-off of 200 μg/g. However, the correlation of FE-1 with mild ductal changes and insufficiency was not as strong, with a sensitivity of 45% [80,81].Therefore, the FE-1 test is not an accurate method for the functional diagnosis of EPI and should not be used to diagnose early CP.

HISTOLOGICAL EVALUATION

EUS-guided tissue acquisition

While the histopathological examination is considered the gold standard of disease diagnosis, direct acquisition of pancreatic tissue is limited due to the retroperitoneal location of the organ. Tissue acquisition with EUS (EUS-TA) can be used to obtain pancreatic tissue samples for microscopic analysis and establish a cytopathological diagnosis of the gastrointestinal tract or adjacent lesions[82]. In patients with suspected pseudo tumoural masses or cystic lesions in the setting of CP, a histopathological examination is necessary to eliminate malignant lesions from the differential diagnosis[72,82]. EUS-TA can be achieved *via* EUS fine-needle aspiration (EUS-FNA) and EUS-fine needle biopsy (EUS-FNB), which is the current gold standard for tissue acquisition from solid masses. FNA is used to rule out malignancy from the differential or to stage CP and can provide both cytological and histological evaluations. FNA is reported to be superior to other modalities for the evaluation of cystic pancreatic lesions in patients with concurrent CP[83]. The fluid obtained by FNA can be tested for amylase and carcinoembryonic antigen (CEA). Moreover, the CEA level can be used to distinguish mucinous and non-mucinous lesions with a cut-off value of 192 ng/mL[83,84]. Additionally, the molecular analysis of mutations in the *KRAS* and *GNAS* genes using the FNA specimen can distinguish malignant lesions from benign cystic lesions[85,86]. FNA has also been reported to be useful for evaluating solid lesions and suitable for distinguishing autoimmune pancreatitis (AIP) from pancreatic cancer[87,88]. FNA has been reported to have a sensitivity of 85% and specificity of 98% for the diagnosis of pancreatic cancer (Table 2)[89]. However, according to a current retrospective analysis of multicentric databases, FNB showed a higher diagnostic sensitivity than FNA for distinguishing between inflammatory masses and malignant lesions in the setting of CP[90]. However, histopathological evaluation by FNB may cause needle tract seeding, which should be taken into consideration when conducting FNB on patients with resectable solid masses[62]. Thus, the appropriate method of tissue acquisition depends on the specific type of pancreatic lesion and the purpose of diagnosis. EUS-TA is limited by its potential complications such as bleeding and post-procedure pancreatitis, and requires an experienced operator.

Confocal laser endomicroscopy

Needle-based confocal laser endomicroscopy (nCLE) is a novel diagnostic method that allows for real-time optical biopsy at a subcellular resolution during a EUS procedure. The patient is administered with 2.5 mL of 10% fluorescein intravenously, and a confocal mini-probe with a 0.632-mm diameter is preloaded into a 19-gauge EUS needle and locked into position with 2 mm exposed beyond the tip. The images are obtained 6-8 min after fluorescein injection. In solid pancreatic masses, residual regular glandular pancreatic structures on nCLE are characteristic of CP (Table 2). In cystic lesions, the presence of villous epithelial structures on nCLE may be associated with pancreatic cystic neoplasms. A study conducted by Karia *et al*[91] compared the interobserver agreement and diagnostic accuracy of nCLE *via* FNA for pancreatic cystic lesions (PCLs) and found that the diagnostic accuracy for PCLs was low, with a mean sensitivity of 46% and an unimpressive agreement (k = 0.13). Another study found that nCLE is a safe and feasible diagnostic method for cystic neoplasms with an overall accuracy of 80% (sensitivity: 66%, specificity: 100%)[92]. Another study reported a sensitivity of 90.3% and specificity of 89.5% for the diagnosis of PDAC *via* nCLE and a sensitivity of 94.3% and specificity of 98.1% for the diagnosis of PCLs *via*

nCLE ($P < 0.05$; Table 2)[93]. These results suggest that nCLE is a promising method that can improve the diagnostic efficiency of EUS technology by providing better imaging accuracy and verifying EUS imaging features by combining subcellular observation with tissue acquisition. Furthermore, this method can be a complementary modality for detecting the subtle changes of early CP and distinguishing malignancies from benign lesions. Limitations of nCLE include the potential complications of infections, bleeding, and pancreatitis. Furthermore, patients with significant coagulopathy or allergy to fluorescein should not undergo nCLE and FNA.

CONCLUSION

No individual diagnostic method can be used to establish a diagnosis of early CP due to the non-specific clinical presentation and subtle morphological changes as well as the lack of globally accepted standards. Various advanced modalities have been used to improve the accuracy of the diagnostic methods for CP. It is important to consider the possible aetiologies, risk factors, and complications of the disease in patients suspected to have CP. Inflammatory complications are mainly due to alcohol consumption and fibrotic complications are mainly due to smoking. Pancreatic insufficiencies have been associated with disease duration and age at onset[94]. CP is typically diagnosed using imaging modalities that can detect morphological changes in the pancreas or detect functional insufficiency (by combining imaging and secretin stimuli). Elastography can quantitatively evaluate the stiffness of the pancreatic parenchyma. However, each imaging modality has limitations that require verification of the diagnosis using an additional modality. Furthermore, there is a lack of consistency among the features and diagnostic criteria of different imaging modalities. The diagnostic criteria of MRCP and ERCP are based on the Cambridge scoring system, which focuses on the morphology of the MPD and the appearance of its side branches; however, a lack of strong concordance between the ERCP- and MRCP-based grading systems for CP using the Cambridge criteria has been recently reported[8,95,96]. Therefore, the imaging standards for CP may need to be revised to improve the consistency of the diagnostic methods. Prospective studies are required to verify the diagnostic accuracy of these imaging modalities. However, ERCP purely for diagnostic purposes for assessing chronic pancreatitis is outdated with risks greater than benefits and should not be done. Each imaging modality has sensitive indicators for pancreatic pathological changes, and some modalities do not have a high sensitivity or specificity for pancreatitis at an early stage, as shown in Table 2. Promising tools, such as nCLE, are currently being developed and require more studies for the verification of their diagnostic efficiency and potential. Furthermore, probable biomarkers for the diagnosis of early CP or to rule out malignancy, such as metabolomic and microRNA signatures in the blood, have been investigated, but they also require further verification[97-100].

A limitation of this review is that it could not identify a single appropriate modality for the diagnosis of early CP; however, comparisons of these clinical approaches provide references for physicians to help establish a diagnosis of early CP. The modalities used may depend on the local availability of a particular test, *e.g.*, pancreatic function testing. MRCP or EUS may not be universally available at each institution. In conclusion, although several imaging modalities can elucidate specific pancreatic features, an accurate and definite diagnosis of early CP should be based on the patient's risk factors, symptoms, imaging results, and histological findings when available. There has been a renewed recent interest in the use of artificial intelligence (AI)[101] in medical imaging and application of AI to EUS images and the other modalities discussed above could potentially further increase the reliability in diagnosis of CP since medical diagnosis based on images is subject to interpretation of the reader and interobserver variability can become a greater issue even more for the diagnosis of an early stage of disease than a late one.

ACKNOWLEDGEMENTS

Abstract

Since it was first reported in December 2019, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection has spread rapidly around the world to cause the ongoing pandemic. Although the clinical manifestations of SARS-CoV-2 infection are predominantly in the respiratory system, liver enzyme abnormalities exist in around half of the cases, which indicate liver injury, and raise clinical concern. At present, there is no consensus whether the liver injury is directly caused by viral replication in the liver tissue or indirectly by the systemic inflammatory response. This review aims to summarize the clinical manifestations and to explore the underlying mechanisms of liver dysfunction in patients with SARS-CoV-2 infection.

that liver injury is common in COVID-19 patients, and many severe cases tend to be associated with dysregulated liver functions. In this review, we summarize the currently available data of liver enzyme abnormalities in patients confirmed to have COVID-19 and analyze multiple risk factors for liver injury. However, the mechanism of liver impairment seems to be multifactorial. The evidence of direct liver injury triggered by SARS-CoV-2 infection or indirect liver injury induced by overwhelmed cytokine storm will also be discussed.

INTRODUCTION

Coronavirus disease 2019 (COVID-19) has broken out worldwide and was declared as a global pandemic by the World Health Organization (WHO) on March 11, 2020 after it was first reported in December 2019. The virus was later isolated[1] and was named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by the International Committee for Taxonomy of Viruses. To date, this virus has spread to 220 countries, infecting 179601602 people with 3891974 deaths (as of June 24, 2021, source: Johns Hopkins University; https://coronavirus.jhu.edu/map.html), which constitutes a public health emergency of international concern.

The severity of symptoms in patients with COVID-19 ranges from mild self-limited respiratory disease to severe progressive pneumonia and respiratory failure, with an overall mortality rate of 2.3%[2]. The typical clinical manifestations of COVID-19 include elevated body temperature (> 37.3 °C), dry cough, dyspnea, leukocytosis, lung infiltration, and no significant improvement after antibiotic treatment for 3 d[3]. In addition to the respiratory system, various organs are reported to be involved in the process of SARS-CoV-2 infection, which caused complications that aggravate the infection[4]. Up to 50% of COVID-19 patients have been reported to have abnormal liver biochemical indicators, including elevated expression of aminotransferases, glutamyl transferase, and alkaline phosphatase (ALP)[3,5,6], and the proportion of infected patients with abnormal liver functions is greater in highly epidemic areas than other regions[7]. In addition, 58%-78% of patients with severe COVID-19 have apparent liver damage. Liver injury in turn increases the risk of other outcomes, such as cardiac arrest, requirement for intubation, acute respiratory distress syndrome, arrhythmia and shock[8]. Therefore, it is crucial to understand the mechanisms of the aberrant liver functions caused by this novel respiratory virus[9]. It is currently believed that three mechanisms may account for the liver damage in COVID-19 patients: (1) Hepatic bile duct endothelial cells and hepatocytes are directly infected by SARS-CoV-2 mediated by the cellular receptors; (2) A cytokine storm is induced by overactivated immune responses and causes inflammatory liver damage; and (3) Multiple risk factors such as underlying liver diseases may cause secondary liver damage following SARS-CoV-2 infection. In this review, we summarize the clinical manifestations and explore the potential underlying mechanisms of liver dysfunctions in patients with SARS-CoV-2 infection.

SARS-CoV-2: GENOME STRUCTURE AND TRANSMISSION

Coronaviruses (CoVs) are a group of enveloped positive single-stranded RNA viruses that belong to the Coronaviridae family of order Nidovirales[10]. CoVs are further grouped into α-, β-, γ-, and δ-coronaviruses. Among them, α- and β-CoVs can infect mammals and γ-coronaviruses infect birds and δ-coronaviruses infect both[11]. SARS-CoV-2, initially isolated from human airway epithelial cells, was identified as the seventh member of the CoVs capable of infecting humans. It genetically belongs to the β-CoV genus in the same clade with SARS-CoV and middle-east respiratory syndrome

coronavirus (MERS-CoV)[1,12].

Genome structure and variability

The SARS-CoV-2 genome shares around 76.5% amino acid sequence identity with SARS-CoV[13] , which might be responsible for the shared transmission mode and pathogenesis of these two viruses. The SARS-CoV-2 genome contains 14 open reading frames, encoding 27 proteins (Figure 1A). Four major structural proteins are encoded by the 3'-terminus of the genome, including the spike surface glycoprotein (S), matrix protein (M), small envelope protein (E), and nucleocapsid protein (N)[11] (Figure 1B). The S protein initiates the infection by interacting with the cellular receptor through its receptor binding domain (RBD). SARS-CoV-2 infects the target cells by S protein on the surface of the virion binding to cellular angiotensin-converting enzyme 2 (ACE2) receptors followed by fusion of the cellular and viral membranes (Figure 1C). In this process, transmembrane protease serine 2 (TMPRSS2), together with the endosomal cysteine proteases cathepsin B and L (CatB/L), are used for S protein priming. The S protein of SARS-CoV-2 is efficiently cleaved at the junction of S1 and S2 proteins to produce an S2 subunit to facilitate SARS-CoV-2 entry[14]. Considering the major role played in the pathogenesis, S protein is considered to be a potential target for vaccine design and drug development[9]. E protein is involved in the assembly and release of virions. As the most abundant viral protein, M protein plays an important role in RNA packaging[15] and N protein mediates the transcription and replication of viral RNA [16].

The variability of the SARS-CoV-2 genome is lower when compared to other human CoVs. There were 149 mutations in 103 sequenced SARS-CoV-2 genomes in the early stage of the pandemic[17]. The virus was classified into two major variants (L and S) through population genetic analysis. The L type, derived from the S type of SARS-CoV-2, was reported to be evolutionarily more aggressive[17]. Recently, a more transmissible phylogenetic cluster (named lineage B.1.1.7), which has 23 specific genetic changes in S protein of SARS-CoV-2, was reported in the UK, and rapidly became the dominant strain in London. Mutation N501Y affects the structure of the RBD and P681H is adjacent to the furin-cleavage site, which increases the binding affinity of the virus to ACE2 receptors by 1000-fold. Moreover, the deletion 69-70del on the S protein facilitates viral evasion from immune surveillance. Collectively, these variations have raised concerns about potential antigenic drift of SARS-CoV-2 similar to that of influenza virus[18].

Transmission of SARS-CoV-2

SARS-CoV-2 is a zoonotic virus that spreads in humans through respiratory droplets [19]. Comparative sequence analysis of the SARS-CoV-2 genome has revealed a striking similarity with bat CoVs, indicating that bats may be the origin of this virus [20,21]. Although many COVID-19 cases initially reported in China were traced to have connection with Huanan Seafood Wholesale Market in Wuhan[6,22,23], several reports clearly indicate that the global spread of the SARS-CoV-2 might have preceded the discovery of the first case in Wuhan. The epidemic likely started between October 6 and December 11, 2019 in the USA, Italy and France[24,25];however, debate still exists about the source of SARS-CoV-2. Since the transmission of SARS-CoV-2 needs intermediate hosts, pangolins have been suggested as a probable intermediate host [26]. In February 2020, evidence of human-to-human transmission of SARS-CoV-2 was first reported[27]. Thereafter, a case of SARS-CoV-2 provided proof that human-to-human transmission occurred during the incubation period[28]. With the appearance of the second-generation patients and many medical staff in the hospital being infected, the strong infectious ability of SARS-CoV-2 was confirmed[29]. With the detection of SARS-CoV-2 RNA in fecal sample from a COVID-19 patient in the USA, SARS-CoV-2 could also be transmitted through the fecal–oral route[30]. Since September 2020, the route of transmission from contaminated objects to people has been reported by tracing the origin of local confirmed cases in Qingdao, Tianjin, Dalian, Chengdu and other cities in China, further complicating epidemic prevention and control.

DYSREGULATED LIVER FUNCTION IN COVID-19 PATIENTS

The common clinical manifestations of patients with COVID-19 are cough, fever, shortness of breath, and other respiratory symptoms[31]. Gastrointestinal symptoms including nausea, vomiting, and diarrhea are also observed in some patients. The

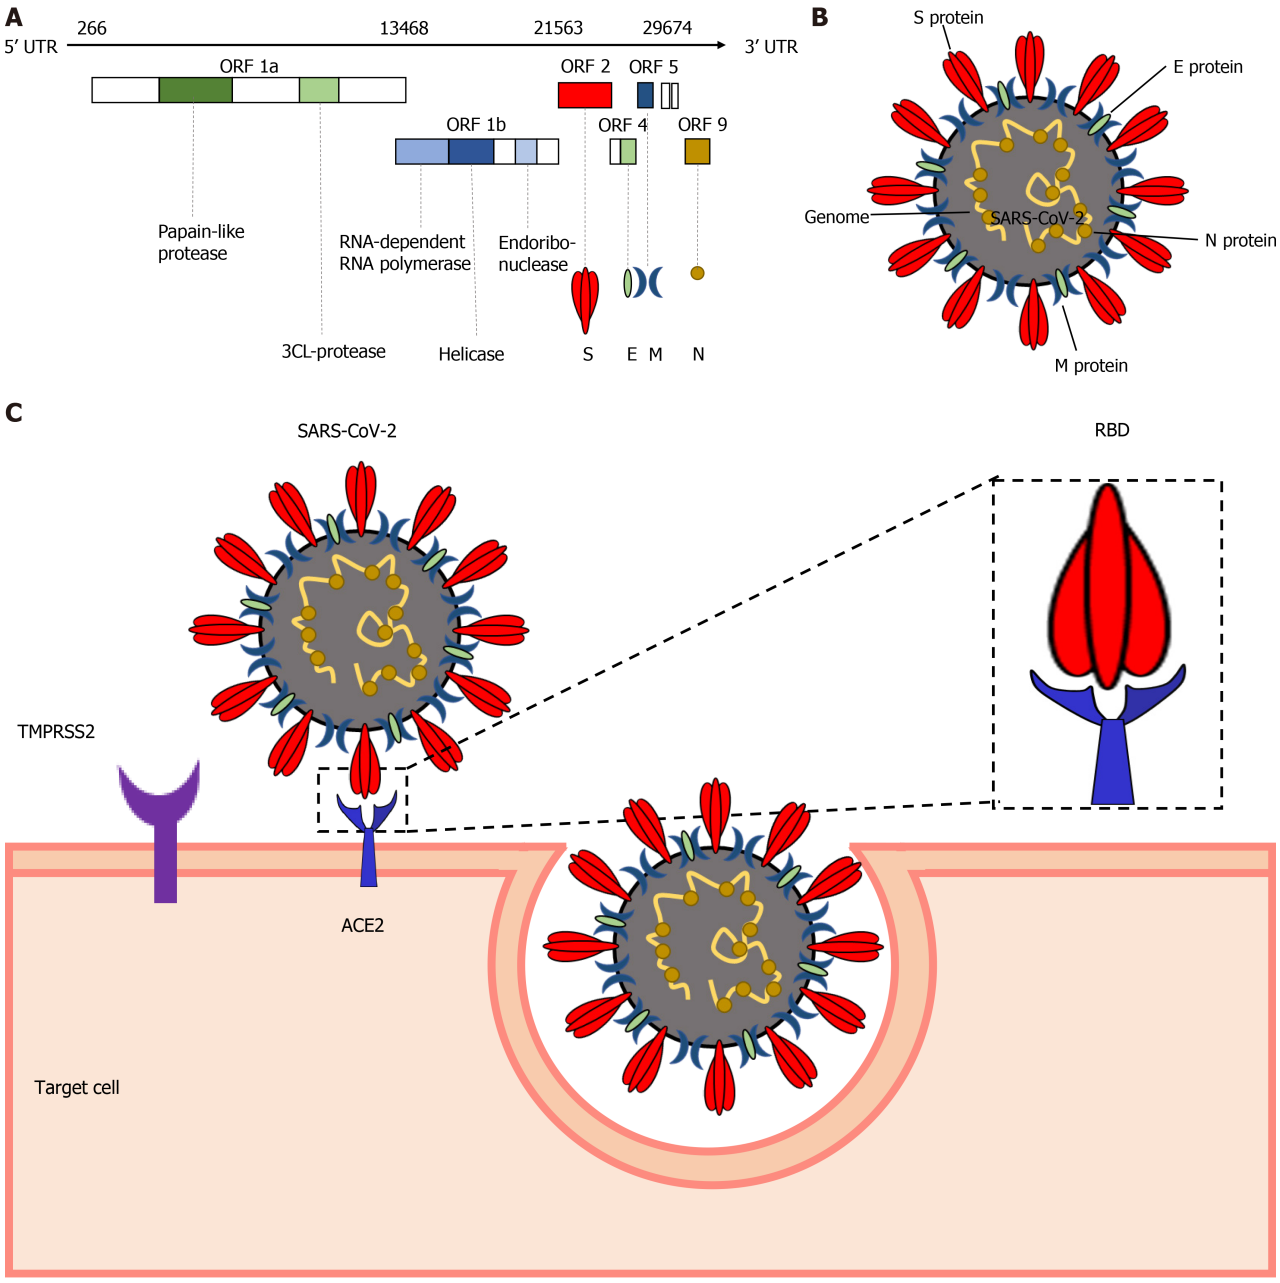

Figure 1 Severe acute respiratory syndrome coronavirus 2 genome and its pathogenesis. abnormal values of liver enzymes have frequently been noted in patients with COVID-19. Existing data suggest that, in most cases, liver enzyme elevations are mild to moderate and rarely severe. Limited pathophysiological studies have indicated that SARS-CoV-2 infection can cause liver injury, although SARS-CoV-2-induced liver injury is not the leading cause of death.

Altered biochemical markers

Liver injury in hospitalized patients is mainly manifested by changes in biochemical liver markers. Many studies have reported the presence of liver dysfunction in COVID-19 patients (Table 1). Respiratory failure is a common characteristic in severe cases, characterized by an imbalance of oxygen supply leading to an increase in transaminases[32]. As reported, 14%-53% of patients have elevated aspartate aminotransferase (AST), alanine aminotransferase (ALT), g-glutamyltransferase (GGT), hypoalbuminemia, and slightly elevated bilirubin[33]. The elevation of AST (39.4%) is more

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GGT: -glutamyltransferase; CRP: C-reactive protein; N/A: Not available.

significant than that of ALT (28.1%) in severe cases. Among these markers affected by viral infections, elevated AST is related to a higher risk of death, while elevated GGT [33-38], ALP[34-36], together with bilirubin levels[6,31,33-35], are associated with biliary tract damage. Some patients have hypoalbuminemia, an independent predictor of mortality, which may be related to inflammation and poor prognosis[39,40]. Some studies have also reported C-reactive protein (CRP) elevation in many severe COVID-19 cases[6,31,35,41-44], indicating that overactivation of the immune system might account for disease severity, which can be used to predict worse outcomes in COVID-19 patients. In the elderly population with underlying liver disease, liver enzymes, especially transaminases, are elevated due to lobular necrosis[45].

Pathophysiological characteristics of liver tissues in COVID-19 patients

Mild portal vein inflammation, moderate microvesicular steatosis, and necrotizing inflammation have been observed in liver autopsy tissue of COVID-19[10]. This is likely due to increase of monocyte chemoattractant protein 1 (MCP-1) in patients infected with SARS-CoV-2, which aggravates fatty hepatitis[46]. Autopsy results from COVID-19 patients in Wuhan have shown infiltration of monocytes and lymphocytes in the portal vein area, accompanied by hepatic sinus congestion and microthrombus formation[45]. Cytologically, hepatocyte degeneration with focal lobular necrosis and neutrophil infiltration are observed together with swollen mitochondria, endoplasm reticulum expansion, and decreased glycogen particles in the hepatocytes. The histological manifestations are apoptosis and binuclear hepatocytes. In addition, immunohistochemical results have shown a lack of $CD4^+$ cells and $CD8^+$ T cells in liver tissue, suggesting that immunopathological insult may not be the main factor leading to liver injury.

POTENTIAL MECHANISMS OF LIVER INJURY IN COVID-19 PATIENTS

SARS-CoV-2 initiates membrane fusion and cytoplasmic invasion by entering respiratory endothelial cells expressing ACE2 and TMPRSS2, triggering an initial immune response characterized by inflammatory cytokine production. Afterwards,

the downstream proinflammatory immune responses of pathogenic Th1 cells and monocyte signaling pathways are activated[47]. Two hypotheses have been proposed to explain the mechanisms of liver dysfunctions in COVID-19 patients: direct injury by SARS-CoV-2[48] and indirect injury from a cytokine storm.

Direct effects of SARS-CoV-2 infection on liver injury

It has been reported that SARS-CoV-2 infection of various types of liver cells causes liver injury through direct cytopathic effects[48]. As a functional receptor for SARS-CoV-2 S protein binding, ACE2 is widely expressed on the surface of various human cells. Due to the low expression level of ACE2 in liver tissue (approximately 0.31%), SARS-CoV-2 was once considered unlikely to infect the liver. However, Li *et al*[49] systematically evaluated the expression of host receptor genes interacting with SARS-CoV-2 in liver tissue and their distribution patterns in different cell types using single-cell transcriptomics. ACE2 protein is expressed in various cell types in the liver, especially in bile duct cells[50], likely leading to direct injury to the liver (Figure 2). Boettler *et al*[51] proved that SARS-CoV-2 has a stronger affinity for bile duct cells than hepatocytes because of higher ACE2 receptor expression.

It has been proposed that SARS-CoV-2 infection of bile duct cells is the source of viral nucleic acid detection in feces[51]. Even in patients with negative throat swabs for viral RNA, 48% of feces were positive for SARS-CoV-2 RNA, which may be derived from portal vein viremia. Although SARS-CoV-2 can infect bile duct cells, the histological characteristics of bile duct injury have not been observed. Wang *et al*[48] observed many SARS-CoV-2 virions in the hepatocyte cytoplasm of two cases with COVID-19. Most of the virosomes were found to have complete envelopes with crown protrusions, providing evidence that SARS-CoV-2 can enter and replicate in hepatocytes. However, the low expression level of ACE2 on hepatocytes cannot fully explain the hepatotropic nature of SARS-CoV-2. One possibility is that there are alternative receptors or co-receptors other than ACE2. This hypothesis has gradually been confirmed by the discovery of more co-receptors that facilitate SARS-CoV-2 entry. For example, tyrosine-protein kinase receptor UFO (AXL), heparan sulfate, scavenger receptor B type 1 (SR-B1), neuropilin-1 (NRP1) and CD147 have been identified as attachment factors for SARS-CoV-2 infection[52-57], although the abundance of these co-receptors in liver tissue remains to be determined. The other possibility is that the expression of ACE2 in hepatocytes is temporarily upregulated when the virus enters the cells, assisting infection. Again, more evidence is needed to support this hypothesis.

Indirect injury caused by cytokine storm

The variable symptoms in severe and asymptomatic patients with COVID-19 suggest that host immune responses contribute to the pathogenesis. SARS-CoV-2 infection leads to excessive production of a series of cytokines by macrophages and neutrophils known as a cytokine storm[47], which is one of the main features in COVID-19 patients and may be a key factor affecting disease severity and mortality. Cytokines are self-antigens that induce autoimmunity, and could account for the multisystem inflammatory syndrome often seen in COVID-19 patients. $CD4^+$ and $CD8^+$ T cells in the peripheral blood of COVID-19 patients are highly activated *via* Toll-like receptors. Elevated proinflammatory $CD4^+$ T cells and cytotoxic granular $CD8^+$ T cells suggests an antiviral immune response and excessive activation of T cells in the peripheral blood[10]. The host cells are attacked by activated T cells leading to necrosis and apoptosis, and many damage-related pattern molecules are involved to amplify the inflammatory signals. Lymphopenia is also observed in the disordered cytokine storm, but it is still unknown whether it is caused by destruction of lymphocytes or tissue infiltration. It has been demonstrated that the proinflammatory cytokines are elevated significantly in patients with severe COVID-19, leading to severe pneumonia. The inflammatory cytokines not only protect the host cells from injury but also cause blood clotting, thereby blocking the vessels and resulting in decrease of oxygen saturation and sepsis, which is considered to be one of the causes of insufficient lung ventilation. Therefore, hypoxic hepatitis is common in patients with severe COVID-19, especially elderly patients with right congestive heart failure who are prone to have hypoxic–ischemic liver injury[48].

More specifically, the cytokine storm induced by SARS-CoV-2 is characterized by high expression of interleukin (IL)-6 and tumor necrosis factor-α (TNF-α). Activated pathogenic Th1 cells produce proinflammatory cytokines, such as granulocyte–macrophage colony-stimulating factor (GM-CSF) and IL-6. GM-CSF in turn stimulates $CD4^+$ T cells to secrete large quantities of cytokines, such as TNF-α, IL-10, IL-6 and type I interferons[58] (Figure 2). The inflammatory response is obvious in COVID-19

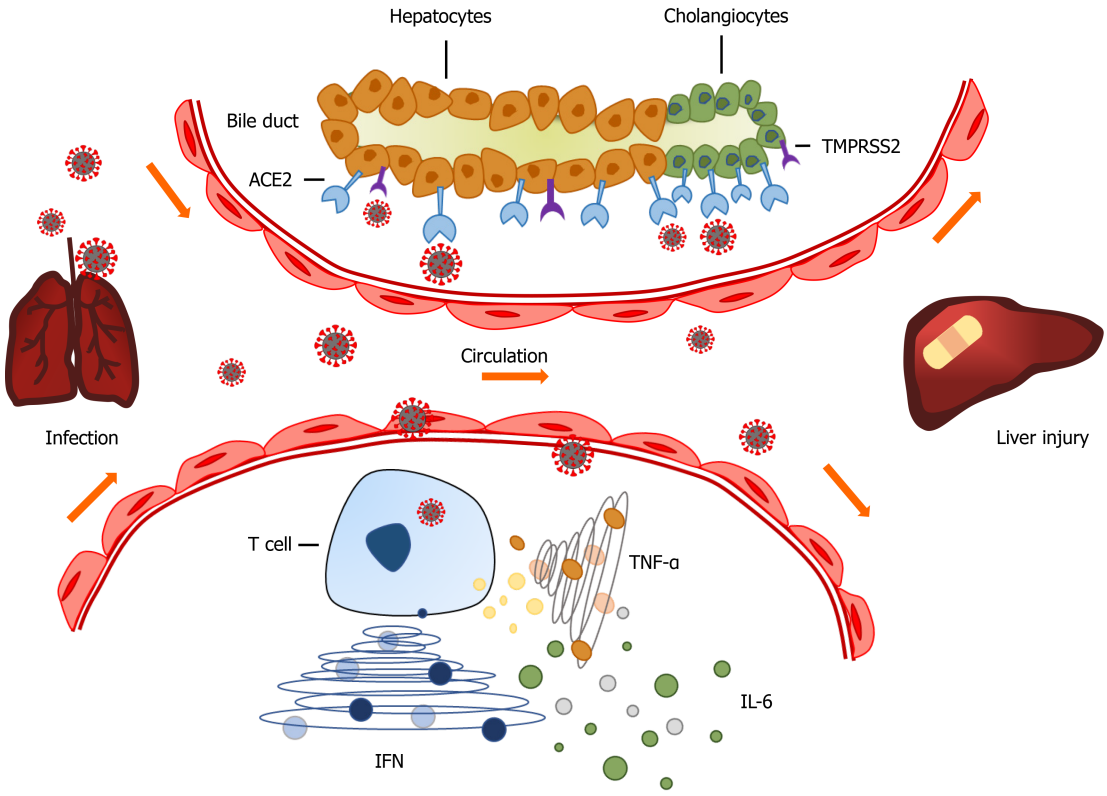

Figure 2 Schematic diagram of the two mechanisms of severe acute respiratory syndrome coronavirus 2-induced liver dysfunction. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) causes direct liver injury through binding to the angiotensin-converting enzyme 2 receptor and transmembrane protease serine 2 expressed on cholangiocytes and hepatocytes. Indirect injury by cytokine storm. T cells are stimulated to secrete large quantities of cytokines including type I interferons, interleukin-6, and tumor necrosis factor-α following SARS-CoV-2 infection, leading to systemic excessive inflammation syndrome. ACE2: Angiotensin-converting enzyme 2; TMPRSS2: Transmembrane protease serine 2; TNF-α: Tumor necrosis factor-α; IL-6: Interleukin-6; IFN: Interferons.

patients as indicated by increased expression of inflammatory biomarkers such as lactate dehydrogenase (LDH), IL-6, IL-2, CRP, serum ferritin, and D-dimer[59-61]. It has been reported that 28% of patients who died of multiple organ damage, including liver failure, was due to an excessive inflammatory response. In the case of liver injury, ACE2 expression is upregulated due to the compensated proliferation of hepatic parenchymal cells derived from bile duct epithelial cells, which increases the opportunities of viral infection in liver tissue.

Neutralizing cytokine release syndrome (CRS) that blocks the signal transduction pathway of these cytokines contributes to the development of effective drugs for the treatment of patients with severe COVID-19, and targeting CRS has significant implications for reducing mortality. One such example is tocilizumab, an IL-6 inhibitor, which improves the condition of patients within 15 d and reduces mortality considerably[62]. Although the cytokine storm is involved in liver injury, these cytokines also function in viral suppression. Therefore, application of treatment regimens to block cytokine signal transduction must be careful. Clinically, the application of synthetic corticosteroid dexamethasone worsens outcomes in milder COVID-19 patients, but reduces mortality in severe cases[63]. Likewise, other studies have supported that immunosuppression has a beneficial effect if given at a late stage, whereas immunostimulation enhances antiviral activity in the early stage[64], indicating that the timing of treatment and the specific patient population need to be identified to personalize the therapeutic schemes.

Liver injury caused by other factors in COVID-19 patients

Current evidence is insufficient to conclude that liver injury in COVID-19 patients results entirely from SARS-CoV-2 infection. Considering the multisystem involvement in severe COVID-19 patients, liver injury may be caused by multiple factors, including drug toxicity, systemic inflammation, liver congestion, microvascular thrombosis, or damage induced by cytotoxic T cells and innate immune responses following SARS-CoV-2 infection.

Drug toxicity: Currently there is no specific treatment for COVID-19, although initial clinical guidelines recommended using antiviral drugs and monoclonal antibodies such as remdesivir, chloroquine, tocilizumab, lopinavir, ritonavir, and traditional Chinese medicine. However, it has been reported that both lopinavir and ritonavir have little clinical effect on COVID-19 patients[65]. According to WHO and National Health Commission of China guidelines, patients with moderate symptoms should receive timely treatment with *Coriolus versicolor*, abidor, chloroquine phosphate, and recombinant human interferon α-2b. For severe/critical patients, respiratory support, appropriate hormone therapy, and traditional Chinese medicine may be beneficial [66]. Chloroquine phosphate has been proved to cause significant liver damage[67]. A more recent study reported that ACE inhibitors and angiotensin II receptor blockers might contribute to liver impairment in COVID-19 patients, although more studies are needed to confirm these findings[33]. In addition, fever is one of the main symptoms for COVID-19 patients. Paracetamol, which is a commonly used antipyretic drug, has been proven to cause fulminant liver failure, so the possibility of excessive use of paracetamol leading to elevated ALT cannot be ruled out[59,68].

Liver congestion: Forty percent of patients are at high risk of venous thromboembolism (VTE) when admitted to hospital. High-risk VTE patients have elevated expression of ALT, AST and CRP[69]. It is well known that viral infection leads to a hypercoagulable state, increasing the risk of thromboembolism[70,71]. The incidence of VTE is 20% on day 7 and 42% on day 21, even among hospitalized patients taking anticoagulants[72]. Recent studies have found that in some younger patients, microvascular thrombosis causes end-stage organ damage and contributes to liver injury. Anticoagulant drugs can be used to prevent the development of VTE. A few studies have concluded that 80% of COVID-19 patients with cirrhosis and portal hypertension received anticoagulant therapy, such as low-molecular-weight heparin, and those patients do not have serious bleeding complications[73,74]. However, Wang *et al*[69] have reported that 11% of COVID-19 patients with high risk of VTE also have a high risk of bleeding. Therefore, evaluating the risk of thromboembolism and rational use of anticoagulants for the treatment of COVID-19 patients is critical.

Underlying liver diseases: Chronic liver diseases, including chronic viral hepatitis and nonalcoholic fatty liver disease (NAFLD), affect approximately 300 million people in China and constitute a major global burden of disease. Although chronic liver disease does not increase the infection risk of patients with SARS-CoV-2 in general, patients with liver cirrhosis or hepatocellular carcinoma tend to be more susceptible to SARS-CoV-2 infection due to systemic immunodeficiency. Furthermore, the underlying liver diseases may worsen disease progression in patients with COVID-19. A study consisting of > 17 million people in the United States found that although < 1% of the confirmed COVID-19 cases had chronic liver diseases, chronic liver disease was an independent risk factor for death from SARS-CoV-2 infection[75].

Hepatitis B virus (HBV) does not predispose COVID-19 patients to more severe outcomes, although HBV patients infected with SARS-CoV-2 normally present with aggravated liver damage together with more severe thrombocytopenia and monocytopenia, coagulation dysfunction, and more disturbed hepatic function in relation to albumin production and lipid metabolism[76], and these co-infected patients have a tendency to HBV reactivation[67]. Astrilizumab and baritinib, which are used clinically to antagonize adverse immune reactions, tend to induce HBV reactivation, leading to impaired liver function in HBV patients[77]. However, it is currently unclear whether viral infection aggravates cholestasis in patients with the cholestatic disease. Further in-depth research should focus on persistent liver damage and active viral replication in HBV patients after co-infection with SARS-CoV-2. Recent studies have demonstrated the possible impact of SARS-CoV-2 infection on NAFLD. It has been shown that SARS-CoV-2 infection increases the possibility of NAFLD progressing to nonalcoholic hepatitis. ACE inhibitors are commonly used in the anti-inflammatory and anti-obesity treatment of NAFLD. Although there have been no reports on the correlation between the use of ACE inhibitors and mortality, one study has shown that ACE inhibitors upregulate expression of ACE2 receptor, thereby increasing the viral entry in patients taking such drugs[78].

How the underlying liver diseases affect liver function in patients with COVID-19 remains elusive. Whatever mechanisms are involved in liver damage, we need to be more cautious in managing COVID-19 patients with underlying liver diseases. For example, the British Liver Foundation recommends that patients taking steroids or immunosuppressive drugs maintain strict social distance[79]. The European Association for Liver Research and the European Association for Clinical Microbiology

and Infectious Diseases recommend priority outpatient visits, prehospital assessment of risk factors, reduction of exposure through modification of waiting areas, reduction of waiting times, and use of online system to order medication.

CONCLUSION

Although liver dysfunction is common in patients with COVID-19, the detailed mechanisms remain incompletely understood. Available evidence suggests that the severity of liver damage is partly due to direct infection by SARS-CoV-2 to the liver and partly due to the cytokine storm produced by an overactive immune response. In addition, multiple risk factors, such as drug toxicity and liver congestion, need to be taken into account. For COVID-19 patients with underlying liver diseases, the causes of liver damage are more complex and more personalized management should be considered. Future directions should focus on deciphering the virus–host interactions to better understand the detailed molecular mechanisms of the liver impairment following SARS-CoV-2 infection. In the meantime, rapid development of effective preventive vaccines and specific antiviral drugs is critical to control this ongoing pandemic.

Abstract

Pancreatic ductal adenocarcinoma is an aggressive tumor with poor long-term outcomes. Chronic pancreatitis (CP) is considered a risk factor for the development of pancreatic cancer (PC). Persistent pancreatic inflammation and activation of pancreatic stellate cells play a crucial role in the pathogenesis of CP-related PC by activating the oncogene pathway. While genetic mutations increase the possibility of recurrent and persistent pancreatic inflammation, they are not directly associated with the development of PC. Recent studies suggest that early surgical intervention for CP might have a protective role in the development of CP-related PC. Hence, the physician faces the clinical question of whether early surgical intervention should be recommended in patients with CP to prevent the development of PC. However, the varying relative risk of PC in different subsets of CP underlines the complex gene-environment interactions in the disease pathogenesis. Hence, it is essential to stratify the risk of PC in each individual patient. This review focuses on the complex relationship between CP and PC and the impact of surgical intervention on PC risk. The proposed risk stratification based on the genetic and environmental factors could guide future research and select patients for prophylactic surgery.

Core Tip: Chronic pancreatitis (CP) is a significant risk factor for pancreatic cancer (PC). However, the relative risk is not as high as previously reported. Persistent pancreatic inflammation plays an important role in pancreatic carcinogenesis, and genetic mutations implicated in the pathogenesis of CP are not directly involved in the development of PC. Although surgery for CP reduces the risk of PC, the evidence is not strong enough to recommend routine prophylactic surgery in CP patients. The risk stratification proposed in this review considers the genetic and environmental factors that could guide future prospective studies and select patients for prophylactic surgery.

INTRODUCTION

Chronic pancreatitis (CP) is a complex fibro-inflammatory disease of the pancreas characterized by destruction and fibrotic replacement of the pancreatic parenchyma [1]. Pain is the dominant symptom of CP, followed by clinical manifestations of exocrine and endocrine dysfunction[2]. Surgery and endoscopic interventions are primarily indicated in symptomatic CP patients to provide pain relief and may prevent disease progression if done early in the disease course[3,4]. Pancreatic ductal adenocarcinoma, the most common type of pancreatic cancer (PC), is an aggressive tumor with a dismal prognosis[5]. Epidemiological studies have identified CP as a risk factor for PC[6-8]. Recurrent or persistent pancreatic inflammation in the setting of CP has been implicated in pancreatic carcinogenesis[9,10]. Recent studies have shown that surgery for CP reduces the risk of PC[11,12]. This evidence raises the question of whether early surgical intervention should be considered in patients with CP to prevent the development of PC. The proposed mechanistic definition for CP highlights the complex gene-gene and gene-environmental interactions in the disease pathophysiology[13]. As not all patients with CP develop PC, and a high proportion of patients with PC do not have a history of CP, this review focuses on the complex relationship between CP and PC and the impact of surgical intervention on the risk of PC.

SEARCH STRATEGY

A PubMed search of relevant articles was performed by three authors The reference lists of the articles also were searched for additional appropriate studies. The keywords and combinations included in the search were: "pancreatitis"; "chronic pancreatitis"; "hereditary pancreatitis"; "pancreatic cancer" and "chronic pancreatitis"; "pancreatic cancer" and "hereditary pancreatitis"; "pancreatitis" and "pancreatic cancer"; "genetics" and "pancreatic cancer"; "pancreatic ductal adenocarcinoma" and "pancreatitis"; "genetics" and "chronic pancreatitis" and "pancreatic cancer"; "surgery" and "chronic pancreatitis" and "pancreatic cancer". The search was limited to publications in English and stressed the latest evidence. All the authors agreed that the articles selected for review were relevant.

CP AND PC

Incidence of PC in CP

It is essential to understand the incidence of PC in CP patients to determine the impact of surgery for CP on the risk of PC. In the 19th century, Rudolph Virchow observed white blood cells within tumor tissue and suggested a relationship between inflammatory pathology and cancer[14]. Well known associations that support the hypothesis of inflammation-induced metaplasia and carcinogenesis include inflam-

matory bowel disease and colorectal cancer, gallstones and gallbladder cancer, Barrett's esophagus, and esophageal cancer[15]. The earliest report of an association between CP and PC dates to the 1950s, when an autopsy study identified CP changes in 49% of 100 patients who died of PC[16]. Since then, multiple studies have documented an increased risk of PC in CP patients[17-19]. Raimondi *et al*[6], in a meta-analysis of 22 case-control and cohort studies, reported a relative risk (95%CI) of 13.3 (6.1-28.9), which means that CP patients had 13.3 times more risk of developing PC compared with the general population. However, the included studies did not consider the lag period, *i.e.* the interval between CP and PC diagnosis. To be labeled as CP-related PC, it is recommended to exclude PC cases diagnosed within 2 years of CP diagnosis to avoid potential misclassification. After considering the lag period, the relative risk of CP-related PC dropped to 11.8 with a 1-year lag period and to 5.8 with a 2-year lag period (Table 1). Tong *et al*[7] in a meta-analysis of 17 studies with acute, chronic, and unspecified pancreatitis, reported that CP patients had a 10.3-fold risk of developing PC compared with the general population. When the association between CP and PC was stratified by time, they reported risk estimates (95%CI) of 23.3 (14.0-38.9), 3.03 (2.41-3.81), 2.82 (2.12-3.76), and 2.25 (1.59-3.19) for lag periods of less than 1, 2, 5, and 10 years, respectively. While the estimated risk was less than reported in the previous meta-analysis, the inclusion of acute and unspecified pancreatitis along with CP might have underestimated the association between CP and PC, as acute pancreatitis is less likely to progress to PC compared with CP. Kirkegård *et al*[8], in a recent meta-analysis of 13 CP studies, estimated 8-fold and 3.5-fold increased risks of PC at 5- and 9-year lag periods, respectively, from CP diagnosis to PC diagnosis (Table 1). The meta-analyses suggest that patients with CP are at increased risk of developing PC compared with the general population. However, the estimated risk was much lower than that reported in some individual studies, especially when a 2-year lag period was included. While the increased duration of CP-related inflammation is expected to increase PC risk, the decrease in PC risk between the 2- and 5-year lag periods in the meta-analyses suggests initial misclassification of PC as CP in some of the included studies. Also, most studies did not evaluate the impact of confounding risk factors like smoking or alcohol intake on the risk estimate of CP-related PC.

Risk factors for the development of PC in CP patients

The current evidence suggests that the incidence of PC in CP patients is variable (2.7- to 13.3-fold increased risk) and influenced by multiple factors[20,21]. Hence, identifying demographic and clinical risk factors for PC in CP patients will help to determine the subgroup of CP patients who might benefit from surgical intervention. A retrospective analysis of 1415 patients from an Indian center reported that a smoking and nonalcoholic CP etiology was a risk factor for developing PC[22] (Table 2). Among the nonalcoholic CP etiologies, idiopathic senile chronic pancreatitis (ISCP), defined as an age of onset of CP of more than 35 years, had a greater risk of PC than idiopathic juvenile CP (5% *vs* 0.2% at 10 years of follow-up). An inverse association between exocrine insufficiency and malignancy risk indicated that steatorrhea and malignant transformation occurred independently. A retrospective analysis of 2037 CP cases in a patient database in China did not find a significant difference in PC risk between alcoholic and idiopathic pancreatitis[23]. However, the analysis did not include a separate risk analysis of patients with IJSP and ISCP. A single-center European study by Müllhaupt *et al*[24] prospectively evaluated the risk of PC in 332 CP patients. The risk of PC was greater in idiopathic juvenile chronic pancreatitis (IJCP) compared with other CP etiological subtypes. The authors concluded that early onset and prolonged disease was a significant risk factor for CP-related PC. In another European study from Sweden, Vujasinovic *et al*[25] evaluated the risk of PC in a retrospective analysis of prospectively collected pancreatic clinical data. In contrast to other studies, they subclassified the CP patients into eight subgroups and calculated the PC risk. Among CP patients, those with diabetes mellitus and a high body mass index (BMI) at diagnosis or patients with a low BMI and pancreatic exocrine insufficiency at diagnosis were identified as groups at risk of developing CP-related cancer. However, relatively few patients (6/581) developed PC 2 years after the CP diagnosis. Studies conducted in different regions of the globe highlight differences in the demographic and clinical risk factors for PC in different CP populations. To evaluate the reason for the diverse predictive factors, the pathogenesis of CP and pathways for PC in those patients have to be well understood.

Inflammatory and oncogene pathways of PC in CP patients

An accepted explanation of the pathogenesis of CP involves a sentinel acute pancreatitis event that initiates an inflammatory cascade in a susceptible individual[26,27]

Table 1 Systematic reviews and meta-analyses evaluating the association between chronic pancreatitis and pancreatic cancer

Ref.	Number of studies	Number of patients	Risk estimate	Remarks
Raimondi *et al*[6]	22 (12 case-control, 10 cohort)	16124	RR, 11.8 (95%CI: for 1-yr lag period; RR, 5.8 (95%CI: 2.1-15.9) for 2-yr lag period; RR, 69.0 (95%CI: 56.4-84.4) for hereditary pancreatitis; RR, 100 (95%CI: 37.0-218.0) for tropical pancreatitis	Details of seven studies included for risk estimate calculation not mentioned; Details of number of patients with pancreatic cancer in included studies not mentioned; High relative risk reported for tropical pancreatitis based on a single study
Tong *et al*[7]	17 (14 case-control, 3 cohort)	14667 pancreatic cancer, 17587 pancreatitis	Pooled OR, 10.35 (95%CI: 9.13-11.75) for chronic pancreatitis; Pooled OR, 6.41 (95%CI: 4.93-8.34) for unspecified type of pancreatitis -	Inclusion of studies with both acute and chronic pancreatitis limits generalizability; Inclusion of acute, chronic and unspecified pancreatitis to calculate the temporality of the association might underestimate the relative risk
Kirkegård *et al*[8]	13 (4 case-control, 9 cohort)	674 pancreatic cancer, 25,329 chronic pancreatitis	EE, 16.16 (95%CI:12.59-20.73) for 2-yr lag period; EE, 7.90 (95%CI: 4.26-14.66) for 5-yr lag period; EE, 3.53 (95%CI: 1.69-7.38) for 9-yr lag period	Some of the included studies had a smaller number of patients with pancreatic cancer or chronic pancreatitis which might inflate the estimated risk; In some of the included studies more than one-third of patients were lost to follow-up

CI: Confidence interval; EE: Effect estimate; OR: Odds ratio; RR: Relative risk.

Table 2 Risk factors for pancreatic cancer in chronic pancreatitis

Ref.	Number of patients	Etiological subtype, *n* (%)	Pancreatic cancer risk	Specific risk group
Agarwal *et al*[22]	1415	ACP, 540 (38.1); IJCP, 668 (47.2); ISCP, 207 (14.6)	5-yr risk of pancreatic cancer: ACP, 0.5%; IJCP, 0.2%; ISCP, 3.7%. 10-yr risk of pancreatic cancer: ACP, 0.9%; IJCP, 0.2%; ISCP, 5.2%	Age of onset > 35 yr (HR 12.1; CI: 4.7-31.2; $P < 0.001$). Smoking (HR 6.48; CI: 2.2-19.0; $P < 0.001$). Nonalcoholic etiology (HR for alcohol use 0.14; CI: 0.04-0.42; $P < 0.001$); Absence of steatorrhea (HR for steatorrhea 0.19; 95%CI: 0.04-0.80; $P < 0.023$)
Hao *et al*[23]	2037	ACP, 404 (19.8); ICP, 1633 (80.2)	5-yr risk of pancreatic cancer: ACP, 0.2%; ICP, 0.7%. 10-yr risk of pancreatic cancer: ACP, 0.9%; ICP, 1.1%	No significant difference in pancreatic cancer development between ACP and ICP patients
Vujasinovic *et al*[25]	581	Idiopathic, 47 (8.1); Alcohol and nicotine, 220 (37.9); Nicotine, 81 (13.9); Alcohol, 49 (8.4); Hereditary, 38 (6.5) Immunological, 59 (10.2) Efferent duct 62 (10.7) Miscellaneous/other, 25 (4.3)	Rate per 100 yr; Idiopathic, 0.00; Alcohol and nicotine, 0.07; Nicotine, 0.44; Alcohol, 0.32; Hereditary, 0.00; Immunological, 0.00; Efferent duct, 0.28; Miscellaneous/other, 0.81	Low BMI and pancreatic exocrine insufficiency. Patients with diabetes mellitus and high BMI
Müllhaupt *et al*[24]	332	ACP, 265; IJCP, 21; ISCP, 46	ACP, 1.5% over 16 yr; IJCP, 4.8% over 22 yr; ISCP, 2.2% over 14 yr	Early onset and prolonged duration of CP (rather than the specific type of CP)

ACP: Alcoholic pancreatitis; BMI: Body mass index; ICP: Idiopathic chronic pancreatitis; IJCP: Idiopathic juvenile chronic pancreatitis; ISCP: Idiopathic senile chronic pancreatitis.

(Figure 1). Of the various predisposing factors, smoking and alcohol intake are the important modifiable risk factors relevant to pancreatic carcinogenesis in a genetically susceptible individual. The genes implicated in the pathogenesis of pancreatitis are protease serine 1 (*PRSS1*), serine peptidase inhibitor Kazal type 1 (*SPINK 1*), Cystic fibrosis transmembrane conductance regulator (*CFTR*), chymotrypsin C (*CTRC*) and calcium-sensing receptor (*CASC*)[28-30]. Recently mutations in the genes encoding carboxypeptidase A1 (CPA1), carboxyl ester lipase, and tight-junction protein claudin-2 (CLDN2) have also been postulated to initiate pancreatitis[29]. Gain-of-function mutations in the *PRSS1* gene, which encodes cationic trypsinogen, facilitate intrapancreatic trypsin activation[31]. Mutation of the *SPINK 1* gene that codes for trypsin inhibitor, together with CTRC and CASC mutations, promotes abnormal trypsin activation[32]. While PRSS1, SPINK1, CTRC and CASC initiate pancreatitis through a trypsin-dependent pathway, CFTR mutation affects the anion channel for chloride and bicarbonate[30]. Disturbed alkalinization of the pancreatic juice results in injury to the duct epithelium followed by protein plug and pancreatic stone formation[29,33]. In addition to the initiation of pancreatic inflammation, these genetic factors play an

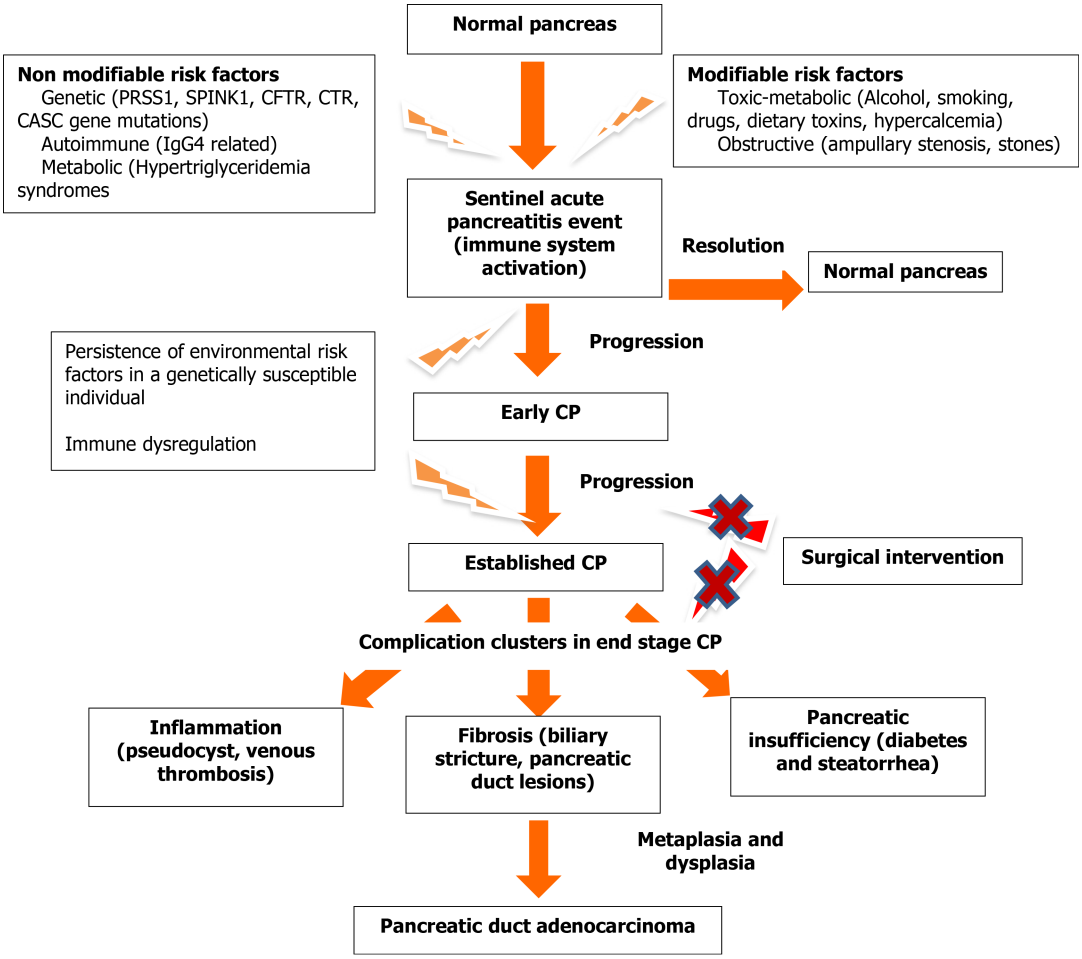

Figure 1 Pathogenesis of chronic pancreatitis and chronic pancreatitis-related pancreatic cancer. *CASC*: Calcium-sensing receptor gene; *CFTR*: Cystic fibrosis transmembrane conductance regulator gene; CP: Chronic pancreatitis; *CTR*: Chymotrypsin C gene; *PRSS1*: Protease serine 1 gene; *SPINK 1*: Serine peptidase inhibitor Kazal type 1 gene.

important role in the progression of acute inflammation to CP[30]. Recent studies have shown that the clinical manifestations of CP can be grouped into three complication clusters[34]. One group of patients has dominant inflammatory complications like pseudocyst, pancreatic ascites, and vascular (splenic or portal vein) thrombosis. The second group has predominant pancreatic exocrine (steatorrhea) and endocrine (diabetes) insufficiency. The third group has fibrotic complications characterized by biliary stricture, duodenal stenosis, and pancreatic duct lesions. Individual patients can have more than one complication cluster, but most have a single dominant complication cluster. As patients with predominant fibrotic complications are at increased risk of PC, understanding the inflammatory and gene pathways can help in the risk stratification of individual patients[22,34].

It is well known that PC tissue includes malignant duct cells surrounded by stroma that accounts for more than 90% of the tumor mass[35]. The histology of CP tissue includes fibrotic destruction of the pancreatic parenchyma, infiltration of inflammatory cells, and ductal and exocrine atrophy[2]. As pancreatic stellate cells are the principal source of fibrosis, their activation has been implicated in the pathogenesis of CP and CP-related PC[36-38] (Figure 2). Activation of the immune system following injury of the pancreatic duct and acini results in the release of multiple proinflammatory cytokines including tumor necrosis factor (TNF)-α and interleukin (IL)-1, IL-6, and IL-8, growth factors, chemokines including monocyte chemoattractant protein (MCP)-1, macrophage inflammatory protein (MIP)-1, adhesion molecules, reactive oxygen and reactive nitrogen species that activate pancreatic stellate cells and induce proliferation[39,40]. Transforming growth factor (TGF) β1 and fibroblast growth factor produced by pancreatic stellate cells stimulate extracellular matrix synthesis and cyclooxygenase-2 mediates extracellular matrix proliferation[36-38]. The benign process of inflammation-related proliferation and fibrosis can turn malignant in the background of uncontrolled inflammation. This is supported by the observation that

mutation of the *K-Ras* proto-oncogene stimulates tumor development only in the presence of inflammatory milieu; inflammatory mediators are required for its activation[41-44]. Approximately 30% of CP patients with CP have K-Ras mutations [44]. K-Ras mutation itself is not sufficient, the pathological activity necessary for PC development is achieved only in the presence of persistent inflammation[41]. Additionally, activation of the Notch signaling pathway and the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) transcription factor promotes carcinogenesis against an inflammatory background[45]. The current understanding of the inflammatory and oncogene pathways of PC in CP patients is that CP significantly increases the risk of PC (relative risk > 2) compared with other risk factors, and that inflammation plays a crucial role in carcinogenesis[20].

Genetic mutations responsible for hereditary pancreatitis are not directly associated with the development of PC. However, genetic susceptibility increases the possibility of recurrent and persistent inflammation, especially in the presence of environmental risk factors like smoking and alcohol intake, thereby increasing the risk of PC[46]. Among the genetic causes of pancreatitis, *PRSS1* mutation carries the maximum risk for PC followed by other mutations. The difference in risk primarily results from the ability to initiate and sustain an inflammatory cascade with or without other environmental factors[47]. Differences in the risk of PC in IJCP in Indian and European studies are caused by differences in the underlying genetic mutations. IJCP is predominantly associated with CFTR and SPINK 1 mutations in the Indian population and with PRSS1 mutation in European populations[48].

Prospective cohort studies of patients with hereditary pancreatitis have reported that avoidance of smoking and alcohol intake, ensuring a smoke-free environment in the home and workplace, maintaining normal BMI, and eating a healthy diet reduces the cumulative risk of PC[20,50]. The success of cancer preventive measures suggests that medical, endoscopic, and surgical interventions to minimize ongoing pancreatic inflammation can reduce the risk of PC. Alcohol consumption increases the risk of pancreatitis and smoking increases the risk of fibrotic complications in CP and related PC. Experimental studies have shown that aryl hydrocarbon receptor ligands in cigarette smoke induce production of interleukin-22 and pancreatic fibrosis. Hence, lifestyle modifications like smoking cessation can minimize the risk of PC[51]. Risk stratification of CP patients is proposed based on the current understanding of the inflammatory and oncogene pathways of CP-induced PC (Figure 3). The proposed risk stratification underlines the need for genetic testing in most patients with CP, as the

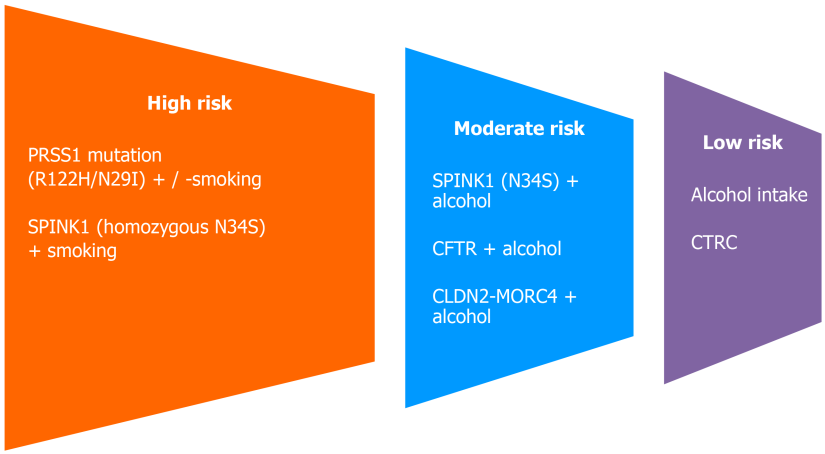

Figure 3 Proposed risk stratification of chronic pancreatitis patients. CFTR: Cystic fibrosis transmembrane conductance regulator; CLDN2: Tight-junction protein claudin-2; CTRC: Chymotrypsin C; PRSS 1: Protease serine 1; SPINK 1: Serine peptidase inhibitor Kazal type 1.

combination of genetic and environmental factors determines the risk of PC.

DOES SURGERY FOR CP REDUCE THE RISK OF PC?

Although CP is considered a risk factor for PC, the impact of surgery for CP on the risk of PC has not been well studied. To investigate the relationship between surgery for CP and PC, Ueda *et al*[12] performed a multicenter retrospective analysis of 893 CP patients at 22 institutions who fulfilled the 2001 Japan Pancreas Society diagnostic criteria for CP. They excluded 387 patients with less than 2 years of follow-up or a lag period of less than 2 years between CP diagnosis and PC. Of the 506 patients included in the study, 19 (3.7%) developed PC (Table 3). The standardized incidence ratio (SIR), defined as the ratio of observed to expected PC cases, was 11.8 (95%CI, 7.1-18.4). The cumulative incidence (95%CI) of PC was 2.0% (1.0-4.1) at 5; 4.6% (2.6-8.2) at 10; 7.5% (4.3-12.9) at 15; 10.7% (4.3-18.4) at 20, and 14.0% (7.5%-25.3%) at 25 years after the CP diagnosis. At a median follow-up of more than 5 years, the PC incidence was significantly lower in patients who had undergone surgery (1/147, 0.7%0) than in those who did not undergo surgical intervention (18/352, 5.1%) for CP (P = 0.03]. Based on the results, the authors concluded that surgery for CP decreased the risk of PC[12].

Zheng *et al*[11] performed a retrospective analysis of 650 surgically managed CP patients to determine the incidence and risk factors for PC after surgery for CP. At a median follow-up of 4.4 years, 12 patients (1.8%) developed PC (Table 3). The SIR (95%CI) for PC in CP patients was 68.12 (35.20-118.99). The cumulative incidence (95%CI) of PC was 1.48% (0.46-2.51) at 3; 2.63% (0.93-4.32) at 6; and 3.71% (1.05-6.37%) at 9 years after CP surgery. The time interval to surgery, defined as the lag time between the initial CP diagnosis and operative intervention, was significantly longer in CP patients who developed PC (96.6 ± 164.4 mo *vs* 36.4 ± 74.2 mo, P = 0.016), with a hazard ratio (95%CI) of 1.005 (1.002-1.008, P = 0.002). Based on the results, the authors concluded that early surgical intervention for CP prevented the development of CP-related PC[11].

The proposed mechanisms by which surgery for CP reduces PC incidence are relief of pancreatic compartment syndrome and inflammation by resection of fibrotic parenchyma and surgical drainage[11]. As mentioned earlier, parenchymal fibrosis plays an essential role in pancreatic carcinogenesis, and its removal reduces the volume of pancreatic tissue at risk of malignancy. This hypothesis is supported by studies in which none of the patients who underwent pancreatoduodenectomy for CP developed PC during the follow-up period[11,12]. As persistent uncontrolled inflammation is a significant risk factor for developing PC, relief of ductal obstruction and pancreatic compartment syndrome attenuates pancreatic inflammation.

Table 3 Studies evaluating the impact of surgery for chronic pancreatitis on the risk of pancreatic cancer

Ref.	Number of patients	Etiological subtype, *n* (%)	Type of surgery, *n* (%)	Pancreatic cancer risk
Ueda *et al*[12]	506	Alcoholic pancreatitis, 345 (68.0); Idiopathic pancreatitis, 109 (22.0); Autoimmune pancreatitis, 16 (3); Hereditary pancreatitis, 9 (2); Miscellaneous, 27 (5)	Drainage operation, 60 (40.8); Pancreatic resection, 87 (59.2)	Surgery, 1/147 (0.7%); No surgery, 18/352 (5.1%)
Zheng *et al*[11]	650	Alcoholic pancreatitis, 361 (55.5); Idiopathic pancreatitis, 227 (34.9); Hereditary pancreatitis, 62 (9.5)	Drainage operation, 189 (29.1); Pancreatic resection, 461 (70.9)	Surgery, 12/650 (1.8%); Time interval to surgery, HR, 1.005 (95%CI: 1.002-1.008); *De novo* endocrine insufficiency, HR, 10.672 (95%CI: 2.567-44.372)

IS PC RISK REDUCTION AN INDICATION FOR SURGERY IN CP PATIENTS?

The standard indications for surgery in CP are intractable pain, suspicion of malignancy, and local pancreatic or extrapancreatic complications, such as biliary stricture, duodenal stenosis, pseudocysts, and vascular complications (*e.g.*, splenic/portal vein thrombosis and arterial pseudoaneurysms)[2,4], and intractable pain is the most common indication. Traditionally, patients are managed by a step-up approach that begins with medical management (analgesics) followed by endoscopic intervention[52,53]. Surgery is generally considered as the last option after multiple endoscopic interventions fail to provide adequate symptomatic relief. However, based on the findings of numerous observational studies and a recent randomized controlled trial, international consensus guidelines for surgery and the timing of intervention in CP recommend early surgery[4]. Early surgery, *i.e.* performed within 3 years of the onset of CP symptoms, is associated with better pain relief and preservation of pancreatic function[3,54]. Considering recent evidence for early surgery in CP and its potential protective role in the development of PC, the clinician faces the question of prophylactic surgery in CP patients. Prophylactic surgery for CP is performed with the primary aim of reducing the risk of PC in the absence of typical surgical indications like pain and local complications. The dilemma is significant in light of the current availability of digitized clinical information for patients and increased litigation. Is the clinician is ethically right or legally justified in not offering a treatment that can prevent a deadly complication of CP? To answer that question, a critical analysis of the current evidence is essential. Many studies have evaluated the risk of PC, but only a few have investigated the protective effect of surgery for CP on reducing the risk of PC [11,12]. Limitations of previous studies are the inclusion of small numbers of patients and retrospective analysis, which make the accuracy and completeness of the study data difficult to control. Confounding risk factors like smoking and alcohol intake were not accurately quantified in most studies, and the proportion of patients who underwent resection procedures was relatively high, in at least in one of the studies, which contrasts with the drainage procedures commonly performed worldwide for CP patients[55]. Another limitation is the lack of objective evidence to document whether pancreatic inflammation was reduced after surgery. As persistent pancreatic inflammation is considered a significant risk factor for pancreatic carcinogenesis, a reliable biomarker to monitor the presence or absence of persistent pancreatic inflammation after surgery could help us better understand the role of surgery in reducing the risk of PC. Hence, to confirm the protective role of surgical procedures for CP, additional prospective studies involving large populations are required. While the risk of PC is increased in patients with CP, it is still too low to recommend routine active screening or prophylactic surgery in all patients[20]. With the available evidence, routine surveillance and prophylactic surgery are recommended only in subgroups of hereditary pancreatitis with a high risk of PC. In contrast to environmental risk factors, genetic factors are not modifiable. Hence, prophylactic surgery will have a greater role in this group of patients. Until we have more evidence, surgery for CP is currently recommended for only the described standard indications.

FUTURE DIRECTIONS: PRECISION MEDICINE IN CP

The mechanistic definition of CP is a "pathologic fibroinflammatory syndrome of the pancreas in individuals with genetic, environmental and/or other risk factors who

develop persistent pathologic responses to parenchymal injury or stress"[13]. The current definition highlights the disease heterogeneity in terms of individual susceptibility, disease onset, modifying factors, rate of progression, and long-term outcomes. Detailed evaluation of an individual patient often identifies a genetic factor that predisposes to pancreatitis in the presence of environmental risk factors[29,30]. The complex interaction of genetic and environmental factors determines the clinical phenotype and risk of PC. Hence, the concept of precision medicine used in various complex benign and malignant gastrointestinal disorders should be employed in CP patients. Molecular pathways leading to CP-related PC should be better defined so that complication clusters in an individual patient and the role of interventions in mitigating the cancer risk can be well studied.

Advances in instrumentation and technology allow increasing use of endoscopic interventions in CP patients. However, long-term studies focusing on the risk of PC in patients undergoing endoscopic intervention are lacking. As previously mentioned, reliable markers for pancreatic inflammation would help to evaluate the success of endoscopic and surgical treatment in individual patients. Hence future prospective studies evaluating the role of surgical and endoscopic intervention in reducing PC should include accurate risk stratification of the study patients and preferably incorporate biomarkers of pancreatic inflammation.

CONCLUSION

CP is a significant risk factor for PC. However, the relative risk is as not high as previously reported. Persistent pancreatic inflammation plays a key role in pancreatic carcinogenesis, and genetic mutations implicated in the pathogenesis of CP are not directly involved in the development of PC. Activation of pancreatic stellate cells and enhanced K-Ras oncogene activity in the inflammatory milieu play a key role in the pathogenesis of CP-related PC. Although surgery for CP reduces the risk of PC, the evidence is not strong enough to recommend routine prophylactic surgery in CP patients. The proposed risk stratification considers the genetic and environmental factors that could guide future prospective studies and select patients for prophylactic surgery.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is an aggressive malignancy that is best treated in a multidisciplinary fashion using surgery, chemotherapy, and radiation. Adjuvant chemotherapy has shown to have a significant survival benefit in patients with resected PDAC. However, up to 50% of patients fail to receive adjuvant chemotherapy due to postoperative complications, poor patient performance status or early disease progression. In order to ensure the delivery of chemotherapy, an alternative strategy is to administer systemic treatment prior to surgery. Precision oncology refers to the application of diverse strategies to target therapies specific to characteristics of a patient's cancer. While traditionally emphasized in selecting targeted therapies based on molecular, genetic, and radiographic biomarkers for patients with metastatic disease, the neoadjuvant setting is a prime opportunity to utilize personalized approaches. In this article, we describe the current evidence for the use of neoadjuvant therapy (NT) and highlight unique opportunities for personalized care in patients with PDAC undergoing NT.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the leading causes of cancer-related deaths worldwide with a 5-year overall survival (OS) rate of only 10%[1]. Despite surgical resection being the only hope for cure, only a small proportion of patients present with resectable disease and the majority of patients will develop locoregional or metastatic recurrence after surgery[2,3]. Adjuvant chemotherapy has shown to have a significant survival benefit in patients with resected PDAC[3]. However, up to 50% of patients fail to receive adjuvant chemotherapy due to postoperative complications, poor patient performance status or early disease progression[4-6].

In order to ensure the delivery of chemotherapy, an alternative strategy is to administer systemic treatment prior to surgery. Neoadjuvant therapy (NT) has been shown to confer several clinical benefits such as improved margin-negative resection rates, decreased lymph node positivity, early treatment of presumed micro-metastatic disease, an optimal window of time to provide prehabilitation before surgery, and the ability to measure *in vivo* response to therapy histologically after resection[7-9]. Moreover, increasing evidence from randomized controlled trials (RCT) suggests NT may improve OS in patients with non-metastatic PDAC compared with upfront resection[10,11]. Despite the advantages of NT, its use in the United States has remained relatively low[12,13]. While NT is now the recommended treatment strategy for borderline resectable (BR) or locally advanced cancer, current NCCN guidelines support either upfront surgical resection or NT for patients with resectable disease[14].

There is growing interest in emphasizing personalized approaches to multidisciplinary cancer care that reflects not only unique differences in cancer biology but also individual circumstances and treatment goals. Precision oncology refers to the application of diverse strategies to target therapies specific to characteristics of a patient's cancer. While traditionally emphasized in selecting targeted therapies based on molecular, genetic, and radiographic biomarkers for patients with metastatic disease, the neoadjuvant setting is a prime opportunity to utilize personalized approaches. In this article, we describe the current evidence for the use of NT and highlight unique opportunities for personalized care in patients with PDAC undergoing NT.

RATIONALE FOR NT

Large cohort and population-based studies have shown that as many as 50% of patients who undergo surgical resection for PDAC are unable to receive adjuvant therapy due to postoperative complications, poor performance status, or early disease progression[4-6,15,16]. Even among healthy patients enrolled in clinical trials, a substantial proportion of patients are unable to initiate adjuvant therapy due to the morbidity of pancreatic surgery[4]. An even greater proportion of patients fail to complete all intended cycles of adjuvant therapy[5]. Thus, the ability to ensure receipt of systemic therapy and facilitate multimodality therapy is one of the strongest reasons to recommend NT. Other advantages that support the use of NT include the early treatment of presumed micrometastatic disease, the ability to potentially downstage BR disease improving the chances of R0 resection, and improved patient selection by

avoiding surgery in those patients with rapid disease progression during preoperative treatment. Additionally, well-oxygenated, non-devascularized tissue is more susceptible to the effects of chemoradiation, which theoretically increases the efficacy of chemoradiation if given prior to surgery[17,18].

These advantages must be carefully weighed against the potential disadvantages of pursuing NT. First, unlike in a surgery-first approach, tissue diagnosis and biliary decompression are uniformly required. These procedures may delay the initiation of treatment and are associated with small, but non-zero, risks. Second, NT is inherently multi-disciplinary and require careful coordination among providers. Third, and most importantly, delivering aggressive chemotherapy and/or radiation prior to surgery can lead to severe toxicity that, in extreme cases, can preclude subsequent surgical resection. Indeed, a systematic review by the Dutch Pancreatic Cancer Group calculated a Grade III or higher toxicity rate of 64% among patients undergoing NT [19]. The recent SWOG S1505 trial of NT for resectable PDAC found that nearly 13% that started NT were unable to undergo surgery because of performance status decline [20]. Finally, while distant progression while on NT is far more common, a small risk of local progression that leads to unresectability exists. These challenges highlight the importance not only of personalizing treatment decisions regarding NT, but also of emphasizing research that improves the delivery of NT for patients with localized PDAC.

CURRENT EVIDENCE FOR NT

Support for the use of NT for localized PDAC has largely come from small prospective trials, single-institutional series, and cancer registries[21]. These studies largely demonstrated its feasibility and proposed NT as an acceptable approach for PDAC. Suggestions of improved outcomes compared to upfront surgery have been limited by study design. However, the completion of several RCT in recent years comparing NT to upfront surgery have generated increased support for NT. For example, two RCTs found improved margin-negative resection rates and OS among patients with BR PDAC[22] who received neoadjuvant CRT compared to immediate surgery. Furthermore, the PACT-15 and Prep-02/JSAP-05 RCTs found improved OS among patients with resectable PDAC treated with neoadjuvant chemotherapy compared to those who underwent immediate surgery[16,23].

In a recent meta-analysis of only prospective RCTs, Cloyd *et al*[13] showed that the OS of patients with resectable or BR PDAC who received NT was nearly 30% better than that of patients who underwent surgery upfront using an intention-to-treat design. Furthermore, the meta-analysis found that NT improved R0 resection rate and decreased lymph node positivity rate. Since then, preliminary results from the ESPAC-5 trial, a four-arm RCT comparing patients undergoing surgery upfront, neoadjuvant gemcitabine/capecitabine (GEMCAP), neoadjuvant FOLFIRINOX, and neoadjuvant capecitabine-based radiation, showed improved one-year OS among patients receiving NT[24]. As a limitation of previous RCTs is the use of non-traditional neoadjuvant regimens (*e.g.*, folfirinox or gemcitabine-abraxane), the long-term results of this trial and other contemporary studies comparing NT to immediate surgery are anxiously awaited.

OPPORTUNITIES FOR PERSONALIZED CANCER CARE

Several factors make the neoadjuvant period an optimal scenario to emphasize precision oncology (Table 1). First, PDAC is anatomically and genetically heterogeneous as is the clinical presentation of patients with localized disease. Second, patient and tumor response to NT differs significantly. Evaluating and responding to this dynamic staging offers an opportunity to personalize subsequent treatment.

Anatomic staging

Using high-quality cross-sectional imaging, localized PDAC is classified as resectable, BR or locally advanced (LA; also termed unresectable) according to its relationship with major vascular structures. While several organizations have published staging criteria with only slight differences, the SSO/SSAT/AHPBA consensus definitions are commonly employed. As these criteria reflect the likelihood of achieving a margin-negative resection with upfront surgery, the development of a uniform anatomic

Table 1 Opportunities for personalized care during neoadjuvant therapy for pancreatic cancer

Concept	Description	Examples	Outcome
Anatomic staging	Characterization of local extent and vascular involvement of tumor	Locally advanced/unresectable; Borderline resectable; Potentially resectable	Anatomic staging can influence the recommended duration and components (*e.g.*, preoperative radiation) of neoadjuvant therapy
Molecular staging	Identification of tumor/germline genetic and molecular markers	*BRCA* mutations; Mismatch repair-deficiency; Molecular markers	Specific tumor/germline mutations may identify opportunity for targeted therapies (*e.g.*, immunotherapy, PARP inhibitors) Standard chemotherapy may be influenced by molecular markers (*e.g.*, resistance/sensitivity to traditional flouropyridamine or gemcitabine-based therapy)
Dynamic staging	Measuring biochemical, radiographic, and histologic response of the tumor to neoadjuvant therapy	Carbohydrate antigen 19-9; Response evaluation criteria in solid tumors response; Pathologic response	Measuring response to neoadjuvant therapy can influence treatment strategies (*e.g.*, changing neoadjuvant regimen, use of radiation, recommendations for adjuvant therapy)

staging system has been pivotal for improved clinical protocol standardization specifically concerning the use of NT[25] (Table 2).

LA PDAC truly represents unresectable disease, typically because of arterial encasement or non-reconstructable venous involvement. Still, recent studies have found that a small but significant proportion of patients can be converted to resectable disease after aggressive NT[26]. For example, a large retrospective study by Hackert *et al*[27] showed that 61% of patients with LA PADC receiving FOLFIRINOX as NT underwent successful surgical resection with a 40.8% R0 resection rate. Another study by Gemenetzis *et al*[28] showed that FOLFIRINOX-based therapy and stereotactic body radiation therapy correlated with increased probability of resection ($P = 0.006$); patients who eventually underwent surgical resection had higher median OS compared with those who did not (35.3 mo *vs* 16.3 mo; $P < 0.0001$). Given the vascular involvement and low likelihood of achieving negative microscopic margins, preoperative radiation therapy is commonly employed after induction systemic chemotherapy prior to attempts at surgical resection. This approach is logical since consolidative radiation is frequently administered for patients with LA disease who are not surgical candidates to enhance locoregional control[29].

A similar approach should be considered for patients with BR PDAC yet with higher likelihood of undergoing surgical resection. Current practice is to typically begin with induction systemic chemotherapy. For example, the Alliance for Clinical Trials in Oncology group A021101, demonstrated a 93% R0 resection rate for patients with BR PDAC after receiving FOLFIRINOX followed by capecitabine-based chemoradiation as NT[30]. Similarly, a single-arm prospective trial of neoadjuvant FOLFIRINOX followed by radiation resulted in a high degree of R0 resection in those who underwent surgery with impressive progression-free survival (PFS) and OS durations [31]. Despite these results, the role of radiation following induction chemotherapy remains controversial for BR PDAC. The Alliance A021501 trial, randomized patients with BR PDAC to either 8 cycles of FOLFIRINOX or 7 cycles of FOLFIRINOX followed by hypofractionated radiation before surgery. Patients who received radiation therapy were less likely to undergo surgical resection and experienced shorter OS[32]. In summary, NT with systemic chemotherapy with selective use of preoperative radiation is currently the preferred approach for BR PDAC.

The use of NT remains the most controversial in patients with resectable PDAC and wide variation in practices exist[21]. Nevertheless, the use of NT continues to increase given the previously described rationale and increasing evidence that highlights improved outcomes. However, given the lesser need for downstaging and higher likelihood of achieving an R0 resection, current neoadjuvant approaches tend to utilize systemic chemotherapy alone. For example, the SWOG S1505 trial was a recent RCT of either neoadjuvant mFOLFIRINOX or gemcitabine/nab-paclitaxel prior to surgical resection for resectable PDAC as NT[33]. In addition, the recently opened Alliance A021806 will randomize patients with resectable PDAC to either perioperative mFOLFIRINOX or surgery upfront followed by adjuvant mFOLFIRINOX[34].

Molecular staging

The last decade has seen dramatic advances in our understanding of the genetic underpinnings of PDAC pathogenesis. With advanced tumor profiling and next-generation sequencing, recent studies have characterized the frequency of genetic and molecular alterations in PDAC tumors[35]. This information, if obtained routinely *via* tissue biopsy or surgical specimen, can contribute to a more personalized approach to

Table 2 Anatomic staging of localized pancreatic ductal adenocarcinoma as defined by the 2008 AHPBA/SSO/SSAT consensus guidelines

	Resectable	Borderline	Locally advanced
SMV-PV	Uninvolved with tumor with clear fat planes around vessels	Abutment, encasement, or occlusion of short segment of vein	Occlusion, thrombosis, or encasement extending several centimeters
SMA	Uninvolved	Tumor abutment < 180°	Tumor abutment > 180° (encasement) or thrombosis of artery
Celiac axis	Uninvolved	Uninvolved celiac axis; short segment encasement or abutment of common hepatic artery may be amenable to resection and reconstruction	Abutment or encasement of celiac axis indicates unresectability

SMV: Superior mesenteric vein; PV: Portal vein; SMA: Superior mesenteric artery.

treatment *via* molecular profiling[36]. In a study by Krepline *et al*[37], 73 out of 78 resected PDAC specimens were found to have a pathogenic variant on NGS of which 18% were potentially actionable. For example, patients with BRCA1/BRCA2 mutations are known to benefit from platinum-based chemotherapy and PARP inhibitors[38,39]. Pancreatic cancer that is mismatch repair-deficient (dMMR), a small but clinically relevant proportion, are known to respond to immunotherapy[40,41]. Finally, the efficacy of standard chemotherapy regimens can be modified depending on thymidylate synthase (TYMS), excision repair cross-complementing (ERCC1) protein, ribonucleotide reductase M1 (RMM1), secreted protein acid and rich in cysteine (SPARC), topoisomerase I (TOP1), and human equilibrative nucleoside transported 1 (hENT1) levels. Low TYMS, ERCC1 protein, and RRM1 Levels predict efficacy of 5-FU based therapies and capecitabine, cisplatin, and gemcitabine respectively[42-44]. Elevated SPARC level predicted sensitivity to nab-paclitaxel while low levels of hENT1 have been associated with gemcitabine resistance[43,45].

These molecular biomarkers, if obtained from preoperative endoscopic ultrasound biopsies, can thus be used to tailor NT. In a recent prospective trial, Tsai *et al*[46] delivered neoadjuvant systemic therapy to 130 patients based on the molecular profile results. In this trial, 6 molecular targets were utilized to predict chemosensitivity: TYMS, ERCC1, RMM1, SPARC, TOP1, and hENT1. Of the 92 patients with predictive molecular profiling, 74 (80%) received fluoropyrimidine-based systemic therapy and 18 (20%) received gemcitabine-based systemic therapy[46]. Of the 130 overall patients enrolled, 107 (82%) completed all intended NT followed by surgical resection including 56 (92%) with resectable PDAC and 51 (74%) with BR PDAC. The importance of this trial was to demonstrate the increased rate of resectability, which suggests that molecular profiling potentially improved the efficacy of NT[46]. Furthermore, the Individualized Molecular Pancreatic Cancer Therapy (IMPaCT) trial documented the feasibility of acquiring and screening pancreatic tumor tissue for HER2 amplification, KRAS mutation, and mutations in BRCA1, BRCA2, PALB2, and ATM[47]. A pilot study using molecular profiling in a wide variety of metastatic cancers demonstrated a longer PFS in 27% of patients receiving molecular profiling-based systemic therapy[36]. The scarcity of studies in this field suggest that this method of personalized care is under-utilized and warrants further investigation.

Dynamic staging

In contrast to standard adjuvant therapy, administering nonoperative therapies prior to surgery provides a unique opportunity to measure the tumor response to treatment *in vivo*. Traditional measures of tumor response to NT include biochemical, radiographic, and histologic. There is abundant data supporting the use of carbohydrate antigen 19-9 (CA 19-9) in the clinical management of patients with PDAC. While baseline CA 19-9 is an important measure of disease burden, numerous studies have highlighted the prognostic significance of CA 19-9 response to NT[48-52]. For example, Boone *et al*[49] found that CA 19-9 response to NT was associated with R0 resection rate, histopathological response, and OS.

Restaging with cross-sectional imaging is routinely performed during and following NT, mostly to rule out disease progression but also to assess the response of the primary tumor to treatment. While the Response Evaluation Criteria in Solid Tumors (RECIST) grading system has historically felt to under-represent treatment response [53], Perri *et al*[54] recently found in a large retrospective study that RECIST partial response and a reduction in tumor volume after NT were independently associated

with pathologic response in patients with localized PDAC. In addition to serologic and radiographic measures, the response to NT can be measured histologically in surgical specimens as the proportion of active cancer cells. Unfortunately, previous studies have found that only a major pathologic response (defined as < 5% active cancer cells) is associated with improved prognosis[8] and that pathologic complete responses are rare[55].

A dynamic assessment of tumor response to treatment may help personalize treatment in several ways. First, non-responders to induction systemic chemotherapy can be switched to alternative regimens. In a study by Vreeland *et al*[56], of 25 BR or LA PDAC patients who did not respond to FOLFIRINOX after 4 mo of treatment as NT, 21 (84%) showed a serologic or radiographic response after switching to gemcitabine/nab-paclitaxel and 11 of them underwent surgical resection (Figure 1). In contrast, responders who are tolerating therapy may be selected to continue this regimen particularly if CA 19-9 has not normalized yet or additional downstaging is required. Second, reassessment of anatomic location may assist decision making regarding the role of preoperative radiation. Third, information on response to NT may guide the use of adjuvant therapy. For example, Liu *et al*[50] showed that in a cohort of patients in whom CA 19-9 normalized with a decrease > 50% after NT, adjuvant therapy was not associated with additional survival benefit whereas in patients with no normalization of CA 19-9 or decrease of > 50%, receipt of adjuvant therapy was in fact associated with a survival benefit[50]. Additional research is needed to determine whether alternative adjuvant regimens (*e.g.*, gemcitabine-based chemotherapy) should be utilized in patients who do not respond to first-line neoadjuvant chemotherapy (*e.g.*, FOLFIRINOX).

FUTURE DIRECTIONS

Novel biomarkers

With an improved understanding of tumor biology, cancer care is becoming increasingly personalized. Integrated genomic analysis has revealed several molecular tumor subtypes of PDAC as well as subsets of the tumor microenviroment (TME)[57,58]. The clinical applications of such classification systems are still in development but perhaps this data can be used to inform about prognosis or aid in treatment decisions [59]. A shift toward personalized NT will depend greatly on the development and validation of novel biomarkers. As an example, SPARC is a protein that is overly expressed in the TME of PDAC tumors. SPARC expression was associated with an inferior survival in patients receiving gemcitabine-based chemotherapy while no association was detected for patients receiving fluoropyrimidine-based chemotherapy suggesting SPARC expression might act as a negative predictive biomarker in patients treated with gemcitabine-based chemotherapy[60]. However, SPARC expression was not associated with survival or response to gemcitabine-based chemotherapy in patients with metastatic PDAC[61]. Similarly, hENT1 is a receptor that is upregulated on the surface of PDAC cells. Gemcitabine exerts its cytotoxic effects after its cellular uptake by hENT1. Therefore, hENT1 expression could potentially predict therapeutic activity of gemcitabine while its under-expression would be a mechanism for resistance[62,63]. hENT1 was studied as a predictor of response to gemcitabine in the adjuvant setting[64,65], but again could not be validated in the metastatic setting[66]. Additionally, microRNA, serum metabolism profiling, or methylation patterns may prove to be useful biomarkers for diagnosis and potential response to therapy in PDAC[67-69].

Improved methods of measuring response

As systemic therapies for PDAC improves, more novel and sophisticated methods of monitoring tumor response are needed. Response to therapy is routinely based on imaging obtained during the course of treatment. Changes in the tumor-parenchyma interface may serve as an early predictor of response to therapy based on computed tomography imaging[70]. Other novel methods such as detection of circulating tumor cells and circulating tumor DNA (ctDNA) are on the horizon for both diagnosis and markers of response to therapy[71,72]. In patients with PDAC, ctDNA levels have been found to correlate with tumor burden and serial monitoring of ctDNA may provide a method to monitor early response to chemotherapy[73]. Patients who received NT had significantly lower circulating tumor cells compared to patients who were eligible for upfront resection who did not receive NT. Interestingly, alterations in circulating tumor cells were not only observed in response to treatment but also seen before

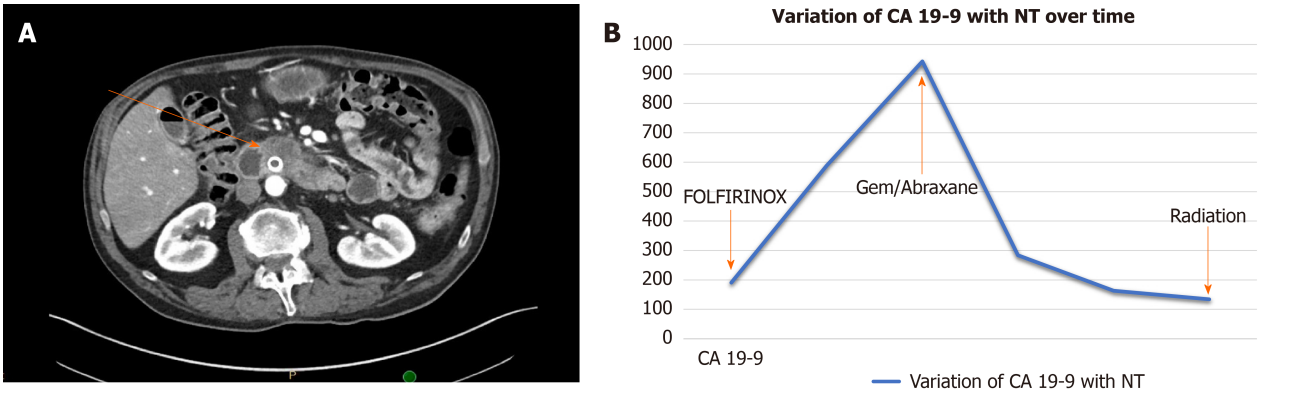

Figure 1 Case example of a 60-year-old man with borderline resectable pancreatic cancer initially treated with FOLFIRINOX. A: Computed tomography image; B: Carbohydrate antigen 19-9 after two months increased so was switched to Gemcitabine/Abraxane with resultant decrease in tumor markers. Given low involvement of superior mesenteric vein, chemoradiation given prior to surgical resection. CA 19-9: Carbohydrate antigen 19-9.

disease recurrence[74]. Future studies will be needed to apply and validate them in the neoadjuvant setting.

Patient-centered outcomes

As the use of NT increases for all stages of PDAC, a greater emphasis on optimizing patient-centered outcomes is necessary and likely to be best achieved through a personalized approach[75]. Despite the advantages of NT, recent evidence has highlighted that some patients will be unable to complete NT and undergo surgery, most commonly because of disease progression or a decrease in their performance status. Recent interest in prehabilitation and advanced nutritional strategies prior to pancreatectomy could be applied to this patient population to improve readiness for surgery[76,77]. Furthermore, although health-related quality of life appears to be preserved during NT, patient symptoms are common during treatment[78]. Prior literature has highlighted the value of monitoring and responding to changes in patient-reported outcomes which could be used to improve and personalize NT[79].

CONCLUSION

PDAC is an aggressive malignancy that is best treated in a multidisciplinary fashion using surgery, chemotherapy, and radiation. NT is an increasingly utilized approach that maximizes the receipt of multimodality therapy, improves margin-negative resection rates, and potentially increases survival durations. In the era of personalized medicine, the neoadjuvant period can also be used to emphasize precision oncology. Already, current methods of anatomically staging, molecularly profiling, and monitoring response to therapy can be used to personalize neoadjuvant treatment for localized PDAC. Ongoing efforts in developing novel biomarkers, innovative methods of measuring response, and patient-reported outcome measurements will expand opportunities for precision oncology during NT. These efforts, along with the development of novel treatment options for this aggressive disease, offer hope for improved multidisciplinary, patient-centered, cancer care.

Abstract

The use of artificial intelligence-based tools is regarded as a promising approach to increase clinical efficiency in diagnostic imaging, improve the interpretability of results, and support decision-making for the detection and prevention of diseases. Radiology, endoscopy and pathology images are suitable for deep-learning analysis, potentially changing the way care is delivered in gastroenterology. The aim of this review is to examine the key aspects of different neural network architectures used for the evaluation of gastrointestinal conditions, by discussing how different models behave in critical tasks, such as lesion detection or characterization (*i.e.* the distinction between benign and malignant lesions of the esophagus, the stomach and the colon). To this end, we provide an overview on recent achievements and future prospects in deep learning methods applied to the analysis of radiology, endoscopy and histologic whole-slide images of the gastrointestinal tract.

Key Words: Artificial intelligence; Machine learning; Radiology; Endoscopy; Pathology; Gastroenterology

Core Tip: Artificial intelligence in general, and machine learning (ML) in particular, have great potential as supporting tools for physicians in the evaluation of neoplastic diseases and other conditions of the gastrointestinal tract. Radiology, endoscopy and pathology images can be read and interpreted using ML approaches in a wide variety of clinical scenarios. These include detection, classification and automatic segmentation of tumor lesions, tumor grading, patient stratification and prediction of treatment response.

INTRODUCTION

Among all the emerging technologies that are shaping the future of medicine, artificial intelligence (AI) is arguably the one which will most alter the way care is delivered in the short and medium term. There is agreement in the field that AI will deeply impact healthcare, allowing for better diagnostics, better treatments, a more efficient use of the medical resources, and a more personalized management of patients[1,2]. In particular, diagnostic techniques based on medical images are spearheading this revolution[3], because their scope (the analysis of images, which, in general, are already digital), is highly accessible for computing systems. In comparison, other specialties such as emergency medicine or cardiac surgery, are less approachable by computers, and penetration of IA in these medical disciplines will be slower and later.

In the field of gastroenterology, several imaging modalities are used for evaluation of the digestive tract and the diagnosis of gastrointestinal (GI) tumors. These include radiology, endoscopy and histologic sections of GI specimens. In automatic analyses of GI images, a subtype of AI called machine learning (ML) is mainly involved. However, other branches of AI, such as natural language processing (NLP), have also been applied in the field of gastroenterology.

The aim of this review is to synthesize the available evidence on the application of AI to the analysis of radiology, histology and endoscopic images of the GI tract. Other applications of AI in the field of digestive disease, such as NLP, have been reviewed elsewhere[4,5] and are out of the scope of this article.

AI IN A NUTSHELL

AI is an umbrella term referring to different techniques used to solve a given problem by a computing method that mimics human intelligence. This includes automatic image identification, classification and interpretation, as well as recognition and processing of natural language. As such, AI encompasses a wide range of technologies, which vary in their complexity, versatility, and applicability to different types of problems.

Of particular interest is ML, which refers to a specific form of AI that endows computers with the ability to learn from and improve with experience, by-passing the need of being explicitly programmed to perform a specific task[6]. This learning process can be supervised or unsupervised, depending on the existence of labels in the sample dataset used to train the ML algorithms. Supervised learning consists of training an algorithm with classified or labeled examples, while unsupervised learning involves training with unstructured, unlabeled bulk data, and requires that the algorithm extracts the inherent structure thereof[7]. Typical techniques used in supervised learning approaches include support vector machine (SVM), naïve Bayes and random forest (RF). For its part, popular clustering algorithms used for unsupervised learning include k-means, k-medoids and Gaussian mixtures.

Both learning schemes can be used to train artificial neural networks (ANN), a subtype of ML algorithms which have a structure loosely inspired by the human brain.

They are made up of several node units, known as neurons, which are mostly structured in successive layers. The products of one layer go through weighted connections to the entries of the next layer, until a final output is produced. As an example, Figure 1 shows a three-layered neural network: When ANN are composed of many layers of nodes between the input and output, they are called deep neural networks (DNN), and using these models is called deep learning (DL). Thanks to their complexity, DNNs are able to model more complex relationships and execute more difficult tasks.

Convolutional neural networks (CNN) are DNN specialized in image recognition and classification. CNNs automatically extract descriptors by using a special neural network whose weights are determined by a training set. Figure 2 shows the typical structure of a CNN. The scheme shows how the image is consumed by the feature extraction network, which is a neural network composed of subsequent pairs of convolutional and pooling layers. Convolutional layers filter and analyze different image features, which are convoluted with the input data. Then, a pooling layer is used to reduce the size of the image produced by the convolutional layer. This process is repeated as *per* the number of layer pairs in the extraction network. Finally, the classification is done by an ANN acting as a classifier network.

The performance of CNN in the analysis of natural images has already attained similar, and even superior levels compared to that of the human eye[8]. Indeed, thanks to the rise in computational power, the reduction of hardware costs, the substantial development of efficient network architectures and the increasing wealth of data, the last years have witnessed a spectacular surge in AI-driven applications related to medicine.

Today, AI is a hot research topic in many medical fields. As a token, the number of publications found in PubMed using the search term "AI" more than doubled in only 3 years, rising from 6761 in 2016 to 15435 in 2019. The number of results *per* year after adding the term "gastroenterology" to that search also speaks for itself, increasing from 30 to 169 over the same time span (Figure 3).

This illustrates a growing interest among both academic and industry groups in the design and clinical validation of novel applications of AI. This task is facilitated by technology companies, which offer cloud-based services to remotely train DL models. It is expected that ML solutions will become increasingly available through their implementation in computer-aided detection (or diagnosis) (CAD) systems[9], thereby facilitating the widespread usage of these tools in clinical practice. These solutions are becoming progressively offered by the main medical technology vendors, as well as independent clinical software firms.

APPLICATIONS OF AI IN GI RADIOLOGY

Reports of the use of AI in GI radiology are abundant in the literature. Advances in ML have been applied to a wide range of clinical problems related with interpretation of images for diagnosis and decision-making in every anatomic site of the GI tract, from the esophagus to the rectum.

ML models have been trained to process quantitatively mineable features from a wide variety of radiologic modalities, such as computed tomography (CT), magnetic resonance imaging (MRI) and ultrasound (US). Within MRI, virtually any type of sequences, including structural such as T1-weighted and T2-weighted, and functional such as diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) maps, have been incorporated into AI-driven models. In addition, some of the most complex networks have been designed to interpret contrast-enhanced multiphasic CT and MRI images (*i.e.*, dynamic contrast-enhanced MRI series) and even analyze, in a conjoined fashion, multimodal (CT, MR) studies.

Many AI applications focus on, or incorporate steps to automatically segment radiologic images, a task which is very time-demanding when done manually. An array of network architectures is available to provide segmented images of the same resolution of the original ones, but with pixel or voxel-based boundary delimitation of adjacent tissue types[10].

The use of ML and DL algorithms is, in many instances, accompanied by radiomic approaches. Radiomics, a term which was coined as late as 2012[11], refers to the quantitative and objective analysis of features in radiologic images by computational means, in order to gain insight into otherwise invisible, or hardly quantifiable information of potential clinical relevance. A cornerstone of radiomic assessments involves the analysis of image texture features. Radiologic textures (Figure 4) refer to

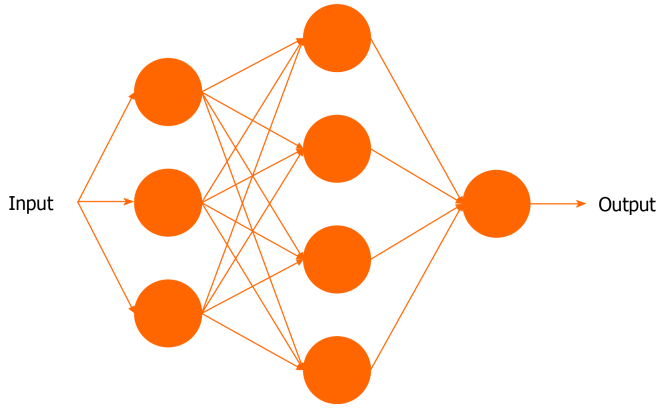

Figure 1 A neural network made up of 3 layers: An input layer, a hidden layer and an output layer. The input data is taken by the neurons (shown as blue circles) in the input layer, and produce an output which is consumed by the next layer (hidden layer). They, in turn, perform similar computations and provide an output to the output layer, which yields a final output.

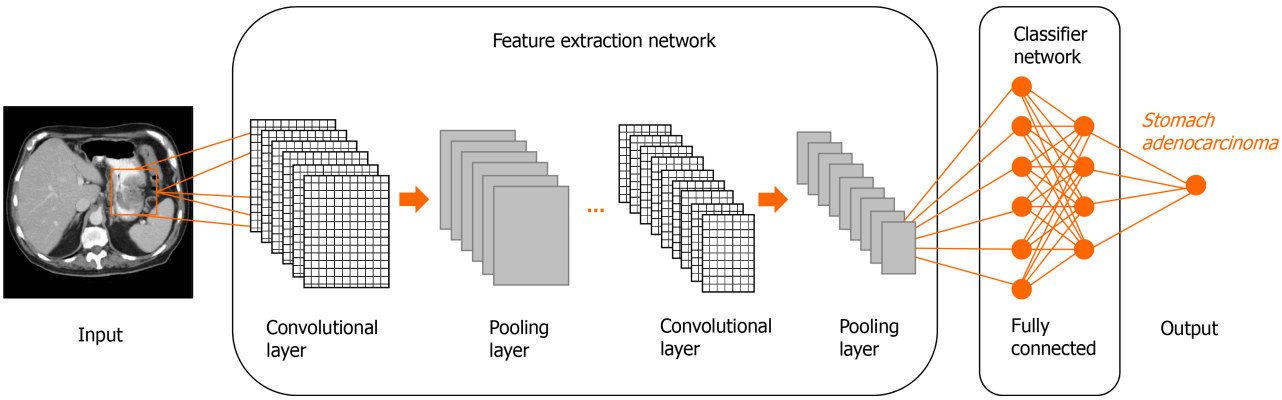

Figure 2 Conceptual example of a simple convolutional neural network used for classification of a stomach tumor.

differences in the grayscale intensities of adjacent pixels or voxels within a region of interest, and have been associated with intratumoral heterogeneity[12]. Radiomics is closely linked to IA, because it often uses ML methods to discover patterns in large datasets[13], although, alternatively, statistical approaches can be used instead.

In the following sections, we review the currently reported experience in the AI-based analysis of GI radiology studies in different clinical scenarios.

Esophageal neoplasia

Esophageal cancer (EC) is a very aggressive neoplasm, with two main histological subtypes: Squamous cell carcinoma (ESCC) and adenocarcinoma. Currently, EC is preferably treated with chemoradiation (CRT), with a positive correlation between the histopathological response and overall survival[14]. However, common derived parameters from CT and positron emission tomography (PET) have shown a limited accuracy in treatment prediction and response assessment. In this scenario, radiomics and DL methods have shown initial promise in prediction of response to treatment in patients with EC. Radiomic signatures in PET images have been used to predict prognosis in patients with esophageal adenocarcinoma[15] and in patients with ESCC [16]. Also, ^{18}F-fluorodeoxyglucose (FDG) PET/CT metrics and textural features showed utility in predicting response to induction chemotherapy followed by neoadjuvant CRT in a mixed cohort including patients with either type of EC[17].

Prognosis prediction of patients with EC has also been addressed from the viewpoint of CT. For instance, Ou *et al*[18] used multivariable logistic regression, RF and SVM classifiers on radiomic biomarkers extracted from CT data to predict resectability of ESCC[18]. Also, Jin *et al*[19] evaluated the potential of an integrated model combining radiomic analyses on CT images and dosimetric parameters in predicting response to CRT in patients with esophageal adenocarcinoma or ESCC. The combined model achieved an accuracy of over 0.7, and displayed a better prediction performance than the model using radiomic features alone[19]. Later, Hu *et al*[20] investigated the

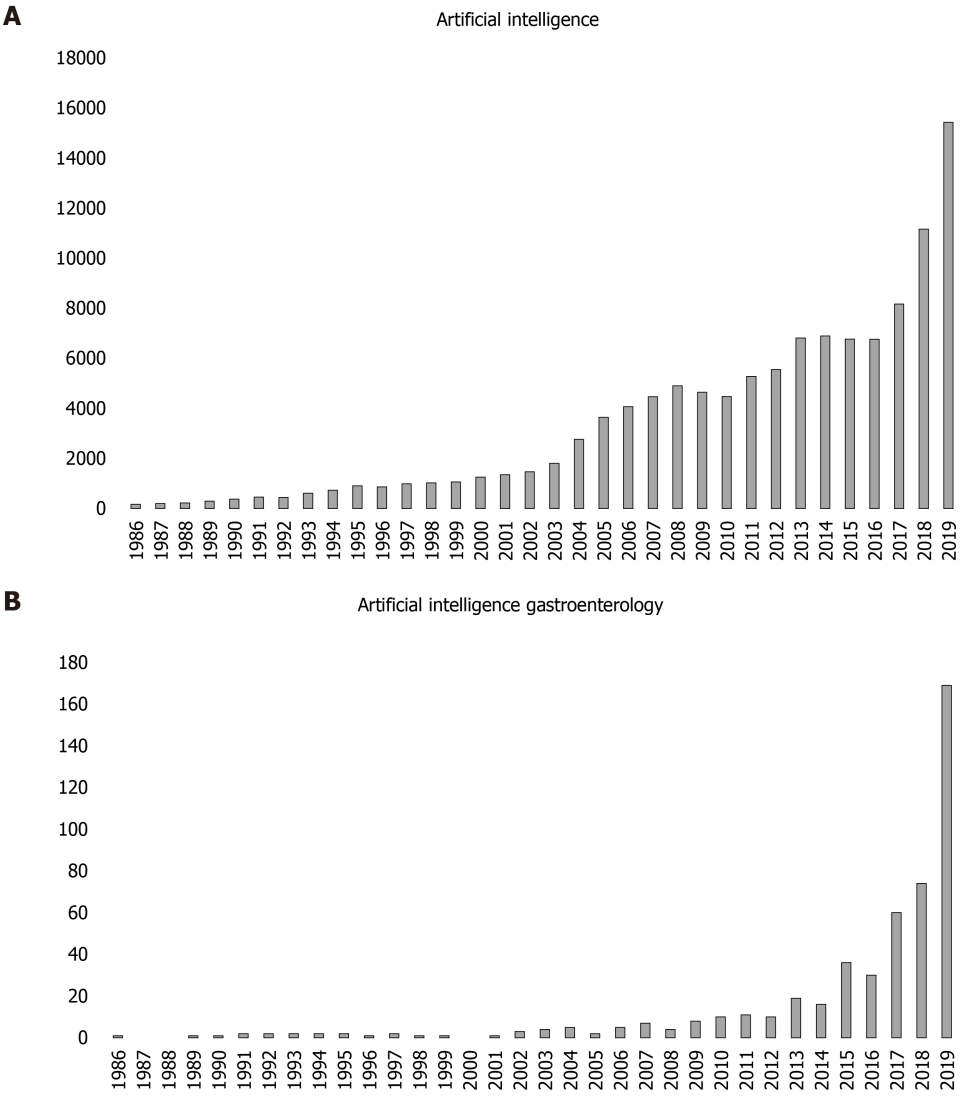

Figure 3 PubMed results by year using the search terms. A: Artificial intelligence; B: Artificial intelligence gastroenterology.

role of radiomic features and DL models in predicting response to neoadjuvant CRT in patients with ESCC eligible for surgery. Manual radiomic feature extraction and feature mapping by CNN were done on pre-treatment CT images. DL modeling based on SVM classifiers showed a greater capacity in assessing tumor heterogeneity and outperformed handcrafted radiomic markers in predicting pathologic complete responses of the tested cohort. Of note, the combination of radiomics and DL did not result in a better predictive performance than DL alone[20]. CT radiomics features have also been successfully used to identify programmed death-ligand 1 and CD8+ tumor infiltrating lymphocyte expression levels in patients with ESCC. Such analyses, performed on pretreatment CT images, allowed for better patient stratification and selection of candidates for immune checkpoint inhibitor therapy[21]. Finally, other encouraging applications of CT radiomics analysis in ESCC are pretreatment local staging[22] and assessment of lymph node status[23,24] with advantage over morphological features and size criteria.

In addition, radiomics analysis has also been applied to MRI, although this technique is challenging to perform in the esophagus due to motion artifacts. Preliminary results of radiomics analyses using pretreatment T2-weighted sequences show promise in the prediction of treatment response to CRT in patients with ESCC [25].

Gastric adenocarcinomas and GI stromal tumors

Radiomic analyses with different techniques have been applied to improve malignant tumor detection and characterization in the stomach. In this regard, a nomogram including multiphasic CT radiomics features was able to predict the presence of gastric adenocarcinomas[26].

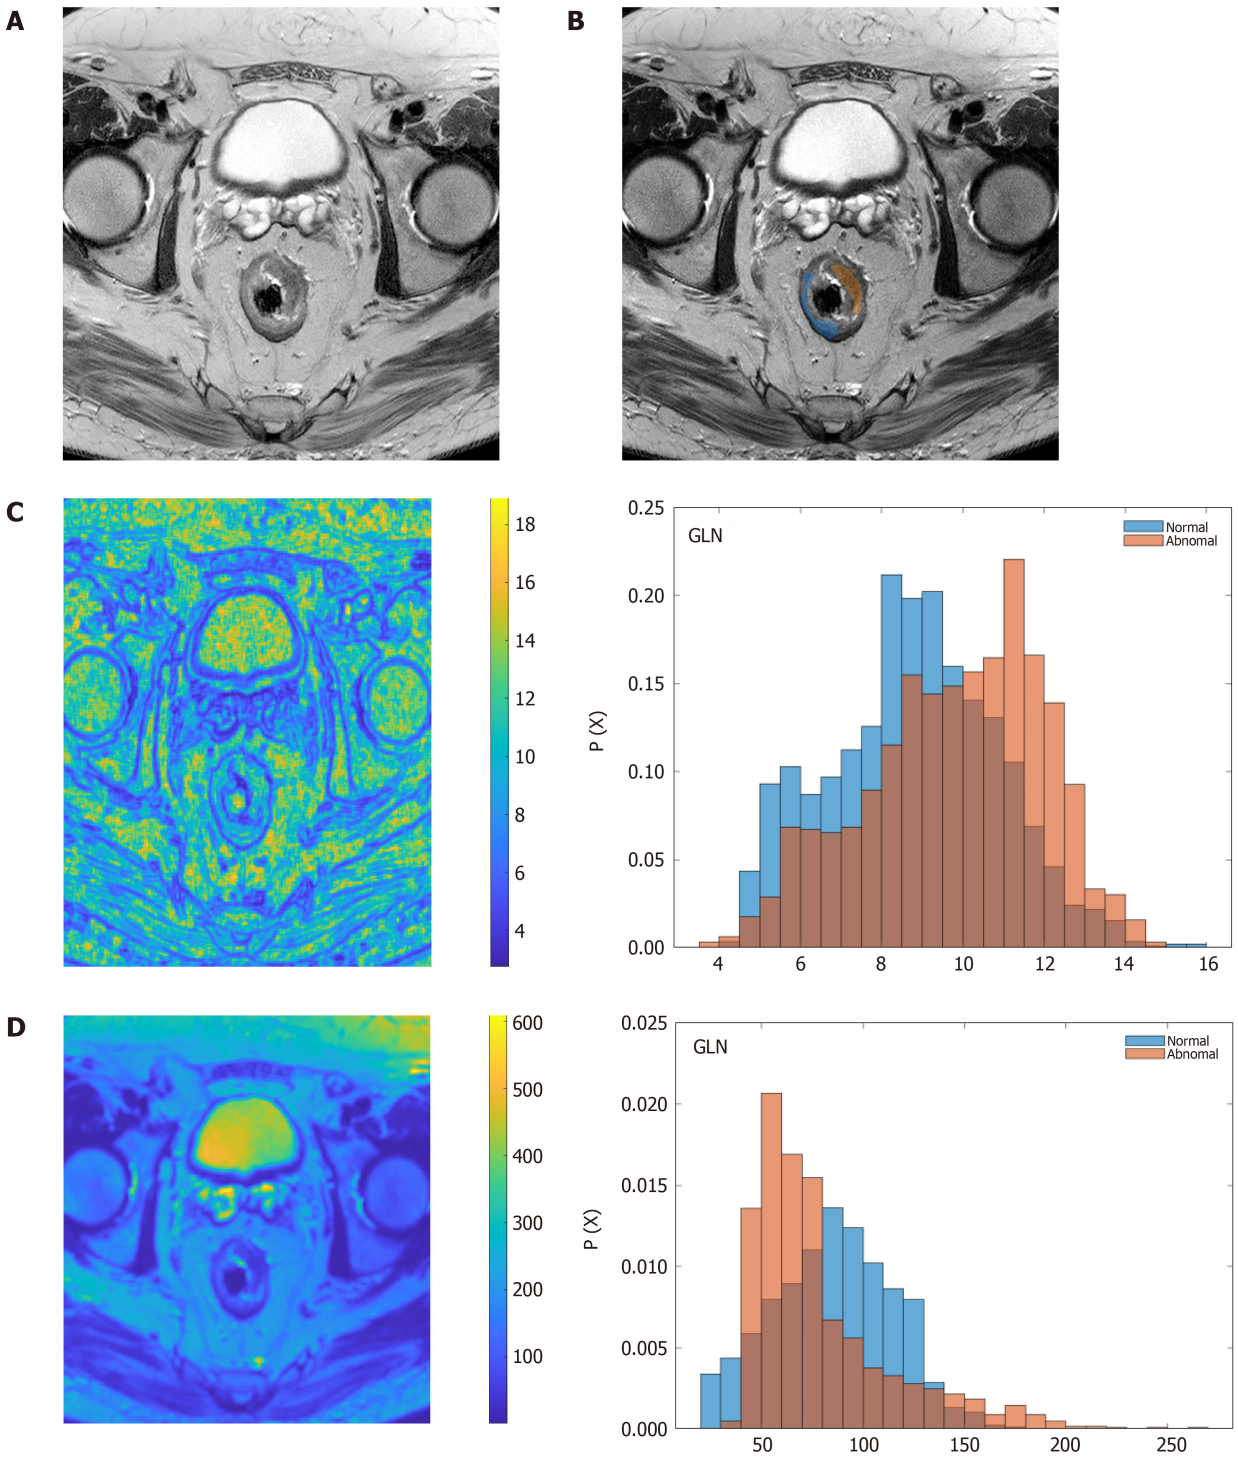

Figure 4 Texture analysis of rectal adenocarcinoma. A: Original, axial T2-weighted image; B: Region of interest delineation of rectal tumor mass (orange) and normal tissue (blue); C and D: Parametric images and histograms of two different texture descriptors, showing differences between normal (blue) and tumor (brown) regions; C: Grey-level nonuniformity; D: High gray-level run emphasis. GLN: Grey-level nonuniformity; HGRE: High gray-level run emphasis.

The aggressiveness potential of gastric adenocarcinomas can be predicted by ML and radiomic analyses on CT and MRI of the stomach. Texture analysis performed in portal venous phase CT scans discovered feature correlates of lymphovascular and perineural invasion potential in patients with tubular gastric adenocarcinomas treated with total gastrectomy. Classifications done with eight different ML models were evaluated, among which naïve Bayes and RF exhibited the best performance in predicting the existence of lymph nodes metastasis, vascular and perineural invasion [27]. Similarly, quantitative assessment of intratumoral heterogeneity of gastric adenocarcinomas by entropy parameters extracted from ADC maps could be correlated with overall stage and prognostic factors of malignant behavior, including vascular and perineural invasion[28]. Another very recent study has shown the

potential role of a double-energy CT radiomics nomogram for prediction of lymph node metastases in gastric adenocarcinomas, with advantages over the current clinical model. In addition, the nomogram demonstrated a significant correlation with patient survival[29]. Also, AI and radiomics analyses have been applied to the prediction of treatment response of metastatic gastric adenocarcinomas. An ANN predictive model using radiomics analyses of pretreatment contrast-enhanced computed tomography (CECT) demonstrated significant differences between responders and non-responders, in a cohort of patients treated with pulsed low dose radiotherapy[30].

In addition, ML has been successfully applied to diagnosis and clinical decision-making of therapeutic strategies in patients with GI stromal tumors (GIST). As reported by Wang *et al*[31], ML showed the ability to differentiate between gastric schwannomas and GISTs by assessing CT images[31]. In that study, radiologists performed worse than all of the five different ML models tested, which included RF, logistic regression and decision trees. Also, analysis of CECT scans by a residual neural network has proved useful to predict the risk of recurrence after curative resection of localized primary GIST[32]. This offers new avenues for non-invasively distinguishing between patients with high risk of recurrence, for which adjuvant treatment with imatinib is recommended, and low-risk patients eligible for curative resection who are not likely to benefit from imatinib adjuvant therapy.

Colorectal cancer

AI has been extensively researched in the detection, characterization and staging of colorectal cancer (CRC)[33]. Several ML techniques have shown utility in the automated detection of polyps by CT colonography[34,35]. Also, radiomic analyses of colorectal CT images were successful in classifying CRC lesions according to their *KRAS* gene mutation status[36].

Currently, MRI is considered the most accurate test for rectal cancer staging[37]. A faster region-based CNN was trained to detect metastatic lymph nodes in T2-weighted and DWI images of the pelvis. The N staging provided by this network was very consistent with that done by radiologists, while average diagnostic time was markedly shorter (20 ms *vs* 600 ms, respectively)[38,39].

In addition, radiomic models aided by SVM were useful in predicting liver metastases of colon cancer. A combined model which included radiomic features of preoperative CT scans with two clinical variables (tumor site and diameter of tumor tissue) showed a higher prediction performance than either the clinical features or the radiomic signatures taken separately[40].

Radiomics analyses of CT, MRI and PET/CT images have been extensively used to predict treatment outcome and survival in patients with CRC. A recent systematic review analyzed 81 studies focused on this task, finding only 13 high-quality reports demonstrating a good performance in predicting treatment response, which mainly involved MRI studies of rectal cancer. Of note, the authors concluded that radiomics research in this field needs more clinical validation, rather than new algorithms[41]. Van Helden *et al*[42] discovered radiomic predictors of response to palliative systemic therapy and survival of patients with metastatic CRC, using pre-treatment ^{18}F-FDG PET/CT images processed with semiautomatic segmentation[42].

Also, in this line, a recent report investigated the prognostic value of a ML model based on liver CT radiomics analyses to predict survival of patients with metastatic CRC[43]. Interestingly, CT-based prediction models were superior to their clinical counterparts for 1-year survival prediction.

Radiomic analyses may be useful to guide treatment of locally advanced rectal cancer (LARC). A radiomic signature comprising 10 texture features from T2-weighted images were modeled by a RF algorithm and used to evaluate treatment responses of subjects with LARC after neoadjuvant chemotherapy. The signature showed good prediction of patient response to treatment, with a good discrimination power among complete responders, partial responders and non-responders, with areas under the curve (AUC) in the 0.83-0.86 range[44].

In another study, Cui *et al*[45] developed and validated a radiomic signature based on 12 features extracted from multiparametric MR images [T2-weighted, dynamic contrast enhanced (DCE) and ADC maps] to predict complete response in patients with LARC after neoadjuvant CRT. The combination of all three image types showed a better predictive value than either of them alone, with an AUC of over 0.94[45]. This was hypothesized to result from the different aspects of tumor behavior reflected by each modality, such as tumor intensity, vascularization and cellularity, respectively.

Segmentation of radiologic images

Segmentation is a key step in the diagnosis and evaluation of tumor diseases, as well as in the treatment volume calculation for radiotherapy planning. However, manually delineating the relation between tumors and adjacent structures is a very time-consuming task for radiologists, requires a considerable level of expertise, and often lacks adequate inter-observer reproducibility.

Several DL models have been developed for automatic delimitation of tissue boundaries, many of which have been specifically tested in GI sites. Of note, automatic segmentation can be particularly challenging in the abdomen, due to the lack of clear boundaries between some organs which are displayed with similar intensities in this anatomy, such as the liver, the stomach, the spleen and the kidneys. Also, peristaltic and breathing motions make the assessment of the GI tract with US and MRI more difficult.

The complexity of networks involved in image segmentation varies. Today, the more recent and sophisticated networks are based on fully convolutional networks (FCN), which are optimal frameworks for semantic image segmentation. Popular FCN-based architectures include SegNet[46] and U-net, a CNN specialized in fast and accurate segmentation of biomedical images[47]. U-net networks can be trained with a relatively limited set of data and are a usual choice for many automatic segmentation approaches.

Automatic segmentation of rectal tumors has been attained using T2-weighted[48,49], DCE[50] and multiparametric (T2, DWI) MRI[51]. Multi-organ, and even full-abdomen segmentation are feasible, although they usually rely on multi-atlas label fusion[52]. This strategy requires registration and fusion of images acquired at different levels of the same patient and is prone to error due to inefficient image registration. Nonetheless, Gibson *et al*[53] recently proposed a registration-free method for multi-organ segmentation of CT images, based on a FCN called DenseVNet[53].

A useful application of automatic segmentation is the calculation of the clinical target volume of tumors in planning CT images for radiotherapy purposes. This approach has the advantage of yielding more reproducible measurements of treatment areas, leading to more consistent radiation doses, and has been explored in the assessment of EC[54] as well as rectal tumor lesions[55,56], among others.

APPLICATIONS OF AI IN ENDOSCOPIC TECHNIQUES

AI in GI endoscopy holds tremendous promise to augment clinical performance, establish better treatment plans, and improve patient outcomes.

In September 2019, the first multidisciplinary global gastroenterology AI meeting (First Global AI in Gastroenterology and Endoscopy Summit) was held in Washington, DC (United States), with a mandate to discuss and deliberate on practice, policy, ethics, data security, and patient care issues related to identification and implementation of appropriate use cases in gastroenterology[57]. Among the many challenges related to the use of AI for gastroenterology applications, Summit attendees highlighted 7 future needs to advance the field of AI in this discipline (Table 1).

Today, a wide variety of AI applications in GI endoscopy are being proposed, developed, and, in some cases, validated in clinical trials. The most current AI algorithms for gastroenterology are in the field of computer vision, which refers to technologies that can "see and interpret" visual data, such as a live video stream from the endoscope.

Polyp detection

Computer-aided polyp detection (CADe) and computer-aided polyp diagnosis (CADx) are two applications of AI-assisted computer vision for colonoscopy, which are already extensively studied[58,59]. CADe and CADx have been the areas of most rapid progress so far in applying AI/computer vision to GI endoscopy. Given the central importance of screening and surveillance colonoscopy for CRC prevention, continued development and validation of CADe and CADx remains a top priority.

AI-assisted polyp detection studies must apply validated outcome parameters, such as adenoma detection rate, adenomas *per* colonoscopy, or adenoma miss rate, among others. Most of these studies are early-stage, but show promising clinical relevance. For instance, a recent study showed that an AI system based on DL and its real-time performance led to significant increases in polyp detection rate[60].

Table 1 Future needs to advance the field of artificial intelligence in gastroenterology

No.	Future needs
1	Identification of relevant and well-defined use cases
2	Development of high-quality metrics
3	Creation of large-scale imaging datasets
4	Clarity on the regulatory path to market
5	Use of appropriate AI methods
6	Clarification of patient privacy issues
7	Education of gastroenterologists on the risks and benefits of AI

AI: Artificial intelligence.

Computer vision and image classification

Prioritization of additional use cases for computer vision in GI endoscopy must consider the prevalence of the targeted disease state, the possible clinical impact of the proposed algorithm, and the potential solvability of the clinical problem by AI.

The most common GI cancers share a common natural history. In this manner, CRC, gastric cancers, and ECs have precursor lesions that can be diagnosed by traditional endoscopic modalities. Additionally, inflammatory bowel disease (IBD) represents a relatively high prevalence group of conditions with an elevated risk of CRC but with dysplastic precursor lesions that are difficult to recognize endoscopically.

A major barrier to progress in ML in GI endoscopy is the relative absence of high-quality, labeled images for training AI algorithms. To overcome this, there is an urgent need to develop rules and recommendations regarding appropriate formats and quality standards for endoscopy image and video, along with accepted protocols for categorizing such images, storing metadata, and transferring and storing images while protecting private health information.

Image classification using AI has been developed to detect gastric cancer in endoscopic images with an overall sensitivity of 92.2%[61]. Another study applied a CNN to quantify the invasion depth of gastric cancer based on endoscopy data[62]. Similarly, a CNN was constructed to characterize EC, achieving a sensitivity as high as 98%[63].

GI bleeding

DL is especially relevant to video capsule endoscopy, given the large amount of data (around 8 h of video) and low efficiency of manual review by the physician. AI tools have also been shown to detect small-bowel bleeding and other relevant images most likely to be clinically relevant. The first studies involving CAD of bleeding from video capsule endoscopy images used color and texture feature extraction to help distinguish areas of bleeding from area of nonbleeding[64]. More recent studies, including those published by Jia and Meng[65], and Hassan *et al*[66], used DL-based features to achieve sensitivities and specificities as high as 99% for the detection of GI bleeding.

Shung *et al*[67] recently published a systematic review summarizing the use of ML techniques to predict outcomes in patients with acute GI bleeding. Fourteen studies with 30 assessments of ML models were included in their analysis. They predicted that ML performed better than clinical risk scores for mortality in upper GI bleeding (UGIB). Overall, the AUC for ANNs (median, 0.93; range, 0.78-0.98) was higher than other ML models (median, 0.81; range, 0.40-0.92)[67].

The emergence of automated lesion recognition endoscopy software combined with the boost in robotic techniques in surgery[68] has captured the attention of GI endoscopists and surgeons. For example, clinical risk-scoring systems offer invaluable, but not always practical, help for better stratification of patients at risk of UGIB and hemodynamic instability. Seo *et al*[69] developed an ML algorithm that predicts adverse events in patients with initially stable non-variceal UGIB[69]. Primary outcomes analyzed in this study included adverse events such as mortality, low blood pressure and rebleeding within 7 d. The authors compared four ML algorithms (logistic regression with regularization, RF classifier, gradient boosting classifier and voting classifier) with clinical Glasgow–Blatchford and Rockall scores. They found that the RF model achieved the highest accuracy and offered significant improvement over

conventional methods used for mortality prediction.

IBD and AI

Recently, AI solutions have been explored to better define mucosal healing in IBD[70]. With the incidence and global burden of IBD still on the rise, involving a large number of young patients with normal life expectancy, there is a constant need for more accurate ways to stratify risks and predict prognosis in these patients. Because the concept of mucosal healing is a rather new concept, the authors expect that AI tools for healing evaluation through endoscopic monitoring, which have recently been developed, could play a key role in better standardizing it[70].

Waljee *et al*[71] used RF methods to develop and validate prediction models of remission in patients with moderate to severe Crohn's disease. In 401 participants, they showed an AUC of 0.78 at week 8 and an AUC of 0.76 at week 6. Also, Klang *et al*[72] reported on the training of a CNN to detect Crohn's disease ulcers, using 17,640 capsule endoscopy images from 49 patients[72].

Assessment of ulcerative colitis (UC) can sometimes be very difficult. In early stages of the disease, erythema can be attributed to a number of other conditions, delaying UC diagnosis. On the other hand, foci of dysplasia in advanced disease are often missed due to the small amount of colonic mucosa sampled in surveillance colonoscopy. Thus, the development of AI solutions aimed at helping assess UC activity is a hot research topic.

For instance, Gutierrez *et al*[73] proposed an automated end-to-end system using DL to binary predict the Mayo Clinic Endoscopic subscore, which showed a high degree of precision and robustness, with an AUC of 0.84[73]. In this connection, Kirchberger-Tolstik *et al*[74] recently reported a non-destructive biospectroscopy technique assisted by neural networks to assess the severity of the disease according to the Endoscopic Mayo Score, with a mean sensitivity of 78% and a mean specificity of 93%[74].

Maeda *et al*[75] developed and evaluated a CAD system for predicting persistent histologic inflammation using endocytoscopy. To do so, they classified the endoscopic studies according to the histological findings of the corresponding biopsies, obtaining a predictive model with a high specificity and sensitivity[75]. In addition, Bossuyt *et al*[76] constructed an algorithm tracking mucosal redness density in the red channel of endoscopic images along with vascular patterns. The results were accurately correlated with the activity of the disease at the endoscopic and histological level[76].

APPLICATIONS OF AI IN GI PATHOLOGY

Today, most pathology labs still rely on fully analogic workflows, including the use of optical microscopes. However, with the availability of digital slide scanners clearly on the rise, there is a growing interest in the development of AI applications for histopathological studies.

Computational analyses of whole-slide images (WSI) of histology sections are regarded as a very promising form of improving diagnostic accuracy, reducing turnaround times and increasing interobserver agreement. Some studies regarding ML applications in pathology are discussed in this section.

Esophageal neoplasia

AI can be used for detection and grading of tumor lesions in the esophagus, and in particular of Barrett´s esophagus (Figure 5). Early detection of this condition is essential to improve patient prognosis. Histopathology is currently the gold standard for the diagnosis of this entity, but its study is characterized by a low degree of interobserver agreement in dysplasia grading.

To overcome this problem, Sabo *et al*[77] developed two computerized morphometry models based on size, shape, texture, symmetry and distribution analyses of the epithelial nuclei of the esophagus. The first neural network model showed an accuracy of 89% in the differentiation of normal esophagus *vs* esophagus with low-grade dysplasia. The second model distinguished between low-grade and high-grade dysplasia with an accuracy of 86%, demonstrating potential for assisting pathologists in the differential diagnosis of indistinguishable lesions[77]. Van Sandick *et al*[78] and Polkowski *et al*[79] also addressed this issue, by combining morphometric analyses in hematoxylin and eosin (H&E) stains with immunohistochemistry data for p53 and Ki67. This hybrid approach improved the accuracy of the differentiation between low-grade and high-grade dysplasia up to 94%. Lastly, Sali *et al*[80] compared the performance of three different models in classifying precursor lesions of Barrett's

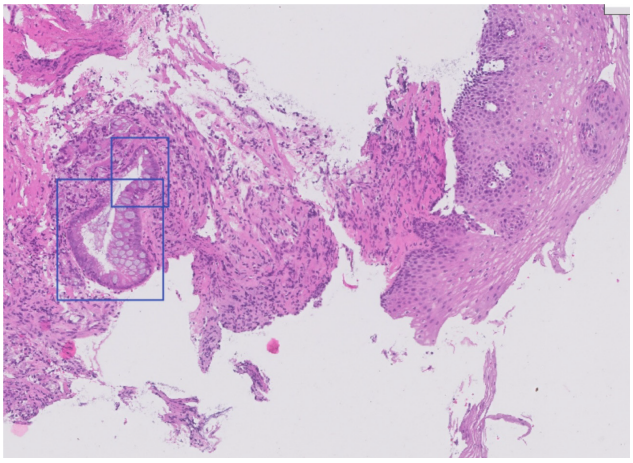

Figure 5 Automatic detection of intestinal metaplasia in a sample of esophagus tissue stained with hematoxylin and eosin. Image analyzed with research software from Cells IA (https://cells-ia.com/).

esophagus, which differed in their training approach (supervised, weakly supervised and unsupervised). The CNN trained with an unsupervised approach extracted the most relevant image features for identifying and classifying the cancer precursors[80].

Inflammatory and infectious lesions of the stomach

Chronic gastritis is a very prevalent condition. Its diagnosis is established by evaluating the degree of chronic and active inflammation, presence of *Helicobacter pylori* (*H. pylori*), atrophy of the mucosa and intestinal metaplasia. Steinbuss *et al*[81] used the Xception CNN architecture for automatic classification of three types of gastritis, namely type A (autoimmune), type B (bacterial), and type C (chemical) gastritis, in histological sections of antrum and corpus biopsies, with an overall accuracy of 84%[81].

H. pylori cells can be visualized in histology sections of gastric biopsy samples using different staining techniques, such as H&E, Giemsa or Warthin-Starry silver stains (Figure 6). Klein *et al*[82] published a DL algorithm for automatic *H. pylori* screening in Giemsa stains, with a sensitivity of 100% and a specificity of 66%[82]. In parallel, Zhou *et al*[83] used a CNN to assist pathologists in the detection of *H. pylori* cells in H&E-stained WSI, but failed to demonstrate significant improvements in diagnostic accuracy and turnaround times in comparison with unassisted case studies[83].

Gastric cancer

Early detection and histopathologic characterization of gastric tumors are essential to improve treatment outcomes. A number of recent studies have paid attention to lesion detection, classification and characterization in this anatomic site. For instance, Song *et al*[84] developed and trained a deep CNN to differentiate between benign and malignant gastric tumors, with a sensitivity of 100% and a specificity of 80.6%[84]. Also, a network developed by Sharma *et al*[85] classified gastric cancer cases according to immunohistochemical response and presence of necrosis, with accuracy rates of 0.699 and 0.814, respectively[85].

Mori and Miwa[86] used a 6-layer CNN to study tumoral invasion depth in gastric adenocarcinoma images, with an accuracy of 85%, a sensitivity of 90% and a specificity of 81%[86]. Later, Iizuka *et al*[87] trained CNN and recurrent neural networks to classify stomach and colon WSI into adenocarcinoma, adenoma and non-neoplastic, with AUC values up to 0.97 and 0.99 for adenocarcinoma and gastric adenoma, respectively[87].

Lastly, Kather *et al*[88] trained a DL model to predict microsatellite instability from H&E-stained gastric cancer images, using a pathomics approach. This represents a very innovative approach, which extracts molecular and histochemical features solely based on H&E images and may circumvent the need to conduct genetic and/or immunohistochemical tests[88].

Colonic inflammatory disease, polyps and CRC

Klein *et al*[89] evaluated the histomorphometric features of colon biopsies from patients with Crohn's disease. These analyses revealed that differences in the number

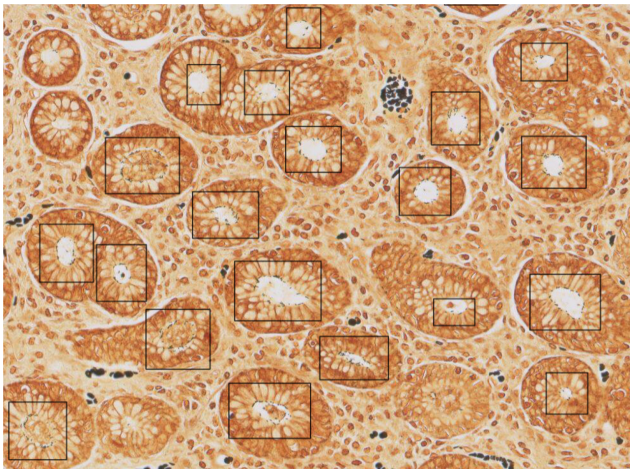

Figure 6 Automatic detection of *Helicobacter pylori* infection in a gastric biopsy section stained with Warthin-Starry stain. Image analyzed with research software from Cells IA (https://cells-ia.com/).

of inflammatory cells, lymphocytic aggregates and collagen density can be used as predictors of clinical phenotypes with an accuracy of 94%[89].

CRC is among the most common malignancies and a major cause of cancer-related death worldwide. Today, it is known that the vast majority of CRC cases arise from the adenoma-carcinoma sequence[90], and early detection of these lesions is considered of utmost importance to reduce CRC incidence rates. Despite this, evidence concerning the application of DL techniques to detect and characterize precancerous lesions in WSI of this anatomic site is still scarce.

Rodriguez-Diaz *et al*[91] developed a DL model to locate areas of malignant transformation inside polyps using semantic segmentation, distinguishing between neoplastic and non-neoplastic polyps, with a sensitivity of 0.96 and a specificity of 0.84 [91]. Haj-Hassan *et al*[92] used a CNN to classify segmented regions of interest into three tissue types related to CRC progression (benign hyperplasia, intraepithelial neoplasia and carcinoma), with an accuracy of 99.17%[92]. Korbar *et al*[93] applied a residual network architecture to classify five polyp types (hyperplastic, sessile serrated, traditional serrated, tubular, and tubulovillous/villous) on WSI with an overall prediction accuracy of over 93%[93]. Also, several studies have proposed DL predictive models of survival for patients with CRC based on the extraction of prognostic markers in H&E images[94,95].

CONCLUSION

In this review, we have summarized the current evidence on the application of AI to the interpretation of radiology, endoscopy and histological images of the GI tract. At this moment, data on the use of AI in the assessment of radiology images of the GI are far more abundant than those from endoscopy and pathology studies. This difference is mainly a consequence of the asymmetrical availability of data and degree of digital transformation of each specialty. In any case, taken together, the available body of knowledge allows us to anticipate the central role that can be expected for AI in the personalized management of patients with high-risk GI tumors and other GI conditions.

On the downside, a large proportion of papers published to date are proof of concept approaches, based on retrospective analyses and single-center studies, usually involving limited data. As a result, and although there is growing evidence on its applicability in many clinical scenarios, the actual contribution of AI to clinical care in gastroenterology is still very limited.

The next several years will likely be a period of rapid development for AI tools in gastroenterology imaging. It is crucial that, as this field advances, there is a focus on technologies that provide real clinical benefits that have been validated in high-quality clinical trials. To this end, prospective, multicenter studies involving large sets of real-world data that reflect the high variability of image quality among institutions, will be key to assess the actual clinical applicability of AI solutions in this field.

As the development and uptake of AI in gastroenterology continues to grow, we will likely see a shift in the way diagnoses of GI conditions rely on AI. Evidence on the superior performance of computers over human experts in most diagnostic scenarios involving image interpretation will soon be notorious. This might ultimately lead to a deskilling of specialists, who would potentially suffer from too great a reliance on AI for their diagnoses, a situation which might be aggravated by the "black-box" nature of many AI applications. Indeed, radiomics and pathomics approaches, which use imaging features that are otherwise invisible to the eye, or highly subjective, have shown a clear value in identifying patient profiles with higher risk, even before clinical symptoms appear. This can facilitate personalized treatment and improve the prognosis of patients with GI conditions, but efforts should be made to increase the "explainability" of AI-rendered results to both physicians and patients, in order to facilitate broad readership and understandability of diagnoses.

Abstract

Radiotherapy (RT) is the backbone of multimodality treatment of more than half of cancer cases. Despite new modern RT techniques, late complications may occur such as radiation proctitis (RP). The natural history of RP is unpredictable. Minor symptoms may resolve spontaneously or require conservative treatment. On the other hand, for similar and uncomplicated clinical contexts, symptoms may

upon this work non-commercially, and license their derivative works on different terms, provided the original work is properly cited and the use is non-commercial. See: http://creativecommons.org/Licenses/by-nc/4.0/

persist and can even be refractory to the progressive increase in treatment measures. Over the last decades, an enormous therapeutic armamentarium has been considered in RP, including hyperbaric oxygen therapy (HBOT). Currently, the evidence regarding the impact of HBOT on RP and its benefits is conflicting. Additional prospective and randomised studies are necessary to validate HBOT's effectiveness in the 'real world' clinical practice. This article reviewed the relevant literature on pathophysiology, clinical presentation, different classifications and discuss RP management including a proposal for a therapeutic algorithm with a focus on HBOT.

Key Words: Radiation proctitis; Radiation proctopathy; Radiotherapy; Radio-induced lesion; Late radiation tissue injury; Delayed radiation injury; Late sequelae; Hyperbaric oxygen therapy; Hyperbaric oxygen; Review

Core Tip: Over the last decades, an enormous therapeutic armamentarium has been considered in radiation proctitis (RP) management including hyperbaric oxygen therapy (HBOT). However, evidence regarding the impact of HBOT on RP and its benefits is conflicting. With the lack of consensus to guide the use of HBOT for the treatment of RP, the goal of this review was to synthesise the existing data, analyse results of previous studies, identify gaps in knowledge, and discuss RP' management including a proposal of a therapeutic algorithm focusing on HBOT.

INTRODUCTION

In recent years and on a global scale, we have witnessed a sustained increase of cancer incidence, with a steady growth rate of approximately 3% per year. According to the International Agency for Research on Cancer of the World Health Organization, it is estimated that worldwide the number of new cancers will reach almost 30 million in 2040, with a mortality of 16.5 million[1].

However, these alarming numbers may be related to the implementation of screening programs with the detection of more cases of cancer at an early stage. Moreover, the survival rates of patients diagnosed with cancer have also increased, largely due to scientific development and the commitment of health professionals in oncology. The progressive increase of this new population cancer survivors with specific clinical and social problems poses a real healthcare challenge. It is in this particular context that radio-induced lesions arise, taking into account their prevention and treatment.

In developed countries, radiotherapy (RT) is the backbone of multimodality treatment of more than half of cancer cases. Despite new modern RT techniques, delayed radiation injury can appear with a latency period of a few months to several decades. The incidence and prevalence of radio-induced lesions and their severity are not well known due to different definitions, underestimation of mild symptoms by both patients and professionals, and the imprecise notification of their appearance in clinical practice[2].

RT is a key treatment of the multimodal approach of neoplasms of the gastrointestinal and pelvic regions. The fixed anatomical position of the rectum in the pelvic brim and the proximity to the irradiated organs makes the rectum especially vulnerable to secondary ionising radiation injury[3]. Radiation proctitis (RP) or radiation proctopathy is defined as a chronic lesion of the mucosa and submucosa of the rectum or rectosigmoid transition secondary to ionising radiation[3].

Acute radio-induced lesions occur from hours or days after exposure to ionising radiation and usually resolve in less than 3 mo. On the other hand, RP is a late lesion with a median onset of 6 to 12 mo after exposure. Rare cases with a latency over 30 years have been reported. Furthermore, RT can develop a continuous process from an acute injury, where symptoms are not specific or non-existent. The clinical presumption is based on intestinal symptoms (*e.g.*, haematochezia, diarrhoea, tenesmus, abdominal pain) and in a cause-effect relationship of previous history of pelvic RT. The diagnosis can be confirmed by endoscopy with or without histologic examination, as imaging findings are usually nonspecific[4-12].

Virtually all patients will experience some clinical manifestation of acute RP during their pelvic RT treatment[8]. Previously, it was thought that only a minority of patients (5%-15%) would develop RP[9,13,14]. However, based on recent data, it is now estimated that near half of the patients may report symptoms related to RP[14,15]. Following RT, 30% of patients with prostate cancer, 12%-17% with rectal cancer, 16% with testicular cancer and 10% with cervical cancer will develop RP[16]. RP's most severe cases have an estimated 4.3%-22% incidence and a 2%-8% mortality rate[11-16].

A high risk of developing RP depends on the total radiation dose and its fractionation, the mode of application (external *vs* intracavitary), the volume of irradiated tissue and the combination of RT techniques. A cumulative dose of RT < 45 Gy is associated with a lower risk of late RT lesion in contrast to what is observed for doses > 70 Gy, for which the risk is significantly higher. The RT technique used is an essential predictor of risk for RP. Compared to brachytherapy, ionising radiation typically administered through a linear accelerator will result in greater and more significant exposure of the contiguous organs. The new RT modalities that comprise three-dimensional conformational RT, intensity-modulated RT and proton and neutron therapies seem to be associated with a lower risk of gastrointestinal toxicity[5-9,17,18].

Advanced age, low body mass index, smoking habits, previous abdominal surgery due to intraperitoneal adhesions, pelvic inflammatory disease, arterial hypertension, diabetes mellitus, previous chemotherapy, collagen and vascular diseases, xeroderma pigmentosa, Cockayne syndrome are other patient-related factors that may be associated with a higher RP risk. Among this array of risk factors, those that seem to have the most significant predictive value for RP are the history of abdominal surgery, chemotherapy, arterial hypertension, and thinness[5-13].

Although the processes of obliterating endarteritis, hypoxia, and fibrosis are already recognised as fundamental factors for their establishment and eventual evolution to chronicity, RP's pathophysiology is complex and has not yet been fully understood[12,19-21]. This chronic condition can stabilise or gradually worsen with periods of acute inflammation.

The beneficial properties of hyperbaric oxygen, together with the growing knowledge about the pathophysiology of delayed radiation injuries, have led to the use of hyperbaric oxygen therapy (HBOT) in the treatment of RP[4]. Currently, HBOT is considered by the European Committee for Hyperbaric Medicine (ECHM) as a treatment modality for late radio-induced lesions, namely, the prevention and treatment of osteoradionecrosis of the mandible, haemorrhagic radiation cystitis and RP (degree of recommendation I/level of evidence B). Although HBOT is used in selected cases of other RT sequelae (*e.g.*, central nervous system and radio-induced laryngeal lesion), its degree and level of recommendation/evidence is lower[22].

Attending to the lack of consensus on guidelines for the use of HBOT in the treatment of RP, the goal of this review is to synthesise the existing data, analyse results of previous studies, identify gaps in knowledge, and discuss RP' management including a proposal for a therapeutic algorithm with a focus on HBOT.

RP PATHOPHYSIOLOGY

Ionising radiation can cause cellular damage, especially in mucosa with rapid renewal such as the intestinal mucosa.

Acute lesions occur predominantly in the mucosa, which consists of depletion of epithelial cells due to cytotoxicity in progenitor cells and consequent apoptosis; inflammation and infiltration of the lamina propria with polymorphonuclear leukocytes and plasma cells; eosinophilic abscesses of intestinal crypts; endothelial lesions of intestinal microvascularisation and eventual oedema of the submucosa. These processes result in mucositis that interferes with the intestinal barrier's function, allowing antigen translocation including microorganisms[23]. If the submucosa

modifications are not impactful, the epithelial cells regenerate and the process resolves spontaneously (Figure 1).

Parallel to what has been described for other late sequelae of RT, RP's pathophysiological mechanisms are not fully understood. Oxidative stress caused by reactive oxygen species (ROS) contributes to obliterating endarteritis with progressive reduction of parietal irrigation and consequent local ischaemia, formation, and diffuse progression of mucosal and submucosal fibrosis through a local proinflammatory cytokines cascade (high levels of interleukin-1β (IL-1β), IL-2, IL-6, IL-8, and transforming growth factor-β), which is promoted by macrophages, neutrophils, and by the differentiation of fibroblasts into myofibroblasts (Figures 1 and 2)[5,23-25]. Recently, an unique intestinal microbiota signature has been identified in an animal model of RP, which seems to be capable of increasing the expression of IL-1β, IL-6, and tumour necrosis factor-α (Figure 2). Mice colonised with previously irradiated intestinal microbiota were more prone to RP than the control colonised with naïve intestinal microbiota[26]. Furthermore, it is postulated that the microbiota can also influence the efficacy of the cancer treatment *per se*.

This transmural pathological regenerative process of the intestinal wall will exacerbate the progressive decrease in vascular density (and consequently the formation of friable telangiectasias and lymphatic vessels dilation), cell depletion, mucosal atrophy, and stenosis of the intestinal wall. Moreover, chronic mucosal ulcers can predispose to haemorrhage, the formation of fistulae and possible risk of intestinal perforation (Figure 2)[6,8,9].

CLINICAL PRESENTATION

Clinically, RP presents itself in two forms: acute or chronic. The acute form is typically resolved within a few weeks and it is characterised by nausea, vomiting, abdominal pain, diarrhoea, urgency, tenesmus, and more rarely, lower gastrointestinal bleeding. The chronic form has a similar clinical presentation; however, it is characterised by an indelible evolution, leading, in the most severe cases, to major digestive haemorrhage, chronic constipation, faecal incontinence, severe proctalgia, stenosis, fistulisation and eventually, intestinal perforation. Moreover, patients may also have other symptoms resulting from pelvic irradiation such as radiation enteritis, haemorrhagic radiation cystitis or urethral stricture. The occurrence of colorectal neoplasms induced by radiation has also been described, mostly after a long latency period, which can be manifested by masses or non-healing ulcers[5,7,8].

For diagnosis, a cause-effect relationship should be established between the history of pelvic RT and intestinal symptoms. A rectal examination will evaluate anal sphincter tonicity and a rectosigmoidoscopy the mucosa characteristics and affected areas, excluding malignancy. Total colonoscopy can be considered to outline the true extent of the disease and/or exclude the possibility of another aetiology for colitis. Endoscopic images usually reveal a pale, friable mucosa, with telangiectasias and/or ulcerations, and a clear separation between the altered and normal region, corresponding to the irradiated zone's limit. A biopsy is usually not recommended to confirm the diagnosis because it may increase the risk of complications[7,8].

In addition, it is essential to exclude other possible causes of subacute or chronic proctitis such as inflammatory bowel disease, diverticular colitis, atherosclerotic disease or previous episodes of chronic ischemic colitis, chronic exposure to the effects of non-steroidal anti-inflammatory drugs, recent use of antibiotics that predispose to *Clostridioides difficile* infection, parasitic (*e.g.*, amebiasis) or bacterial (*e.g.*, *Salmonella* spp., *Campylobacter* spp.) infections due to recent travelling to endemic countries, history or risk factors for sexually transmitted diseases (*e.g.*, *Neisseria gonorrhoeae* and herpes simplex virus) and cytomegalovirus infection in the immunocompromised patient[7,8].

In several studies, the severity of RP is objectively graded using symptom scores, such as the Radiation Proctopathy System Assessment Scale or the Late Effects Normal Tissue (LENT-SOMA) scale and considering the intraluminal findings by endoscopic grade (modified Chi grading or scales Chutkan and Gilinski). The comparison of data between studies is difficult due to the use of different severity scores. The same is true for outcome measures. Table 1 summarises some of the different classifications of RP that have been proposed in the literature[27-37].

Table 1 Classification of stages/grades of radiation proctitis

Ref.	Stages/grades	Description
Sherman[27], 1954	I-IV	Based on endoscopic findings: I: (a) Localised erythema and telangiectasia, friable mucosa with easy bleeding: no ulceration or stricture formation, and (b) More diffuse erythema along with periproctitis, marked pain, and sensitivity; II: Presence of ulceration with a greyish tenacious slough, usually involving the anterior rectal wall, and proctitis with grade I lesions; III: Presence of rectovaginal fistulae or bowel perforation and varying degrees of proctitis with ulceration; IV: Presence of rectovaginal fistulae or bowel perforation and varying degrees of proctitis with ulceration.
Dean and Taylor[28], 1960	I-III	Based on clinical and endoscopic findings: I: Symptoms: Rectal bleeding, tenesmus, sphincter instability, mucoid discharge; endoscopic findings of vascular congestion, friability of the mucosa, mucosal thickening, mucoid discharge; II: Same symptoms as before; endoscopic findings of ulcerations, underlying thrombosis of the small vessels; III: Same symptoms as before plus perineal sepsis, incontinence, diarrhoea, perianal purulent discharge; endoscopic findings of necrosis, fistulae, strictures.
Gilinsky *et al*[29], 1983	Normal; Mild; Moderate; Severe	Based on endoscopic findings: Score 0: Normal mucosa; Score 3: Erythema and/or telangiectasia, oedema, thickening, pallor of mucosa; Score 6: Friability; Score 9: Ulceration and/or necrosis.
Langberg *et al*[30], 1992	1-3	Based on histopathologic findings: Thickening of serosa: (1) Slight thickening of serosa, hyperplasia of peritoneal mesothelium; and (2) Marked thickening of serosa; and (3) Extreme thickening and fibrosis serosa. Mucosal alterations: (1) Small superficial ulcerations; and (2) Ulcerations involving more than half of the intestinal circumference. Epithelial atypia: (1) Abnormally oriented crypts; (2) Irregular crypt regeneration with atypical epithelial cells; and (3) Adenocarcinoma. Vascular sclerosis: (1) Slight double normal thickness, broadened and hyalinised collagen fibres; (2) Submucosa three to four times normal thickness, abnormal collagen fibres; and (3) Massive fibrosis including muscularis. Lymph congestion: (1) Dilated lymph vessels or cystic collections of lymph. Ileitis cystica profunda: (1) Submucosal glandular inclusions; (2) Submucosal cysts with polypoid elevation of the mucosa; and (3) Large cysts extending into the muscularis.
Chutkan *et al*[31], 1997	0-4	Based on clinical findings: 0: No haemorrhage; 1: Blood on toilet paper or mixed with faeces; 2: Drops of blood in the toilet; 3: Severe haemorrhage with expulsion of clots; 4: Haemorrhage that requires transfusion.
Wachter *et al*[32], 2000. Vienna Rectoscopy Score	0-5	Based on endoscopic findings: Score 0: Congested mucosa (grade 1); Score 1: Congested mucosa (grade 2), telangiectasia (grade 1); Score 2: Congested mucosa (grade 3), telangiectasia (grade 2); Score 3: Congested mucosa (any grade), telangiectasia (grade 3), ulceration (grade 1); Score 4: Congested mucosa (any grade), telangiectasia (any grade), ulceration (grade 2), stricture (grade 1); Score 5: Congested mucosa (any grade), telangiectasia (any grade), ulceration (grade 3), stricture (grade 2), necrosis (any grade).
Zinicola *et al*[33], 2003. Bleeding Scale for Radiation-Induced Haemorrhagic Proctitis	0-4	Based on clinical findings: 0: No bleeding; 1: Intermittent bleeding (once weekly or less); 2: Persistent bleeding (twice or more weekly); 3: Daily bleeding or anaemia; 4: Require blood transfusion.
Chi *et al*[34], 2005. RTD grading scale	0-3	Based on RTD endoscopic findings: 0: Normal mucosa; 1: < 10 telangiectasias; 2: > 10 telangiectasias; 3: Confluent lesions, active bleeding or friable mucosa.
Ehrenpreis *et al*[35], 2005. Radiation Proctopathy System Assessment Scale (RPSAS)	1-5	Based on clinical findings: Diarrhoea. Urgency. Rectal pain. Tenesmus. Rectal bleeding. Faecal incontinence. Severity: 1: No problem. 2: Mild problem–can be ignored when you do not think about it. 3: Moderate problem–cannot be ignored; no effect on ADL. 4: Severe problem–influences your concentration on ADL. 5: Very severe problem–markedly influences your ADL and/or requires rest. Frequency: 1: Monthly; 2: Weekly; 3: Several times *per* week; 4: Daily; 5: Throughout the day.
Cox *et al*[36], 1995. Late Radiation Morbidity Scoring Criteria Radiation Therapy Oncology Group/European Organisation for Research and Treatment of Cancer	0-5. Late (> 3 mo)	Based on clinical and imaging findings: 0: No changes; 1: Mild diarrhoea, mild cramping, bowel movement 5 times daily, slight rectal discharge or bleeding; 2: Moderate diarrhoea or colic, bowel movement > 5 times daily, excessive rectal mucus or intermittent bleeding; 3: Obstruction or bleeding requiring surgery; 4: Necrosis, perforation, or fistulae; 5: Death related to adverse event.
NCI CTCAE version 5.0[37], 2017	1-5	Based on clinical findings: 1: Mild adverse event; rectal discomfort, intervention not indicated; 2: Moderate adverse event; rectal discomfort, passing blood or mucus, medical intervention indicated, limiting instrumental ADL; 3: Severe and undesirable adverse event, faecal urgency or stool incontinence, limiting self-care ADL; 4: Life-threatening or disabling adverse event, urgent intervention needed; 5: Death related to adverse event.

ADL: Activities of daily living; RTD: Rectal telangiectasia density.

RP TREATMENT

The treatment of acute RP is essentially symptomatic and in accordance with the guidelines for the treatment of mucositis of other aetiologies[38,39]. In the absence of response to first-line antidiarrheal medication, it must be recommended treatment with octreotide or other somatostatin analogues and butyrate enemas that seem to accelerate the intestinal mucosa regeneration process. There is clinical evidence that

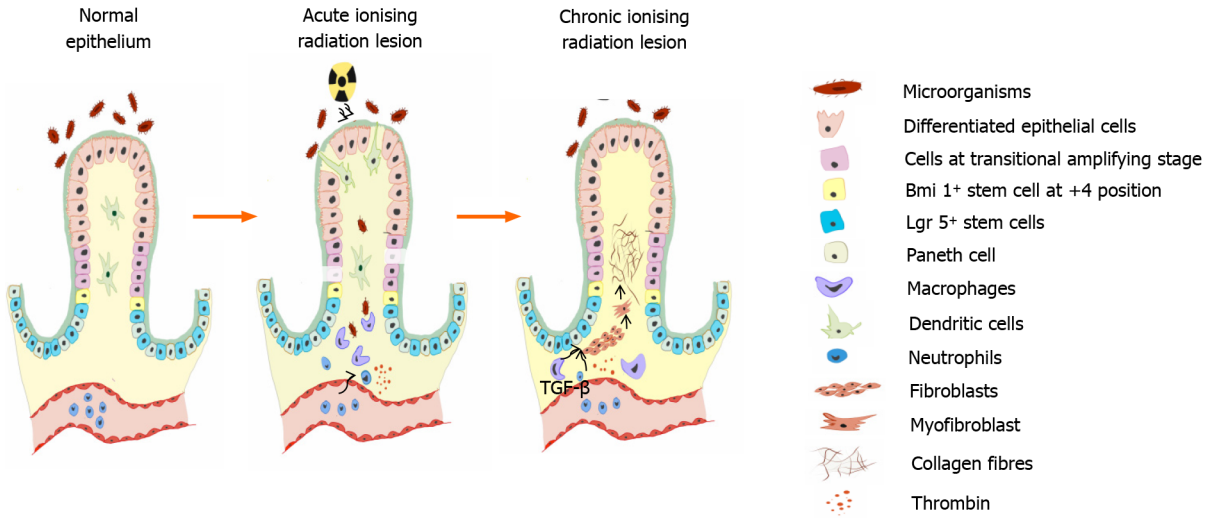

Figure 1 Representative scheme of intestinal injury induced by ionising radiation. In a healthy gut, crypts are with intact mucosa. Lgr5$^+$ stem cells proliferate and cells migrate upwards to provide differentiated epithelial cells of the villi. Acute lesions occur predominantly through different pathological processes: Depletion of epithelial cells due to cytotoxicity in progenitor cells and consequent apoptosis; inflammation and infiltration of the lamina propria with polymorphonuclear leukocytes and plasma cells; eosinophilic abscesses of intestinal crypts; endothelial lesions of intestinal microvascularisation with the release of thrombin and eventual oedema of the submucosa; influx of antigenic material, including gut microbiota into the lamina propria. If the submucosa modifications are not impactful, the epithelial cells regenerate, and the process resolves spontaneously. The constitutive and chronic phase comprises obliterating endarteritis with progressive reduction of parietal irrigation and consequent local ischaemia; formation and diffuse progression of mucosal and submucosal fibrosis through a local proinflammatory cytokine cascade (high levels of interleukin-1β (IL-1β), IL-2, IL-6, IL-8, and transforming growth factor-β), which is promoted by macrophages, neutrophils and by the differentiation of fibroblasts into myofibroblasts. Citation: Adapted from Costa *et al*[21] and Kumagai *et al*[23].

intrarectal amifostine (ROS scavenger) could be, in selected patients, a possible protective pharmacological measure against the acute effects of RT. Generally, the acute RP is a self-limiting situation, although in about 20% of cases, it is necessary to suspend or even interrupt RT treatments[7,38,39].

The natural history of RP *per se* is unpredictable. Minor symptoms may resolve spontaneously or require conservative treatment. On the other hand, symptoms may persist for similar and uncomplicated clinical contexts and become refractory to the progressive increase in therapeutic intervention. Thus, early diagnosis and intervention are essential and symptoms should not be overlooked, even if they have little impact on the patient's quality of life (QoL).

The management of RP can be challenging and requires a holistic approach for which there is no gold standard protocol. Furthermore, there are no prophylactic measures that have been shown to be beneficial in reducing RP incidence. Concerning treatment options, most of the clinical evidence is based on case studies and small series. Therapeutic management should be personalised according to the patient, the severity of the clinical condition, and the institution's experience. The non-invasive or minimally invasive measures include changing the diet and symptom control with pharmacological and endoscopic support. In terms of medical treatment, the intrarectal application of formalin (4%-10% formaldehyde) and sucralfate enemas stand out as effective measures to control bleeding in patients with haemorrhagic RP. Studies present conflicting results for the use of short-chain fatty acid enemas. There is a lack of scientific evidence to recommend the use of alternative treatments such as mesalamine, ozone therapy, metronidazole, vitamin A, antioxidant vitamin complexes (vitamin C and E) and pentoxifylline. Endoscopic treatment with plasma argon has been effective in controlling and treating lower gastrointestinal bleeding. Endoscopic bipolar electrocoagulation, radiofrequency ablation, Nd: YAG laser and cryotherapy are possible alternatives to argon, although their evidence level is low. Despite the enormous therapeutic armamentarium, the more severe RP cases may require radiological intervention for lower gastrointestinal bleeding and surgical intervention, especially in complications such as effective control of lower gastrointestinal bleeding, fistulisation, occlusion, and intestinal perforation[3,5,7,8,38,39].

HBOT

HBOT is a treatment based on the inhalation of pure oxygen (100%) in an environment with an atmospheric pressure higher than that existing at sea level (1 atmosphere absolute [ATA]). The HBOT sessions are held inside hermetically sealed hyperbaric chambers, classified as type IIb medical devices (directive 93/42 ECC of June 14, 1993, concerning medical devices). HBOT is used in several clinical conditions as well as in professional and military training. Therapeutic HBOT usually involves pressures higher than 1.4 ATA (141.8 kPa), most frequently ranging between 2.0 (202.6 kPa) and 2.5 ATA (253.3 kPa) for 60 to 120 min[40].

Currently, the ECHM recommends HBOT for the treatment of RP (degree of recommendation I/ level of evidence B)[22]. Unlike most conventional treatment that only alleviated symptoms, HBOT can favourably change the natural history of other RT late sequelae[4]. Its clinical benefit emanates from the therapeutic effects of hyperbaric oxygen that include, among others, the promotion of tissue oxygenation, neovascularisation, reepithelialisation, and the reversal of the fibroatrophic process induced by ionising radiation[16,21,41,42].

The mechanisms that result in HBOT beneficial effects can also cause side effects in some patients, primarily due to pressure and oxygen toxicity. However, when appropriate therapeutics protocols are applied, HBOT is a safe and low-risk intervention, with the adverse events being infrequent and typically not severe[40-43].

In 1991, Charneau *et al*[44] treated the first RP patient with HBOT. The 74-year-old patient had a 5-mo history of transfusion-dependent haemorrhagic RP. For this patient, after the failure of previous treatments (enema with corticosteroids and Nd: YAG laser), HBOT was considered a strategy to avoid surgery. After 82 sessions of HBOT (2.5 ATA, for 90 min, twice daily), a complete clinical response was observed, which remained during the follow-up period of at least 9 mo. After this pioneering

report, others were published, including case reports, retrospective, (non)-randomised studies and clinical trials, as well as several reviews and meta-analyses that studied the clinical impact of HBOT on RP (Table 2)[16,45-71]. However, most studies had both a small number of cases treated and a short follow-up period.

In 1997, Warren *et al*[47] conducted a study with 14 patients undergoing two pressurisation regimens (n = 9; 2 ATA, for 120 min, 5-6 times per week; n = 5; 2.35 ATA, for 90 min, 5 times per week). The authors documented an overall response rate of 64.3% (57.1% with complete responses) for an average follow-up period of 14.6 (range 2-35) mo. In the same year, Woo *et al*[48], published a study with 18 patients submitted to 24 sessions of HBOT (2 ATA, for 105 min, 6 times per week) with a follow-up period of 14 (range 3-65) mo. In this study, different response rates were reported according to the symptoms analysed: Haemorrhage 41.2% (7/17); rectal pain 50% (2/4); incontinence 75% (3/4) and diarrhoea 50% (4/8). Furthermore, most patients (77.7%) had already undergone other treatments but with little clinical benefit (n = 13, enema with corticosteroids; n = 1, formalin). Gouëllo *et al*[52], published a study with 36 patients submitted to an average of 67 sessions of HBOT (2.5 ATA, for 90 min, 5 times per week). An overall response rate of 53% (19/36) was observed immediately after the end of treatment. In the 52-mo follow-up period, the overall response rate was 66% (21/32). In 2002, in a systematic review published by Feldmeier and Hampson[2], 14 publications were evaluated in the context of RP and radiation enteritis (12 studies in humans and 2 in animals). Of the 9 studies, 114 patients were considered, and an overall response rate of 95.6% was documented (36%, 41 patients with complete response; 60%, 68 patients with better symptomatic control). Despite these studies have shown an improvement in RP with HBOT, a clinical benefit has also been verified in the small intestine radio-induced malabsorption syndrome. In 2007, Marshall *et al*[16], published the largest study carried out up to that time, with 65 patients with enteritis and RP (85% of patients). The authors described an overall response rate of 68% (43% with complete responses) after at least 30 sessions of HBOT (2.4 ATA, for 90 min, 5 times per week). However, half of the patients (49.2%, 32) had to be submitted to more HBOT sessions, up to a maximum of 60, due to partial response or recurrence of symptoms. The mean follow-up time was 23 (range 1-70) mo. The response rate of patients with low gastrointestinal bleeding was 70%. In those dependent on transfusions, the response rate was very satisfactory since 75% of these patients no longer needed transfusion support. For symptoms other than haemorrhage, the response rate was 58%, with pain reduction, nutritional status improvement, intestinal transit regularisation and even fistulae closure. Moreover, no correlation was established between the treatment response rate and the duration of symptoms or the time between RT and initiation of HBOT.

In 2008, Clarke *et al*[65] published the results of the first multicentre, randomised, sham-controlled, double-blind clinical trial (HORTIS) that included patients with RP refractory to other therapeutic interventions. A total of 150 patients were enrolled, but only 120 completed the study. Patients were randomised to HBOT (Group 1: 2.0 ATA, for 90 min, 5 times per week) or sham treatment with 21% oxygen (Group 2: 1.34-> 1.1 ATA, for 90 min, 5 times per week). The clinical response evaluation was performed after 30 treatment sessions, with the possibility of 10 additional sessions, depending on the investigator's decision. Only 3 patients did not accept the crossover to the active arm of the initial HBOT (Group 1). After adjusting covariates and for an average follow-up period of 2 years, Group 1 significantly improved the mean LENT-SOMA score (5.00 *vs* 2.61, P = 0.0019). In the initial allocation phase and after the first efficacy assessment, the experimental group's overall response rate was higher than in the control group (88.9% *vs* 62.5%, P = 0.0009). Furthermore, there was also a significant improvement in QoL (pattern of pain, bleeding and intestinal transit) in Group 1 (including in the crossover subgroup of patients). It is noteworthy that, for Group 1, the improvement in QoL in terms of faecal incontinence, faecal urgency, pain and intestinal transit was consistent throughout the follow-up period. In 2015, Tahir *et al*[69] reported an overall response rate of 95% in the 59 patients treated with RP (51% of patients with complete response for a median duration of 15 mo). Bennett *et al*[72], in a Cochrane meta-analysis published in 2016, documented a significant increase in the clinical improvement or even remission of RP after HBOT (relative risk 1.72; 95% confidence interval 1.0-2.9, P = 0.04, NNT to benefit 5).

In 2016, Glover *et al*[70], in a multicentre, randomised, double-blind, sham-controlled phase 3 trial (HOT2), evaluated the clinical benefit of HBOT in patients with chronic bowel dysfunction after RT in the context of pelvic neoplasms. Treatment efficacy was determined by comparing the Inflammatory Bowel Disease Questionnaire (IBDQ) and the IBDQ rectal bleeding scores assessed before and 12 mo after starting treatment. Moreover, other secondary endpoints were evaluated: LENT-SOMA, the

APC: Argon plasma coagulation; ATA: Atmosphere absolute; HBOT: Hyperbaric oxygen therapy; IBDQ: Inflammatory Bowel Disease Questionnaire; IQR: Interquartile range; min, minute; NA: Not available or not applicable; NCI CTCAE: National Cancer Institute Common Terminology Criteria for Adverse Events; O_2: Oxygen; QoL: Quality of life; RP: Radiation proctitis; SD: Standard deviation; Δ: Median change from baseline to 12 mo.

11-question questionnaire related to symptoms selected from the CTCAE gastrointestinal scale (version 4.0) and QoL through validated questionnaires (Questionnaire basic EORTC QLQ-C30 and colorectal module QLQ-CR38). Patients of both sexes with ages over 18 years were included, with at least grade 2 gastrointestinal symptoms of any category of LENT-SOMA or grade 1 with intermittent symptoms due to RT performed at least 12 mo before in the context of rectal, prostate, testicle, bladder, cervix, vagina, vulva or ovary neoplasms. Patients with grade 3 symptoms LENT-SOMA were excluded since they have higher affectation on activities of daily living and require, generally, more aggressive treatments. Patients with RT symptoms were considered eligible for the trial only if they had been submitted to other general interventions for at least 3 mo (*e.g.*, diet change, oral therapeutic optimisation) with no improvement. Patients were randomised in a 2:1 ratio in favour of HBOT and stratified by centre. Patients were randomised to HBOT (2.4 ATA, for 90 min, 5 times per week) or 21% oxygen (1.3 ATA, for 90 min, 5 times per week). Of the 84 patients included in this clinical trial, 55 underwent HBOT and 29 sham treatment. In the analysis of clinical efficacy, no difference was identified between the two arms, when comparing the main endpoints: IBDQ bowel component [HBOT = 46; sham treatment = 23; HBOT: 4 (-3 to 11) *vs* sham treatment: 4 (-6 to 9), $P = 0.50$] and IBDQ rectal bleeding [HBOT = 29; sham treatment = 11; HBOT: 3 (1 to 3) *vs* sham treatment: 1 (1 to 2), $P = 0.092$].

The results of the HOT2 clinical trial are inconsistent with most previous clinical evidence, including the Cochrane meta-analysis[72], primarily based on the HORTIS [65] clinical trial. The HOT2 study[70] is a very relevant clinical trial from a methodological point of view: Phase 3, randomisation 2:1, stratification by centre, double-blind, sham-controlled, with primary and secondary endpoints with previously validated scores and questionnaires and with well-defined inclusion/exclusion criteria, including a period of at least 3 mo for possible symptom optimisation and control. However, one can enumerate some aspects that can be criticised (not only exclusively for this trial): (1) The sample size is debatable for a phase 3 clinical trial when it is supposed to comprises a total number of patients over 300. The statistical calculation was based on assumptions defined and validated in previous studies. However, the comparison between the two arms was performed with an insufficient number of patients (HBOT: 46 *vs* sham treatment: 23); (2) The drop-out rate was 17.86% (15 patients: 9 from the HBOT group and 6 from sham treatment), with only 69 out of 84 patients having a 12-mo follow-up period. The final statistical power was 75%, although the study had been designed for 80% power; (3) Patients with symptoms ≥ grade 3 LENT-SOMA (*e.g.*, severe faecal incontinence or transfusion-dependent RP) were not included. Thus, one cannot generalise the results for this subgroup; (4) It is unknown whether the percentage of patients with a medical history of lower gastrointestinal bleeding influences their progress during the study (HBOT: 62% *vs* sham treatment: 79%); (5) The dietary and/or pharmacological measures performed in the period prior to randomisation were not discriminated (*e.g.*, diet type, probiotics, antibiotic cycles). Did these different procedures influence the natural history of the disease and the potential response to treatment? (6) The smoking habits of the patients were not quantified. Otto *et al*[73], in a study on diabetic foot, determined that patients with above a 10 pack-year (P-Y) history of smoking would need an average of more than 8 to 14 sessions of HBOT to obtain the same therapeutic effect as non-smokers. Freiberger *et al*[74] reported that in patients with mandible osteoradionecrosis, those who smoked showed a shorter maintained treatment period response to HBOT when compared to non-smoking patients (15.8 *vs* 86.1 mo). The stratification by smoking

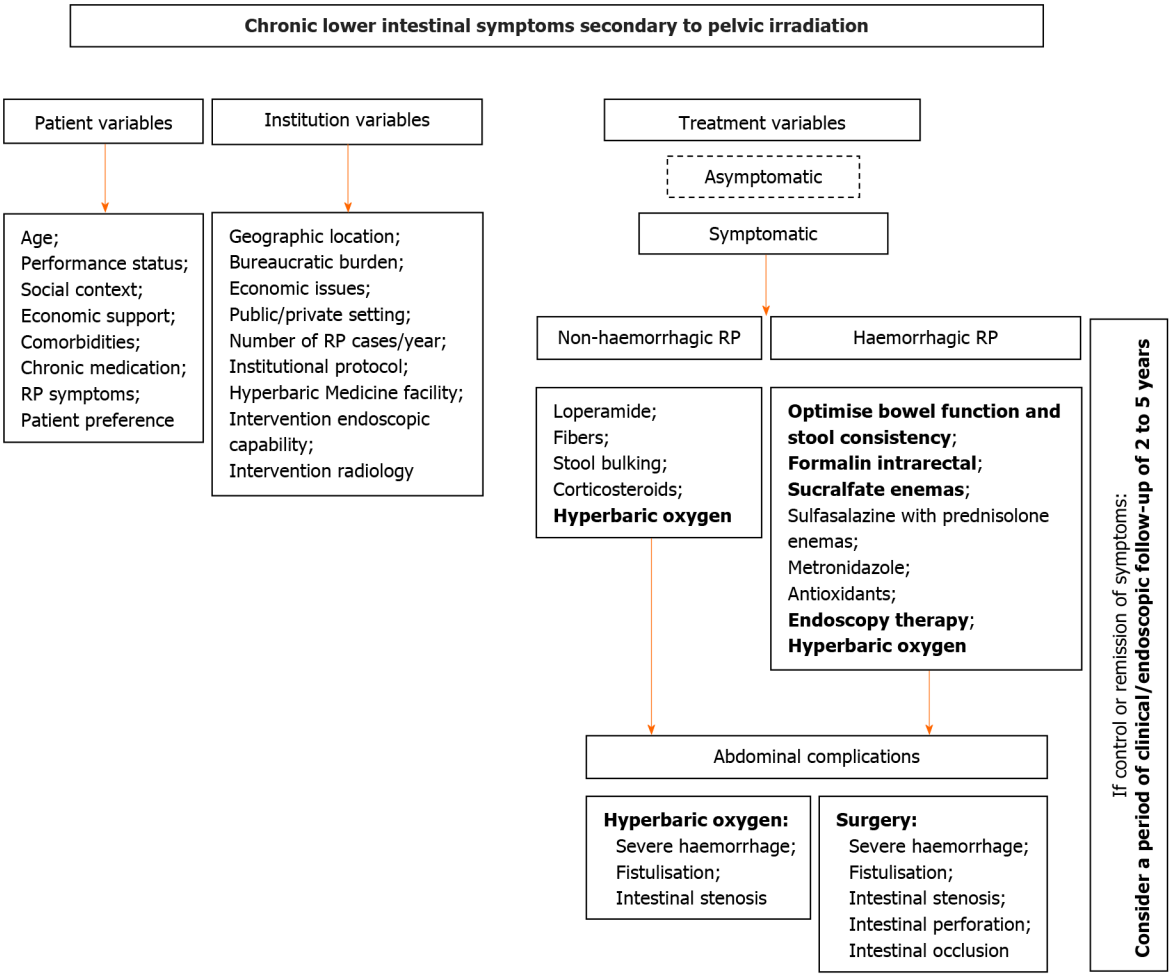

Figure 3 Suggested treatment algorithm for radiation proctitis based on variables related to the patient, institution, and the severity of the clinical context. RP: Radiation proctitis; RT: Radiotherapy.

habits could have been relevant in this trial (non-smoker or smoker ≤10 P-Y *vs* >10 P-Y); (7) The distribution of the subgroup of patients (n = 9; 11%) who did not complete the 40 treatment sessions in both arms of the clinical trial is unknown; (8) The endoscopic response to the recommended treatments is unknown; (9) The clinical and endoscopic evolution beyond the median follow-up period 13.2 (range 12.4-14.2) is also unknown. In HORTIS clinical trial[65] it was observed and additional and maintained response beyond 12 mo of the follow-up period; and (10) The absence of a third arm in the study comparing HBOT to another conventional treatment for RP.

We recommend that HBOT, combined with nutritional support and local treatment, may be beneficial for patients with moderate to severe symptoms that do not require surgical intervention. The HBOT regimen should include at least 20-30 sessions with a pressure of 2 to 2.5 ATA for 60 to 120 min/d to ensure a more effective clinical response. The treatment protocol total duration may be extended to several weeks until a clinical and radiological complete response is obtained, and the follow-up should be personalised to each clinical context, considering a period of 2 to 5 years (Figure 3).

CONCLUSION

Although there are several effective therapeutic strategies to treat RP and improve its clinical condition, gold standard management has not yet been established. RP's management approach must be personalised according to the patient, clinical condition severity, and the institution's experience. The most conservative treatment comprises diet modulation and nutritional support, oral and intrarectal pharmacological treatment and HBOT. Endoscopic treatment may be indicated for the control and treatment of lower gastrointestinal bleeding. In severe refractory disease with

complications, surgical intervention should be considered.

During HBOT, the occurrence of adverse events is relatively infrequent. HBOT may potentially alleviate gastrointestinal radio-induced complications, including rectal bleeding, diarrhoea and pain. The authors' expectancies are that, in the near future, the controversy regarding HBOT in RP will be dimmed. More prospective and randomised studies are needed to validate the effectiveness of HBOT in the 'real-world' clinical practice.

Retrospective Study

Multifocal autoimmune pancreatitis: A retrospective study in a single tertiary center of 26 patients with a 20-year literature review

Xin-Ming Huang, Zhen-Shan Shi, Cheng-Le Ma

ORCID number: Xin-Ming Huang 0000-0002-2354-8082; Zhen-Shan Shi 0000-0002-1544-9674; Cheng-Le Ma 0000-0002-0867-4347.

Author contributions: Huang XM did the imaging analysis and supervised all the procedures of this study; Shi ZS designed this study, wrote the main manuscript, revised the manuscript, and did statistical analysis; Shi ZS and Ma CL performed dynamic contrast enhanced-computed tomography scanning; Huang XM and Ma CL contributed equally.

Supported by the Science and Technology Committee of Fujian Province, No. 2016Y0039; and the Subsidizing Provincial Universities Project of Educational Commission of Fujian Province, No. JK2017019.

Institutional review board statement: This retrospective study was reviewed and approved by the Institutional Review Board of the First Affiliated Hospital of Fujian Medical University (Fuzhou, China), and written informed consent from patients was waived.

Informed consent statement: The study has obtained after each patient agreed to treatment by written consent.

Conflict-of-interest statement:

Abstract

BACKGROUND

Multifocal-type autoimmune pancreatitis (AIP), sometimes forming multiple pancreatic masses, is frequently misdiagnosed as pancreatic malignancy in routine clinical practice. It is critical to know the imaging features of multifocal-type AIP to prevent misdiagnosis and unnecessary surgery. To the best of our knowledge, there have been no studies evaluating the value of diffusionweighted imaging (DWI), axial fat-suppressed T1 weighted image (T1WI), and dynamic contrast enhanced-computed tomography (DCE-CT) in detecting the lesions of multifocal-type AIP.

AIM

To clarify the exact prevalence and radiological findings of multifocal AIP in our cohorts and compare the sensitivity of DWI, axial fat-suppressed T1WI, and DCE-CT for detecting AIP lesions. We also compared radiological features between multifocal AIP and pancreatic ductal adenocarcinoma with several key imaging landmarks.

METHODS

Twenty-six patients with proven multifocal AIP were retrospectively included. Two blinded independent radiologists rated their confidence level in detecting the lesions on a 5-point scale and assessed the diagnostic performance of DWI, axial fat-suppressed T1WI, and DCE-CT. CT and magnetic resonance imaging of multifocal AIP were systematically reviewed for typical imaging findings and compared with the key imaging features of pancreatic ductal adenocarcinoma.

RESULTS

Among 118 patients with AIP, 26 (22.0%) had multiple lesions (56 lesions).

Ulcerative colitis was associated with multifocal AIP in 7.7% (2/26) of patients, and Crohn's disease was present in 15.3% (4/26) of patients. In multifocal AIP, multiple lesions, delayed homogeneous enhancement, multifocal strictures of the main pancreatic duct, capsule-like rim, lower apparent diffusion coefficient values, and elevated serum Ig4 level were observed significantly more frequently than pancreatic ductal adenocarcinoma, whereas the presence of capsule-like rim in multifocal-type AIP was lower in frequency than total AIP. Of these lesions of multifocal AIP, DWI detected 89.3% (50/56) and 82.1% (46/56) by the senior and junior radiologist, respectively.

CONCLUSION
Multifocal AIP is not as rare as previously thought and was seen in 22.0% of our patients. The diagnostic performance of DWI for detecting multifocal AIP was best followed by axial fat-suppressed T1WI and DCE-CT.

Key Words: Autoimmune pancreatitis; Magnetic resonance imaging; Diffusion-weighted magnetic resonance imaging; Multidetector computed tomography; Pancreatic ductal adenocarcinoma; Ulcerative colitis

INTRODUCTION

Autoimmune pancreatitis (AIP) is a distinctive type of chronic pancreatitis generally characterized by an autoimmune inflammatory condition in which prominent lymphoplasmacytic infiltration with associated pancreatic fibrosis causes organ dysfunction[1]. Previous studies have shown that AIP is recognized as a heterogeneous disease classified into at least two subtypes, including lymphoplasmacytic sclerosing pancreatitis (type 1) and idiopathic duct-centric pancreatitis (type 2) with granulocytic epithelial lesions[2]. Meanwhile, AIP has also been classified radiologically as diffuse, unifocal, or multifocal[3-5]. Diffuse-type AIP is easily distinguished from pancreatic ductal adenocarcinoma (PDA) by typical imaging features, *i.e.* diffuse sausage-like swelling of pancreatic parenchyma with capsule-like peripancreatic rim[6,7]. Moreover, some studies[4,8] recently attempted to identify differential imaging findings between unifocal AIP and PDA by using computed tomography (CT), magnetic resonance imaging (MRI), or magnetic resonance cholangiopancreatography. Several key imaging landmarks, with reference to radiological morphology of the pancreatic mass lesion and stricture pattern of the main pancreatic duct (MPD), were clearly identified to be crucial to distinguish unifocal AIP from PDA. Hence, the differential diagnosis between unifocal AIP and PDA may not be as challenging as before.

However, multifocal-type AIP, sometimes forming multiple pancreatic masses, is frequently misdiagnosed as pancreatic malignancy in routine clinical practice[9,10]. It is critical to know the imaging features of multifocal-type AIP to prevent misdiagnosis and unnecessary surgery. Consequently, a clearer diagnostic consensus on the imaging characteristics of multifocal AIP is needed to differentiate from pancreatic malignancy. For this purpose, we herein report 26 cases of multifocal AIP and a review of the previous literature with an emphasis on CT and MRI imaging features that may help

definitively distinguish between multifocal AIP and PDA.

CT is the most commonly performed, noninvasive modality to evaluate both pancreatic and extrapancreatic manifestations in patients with suspected AIP[4,11]. In our experience and according to the previous literature, CT has certain limitations in showing some specific findings of focal AIP, *i.e.*, focal masses and focal MPD strictures, while these imaging findings seem to be more clearly demonstrated on MRI, especially on diffusionweighted imaging (DWI)[12]. In our previous study, we confirmed that axial T1 weighted image (T1WI) is the optimal sequence of identifying homogenously isoattenuating insulinoma on dynamic contrast enhanced-computed tomography (DCE-CT)[13]. Zhu *et al*[14] found that the appearance of multiple solid lesions can provide a diagnostic clue for identifying pancreatic nonmalignancies. Therefore, it is essential to find an optimal modality to identify pancreatic lesions as correctly as possible. To the best of our knowledge, there have been no studies evaluating the value of DWI, axial fat-suppressed T1WI, and DCE-CT in detecting the lesions of multifocal-type AIP.

We aimed to clarify the exact prevalence and radiological findings of multifocal AIP in our cohorts and compare the sensitivity of DWI, axial fat-suppressed T1WI, and DCE-CT for detecting AIP lesions. We also compared radiological features between multifocal AIP and PDA with several key imaging landmarks.

MATERIALS AND METHODS

Study population

This retrospective study was approved by the Institutional Review Board of the First Affiliated Hospital of Fujian Medical University (Fuzhou, China), and written informed consent from patients was waived. The clinical, radiological, and pathological databases at our hospital between January 2005 and July 2020 were reviewed. A total of 234 consecutive patients who had undergone DCE-CT on multidetector computerized tomography and conventional MRI imaging protocols on a 3T scanner within 5 wk of each other for suspected AIP were included. Of these initially suspected cases, we finally identified 118 patients who were diagnosed with AIP according to international consensus diagnostic criteria[15].

Among these confirmed patients, 26 patients with 56 lesions were retrospectively included in our study, based on the following inclusion criteria: (1) the use of DCE-CT with the acquisition on the pancreatic arterial, pancreatic parenchyma, and portal venous phases; (2) conventional MRI sequences, including both axial fat-suppressed T1WI and DWI before steroid treatment; and (3) multiple focal-type AIP. In criterion (3), the multiple focal-type was defined by the presence of two or more focal lesions observed on DCE-CT or MRI, and lesions of AIP were separate (*i.e.* continuous lesion that involves at least one segment of the pancreas was previously considered to be a single lesion[14] and were thus excluded from this study).

From January 2001 to July 2020, 908 patients underwent pancreatic curative-intent surgery for PDA at our institution. To enable a 1:2 matching with the multifocal AIP group, we randomly chose 112 [78 men and 34 women; mean age ± SD, 61 ± 8.7 years (range: 38-86 years)] among the 613 patients with PDA who also underwent both DCE-CT and conventional MRI before surgery, using Statistic Package for Social Science software to generate the random numbers.

Imaging examinations

CT protocols: DCE-CT examinations were performed using 16-, 80-, or 320-detector CT scanner (Aquilion; Toshiba Medical Systems, Tokyo, Japan), using the following pancreatic scanning parameters: (1) detector collimation, 320.0 mm × 0.5 mm, 80.0 mm × 0.5 mm or 16.0 mm × 0.5 mm; (2) pitch, 1.0-1.4; (3) gantry rotation time, 0.35-0.50 s; (4) tube voltage, 120 kV; and (5) pancreatic reference tube current, 80-120 mA. All images were routinely reconstructed from the contrast-enhanced CT scans with thin-section images (slice thickness = 0.75-1.00 mm, reconstruction increment = 0.5 mm). Unenhanced and DCE-CT including the arterial, pancreatic parenchymal, and portal venous phases were acquired before and after intravenous administration of contrast agent. After unenhanced CT scanning, 300 mg/mL iodine (Ultravist 300; Schering; Bayer Healthcare Pharmaceuticals, Leverkusen, Germany) was injected intravenously using a power injector *via* an 18-gauge plastic antecubital catheter. An iodine dose of 1.5 mL/kg body weight was given at a flow rate of 4 mL/s. The administration of contrast agent was immediately followed by a flush of 30 mL saline. To accurately determine the timing for the standard triple-phase pancreatic imaging, a scanning

delay was performed based on an automated bolus-tracking technique offered by the supplier of the Toshiba CT system. Three phases enhanced scanning were obtained at a fixed delay of 20- to 25-s, 40- to 50- s, and 80- to 90-s after the contrast agent injection.

MR protocols: The MRI examinations were conducted using a 3.0 T imaging system (Magnetom Trio; Siemens Healthineers, Erlangen, Germany) with an 8-channel phased-array coil. The routine MR sequences for imaging the pancreas, including axial fat-suppressed T1-weighted turbo spin echo sequence, coronal T2-weighted (half-Fourier acquisition single-shot turbo spin echo) sequence, axial fat-suppressed T2-weighted turbo spin echo sequence, axial T1-weighted in-phase and out-of-phase sequences with fixed echo times of 1.4 and 2.8 ms, respectively, and DWI were performed at our institution. Axial single-shot echo-planar DWI sequence was completed using the following scanning parameters: repetition time, 6900 ms; echo time, 73 ms; intersection gap, 6 mm; slice thickness, 3 mm; field of view, 350 mm × 350 mm; matrix size, 128 mm × 128 mm; flip angle, 90°; partial Fourier factor, 6/8; parallel imaging reduction factor, 2; bandwidth, 2441 Hz per pixel; and the number of excitations, 8 (water excitation technique with b-value of 50 s/mm^2 and 800 s/mm^2). Axial fat-suppressed T1WI was performed with the following parameters: echo time, 1.4 ms; repetition time, 3.9 ms; flip angle 9°; slice thickness, 3 mm; matrix, 320 mm × 182 mm; field of view, 250 mm × 280 mm; and the number of excitations, 1. DWI and axial fat-suppressed T1WI sequences were performed with breath hold and free breathing, respectively. The main scan parameters of the MR sequences were presented in our earlier paper[13]. Apparent diffusion coefficient values (ADC) maps were automatically generated from DW images, and ADC values were calculated on a Syngo workstation (Syngo Multimodality Workplace; Siemens Healthineers). One radiologist, who had precise knowledge of the lesion's location based on the overall findings from the radiological images and pathological and surgical datasets, retrospectively manually drew and placed the largest possible regions of interest within the pancreatic lesion and surrounding parenchyma. ADC values of pancreatic lesions were measured and compared with the surrounding parenchyma.

Image analysis: The detection of each multifocal AIP lesion was divided into three image sets: axial fat-suppressed T1WI, DWI, and DCE-CT. Each image set was independently analyzed on a picture archiving and communication workstation (Shida picture archiving and communication system, Fuzhou, China) with the free adjustment of window width and level by two abdominal radiologists (21 and 7 years of experience in interpreting abdominal CT/MRI). The two radiologists knew that this study was being conducted to detect the lesions of multifocal AIP but were unaware of any clinical information, biological data, other conventional imaging findings, histopathological, and surgical results. The radiologists identified the absence or presence of the lesion with a 5point diagnostic confidence scales as follows: Score 1, definitely absent; Score 2, probably absent; score 3, indeterminate; Score 4, probably present; and Score 5, definitely present. In cases with diagnostic confidence score of 4 or 5, a lesion was present, and the location of the lesion was recorded on a report sheet. The signal intensity of the lesion was assessed on axial fat-suppressed T1WI and DWI image sets compared with the surrounding parenchyma and was categorized as low, intermediate, or high.

One month after the completion of the detection rating for all patients of multifocal AIP, two radiologists subsequently analyzed the DCE-CT and MRI images of all 168 patients (56 AIP and 112 PDA) in a random sequence and determined, in consensus, the absence or presence of the following characteristic imaging features as previous reports[4,16-18] for differentiating between AIP and PDA: multiple pancreatic masses; ill-defined margin; delayed homogeneous enhancement; capsule-like rim; marked upstream MPD dilation; upstream pancreatic atrophy; multiple MPD strictures; and extrapancreatic manifestations, including vascular invasion, peripancreatic fat infiltration, and peripancreatic and retroperitoneal lymphadenopathy.

Laboratory data: The serum immunoglobulin G fraction 4 (IgG4) concentrations, if available, were carefully recorded.

Statistical analysis

Statistical analysis was performed using Statistic Package for Social Science (version 19.0; IBM Corp., Armonk, NY, United States) software. Quantitative variables were summarized as the mean ± SD. Descriptive variables were determined using percentages and medians. The Wilcoxon signed rank test was performed to analyze the mean ADC values in multifocal AIP lesions and the surrounding parenchyma and to compare the ADC values in multifocal AIP and PDA. Prior to determining the

agreement between the two radiologists with respect to confidence ratings for a detection task of multifocal AIP lesions, κ-values were used to assess interobserver agreement interpreted as follows: 0.81-1.00, excellent agreement; 0.61-0.80, good agreement; 0.41-0.60, moderate agreement; and 0.21-0.40, fair agreement[19,20]. Friedman's nonparametric test was performed to evaluate the differences of diagnostic confidence level among axial fat-suppressed T1WI, DWI, and DCE-CT image sets for each radiologist. The frequency of the characteristic imaging findings for differentiating multifocal AIP from PDA was compared *via* the chi-squared or McNemar's test, as appropriate. A two-tailed P value of < 0.05 was deemed to be a statistically significant difference.

RESULTS

Overall profile of 26 patients with multifocal AIP at our center

Clinical findings: From 26 patients, 18 were female, and 8 were male. The median age was 60.7 ± 17.0 years (range: 26-89 years). Among 118 patients with AIP, 54 (45.8%) showed diffuse-type AIP, 38 (32.2%) showed unifocal-type AIP, and twenty-six cases (22.0%) showed multifocal-type AIP. Of the 26 patients with multifocal-type AIP, 4 (15.3%) were associated with Crohn's disease, and 2 (7.7%) were associated with ulcerative colitis (Figure 1). A total 56 lesions were found in these 26 patients with multifocal AIP. Twenty-two patients had two lesions, and four patients had three lesions. The lesions of 16 patients were in the pancreatic head/uncinate process and tail. The lesions of 6 patients were in the pancreatic head and body; 4 patients with 3 lesions each were in the pancreatic head, body, and tail. Pancreatic tissue samples were obtained in 18 patients (69.2%) including three from surgical resection, five from endoscopic ultrasound-guided fine-needle aspiration biopsy, and ten from CT guided percutaneous biopsy. All patients were affected by type 1 AIP.

The serum concentrations of IgG4 (0.03-2.01 g/L) were elevated above the normal limit in 94.9% (112/118) of the patients with AIP, 96.2% (25/26) of the patients with multifocal-type AIP, 96.3% (52/54) of the patients with diffuse-type AIP, and 92.1% (35/38) of the patients with unifocal-type AIP. The mean serum concentration of IgG4 of the patients with multifocal-type AIP was 14.77 ± 8.05 g/L. IgG4 levels were not elevated in 53 patients with PDA, and the remaining 59 patients with PDA had no measurement of serum IgG4 before surgery.

Treatment and relapse of patients with multifocal-type AIP: Initial treatment of all patients with multifocal AIP consisted of steroid therapy in 23 patients (88.5%) or surgical resection in three patients (11.5%). After the diagnosis was rendered, 22 patients received treatment with high-dose steroid. They received an intravenous injection of daily methylprednisolone 40-80 mg for 3 to 7 d, after which 10-20 mg of oral prednisone was given per day. During the median 8.6 mo (interquartile range: 5.1 to 23.0 mo) of follow-up, all patients who underwent steroid treatment with/without surgical resection showed complete radiological and clinical remission. The remaining 4 patients refused steroid treatment and were lost to follow-up.

Diagnostic performances of DWI, axial fat-suppressed T1WI, and DCE-CT

The senior and junior radiologist detected 50/56 and 46/56 lesions on DWI, 34/56 and 38/56 on axial fat-suppressed T1WI, and 22/56 and 24/56 on DCE-CT, respectively. DWI MRI had the highest relative sensitivity [4650/56 (82.1%89.3%) lesions] in the detection of lesions in multifocal AIP (Figures 2 and 3).

Statistically significant differences of the confidence level score were observed among these three image sets for the two radiologists. Diagnostic confidence level score of DWI alone was the highest, while that of DCE-CT was the lowest for each radiologist (Table 1). Weighted κvalues that rated the confidence levels of the readers in terms of image interpretation are summarized in Table 2. Good interobserver agreement was observed between the two radiologists for determining the presence or absence of lesions on DWI datasets (weighted κ = 0.878). Moderate interobserver agreement was observed between two readers on axial fat-suppressed T1WI and DCE-CT image datasets (weighted κ = 0.742 and weighted κ = 0.683, respectively).

The mean ADC values ($\times 10^{-3}$ mm^2/s) of multifocal AIP lesions and the surrounding pancreatic parenchyma were 0.96 ± 0.14 (range: 0.681.26) and 1.15 ± 0.15 (range: 0.891.40), respectively. ADC values of the AIP lesions were significantly lower compared with those of the surrounding pancreatic parenchyma according to the Wilcoxon signedrank test (P = 0.001; Table 3).

Table 1 Friedman analysis of variance by ranks for the diagnosis confidence level score

Groups	Junior radiologist	Senior radiologist
DWI	2.32	2.32
Axial-suppressed T1WI	1.95	2.07
Dynamic contrast enhanced CT	1.73	1.61
P value	0.033	0.004

CT: Computed tomography; DWI: Diffusionweighted imaging; T1WI: T1 weighted image.

Table 2 Interobserver agreement in image interpretation

Groups	*κ*-value
DWI	0.878
Axial fat-suppressed T1WI	0.742
Dynamic contrast enhanced CT	0.683

CT: Computed tomography; DWI: Diffusionweighted imaging; T1WI: T1 weighted image.

Table 3 Apparent diffusion coefficient values of autoimmune pancreatitis lesions compared with those of surrounding pancreatic tissue[1]

	AIP lesions ADC	Surrounding parenchyma ADC	Wilcoxon signed-rank test	
	Values (n = 56) ($\times 10^{-3}$ mm^2/s)	Values (n = 56) ($\times 10^{-3}$ mm^2/s)	Z value	P value
Mean	0.96	1.15	-5.11	0.001
SD	0.14	0.15		
Median	0.96	1.16		
Minimum	0.68	0.89		
Maximum	1.26	1.40		

[1]Apparent diffusion coefficient values in autoimmune pancreatitis lesions were lower (0.96 ± 0.14) compared with those in the surrounding pancreatic parenchyma (1.15 ± 0.15), Wilcoxon signed-rank test demonstrated this difference to be statistically significant (P = 0.001). ADC: Apparent diffusion coefficient; AIP: Autoimmune pancreatitis; SD: Standard deviation.

Evaluation of radiological findings between multifocal-type AIP and PDA

Fifty-six patients with multifocal-type AIP and 112 patients with PDA were compared. The differences in the imaging features between multifocal-type AIP and PDA are summarized in Table 4. Multifocality (100% *vs* 1.7%, $P < 0.01$), capsule-like rim (21.4% *vs* 3.6%, $P < 0.01$), multiple MPD strictures (47.3% *vs* 1.8%, $P < 0.01$), and delayed homogeneous enhancement (92.8% *vs* 13.4%, $P < 0.01$) were significantly more frequent in multifocal AIP. Peripancreatic fat infiltration (46.4% *vs* 91.0%, $P < 0.01$), vascular invasion (14.3% *vs* 71.4%, $P < 0.01$), upstream pancreatic atrophy (19.6% *vs* 58.9%, $P < 0.01$), peripancreatic and retroperitoneal lymphadenopathy (3.6% *vs* 61.6%, $P < 0.01$), and marked upstream MPD dilatation (3.6% *vs* 52.7%, $P < 0.01$) were significantly more frequent in PDA than in multifocal AIP. ADC values of the multifocal AIP lesions were significantly lower than that of PDA. However, the indistinct margin between multifocal AIP and PDA was not statistically different. Furthermore, the capsule-like rim was present with a lower frequency (21.4%) in multifocal AIP in our study. Additionally, three multifocal AIP patients underwent ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography/CT, and increased FDG uptake was noted in seven lesions in the whole pancreas (Figures 2 and 3).

Table 4 Comparison of radiological findings between patients with multifocal autoimmune pancreatitis and pancreatic ductal adenocarcinoma, *n* (%)

	Multifocal AIP	PDA	*P* value
No. of radiological findings of the pancreas	56	112	
Multifocal lesion	56 (100)	2 (1.7)	< 0.01
Capsule-like rim	12 (21.4)	4 (3.6)	< 0.01
Delayed homogeneous enhancement on MDCT	52 (92.8)	15 (13.4)	< 0.01
Margin (indistinct)	48 (85.7)	89 (79.5)	0.325
Peripancreatic fat infiltration	26 (46.4)	102 (91.0)	< 0.01
Vascular invasion	8 (14.3)	80 (71.4)	< 0.01
Multiple MPD strictures	53 (47.3)	2 (1.8)	< 0.01
Marked upstream MPD dilatation	2 (3.6)	59 (52.7)	< 0.01
Upstream pancreatic atrophy	11 (19.6)	66 (58.9)	< 0.01
Lymphadenopathy	2 (3.6)	69 (61.6)	< 0.01
ADC values ($\times 10^{-3}$ mm^2/s)	0.96 ± 0.16	1.15 ± 0.14	< 0.01

ADC: Apparent diffusion coefficient; AIP: Autoimmune pancreatitis; MDCT: Multidetector computed tomography; MPD: Main pancreatic duct; MRI: Magnetic resonance image; PDA: Pancreatic ductal adenocarcinoma.

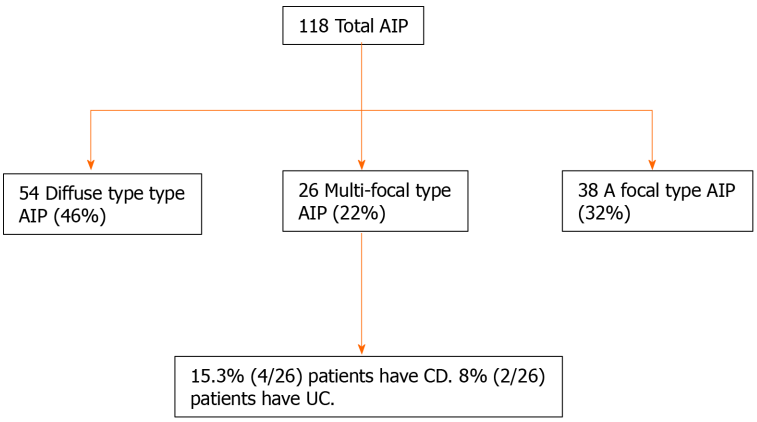

Figure 1 Flowchart of patients with multifocal autoimmune pancreatitis have Crohn's disease and ulcerative colitis. AIP: Autoimmune pancreatitis; CD: Crohn's disease; UC: Ulcerative colitis.

DISCUSSION

AIP is an uncommon form of chronic pancreatitis that typically affects men in their fifth to sixth decades and usually presents with pancreatic enlargement and obstructive jaundice, with a reported incidence rate of up to 6% in chronic pancreatitis patients[1,21,22]. The most common radiological manifestation of AIP is a grossly enlarged sausage-shaped hypoattenuating pancreas with homogeneous decreased enhancement at the arterial phase and delayed rim-like enhancement at the portal venous phase. The unifocal form of AIP at the pancreatic head is by far the second-most common type[6]. As in our cases, the most uncommon type is the multifocal form that has only been described in a few reports[3,10,23]. All patients with multifocal AIP in our study were type 1 and responded well to steroid therapy, consistent with previous study results.

In this cohort of 118 patients of AIP, 22.0% showed multifocal-type AIP, suggesting it is not as uncommon as previously thought in actual clinical practice. One possible reason for overlooking is the radiologists have been extremely unfamiliar with its characteristic imaging features. Another possible reason may be attributed to some CT and MR imaging findings of unifocal-type or diffuse-type AIP may overlap with multifocal-type AIP. It has also been hypothesized that different diagnostic

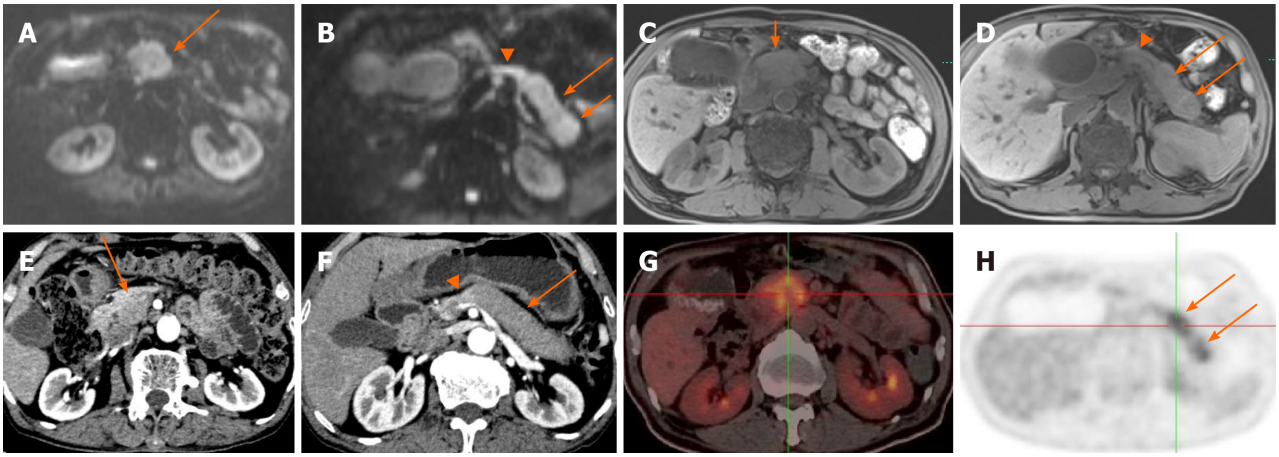

Figure 2 A 72-year-old man with multifocal autoimmune pancreatitis. A-D: Diffusionweighted imaging and axial fat-suppressed T1 weighted image showed three indistinct mass-like swelling (arrows) in the pancreatic head, body, and tail; E: The pancreatic head lesion (arrow) could not be clearly shown on dynamic contrast enhanced-computed tomography; F: Dynamic contrast enhanced-computed tomography could only show a merged lesion in the pancreatic body/tail (arrow); G-H: Positron emission tomography-computed tomography images showed three focal intense uptakes of fluorodeoxyglucose in the whole pancreas, which were not detectable on dynamic contrast enhanced-computed tomography. B, D, and F: The computed tomography and magnetic resonance images demonstrated relatively normal volume of pancreas (arrowheads) in the pancreatic neck.

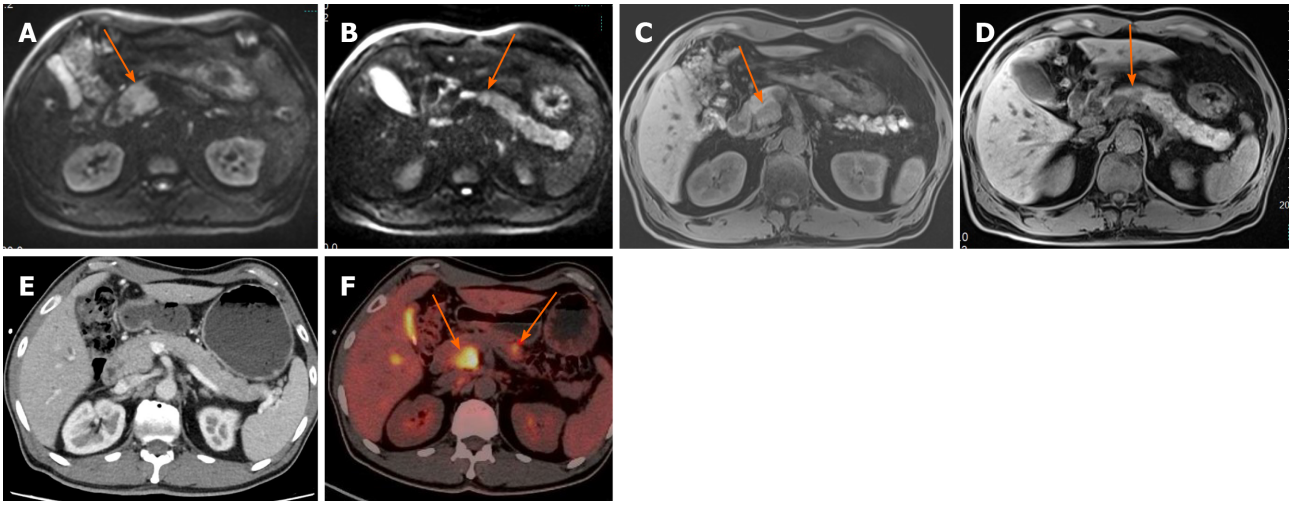

Figure 3 A 68-year-old man with multifocal autoimmune pancreatitis. A-D: Diffusionweighted imaging and axial fat-suppressed T1 weighted image showed two indistinct mass-like swelling (arrows) in the pancreatic head and body; E and F: Positron emission tomography-computed tomography image showed two focal intense uptakes of fluorodeoxyglucose in the pancreatic head and body, which were not detectable on dynamic contrast enhanced-computed tomography.

approaches in China may greatly contribute to the relatively lower incidence rate of multifocal AIP.

Current diagnostic methods available for the differentiation of pancreatic lesions are various, among which contrast-enhanced ultrasonography, endoscopic ultrasonography (EUS), contrast enhanced-CT, contrast enhanced-MRI, contrast-enhanced elastography, EUS-fine-needle aspiration, and contrast enhanced-EUS have been widely used in recent years. As one of the current gold standards for diagnosis of pancreatic neoplasms, EUS- fine-needle aspiration with 100% specificity can correctly access the pathological diagnosis directly. In addition, an accurate tissue diagnosis based on a EUS- fine-needle aspiration biopsy specimen may render surgery for those benign neoplasms or indolent cancer unnecessary. However, the best method for pancreatic mass diagnosis remains unclear[24]. In our country, DCE-CT, diagnostic endoscopic retrograde pancreatography, endoscopic biopsy, and the following therapeutic trial of steroids have been more actively conducted in the management of patients with suspected AIP than before[9,14,25]. Multifocal AIP can be mistakenly classified as diffuse or unifocal AIP when only using CT, as our study results showed that DWI and axial fat-suppressed T1WI have higher sensitivity than DCE-CT to find AIP lesions.

A literature search with the medical subject headings term 'autoimmune pancreatitis' in PubMed, Wanfang Database, and the China National Knowledge Infrastructure was performed by authors (Zhen-Shan Shi) on August 8, 2020. The reference lists of relevant studies were searched to identify other additional eligible articles. A PubMed search of the past 20 years revealed 783 articles describing focal-type AIP in the English and Chinese literature. However, most reported studies of focal AIP have focused on the imaging features of unifocal and not multifocal; only 18 articles involved the imaging features of multifocal-type AIP. Most of these studies were small case series or single case reports. A total of 132 cases of multifocal AIP, including our current cases, were retrospectively analyzed and summarized in the present study. We found that multifocal AIP accounted for 22% of total AIP, and most patients presented above the age of 60 years with more females than males[1,21]. The gender difference of multifocal AIP was not consistent with that of total AIP with more males than females.

In our study, 23.3% of multifocal AIP patients had associated IBDs (15.3% had Crohn's disease, and 7.7% had ulcerative colitis) and were type 1 AIP. Most cases with coexisting AIP and IBD were type 2 AIP in the previous studies[2,26]. The possible reason is type 1 AIP is significantly more frequent in East Asia, and type 2 AIP generally prevails in Western countries[26]. Our data suggest that elevated serum IgG4 concentrations are also helpful in identifying multifocal AIP, like in previous studies[4,27].

This study confirmed the high sensitivity (82%89%) of DWI for the detection of AIP lesions[7,28], which also provided an important contribution to the highest radiologist diagnostic confidence score and the highest level of interobserver agreement (weighted κ = 0.878) between the two radiologists and also demonstrated that DWI was the optimal image sequence among the three image sets (DWI, axial fat-suppressed T1WI, and DCE-CT). We speculate that the lowest confidence score and interobserver agreement of DCE-CT between the two radiologists with different experience may be due to the inferior resolution in showing the slight difference of CT value between AIP lesions and the surrounding pancreas, which may make images more difficult to interpret than with DWI and axial fat-suppressed T1WI. Conversely, MRI has the excellent soft tissue contrast resolution, and DWI has outstanding imaging capability to detect pancreatic focal lesions, even minor lesions[29,30].

A significant difference in ADC value was also found between multifocal AIP lesions and the surrounding pancreas, similar to the results of unifocal-type AIP[4]. We hypothesize that DWI, which can be conducted without contrast media and in a relatively short time, will become a crucial imaging technique in the detection of AIP lesions.

Our present study showed that seven key distinguishing features of PDA and multifocal AIP were as follows among various CT and MR findings, particularly for multifocal AIP: (1) multiple pancreatic lesions; (2) hypoattenuating capsule-like rim; (3) delayed homogeneous good enhancement; (4) absence of distal pancreatic atrophy; (5) mild upstream MPD dilatation; (6) multiple MPD strictures; and (7) a lower ADC value are more frequently observed in multifocal AIP like other prior reports of unifocal-type AIP, which could be deemed reliable findings to prevent unnecessary invasive procedures and surgical treatment in the management of the suspected patients.

On the contrary, peripancreatic fat infiltration, vascular invasion, and peripancreatic and retroperitoneal lymphadenopathy are more often observed in PDA. Additionally, even with ^{18}F-FDG-positron emission tomography/CT examination, when the pancreatic lesion is accurately localized, it can be often confused with PDA because it has been recently reported to show increased FDG uptake at the locally affected lesions of AIP[31-33], which is also an observation from our study. We consider that the use of these seven key differentiating features can be helpful in supporting the diagnosis of AIP when the clinical, laboratory, and other imaging features are equivocal for distinguishing between focal-type AIP and PDA.

We found that there was no statistically significant difference between multifocal AIP and PDA with respect to ill-defined margin, as in previous studies[4,16]. The capsule-like rim or halo sign has already been reported as a specific feature of AIP, with a varying frequency up to 63%[5,14,34]. This sign was observed with lower frequency (21%) in multifocal AIP in our study. We presume that multifocal-type AIP is the early manifestation of AIP, and the multiple lesions will be merged into diffuse-type along with the progression of this entity. Then, typical or uncommon imaging features will be typical, and the halo sign may be more frequently seen. However, further work is needed to confirm this hypothesis.

Our study has a few limitations. First, this study was performed by a retrospective research design, and the number of cases is relatively small. However, AIP itself is a rare entity, and multifocal AIP is even rarer. Second, the incidence rate of multifocal AIP in this study was at a single tertiary center with a specialized care clinic that has been widely recognized for its expertise and experience with pancreatic diseases in our country and may confer a considerable potential referral bias with an overestimated frequency of multifocal AIP. Third, the blinded radiologists had initially determined patient diagnosis in daily clinical practice; recall bias might have occurred. Last, we used a variety of CT scanners with different detectors (*e.g.*, 320-, 80- and 16- detectors) from the same manufacturer with scan parameters that slightly varied from each other, which may affect the diagnostic performance among these modalities.

CONCLUSION

In conclusion, multifocal AIP is not as rare as previously thought. DWI as part of pancreatic conventional MRI protocol has the potential benefit in the detection of AIP lesions. The combinations of CT and MRI imaging features may be helpful for differentiating multifocal AIP from PDA by the key distinguishing findings, including multiple pancreatic lesions, capsule-like rim, delayed homogeneous enhancement, multiple MPD strictures, and lower ADC values.

ARTICLE HIGHLIGHTS

Research background

Multifocal-type autoimmune pancreatitis (AIP), sometimes forming multiple pancreatic masses, is frequently misdiagnosed as pancreatic malignancy in routine clinical practice. It is critical to know the imaging features of multifocal-type AIP to prevent misdiagnosis and unnecessary surgery. To the best of our knowledge, there have been no studies evaluating the value of diffusionweighted imaging (DWI), axial fat-suppressed T1 weighted image (T1WI), and dynamic contrast enhanced-computed tomography (DCE-CT) in detecting the lesions of multifocal-type AIP.

Research motivation

The key issue is whether CT and magnetic resonance imaging features of multifocal-type AIP can help definitively distinguish from pancreatic ductal adenocarcinoma (PDA) and whether there is an optimal modality to identify pancreatic lesions as correctly as possible. The results will provide important information on the diagnostic performances of DWI, axial fat-suppressed T1WI, and DCE-CT and the key imaging features for differentiating multifocal-type AIP from PDA.

Research objectives

We aimed to clarify the exact prevalence and radiological findings of multifocal AIP in our cohorts and compare the sensitivity of DWI, axial fat-suppressed T1WI, and DCE-CT for detecting AIP lesions. We also compared radiological features between multifocal AIP and PDA with several key imaging landmarks.

Research methods

Twenty-six patients with proven multifocal AIP were retrospectively included. Two blinded independent radiologists rated their confidence level in detecting the lesions on a 5-point scale and assessed the diagnostic performance of DWI, axial fat-suppressed T1WI, and DCE-CT. CT and magnetic resonance images of multifocal AIP were systematically reviewed for typical imaging findings and compared with the key imaging features of PDA.

Research results

Among 118 patients with AIP, 26 (22.0%) had multiple lesions (56 lesions). Ulcerative colitis was associated with multifocal AIP in 7.7% (2/26) of patients, and Crohn's disease was associated in 15.3% (4/26) of patients. In multifocal AIP, multiple lesions, delayed homogeneous enhancement, multifocal strictures of main pancreatic duct, capsule-like rim, lower apparent diffusion coefficient values, and elevated serum Ig4 Level were observed significantly more frequently than in PDA, whereas the presence

of capsule-like rim in multifocal-type AIP was lower in frequency than total AIP. Of these lesions of multifocal AIP, DWI detected 89.3% (50/56) and 82.1% (46/56) by the senior and junior radiologist, respectively.

Research conclusions

Multifocal AIP is not as rare as previously thought and was seen in 22% of our patients. The diagnostic performance of DWI for detecting multifocal AIP was best followed by axial fat-suppressed T1WI and DCE-CT.

Research perspectives

Larger and longer term prospective studies to investigate the important radiological findings for differential diagnosis between multifocal AIP and PDA should be performed in future studies.

Abstract

BACKGROUND

Computed tomography colonography (CTC) may be superior to colonoscopy and barium enema for detecting diverticula. However, few studies have used CTC to diagnose diverticula.

AIM

To evaluate the current prevalence and distribution of colonic diverticula in Japan using CTC.

METHODS

This study was conducted as part of the Japanese National Computed Tomographic Colonography Trial, which included 1181 participants from 14 hospitals in Japan. We analyzed the prevalence and distribution of colonic diverticula and their relationships with age and sex. The relationship between the diverticula and the length of the large intestine was also analyzed.

RESULTS

Diverticulosis was present in 48.1% of the participants. The prevalence of diverticulosis was higher in the older participants ($P < 0.001$ for trend). The diverticula seen in younger participants were predominantly located in the right-sided colon. Older participants had a higher frequency of bilateral type (located in the right- and left-sided colon) diverticulosis ($P < 0.001$ for trend). The length of the large intestine with multiple diverticula in the sigmoid colon was significantly shorter in those without diverticula ($P < 0.001$).

CONCLUSION

The prevalence of colonic diverticulosis in Japan is higher than that previously reported. The prevalence was higher, and the distribution tended to be bilateral in older participants.

Key Words: Computed tomography colonography; Diverticulosis; Diverticular disease; Colon

INTRODUCTION

Colonic diverticulosis is a common abnormality of the colon. Almost all colonic diverticula are pseudodiverticula, which are small outpouchings of the colonic mucosa and submucosa that herniate through the muscle layers at sites of vascular perforation [1]. Diverticulosis refers to asymptomatic diverticula, whereas diverticular disease

L-Editor: A
P-Editor: Xing YX

refers to symptomatic diverticula. Diverticular disease is classified into uncomplicated and complicated diseases, including perforation, fistulae, obstructions, and bleeding [1]. The cumulative incidences of bleeding and diverticulitis in patients with colonic diverticulosis are 10% and 10%-25%, respectively[2,3]. Additionally, the prevalence of colonic diverticulosis increases with age[1,4,5]. Due to Japan's aging population, the incidence of diverticular diseases in older patients who need treatment will also likely increase[6].

Findings from studies involving colonoscopy or barium enema have shown that the prevalence and distribution of diverticulosis differ according to country, region, and race[7-11]. These reports are from the early 2000s until the mid-2010s, and also reported that the incidence of diverticula increased with time[5,8]. Colonic diverticula occur mainly in the left colon in Western populations and in the right colon in Japanese and other Asian populations[7-9,11,12]. Recent studies have reported that the overall prevalence of diverticulosis in Japan is 20%-26.0%[5,7,8].

Colonoscopy is a standard technique that is widely performed for the screening and diagnosis of colonic and rectal diseases. However, there are reports suggesting that compared to colonoscopy, assessments based on barium enema are superior for diagnosing colonic diverticula, especially in the sigmoid colon[13,14]. In recent years, computed tomography colonography (CTC) has been widely used as an alternative colon cancer screening method. CTC can detect diverticula as outpouchings of the colonic wall from a more advantageous perspective, and it may be superior to colonoscopy and barium enema for detecting diverticula. Only one large study has evaluated the prevalence and distribution of colonic diverticula using CTC[15]. Hence, this study is the largest study in the world and is the first to accurately evaluate the prevalence and distribution of colonic diverticula in Japanese patients using CTC.

MATERIALS AND METHODS

This study was conducted as a part of another study on the application of CTC for detecting polypoid lesions [Japanese National Computed Tomographic Colonography Trial (JANCT)][16]. The trial was registered with Clinical Trials. gov (No. NCT00997802) and the UMIN Clinical Trials Registry (No. UMIN000002097). The medical ethics committee of Fukushima Medical University reviewed and approved the study design. The JANCT data were analyzed using the Digital Imaging and Communications in Medicine protocol. Patients from 14 hospitals in Japan were enrolled between September 2009 and August 2011. This study was conducted in accordance with the principles of the Declaration of Helsinki. The institutional review board of each hospital approved the study. All patients provided written informed consent prior to enrollment. The patients included in this study underwent CTC for screening purposes or because they had abdominal symptoms, positive fecal immunochemical test (FIT) results, a personal history of polyps, or a familial history of colorectal cancer (CRC) or polyps. Moreover, 847 participants were screened, 96 for abdominal symptoms or change in bowel habits, 165 for positive FIT, 42 for melena or hematochezia, 11 for surveillance after polypectomy, and 19 for abnormal blood test results (anemia or tumor marker elevation). The exclusion criteria have been described in detail previously[16]. Briefly, participants with serious medical conditions for bowel preparation and colonoscopy or CTC, who underwent colonoscopy or barium enema during the preceding 3 years, with known colorectal polyps or cancers, a history of inflammatory bowel disease, and familial polyposis, and who underwent colorectal surgery were excluded from the study.

Computed tomography colonography

Details of the CTC procedure have been previously published[16]. A polyethylene glycol electrolyte lavage solution (Niflec; Ajinomoto Pharmaceuticals, Tokyo, Japan) was used for bowel preparation, and contrast medium containing sodium diatrizoate (Gastrografin; Bayer Yakuhin, Osaka, Japan) was added to tag the residual fluid. A tube was inserted while the patients were in the left decubitus position before CO_2 insufflation and CTC scanning. CO_2 insufflation was performed using an automated CO_2 insufflator (HP-2; Horii Pharmaceutical Industries, Ltd., Osaka, Japan). All CTC examinations were performed using 64- or 16-channel multidetector row computed tomography (CT) scanners. CT scanning was performed under single breath-holds while the patients were in the supine and prone positions.

Evaluation of the diverticula using computed tomographic colonography

Four radiologists and six gastroenterologists participated in this study as readers of the CTC images. The readers analyzed CTC images from a median of 1750 patients (range: 400–8000 patients). Identification of the colonic diverticula and measuring the length of the large intestine were performed at workstations at each hospital, namely: AZE Virtual Place (AZE, Tokyo, Japan), Synapse Vincent (Fujifilm Medical Co., Tokyo, Japan), and Ziostation (Ziosoft, Tokyo, Japan). Axial 2-dimensional (2D) images, captured while the patients were in the supine position, were primarily used to determine the number of diverticula. A diverticulum was identified as an outpouching from the colonic wall. If necessary, other 2D and 3-dimensional (3D) images, comprising luminal fly-through or air-contrast barium enema images, were analyzed (Figure 1). The readers recorded the number of diverticula in each colonic segment, including the cecum and as well as the ascending, transverse, descending, sigmoid, and rectosigmoid colons. The rectosigmoid colon was defined as the segment between the promontrium and the inferior margin of the second sacral vertebra. Diverticula in the terminal ileum and appendix were also evaluated. The terminal ileum was defined as the portion of the ileum 10 cm from the ileocecal valve. If there were < 20 diverticula, the readers recorded the numbers as is; if there were > 20 diverticula, the readers recorded their findings as severe. When diverticula were found in multiple colonic segments, we evaluated the number of diverticula in each segment in duplicate. In analysis, the grading of diverticula was in accordance with a previous study to allow for comparison with the previous study[15]. The number of diverticula was graded in each segment: 1-5 diverticula were classified as rare, 6-20 diverticula were classified as multiple, and more than 20 diverticula were classified as severe. The length of the large intestine was defined as the distance from the anus to the appendiceal orifice and was measured automatically using 3D workstations.

Endpoints

The primary endpoint of this study was to clarify the prevalence of colonic diverticulosis by CTC and to evaluate it by sex, age group, and segment. There were two secondary endpoints; the first of which was to investigate the prevalence of diverticulosis in the terminal ileum and appendix (which have not been evaluated accurately so far), and the second was to investigate the relationship between diverticulosis and the length of the large intestine.

Statistical analyses

Continuous variables are reported as medians and ranges. To evaluate differences in the prevalence of diverticula and the length of the large intestine, the Mann-Whitney *U* test for unpaired samples was performed. We used the chi-squared test to assess the relationship between the prevalence of diverticulosis and sex. Trends in age-related difference and increases in the prevalence of diverticula were evaluated using the Cochran-Armitage test. Statistical significance was set at $P < 0.05$. Test of normal distribution was evaluated using Shapiro-Wilk test. All statistical analyses were performed using IBM® SPSS® software, version 26 (IBM Corp., Armonk, NY, United States), except for the Cochran-Armitage test and Shapiro-Wilk test, which was performed using Bell Curve for Excel version 2.20 (Social Survey Research Information Co., Ltd., Tokyo, Japan).

RESULTS

Characteristics of the participants and relationship between age, sex and location

Our study population comprised 1181 participants, including 669 men (56.6%) and 512 women (43.4%) with a median age of 62 years (range: 23-91 years). Of the 1181 participants, 568 (48.1%) had ≥ 1 diverticula. The median age of the participants with diverticula was 64 years (range: 27-91 years); that of participants with no diverticulum was 60 years (range: 23-84 years). Participants with diverticula were significantly older than participants with no diverticulum ($P < 0.001$) (Table 1). The participants were stratified into five groups according to age. There were 108 participants in the 40 years or younger group, 165 in the 41-50 years group, 268 in the 51-60 years group, 327 in the 61-70 years group, and 313 in the 71 years and over group. A normal distribution of age dates was performed.

Diverticulosis was present in 346 men (29.3%) and 222 women (18.8%). The frequency of diverticulosis in men was significantly higher than that in women (P =

Characteristics of the 1181 participants analyzed in this study. The prevalence of diverticulosis according to age group and the relationship between diverticulosis and sex were analyzed.

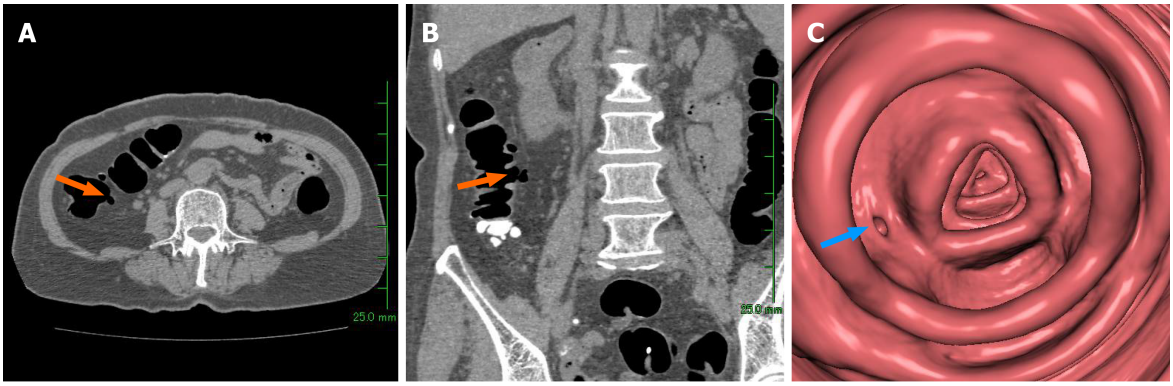

Figure 1 Detection of diverticula using computed tomography colonography. The diverticula were detected mainly in 2-dimensional (2D) supine axial images. If necessary, other 2D or 3-dimensional (3D) images were used. The arrow indicates a diverticulum. A: 2D-supine axial image; B: 2D-supine coronal image; C: 3D-virtual colonoscopy image.

0.004). The frequency of diverticulosis was significantly higher or tended to occur in men in other age groups, but did not differ between sexes in the 60s. The distribution of diverticula and the relationship between sex and location of diverticula are also shown in Table 2. Diverticula were most often found in the ascending colon. The frequency of diverticulosis in men was higher in all segments except the rectosigmoid colon. Regarding the relationship between age and frequency of diverticulosis, the prevalence of diverticulosis significantly increased with age ($P < 0.001$ for trend) (Figure 2). Over half of the participants aged > 60 years had diverticula.

Distribution and grade of diverticula in each age group

The prevalence and the number of diverticula in each colonic segment increased with age, and diverticula were also found in the terminal ileum and appendix (Table 3). Thirteen participants (1.1%) had diverticula in the terminal ileum, and all had less than six diverticula. The appendix was visualized in 680 participants (57.6%), six (0.5%) of whom had appendiceal diverticula. Five participants had one diverticulum, with one participant in his 60s having three diverticula in the appendix.

Relationship between age and location of diverticula

Participants with diverticula were divided into three groups according to the location of the diverticula: The right-sided type was defined as diverticula located from the ileum to the transverse colon only; the left-sided type was defined only from the descending to rectosigmoid colon; and the bilateral type was defined as located on both sides of the colon. We investigated the proportion of diverticula in each type in all patients (Figure 3). As mentioned above, the prevalence of diverticula increased with age, while the prevalence of right-sided and left-sided diverticula did not differ

Table 2 Relationship between sex and location of diverticia

Segment	*n* (%)	Male:Female
Ileum	13 (1.1)	9:4
Appendix	6 (0.5)	5:1
Cecum	258 (21.8)	153:105
Ascending colon	431 (36.5)	266:165
Transverse colon	124 (10.5)	78:46
Descending colon	149 (12.6)	102:47
Sigmoid colon	200 (16.9)	129:71
Rectosigmoid colon	4 (0.3)	1:3

The distribution of diverticula and the relationship between sex and location of diverticula were analyzed. When there was overlap in segments of the diverticula in one participant, all segments were evaluated in duplicate. The percentages of all participants are also listed.

(P = 0.236, P = 0.346 for trend), even among older patients. The presence of the bilateral type increased significantly with age (P < 0.001 for trend).

Relationship between diverticula and the length of the large intestine

There was no significant difference between the length of the large intestine without diverticula and that with diverticula (P = 0.104): median length was 157.2 cm (range: 104.9-259.3 cm) and 154.7 cm (range: 103.9-246.6 cm), respectively. The median length of the large intestine with ≥ 6 diverticula in cecum and/or ascending colon was 154.5 cm (range: 114.6-246.6 cm). This result also did not differ when compared to the length of the large intestine with no diverticula (P = 0.260). The median length of the large intestine with ≥ 6 and ≥ 21 diverticula in the sigmoid colon was 149.9 cm (range: 113.5-195.6 cm) and 145.1 cm (range: 115.0-192.0 cm), respectively, which were both significantly shorter than those with no diverticula (P < 0.001) (Table 4).

DISCUSSION

Geographical and racial variations have been reported in relation to the prevalence and distribution of colonic diverticula[1,4,17]. In developed Western countries, the prevalence of diverticulosis is high, affecting 5% of people in their 40s and approximately half of those in their 80s[18], with an estimated mortality rate of 2.5% per 100000 per year. This disease is the fifth most important gastrointestinal disease in terms of healthcare costs[19]. The incidence of diverticula has also been reported to increase over time[5,8]. The most recent large studies using colonoscopy showed that the prevalence of diverticulosis was 42% in the United States[4] and 23.9% in Japan[8]. Diverticula are mainly left-sided in patients in the United States and in other western countries. On the other hand, patients in Japan often manifest right-sided diverticula, with an associated age-related increase in disease prevalence[1,4,5,8,12]. In our study, the prevalence of colonic diverticulosis detected using CTC was 48.1%, which is much higher than the rates reported in previous studies using colonoscopy in Japan[5,8]. A report from Europe on the prevalence of diverticula diagnosed by CTC reported a prevalence of 51.6%, similar to ours, with a higher prevalence in the right-sided colon than expected[15]; however, compared to our results, the prevalence of diverticula in the right-sided colon in Caucasians was lower than that in Japanese. Most of the recent epidemiologic studies of diverticulosis have been evaluated through colonoscopy, which is a standard technique that is performed worldwide for the screening and diagnosis of colonic diseases[4,5,8]. However, investigators have reported that compared to colonoscopy, assessments evaluated using barium enema are superior for diagnosing colonic diverticulosis[13,14]. Among diverticula that had been detected using barium enema, Niikura *et al*[14] reported colonoscopy detection ratios of 41% and 32% for diverticula in the entire colon and in the left colon, respectively. Therefore, the actual prevalence of colonoscopy-detected diverticulosis in Japan may be over 25%. Conducting clinical studies on the prevalence of diverticulosis determined that the use of barium enema is difficult, given the widespread use of

In each colonic segment, the prevalence and the number of diverticula increased with age. Diverticula identified in the appendix, terminal ileum, and rectosigmoid colon were also evaluated. Rare: 1-5 diverticula; Multiple: 6-20 diverticula; Severe: ≥ 21 diverticula.

colonoscopy. According to the European Society of Gastrointestinal Endoscopy and the European Society of Gastrointestinal and Abdominal Radiology Guideline -

Table 4 Length of the large intestine by states of diverticula

	Median (cm)	Range (cm)
Diverticula negative in any segment	157.2	104.9-259.3
Diverticula positive in any segment	154.7	103.9-246.6
Multiple in cecum to ascending colon	154.5	114.9-246.6
Severe in cecum to ascending colon	151.6	119.6-198.4
Multiple in sigmoid colon	149.9	113.5-195.6
Severe in sigmoid colon	145.1	115.0-192.0

The large intestine of participants with multiple and severe diverticula in the sigmoid colon was significantly shorter than that of the participants with no diverticula ($P < 0.001$).

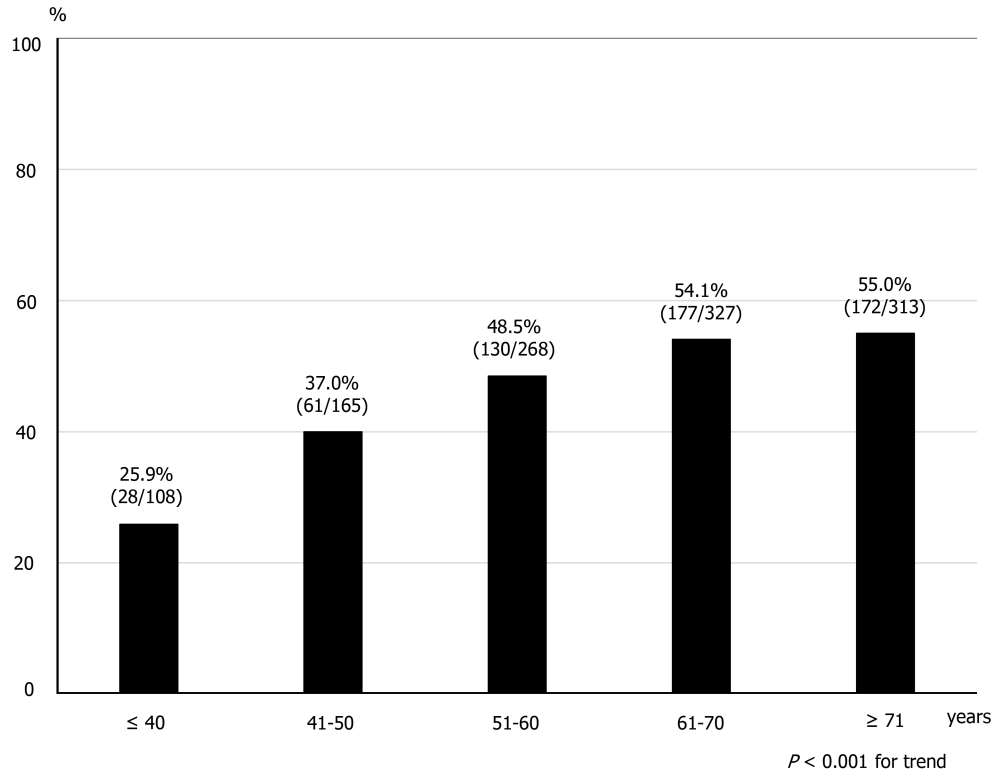

Figure 2 Prevalence of diverticulosis by age group. The prevalence of diverticulosis increased with age ($P < 0.001$ for trend).

Update 2020[20], barium enema for the diagnosis of colorectal neoplasia was not recommended (strong recommendation); in this regard, barium enema cannot be used in this setting.

In recent years, CTC has become more popular for screening and diagnosing colorectal cancer[21,22]; therefore, CTC could be used as an alternative to colonoscopy due to its diagnostic ability and safety[20,23]. It might be superior for detecting diverticula because it can evaluate the colon from more advantageous perspectives and avoid impediments caused by overlapping adjacent sections of the colon. In fact, De Cecco *et al*[15] reported that the prevalence of diverticulosis identified using CTC was 51.6%, which was much higher than that previously reported using colonoscopes in Western countries[4]. This result is similar to our results.

Our results showed that the prevalence of diverticulosis is increasing in Japan, mimicking the trend seen in Western countries. Several studies have shown that age, low intake of dietary fiber, fat intake, red meat intake, alcohol consumption, smoking, and increasing body weight are pathogenic risk factors associated with colonic diverticulosis[1,4,7,8,24]. Increasing age and changing to a westernized diet might be the most closely associated risk factor for the increasing prevalence of diverticulosis in

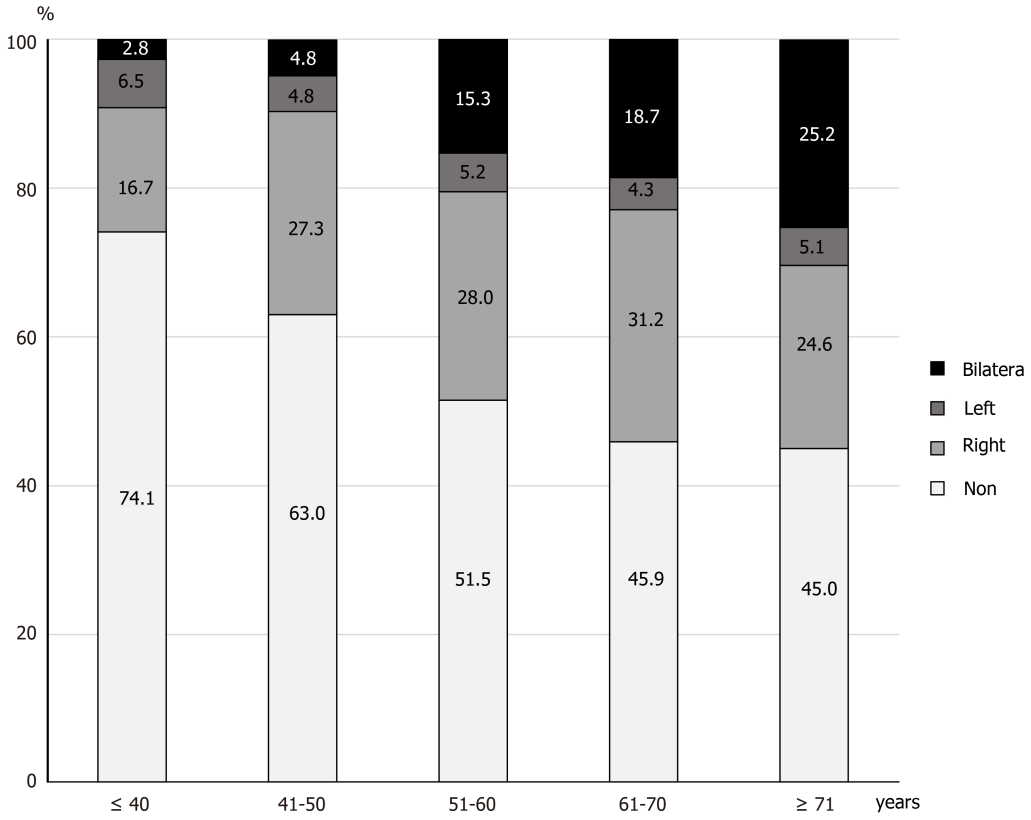

Figure 3 Location of diverticula by age group. An analysis of all participants showed that diverticulosis of the younger generation was predominantly right-sided, and bilateral diverticulosis increased with age ($P < 0.001$ for trend).

Japan.

In our study, the prevalence and grades of colonic diverticula increased with age, which concurs with the findings of previous studies[1,4,8]. Moreover, right-sided colonic diverticula were more predominant in patients aged < 70 years. While the prevalence of diverticula in the right- and left-sided colon did not differ, even in older patients, the prevalence of bilateral diverticula was higher in older patients. Patients with right-sided diverticula only may eventually develop left-sided diverticula with aging. Consequently, they may ultimately develop bilateral diverticula[25]. Although reports from Western countries suggest that the rate of diverticulosis does not differ between the sexes, our results showed that diverticulosis was more common in men, which is consistent with the findings of previous studies in Japan[1,4,5,8].

In this study, diverticula were also identified in the terminal ileum and appendix. Although there are few case reports and research on resected specimens[26-28], this is the first epidemiological report of asymptomatic diverticulosis of the appendix and terminal ileum. This should be considered in the differential diagnosis of acute abdomen and lower gastrointestinal bleeding. Diverticula in the appendix and terminal ileum, and as well as low numbers of right-sided diverticula, might be congenital. Similar to colonic diverticula, inflammation and hemorrhage are occasional consequences.

This is the first study to investigate the relationship between the length of the large intestine and the presence of diverticula. The large intestine with multiple (≥ 6) diverticula in the sigmoid colon was significantly shorter than that with no diverticula. There have been no reports of studies on the relationship between colonic diverticulosis and the length of the large intestine. The ability to accurately measure the length of the large intestine using a workstation is an advantage of CTC, a study made possible because of CTC. However, the length of the large intestine did not differ between the participants with multiple diverticula in the cecum and/or ascending colon in those with no diverticula. When multiple diverticula are present, the colonic wall can thicken and become rigid[18], and the sigmoid colon may shorten because it is free in the peritoneal cavity. In contrast, the colon is unlikely to shorten in patients with multiple right-sided diverticula because it is attached to the retroperitoneum.

This study had several limitations. First, about 70% of asymptomatic participants participated for screening purpose. The study also included participants who underwent CTC for the purpose of examination for any abdominal symptoms, or positive FIT, or abnormal blood test, or a familial history of CRC and polyps, or for the surveillance of polyps. Hence, the findings of this study may not necessarily reflect those of an asymptomatic general population. Second, participants aged > 50 years accounted for > 75% of the study population, and only a small number of patients aged < 40 years were included in this study. This differs from the age structure of the general population in Japan, which may explain why the prevalence of colonic diverticula in this study was much higher than what was previously reported. However, asymptomatic younger people have not been evaluated in previous studies. There might be the same bias in previous studies diagnosed by colonoscopy or barium enema on the prevalence of diverticula. Third, the patients' diet, lifestyle, and physical factors could underlie the increase in the prevalence of diverticulosis; however, data describing these factors were absent from this study. Fourth, the number of participants was smaller than the number of studies conducted based on colonoscopy [5,7,8]. This is because CTC is not yet widely used as a screening modality for colorectal neoplasms, and the facilities that can be used are limited. However, the number of participants in this study was slightly larger than that in a previous study conducted by CTC[15]. Moreover, the data used in this study are approximately 10 years old and are a bit out of date. We believe that a large-scale prospective study should be conducted after standardization of bowel preparation and imaging protocols in the future.

CONCLUSION

This is the first investigation to use CTC to evaluate the prevalence and distribution of colonic diverticula in Japan. The prevalence of colonic diverticulosis was higher than that reported previously. In addition to the superiority of CTC in detecting colonic diverticula, the aging of the Japanese population and the change to a Western diet may be behind the high prevalence of colonic diverticulosis observed in this study. The diverticula were predominantly right-sided in the younger generation, while right- and left-sided diverticula were more common in older participants. The prevalence of asymptomatic diverticulosis in the terminal ileum and appendix can be clarified for the first time. These results may be helpful in the management of diverticular diseases.

ARTICLE HIGHLIGHTS

Research background

Colonic diverticulosis is a common abnormality of the colon. The prevalence of diverticulosis and diverticular disease in Japan is increasing due to aging and a westernized diet.

Research motivation

Recent trends in the prevalence and distribution of colonic diverticula in Japan are not clear. Most recent studies on diverticulosis in Japan involved the use of colonoscopy. In recent years, computed tomography colonography (CTC) has been widely used as an alternative colon cancer screening method. We considered CTC to detect diverticula as outpouchings of the colonic wall from a more advantageous perspective, and it may be superior to colonoscopy and barium enema for detecting diverticula.

Research objectives

The main objective of this study was to evaluate the prevalence and distribution of colonic diverticula in Japan.

Research methods

This study included 1181 participants from 14 hospitals in Japan. We analyzed the prevalence and distribution of colonic diverticula and their relationships with age and sex using CTC and analyzed the relationship between the diverticula and the length of the large intestine.

Research results

Diverticulosis was present in 48.1% of the participants. The prevalence of diverticulosis was higher in the older participants. The diverticula seen in younger participants were predominantly located in the right-sided colon and on the bilateral side for older participants. The length of the large intestine with multiple diverticula in the sigmoid colon was significantly shorter in those without diverticula.

Research conclusions

The prevalence of colonic diverticulosis in Japan is 48.1%. This was much higher than that previously reported. In older participants, the prevalence was higher, and the distribution tended to be bilateral.

Research perspectives

The data used in this study were slightly limited and a bit out of date. We hope to perform a large-scale prospective study after standardization of bowel preparation and imaging protocols, and CTC use will become widespread in the future. We also hope to determine the relationship between the trends in diverticulosis and its accompanying symptoms.

Abstract

BACKGROUND

Most hepatocellular carcinomas (HCCs) are hypervascular, with characteristic features of hepatic arterial supply to the tumor. The factors involved in tumor angiogenesis include angiopoietin-1 (Ang-1), angiopoietin-2 (Ang-2), and vascular endothelial growth factor (VEGF).

AIM

To investigate the profiles of plasma levels of angiogenesis markers in patients with HCC and evaluate their roles in predicting overall survival (OS) and progression-free survival (PFS).

METHODS

Plasma samples from 240 prospectively enrolled HCC patients in the very early to advanced stages were used to measure the levels of Ang-1, Ang-2, and VEGF. Their associations with clinical characteristics, OS, and PFS were analyzed.

RESULTS

The median plasma levels of Ang-1, Ang-2, and VEGF were 3216 pg/mL, 1684 pg/mL, and 26.5 pg/mL, respectively. The plasma level of Ang-2 showed a significant increase from early stage [Barcelona clinic liver cancer (BCLC) A] to intermediate (BCLC B) and advanced stage HCC (BCLC C/D), whereas Ang-1, VEGF, and alpha-fetoprotein (AFP) levels in the plasma did not show any such changes. Multivariable analysis, propensity score-matched analysis, and time-dependent receiver operating curve analysis revealed that Ang-2 levels had the highest predictive power for OS and PFS. Neither Ang-1 nor VEGF was significantly associated with OS or PFS. The neutrophil-to-lymphocyte ratio was an independent factor for OS and PFS.

data.

CONCLUSION

The plasma levels of Ang-2 correlated with liver function, tumor stage, and tumor invasiveness, showing better performance in predicting OS and PFS than AFP, Ang-1, or VEGF.

Key Words: Hepatocellular carcinoma; Angiogenesis; Biomarker; Prognosis; Survival

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Most hepatocellular carcinomas (HCCs) are hypervascular tumor, thus angiogenesis markers can be a potential biomarker. This study explored the potential of each plasma level of angiopoietin (Ang)-1, Ang-2, and vascular endothelial growth factor as a prognostic biomarker for very early to advanced stages of HCC *via* detailed analysis in comparison with alpha-fetoprotein. The plasma level of Ang-2 correlated with liver function, tumor stage, and tumor invasiveness. Multivariable and propensity score-matched analyses revealed Ang-2 levels with the highest predictive power for overall survival in patients with HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third most common malignancy in men, and seventh in women, and the second leading cause of cancer-related deaths worldwide [1]. Most HCCs are hypervascular with characteristic features of hepatic arterial supply to the tumor, frequent portal vein invasion, and intrahepatic metastasis. Based on these characteristics, the diagnosis of HCC based on radiological criteria was established to minimize the bleeding and seeding complications of tumor biopsy in most cases.

Therapeutically, transarterial chemoembolization (TACE), a standard treatment modality for the intermediate stage of HCC, uses the characteristic tumor blood supply for the selective arterial delivery of chemotherapeutic agents and the blockade of tumor-supplying vessels with embolic material. In advanced-stage HCC, several targeted therapeutics, including sorafenib, regorafenib, lenvatinib, ramucirumab, and cabozantinib, inhibit the angiogenic pathway along with other signaling pathways[2-4]. Recently, the combination of an anti-angiogenic agent and an immune checkpoint inhibitor showed a superior effect to sorafenib in the treatment of advanced HCC[5]. Therefore, the development of biomarkers for angiogenesis to assess treatment response and prognosis for HCC is becoming important.

Angiogenesis, the formation of new blood vessels from pre-existing ones, is a fundamental process in HCC development, progression, and metastasis[6,7]. In contrast to normal vessels, tumor vessels have highly proliferative endothelial cells with a leaky vasculature, which is unable to provide oxygen and nutrient supply to the tumor, leading to aberrant tumor microenvironments. The factors involved in tumor angiogenesis include vascular endothelial growth factor (VEGF), angiopoietin (Ang), fibroblast growth factor, epidermal growth factor, insulin-like growth factor, and platelet-derived growth factor. This makes the tumor angiogenesis system highly complex[8]. Among these, VEGF and Ang-tyrosine kinase with Ig and EGF homology domains-2 (Tie2) pathways, including Ang-1 and Ang-2[7,9,10], are the two dominant therapeutic targets of anti-angiogenesis in HCC.

However, investigations on the prognostic value of blood angiogenesis biomarkers across all HCC stages till date are limited. Therefore, this study aimed to investigate the plasma levels of Ang-1, Ang-2, and VEGF, and to evaluate their roles in predicting the overall survival (OS) and progression-free survival (PFS) in patients with very early to advanced stages of HCC.

MATERIALS AND METHODS

Study subjects

A total of 251 newly diagnosed HCC patients who agreed to the collection of their information and blood samples at the time of diagnosis were prospectively enrolled in the Hepatology unit of the Seoul National University Bundang Hospital (SNUBH) between March 2012 and April 2016 (Supplementary Figure 1). Patients with extrahepatic malignancies that might affect survival (n = 9) and those with combined hepatocellular cholangiocarcinoma (n = 2) were excluded accordingly. The final HCC group hence, included 240 patients. HCC diagnosis was based on histologic examination and/or typical features (nodules ≥ 1 cm with arterial hypervascularity and portal or delayed washout) on dynamic computed tomography and/or magnetic resonance imaging[11]. Written informed consent was obtained from each HCC patient after approval by the Institutional Review Board (IRB) of the SNUBH. (IRB No. B-1201/143-002)

Data collection and follow-up of patients with HCC

Clinical and pathological data of the HCC group were collected from electronic medical records. Data included age, sex, height, weight, etiology of HCC, comorbidities, complete blood cell count, neutrophil-to-lymphocyte ratio (NLR), platelet-to-lymphocyte ratio (PLR), blood levels of alpha-fetoprotein (AFP), serum aspartate aminotransferase, alanine aminotransferase, albumin, total bilirubin, prothrombin time expressed as the international normalized ratio, creatinine, Child-Pugh score and class, model for end-stage liver disease (MELD) score, tumor size, tumor number, tumor distribution, presence of macrovascular invasion and/or distant metastasis, tumor-node metastasis (TNM) stage based on the American Joint Committee on Cancer, 8th edition[12], and Barcelona clinic liver cancer (BCLC) stage[2,3].

The primary outcome was OS, and the secondary outcome was the PFS. The index date was defined as the date when patients were diagnosed with HCC on their first liver protocol computed tomography or magnetic resonance imaging. The HCC patients were followed up until December 2019 for a median duration of 3.6 years. The mortality of each patient was confirmed by the requested data from Statistics Korea, and the cause of death was checked with the help of their medical records. PFS was estimated as the interval between the date of diagnosis and the date of progression confirmed on imaging study, death, or the end of follow-up.

Measurement of plasma levels of Ang-1, Ang-2, and VEGF in HCC patients

Blood samples were collected from patients with HCC before treatment. The collected samples were centrifuged at 4000 × g for 10 min to obtain plasma and stored at −70 °C until use. Plasma levels of Ang-1, Ang-2, and VEGF were measured using a commercial enzyme-linked immunoassay (Luminex® screening and performance assays, R&D systems, Minneapolis, MN, United States) according to the manufacturer's instructions. All samples were analyzed at least twice.

Statistical analysis

The baseline characteristics of the patients were compared using the chi-square test for categorical variables, and a t-test was used to compare continuous variables. Spearman rank correlation was used to calculate the correlation coefficient between the ranked variables. OS and PFS were estimated using the Kaplan–Meier method and compared using the log-rank test. The Cox proportional hazards model was employed to determine the hazard ratio (HR) of OS and PFS in the univariate and subsequent multivariate analyses.

The prognostic values of the plasma biomarkers were determined by time-dependent receiver operating characteristic (ROC) curve analysis from censored survival data using the nearest-neighbor estimation method. All P values were two-sided, and values < 0.05, were considered significant. SPSS (version 21; SPSS, Inc., Chicago, IL, United States) and R (version 3.6.3., http://cran.r-project.org/) software was used for the statistical analyses.

To confirm the prognostic value of Ang-2 by reducing the impact of potential confounding effects, significant differences in baseline characteristics between the high and low Ang-2 groups were adjusted by propensity score (PS) matching. We used nearest-neighbor matching with a caliper size of 0.1, and matched the patients in a 1:1 ratio.

RESULTS

Baseline characteristics and plasma levels of Ang-1, Ang-2, VEGF, and AFP in patients with HCC

Baseline characteristics of the subjects are presented in Table 1. The 240 HCC patients had a mean age of 60.9 years, and there was a male proportion of 80.4%. The etiologies of HCC were as follows: Hepatitis B virus (HBV) (69.6%), hepatitis C virus (10.0%), alcohol (11.7%), and others (7.9%). The HCC group included patients with Child-Pugh class B or C (14.9%), TNM stage I or II (65.5%), and BCLC stage 0 or A (55.5%) (Table 1). There were no missing values for the variables.

The median plasma levels of Ang-1, Ang-2, VEGF, and AFP were 3216 pg/mL, 1684 pg/mL, 26.5 pg/mL, and 17.9 ng/mL, respectively. All biomarkers showed an increasing trend as the BCLC stage progressed (Figure 1). However, only the median plasma level of Ang-2 showed a significant increase from the early stage HCC (BCLC A: 1289 pg/mL) to intermediate (BCLC B; 1808 pg/mL) and advanced stage HCC (BCLC C/D; 3653 pg/mL), whereas Ang-1, VEGF, and AFP levels did not show any changes. Ang-2 and AFP levels showed an increasing trend as the TNM stage progressed, while Ang-1 and VEGF levels did not (Supplementary Figure 2). NLR and PLR showed an increasing trend as the BCLC stage progressed (Supplementary Figure 3).

Factors correlated with plasma levels of Ang-1, Ang-2, and VEGF in HCC patients with their interrelationship

The correlation plot between each plasma level of the three biomarkers and clinical factors is shown in Figure 2. Ang-2 levels were significantly correlated with tumor extent and poor liver function, while VEGF levels were correlated with tumor extent. Meanwhile, the rho value between Ang-1 or VEGF levels and liver function or tumor extent was not significant. Ang-2 was significantly correlated with both NLR and PLR, while Ang-1 and VEGF were correlated with PLR only. Ang-2 levels were not correlated with VEGF, but negatively correlated with Ang-1 levels. Meanwhile, Ang-1 was positively correlated with VEGF levels in the HCC group (Figure 2).

The median plasma levels of Ang-2 and VEGF did not differ according to the etiology of HCC (Supplementary Figure 4A and B). The correlation plot between each plasma level of the biomarkers and HBV DNA is shown in Supplementary 4C and D among CHB patients (n = 156). HBV DNA levels were not significantly correlated with either Ang-2 or VEGF levels.

The comparison of the clinical factors between high- and low-level groups of Ang-2 or VEGF using the median level as a cutoff is shown in Supplementary Table 1. The high Ang-2 and high VEGF groups showed more advanced tumor stages than the low Ang-2 and low VEGF groups. The high Ang-2 group had a significantly higher proportion of Child-Pugh class B or C than the low Ang-2 group (26.1% *vs* 4.1%, P < 0.001). On the contrary, the high VEGF group showed a significantly lower MELD score than the low VEGF group (3.8 *vs* 5.6, P = 0.01). The NLR and PLR of the high Ang-2 group were significantly higher than those of the low Ang-2 group (3.5 *vs* 2.2, P = 0.007; 138.3 *vs* 98.5. P = 0.01). However, there was no difference in the NLR and PLR between the high and low VEGF groups.

Potential of the plasma levels of Ang-1, Ang-2, or VEGF as prognostic markers for HCC compared to AFP level in the aspect of OS

During a median follow-up of 3.6 years, 118 deaths were observed in the HCC group. The OS curves between the low and high levels of Ang-1, Ang-2, VEGF, and AFP using the median level as a cutoff are shown in Figure 3. The OS was significantly shorter in the high Ang-2 group [HR 4.76, 95% confidence interval (CI): 3.15–7.19, P < 0.001; Figure 3B] and high AFP group (≥20 ng/mL) (HR 2.97, 95%CI: 2.02–4.37, P < 0.001; Figure 3D) than in the low Ang-2 and low AFP groups, respectively. However, the OS rate was not significantly different between the high and low Ang-1 groups (HR 1.02, 95%CI: 0.71-1.56, P = 0.82; Figure 3A) and between the high and low VEGF groups (HR 1.39, 95%CI: 0.97–2.00, P = 0.07; Figure 3C).

The results of the univariate and multivariate analyses for the factors associated with OS are shown in Table 2. The high Ang-2 group was an independent factor (HR 5.96, 95%CI: 1.58–22.43, P < 0.001) associated with OS, along with NLR (HR 4.45, 95%CI: 1.77–11.23, P = 0.002), Child-Pugh class B or C, and TNM stage. Meanwhile, VEGF and AFP levels were not associated with OS (Table 2).

Table 1 Baseline characteristics and plasma levels of angiopoietin-1, angiopoietin-2, and vascular endothelial growth factor

Characteristic	HCC patients (*n* = 240)
Age, mean age ± SD, year	60.9 ± 11.2

Cox proportional hazards model with a backward elimination approach was used for multivariable analysis. HR: Hazard ratio; CI: Confidence interval; VEGF: Vascular endothelial growth factor; AFP: Alpha fetoprotein; BMI: Body mass index; MELD: Model for end stage liver disease; HCC: Hepatocellular carcinoma; TNM: Tumor-node-metastasis.

To analyze the survival prediction power of Ang-2 levels, time-dependent area under the ROC (AUROC) analysis for survival prediction showed that the AUROC of baseline Ang-2 levels (0.909) for the 1-year survival prediction was significantly higher than that of AFP (AUROC 0.817, $P = 0.03$), Ang-1 (AUROC 0.535, $P < 0.001$), and VEGF (AUROC 0.577, $P < 0.001$; Figure 4). The AUROC of Ang-2 (0.873) for the two-year survival prediction was also significantly higher than that of AFP (AUROC 0.767, $P = 0.01$), Ang-1 (AUROC 0.541, $P < 0.001$), and VEGF (AUROC 0.581, $P < 0.001$). Moreover, baseline Ang-2 levels showed better survival predictive power than the other plasma biomarkers throughout the 5 years (Figure 4).

PS-matching yielded 37 matched pairs of patients from the high Ang-2 and low Ang-2 groups (Supplementary Table 2). Within this matched cohort, there were no significant between-group differences in most baseline characteristics, except for the proportion of male patients (75.8% *vs* 83.8%). The high Ang-2 group showed a significantly higher risk of death (HR 2.29, 95%CI: 1.10–4.76, $P = 0.03$) than the low

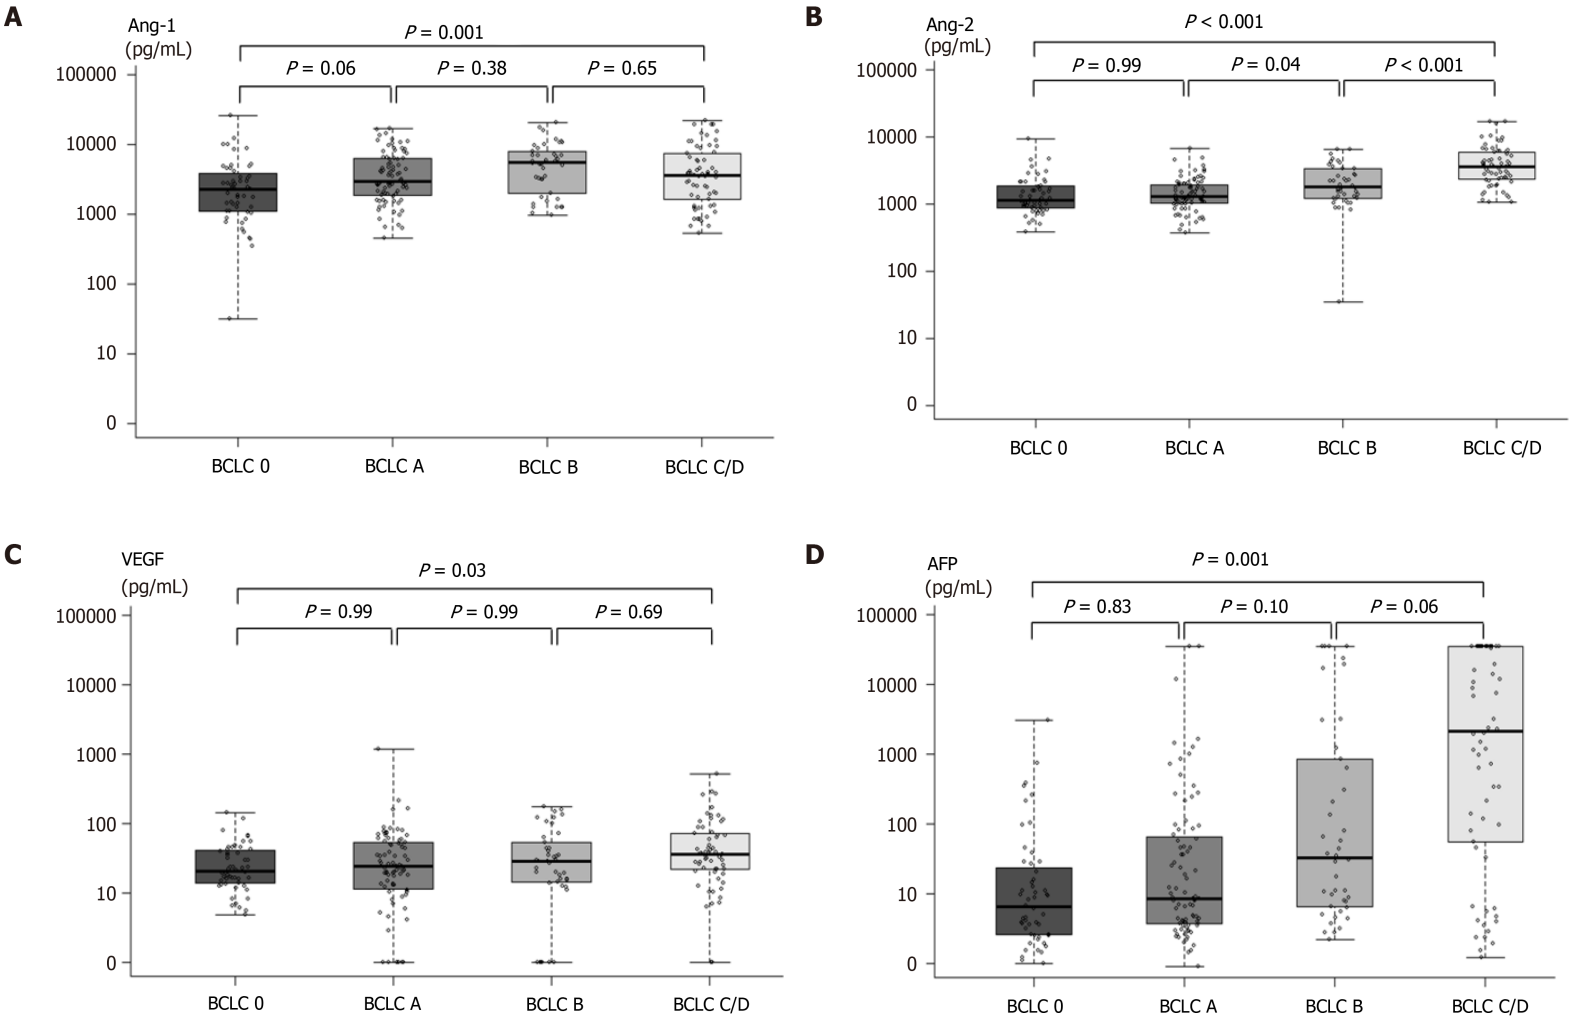

Figure 1 Plasma levels of angiopoietin-1, angiopoietin-2, vascular endothelial growth factor, and alpha fetoprotein in the hepatocellular carcinoma patients according to tumor stage. AFP: Alpha-fetoprotein; Ang-1: Angiopoietin-1; Ang-2: Angiopoietin-2; BCLC: Barcelona clinic liver cancer; VEGF: Vascular endothelial growth factor.

Ang-2 group (Supplementary Figure 5A).

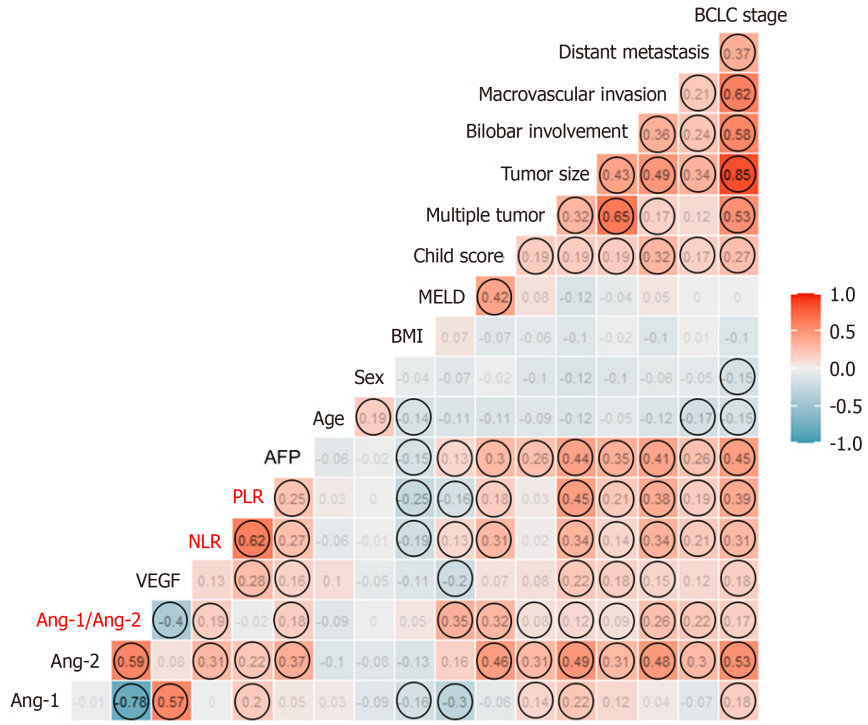

Figure 2 Factors correlated with plasma level of angiopoietin-1, angiopoietin-2 and vascular endothelial growth factor in hepatocellular carcinomas patients with their interrelationship. The heat map showing a red background indicates a positive correlation, the blue background indicates negative correlation, and the numbers in the box indicate rho (ρ). AFP: Alpha-fetoprotein; Ang-1: Angiopoietin-1; Ang-2: Angiopoietin-2; BCLC: Barcelona clinic liver cancer; BMI: Body mass index; MELD: Model for end stage liver disease; NLR: Neutrophil-lymphocyte ratio; PLR: Platelet-lymphocyte ratio; VEGF: Vascular endothelial growth factor.

Potential of the plasma levels of Ang-1, Ang-2, or VEGF as prognostic markers for HCC compared to AFP level in terms of PFS

During the median follow-up period, 171 progressions and 18 deaths were observed in the HCC group. The PFS curve between low and high levels of Ang-1, Ang-2, VEGF, and AFP using the median level as a cutoff are shown in Figure 5. The PFS was significantly shorter in the high Ang-2 group (HR 2.53, 95%CI: 1.89–3.39, $P < 0.001$; Figure 5B) and high AFP group (≥ 20 ng/mL) (HR 2.27, 95%CI: 1.71–3.04, $P < 0.001$; Figure 5D) than in the low Ang-2 and low AFP groups, respectively. However, the PFS rate was not significantly different between the high and low Ang-1 groups (HR 1.31, 95%CI: 0.99–1.74, $P = 0.06$; Figure 5A) or between the high and low VEGF groups (HR 1.29, 95%CI: 0.97–1.71, $P = 0.08$; Figure 5C).

The results of univariate and multivariate analyses for the factors associated with PFS are shown in Table 3. The high Ang-2 group was an independent factor (HR 1.55, 95%CI: 1.10–2.20; $P = 0.01$) associated with PFS, along with NLR (HR 1.95, 95%CI: 1.23–3.08, $P = 0.004$), AFP (HR 1.54, 95%CI: 1.13–2.11, $P = 0.007$), Child-Pugh class B or C, BMI, and TNM stage. However, VEGF and PLR were not (Table 3).

Within 37 pairs of PS-matched cohorts, PFS was not significantly different between the high and low Ang-2 groups (HR 1.19, 95%CI: 0.72–1.96, $P = 0.51$; Supplementary Figure 5B). This is probably due to the small sample size of PFS during follow-up.

DISCUSSION

This study explored the potential of each plasma level of Ang-1, Ang-2, and VEGF as a prognostic biomarker for very early to advanced stages of HCC *via* detailed analysis in comparison with AFP. Multivariable and PS-matched analyses revealed Ang-2 levels with the highest predictive power for OS in patients with HCC. Moreover, Ang-2 and AFP levels were independent factors for PFS. In contrast, neither Ang-1 nor VEGF was significantly associated with OS or PFS. NLR was an independent factor for both OS and PFS.

Cox proportional hazards model with a backward elimination approach was used for multivariable analysis. HR: Hazard ratio; CI: Confidence interval; VEGF: Vascular endothelial growth factor; AFP: Alpha fetoprotein; BMI: Body mass index; MELD: Model for end stage liver disease; HCC: Hepatocellular carcinoma; TNM: Tumor-node-metastasis.

In this study, the median levels of Ang-1, Ang-2, and VEGF were lower than those in previous reports that included only patients with advanced-stage HCC, mostly treated with sorafenib. This may be due to the relatively low proportion of advanced-stage HCC cases included in this study (27%). Ang-2 levels were higher in patients with advanced HCC than in those with early HCC. Moreover, the majority of our patients underwent locoregional therapy (radiofrequency ablation, 11.3%; TACE, 69.2%). Ang-2 Levels showed a positive correlation with liver function indicators, such as MELD score and Child-Pugh score, and tumor extent or aggressiveness, which are the two major axes of HCC prognosis. Similarly, a recent study reported that Ang-2 levels were associated with 90-d mortality, acute kidney injury stage, and risk of renal replacement therapy in a cohort of patients with decompensated cirrhosis[13]. Meanwhile, Ang-1 and VEGF levels were generally associated with tumor extent rather than liver function. Therefore, this study suggests that Ang-2 levels are better prognostic biomarkers for HCC than Ang-1 or VEGF levels, especially after locoregional treatment.

The potential of Ang-2 as a prognostic marker was confirmed by survival analysis. Our multivariable analysis showed that the plasma level of Ang-2 (median 1684 pg/mL), but not of VEGF (median 26.5 pg/mL), was an independent predictor of OS. In addition, time-dependent ROC curve analysis also demonstrated that Ang-2 level is a better predictor of OS than AFP, Ang-1, and VEGF levels, which was supported by PS-matched analysis.

Several studies have investigated the prognostic role of Ang-2 in patients with advanced HCC. In 2013, Miyahara *et al*[14] investigated eight cytokine levels in 120 patients with advanced HCC who were treated with sorafenib. The results showed that the Ang-2 level (median, 721.3 pg/mL) was associated with OS and PFS, but

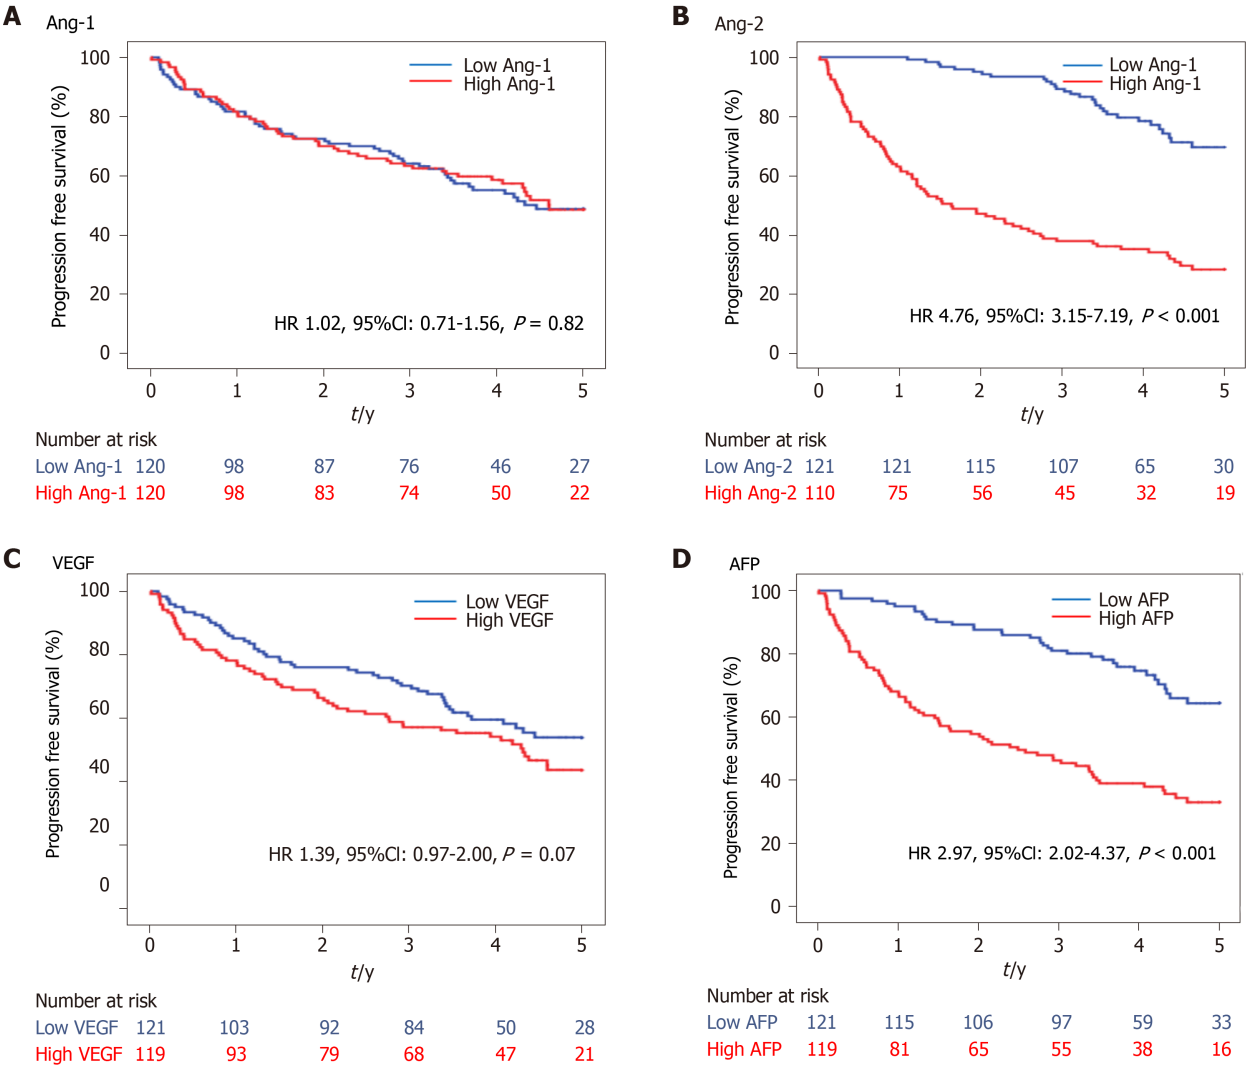

Figure 3 Overall survival according to plasma angiogenesis marker level. A: Angiopoietin-1; B: Angiopoietin-2; C: Vascular endothelial growth factor; D: Alpha-fetoprotein. AFP: Alpha-fetoprotein; Ang-1: Angiopoietin-1; Ang-2: Angiopoietin-2; VEGF: Vascular endothelial growth factor; HR: Hazard ratio; CI: Confidence interval.

VEGF (median 68.6 pg/mL) was not[14]. This result is consistent with that of our study. However, in our study, the median levels of Ang-2 (1684 pg/mL) and VEGF (26.5 pg/mL) were different. Llovet *et al*[15] reported that the plasma levels of Ang-2 (median, 6043.5 pg/mL) and VEGF (median, 1019 pg/mL) were independent predictors of OS in 602 advanced HCC enrolled in the phase 3, randomized controlled sorafenib HCC assessment randomized protocol (SHARP) trial, both of which were not significant response-prediction biomarkers in the sorafenib-treated cohort[15].

In a Chinese study of 173 HCC patients, Ang-2 level (mean, 18000 pg/mL) was an independent prognostic factor with a cutoff level of 6433 pg/mL[16]. Pestana *et al*[6] reported that a high plasma Ang-2 level (above mean value of 15300 pg/mL) was associated with lower OS, but a high Ang-1 level (above mean value of 16000 pg/mL) was associated with longer OS in 767 HCC patients treated at MD Anderson Cancer Center (77% in advanced stage)[6]. In this study, the Ang-1 and Ang-2 levels were markedly higher than that of ours and of previous studies because they showed mean rather than median values and used a different ELISA kit. A small-scale study in Spain (n = 33) showed that Ang-2 levels in peripheral blood and hepatic veins were well correlated (r = 0.95), and serum Ang-2 levels were significantly associated with tumor extent and aggressiveness. However, it was not related to treatment response.

VEGF is secreted by HCC cells and enhances endothelial cell survival, proliferation, invasion, and migration in response to tumor hypoxia[9]. Ang-1 and Ang-2 are both secreted proteins with 60% amino acid sequence homology, and they interact with Tie2, the endothelial cell-specific tyrosine kinase receptor[10]. While Ang-1 binds Tie2 to promote vessel stability and quiescence, Ang-2 binds to Tie2 to promote vessel

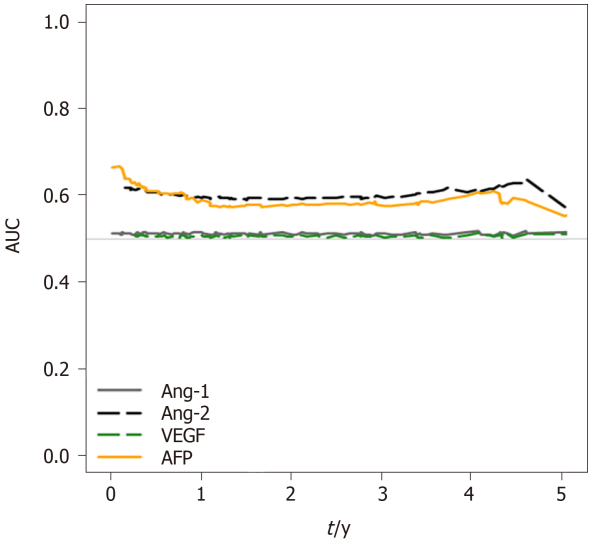

Figure 4 Time-dependent receiver operating characteristic for survival at each time point. AFP: Alpha-fetoprotein; Ang-1: Angiopoietin-1; Ang-2: Angiopoietin-2; VEGF: Vascular endothelial growth factor; ROC: Receiver operating characteristic; AUC: Area under the ROC curve.

permeability, instability, and eventual tissue hypoxia. This antagonistic relationship was consistent with the negative correlation between the plasma levels of Ang-1 and Ang-2 in our study. Angiogenic switch by Ang-2 promotes VEGF expression and promotes tumor angiogenesis.

On the other hand, Ang-2 acts as a chemoattractant by promoting recruitment of proangiogenic myeloid cells, especially Tie2 expressing macrophages (TEMs)[17,18]. TEMs become more proangiogenic and immunosuppressive in the tumor microenvironment. This is a potential mechanism for resistance to antiangiogenic therapy and poor survival in patients with high Ang-2 expression in HCC[19]. Interestingly, NLR and PLR, both inflammatory biomarkers, were significantly correlated with Ang-2 levels in this study. A recent meta-analysis showed that preoperative NLR was positively correlated with the risk of microvascular invasion in HCC[20]. Moreover, many studies have confirmed that a high baseline NLR is an independent factor for OS and PFS[21-23]. This is consistent with the results of our study.

Angiogenesis inhibitors have become an important therapeutic approach for the treatment of solid cancers. First-generation anti-angiogenic agents, including bevacizumab, sorafenib, pazopanib, vandeltanib, cabozantinib, axitinib, VEGF-trap ziv-aflibercept, and ramucirumab, target VEGF signaling[8]. Second-generation antiangiogenic agents, including trebananib, nesvacumab, rebastinib, and MEDI3617, target Ang/Tie2 signaling in clinical development[8,19,24]. However, resistance to these agents, lack of improvement of OS, and common adverse events, including hypertension and bleeding, are challenges faced by current anti-angiogenic therapies. Therefore, combination therapy of VEGF and Ang-2 targeted agents as well as a combination of anti-angiogenic and chemotherapeutic agents, radiation, or immune modulators are being developed accordingly. Recent studies suggested that predicting OS was made possible by periodically measuring serum angiogenic cytokines, especially Ang-2 or VEGF, in patients with HCC treated with sorafenib or lenvatinib [14,25,26]. Moreover, a single-nucleotide polymorphism of Ang-2 is an independent prognostic factor for sorafenib-treated advanced HCC[27]. A high increase in the serum VEGF level after TACE among patients with HCC was associated with distant metastasis and unfavorable outcomes[28,29]. Therefore, identifying tumors using circulating biomarkers that are sensitive to antiangiogenic therapy and predictive of OS and PFS could improve therapeutic approaches.

This study had several limitations. First, this was a single-center study in an HBV-endemic area[30]. Although there was no difference in Ang-2 and VEGF levels according to the etiology of HCC in this study, the results need external validation. Second, the angiogenic biomarkers were measured only once at the time of HCC diagnosis, so the longitudinal profile according to tumor progression or treatment response could not be analyzed. Third, this study did not evaluate the plasma levels of these three angiogenesis factors in normal control subjects or cirrhotic patients because we focused on the role of Ang-1, Ang-2, and VEGF as prognostic rather than diagnostic markers. Fourth, this study did not evaluate other valuable angiogenesis

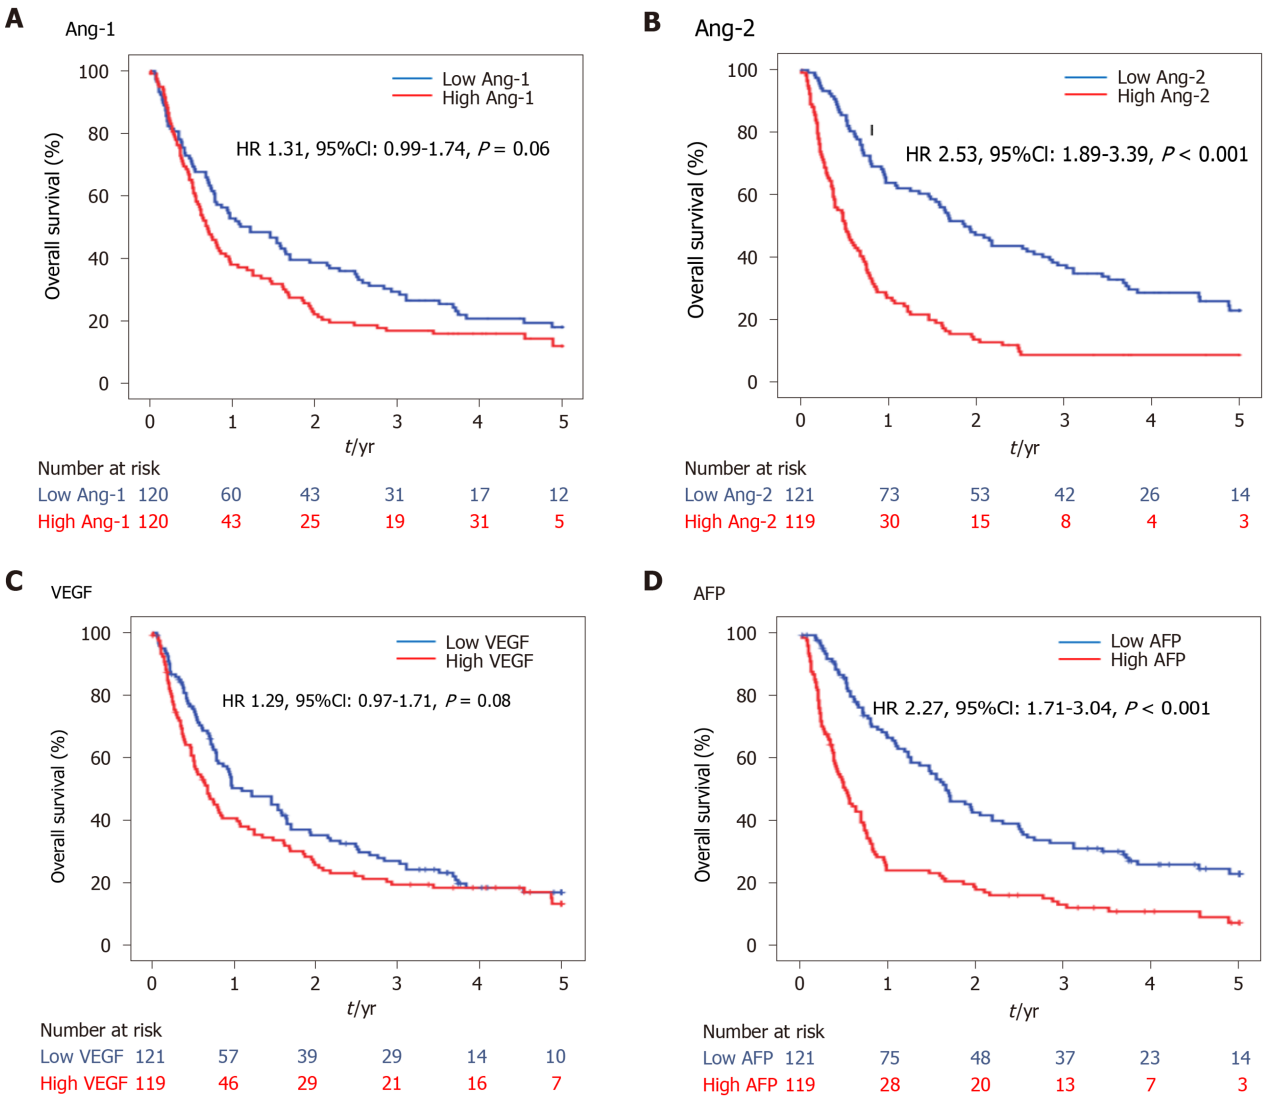

Figure 5 Progression-free survival according to plasma angiogenesis marker level. A: Angiopoietin-1; B: Angiopoietin-2; C: Vascular endothelial growth factor; D: Alpha-fetoprotein. AFP: Alpha-fetoprotein; Ang-1: Angiopoietin-1; Ang-2: Angiopoietin-2; VEGF: Vascular endothelial growth factor; HR: Hazard ratio; CI: Confidence interval.

markers, such as microvessel density, PDGF/PDGFR, FGF/FGFR, and endoglin (CD105)[9,31]. Further comprehensive studies including these angiogenesis markers are hence needed. Lastly, the number of patients who underwent surgery and sorafenib treatment was small. Therefore, it is difficult to generalize that angiogenesis markers can predict the prognosis of patients receiving these treatments.

CONCLUSION

In conclusion, the plasma level of Ang-2 correlated with liver function, tumor stage, and tumor invasiveness. It also performed better than AFP, Ang-1, and VEGF in terms of predicting OS and PFS.

ARTICLE HIGHLIGHTS

Research background

Most hepatocellular carcinomas (HCCs) are hypervascular, with characteristic features of hepatic arterial supply to the tumor. The factors involved in tumor angiogenesis include angiopoietin-1 (Ang-1), angiopoietin-2 (Ang-2), and vascular endothelial growth factor (VEGF).

Research motivation
Angiogenesis markers can be a potential biomarker.

Research objectives
To investigate the profiles of plasma levels of angiogenesis markers in patients with HCC and evaluate their roles in predicting overall survival (OS) and progression-free survival (PFS).

Research methods
Plasma samples from 240 prospectively enrolled HCC patients in the very early to advanced stages were used to measure the levels of Ang-1, Ang-2, and VEGF. Their associations with clinical characteristics, OS, and PFS were analyzed.

Research results
The plasma level of Ang-2 correlated with liver function, tumor stage, and tumor invasiveness. Multivariable and propensity score-matched analyses revealed Ang-2 Levels with the highest predictive power for OS in patients with HCC.

Research conclusions
The plasma levels of Ang-2 can be a better biomarker than AFP in predicting OS or RFS.

Research perspectives
Identifying HCCs using circulating biomarkers that are sensitive to antiangiogenic therapy and predictive of OS and PFS could improve therapeutic approaches.

ACKNOWLEDGEMENTS

We are grateful to our research coordinator (Da Woon Jeong) and the laboratory technician (Yun Suk Choi).

Abstract

BACKGROUND

Disease knowledge is associated with increased treatment compliance and improvement of symptoms in inflammatory bowel disease (IBD). IBD-knowledge inventory device (IBD-KID) was developed and validated specifically as a tool to measure disease-related knowledge in children with IBD and their parents.

AIM

To prospectively assess the determinants of disease-related knowledge regarding paediatric IBD patients and their parents, using the IBD-KID.

METHODS

A questionnaire-based survey was carried out in paediatric patients and their parents. The determinants of patients' and parents' IBD-KID scores were assessed according to hierarchical linear regression models.

revisions related to important intellectual content of the manuscript; all authors read and approved the final manuscript.

Institutional review board statement: The study was approved by the University Bioethical Committee (Consent No. AKBE/120/16).

Conflict-of-interest statement: The authors declare no conflict of interests.

Data sharing statement: No additional data are available.

CONSORT 2010 statement: The authors have read the CONSORT 2010 Statement, and the manuscript was prepared and revised according to the CONSORT 2010 Statement.

First decision: May 27, 2021
Revised: June 2, 2021

RESULTS

The study group consisted of 269 IBD patients and 298 parents. The patients' mean (standard deviation, SD) IBD-KID score was 10.87 (± 3.97), while the parents' was 11.95 (± 3.97). Both groups exhibited poor knowledge of the side effects of steroid therapy, the role of surgical treatment in IBD, dietary restrictions and the risks associated with the use of herbal medicines. The patients' IBD-KID scores were statistically associated with patient sex [B coefficient (standard error, SE) = 1.03 (0.44), $P = 0.021$] and patient age [B (SE) = 0.03 (0.01), $P < 0.001$]. The parents' IBD-KID scores were significantly related to patient age [B (SE) = 0.02 (0.01), $P = 0.003$], and treatment with immunosuppressive agent [B (SE) = 1.85 (0.48), $P < 0.001$]. The final models explained 26.9% of the variance of patients' IBD-KID scores and 18.5% of the variance of parents' scores.

CONCLUSION

The variables originating from parents' knowledge were significantly associated with patients' IBD-KID scores. The study results indicate the need to implement better education programmes for patients and parents.

Core Tip: This was a prospective study that assessed the disease-related knowledge regarding paediatric inflammatory bowel disease (IBD) among children and their parents using previously validated IBD-knowledge inventory device (IBD-KID). The variables originating from parent's knowledge, were significantly associated with patient's IBD-KID score. Parents of patients treated with immunosuppressive agents showed higher diseases-specific knowledge. The results of the study indicate the need to implement better education programmes for patients and parents.

INTRODUCTION

The burden and prevalence of inflammatory bowel disease (IBD), comprising Crohn's disease (CD) and ulcerative colitis (UC), are increasing among children and adolescents in many regions of the world, including Poland[1-3]. IBD is chronic in nature, potentially occurring with unpredictable periods of exacerbation even during pharmacologically supported remission. The chronic course of the disease is characterised by numerous exacerbations and complications and the need for a wide range of medication (including aminosalicylates (5-ASA), corticosteroids (CS), immunosuppressants, biologics) and, sometimes, surgical treatment, significantly affecting the quality of life of young patients and their families[4]. The disease poses challenges to participation in school activities, social life and travelling, along with dietary restrictions and concerns about the future[5,6]. Parents of sick children and teenagers may experience difficulties understanding and complying with the necessary treatment regimens and dietary recommendations at different stages of the disease. Research has shown that understanding the causes of chronic disease and the principles of treatment results in improved adherence to therapeutic recommendations, facilitated contact with medical personnel and higher quality of life[7-9]. In the case of paediatric patients, especially the youngest ones, the sources of information and the knowledge that parents and guardians gain is of utmost importance. The use of common sense or popular but unproven opinions, instead of reliable sources of

information, can augment the frustration associated with childhood chronic disease and adversely impact the treatment process. Moreover, the lack of professional dietary or psychological support may further affect the quality of life, resulting in excessive restrictions of a young patient's diet or age-appropriate activity.

IBD-Knowledge Inventory Device (IBD-KID) was developed and validated specifically as a tool to measure disease-related knowledge in children with IBD and their parents[10]. It was previously used among children Canada, Australia and France[10-12]. In Poland, no study has yet assessed the disease-related knowledge of children and teenagers having IBD, nor that of their parents. Therefore, a multicentre study of disease-specific knowledge and its determinants among paediatric patients and their parents was carried out with the use of IBD-KID that was translated into polish and validated.

MATERIALS AND METHODS

Sampling and ethics

The survey involved a convenience sample of patients with IBD and their parents from four Polish university centres specialising in paediatric gastroenterology between 2016 and 2018. The participating departments were based in Warsaw, Olsztyn, Wroclaw and Krakow. Patients aged 10 years and older and their parents or guardians completed the questionnaire used in the survey. In the case of younger patients, parents filled out the questionnaires.

The study was approved by the University Bioethical Committee (Consent No AKBE/120/16). After participants were informed about the study aims, only those who provided their consent were invited to fill the questionnaire. Each pair of surveys (or survey) was assigned a unique code to preserve respondents' anonymity.

Questionnaire

The questionnaire used in the survey consisted of the IBD-KID instrument that is available at https://cdn-links.lww.com/permalink/mpg/a/mpg_2013_10_11_otley_135_sdc1.pdf; the 23 items asking about general knowledge (2), IBD course (6), risk factors (4), therapeutic modes and adverse effects of treatment (11). Scoring of the questionnaire was one point for each correct answer with no negative marking; the maximum score was 23 points. Demographic characteristics of patients and parents and membership of the Polish patient Crohn's & Ulcerative Colitis Association *J-elita* were also collected. Parents were also queried about preferred sources of information and asked to provide a self-assessment of their knowledge about their child's disease.

The Polish version of the BID-KID scale used in the study was obtained after cultural adaptation consisting of three stages, including forward translation, backward translation and cognitive debriefing, according to the guidelines provided by Prof. Anthony Otley, the author of the original version of the scale[10]. The conformance to the guidelines provided by the authors of the scale was confirmed with the validation certificate from 31 March 2015[13].

Statistical analysis

Statistical analysis was carried out using IBM SPSS v25 software (IBM Corp. Armonk, NY, United States). The mean and standard deviation were provided for the continuous variables as well as absolute and relative frequencies for categorical variables. The Kolmogorov–Smirnoff test was applied to check whether continuous variables conformed to the normal distribution. The internal consistency of the IBD-KID scale was assessed using Cronbach's alpha. A P value < 0.05 was deemed to be statistically significant.

In the first stage of analysis, the association between IBD-KID scores and potential predictors was assessed using univariate linear regression. Next, hierarchical linear regression models were developed for both patients' and parents' IBD-KID scores. In multivariate models, only those independent variables for which the p-value in the univariate model was at least 0.1 were included.

Hierarchical multivariate linear regression modelling was performed for both parents' and patients' IBD-KID scores. In three consecutive steps of the hierarchical multivariate regression for patients' scores, the following independent variables were introduced: (1) Patient's demographic characteristics and self-assessment of knowledge; (2) Parent's IBD-KID score and their self-assessment of knowledge, membership in the J-elita Association and the use of the Internet as a source of knowledge; and (3) The use of treatment options.

Hierarchical regression modelling for parents' IBD-KID scores also consisted of three steps, in which the following variables were introduced: (1) Patient's demographic characteristics and their self-assessment of knowledge; (2) Parent's demographic characteristics, self-assessment of knowledge, membership in the J-elita Association and the use of books and journals as sources of knowledge; and (3) The use of treatment options.

Hierarchical regression was chosen to expose the relative importance of variables potentially associated with the level of IBD-KID scores in both groups of respondents. The assumption was also made that a parent's IBD-KID score might play the role of a predictor of the patient's score.

Unstandardised regression coefficients (B), standard errors (SE), standardised regression coefficients (beta), 95% confidence intervals, and *P*-values were reported for independent variables included in the univariate analysis. For those included in the hierarchical linear regression models, 95% confidence intervals were omitted. In the case of hierarchical linear regression models, standardised R2 values and F for the change in R2 were also provided.

RESULTS

Study group characteristics

The survey was completed by 269 IBD patient-parent pairs (for patients 10 years and older) and 29 parents of patients under 10 years old. The mean age (SD) of patients was 167.3 (37.5) mo, and the mean duration of disease (SD) was 40.7 (33.8) mo. Table 1 displays patient characteristics.

IBD-KID scores

Cronbach's alpha coefficient for patients' IBD-KID scale was 0.75, while this value for parents was 0.60. The patients' and parents' mean (SD) IBD-KID scores were 10.87 (3.97) and 11.95 (3.97), respectively. Both patients with CD and their parents reached higher scores [mean (SD): 11.06 (3.99) and 12.18 (4.14), respectively] than those with UC and their parents [10.52 (SD ± 3.93) and 11.52 (SD ± 3.60), respectively]. The percentage of correct answers given by patients was in the range of 74.83% (item No 13) and 12.08% (item No 20). In the case of parents' responses, the range was 87.92% (item No 3) - 11.74 (item No 17). The distribution of correct answers to the KID-IBD scale items is shown in the supplementary file (Supplementary Table 1).

Regression modelling of IBD-KID scores

Univariate linear regression analysis showed that patients' scores were significantly associated with patient age and sex, patient's and parent's self-rated knowledge, membership in the Jelita Association, parent's use of the Internet as a source of knowledge and parent's IBD-KID score (Table 2, Supplementary Figure 1). Furthermore, nutritional and surgical therapy and the use of immunosuppressive or biological agents were also statistically related to the patient's score. Parents' IBD-KID scores showed a significant relationship with parent sex and education, place of residence, parent's and patient's self-assessment of knowledge, membership in the J-elita Association, and the use of books or journals for accessing knowledge about the disease (Table 2, Supplementary Figure 2). As in the case of the patients' scores, the use of immunosuppressive or biological agents was associated with higher scores.

Tables 3 and 4 show the final model obtained with hierarchical linear regression for the IBD-KID scores of both patients and parents, respectively (details of all three models are shown in Supplementary Tables 2 and 3). The assumptions for multiple linear regression were met for both models. In the first step, patient sex and age, place of residence and self-assessment of knowledge were introduced to the model for the patient's IBD-KID score. All four independent variables were significant predictors, as the resulting model explained 14.1% of the variance of the score (Supplementary Table 2). In the second step, parent's self-assessment of knowledge, J-elita Association membership, using the Internet as a source of knowledge and parent's IBD-KID score were added. The resulting model explained an additional 12.7% of the variance of the patient's IBD-KID score (Supplementary Table 2). The third step included variables reflecting specific therapeutic modalities used in a patient. This technique explained an additional 0.1% of the variance, and the change in R^2 was not statistically significant (Table 3).

Table 1 Demographics of inflammatory bowel disease patients participating in inflammatory bowel disease-knowledge inventory device study

Variable	Categories of variable	Patients, *n* (%)
Patient's gender	Female	140 (52.0)
	Male	129 (48.0)
Parent's gender	Female	232 (80.0)
	Male	58 (20.0)
Place of residence	Rural	172 (57.9)
	Urban	125 (41.1)
Parent's education	Lower than secondary	48 (16.2)
	Secondary	123 (41.6)
	Higher than secondary	125 (42.2)
Disease type	CD[1]	196 (65.8)

Nurse	66 (22.1)
Internet	197 (66.1)
Journals	82 (27.5)
Books	77 (25.8)

[1]One hundred and seventy-four questionnaires filled both by a child and a parent and 22 only by parents.
[2]Nity-five questionnaires filled both by a child and a parent and 7 filled only by parents. CD: Crohn's disease; UC: Ulcerative colitis.

As for the parents' IBD-KID scores, the first step of hierarchical linear regression introduced patient age, patient's self-assessment of knowledge and place of residence. All three variables exerted a significant effect on the parent's IBD-KID score (Supplementary Table 3). The model explained 7.5% of the variance of the parent's score. The second step added the parental education level and self-assessment of knowledge, J-elita Association membership and the use of books and journal as sources of knowledge (Supplementary Table 3). The change in R^2 with this model was equal to 0.045 and statistically significant. The third step introduced the variables reflecting treatment modalities. The results explained a further 6.5% (18.5% in total) of the variance of the parent's score. In the final model, patient age, parental education level, and the use of immunosuppressive agent were significant predictors of the parent's score (Table 4).

DISCUSSION

This study assessed the disease-specific knowledge of a large sample of paediatric IBD patients and their parents. This investigation is the first to be based on the dedicated tool in this particular group in Poland. We found that both patients and their parents had insufficient IBD-related knowledge. Univariate models developed for the patients' IBD-KID scores showed that these scores were higher among older than younger patients, among girls compared to boys, among patients who more highly assessed their knowledge about the disease and whose parents did the same. Furthermore, higher scores were found among patients whose parents indicated the Internet as a main source of information, reported membership in the J-elita Association and noted nutritional, surgical immunosuppressive or biological treatment. The patient's score was also positively associated with the parent's score. A fully developed hierarchical regression model maintained a significant association between patients' scores and their gender and age, parents' self-rated knowledge, and IBD-KID scores. Univariate analysis revealed that parents' scores were significantly higher among women compared to men, among the parents of younger *vs* older children, among those with higher self-rated knowledge and whose children better assessed their knowledge, among parents with higher *vs* lower levels of education, and among those using books and journals as sources of information. Membership in a patients' association and earlier immunosuppressive or biological treatment in a child were also associated with a higher score. The hierarchical regression model showed that a significant association was retained only for patient's age, prior immunosuppressive therapy and parental education level.

The average scores of our study's parents and patients agree with results obtained in paediatric studies carried out using the same questionnaire in Canada, Australia and New Zealand[11,14]. Other studies reported similar findings on factors influencing the IBD-KID scores as in our study. For example, a significant relationship between patients' and parents' IBD-KID scores and self-rated knowledge was reported by Haaland *et al*[10]. We have shown, as have they, a correlation between parents' level of education and parents' but not patients' scores [10]. However, this relationship was not observed by Vernon-Roberts *et al*[15] in an investigation using a modified version of the questionnaire: IBD-KID2.

We have found no correlation between IBD-KID score and disease duration. On the other hand, both uni- and multivariate analysis revealed a link between the IBD-KID

scores and patient's age. Other authors have suggested that the patients' and parents' core knowledge is obtained during the period of diagnosis of the disease. However, while patients' awareness and knowledge of the disease increases with age, parents gradually become less involved, eventually forgetting some information[10,16].

Numerous studies, both in children and adults with IBD, confirm that membership in organisations supporting IBD patients increases disease awareness and disease-specific knowledge[14,17,18]. Our study findings also seem to confirm these observations. Membership in the patient Crohn's and Ulcerative Colitis Association J-elita correlated with higher patient and parent scores. J-elita is a Polish patient association of adults and children diagnosed with IBD and a member of The European Federation of Crohn's & Ulcerative Colitis Associations. The aims of J-elita are to raise awareness about IBD and improve the life of the several thousand people living with IBD in Poland. This outcome may reflect patients' and their parents' involvement in the organisation's educational activities. Interestingly, the effect of membership was not retained in the multivariate models, possibly because both membership and higher scores could be achieved by more active patients or parents as reflected by the preserved effect of self-rated knowledge.

Our study revealed that the therapy modes used in a patient might be related to both patients' and parents' scores. Concerning exclusive enteral nutrition, which is recommended as a treatment inducing remission in paediatric CD patients[19], the specific nature of this treatment and the need for medical follow-up may explain why these patients usually remain longer under close medical monitoring during the first period of illness. Consequently, they have more frequent contact with qualified staff who can provide them with reliable information. Presumably, this situation contributes to greater and more systematic involvement in the treatment process.

In the case of the parent's score, a significant association was present for immunosuppressive treatment even after adjusting for other factors included in the multivariate model. Both immunosuppressive therapy and biological treatment are applied in more severe forms of IBD, and surgical intervention may be necessary when treating complications. Such patients usually have a longer history of multiple hospitalisations and treatment of exacerbations. Studies performed in adult IBD patients showed that more frequent hospitalisations were associated with better disease-

specific knowledge on the part of patients[20]. Therefore, in such circumstances, paediatric patients and their parents are also highly likely to be strongly motivated and more engaged in searching for additional information about the disease. Moreover, it is probable that greater parent's knowledge may lead to better disease management; the immunosuppressive therapy is currently most recommended in IBD.

In general, our study revealed that parents were much more likely to give correct answers compared to children (Supplementary material, Table 1). Both patients and parents revealed relatively adequate knowledge about anatomical conditions, risk of disease transmission, factors leading to exacerbations, and principles of treatment in remission. Areas of insufficient knowledge included the side effects of steroid therapy, the role of surgical treatment in IBD, dietary restrictions and the risks associated with the use of herbal medicines.

The pattern of knowledge seems very similar to that found in other countries[10-12, 14]. Fewer than 40% of children and slightly more than 50% of parents were aware that the disease itself, as well as poor nutrition and the use of steroids, could cause osteoporosis. Fewer than one-third of respondents knew that steroids could suppress a child's growth. Lack of sufficient knowledge regarding side effects caused by corticosteroids may be at least partially related to actual recommendations of avoiding steroid therapy, particularly on a long-term basis. Therefore, the side effects of steroid therapy may currently be seen less often than decades ago.

Particularly important is the lack of proper knowledge of nutrition for sick children. A significant proportion of those surveyed expressed the opinion that dietary restrictions, including the withdrawal of certain products from the diet, could prevent aggravation of the disease. This misunderstanding is a cause for serious concern, as frequent and unjustified food avoidance may influence the nutritional status and general well-being of paediatric patients[6]. Lack of awareness of the risks associated with the use of herbal medicines related to their potential interaction with other drugs turned out to be another area of poor knowledge. Similar results were obtained using

the shortened, simplified research tool IBD-KID2[21]. Therefore, this problem is not an isolated concern affecting only Polish patients. We can assume that certain information that doctors and medical staff consider obvious is not properly passed on to patients and their parents.

Proper education of patients with IBD, including paediatric patients and their parents, regarding their disease and treatment principles, may have a significant impact on the treatment compliance and ability to self-cope with the disease[22-24]. Research has also proved that the benefits of educational programmes outweigh anxiety regarding greater disease knowledge[25].

Better knowledge regarding drug mechanisms and drug side effects as well as better IBD-specific knowledge have also been shown to contribute to treatment compliance[7,8,26,27].

The strength of our study is its sample size; to date, this study is the largest investigation that has assessed disease-related knowledge in children with IBD. Polish validation of the questionnaire allowed comparing the IBD knowledge of both children with this disease and their parents to their peers in different countries undergoing different types of health care. The survey's main limitations include the use of the first version of the IBD-KID, which was recently revised. The new, simplified and shortened version, the IBD-KID2, was not available at the time of our study.

CONCLUSION

This study identified gaps in the IBD-related knowledge of Polish children with IBD

and their parents. The variables originating from the parents' knowledge, apart from the patients' demographic characteristics, were significantly associated with the patients' IBD-KID scores. Parents of patients treated with immunosuppressive agents showed higher disease-specific knowledge. The study results also confirmed that information acquired from a patient organisation can play a vital role in correct IBD-related knowledge. This finding forms a basis for intensified action aimed at creating educational programmes. Increased awareness of the disease and knowledge about treatment can have a positive effect on compliance with therapeutic recommendations.

ARTICLE HIGHLIGHTS

Research background

Patient knowledge is associated with increased treatment compliance and improvement of symptoms in a variety of chronic diseases, including inflammatory bowel disease (IBD). IBD-knowledge inventory device (IBD-KID) was developed and validated specifically as a tool to measure disease-related knowledge in children with IBD and their parents.

Research motivation

Until now, assessment of IBD-related knowledge in children with IBD and their parents were performed in Canada, Australia and France. However, the results of these studies cannot be simply projected to Poland due to the differences in lifestyle, diet and healthcare model. The importance of such factors for understanding and knowledge about disease in Polish patients with IBD requires a separate study.

Research objectives

Our present study aimed to assess disease-related knowledge in children with IBD and their parents.

Research methods

A questionnaire-based survey was carried out in 269 children with IBD and 298 parents. The determinants of patients' and parents' IBD-KID scores were assessed with hierarchical linear regression models.

Research results

We found that both patients with IBD and their parents had insufficient IBD-related knowledge. Patients' IBD-KID scores were higher among older than younger patients, among girls compared to boys, among patients who more highly assessed their knowledge about the disease and whose parents did the same. Furthermore, higher scores were found among patients whose parents indicated the Internet as a main source of information, reported membership in the patient Crohn's and Ulcerative Colitis Association J-elita and noted nutritional, surgical immunosuppressive or biological treatment. The patient's score was also positively associated with the parent's score.

Research conclusions

This study identified gaps in the disease-related knowledge of Polish children with IBD and their parents. Increased awareness of the disease and knowledge about treatment can have a positive effect on compliance with therapeutic recommendations.

Research perspectives

Further studies on disease-related knowledge among patients with IBD in countries undergoing economic transformation are needed. IBD-KID may be a good tool to assess transition of adolescents with IBD from pediatric to adult care. It could be also used in assessment of any intervention aimed to increase the level of patients' self-care.

Abstract

Detection of prevalence and development of osteopenia or osteoporosis in patients with inflammatory bowel disease using only bone mineral density could be inappropriate to detect all individuals at risk for osteoporosis. Numerous patients could remain undetected by using only bone mineral density as a screening method, especially in patients with ulcerative colitis. Therefore, trabecular bone score should be used as a complementary method.

Key Words: Inflammatory bowel disease; Osteoporosis; Bone mineral density; Trabecular bone score

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Lower body mass index is a predictor of osteoporosis in patients with inflammatory bowel disease however, fracture risk can be increased desite normal bone mineral density. Therefore, use of trabecular bone score would ensure recruitment of individuals with normal bone mineral density at increased risk of fractures in trials.

TO THE EDITOR

We read with a great interest the study by Ewid *et al*[1], that evaluated the connection between inflammatory bowel disease (IBD) and bone mineral density (BMD) in a sample of adult Saudi patients with IBD from a single center.

One important finding of this study was that Crohn's disease (CD) patients are at a higher risk of developing both osteoporosis and osteopenia than ulcerative colitis (UC) patients, even though the study included more patients with severe clinical disease activity and endoscopic activity in the UC group than in the CD group (25% *vs* 5%, respectively). In spite of disease severity, 78% of UC patients had normal BMD *vs* 44% of CD patients. Fracture risk can be increased despite normal BMD. Maldonado *et al*[2] suggested that current screening does not include all IBD patients at increased risk of fractures. We propose using trabecular bone score (TBS) as a complementary tool; as it discriminates patients at higher risk of fractures better than BMD[3].

According to demographic characteristics in the study, mesalamine use was significantly higher in the UC compared to CD group (81% *vs* 10%, respectively). Due to the sample size of UC group an analysis of BMD according to mesalamine use probably could not have been performed nevertheless, the analysis would be highly informative. Hence, we postulate a question: could mesalamine use have contributed to lower risk of developing osteoporosis in UC compared to the CD cohort?

Krajcovicova *et al*[4] observed no significant difference in the prevalence of low BMD in groups of patients with UC and CD. They observed that corticosteroid therapy and menopause had significant negative effects, whereas combined treatment with an anti-tumor necrosis factor (TNF) α agent and azathioprine had a significant positive effect on Δ BMD at the lumbar spine (BMDL) per year[4].

The study also showed that low BMI is a risk factor for reduced BMD. According to Fawzy *et al*[5] and Steinschneider *et al*[6], increased BMD commonly reported in overweight women may be a result of soft tissue interference, further supporting addition of TBS as a screening method for osteoporosis in research and clinical practice.

An unexpected finding in this study is the lack of correlation between steroid use and BMD. Paggiosi *et al*[7] demonstrated that TBS alone and BMDL in combination with TBS, but not BMDL alone were able to discriminate between glucocorticoid-treated and glucocorticoid-naïve women. In the study by Gulyás *et al*[8] TNF-α inhibition slowed down generalized bone loss in rheumatoid arthritis and ankylosing spondylitis. Effect of anti TNF therapy on bone metabolism was not confirmed by Ewid *et al*[1] hence, the effect is questionable in IBD.

Addition of TBS would enable inclusion of individuals with normal BMD at increased fracture risk. In conclusion, by including both screening methods osteoporotic fracture risk in UC *vs* CD cohort could be assessed more accurately.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

It is often difficult to explain why ulcerative lesions are found in the small intestine because there are no obvious aggressors such as gastric acid. In particular, the treatment of small intestinal ulcerative lesions in asymptomatic patients with no symptoms, normal physical examinations, and normal blood test findings is not well documented. According to a summary of capsule endoscopy studies in healthy subjects, approximately 10% of subjects have small intestinal mucosal breaks. The number of mucosal breaks in these instances is approximately 1-3. We examined small intestinal mucosal breaks in healthy subjects recruited from our past two studies. Mucosal breaks were observed in approximately 10% of subjects, and the average number was 0.24 ± 1.21. The number of mucosal breaks in the small intestine was correlated with body mass index and was significantly higher in *Helicobacter pylori*-infected subjects and higher in males. These results indicate that 1-2 small ulcerative lesions, such as erosions in the small intestine, can be considered to be in the normal range, and close examination is not required. It is assumed that a follow-up medical examination is required for such asymptomatic persons. The presence of many small ulcerative lesions or an unequivocal ulcer indicates an abnormality for which close examination is desired. However, in many cases, it is sufficient to scrutinize after detecting anemia, but it is difficult to make a judgment due to insufficient reports, and future studies are required.

small intestinal mucosal breaks. A reanalysis of our previous studies showed that small intestinal mucosal breaks were strongly correlated with body mass index, were significantly more prevalent in *Helicobacter pylori*-infected individuals and were more prevalent in men. These may be risk factors for small intestinal mucosal breaks. Overall, 1-2 small ulcerative lesions in asymptomatic patients are considered to be in the normal range and do not require close examination, and it is assumed that a follow-up medical examination is required.

INTRODUCTION

Ulcerative lesions are less common in the small intestine, except in the duodenum, than in the stomach. Even if some small ulcerative lesions such as erosions are found in the stomach, we do not care much because of the many accumulated reports and experiences. However, we are concerned with the cause of ulcerative lesions of the small intestine. This is because the small intestine lacks obvious aggressors such as gastric acid, making it difficult to explain the cause of ulcerative lesions. Moreover, there is insufficient knowledge about ulcerative lesions of the small intestine.

Screening colonoscopy occasionally detects a small number of small ulcerative lesions at the terminal ileum. Patients with small ulcerative lesions at the terminal ileum who do not take nonsteroidal anti-inflammatory drugs (NSAIDs) are often doubtful about Crohn's disease (CD) in endoscopic results reports. Some patients had small ulcerative lesions that could potentially progress to CD, and a case was reported [1]. Recently, a report described that CD was detected in 0.28% (13 out of 4640 cases) by colorectal cancer screening[2]. The report indicated that ileal ulcers were detected in 6 of 13 cases, suggesting that ileal ulcers were associated with CD. Four of the 6 patients had no lesions other than ileal ulcers, and the simple endoscopic score for CD was 2-6 points. In other words, some patients had a slightly larger ileal ulcer; however, all patients were scheduled only for a followed up without treatment. It is considered difficult to make an endoscopic diagnosis of the 4 patients with CD, and it is not stated whether granuloma was detected by histological examination. The diagnosis of CD is difficult in the early stages, but the patients in this study did not appear to meet the diagnostic criteria for CD[3]. The question remains as to the diagnosis of CD in these patients, and the follow-up results are considered important.

Subjects who were asymptomatic with no abnormalities in blood tests or physical tests and were not taking medication were defined as healthy subjects. This may include patients with asymptomatic diseases; however, these were subjects without any obvious disease. It is not easy to frequently follow-up with an endoscopy for asymptomatic small ulcerative lesions of the small intestine identified the screening test of healthy subjects because of the physical and financial burdens imposed on the subject. In addition, even if an asymptomatic small ulcerative lesion is found at the terminal ileum, it is considered to be rare and not enough reason to conduct close examination, such as capsule endoscopy. However, it is not clear whether this research policy is correct. This is because the treatment of small intestinal ulcerative lesions in asymptomatic patients is not reported. This is thought to be because reports on the proportion of ulcerative lesions in the small intestine found in healthy subjects and the cause of small intestinal ulcerative lesions are extremely few. In this paper, we summarize how many small intestinal ulcerative lesions are found in healthy subjects, analyze the degree of appearance of small intestinal ulcerative lesions, and investigate the causes of small intestinal ulcerative lesions where possible. Then, we would like to consider the research policy when small intestinal ulcerative lesions are found.

ANALYSIS OF SMALL INTESTINAL ULCERATIVE LESIONS IN HEALTHY SUBJECTS

Definition of small intestinal ulcerative lesions

Ulcerative lesions of the small intestine are often evaluated as mucosal breaks. A mucosal break is a lesion in which white slough is observed, and the degree varies from small ulcerative lesion erosion (Figure 1A) to ulcer (Figure 1B). It is difficult to clearly distinguish this lesion, and there are many cases in which it is not clear which category a specific lesion should be classified into, as shown in Figure 1C. This ulcerative lesion has white slough over 3 mm and approximately 5 mm. Since it is expected that the judgments by researchers will be different in categorizing this lesion, the frequency of appearance of mucosal breaks of healthy subjects was analyzed here.

Analysis of drug administration studies

In many studies, nonselective NSAIDs and cyclooxygenase 2-selective NSAIDs are administered to healthy subjects to compare the occurrence of small intestinal mucosal breaks. There are other studies in which mucosal protective drugs are administered at the same time as NSAIDs and aspirin to compare the effects of this combination. Capsule endoscopy has been performed in more than 1000 healthy subjects in various studies. In these studies, healthy subjects underwent capsule endoscopy before drug administration, and small intestinal evaluation of the healthy subjects was performed first. Table 1 summarizes the studies describing small intestinal mucosal breaks in healthy subjects before drug administration. Studies that do not describe these premedication small intestinal mucosal breaks and reports with a small number of subjects were not included in the Table 1.

According to the summarized results, approximately 10% of healthy subjects have small intestinal mucosal breaks. In addition, the number of mucosal breaks in subjects with mucosal breaks was approximately 1-3 in most examinations.

Analysis of small intestinal mucosal breaks in healthy subjects from our study

Our group has conducted several capsule endoscopy studies on healthy subjects. Two of these consisted of detailed tests and interviews, including tests for *Helicobacter pylori* (*H. pylori*) infection which bacterium is known to cause gastric ulcer, duodenal ulcer, atrophic gastritis, gastric cancer, *etc.*, at the start of the study. Since the number of subjects in each study was insufficient for analysis, we combined these two studies to analyze the background of healthy subjects. In two studies we tested for *H. pylori* infection with a breath test[4] and with serum antibodies[5] prior to the NSAID dosing experiment. In particular, the latter study was investigated to block randomize *H. pylori*-infected individuals evenly when randomized.

Table 2 shows the cases that were analyzed. The total number of cases included in the two studies was slightly higher than that shown in Table 1. This is because the first capsule endoscopy was completed, but the subjects who dropped out of the study were added. The subjects enrolled in the study were those who were considered to be healthy subjects after screening, the results of basic blood tests and physical tests were normal, and were not taking any medication. The number of mucosal breaks in the small intestine determined by capsule endoscopy in these healthy subjects was 0.24 ± 1.21 (mean ± SD). Based on these results, if the average ± 2 SD of healthy subjects is considered to be the normal range, up to 2 mucosal breaks of the small intestine are in the normal range.

Next, since the number of mucosal breaks recognized in the subjects was 1-2 in most cases, subjects were divided into 21 cases with mucosal breaks and 201 cases without mucosal breaks. Then, sex, age, body mass index (BMI), smoking, alcohol consumption, and *H. pylori* infection were compared and analyzed. The results of the univariate analysis showed that the incidence of mucosal breaks was higher in men, in subjects that had a higher BMI, and in *H. pylori*-infected subjects. Therefore, when multivariate analysis was performed with these factors, mucosal breaks were strongly correlated with BMI and were significantly more common in *H. pylori*-infected subjects (Table 3).

MUCOSAL BREAKS ARE SIGNIFICANTLY ASSOCIATED WITH BMI AND *H. PYLORI* INFECTION

The results of this analysis revealed that small intestinal mucosal breaks were

Premedication capsule endoscopy was completed, and subjects who dropped out in subsequent studies were included.

correlated with BMI. In many reports, it has been reported that obese people have different intestinal flora compared to those with proper weight. Additionally, specific bacteria, which are predominantly present in obese people, cause tight junctions in the intestinal tract to malfunction allowing bacterial products to pass through the intestinal wall[6]. The results of the analysis are considered to support this idea. High-fat diet also affects gut flora[7]. In addition, blood flow disorders due to arteriosclerosis and lack of exercise may be involved.

In addition, small intestinal mucosal breaks was higher in *H. pylori*-infected subjects. We do not consider *H. pylori*-infected subjects to be completely healthy individuals, so *H. pylori* infection was investigated prior to the capsule endoscopy study to evenly distribute *H. pylori*-infected subjects between the two groups in our previous study[5]. The results of this study support the idea that *H. pylori* infection also affects the small intestine. Currently, it is easy to understand that the reason why *H. pylori*-infected individuals have many small intestinal mucosal breaks is that *H. pylori* infection causes atrophic gastritis, which is caused by changes in the intestinal flora due to a decrease in gastric acid concentration. Experimental reports of exacerbation of NSAID ulcers by administration of proton pump inhibitors (PPIs) are widely known[8]. Since the bacterial cell components and bacterial products of *H. pylori* flow in the lumen of the small intestine and their involvement is doubtful, such examination may be necessary in the future.

Table 3 Analysis of mucosal breaks and background factors

Valuable	Mucosal break + (*n* = 21)	Mucosal break – (*n* = 201)	*P* value[1]	*P* value[2]
Sex	Male/female: 19/2	Male/female: 129/72	0.015	0.13

Drinking	14 (66.7%)	140 (70.0%)	0.78	
Helicobacter pylori	8 (38.1%)	13 (6.4%)	0.054	0.035

[1]Sex, smoking, alcohol consumption, and *Helicobacter pylori* were analyzed by the chi-square test, and age and body mass index were analyzed by the Mann-Whitney *U* test.
[2]*P* value by logistic multivariate analysis. BMI: Body mass index.

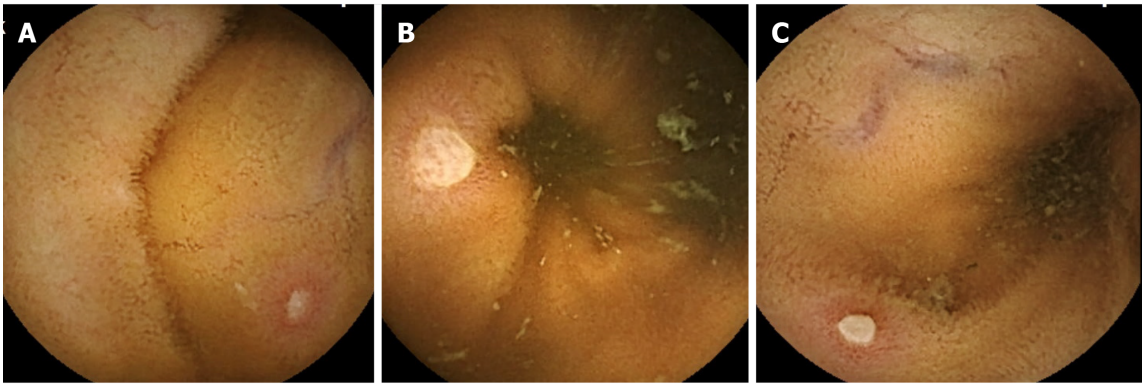

Figure 1 Endoscopic findings of small intestinal mucosal breaks. A: Erosion with white slough of approximately 3 mm; B: Ulcer with white slough of approximately 7 mm; C: The white slough is approximately 5 mm, and opinions of evaluation are divided by researchers.

In addition, small intestinal mucosal breaks tended to be higher in men. We were doubtful that smoking and alcohol consumption were related to mucosal breaks and no relationship was found between them in the analysis. CD is more common in men, and men may have some sex differences that are more likely to cause ulcerative lesions in the small intestine.

WHAT TO DO WITH SMALL INTESTINAL MUCOSAL BREAKS?

Any obvious ulcer should be considered abnormal. Table 4 summarizes the diseases and causes that cause small intestinal ulcers. Although it is not possible to mention the ulcer size here, it is natural to consider even one ulcer that is considered to be large or deep, such as white slough exceeding 1 cm, to be abnormal. However, what should we think of a small mucosal break with white slough up to approximately 5 mm?

As mentioned above, nearly 10% of healthy people have 1-2 small mucosal breaks. It would be physically and economically burdensome to follow-up with a capsule endoscopy for a person with a small number of asymptomatic mucosal breaks. Among the subjects examined in this study (Table 2), there were 3 male subjects with 5 or more mucosal breaks, but it was only confirmed at the end of the study that there were no abnormal symptoms or abnormal blood data. On the other hand, there is a case report in which a PPI was administered to a patient who had 6 mucosal breaks by capsule endoscopy before the study, and an increase in mucosal breaks was confirmed[9]. No abnormalities were found in this subject at a follow-up examination 2 years after the study.

If 3 or more small mucosal breaks are found in the small intestine, it is considered to exceed ± 2 SD on average and should be judged to be out of the normal range. There is a possibility that some of these asymptomatic lesions may develop into other diseases, such as CD, but there are few reports at this time, and there is not enough information

to consider follow-up guidelines. Considering the financial and physical burden of capsule endoscopy, it cannot be stated in detail how many mucosal breaks warrant followed-up, so presently the decision is left to each medical professional. Therefore, we think it is appropriate to perform a re-examination with a capsule endoscopy, *etc.*, when anemia or similar symptoms appear during follow-up at a normal health examination.

CONCLUSION

Based on this analysis, approximately 10% of healthy individuals have small intestinal mucosal breaks, and high BMI, *H. pylori*-infected individuals, and men are more likely to present with mucosal breaks. When up to 2 small mucosal breaks of 5 mm or less are found, this is considered to be within the normal range; therefore, asymptomatic persons with mucosal breaks could be followed up at a normal annual health examination. When a person has 3 or more small mucosal breaks, it is considered to be out of the normal range, but presently a follow-up schedule cannot be considered due to insufficient information. Nevertheless, when there is no significant number of mucosal breaks, follow-up should be carried out at a normal medical examination, and if anemia occurs, a close examination policy is sufficient. When a patient has an obvious ulcer, abnormality exists; therefore, close examination is desired. However, there is not enough information at this time to consider how to treat asymptomatic small intestinal ulcers.

We also hope that it should be clarified in future whether *H. pylori* and BMI really affect small intestinal ulcerative lesions in healthy subjects. 16s rRNA or metabolite sequencing of the intestinal flora between *H. pylori*-infected and uninfected as well as between high- and low-BMI assess whether small intestinal ulcerative lesions correlate with changes in the microbial flora. These researches such as comparing the intestinal

flora of objects is considered necessary. Future studies are required to address this issue.

Abstract

Gastrointestinal cancers occur in a total of eight different locations, each of them with a different standard of care. This article is not an exhaustive review of what has been published in 2020. We have concentrated on the thirteen phase III randomized studies that are practice-changing. All these studies are oral presentations which have been given in one of the four major oncology congresses, namely American Society of Clinical Oncology (ASCO), ASCO gastrointestinal (GI), European Society of Medical Oncology (ESMO) and ESMO-GI. We provide a concise view of these major trials and their main outcomes, and put these results into context.

Key Words: Practice changing trials; Immunotherapy; Gastrointestinal cancers; Gastrointestinal; Gastric cancer

Core Tip: Gastrointestinal cancers are one of the most frequent cancers and a leading cause of cancer deaths worldwide. Gastroenterologists, hepatologists and visceral surgeons interact daily with these patients. Bringing the community up to speed with new treatment paradigms in gastrointestinal oncology could improve patient care. Here we provide a clear, comprehensive and short overview of the most important practice changing trials from 2020.

INTRODUCTION

Gastrointestinal cancers are the most common form of cancer, affecting both men and women. A multidisciplinary approach is critical to ensure the most effective treatment and best care for each individual patient. 2020 has been a significant year with regard to gastrointestinal cancers, with many practice-changing trials taking place. Here, we aim to provide a clear, comprehensive and brief overview of highlights in the care of gastrointestinal cancer in 2020.

GASTROEOSOPHAGEAL CANCER

Neoadjuvant

Human epidermal growth factor receptor 2 (HER2) inhibition by trastuzumab and chemotherapy has shown clinically and statistically significant improvements in disease-free survival (DFS) and overall survival (OS) in HER2-positive advanced gastroesophageal cancer compared to chemotherapy alone and is now the standard of care for these patients[1].

NRG-RTOG 1010, presented at American Society of Clinical Oncology (ASCO) 2020, was an open-label randomized phase III trial including 203 patients with newly diagnosed HER2-positive (immunohistochemistry 3+ or FISH positive) esophageal cancer (EC) or gastroesophageal junction (GEJ) cancer[2]. Patients were randomized to receive trimodal standard of care (chemotherapy, radiotherapy and surgery) with or without trastuzumab. Participants in the standard of care arm received chemo-radiation therapy (CXRT) for 6 wk followed by surgery. Participants on the experimental treatment arm received weekly neoadjuvant trastuzumab during CXRT followed by adjuvant trastuzumab for 13 treatments after surgery. The primary endpoint of the trial was DFS. The median DFS was 14.2 mo in the standard of care arm and 19.6 mo in the experimental arm with a hazard ratio (HR) 0.97 (0.69, 1.36) and P = 0.85. OS was similar in both arms, 38.9 mo *vs* 38.5 mo in the experimental arm. Pathological complete response was equivalent in both arms: 29% *vs* 27% in the experimental arm.

Impact: HER2 inhibition is currently not recommended in the neoadjuvant setting for localised HER-2 amplified EC or GEJ cancer.

CXRT improves local control and survival in EC; however, local recurrence will occur in 50% of patients.

The ARTDECO trial presented at ASCO-GI 2020 was a randomised phase III multicentre study which randomised 260 patients with locally advanced unresectable EC (93%) and GEJ cancer (7%)[3]. Patients were treated with a standard dose of 50.4 Gy/1.8 Gy/5.5 wk to the tumor and regional lymph nodes *vs* the same dose combined with an integrated boost of 0.4 Gy per fraction (total 61.6 Gy) to the primary tumor. Chemotherapy consisted of 6 weekly concurrent carboplatin and paclitaxel in both arms. The primary endpoint was local progression-free survival (LPFS). There was no statistical difference in 3-year LPFS with 71% in the standard arm *vs* 73% in the experimental arm, nor was there a statistically significant difference in OS, with 41% *vs* 40% for the standard arm and experimental arm, respectively. LPFS was similar per histology. Overall grade 4 and 5 toxicity was 12% and 4% in the standard arm *vs* 14% and 10% in the experimental arm.

Impact: Radiation dose escalation in definitive CXRT treatment for locally advanced EC does not improve local control or OS.

Adjuvant

The risk of recurrence after neoadjuvant CXRT followed by surgery remains high, > 50% during the first 2 years in EC and GEJ cancer[4]. Currently there is no established adjuvant treatment in this setting. Nivolumab — an anti-PD1 checkpoint inhibitor — demonstrated superior survival in previously treated unresectable advanced or recurrent esophageal squamous cell carcinoma (ESCC) *vs* chemotherapy (ATTRACTION-3 trial)[5] and in gastric cancer (GC)/EGJ cancer *vs* placebo (ATTRACTION-2 trial)[6].

The CheckMate 577 study presented at European Society of Medical Oncology (ESMO) 2020 and recently published in the New England Journal of Medicine was a randomised, double-blind phase III study, evaluating nivolumab *vs* placebo in the adjuvant setting after trimodal therapy for EC and GEJ cancer[7]. Following R0 resection, 794 patients with stage II (approximately 35%) or III (approximately 65%), EC (approximately 60%) and EGJ cancer (approximately 40%) and residual pathologic disease were randomised to receive nivolumab for one year or placebo. Most patients (approximately 70%) had adenocarcinomas. The primary endpoint was DFS. At a pre-specified interim analysis, adjuvant nivolumab showed an improved DFS of 22.4 mo compared to 11 mo in the placebo arm with HR = 0.69 (0.56-0.86) and P = 0.0003. Treatment-related adverse events (TRAEs) occurred in 13% of the nivolumab arm *vs* 6% in the placebo arm (Figure 1), patient-reported outcomes were similar in both arms.

Impact: Nivolumab is the first adjuvant therapy to provide a reduction in the risk of recurrence or death in resected EC/GEJ cancer with residual disease after trimodal treatment. These results establish nivolumab as a new standard of care in these patients.

Advanced/metastatic

Patients with inoperable or metastatic GC have a median OS of less than 1 year[8,9]. Currently, these patients are treated with doublet chemotherapy which has improved OS and quality of life (QoL) compared to single-agent chemotherapy or best supportive care alone[10,11].

The CheckMate 649 trial, presented at ESMO 2020, evaluated in an open label, randomised phase III trial the efficacy of nivolumab in the treatment of previously untreated, unresectable advanced or metastatic GC/EGJ cancer and esophageal adenocarcinoma[12]. A total of 1581 patients were treated with nivolumab plus chemotherapy (FOLFOX or XELOX) or chemotherapy alone. Programmed cell death ligand 1 (PD-L1) protein expression in gastric or GEJ adenocarcinoma is determined by using the combined positive score (CPS), which is the number of PD-L1 staining cells (tumour cells, lymphocytes, macrophages) divided by the total number of viable tumour cells, multiplied by 100. The specimen should be considered to have PD-L1 expression if CPS ≥ 1. Primary outcomes were OS and PFS in patients with CPS > 5%. OS in CPS > 5% was 14.4 mo in the nivolumab and chemotherapy arm *vs* 11.1 mo in the chemotherapy arm alone with HR: 0.71 (0.59-0.86, P < 0.0001) (Figure 2A). PFS in CPS > 5% was 7.7 mo in the experimental arm *vs* 6 mo (P < 0.0001) in the control arm (Figure 2B). A statistically significant benefit was also seen with nivolumab when assessing OS and PFS in patients with PD-L1 CPS ≥ 1% and the overall randomised population. Serious TRAEs occurred in 22% of the experimental arm *vs* 12% in the control arm.

The ATTRACTION-4 trial, presented at ESMO 2020, was a double-blind, phase III randomised trial evaluating the combination of nivolumab with chemotherapy (SOX or CAPOX) *vs* chemotherapy alone in GC/EGJ cancer[13]. Primary outcomes were PFS and OS. At an interim-analysis, median PFS was improved in the experimental arm at 10.45 mo *vs* 8.34 mo, HR: 0.68 (0.51-0.90) and P = 0.0007. However, OS was comparable in both arms 17.45 mo *vs* 17.15 mo in the experimental arm (P = 0.257).

The Keynote 590 study, presented at ESMO 2020, was a double-blind, placebo-controlled study evaluating pembrolizumab (anti-PD-1) plus chemotherapy (cisplatin and 5FU) *vs* placebo plus chemotherapy as first-line treatment for locally advanced unresectable or metastatic AEC or ESCC or advanced/metastatic EGJ Siewert I adenocarcinoma[14]. Primary outcomes were OS in ESCC with CPS > 10% and whole population and PFS in the whole population. The majority of subjects (approximately 70%) had ESCC, AEC represented approximately 15% and EGJ approximately 12% of the study population. OS was significantly increased in the experimental arm in ESCC with CPS > 10% with a median OS of 13.9 mo *vs* 8.8 mo in the control arm (P < 0.0001) as well as in the ESCC overall population with OS of 12.4 mo *vs* 9.8 mo (P = 0.0006). PFS in ESCC was significantly increased in the experimental arm with 6.3 mo *vs* 5.8 mo (P < 0.0001).

Impact: The combination of PD-1 blockage (nivolumab or pembrolizumab) with chemotherapy could be considered a new standard first-line option for advanced or metastatic ESCC CPS > 10%, GC and EGJ CPS > 5%.

DFS: Disease-free survival.

HEPATOCELLULAR CARCINOMA

Advanced/metastatic

For the last 10 years the first-line treatment of unresectable hepatocellular carcinoma (HCC) was sorafenib. In 2018, lenvatinib showed its non-inferiority compared to sorafenib, offering a second option in first-line treatment[15].

The IMbrave150 trial was an open-label, phase III trial. Patients with unresectable HCC and without previously systemic treatment were randomly assigned to receive either atezolizumab (anti-PD-L1) plus bevacizumab (anti-VEGF) or sorafenib[16]. All patients were Child-Pugh A and the aetiology of underlying liver disease was viral hepatitis in approximately 70% of the study population. The co-primary endpoints were OS and PFS. At the first interim analysis, OS at 12 mo was 67.2% in the experimental arm and 54.6% in the standard arm with HR 0.58 (0.42-0.79, $P < 0.001$). Median PFS was 6.8 mo in the experimental arm *vs* 4.3 mo ($P < 0.001$). Grade 3 or 4 adverse events occurred in 56.5% in the experimental arm and in 55.1% in the control arm. Moreover, this combination delayed the deterioration of patient-reported functioning and QoL *vs* sorafenib in this patient population to a meaningful degree.

Impact: Atezolizumab + bevacizumab is now considered first-line standard of care therapy in patients with unresectable HCC.

COLON CANCER

Adjuvant

For stage III colon cancer, the addition of oxaliplatin to a fluoropyrimidine improved DFS and OS in the adjuvant setting. Since 2004, a 6-mo regimen of FOLFOX or CAPOX is the standard adjuvant therapy in stage III disease[17-19]. However, oxaliplatin is associated with cumulative neurotoxicity that can be severe, which potentially affects patients' activities of daily living, and can persist long beyond the actual treatment. If efficacy were maintained, shorter adjuvant therapy duration would be beneficial for patients as it could spare them toxic effects and health expenditures.

An international duration evaluation of adjuvant therapy trial investigated the non-inferiority of 3 mo of adjuvant therapy (either FOLFOX or CAPOX) compared to 6 mo of treatment[20]. The primary endpoint was the rate of DFS at 3 years. Non-inferiority of 3 mo of therapy, as compared to 6 mo, was not confirmed in the overall population. However, in patients treated with CAPOX, 3 mo of therapy was as effective as 6 mo, particularly in the lower-risk subgroup.

At this year's ASCO, Sobrero *et al*[21] presented the OS (secondary outcome) and an update of the DFS (median follow-up of 6 years). Again non-inferiority of OS for 3 mo

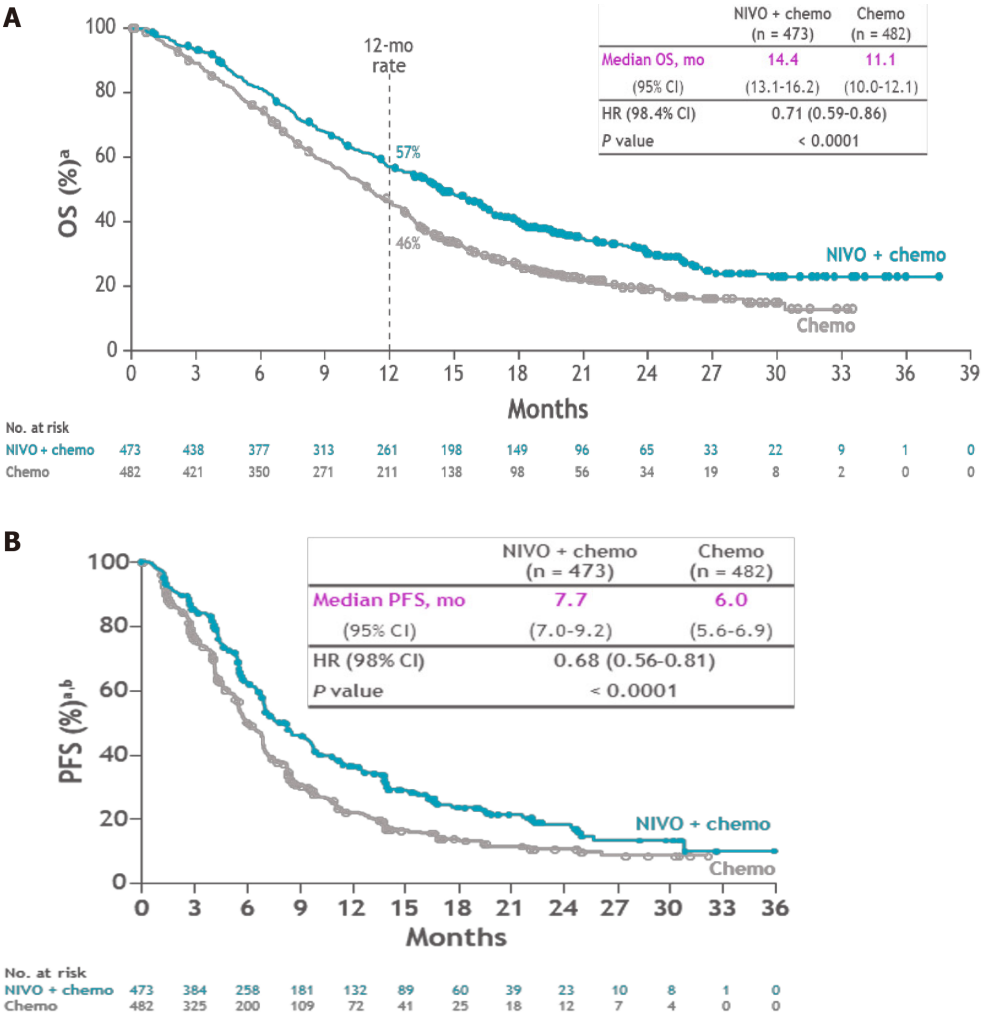

Figure 2 Overall survival and progression-free survival in patients with programmed cell death ligand 1 combined positive score of more than 5% (CheckMate 649). A: Overall survival; B: Disease-free survival. Citation: Moehler M, Shitara K, Garrido M, Salman P, Shen L, Wyrwicz L, Yamaguchi K, Skoczylas T, Bragagnoli AC, Liu T, Schenker M, Yanez P, Tehfe M, Poulart V, Cullen D, Lei M, Kondo K, Li M, Ajani JA, Janjigian YY. Nivolumab (nivo) plus chemotherapy (chemo) *vs* chemo as first-line (1L) treatment for advanced gastric cancer/gastroesophageal junction cancer (GC/GEJC)/esophageal adenocarcinoma (EAC): First results of the CheckMate 649 study. *Ann Oncol* 2020; 31(4): S1191. Copyright ©The Author(s). Published by European Society of Medical Oncology[12]. PFS: Progression-free survival; HR: Hazard ratio; CI: Confidence interval; OS: Overall survival.

(82.4%) *vs* 6 mo (82.8%) treatment was not demonstrated (P = 0.0583). OS was 82.1% for patients treated with 3 mo of CAPOX compared to 81.2% in those receiving it for 6 mo. In patients treated with FOLFOX, 3 mo survival was 82.6% compared to 83.8% for 6 mo survival (Figure 3A). Five-year DFS was 70% for 3 mo CAPOX compared to 69.3% for 6 mo and 68.4% for 3 mo FOLFOX compared to 71.7 for 6 mo (Figure 3B). Finally, for low risk (T1-3, N1) cancers, OS with 3 mo treatment was 89.6% compared to 88.9% for 6 mo. In high risk (T4 / N2) cancers, OS was 72% for 3 mo and 74.1% for 6 mo.

Impact: Stage III low risk colon cancer can be treated with either 6 mo FOLFOX or 3 mo CAPOX. High-risk stage III colon cancer can be treated with 6 mo FOLFOX or 6 mo CAPOX, although the difference in clinical benefit between 3 and 6 mo CAPOX is small.

Follow-up

In colon cancer, 30%-50% of all patients will relapse and die of the disease. Intensive follow-up of patients after curative surgery to detect recurrence and/or metachronous cancers is recommended[22]. However, these recommendations are based on expert opinions, and clinical trials have shown contrasting results[23]. A Cochrane meta-analysis showed no survival benefit of intensive follow-up[24]. Which tests should be performed and what the optimal frequency for surveillance of cancer recurrence might be are still unknown.

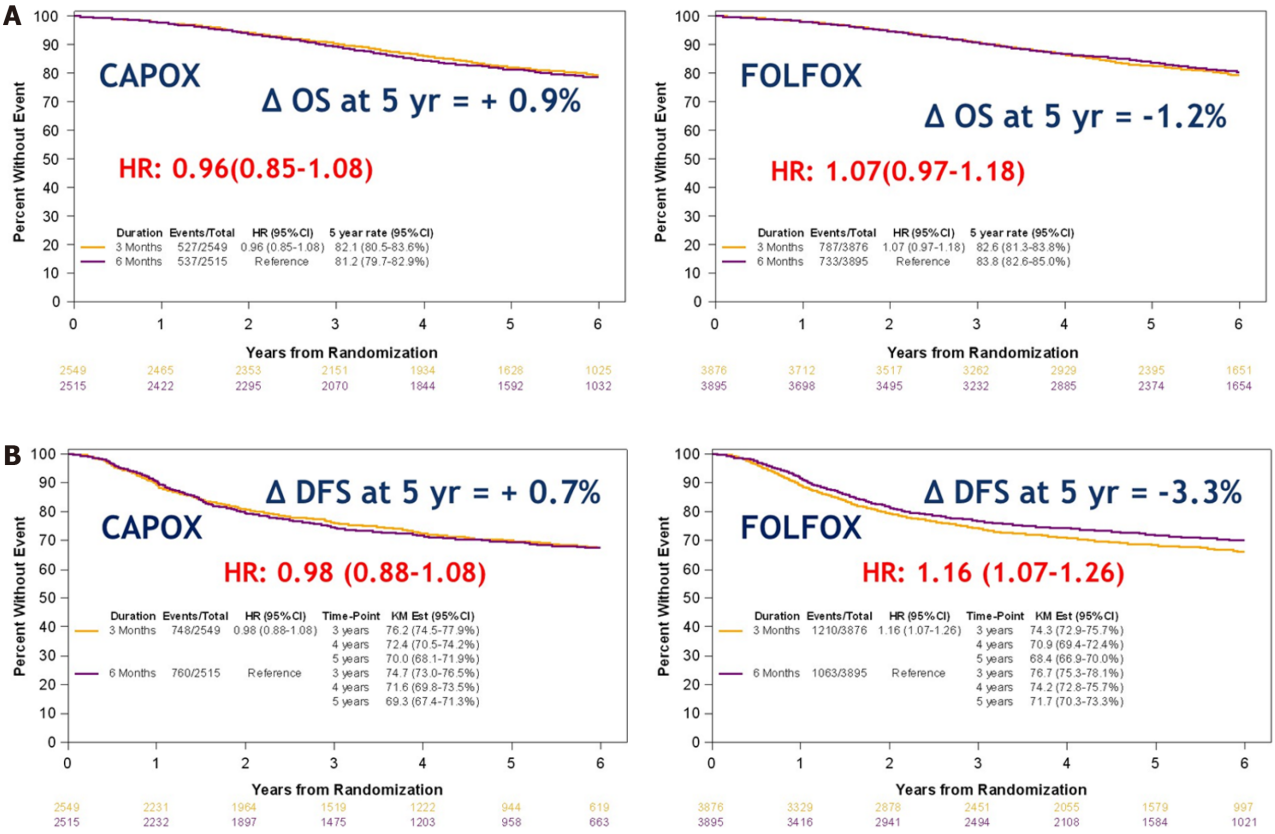

Figure 3 Overall survival and disease-free survival with 3 mo *vs* 6 mo of adjuvant therapy (international duration evaluation of adjuvant therapy). A: Overall survival; B: Disease-free survival. Overall survival (OS) and long-term disease-free survival (DFS) of three *vs* six months of adjuvant (adj) oxaliplatin and fluoropyrimidine-based therapy for patients (pts) with stage III colon cancer (CC): Final results from the IDEA (International Duration Evaluation of Adj chemotherapy) collaboration. *J Clin Oncol* 2020; 38(15): 4004-4004. Copyright ©The Author(s). Published by the American Society of Clinical Oncology[21]. DFS: Disease-free survival; HR: Hazard ratio; OS: Overall survival.

The PRODIGE 13 study, presented at ESMO 2020, was a prospective multicentre phase III-controlled trial evaluating the impact of intensive follow-up on OS in 1995 resected stage II or III colorectal cancer (CRC) patients[25]. Patients were double randomised, first in the CEA assessment arm *vs* no assessment and then in the intensive radiological follow-up arm [computed tomography (CT)-scan every 6 mo] *vs* low intensity follow-up (abdominal ultrasound every 3 mo and thoracic radiography every 6 mo). The primary endpoint was 5-year OS.

The majority (77%) of patients were less than 75 years old and had CRC (16% rectal, 84% colon cancer). Half of them had stage II disease, 50% being high risk stage II. This study showed no difference in terms of OS and recurrence-free survival for any of the surveillance arms. In the sub-group of patients with recurrence, curative surgery was achieved in 40.9% of the ''minimum follow-up'' group, 66.3% in the ''CEA'' group and standard imaging, 50.7% in the ''no CEA and CT scan'' group, and 59.5% in the maximum follow-up group. Although the differences were significant (P = 0.0035), OS was identical in all arms (P = 0.887).

Impact: A low intensity surveillance (no CEA, abdominal ultrasound and chest X-ray) could soon be the new standard for CRC surveillance after curative resection for patients not amenable to a second curative resection.

Metastatic

Patients with microsatellite instability-high (MSI-H) or mismatch repair deficient (dMMR) CRC represent 5% of all patients with metastatic CRC. The presence of MSI-H is associated with decreased survival rates and less response to conventional chemotherapy[26]. However, MSI-H or dMMR tumours respond better than microsatellite stable tumours to anti-PD1 or antiPD-L1, immunotherapy. In May 2017, the FDA approved the use of pembrolizumab (anti-PD-1), for the treatment of metastatic MSI-H/dMMR CRC patients who have progressed on chemotherapy.

The KEYNOTE-177 trial presented at the plenary session at ASCO 2020 and recently published in the New England Journal of Medicine was a randomised, phase III clinical trial that evaluated the efficacy of pembrolizumab in the first-line treatment of newly diagnosed MSI-H/dMMR metastatic CRC compared to chemotherapy (doublet +/- biologic)[27]. The co-primary outcomes were PFS and OS. At a median follow-up of 32.4 mo, the median PFS with pembrolizumab was 16.5 mo compared to 8.2 mo with chemotherapy HR: 0.60 (0.45-0.80, $P = 0.0002$). Adverse events grade ≥ 3 were less common (22%) in the experimental arm compared to the standard arm (66%). QOL assessed with QLQ-C30 and EQ-5D was improved with pembrolizumab compared to chemotherapy ($P = 0.002$).

Impact: Pembrolizumab (anti-PD1) is a new standard of care in the first-line treatment of MSI-H/dMMR metastatic CRC.

Approximately 20% of patients with CRC are diagnosed with stage IV disease. For those with an asymptomatic primary tumour, the question remains whether the primary tumour should be removed first.

The iPACS study presented at ASCO-GI 2020 was a randomised phase III trial comparing primary tumour resection (PTR) plus chemotherapy compared to chemotherapy alone in asymptomatic stage IV CRC patients[28]. The primary endpoint was OS. Investigators aimed to recruit 770 patients but due to slow accrual the sample size was decreased to 280. The Data and Safety Monitoring Committee (DSMC) recommended early termination of the trial due to futility at the first interim analysis in September 2019. With a median follow-up period of almost 2 years, there was no OS difference ($P = 0.69$) between PTR plus chemotherapy (OS: 25.9 mo) and the chemotherapy alone arm (26.7 mo). Median PFS was 10.4 mo for PTR plus chemotherapy *vs* 12.1 mo for chemotherapy alone. There were three treatment-related deaths following PTR due to postoperative complications.

Impact: Currently, PTR in asymptomatic stage IV CRC patients cannot be recommended.

RECTAL CANCER

Neoadjuvant

Locally advanced rectal cancer is treated with neoadjuvant CXRT followed by surgery 8 to 12 wk later. Neoadjuvant CXRT provides a significant reduction in local recurrence but not in distant metastasis rate[29]. Furthermore, adjuvant chemotherapy in rectal cancer is difficult to administer due to poor compliance[30-32]. Indeed, rectal cancer surgery is frequently associated with a high complication rate and patients are not always able to receive chemotherapy postoperatively.

To ensure efficient treatment of both the local tumour and possible micrometastases, an alternative approach would be to administer the systemic therapy preoperatively after short-course radiotherapy (5 d). During this waiting period the patient is in a good condition to receive an optimal dose of chemotherapy. Two phase III trials (RAPIDO and PRODIGE 23) hypothesized that neoadjuvant chemotherapy will result in increased survival in locally advanced rectal cancer patients.

The RAPIDO trial, presented at ASCO 2020 and recently published in The Lancet Oncology, is a phase III randomised trial comparing standard CXRT before surgery +/- adjuvant chemotherapy (standard arm) to total neoadjuvant treatment (TNT) with short-course radiotherapy (5 × 5 Gy) followed by chemotherapy (XELOX 6 cycles or FOLFOX 9 cycles) before surgery (experimental arm)[33]. The trial accrued only patients with locally advanced rectal cancers defined as cT4a/b, extramural vascular invasion, cN2, involved mesorectal fascia, or enlarged lateral lymph nodes. The primary outcome was disease-related treatment failure (DrTF) defined as distant metastasis, locoregional failure, new primary CRC or treatment-related death. The 3-year DrTF was improved in the experimental arm at 23.7% *vs* 30.4% for the control arm ($P = 0.019$). The experimental arm showed an improved pathological complete response (28% *vs* 14%; $P < 0.001$) and reduced distant metastases (20.0% *vs* 26.8%, $P = 0.005$), but no improvement in locoregional failure rates (8.7% *vs* 6.0%, $P = 0.09$), 3-year OS (89.1% *vs* 88.8%, $P = 0.59$) or QoL.

The PRODIGE 23 trial presented at ASCO was a phase III randomised trial investigating TNT with modified (m)FOLFIRINOX (leucovorin, infusional 5-FU, irinotecan, oxaliplatin) before standard CXRT, followed by surgery and adjuvant treatment in locally advanced rectal cancer patients compared to standard CXRT followed by surgery and compulsory adjuvant treatment[34]. This trial also accrued only patients

Table 1 Overview of latest phase III trials in gastrointestinal cancers

Studies	Population	Intervention	Control	Primary endpoints	Results
Gastroesophageal cancers					
Neoadjuvant					
NRG-RTOG 1010	HER2-positive EC or GEJ	Trastuzumab + CXRT + surgery	CXRT + surgery	DFS	19.6 mo *vs* 14.2 mo (HR = 0.97)
ARTDECO	Locally advanced unresectable EC and GEJ	Standard CXRT + RT boost	Standard CXRT	3-yr LPFS	73% *vs* 71% (NS)
Adjuvant					
Checkmate-577	EC and EGJ and residual pathologic disease	Nivolumab	Placebo	DFS	22.4 mo *vs* 11 mo (HR = 0.69)
Advanced/metastatic					
Checkmate-649	Untreated, unresectable advanced or metastatic GC/EGJ	Nivolumab + CT	CT	OS; PFS	14.4 mo *vs* 11.1 mo (HR = 0.71); 7.7 mo *vs* 6 mo (HR = 0.68)
ATTRACTION-4	Untreated, unresectable advanced or metastatic GC/EGJ	Nivolumab + CT	CT + placebo	OS; PFS	17.45 mo *vs* 17.15 mo (HR = 0.90); 10.45 mo *vs* 8.34 mo (HR = 0.68)
Keynote-590	Untreated, unresectable advanced or metastatic EC/EGJ	Pembrolizumab + CT	CT + placebo	OS; PFS	12.4 mo *vs* 9.8 mo (HR = 0.73); 6.3 mo *vs* 5.8 mo (HR = 0.65)
Hepatocellular carcinoma					
Advanced/metastatic					
Imbrave 150	Untreated, unresectable HCC	Atezolizumab + bevacizumab	Sorafenib	12-mo OS; PFS	67.2% *vs* 54.6% (HR = 0.58); 6.8 mo *vs* 4.3 mo (HR = 0.59)
Colon cancer					
Adjuvant					
IDEA	Resected stage III CRC	3 mo adj. CAPOX 3 mo adj. FOLFOX	6 mo adj. CAPOX ; 6 mo adj. FOLFOX	5-yr DFS	70% *vs* 69.3% (HR = 0.95); 68.4% *vs* 71.7% (HR = 1.16)
Follow-up					
PRODIGE 13	Resected stage II or III CRC	Low intensity follow-up	High intensity follow-up	5-yr OS	NS
Metastatic					
Keynote-177	Untreated, unresectable metastatic MSI-H/dMMR CRC	Pembrolizumab	CT	PFS	16.5 mo *vs* 8.2 mo (HR = 0.6)
iPACS	Asymptomatic stage IV CRC	Tumor resection + CT	CT	OS	25.9 mo *vs* 26.7 mo (HR = 1.10)
Rectal cancer					
Neoadjuvant					
RAPIDO	Locally advanced rectal cancer	RT + Neoadj. CT + surgery	CXRT + surgery +/-adj. CT	3-yr DrTF	23.7% *vs* 30.4% (HR = 0.76)
PRODIGE 23	Locally advanced rectal cancer	Neoadj. CT + CXRT + surgery + adj. CT	CXRT + surgery +/-adj. CT	3-yr DFS	75.7% *vs* 68.5% (HR = 0.69)

CRC: Colorectal cancer; CT: Computed tomography; CXRT: Chemo-radiation therapy; DFS: Disease-free survival; dMMR: Mismatch repair deficient; DrTF: Disease-related treatment failure; EC: Esophageal cancer; GC: Gastric cancer; GEJ: Gastroesophageal junction cancer; HCC: Hepatocellular carcinoma; HR: Hazard ratio; LPFS: Local progression-free survival; MSI-H: Microsatellite instability high; NS: Not significant; OS: Overall survival; PFS: Progression-free survival; RT: Radiotherapy.

with locally advanced rectal cancers defined as cT3 or cT4 M0. The primary endpoint

was DFS. Surgical morbidity did not differ between the two arms. TNT significantly improved pathological complete response rate at 27.5% compared to 11.7% in the CXRT alone arm (P = 0.001). TNT significantly improved 3-year DFS (75.7% *vs* 68.5%, HR 0.69, P = 0.034) and 3-year metastasis-free survival (78.8% *vs* 71% in CXRT alone, HR 0.64, P = 0.02). Global quality-of-life scores were similar.

Impact: TNT could be an option in locally advanced rectal cancer patients.

CONCLUSION

This year has been particularly significant in gastrointestinal oncology (Table 1). Immunotherapy has finally entered the scene with numerous indications - first-line MSI-H/dMMR metastatic CRC, first-line metastatic ESCC CPS > 10%, as adjuvant treatment in GC with CPS > 5%, as adjuvant treatment in resected EC/GEJ cancer with residual disease after trimodal treatment and first-line advanced HCC. The field has reached maturity with treatment de-escalation in the adjuvant setting for CRC and in the follow-up after curative surgery for CRC. On the other hand, in locally advanced rectal cancer intensification with TNT has found its place in the treatment landscape.

Abstract

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is considered the causative pathogen of coronavirus disease 2019 (COVID-19) and has become an international danger to human health. Although respiratory transmission and symptoms are still the essential manifestations of COVID-19, the digestive system could be an unconventional or supplementary route for COVID-19 to be transmitted and manifested, most likely due to the presence of angiotensin-converting enzyme 2 (ACE2) in the gastrointestinal tract. In addition, SARS-CoV-2 can trigger hepatic injury *via* direct binding to the ACE2 receptor in cholangiocytes, antibody-dependent enhancement of infection, systemic inflammatory response syndrome, inflammatory cytokine storms, ischemia/reperfusion injury, and adverse events of treatment drugs. Gastrointestinal symptoms, including anorexia, nausea, vomiting, and diarrhea, which are unusual in patients with COVID-19, and some digestive signs may occur without other respiratory symptoms. Furthermore, SARS-CoV-2 can be found in infected patients' stool, demonstrating the likelihood of transmission through the fecal-oral route. In addition, liver function should be monitored during COVID-19, particularly in more severe cases. This review summarizes the evidence for extra-pulmonary manifestations, mechanisms, and management of COVID-19, particularly those related to the gastrointestinal tract and liver.

Core Tip: The coronavirus disease 2019 (COVID-19) pandemic has affected millions worldwide, with high lethality. In addition to typical respiratory symptoms of COVID-19, gastrointestinal and hepatic symptoms have been frequently observed in COVID-19 patients. The main purpose of this article is to focus on the manifestations, mechanisms, and management of the gastrointestinal tract and liver that occurred during the course of COVID-19. Therefore, physicians must not undervalue the digestive symptoms during COVID-19 and rapidly adjust the treatment options for COVID-19 patients with gastrointestinal symptoms and liver enzyme abnormalities.

INTRODUCTION

Coronaviruses (CoV) is the largest group of spike-like viruses in the Nidovirales family. In the last two decades the CoVs have caused three worldwide outbreaks, with the most recent pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) which has resulted in coronavirus disease 2019 (COVID-19). The first 21st century outbreak in Guangdong Province, China, in November 2002, caused by SARS-CoV (SARS-CoV-1), an extreme SARS, resulted in 8098 fatalities (9.6%) globally [1,2]. The second outbreak in Saudi Arabia in 2012 was caused by Middle East respiratory syndrome (MERS)-CoV, with 2521 (36%) confirmed deaths[3].

SARS-CoV-2 first originated in China in December 2019 and critically threatened worldwide health[4,5]. On February 12, 2021, 108 million cases and 2 million deaths have been recorded in over 219 countries and regions worldwide[6]. The lung is the primary organ involved in COVID-19 pneumonia, and most COVID-19 patients suffer typical respiratory symptoms (*e.g.*, dyspnea, cough with sputum production, fatigue, and in severe cases, acute respiratory distress syndrome (ARDS), respiratory failure, and even death). On the other hand, extrapulmonary clinical manifestations of COVID-19 affect multiple other organs including cardiovascular (*e.g.*, arrhythmias, myocarditis, pericarditis, acute coronary syndrome, and heart failure), renal (*e.g.*, acute kidney injury and acute tubular necrosis), hepatic [*e.g.*, elevated alanine aminotransferase (ALT), aspartate aminotransferase (AST), and bilirubin], gastrointestinal (*e.g.*, diarrhea, nausea, vomiting, and abdominal pain), ocular (*e.g.*, epiphora, conjunctivitis, and chemosis), dermatologic (*e.g.*, erythematous rash, urticaria, and chickenpox-like vesicles), and neurological systems (*e.g.*, headache, neuropathy, encephalopathy, cerebrovascular disorders, and dizziness)[7] (Figure 1). Considering all the previously mentioned data, this article examines the effects of gastrointestinal (GI) and hepatic symptoms, their associated mechanisms, and management caused by SARS-CoV-2 infection and provides a guide for clinical prevention and treatment (Figure 2).

DISEASE COURSE OF COVID-19

For SARS-CoV-2, the incubation period is an average of 4-5 d, with most patients having symptoms before 14 d, although there have been instances where the incubation period was longer[8]. The infection and hospitalization onset was documented from 9.1 to 12.5 d and emphasizes the difficulty in the early stage of the diagnosis and isolation of populations[9]. The average period for recovering patients from initial symptoms is 22 d, and for those who succumbed the time to death is approximately

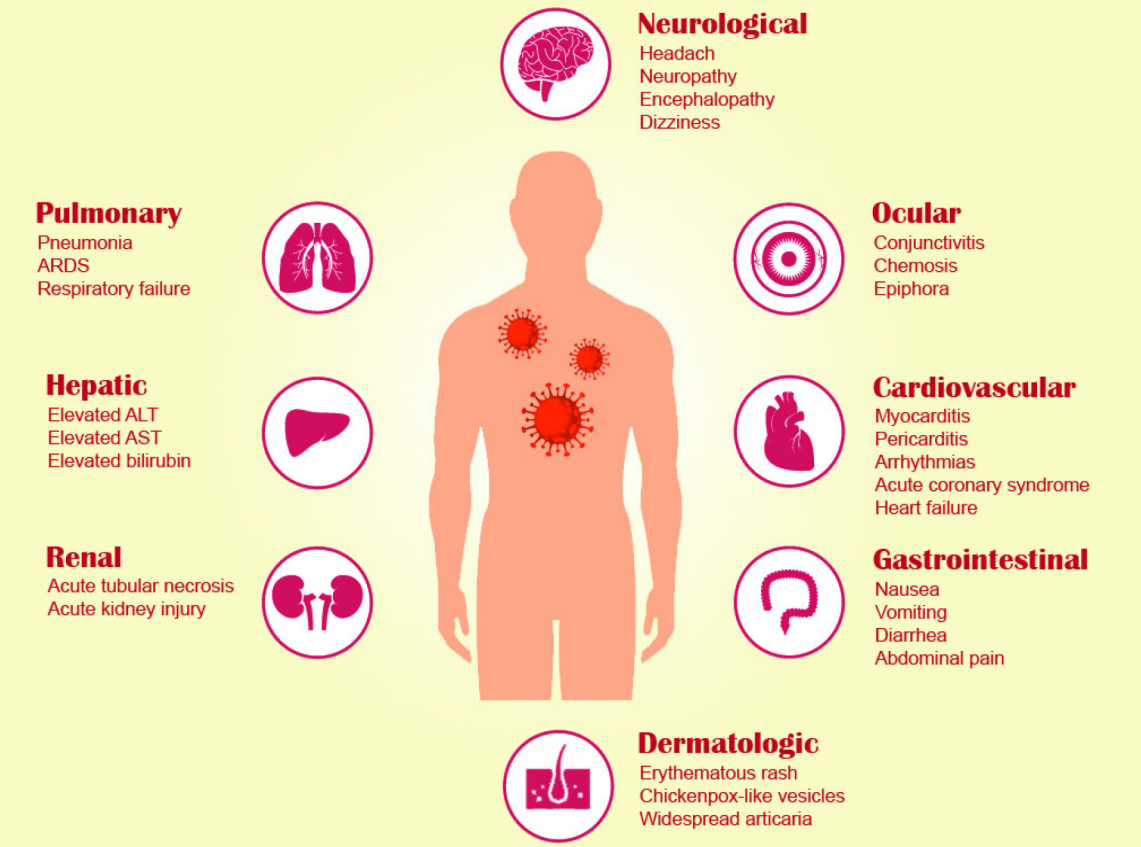

Figure 1 Pulmonary and extrapulmonary manifestations of coronavirus disease 2019. ARDS: Acute respiratory distress syndrome; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase. Headache and urticaria spelled wrongly.

18.5 d[9].

Overall, the case fatality ratio of COVID-19 is reported to be around 1-2% in patients aged 80 years, to over 15%[10]. Currently, WHO data show that most COVID-19 cases have mild to moderate signs of illness (80%), and 13.8% of cases have serious signs within 24-48 h with the following symptoms: shortness of breath; hypoxia < 300% and/or pulmonary infiltration > 50%; tachypnea > 30 breaths/min[11]. 6.1% of patients with critical infections also have septic shock, respiratory and multiple-organ failure[11,12]. Approximately 25% of hospitalized patients require intensive care unit (ICU) care, and 4.3% die[12].

GENDER AND RACE DURING COVID-19

It has been demonstrated that 51% of reported cases of COVID-19 are male patients. This may be due to the higher levels of estrogen in female COVID-19 patients which can reduce COVID-19 severity and mortality *via* the elevation in innate and humoral immunity[13-19]. Moreover, *in vivo* studies have demonstrated that there are higher levels of angiotensin-converting enzyme 2 (ACE2) expression in male kidneys than in female kidneys, which may explain the differences in the susceptibility and development of COVID-19 between male and female patients.

Whether ACE2 expression varies in the lungs of male and female COVID-19 patients, is still unclear[20,21]. Furthermore, preclinical trials have suggested that ACE2 expression may increase vulnerability to COVID-19 in pregnant patients[22,23].

In the same way, COVID-19 varies between different ethnic groups in terms of severity and mortality. During the COVID-19 pandemic, American, Hispanic, and African communities have displayed higher rates of infection and hospitalization in comparison to Caucasian communities[24]. These discrepancies may be due to the higher occurrence of heart diseases, hypertension, obesity, diabetes, and asthma in minority groups[24].

GASTROINTESTINAL SYMPTOMS AND COVID-19

GI manifestations in COVID-19 patients

Gastrointestinal symptoms including, nausea, anorexia, vomiting, diarrhea, and abdominal pain are common in COVID-19 patients (Table 1)[12,25-35]. In the SARS infection of 2002-2003, diarrhea was the main feature and appeared in 16%-73% of SARS patients mainly in the first week of infection[36]. Similarly, diarrhea is considered a common digestive sign in COVID-19 patients, with an incidence of 1.3%-29.3%. However, the criteria for the diagnosis of diarrhea may be different in various hospitals, and its prevalence varied in different studies[37].

Among 204 COVID-19 patients in Hubei China, only 99 (48.5%) had gastrointestinal signs as their chief complaint. These COVID-19 patients had a diversity of digestive symptoms, including abdominal pain (0.4%), anorexia (83.8%), diarrhea (29.3%), and vomiting (0.8%)[38]. A retrospective study conducted by Guan *et al*[39] reported that among 1099 COVID-19 patients from 552 centers across China, 5% of cases had nausea and vomiting, and 3.8% of cases had diarrhea. A further study indicated that 32.5% of COVID-19 patients had at least one gastrointestinal tract (GIT) symptom. These symptoms included diarrhea (37.8%), anorexia (56.7%), abdominal pain (10.4%), nausea (16.5%), and vomiting (7.9%)[40]. Additionally, Luo *et al*[41] documented that 16% of 1141 cases, had at least one GIT symptom including, anorexia (98%), nausea, vomiting (66%), diarrhea (37%), and abdominal pain (25%). Furthermore, a research

SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; NA: Not applicable; COVID-19: Coronavirus disease 2019.

study conducted by Jin *et al*[42], which was the first COVID-19 study outside Wuhan, reported that the incidence of GIT symptoms was 11.4%; diarrhea was the most common of these symptoms (8.14%)[42].

In New York, GIT symptoms have been identified in a single-center-case series, which included 892 cases. The most common symptom was diarrhea (19.8%), accompanied by nausea (16.6%), abdominal pain (7.8%), vomiting (10.2%), and anorexia (11.8%)[43]. An additional retrospective study conducted in New York showed that of 1059 COVID-19 patients, 22% had diarrhea, 6% had nausea, 19% had vomiting, and 7% had abdominal pain[44]. In addition to these studies, the pooled prevalence of GI symptoms was found to be 17.6 % in a meta-analysis of 60 studies involving 4243 cases in 6 countries The most frequent symptom was anorexia (26.8%), accompanied by diarrhea (12.5%), nausea/vomiting (10.2%) and stomach pain/discomfort (9.2%)[45].

Furthermore, Goyal *et al*[46] indicated that hyperlipidemia was found in 11.7% of patients affected by SARS-CoV-2 where 92 patients out of 756 with COVID-19, had elevated serum lipase levels, resulting in acute pancreatitis. Therefore, COVID-19 patients with hyperlipidemia have an approximately 3-fold higher risk of poor clinical outcomes, including the need for ICU admission, mechanical ventilation, and death [46].

The study by Gadiparthi *et al*[47] showed that the higher Glasgow Blatchford bleeding score was 7 and 11 in 2 of 3 patients on admission and represents a high risk of gastrointestinal bleeding (GIB) with a need for intervention of more than 50%. However, both young patients responded by carefully controlling hemodynamic parameters, levels of hematocrit or hemoglobin, transfusion of packed red blood cells as needed and medical therapy. Although GIB was resolved, two patients died due to respiratory failure[47].

Besides GIT symptoms, autopsies of COVID-19 patients showed that there are gross and microscopic changes in the GIT. Segmental dilation and stenosis of the small intestine, accompanied by mucosal shedding and necrosis was described at autopsy, whereas colitis, inflammatory infiltrates, and interstitial edema, were found on histopathology imaging[48,49]. Lui *et al*[50] have shown pneumatosis, intestinalis, pneumoperitoneum, ascites, and thickening bowel wall in addition to ileus on abdominal imaging. Therefore, abnormalities of the GIT can be obvious on imaging.

Based on these previous data, physicians must realize that the key characteristics of COVID-19 infection before respiratory symptoms may be digestive symptoms and, in rare instances may be the only COVID-19 symptoms to occur.

Mechanisms of GI injury during COVID-19

Direct infection of gastrointestinal cells: The entry of SARS-CoV-2 virus into host cells is the main part of cross-species transmission. All coronaviruses bind to receptors

and mediate their entry *via* glycoprotein and spike proteins[51]. It has been recognized that ACE2 mainly contains receptors for SARS-CoV[52], and dipeptidyl peptidase 4, for MERS-CoV[53]. A plethora of studies has shown that the spike (S) protein of SARS-CoV-2 has a high host ACE2 affinity[54], and enters host cells *via* the ACE2 receptor [55] as shown in Figure 3.

In small intestine cells, ACE2 is usually located and strongly expressed in type II epithelial cells[56,57]. It is considered an important enzyme in the renin-angiotensin system (RAS)[58,59] and plays an essential role in controlling inflammation and diarrhea[60]. Moreover, its deficiency leads to the accumulation of angiotensin II (ANG II)[61]. Subsequent studies[12,62-64] have proven that SARS-CoV-2, in COVID-19 patients, may invade the GIT *via* ACE2 receptors, causing digestive symptoms. It is now well acknowledged that the significant upsurge of ANG II level in COVID-19 patients is the cause of progression and severity of the disease.

Although in the mouse colon, the knockdown of ACE2 by the virus leads to an upsurge of ANG II levels; ACE2 does not primarily act *via* the intestinal RAS system but controls the homeostasis of intestinal amino acids, gut microbes and the expression of antimicrobial peptides[65]. Mice with blocked ACE2, for example, have significantly inhibited serum tryptophan that is important to the body's niacin synthesis[66], therefore, inadequate intake of tryptophan or niacin results in pellagra[65]. It is well-recognized that tryptophan is absorbed on the lumen surface of intestinal epithelial cells *via* the B0AT1/ACE2 transport route and induces the mammalian target of rapamycin, which controls the consequently appearance of antimicrobial peptides, thereby having a direct influence on components of intestinal flora[65]. Ultimately, more than 90% of pellagra patients will develop colitis[67]. Hence, it is considered that SARS-CoV-2 attachment to the ACE2 in the GIT lowers the critical receptor level, disrupting the absorption of tryptophan and ultimately destroying the steady-state of the gut flora, resulting in diarrhea.

Furthermore, He *et al*[68] demonstrated that the pathological results of autopsies on COVID-19 patients indicated that proinflammatory cytokines (PICs) such as tumor growth factor-β1, monocyte chemokine-1 (MCP-1), tumor necrosis factor-α (TNF-α), interleukin (IL)-1β, and IL-6 were highly expressed in ACE2-expressing cells. There is an absence of PICs in cells that do not express ACE2. Numerous PICs produce the cytokine storm, which finally leads to multiple organ failure. Besides, plasma IL-2, recombinant human interferon (IFN)-induced protein-10, MCP-1, macrophage inflammatory protein-1A, IL-7, granulocyte colony-stimulating factor, IL-10, and TNF-α levels in COVID-19 patients were higher than those in healthy people[25]. Dendritic cells and macrophages show low levels of IFN and high levels of PICs and chemokines in the early stage of SARS-CoV infection[69-71]. Later, there is a rise in cytokine and chemokine levels, which causes severe tissue damage due to the large number of inflammatory cells, such as neutrophils and monocytes. In the same manner, SARS-CoV-2 can induce cells expressing ACE2 to release inflammatory cytokines, leading to the cytokine storm and multiple organ failure[72]. Furthermore, cytokine storms can have an effect on immune cells; lymphocytosis is known to be a common sign in severe cases of COVID-19, with a significant decline in the number of B, CD8+ and CD4+T cells as well as natural killer cells, which leads to lymph node necrosis, spleen atrophy, hepatomegaly, renal hemorrhage, necrosis, and degeneration of neurons[73].

Thromboembolic complications are being increasingly documented in COVID-19 [74]. Acute mesenteric ischemia (AMI) has been reported in severe COVID-19 patients in addition to deep venous thrombosis and pulmonary embolism[75]. It has been demonstrated that ANG II stimulates the expression of tissue factor VIII (FVIII), von Willebrand factor, and plasminogen activator inhibitor-1 by endothelial cells, resulting in a state of hypercoagulation[76,77]. Histology of the small intestine secondary to mesenteric thrombosis revealed a prominent endothelium of the submucosa with evidence of direct viral invasion of endothelial cells along with diffuse endothelial swelling with mononuclear cell infiltrate. It is understood that there is stimulation of alternate and lectin complement trajectories [C5b-9 (membrane attack complex), C4d, and mannose-binding protein-associated serine protease 2] that destroy endothelial cells[78]. SARS-CoV-2 infection also resulted in an elevation of ANG II levels and other prothrombotic proteins, which led to AMI[78-81].

Gastrointestinal damage caused by lung infection: Any change in intestinal flora constituents affects the respiratory tract, *via* the common mucous immune system. Reciprocally, any damage to the respiratory tract mainly affects the digestive tract *via* immune regulation. This effect is known as the "gut-lung axis"[82,83]. Furthermore, SARS-CoV-2 cannot be detected in the stools of COVID-19 patients with digestive symptoms and thus GIT symptoms may not be affected by the direct damage caused

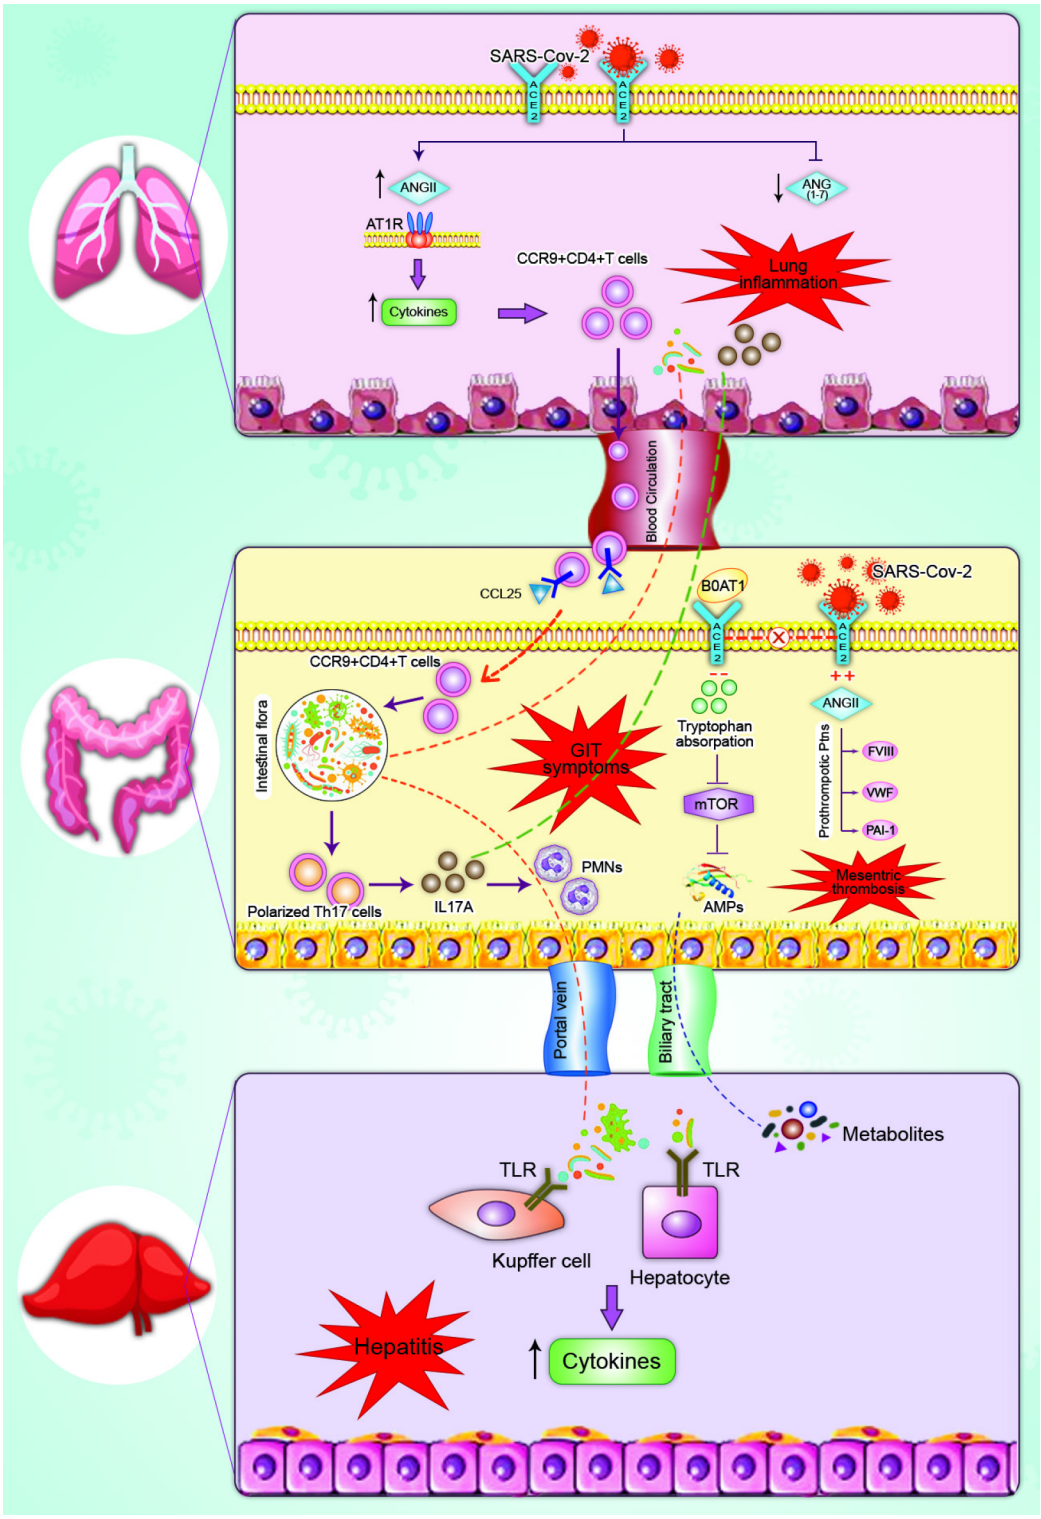

Figure 3 Mechanism of gastrointestinal symptoms in patients with coronavirus disease 2019. (1) Gut-lung axis: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) binds with angiotensin-converting enzyme 2 (ACE2) to enter the lung, which leads to the accumulation of angiotensin II (ANG II) and the reduction of Angiotensin (1-7). ANG II combined with angiotensin 1 receptor stimulates cytokine release and causes an upsurge of C-C chemokine receptor type 9 (CCR9) CD4T cells. Chemokine (C-C motif) ligand 25 subsequently enhances the recruitment of CCR9 CD4T cells into the small intestine. The changing flora then stimulates the polarization of T helper 17 cells, and eventually, interleukin 17A induces the recruitment of neutrophils. Cytokines and intestinal bacteria also enter the lung through the bloodstream, further affecting lung inflammation; and (2) Gut-liver axis: SARS-CoV-2 binds with ACE2 to enter the intestine, prevents absorption of the B0AT1/ACE2 transport pathway, and then decreases the stimulation of mammalian target of rapamycin to diminish the expression of antimicrobial peptides which result in gastrointestinal tract symptoms or enhanced ANG II that leads to the upregulation of tissue factor VIII, Von Willebrand factor, and plasminogen activator inhibitor-1 expression by endothelial cells resulting in mesenteric thrombosis. The intestinal flora, through the portal vein, is transferred to the liver, where it binds to toll-like receptors resulting in hepatitis. Additionally, the liver, can transport metabolites to the intestine *via* the biliary tract,. COVID-19: Coronavirus disease 2019; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; ACE2: Angiotensin-converting enzyme 2: ANG II: Angiotensin II; Ang1–7: Angiotensin (1-7); AT1R: Angiotensin 1 receptor; CCR9: C-C chemokine receptor type 9; CCL25: Chemokine (C-C motif) ligand 25; Th17: T helper 17; IL-17: Interleukin 17; PMNS:

Polymorphonuclear neutrophils; B0AT1: Sodium-dependent neutral amino acid transporter; mTOR: Mammalian target of rapamycin; AMPs: Antimicrobial peptides; FVIII: Tissue factor VIII; VWF: Von Willebrand factor; PAI-1: Plasminogen activator inhibitor-1; TLR: Toll-like receptor.

by SARS-CoV-2. The entry of CD4+ T cells is essential to immunity and chronic enteritis in the intestinal mucosa. It is known that C-C chemical receptor type 9 (CCR9) is an important chemical receptor for the introduction of CD4+T cells into small gut cells [84]. Wang *et al*[84] showed after viral infection, that CCR9+ CD4+ T lung derived cells were amplified. The small intestinal epithelium can include chemokine (C-C motif) ligand 25[85], which promotes the recruitment of CCR9+ CD4+ T cells into the small intestine[86], which leads to impairment of the gut's immune system and to destruction of intestinal flora homeostasis. This, in turn, stimulates the polarization of T helper 17 (Th17) cells in the intestine, and recruitment of neutrophils due to the production of large amounts of IL-17A[87], causing diarrhea, intestinal immune damage, and other gastrointestinal symptoms. Inflammation in the intestine may lead to the entry of intestinal flora and cytokines into the lung through the bloodstream, which affects the lung immune system[88]. Additionally, bacterial imbalance and intestinal mucosal damage can affect the gut-liver axis. In the intestine, host metabolites are transported through the portal vein to the liver and affect the function of the liver. The liver releases bioactive contents and bile acids and transfers them into the intestines through the systemic circulation[89]. This may lead to liver dysfunction in COVID-19 patients, due to these abnormalities[90] (Figure 3).

Gastrointestinal symptoms caused by drug side effects: Diarrhea due to antibiotics is the most common unwanted side effect of antimicrobial agents, including cephalosporins, macrolides and β-lactams. A retrospective study, in China, demonstrated that 260 COVID-19 patients treated with macrolides, fluoroquinolones, and cephalosporins resulted in 24.2% of patients developing diarrhea[91]. Another study of 138 patients with SARS-CoV-2 found that 38% had diarrhea with a medium period of 3-7 d during treatment[92]. The abovementioned data indicate that the early use of large quantities of antimicrobial agents could be linked to symptoms of diarrhea during COVID-19. Similarly, the prevalence of diarrhea in patients treated with antiviral agents such as oseltamivir is about 55.2%[93]. Other antiviral agents which can cause diarrhea as an adverse effect during the management of COVID-19 include lopinavir, chloroquine phosphate, remdesivir, and Chinese patent medicines (*e.g.*, lianhuaqingwen capsules) [94]. Additionally, treatment with broad-spectrum antibiotics is a major risk factor for *Clostridium difficile* infection, which is considered the primary reason for nosocomial diarrhea[95]. It is unclear whether the above-mentioned factors including, the use of antibiotics or antiviral agents and increased gut inflammation along with a decrease in mammalian target of rapamycin (mTOR) activity, and antimicrobial peptides, are partly responsible alone or in combination for causing diarrhea in patients infected with COVID-19 *via* alterations in the gut flora[96].

Proton pump inhibitors (PPIs) are mainly used as a therapy for patients with peptic ulcers and gastroesophageal reflux disease. By blocking the proton pump, PPIs decrease gastric acid released into the stomach. Although the decrease in stomach acid can be beneficial in patients with stomach diseases, it can make the gut more susceptible to COVID-19 infection[97-99]. SARS-CoV S protein was suggested to fuse with patients' cells in neutral pH conditions. Additionally, Darnell *et al*[100] also established that highly acidic pH (1-3) and alkaline pH (12-14) may lead to inactivation of SARS-CoV, while, in the case of neutral pH, the virus remains stable[101]. Zhou *et al* [102] reported that, under the conditions of pH 1.0 and 2.0, SARS-CoV-2 was inactivated and unable to infect cells which was related to the pH in an empty stomach by creating viruses pseudotyped with SARS-CoV-2 S protein. In addition, the study by Ramachandran *et al*[103] found that prehospitalization PPI-exposed patients had worse clinical outcomes, involving mortality of COVID-19 patients, irrespective of the existence of cardiovascular diseases. A possible explanation for this is that secretions in the stomach are in the pH range 1.0 to 3.5, while the pH in the small and large bowels ranges from 7.5 to 8.0. SARS-CoV-2 can cause gastric acid to inactivate most virus particles. If a person has a long period of acid suppression with PPIs, the pH in the stomach decreases. SARS-CoV-2 can also have a higher rate of entry in the gut, which leads to viral infection.

COVID-19 and pre-existing digestive diseases

In general, the existence of comorbidities is associated with dramatically low outcomes

in COVID-19 patients. This may cause consequences for the management of previous gastrointestinal patients[104]. Patients that have inflammatory bowel disease (IBD) and have been treated with immunosuppressive drugs are more at risk for regular and serious infections and may be more at risk for SARS-CoV-2 infection[105]. It was reported in the IBD registry in Wuhan that none of 318 patients (204 patients with ulcerative colitis and 114 patients with Crohn's disease) had been infected with SARS-CoV-2 following precautions for COVID-19 control and prevention[106]. Thus, the use of biologics and immunosuppressants, diet therapy, deliberate postponement of elective and endoscopic surgery and provisions for personal safety are recommended [107].

Considerations and management of IBD medications during COVID-19 infection: It is currently not recommended that IBD patients stop immunosuppressant drugs[11]. This is because there is a risk of disease reactivation in patients who discontinue their treatment, leading to severe inflammation, surgery, increased risk of hospitalization, and infection[108,109]. Non-hormonal anti-inflammatory drug use should be prohibited as the adverse effects of viral respiratory infections have been associated with triggering the reactivation of IBD[110].

No evidence-based recommendations for immunosuppressed patients have been made by clinical parties. Table 2 shows the specific considerations for the treatment of IBD patients mainly based on specialist beliefs. These suggestions can be edited and updated as new evidence emerges[108,110]. Overall, the same therapies can be used by patients with moderate to serious Crohn's disease or ulcerative colitis, regardless of COVID-19 infection[110]. IBD therapies can be restarted after 14 d for asymptomatic IBD patients with SARS-CoV-2 infection whose therapy has been stopped[110].

It is noteworthy that IBD patients should discontinue immunosuppressant drugs until COVID-19 is resolved, and medications can be resumed after complete resolution of COVID-19 symptoms or after two negative polymerase chain reaction (PCR) tests [111].

IBD surgery in the context of the COVID-19 pandemic: The new strain of coronavirus has increased the risk of severe pulmonary infection and extended hospitalization for IBD patients waiting for surgery, which is critical for IBD immunosuppressed patients. A recent report in Wuhan, China, demonstrated that 34 patients who underwent elective surgical procedures during the COVID-19 incubation period, developed COVID-19 pneumonia after surgery; 44.1% of patients were admitted to the ICU, and 20.5% of patients died[112]. Therefore, the majority of physicians have recommended postponing both elective and endoscopic surgery to protect patients and healthcare personnel and to minimize the usage of healthcare services and use personal protection equipment[113,114]. Eventually, the ultimate goal is to ensure the safety of patients and health care workers.

COVID-19 and the fecal–oral transmission route

A number of articles have disclosed that SARS-CoV-2 RNA can be found in patients' stool, suggesting that SARS-CoV-2 has the ability to be transmitted *via* the fecal-oral route[115-117]. It has been demonstrated that some COVID-19 patients had positive fecal but negative PCR tests[118]. Wang *et al*[117] revealed that of 153 (29%) patients with COVID-19, 44 showed positive stool virus. Moreover, Xiao *et al*[49] indicated that of 73 COVID-19 patients hospitalized in China, 39 (53.42%) showed SARS-CoV-2 RNA in stools[49]. Surprisingly, stool samples were positive in 17 (23.29%) patients but respiratory samples were negative and the period of positivity ranged from 1 to 12 d in stools. Xiao *et al*[49] demonstrated that infectious SARS-CoV-2 may be secreted from virus-infected gastrointestinal cells. Therefore, stool samples should be frequently tested using real-time-PCR and transmission-based precautions should be taken into consideration[119].

Furthermore, the probability of SARS-CoV-2 fecal-oral transmission has highlighted the importance of adequate hand hygiene, especially in certain areas. Strict measures must be taken to deal with the stools of COVID-19 patients and the sewage from hospitals. Therefore, patients with preexisting gastrointestinal diseases will be more worried when they are infected with SARS-CoV-2 in addition to potential fecal microbiota transplant donors.

Pharmacologic management of GI symptoms in COVID-19

Microecological preparation: The intestinal flora generates various vitamins, bile acids, immune factors, and fatty acids *via* the decomposition of food and participates in immune system regulation[120]. If there is dysfunction or damage in the intestinal

Table 2 Therapy-specific considerations for inflammatory bowel disease patients

Drug	Effects
Aminosalicylate acid derivatives (5-ASA)	No proof of increased risk of COVID-19 infection
	Continue treatment even in the case of COVID-19 infection
Corticosteroids	Their safety during COVID-19 infection is uncertain
	They can be used at a low dose and for a short period to treat disease relapses
	Discontinue as soon as possible
	Ileo-cecal CD patients can be treated with Budesonide; IUC patients can be treated with Budesonide MMX
Immunomodulators (Thiopurines and Methotrexate)	No proof of increased risk of COVID-19 infection
	Accompanied by increased risk of other viral infection
	Not recommended to start with monotherapy
	Combination therapy with biologics should be maintained
	Recommendations in stopping
	Stable disease
	Sustained reduction in the case of elderly patients and/or significant comorbidities
	Symptom progression of COVID-19 infection
Anti-TNF therapy	No proof of increased risk of COVID-19 infection
	Infusion and dose intervals should be maintained
	Starting with monotherapy (adalimumab or certolizumab)
	Stop in the case of developing symptoms of COVID-19
Anti-IL-12/23p40 therapy (Ustekinumab)	No proof of increased risk of COVID-19 infection
	Monotherapy is recommended
	Stop in the case of developing symptoms of COVID-19
Anti-a4b7 integrin therapy (Vedolizumab)	No proof of increased risk of COVID-19 infection
	Monotherapy is recommended
	Stop in the case of developing symptoms of COVID-19
Janus Kinase inhibitors (tofacitinib)	Although there is no proof of increasing the risk of COVID-19 infection, it may inhibit the immune reaction against viral infections
	Starting is not recommended
	Therapy should be maintained without elevating the dose
	Stop if symptoms of COVID-19 develop

UC: Ulcerative colitis; CD: Crohn's disease; COVID-19: Coronavirus disease 2019; TNF: Tumor necrosis factor; IL: Interleukin.

flora and/or mucosa, the virus may further stimulate infection through this pathway. Other studies have stated that probiotics have the availability to manage diarrhea caused by rotavirus[121]. Also, lactic acid bacteria and Bifidobacteria can contribute to antiviral antibodies in the human body, accelerating virus removal. Therefore, probiotic treatments and/or antiviral drugs, and antibacterial drugs may enhance the symptoms of SARS-CoV-2 diarrhea. Regarding the diagnosis and treatment protocols of COVID-19 in China, the use of intestinal flora regulators is preferred to preserve the intestinal micro-environmental balance and avoid secondary bacterial infection[122].

ACE2 inhibitors: As previously mentioned, ACE2 binds SARS-CoV-2 in cells. Therefore, to avoid SARS-CoV-2 infection the interaction between the receptor connection domain (RBD) of the virus and ACE2 could be blocked. A number of studies have shown that ACE2 inhibitors can regulate bowel metabolism, innate immunity, secretion of antibacterial peptides, and intestinal microbial homeostasis [122]. It was experimentally confirmed that the ACE2 pathway in epithelial cells of the small intestine trigger mTOR *via* nutrient stimulation and/or the tryptophan-nicoti-

namide pathway, thus affecting the composition of intestinal flora, and decreasing GIT indications in mice[60]. Azathioprine is an immunosuppressive agent similar to chloroquine. A recent study evaluated azathioprine and found that it could be regarded as an ACE2 inhibitor[123]. Additionally, *in vitro* studies have shown that Vaccinia virus can be inhibited by azathioprine[124]. With regard to molecular immunity, azathioprine competitively binds to ACE2, using a single chain (ScFv) antibody fragment attached to ACE2 or SARS-CoV-2, *via* the RBD. Thus, the human recombinant ACE2 antibody Fc segment bound by the S protein works by inhibiting attachment of the virus to ACE2[55]. It has been documented that a combination of Chinese medicines (*e.g.*, baicalin in the Chinese medicine Scutellaria baicalensis, scutellarin in Erigeron breviscapus, hesperetin in lime and orange peel, glycyrrhizin in liquorice, and nicotinamide in soybean) and ACE2 resulted in the prevention of SARS CoV-2 infection.

Diet and enteral nutrition: A number of COVID-19 patients have significant anorexia. To ensure effective therapy, the basic energy, absorption, enteral and peristalsis movement of the intestine, and normal function of GIT micro-organisms and mucosal immunity should be taken into account as well as the functioning of the GIT and patients' nutrition[94]. Nutritional risk assessment should be performed in patients with serious COVID-19 and gastrointestinal symptoms[125]. Once the risk of enteral nutrition has been eliminated, enteral nutrition should immediately be restored. If the patient has a gastrointestinal disorder and cannot withstand enteral nutrition, parenteral nutrition should be supplemented with a sufficient supply of energy. Patients in poor condition can be given digestive enzymes[125]. A nasogastric tube can be used for enteral feeding in patients who have undergone mechanical ventilation and are unable to take food orally. A nasal jejunal tube can be inserted when patients are at high risk of reflux aspiration or cannot handle nasogastric tube feeding. Generally, the patient gastrointestinal tolerability should be estimated appropriately and the enteral nutrition program correspondingly adjusted.

LIVER AND COVID-19

Clinical manifestations and pathological changes in hepatic injury in patients with COVID-19

Hepatic injury is a frequent adverse event in both SARS-CoV and Middle East respiratory coronavirus-infected patients and is associated with the severity of disease [126]. A substantial systematic analysis of 11 studies assessing the liver laboratory parameters of 2541 patients with COVID-19 showed increased AST and/or ALT (25%), lactate dehydrogenase (20%), bilirubin (3%) and normal alkaline phosphatase (ALP) [127]. This may indicate minimal direct liver damage caused by ACE2 overexpression in cholangiocytes. A major published study of 5700 patients found that AST and ALT were increased in COVID-19 patients by 58.4% and 39.0%, respectively[128]. Cai *et al* [129] showed that in 41% of patients, gamma-glutamyl transferase (GGT) was increased more than 3 × ULN, while, another research study demonstrated that GGT was raised in severe cases, but without an elevation in ALP[126].

Data from a preprint meta-analysis involving 20 retrospective studies and 3428 COVID-19 patients showed that increased levels of COVID-19 were related to significant increases in the levels of ALT, AST, and bilirubin[130]. Recently, a plethora of studies reported increased serum ALT, AST, and GGT levels in severe compared with mild or non-severe COVID-19 patients[39,131]. A recent meta-analysis associated high marker admission levels with patient mortality[132]. Other studies have shown that the increase in these parameters resulted in a worse pulmonary computed tomography (CT) score[133], increased numbers of ICU patients[12] and longer hospital stays[134]. In patients who died due to COVID-19, the incidence of elevated liver parameters ranged from 58.06% to 78%[32,135].

According to a study conducted by Lei *et al*[132], AST was the first indicator to be considered high when patients were admitted to hospital and was correlated with the highest COVID-19 death rates. A recent study carried out by Guan *et al*[39], around 1100 Chinese patients reported elevated levels of serum AST and ALT of 18% and 26% in non-severe COVID-19 patients, respectively, compared with 56% and 28% in severe COVID-19 patients. Previous findings revealed the crucial role of immune-mediated systemic inflammation in liver dysfunction in patients with serious COVID-19[9]. Recently, Gordon *et al*[136] proposed that mitochondrial proteins may interact directly

with the virus, providing a cause for the high level of AST in the liver profile[136]. Wang *et al*[137] also identified anomalies in liver enzymes, higher radiologic scores as well as a partial pressure differential between alveolar arterial oxygen, higher GGT, disease intensity, higher ferritin, lower CD4+ T and B cells and lower albumin. It is considered that total bilirubin, AST/ALT, and ALT/ALP ratios have helped to predict survival in cirrhotic COVID-19 patients[138]. Serum albumin levels were also markedly lower in patients who died of COVID-19[32]. The adverse path of COVID-19 patients has been shown to include elevated serum levels of IL-6, ferritin, procalcitonin, and C-reactive protein. In addition to reduced albumin content and platelet count, the parallel increase in the level of ferritin, ALT and IL-6 indicates a greater role for liver participation in COVID-19[32,134]. The CT imaging score for pulmonary lesions is known as a hepatic injury indicator. Therefore, patients must undergo careful monitoring of liver function in order to identify any liver insults at an early stage[133]. The incidence of hepatic abnormalities in COVID-19 patients are depicted in Table 3.

Morphological findings regarding the interpretation and description of liver parenchymal changes accompanying COVID-19 are rare, and most are seen at autopsy. It is noteworthy that the first autopsy liver specimen examinations carried out by Xu *et al*[139] showed moderate microvesicular steatosis and both portal activity and mild lobular activity. SARS-CoV-2 infection or drug-related hepatic damage may result in this liver insult. These results matched with those of Liu *et al*[140]. Preliminary research, consisting of 49 patients with COVID-19, showed that the portal intrahepatic system was affected with acute (thrombotic and luminal ectasia) or chronic (fibrous thickening of the vascular wall) features and the intrahepatic blood vessels were abnormally configured. These findings indicated that the major trigger in the pathogenesis of COVID-19 hepatitis is considered endothelial damage or coagulation dysfunction[141]. Additionally, in patients with critical COVID-19 there were no signs of damage to bile ducts or histological changes in liver failure[140]. Several studies failed to identify viral inclusion bodies in liver tissue[139,142]. Furthermore, the study by Li and Xiao[143] demonstrated that cirrhosis and regeneration signs with macrovesicular steatosis and accumulation in hepatocytes, along with atypical lymphocytic infiltration in the portal tract, may occur due to COVID-19. In the portal triad and centrilobular zones, sinusoidal expansion dilatation in zone 3, mild lymphocytic infiltrations and patchy liver necrosis were also revealed.

Moreover, the study by Ramachandran *et al*[144] showed that in hospitalized COVID-19 patients, elevated aminotransferases were associated with higher mechanical oxygen concentrations but did not achieve statistical significance after inflammatory marker measurement. In addition, patients with elevated aminotransferases did not have higher rates of mortality or prolonged length of stay as shown in Table 4.

In China, some patients recovering from extreme COVID-19 were confirmed to have experienced special manifestations including a darkened face and pigmentation during treatment. The key causes of a darkened face and pigmentation were multiple organ injury, in particular liver injury[145,146]. Abnormal hepatic function can easily lead to pigmentation *via* the following three pathways: (1) Liver dysfunction can prevent estrogen from being inactivated[147]. The rise in estrogen decreases thiamine inhibition of tyrosinase *in vivo*, thus increasing the transformation of tyrosine into melanin[148]; (2) Abnormal liver function can cause hypofunction of adrenocortical hormones. The liver does not metabolize melanocytic stimulatory hormone produced by the anterior pituitary gland, which causes greater melanin secretion[149]; and (3) Liver damage can cause bleaching of the face due to iron in the blood that provides the facial skin[150,151] (Figure 4).

Mechanisms of liver injury during COVID-19

Direct damage: It is established that SARS-CoV-2 enters the host cells *via* its binding to ACE2 on the surface of the host cell by the S protein[152,153]. However, the expression of ACE2 levels in liver tissue was estimated to be approximately 0.31% and its expression in bile duct cells was 20 times higher than that in hepatocytes on the basis of single cell sequencing and animal model analysis[154]. Furthermore, elevated levels of γ-glutamyl transferase and alkaline phosphatase were observed in COVID-19 patients[155], and inconsistent with biliary epithelial cells injury, approximately 10% of COVID-19 patients have high levels of total bilirubin. Thus, suggesting that SARS-CoV-2 can bind to cholangiocytes expressing ACE2, resulting in their injury (Figure 5).

Antibody-dependent enhancement: Antibody-dependent enhancement of infection (ADE) may arise in patients with SARS[156]. ADE indicates that the interplay between the virus-based antibody and the CR and/or FC receptor complements increases the

ability of the virus to reach macrophages, granulocytes, and monocytes (Figure 5). The virus frequently replicates in the aforementioned cells, leading to an increase in virus production and worsening of infection. Previous findings have indicated that SARS-CoV antibodies activate ADE, triggering SARS-CoV in immune cells that do not have ACE2 expression or harm the immune system[157]. Whether ADE can help SARS-CoV-2 infect immune cells through a non-ACE2-dependent pathway and participate in SARS-CoV-2 hepatic injury is an issue of concern.

Systemic inflammatory response syndrome and cytokine storms: Research has revealed that the inflammatory cytokines, including endotoxin ILs, and TNF-α in SARS patients who have liver function impairment have significantly higher levels than patients with normal liver function. Therefore, systemic inflammatory response syndrome (SIRS) and cytokine storms are risk factors for liver impairment in SARS-CoV and in MERS-CoV infected patients[158-160]. Limited pathological findings have indicated that COVID-19 hepatocytes exhibit non-specific inflammatory modifications in patients with serious infection such as Kupffer-cell hyperplasia and moderate proliferation, hepatocyte swelling and steatosis and a limited number of lymphocytes.

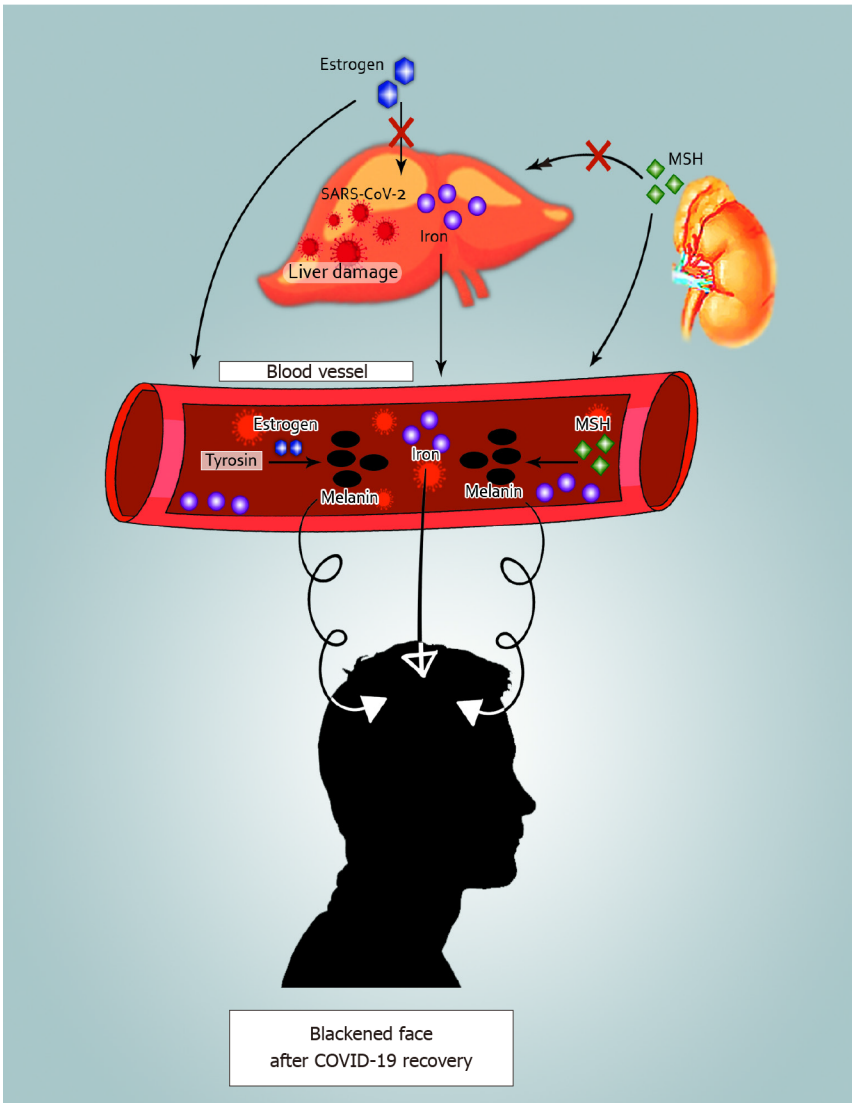

Figure 4 Facial blackness and dull skin after coronavirus disease 2019 recovery. Three possible mechanisms are shown: (1) Iron in the damaged liver drains into blood vessels. Blood with high iron levels can lead to blackening of the face when it supplies the facial skin; (2) Estrogen cannot be metabolized in the damaged liver. Thus, elevated estrogen in the blood enhances the conversion of tyrosine to melanin; and (3) When liver function is impaired, adrenocortical function is hypoactive, and melanocyte-stimulating hormone increases resulting in an elevation in the secretion of melanin. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; MSH: Melanocyte-stimulating hormone; COVID-19: Coronavirus disease 2019.

Furthermore, the amount of IL-2 and IL-6 in COVID-19 serum has been shown to be substantially increased and linked to the seriousness of the disease[4]. Moreover, cytokines secreted by Th1 and Th2 cells in the serum of COVID-19 patients, such as TNF, IL-6, IL-18, IL-4, and IL-10 were significantly intensified in pro-inflammatory cells (CCR4 + CCR6 + Th17)[25,30,139]. Following SARS-CoV-2 infection, a large number of immune cells activate and induce excessive cytokines, such as TNF-α, IFN-μ, IL-6, IL-8, *etc.*, leading to SIRS, acute respiratory distress syndrome, and induction of ischemia, eventually, resulting in cell destruction and necrosis as shown in Figure 4. Not only does such a vicious cycle lead to lung injury but may also progress to multiple organ damage. These results suggest that cytokine inflammatory storms may be one of the essential routes of liver injury (Figure 5).

Ischemia and hypoxia reperfusion injury: COVID-19 patients have various degrees of hypoxia, as more than 40% of cases required oxygen supplementation[30]. Complications such as aspiration and multiple organ failure can cause hypoxia, ischemia and subsequent shock. The suppression of cell survival signal transduction and hepatocyte death may be caused by ischemia and hypoxia, ATP depletion in hepatocytes, lipid accumulation, and glycogen consumption (Figure 5). Furthermore, the respiratory distress syndrome can cause oxidative stress that increases the production of reactive oxygen species (ROS). The ROS and lipid peroxidation products can induce redox-

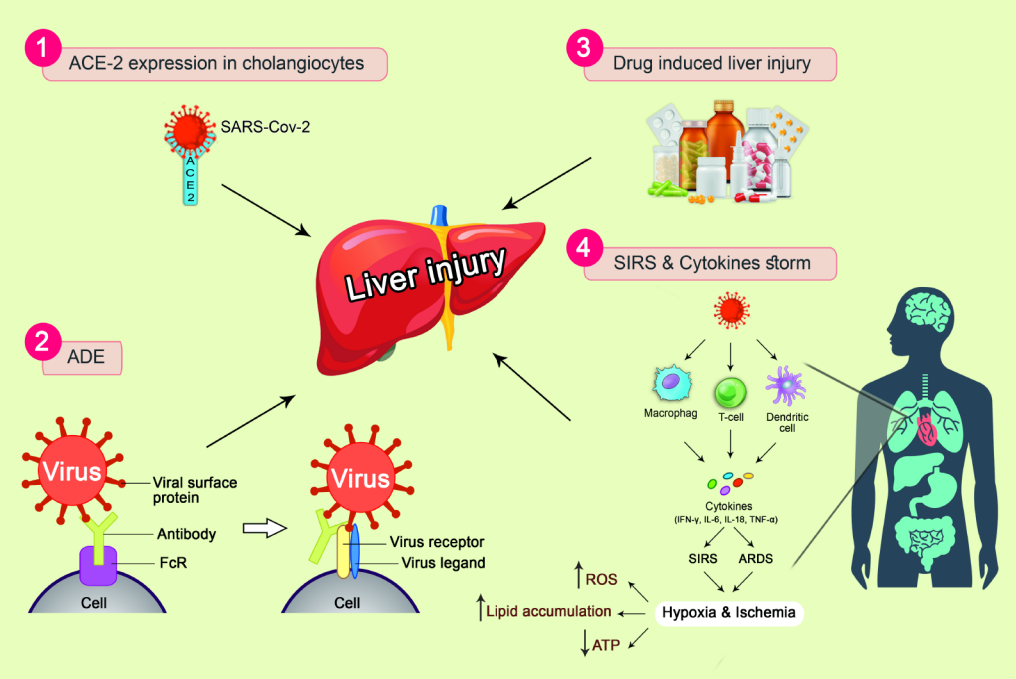

Figure 5 Mechanisms of liver injury in patients with coronavirus disease 2019. sensitive transcription factors and then release various pro-inflammatory factors leading to liver damage. These changes can exaggerate the ischemia of hepatocytes, influence the excretion of toxic metabolites and eventually stimulate liver injury. Hypoxia is also one of the main causes of liver injury in patients with serious COVID-19[161].

Drug hepatotoxicity: In China, the occurrence of drug-induced hepatic damage including, traditional Chinese patent medicines[162,163], antitumor drugs, antibiotics, antimalarial drugs, and anti-tuberculosis drugs[164,165], is second only to fatty liver disease and viral hepatitis (alcoholic and nonalcoholic). Several COVID-19 patients have a fever and consequently, use antipyretic and analgesic drugs. Therefore, a drug overdose can cause hepatic damage.

Recently, this was observed with abidol, lopinavir, ritonavir and other antiviral medications used to control COVID-19. A recent study published in JCI[166] demonstrated that CAP3A4 plays a critical role of the side-effect and metabolic pathways of ritonavir which can generate electrophilic material, radical free oxygen that can be covalently linked with liver cells leading to lipid membrane peroxidation, membrane integrity disruption of the Ca2+-ATPase membrane, interruption of the internal and external Ca2+ homeostasis of the cells, and finally leading to death. Furthermore, an overdose of the combination of lopinavir and ritonavir can stimulate the hepatic endoplasmic reticulum stress cascade, induce inflammatory reactions, trigger hepatocyte apoptosis through the caspase mechanism, suppress hepatocyte growth, and aggravate liver damage by the production of oxidative stress[167,168]. Some scientists have assumed that SARS-CoV-2 replication can be effectively inhibited by human immunodeficiency virus (HIV) protease inhibitors; although Shen *et al* stated that the risk of liver damage is increased in patients receiving hormones and HIV protease inhibitors[169]. The incidence of liver damage due to different medicines varies. However, the prevalence of liver damage due to more drug types is increasing. The diagnosis of hepatic damage due to medication includes a combination of medical history and appropriate testing to rule out other liver disorders and to estimate the relationship between hepatic injury and suspected medications by causality.

COVID-19 and previously-existing liver disease

Due to the global spread of chronic liver disorders, correlations among patients

presenting with hepatic illness and COVID-19 need to be examined. A preliminary analysis showed that 2%–11% of patients had hepatic disease and COVID-19[170]. In a study of 1099 COVID-19 patients, hepatitis B infection occurred in 23 (2.1%) patients. Serious cases of hepatitis B infection were more likely (2.4% *vs* 0.6%) than milder cases [39]. SARS patients with hepatitis B virus (HBV) or hepatitis C virus (HCV) infection were more vulnerable to serious hepatitis, likely because viral replication was increased during SARS-CoV infection[171]. Older patients with COVID-19 and have other conditions such as diabetes, cardiovascular disease, hypertension, and nonalcoholic fatty liver disease, are more susceptible to liver injury.

Moreover, patients with liver cirrhosis may be more susceptible to infection due to their systemic disease[172], thus, preventing COVID-19 is extremely important. None of 111 patients with COVID-19 in Wuhan had decompensated cirrhosis due to preventive measures. In contrast to this, 17% of 101 patients with COVID-19 developed decompensated cirrhosis at other hospitals where preventive measures were not implemented[173]. Viral transmission could occur during liver transplantation from donor to recipient, as previously described in SARS infection[174]. Recently, Michaels and colleagues showed potential transplantation risks in COVID-19 recipients[175]. The Italian Transplant Authority is carrying out nasopharyngeal swabs to diagnose COVID-19 before donation, with the subsequent exclusion of positive donors[176].

COVID-19 in liver transplant recipients: The worldwide spread of COVID-19 raises additional challenges for organ transplants. Transplant recipients with preoperative decompensated organs and chronic illness tend to contract respiratory viruses. Liver transplant patients, who are exposed to more people, during their wait for transplantation, have an increased risk of cross-infection with COVID-19. Qin *et al*[177] confirmed COVID-19 hepatocellular carcinoma in a patient following liver transplantation. On the 11th day after hepatic transplantation, the patient was diagnosed with COVID-19 following a positive PCR-test, with multiple ground-glass opacities in the left lobes. Long-term immune treatment in transplantation recipients prevents allograft rejection but significantly reduces the ability to protect them against COVID-19 due to their compromised immune system. A systematic analysis of 15 studies involving 223 patients with confirmed COVID-19 showed that simultaneous diarrhea was more likely to be present in patients who had undergone liver transplantation. The higher mortality rates in elderly patients with dyspnea and diabetes were approximately 23% in COVID-19 patients[178]. However, the latest data still do not confirm susceptibility to COVID-19 in liver transplant patients. A number of cases in Italy have indicated that children receiving liver transplants were not at elevated risk of serious lung disease relative to the general population despite being immunocompromised [179]. Similarly, three COVID-19-related deaths observed by D'Antiga[179] at an Italian transplant center were long-term patients on a minimal immunosuppression regimen, rather than recently transplanted patients with complete immunosuppression. Furthermore, a large global observational study by Webb *et al*[180] showed that the risk of death in COVID-19 patients does not substantially increase following liver transplantation.

Pharmacologic management of liver injury in COVID-19

COVID-19 causes mainly transient and indirect liver injuries, which can be caused by hypoxia, systemic inflammatory reactions, and medication. Thus, hepatic damage should be treated by elimination of the basic etiology in the COVID-19 patients. Correction of hypoxia by oxygen supplementation or mechanical ventilation, renal replacement treatment for cytokine storm, and restoration of intravascular effectiveness can enhance liver injuries in the event of septic shock[181]. Also early identification and reduction in the dosage of drugs inducing hepatic damage is crucial. Hepatoprotective anti-inflammatory medicines including L-ornithine-L-aspartate can be used in extreme cases as an adjuvant treatment[182]. It is worth noting that therapeutic drugs may be hepatotoxic, especially in chronic liver disease (CLD) patients. Furthermore, patients treated with immunosuppressive agents should be closely monitored due to drug interactions. Recommendations for the management of CLD, AIH, and immunosuppressed patients during a pandemic are summarized in Tables 5, 6 and 7[183,184].

COVID-19 IN THE ENDOSCOPY UNIT

Although millions of people have remained at their houses to decrease the transmi-

Table 5 Recommendations of the American Association for the Study of Liver Diseases, Asian Pacific Association for the Study of the Liver, and European Association for the Study of the Liver for management of liver disease during coronavirus disease 2019

	Selected recommendations
To limit nosocomial spread	(1) Decrease in-person visits *via* other alternatives such as virtual platforms
	(2) Symptom investigation before entering hospitals to identify COVID-19 patients
	(3) Reduce staffing to essential staff only
	(4) Reduce the frequency of screening and laboratory examinations
	(5) Adhere to recommended PPE by HCW and patients
	(6) Maintain proper social distancing in hospitals
	(7) Postpone unnecessary or elective operations
Management of CLD patients with COVID-19	(1) These patients should be admitted to hospital early
	(2) Prioritization of COVID-19 testing for patients with cirrhosis, CLD patients taking immunosuppressive agents and acute decompensated patients
	(3) Repeated LFTs are advisable
	(4) Early registration in clinical trials as much as possible
	(5) COVID-19 patients with NAFLD should be kept under supervision
	(6) Screening of hepatitis B surface antigen should be taken into consideration
	(7) Drug-induced liver injury should be monitored
	(8) These patients can receive 2-3 g/d of acetaminophen, while limiting the use of NSAIDs when possible
	(9) HBV prophylaxis should be considered before starting immunosuppressive agents
	(10) Stopping Remdesivir in decompensated liver disease patients with ALT more than 5 times the upper limit of normal
Management of chronic viral hepatitis (HCV and HBV)	(1) Despite COVID-19 status, treatment continuity of chronic HCV and HBV is recommended
	(2) In the absence of flare, HBV treatment should be stopped
	(3) For uninfected individuals, HCV and HBV treatment should be continued according to guidelines
Management of HCC	(1) HCC treatment should be continued according to guidelines; however, it can be delayed if necessary
	(2) In the case of COVID-19 patients, delaying elective transplants and resection surgery, and stopping immunotherapy are advisable
	(3) Early admission to hospital is recommended for HCC patients
Management of pre- and post-transplant recipients	(1) Screening donor and recipient for COVID-19 is suggested
	(2) For donors testing positive for COVID-19, transplantation surgery should be postponed
	(3) Prioritization of patients with short-term prognosis
	(4) For post-transplant patients, a reduction in immunosuppressive dose can be considered for moderate COVID-19 cases, while for mild COVID-19 cases, the dose should not be reduced
	(5) For post-transplant recipients, vaccination against pneumonia and influenza is advisable

PPE: Personal protective equipment; HCWs: Healthcare workers; CLD: Chronic liver disease; COVID-19: Coronavirus disease 2019; LFTs: Liver function tests; NAFLD: Nonalcoholic fatty liver disease; NSAIDs: Non-steroidal anti-inflammatory drugs; HBV: Hepatitis B virus; ALT: Alanine aminotransferase; HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

ssion of SARS-CoV-2, the risk of COVID-19 amongst health workers is high.

For example, the Chinese National Health Commission determined that approximately 3300 health workers were infected in early March[185]. It is well-known that endoscopic staff are at high risk of airborne droplet infection, conjunctiva contact and surface contact contamination[182,186]. Airway suction and other cough-induced procedures result in an increased risk of SARS-CoV-2 transmission[182]. It must be noted that the possible risk of exposure to feces removal is not confined to upper endoscopy[35].

Table 6 Recommendations of the American Association for the Study of Liver Diseases and European Association for the Study of the Liver for the management of auto-immune hepatitis during coronavirus disease 2019

Selected recommendations	
Virtual platforms are recommended to minimize in-person visits as much as possible	
COVID-19 testing is advised in cases of acute deterioration and liver failure	
Patients with low risk of complications (patients on chronic immunosuppressive therapy)	(1) Frequent patient-provider communications should be closely supervised; (2) Virtual platforms should be used to decrease contact; and (3) Ensure enough drug supply and refills to decrease running out of medications
Patients with moderate risk of complications (symptomatic disease without cirrhosis)	(1) Empiric therapy *via* virtual healthcare platforms as much as possible; and (2) Preventing liver biopsy whenever possible
Patients with high risk of complications (acute flare, decompensated cirrhosis)	(1) Reduce invasive procedures as much as possible; (2) In the case of COVID-19 patients, if lymphopenia develops, dose reduction of antimetabolites is recommended; and (3) In the case of infection, corticosteroids should be attenuated

COVID-19: Coronavirus disease 2019.

Table 7 Recommendations of the American Association for the Study of Liver Diseases and European Association for the Study of the Liver on the use of immunosuppressive therapies in chronic liver disease during coronavirus disease 2019

Suggestions	
(1) Starting with corticosteroids and immunomodulators should proceed; and (2) Risk benefit ratio assessments should be carried out	
Patients on immunosuppressive treatment and not infected with COVID-19	Decreases or adjustment of doses is not advisable
Patients infected with COVID-19 on immunosuppressive drugs	(1) Reduce corticosteroids dose after specialist physician (consider tapering to prevent adrenal insufficiency); and (2) Decreasing the doses of cyclosporine, mycophenolate, and azathioprine is recommended in severe COVID-19 (especially patients with lymphopenia)
Patients requiring initiation of immunosuppressive agents	Starting treatment is suggested in these patients regardless of COVID-19 status

COVID-19: Coronavirus disease 2019.

A prospective study conducted by Johnston *et al*[187], revealed the quantification of unrecognized bacteria to endoscopists exposed to biological samples leading to infection transmission. In this investigation, 227 endoscopic face shields were examined for colony-forming units (CFUs), and 1-15 CFU, 91/227 (40%); 16-30 CFU, 6/227 (2.6%); 30 or more CFU, 6/227 (2.6%) significantly increased after endoscopy. Similarly, in 1999, a research study carried out by Mohandas and Gopalakrishnan[188] in a tertiary care hospital in India of 786 endoscopies (149 lower and 162 therapeutic endoscopies) concluded that the splash rate to the skin of the forearms, feet, and face was 9.5%, while the splash rate to the eyes was 4.1%.

The duodenoscope is the most complex medical equipment that undergoes disinfection after patient use[189]. Virus risk factors include non-compatibility with disinfection guidelines, the promotion of biofilm deposition because of its complicated nature, surface defects and infected automated endoscopes[190,191]. It is considered that endogenous infections due to the gut flora of patients are the most common infections after endoscopy[192]. Exogenous infections such as *Escherichia coli* (71%), *Klebsiella* (14%), and *Enterobacter* (5%) can occur due to contaminated scopes and may be avoided by thorough cleaning[192,193]. Currently, *Pseudomonas aeruginosa* is the most common organism isolated from contaminated endoscopes[194]. Other microorganisms include, *Mycobacteria*, *Helicobacter pylori*, *Clostridium difficile*, HBV and HCV [195]. Recently, studies on duodenoscopy-associated infections including multidrug-resistant organisms, particularly carbapenem-resistant *Enterobacteriaceae*, have surfaced [196]. Numerous infections occurred despite sufficient disinfection, indicating that professional and government bodies should provide additional recommendations for duodenoscope processing[197,198]. To date, The Food and Drug Administration and Centers for Disease Control and Prevention have recommended comprehensive cleaning followed by high-level disinfection for reprocessing of flexible GI endoscopes [199-201].

In COVID-19 patients single-use duodeno-scopes may be important. However, they are not accessible worldwide and have cost-related constraints[202]. Several societies have advocated the use of room negative pressure, particularly for COVID-19 patients, or if endoscopy is urgently needed[203]. Intraprocedural changes such as minimal verbal communication, avoiding procedures in patients with inadequate bowel preparation, and avoiding spillage of GI contents *via* the biopsy channel should be introduced[204]. A previous study reported the use of a "double gauze technique"; one for the endoscopists and the other for technicians in a controlled fashion to prevent the "whip" effect of accessories and spillage of GIT secretions[204] Institutional requirements for minimum staff involved in the procedure have been developed [205]. Thus, the risk of exposure among endoscopy personnel is diminished. Endoscopy techniques performed with moderate sedation without the need for anesthetic agents (endoscopy driven sedation) can also reduce the risk of transmission. However, in the case of procedures requiring general anesthesia, policymakers recently recommended the use of endotracheal intubation to diminish the risk of aerosolization due to suspected or confirmed COVID-19[206]. Other methods to avoid splashes include the use of regular precautions such as full-sleeve gowns and suitable footwear [187].

GAPS IN KNOWLEDGE

Although there is a theoretical risk of fecal-oral transmission of COVID-19, the actual risk of transmission is extremely low. Despite this risk, endoscopy units have been functioning and reopening with no significant outbreaks noted.

CONCLUSION

COVID-19 can lead to lead to acute respiratory infection, and a high rate of morbidity and mortality. The main signs of COVID-19 are respiratory system reactions, and gastro-intestinal symptoms are also very common. COVID-19 patients with GIT symptoms are more probably associated with severe complications such as ARDS and liver damage, with a poor prognosis. Hence, during diagnosis and treatment of the disease, GIT symptoms should be taken into consideration as well as virus transmission *via* the fecal-oral route. In addition, it is advisable to take care of patients with chronic liver disease and they should be treated with medications that are able to prevent inflammatory responses and protect liver functions during COVID-19. Furthermore, the harmful effects of some drugs on the gut and liver during hospitalization must be identified and evaluated frequently. Further studies on the intrinsic relationship between COVID-19, hepatology and gastroenterology are urgently required.

Abstract

Gallstone disease and complications from gallstones are a common clinical problem. The clinical presentation ranges between being asymptomatic and recurrent attacks of biliary pain requiring elective or emergency treatment. Bile duct stones are a frequent condition associated with cholelithiasis. Amidst the total cholecystectomies performed every year for cholelithiasis, the presence of bile duct stones is 5%-15%; another small percentage of these will develop common bile duct stones after intervention. To avoid serious complications that can occur in choledocholithiasis, these stones should be removed. Unfortunately, there is no consensus on the ideal management strategy to perform such. For a long time, a direct open surgical approach to the bile duct was the only unique approach. With the advent of advanced endoscopic, radiologic, and minimally invasive surgical techniques, however, therapeutic choices have increased in number, and the management of this pathological situation has become multidisciplinary. To date, there is agreement on preoperative management and the need to treat cholelithiasis with choledocholithiasis, but a debate still exists on how to cure the two diseases at the same time. In the era of laparoscopy and mini-invasiveness, we can say that therapeutic approaches can be performed in two sessions or in one session. Comparison of these two approaches showed equivalent success rates, postoperative morbidity, stone clearance, mortality, conversion to other procedures, total surgery time, and failure rate, but the one-session treatment is characterized by a shorter hospital stay, and more cost benefits. The aim of this review article is to provide the reader with a general summary of gallbladder stone disease in association with the presence of common bile duct stones by discussing their epidemiology, clinical and diagnostic aspects, and possible treatments and their advantages and limitations.

Key Words: Gallbladder stones; Choledocholithiasis; Laparoscopic cholecystectomy; Rendezvous technique; Management of biliary lithiasis; Endoscopic retrograde cholangio-pancreatography

Core Tip: Gallstone disease associated with common bile duct stones is a common clinical scenario. Laparoscopic cholecystectomy is considered the gold standard for treatment of symptomatic gallbladder stones; conversely, the best treatment option for bile duct stones remains uncertain and controversial. We discuss herein the epidemiology, natural history, clinical presentations, preoperative diagnosis, management, complications, and different methods of treatment.

INTRODUCTION

Gallstones are a very common condition among the general population[1]. Generally, this situation does not cause symptoms, but 10%-25% of affected people may have specific symptoms, such as biliary pain and acute cholecystitis, and 1%-2% of these may have major complications[2,3]. In most cases, symptoms and major complications occur due to the migration of stones into the common bile duct (CBD) and this circumstance can cause obstruction of the bile flow in the small intestine, resulting in pain, jaundice, and sometimes cholangitis[4,5]. Primary choledocholithiasis refers to stones formed directly within the biliary tree, while secondary choledocholithiasis refers to stones migrated from the gallbladder. Primary stones are generally brown in colour and composed mainly of calcium bilirubinate; these stones are rare in Western populations and more common in Asia, but the exact aetiology and overall prevalence remain unclear. Secondary choledocholithiasis stone composition parallels that of cholelithiasis, with cholesterol as the most common type[6].

Of the total of cholecystectomies performed every year for cholelithiasis, the presence of CBD stones (CBDSs) is 5%-15%; another small percentage of these will develop CBDS after intervention[7]. The management of CBDSs represents an important clinical problem. In symptomatic patients, the primary goal is to obtain complete clearance of the CBD and cholecystectomy; on the contrary, in asymptomatic patients, there is still no shared diagnostic and therapeutic path[8]. In the last 20 years, the development of new technologies has allowed new diagnostic and therapeutic scenarios, with a consequent critical evaluation of management options. All these have led to a more cautious and patient-tailored preoperative workup based on the patient's risk and ultimately to a multidisciplinary approach[9-11]. However, if on the one hand multidisciplinarity has improved the management of patients with symptomatic cholelithiasis, on the other hand it has shown non-unanimous consent in the choice of treatment for choledocholithiasis: Endoscopic or surgical?

Since the early 1990s, laparoscopic cholecystectomy (LC) has been considered the gold standard of treatment for cholelithiasis[12,13], while endoscopic retrograde cholangio-pancreatography (ERCP) was chosen for isolated CBDSs[5]; no consensus exists to address choledocholithiasis[14,15]. To date, many therapeutic options are available, including laparoscopic, endoscopic, percutaneous, and traditional open techniques, applied both as a combination in a simultaneous way or as a gradual sequence. The most followed therapeutic options are preoperative ERCP followed by LC; LC plus intraoperative laparoscopic CBD exploration (LCBDE); LC plus intraoperative ERCP (rendezvous technique); and, finally, LC plus postoperative ERCP. The preference between one technique and the other is, most of the time, guided by the presence of professional resources and local skills rather than by its verified effectiveness[16-20].

The aim of this review is to provide practical advice and an overview of how to manage patients with cholelithiasis and choledocholithiasis. We take into consideration different diagnostic strategies, as well as the different therapeutic options available.

EPIDEMIOLOGICAL NOTES AND CLINICAL MANIFASTATIONS

Gallstones have a prevalence of 10%-15% in adult Caucasian populations and in the American Indians it can reach up to 70%[1,21]; on the contrary, Asian populations have a very low prevalence[22,23]. The risk factors associated with the most frequent formation of cholesterol stones are female sex, age over 40 years, obesity, and rapid weight loss[24]. The presence of gallstones remains asymptomatic in over 80% of cases, without any complications[21,25]. The risk of developing symptoms or complications varies between 1% and 2.3% per year[2,3,26-29] and in these patients, surgery is necessary.

The most frequent symptom is biliary pain, which is usually constant rather than discontinuous and appears when the gallbladder exit is obstructed by a stone. Most often it occurs in the right upper quadrant but can occur in the epigastrium, retrosternal area, or also the upper left quadrant. This pain has a typical irradiation to the ipsilateral scapula. Pain may be associated with vomiting, and it usually resolves completely but is often associated with other symptoms including flatulence, dyspepsia, and abdominal bloating. If biliary pain persists for more than 12 h, it is very likely that acute cholecystitis is occurring with associated fever, tachycardia, and then systemic inflammation.

Among the classic complications of gallbladder stones, we must remember acute cholecystitis which can resolve spontaneously or result in mucocoele, empyema, gangrenous cholecystitis, and emphysematous cholecystitis. Another complication is chronic cholecystitis, which usually occurs after recurrent episodes of biliary pain associated with phases of acute inflammation that result in fibrosis. Less frequent but not uncommon are Mirizzi syndrome, cholecysto-enteric fistulas, and the risk of malignant transformation in association with chronic cholecystitis. Migration of stones from the gallbladder to the CBD facilitated by gallbladder contractions can also be listed as a complication of gallstones. In the CBD, they can reach the duodenum following the bile flow or they can remain in the choledochus. In the latter case, they can remain asymptomatic or cause a variety of biliary problems. Incidence of choledocholithiasis increases with age, and between 20% and 25% of these patients with symptomatic gallstones have stones in the CBD and in the gallbladder[7,8]. The Swedish registry[30] showed a prevalence of 11.6% of choledocholithiasis detected during intraoperative cholangiography in patients with symptomatic gallbladder stones. Important studies concerning the prevalence of choledocholithiasis in patients with asymptomatic cholelithiasis are currently lacking.

Complications due to the presence of stones of the CBD are biliary pain and obstructive jaundice secondary to obstruction and subsequent dilation of the biliary tree[31], cholangitis due to bacterial infection facilitated by biliary obstruction, and ultimately acute biliary pancreatitis, which together with pain represent the largest percentage of such. Complications that most require endoscopic or surgical intervention are those that occur in the presence of choledocholithiasis.

PREOPERATIVE INVESTIGATIONS

The main issue for the correct management of cholecysto-choledocholithiasis is to arrive at the diagnosis by reducing the useless and invasive diagnostic procedures that are often performed inappropriately following non-linear clinical hypotheses. Generally, suspicion of the disease arises from the presence of specific symptoms associated with an alteration of the cholestasis indexes followed by an abdominal ultrasound (US) examination. Signs and symptoms of these are well known and previously mentioned. Instead, it is necessary to focus on preoperative serological and instrumental diagnostic investigations.

Serology

Normal values of liver function tests are considered predictive of the absence of CBDS. Yang *et al*[32] in 2008 presented a study conducted on 1002 patients undergoing LC, which confirmed the absence of CBDSs in the presence of normal values of liver function indexes. Total and direct bilirubin and gamma-glutamyltransferase demonstrated the highest sensitivities at 94.7% and 97.9%, respectively. Gurusamy *et al* [33] in 2015 proposed a systematic review on the diagnostic accuracy of liver function tests, concluding that the sensitivities of bilirubin and alkaline phosphatase were 84% and 91%, respectively, while the corresponding specificities were 91% and 79%.

Therefore, an alteration of total and direct bilirubin, gamma-glutamyltransferase, and alkaline phosphatase[34,35] has always been associated with the suspicion of choledocholithiasis, as well as the presence of elevated hepatic cytolysis values, as it was found in the presence of unrecognized CBDSs[34,36,37]. To date, total and direct bilirubin are considered the most reliable markers for the suspicion of choledocholithiasis, but the other liver biochemical tests should not be underestimated[38].

Radiological examinations

Diagnostic suspicion is essential to select patients to be directed to a more accurate study. Several predictive models have been developed but the association between the presented symptoms, biochemical data, and an US examination of the abdomen is often the most suitable way to identify high risk patients[35,39-42]. Abdominal US is the first non-invasive, inexpensive, and practicable examination to be performed almost anywhere[38,43,44]. This examination is also useful for evaluating the presence of other liver diseases. The high sensitivity of US (96%)[45] for the study of the gallbladder and the identification of stones inside it is due to the proximity of the organ to the abdominal wall and the absence of interposed gas.

Unfortunately, US often fails to confirm the presence of CBDSs because they do not show the characteristic acoustic shading or are located in the distal part of the choledochus, where they can be obscured by gas[46]. In these situations, it is necessary to evaluate the presence of indirect signs of obstruction, such as dilation of the CBD. Even the definition of the concept of dilation of the CBD is not very clear, the most used range is between 5 mm and 11 mm[47-49], bearing in mind that some dilation can also occur after cholecystectomy and with advancing age. Another indirect sign of suspected choledocholithiasis can be provided by the number and size of gallbladder stones[44,50]. US confirmation of small gallstones increases the possibility that they can migrate into the CBD[51,52]. Wilcox *et al*[53] in 2014 and Qiu *et al*[54] in 2015 reported two studies that had demonstrated, with different techniques and percentages, the presence of CBDSs in patients who had normal findings on liver function tests and US. For these reasons, abdominal US is certainly to be performed in the first instance, but in the suspicion of choledocholithiasis even with a normal serology and US evaluation it is a good rule to deepen the diagnosis with second-line examinations, which are more expensive and invasive.

Computed tomography (CT) is often done in emergency situations and for abdominal pain assessment. It is considered a second-line examination for the diagnosis of this pathological condition, but the literature expresses heterogeneous judgments regarding its diagnostic value and it is usually considered a non-definitive test. In fact, many gallstones are similar in density to the surrounding bile and lack of calcium; these occurrences limit the visibility of CT and therefore its sensitivity. The CT scan increases exposure of patients to X-rays and leads to higher costs than US. It is considered more accurate than the latter in the identification of CBDSs[55] but certainly inferior to magnetic resonance cholangiography (MRC)[56]. Greater diagnostic precision has been achieved with helical CT[38,57] and CT cholangiography [56,58]. CT cholangiography has shown a sensitivity in some studies and a specificity almost comparable to that of MRC[56,58]. The new multi-detector CT has shown a sensitivity of 78% in the portal venous phase and a specificity of 96% in the identification of CBDSs[57]. On the other hand, Kim *et al*[59] in 2013 reported that in 17% of cases, the 64-detector CT does not visualize CBDSs, due to size of < 5 mm, black/brown colour, and the patient's age. The greater radiological exposure and lower diagnostic power of CT compared to MRC make the latter examination preferable. However, CT examination has reduced execution times and extreme availability and diffusion, and these aspects could in the future assign it a new role in this field.

MRC and endoscopic US (EUS) are currently the radiological examinations used routinely to avoid unnecessary and more invasive procedures, such as ERCP. Specifically, MRC is now considered the most accurate non-invasive procedure for the detection of CBDS, with a sensitivity of 93% and specificity 96%[60]. It is non-invasive, does not require contrast, and can be performed without anaesthesia.

Meeralam *et al*[61] in 2017 demonstrated that diagnostic accuracy of EUS and MRC was high for both methods: Sensitivity of 97% *vs* 90% and specificity of 87% *vs* 92%. This was mainly due to the significantly higher sensitivity of EUS in the identification of small stones, while the specificity was not significantly different. The major limitation is the cost, and routine MRC for biliary disease without positive laboratory tests for CBDSs is not cost-effective[62]. Other disadvantages of MRC are its suboptimal availability in non-tertiary care centres and non-therapeutic purposes of the technique; in fact, in the case of CBDS diagnosis, it will be necessary to use other

treatment procedures. Its use is difficult in patients with severe obesity and claustrophobia, and in the presence of metallic foreign bodies or other metallic devices. Small stone diameter (< 5 mm) and peripancreatic oedema have been shown to reduce the accuracy of CBDS identification[63]. Regardless of the overall effectiveness, the points in favour of this diagnostic procedure are its non-invasiveness and higher spatial and three-dimensional resolution, with the use of dedicated software, compared to EUS; in any case, it remains an operator-dependent diagnostic investigation. However, despite some of its limitations and low territorial diffusion, it should always be preferred before referring patients to other more invasive procedures.

Percutaneous transhepatic cholangiography (commonly referred to as PTC) is a procedure that is performed with percutaneous cannulation of the intrahepatic biliary system, with contrast injection monitored by fluoroscopy. This technique can demonstrate biliary anatomy, including the size, number, and position of the stones, in the same way as ERCP. PTC is rarely used for the diagnosis of choledocholithiasis following the advent of modern radiological and endoscopic imaging techniques. However, it can be the initial component of the percutaneous transhepatic therapies for biliary tract disease, including choledocholithiasis, often when ERCP is not feasible.

Endoscopic examinations

All endoscopic procedures are invasive for the patient. They are also diagnostic and therapeutic procedures. ERCP involves cannulation of the ampulla of Vater and then of the CBD; through the injection of contrast medium under fluoroscopy, defects in filling are observed. This method is often used as a procedure of choice for evaluating the presence of choledocholithiasis, but complications can occur in as many as 8% to 12% of patients, usually manifesting as pancreatitis[64-66]. Due to its invasiveness and possible complications, ERCP is recommended for patients with a high probability of choledocholithiasis; this endoscopic examination conducted by expert operators can also be an adequate treatment[38]. Although most endoscopists routinely reach the second portion of the duodenum, there are some situations that can make this manoeuvre difficult. Sometimes, the papilla major is difficult to identify and cannulate; this then represents a time of stress and danger for the operator as well as for the patient, such as when the cannula is placed in a duodenal diverticulum[67]. Previous surgical procedures on the stomach are another frequent cause of ERCP failure. The second duodenal portion is difficult to reach after a Roux-en-Y reconstruction, omega anastomosis, and gastric by-pass, and after gastrectomy with duodenal stump closure and Billroth II reconstruction[68,69]. In those cases, diagnosis and treatment must be conducted surgically.

In the past decades, ERCP has been widely used for the diagnosis of CBDS; today, this procedure is being abandoned, especially in those patients who have a low or moderate risk of disease[70]. ERCP accuracy is lower than that of EUS and MRC, especially in cases of dilation of the CBDS and presence of small stones[71]. Furthermore, this procedure has a non-negligible morbidity and exposes the patient to X-rays and complications such as pancreatitis. The use of sphincterotomy during ERCP is therapeutic and mandatory in high-risk patients, but this procedure in untrained hands can increase morbidity and mortality, possibly causing duodenal perforation or haemobilia. Therefore, the use of ERCP is recommended in those patients with strong suspicion of choledocholiasis; in other cases, the use of EUS or MRC is preferable[38]. The increase of the laparoscopic approach for the treatment of patients with cholelithiasis, which has completely replaced open surgery, has revived the therapeutic role of ERCP. To date, for the management and treatment of cholecysto-choledocholithiasis, the most used approaches are in two sessions or in a single session, and in both cases the ERCP retains a fundamental role.

A further refinement of the classic endoscopic procedures is represented by the endoscopic US, which uses an US probe mounted on the tip of an endoscope. EUS does not use ionizing radiation. In comparison to ERCP, it is more useful for stones smaller than 5 mm and has a complication rate between 0.1% and 0.3%[38]. EUS may not be adequate in patients undergoing gastric surgery, as the anatomical situation would be altered. Like transabdominal US, EUS is not limited by bowel gas, but it is always an operator-dependent procedure. Giljaca *et al*[72] in 2015 published the results of a systematic review, reporting high rates of diagnostic accuracy for both EUS and MRC for choledocholithiasis. The authors found a sensitivity of 95% and specificity of 97% for EUS, and a sensitivity of 93% and specificity of 96% for MRC. The choice between EUS and MRCP, for intermediate probability choledocholithiasis, is based on the resource availability, personal experience, and costs[73].

INTRAOPERATIVE MANAGEMENT

LC is confirmed as the gold standard for the treatment of symptomatic cholelithiasis [12,13], but the therapeutic choice for CBDS is not clear. For the latter situation, the available strategies, conducted in a minimally invasive way, can be divided into two-session treatments and single-session treatments. The first category includes preoperative ERCP followed by LC, and LC followed by postoperative ERCP; the second category includes LC with LCBDE, and LC with intraoperative ERCP, also called the rendezvous technique.

Two-session options

Preoperative ERCP followed by LC is the most frequently used treatment worldwide [74]. Various studies have shown that this two-session approach is safe and effective [17,75,76]. Its limits are represented by a percentage between 40% and 70% of negative results that expose patients to unnecessary and risky endoscopic manoeuvres[77-79]. The development of diagnostic techniques such as MRC and EUS have increased the anatomical visualization of the biliary tract and have showed a high sensitivity and specificity for preoperative diagnosis of CBDS, all without the aid of special instruments and with less invasive approaches[80,81]. Lefemine *et al*[82] demonstrated that more than 50% of patients with CBDS have spontaneous passage of the stones, and 12.9% of patients already undergoing ERCP still had CBDSs during LC[83]. These events could be due to an ineffective ERCP or to a further migration of stones during the latency time between endoscopic and surgical intervention. Preoperative ERCP could increase the conversion rate from LC to open surgery, prolong the operating times, and have higher morbidity. It should also be emphasized that the high morbidity mainly translates into postoperative infections and consequently a longer hospital stay[84-86]. Preoperative ERCP followed by LC often requires two rounds of anaesthesia and two hospitalizations, and in the time between the two procedures, some patients may escape LC, being satisfied by the results of the preoperative ERCP [87,88]. Therefore, for this treatment modality, it is a good rule not to delay the LC too much and also to avoid the occurrence of recurrent events[89].

Another option is LC followed later by postoperative ERCP. This technique is rarely performed as the first choice for the treatment of cholelithiasis with choledocholithiasis because in a low percentage of cases it fails the intended purpose. The failure may be due to the operator's lack of experience, the absence of a guide wire, and a site altered by the previous surgery for inflammatory phenomena. The negative result of the endoscopic treatment necessarily leads to surgery, which can be more demanding than if it had been performed before. The postoperative ERCP retains a role when the intraoperative laparoscopic exploration fails or if during a LC, the presence of CBDS is found with the impossibility of performing it intraoperatively. Obviously, also in this case, the patient is subjected to two rounds of anaesthesia, with possible increase in morbidity, lengthening of the hospital stay, and higher costs[90,91].

One-session options

One-session procedures have confirmed benefits now, both in suspected cases and in proven cases of CBDS. These procedures are believed to be efficient, safe, convenient, and well accepted by patients, as the two different pathological conditions are resolved in a single surgery with single anaesthesia[92,93]. Regarding laparoscopic exploration of the CBD (Figure 1), some authors have described stone removal rates ranging from 94% to 98%, low morbidity, and a mortality rate of 0%[94,95]. Through laparoscopic exploration, negative events that can occur during endoscopic sphincterotomy, such as pancreatitis, perforation, bleeding, cholangitis, and malignancies of the CBD, are avoided. However, this technique has some drawbacks.

First, the procedure requires high-level skills in laparoscopic surgery with long learning curves and there is a need for dedicated instruments; it is understandable that these qualities may not be present in all treatment centres[96]. Many surgeons prefer the transcystic approach, which is considered less invasive and less complicated; however, choledochotomy is recommended in cases of dilated CBD, large diameter or multiple stones, impacted stones, and stones with intrahepatic localization[97-99]. The transcystic exploration route is often more challenging, due to a small diameter and tortuous and low-base implant duct. We can affirm that it is logical to start transcystically but in case of difficulty to move on to exploration through choledochotomy[100,101]. During laparoscopic exploration, stone removal can be guided fluoroscopically or by choledochoscopy. The use of a flexible choledochoscope is the most preferred because it increases precision and is under direct visual control. The

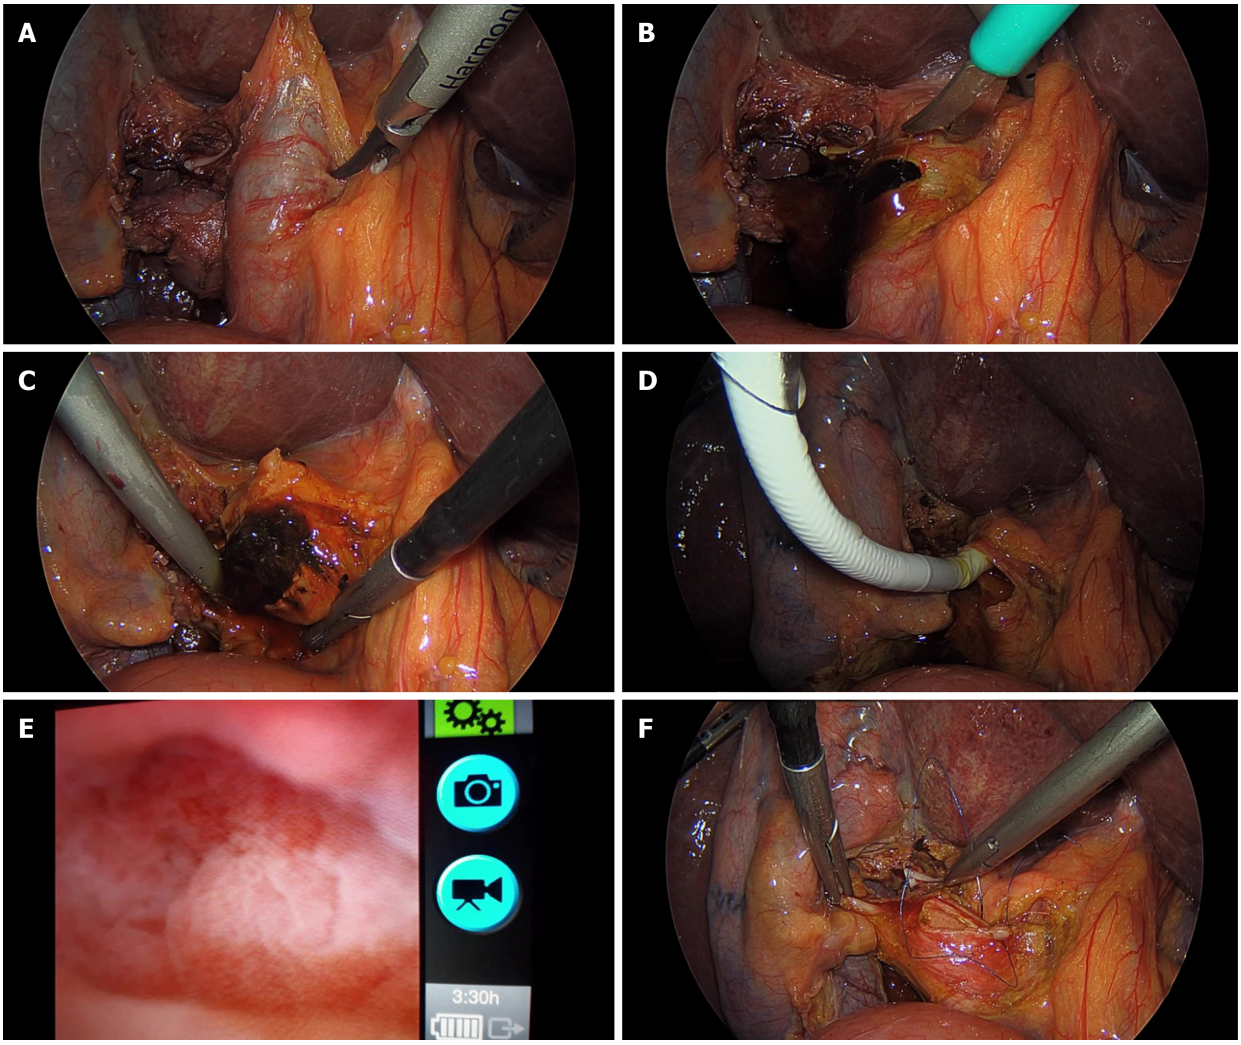

Figure 1 Intraoperative images: Laparoscopic exploration of the common bile duct. A: Common bile duct (CBD) dilation; B: CBD section; C: Stone extraction; D: Insertion of the choledochoscope into the CBD; E: Choledochoscopic image of the CBD; F: Suture of CBD.

choledochoscope also presents some criticalities; first of all, it is a fragile instrument that can break during the procedure, thereafter needing a double monitor for laparoscopic and choledochoscopic viewing and causing an increase in costs. Fluoroscopic guidance exposes the patient to radiation, increases the length of the procedure, and requires instrumentation that can hinder the operator's movements. In this regard, Topal *et al*[102] in 2007 compared the two procedures; the results showed a difference in the duration of the surgical time, being shorter in the group of patients treated with a flexible choledochoscope.

After the choledochotomy, the closure of the CBD can be performed directly or with the positioning of the T-tube endoprosthesis[103,104]. The T-tube provides easy percutaneous access for cholangiography and extraction of preserved stones[105]. However, the T-tube can accidentally detach, promoting CBD obstruction, bile loss, persistent biliary fistulas and skin abrasions, cholangitis from exogenous sources through the T-tube, and dehydration and salt depletion[106-109]. The T-tube also requires long and continuous management, limiting the patient's quality of life[110]. Some authors have concluded that primary closure is preferred over T-tube placement, as the latter increases operative time and hospital stay[111]. The most common complications of this technique are CBD tearing, leakage of bile, stitched T-tubes, and the formation of strictures[99]. The results of three recent studies did not show biliary strictures, and approximately 640 patients were observed undergoing LCBDE with an average follow-up of more than 3 years[112-114]. LCBDE for the treatment of primary choledocholithiasis showed a high rate of stone recurrence (36.4%-41.7%)[115,116], possibly because it does not affect the biliary tract structure and lithogenic environment[117]. Endoscopic and surgical techniques for extracting these stones are equally valid in terms of efficacy, morbidity, or mortality[5]. However, endoscopic sphincterotomy may leave a higher incidence of retained stones (16%) compared to the

surgical approach (6%)[31]. Currently, endoscopic sphincterotomy or endoscopic papillary balloon dilation represent the first-line treatment for initial primary choledocholithiasis, while the LCBDE should be performed for large stones, keeping the sphincter of Oddi intact.

Another single-session minimally invasive procedure for the treatment of cholecysto-choledocholithiasis is ERCP during the LC, also called the rendezvous technique (Figure 2). This approach was found by many experts to be safe and effective[77,118-120], and to require single hospitalization and single anaesthesia. For the exploration and extraction of the stones, the CBD is not opened, postoperative ERCP is avoided, and in case of extraction failure, surgical exploration is carried out during the same operation, with cost reduction. Despite these benefits, the procedure is not widespread, probably because operative endoscopy is not present in all treatment centres, and often when this exists, there is no expert operator. Intraoperative ERCP can be conducted in several ways. One of these is that after catheterization of the cystic duct, cholangiography is performed and in the event of a positive result, ERCP is performed and subsequently the LC is completed[121]. Some authors have proposed performing LC as a first step and then intraoperative ERCP[122]. Cavina *et al*[123] in 1998 proposed the rendezvous technique, a combined laparo-endoscopic approach which, due to its simplicity, has been widely used as a single-session treatment. A guide wire is introduced through the cystic duct and out the ampulla of Vater into the duodenum. Using side-viewing duodenoscope, the protruding guide wire is grasped by a snare or basket and a standard sphincterotome is threaded over it to facilitate endoscopic sphincterotomy and/or stone removal.

Other authors have proposed further variations to the rendezvous technique[124]. In one, after the endoscopic sphincterotome is passed over the guide wire through the papilla, an endoscopic sphincterotomy is performed under the direct vision of a simultaneously positioned duodenoscope. The rendezvous technique compared to classical ERCP has shown advantages in cannulation in the supine position and lower incidence of postprocedural pancreatitis[125]. The explanation for these results is that during classical ERCP, contrast medium is injected and often inadvertently cannulated into the pancreatic duct[126,127]. However, problems can occur during the rendezvous technique. The insertion of the guide wire may not be easy, due to the valves present in the cystic duct; inside the CBD, it can twist, due to the presence of impacted stones, and can not enter the papilla. During the ERCP, due to the insufflation of air, the bowel can stretch and cause difficulties for the LC. In expert hands, these obstacles can be overcome; the use of an atraumatic laparoscope has been proposed for a clamp positioned on the first jejunal loop or a bowel desufflator[128,129], as well as to completely dissect the Calot triangle and the attachment between the liver and gallbladder or to even remove the gallbladder from the liver bed until the last centimetres are left at the fundus before the starting of the endoscopic phase[130].

There are no definitive indications and contraindications in the literature for two-session or one-session treatment. It is clear that, in those centres that have technical and human resources available, all patients with cholelithiasis and concomitant choledocholithiasis can be treated *via* a one-session approach. La Greca *et al*[131] in 2008, after observing 80 consecutive patients affected by cholecystolithiasis and diagnosed or suspected CBDSs treated by the rendezvous technique, evaluated the factors that suggest the preference of the rendezvous technique over other treatments (laparoscopic CBD exploration and sequential ERCP-endoscopic sphincterotomy, commonly referred to as ERCP-ES) (Table 1)[131]. On the other end, the advantages and disadvantages of one-session compared to two-session are clearer. The first procedure is associated with a shorter hospital stay, fewer procedures, and less cost, but local resources and expertise must be present. Other factors that can influence its choice are patient fitness, clinical presentation, timing of CBDS diagnosis (preoperative or intraoperative), and the surgical pathology. Finally, patients with acute biliary pancreatitis and septic shock from cholangitis are not ideal candidates for the one-session option, and could benefit from two-session[132,133].

HINTS ON SUPPLEMENTARY TREATMENTS

Through an endoscopic biliary sphincterotomy or a laparoscopic procedure, the extraction of ductal stones may not be completed or be difficult; in these cases, the open surgical approach still retains an important role, like other additional techniques.

Table 1 Factors that suggest the preference of the rendezvous technique over other treatments

Main indications for the laparo-endoscopic RV	RV preferable *vs* laparoscopic CBD exploration	RV preferable *vs* sequential ERCP-ES
(1) CBD stones not easily extractable	(A) Need of higher surgical skill	(a) Risk of synchronization
through the cystic duct	(B) Longer operation time	(b) Risk of unnecessary ERCP
Positive factor - > (time reduction)	(C) Need of biliary drain	(c) Risk of difficult retrograde
		cannulation
(2) Multiple small CBD stones and large friable stones	A, B, C +	a, b, c
Positive factor - > (reduction of risk of recurrence)	(D) High risk of residual fragments and recurrence	
(3) Any type of CBD stones with delayed passage of the	A, B, C, D +	a, b, c
contrast medium during IOC or T-tube-IOC after	(E) High risk of undertreatment of chronic	
laparoscopic CBD exploration	papillitis and of maintenance of underlying causes	
Positive factor - > (reduction of risk of recurrence)		
(4) CBD stones with previous cholangitis	A, B, C, D +	a, b, c +
Positive factor - > (reduction of risk of recurrence)	(E) High risk of maintenance of underlying causes	(d) Avoidance of contrast medium injection
	at the papilla	with risk of recurrence of cholangitis
(5) CBD stones after recurrent acute biliary pancreatitis	A, B, C, D, E	a, b, c, d +
or hyperbilirubinemia		(e) risk of recurrence of ERCP
Positive factor - > (iatrogenic risk reduction)		related acute pancreatitis
(6) Known or unsuspected sphincter of Oddi dysfunction,	A, B, C, D, E	a, b, c, d, e
cholecysto-lithiasis with or without CBD stones		
Positive factor - > (iatrogenic risk reduction)		
(7) CBD stones and/or abovementioned problems in patients	A, B, C, D, E +	a, b, c, d, e +
with Billroth II during open cholecystectomy	(F) Manual drive of the endoscope by the surgeon	(f) more difficult ERCP
Positive factor - > (iatrogenic risk reduction)	in the afferent jejunal loop	
(8) CBD stones, SOD, acute pancreatitis in children/CBD	A, B, C, D, E +	a, b, c, d, e, f +
stones in patients with normal or thin CBD	(G) difficult laparoscopic CBD exploration and risk	(h) avoidance of
Positive factor -> (iatrogenic risk reduction)	of stenosis of the suture	sphincterotomy in children
(9) CBD stones and/or SOD after failure of preoperative	A, B, C, D, E	a, b, c, d, e, f
ERCP-ES or recurrence of acute biliary pancreatitis		
Positive factor - > (iatrogenic risk reduction)		
(10) Inexperienced surgeon for laparoscopic CBD exploration	A, B, C, D, E, G	a, b, c, d, e, f
Positive factor - > (iatrogenic risk reduction)

Open surgical procedure

Four decades ago, cholelithiasis was treated exclusively by open cholecystectomy and similarly, choledocholithiasis was managed by open CBD exploration, which was performed by duodenotomy and sphincterotomy or bilioenteric anastomosis[134]. Open surgery is now considered obsolete, but the recent literature has shown its superiority over ERCP in the clearance of CBDS, with lower morbidity and mortality rates (20% *vs* 19% and 1% *vs* 3%, respectively)[31,135]. Open exploration of the CBD can be conducted through a coledochoenterostomy or a sphincterotomy; the choice depends on the surgeon's experience[136]. Some authors prefer coledochoenterostomy for CBD with a diameter greater than 2 cm, in order to create a large opening between the bile duct and intestine. An emerging problem is that open biliary surgery is performed increasingly less outside specialized centres in hepato-bilio-pancreatic surgery; this raises new questions regarding the most appropriate management of those patients. Their number is scarce but not negligible, and their complex cases often need conversion or revision using an open approach by skilled surgeons.

During the sphincterotomy, an incision of approximately 1 cm is made in the distal part of the sphincter musculature. A catheter or dilator is passed distally and a Kocher manoeuvre is performed, followed by duodenotomy at the level of the ampulla. The dilator exposes the ampulla in the operating field, where it is sufficiently incised along its anterosuperior border with subsequent removal of the impacted stone[137]. Choledocoenterostomy is commonly performed as a side-to-side choledochoduodenostomy for dilated CBD with multiple stones. These patients require drainage for good long-term results without recurrence of jaundice or cholangitis[138]. The most used technique is that of a side-to-side hand-sutured anastomosis between the supraduodenal CBD and the duodenum[139]. Kocher's manoeuvre is performed to expose the distal CBD. Choledochotomy is performed for 2-3 cm to the lateral border of the duodenum. Anastomosis is performed with interrupted absorbable sutures. The biggest complication that can occur is sump syndrome caused by food or other debris trapped in the distal part of CBD[140]; its management is endoscopic with ERCP/ES. Another option may be choledochidjejunostomy with a roux-en-Y loop, but performed by expert hands.

Lithotripsy

Lithotripsy could be considered the ideal management of CBDS, as it resolves the disease without interruption of the CBD wall and without performing a sphincterotomy. However, this technique cannot be considered definitive in the treatment of cholecysto-choledocholithiasis since the genesis of the stones is secondary to the lithogenic bile in the gallbladder, and for this reason the recurrence rate would be very high. Fragmentation of gallbladder stones would increase the percentage of their migration into the choledochus. Another advantage of this technique is certainly that of being performed in a single application. Lithotripsy is not able to avoid cholecystectomy but it can be a valid therapeutic alternative in those patients already cholecystectomized or for whom it is not indicated. However, it cannot be overlooked that lithotripsy requires dedicated instrumentation and skilled personnel, which are not always available, thus limiting its diffusion. There are various approaches described for stone fragmentation: Mechanical, electrohydraulic, laser, and extracorporeal shock wave[141-143].

Endoscopic mechanical lithotripsy is usually performed after failed endoscopic sphincterotomy for CBDS through a Dormia basket or balloon catheter. CBD clearance is reached in about 80%-90% of cases[143]. Failure may be due to CBDS size exceeding 3 cm, since stones could not be captured, and stone impaction in the CBD[144].

Endoscopic electrohydraulic lithotripsy may be used in cases of difficult CBDS. A large operating channel accommodates a 4.5 Fr calibre probe with an electrohydraulic shock wave generator sending high-frequency hydraulic pressure waves. In order not to cause damage to the surrounding tissue, the probe must be positioned as close as possible to the stone. The stone removal rate ranges from 74% to 98%[145,146]. This procedure requires costly and fragile instrumentation and good coordination of two skilled endoscopists.

Endoscopic laser lithotripsy has been used to fragment large stones under fluoroscopic visualization, because of the risk of heat-induced biliary damage[147]. Today, single-operator steerable cholangioscopy allows the safer use of laser lithotripsy with direct vision[148]. A removal rate of CBDS has been reported of about 93%-97%, with a complications rate of 4%-13%[149,150]. The holmium laser is the newest one, but its use is very expensive[151]. Laser lithotripsy has recently been proposed with laparoscopic, open surgery, or percutaneously approaches.

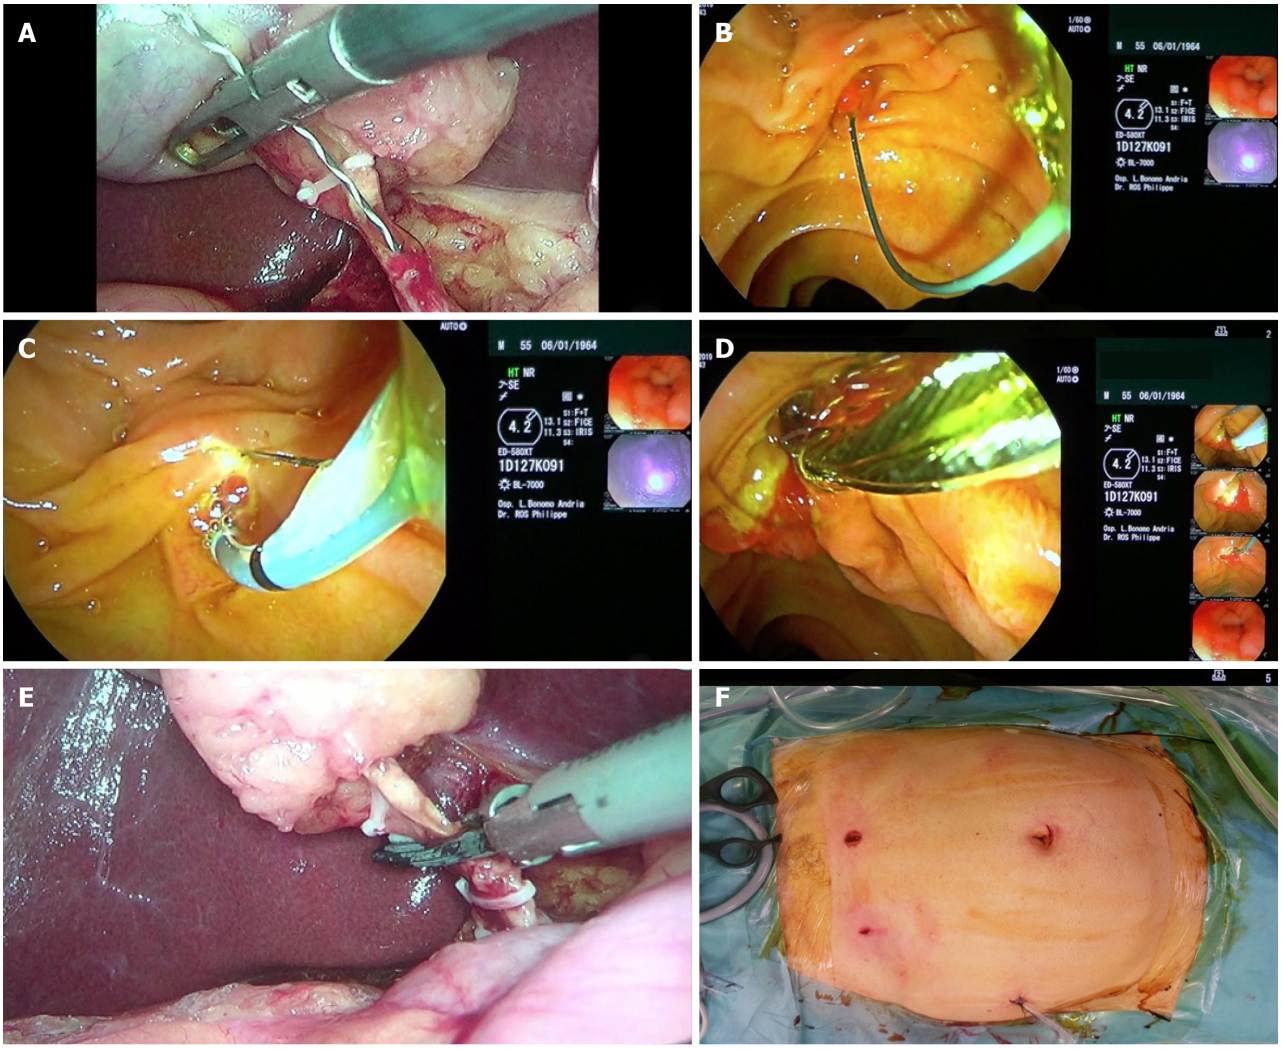

Figure 2 Intraoperative images: Endoscopic retrograde cholangio-pancreatography during laparoscopic cholecystectomy ("rendezvous technique"). A: Insertion of the guide wire into the cystic duct; B: Guide wire exits through the papilla into the duodenum; C: Endoscopic sphincterotomy on guide wire; D: Extraction of stones from the common bile duct with a dormia basket; E: Section between clips of the cystic duct and subsequent retrograde cholecystectomy; F: Postoperative final scars.

Extracorporeal shock-wave lithotripsy is also used in cases of difficult CBDS with US or fluoroscopic guidance. Modern lithotriptors employ water-filled compressible bags; because of the discomfort experienced by the patient, general anaesthesia is often required. Contraindications to this technique are portal thrombosis and varices of the umbilical plexus, and it can also cause adverse events, such as transient biliary colic, subcutaneous ecchymosis, cardiac arrhythmia, self-limited haemobilia, cholangitis, ileus, and pancreatitis[152,153]. More sessions are typically required. The recurrence rate during a 1-2 year follow-up period is about 14%[154]. Currently, extracorporeal shock-wave lithotripsy is not considered the first-line treatment for difficult bile duct stones[155].

CONCLUSION

Management of cholelithiasis with choledocholithiasis must be conducted appropriately. A delay in the diagnosis of this pathological condition can increase morbidity and mortality. Unlike other diseases that have a certain diagnosis, the presence of stones in the CBD is sometimes only suspicious. Historically, diagnosis was achieved through a careful association between clinical symptoms, serology, and radiological images. Today, the development of new radiological imaging, interventional endoscopy, and laparoscopy techniques has allowed us to arrive at a faster and more accurate diagnosis. The management of cholelithiasis with choledocholithiasis has become multidisciplinary, and more professional figures are involved

(radiologists, gastroenterologists, endoscopists, and surgeons), and will be increasingly adapted not only to a specific patient but also to the available resources of a specific environment in order to have the best possible management. However, endoscopy and surgery always retain a central diagnostic and therapeutic role.

Many studies and meta-analyses have been conducted by various authors regarding the comparison between one-session and two-session treatments for patients with concomitant gallbladder and CBD stones[17,31,76,92,156,157]. The findings have shown equivalent success rates, postoperative morbidity, stone clearance, mortality, conversion to other procedures, total operation time, and failure rate, but one-session treatment is characterized by a shorter hospital stay and more cost benefits[158]. Consequently, the latter option, when local resources and expertise are available, should be offered as a treatment of choice. However, in cases of incomplete or difficult removal of CBDSs, other additional techniques can also be used, which can be of valuable help in selected patients.

Abstract

The hepatitis C virus (HCV), an obligatory intracellular pathogen, highly depends on its host cells to propagate successfully. The HCV life cycle can be simply divided into several stages including viral entry, protein translation, RNA replication, viral assembly and release. Hundreds of cellular factors involved in the HCV life cycle have been identified over more than thirty years of research. Characterization of these cellular factors has provided extensive insight into HCV replication strategies. Some of these cellular factors are targets for anti-HCV therapies. In this review, we summarize the well-characterized and recently identified cellular factors functioning at each stage of the HCV life cycle.

Key Words: Hepatitis C virus; Cellular factor; Viral entry; Translation; Replication; Assembly; Release

Core Tip: The hepatitis C virus (HCV) depends on its host cells to propagate successfully. Hundreds of cellular factors involved in the HCV life cycle have been identified. Some of these cellular factors are potential targets for anti-HCV therapies (*e.g.*, scavenger receptor class B type 1, epidermal growth factor receptor, Niemann–Pick C1-like 1, microRNA-122, cyclophilin A). A successful vaccine for HCV is still a challenge in the near future. Investigating the cellular factors involved in viral entry should help vaccine development. HCV is also a unique model to study the interactions between viral infection and cellular lipid metabolisms.

INTRODUCTION

Around 50%–80% of patients infected with the hepatitis C virus (HCV) will develop chronic infection. Approximately 71 million individuals are chronically infected by the HCV worldwide according to an estimation by the World Health Organization (https://www.who.int/hepatitis/publications/global-hepatitis-report2017/en/).

Chronic hepatitis C (CHC) patients are at high risk of developing liver cirrhosis and even hepatocellular carcinoma. Although CHC can now be cured using various direct-acting antivirals, the majority of CHC patients remain undiagnosed and, thus, untreated. Furthermore, a successful antiviral treatment does not prevent HCV reinfection. Therefore, HCV eradication remains a challenge and will probably require an effective vaccine[1] (for a review see References[2,3]).

HCV belongs to the family *Flaviviridae* and genus *Hepacivirus*. Its genome is a single-stranded RNA with positive polarity that is packaged by viral core protein and enveloped by a lipid membrane containing two viral glycoproteins (*i.e.*, E1 and E2) to form the virion. HCV genomic RNA sequences are highly heterogeneous among different isolates. At present, HCV is classified into at least six major genotypes (1 to 6). HCV heterogeneity hinders the development of an effective vaccine to protect against infection from all HCV genotypes. Despite the sequence variations, all currently recognized HCV genotypes are pathogenic, hepatotropic and preserve the similarity of the life cycle in cells (for a review see References[4,5]).

The HCV life cycle begins with the binding of a virion to its specific entry factors (or receptors) on hepatocytes. After binding, the virion is internalized into the cytoplasm and its genomic RNA is released. Then, the HCV genomic RNA is used for both polyprotein translation and viral replication. HCV replication takes place within the membranous web (MW) in the endoplasmic reticulum (ER). At last, HCV uses the biosynthetic pathway of very-low-density lipoprotein (VLDL) to assemble and release the viral particles from cells (for a review see Reference[6]).

HCV relies significantly on its host cells to establish a successful infection due to the fact of its limited genetic content. Hundreds of cellular factors have been identified as being involved in the HCV life cycle over more than thirty years of research. In this review article, due to the limited space, we can only summarize the well-characterized and recently identified cellular factors involved in the HCV life cycle but not including immune responses against viral infections (for a review see Reference[7]).

HCV PARTICLES

It has been demonstrated that purified HCV particles are spherical and heterogeneous in size (40–100 nm in diameter) with no obvious symmetry under cryo-EM[8]. The density of HCV particles in the plasma of CHC patients also varied (from 1.03 to 1.25 g/mL). Low-density HCV particles with 81–85 nm diameters are highly infectious[8,9]. The HCV particles with low density are associated with apolipoproteins (Apo such as Apo-E, Apo-AI, Apo-CI and Apo-B), phospholipids (such as phosphatidylcholine and sphingomyelin) and cholesterol (free and esterified), while they have almost no phosphatidylserine (PS) and very little amounts of phosphatidylethanolamine[8,10-12]. HCV particles derived from cultured cells show characteristics similar to those from CHC patients[9,10,13]. Thus, these circulating HCV particles are referred to as "lipo-viro particles" (LVPs)[14] and have very low buoyant densities due to the fact of their interactions with lipoproteins in the blood[15] (Figure 1) (for a review see Reference[16]).

Modifications of LVPs could be mediated by lipoprotein lipases (LPLs)[17,18]. LPL was shown to shift the HCV particles to higher densities with diminished HCV infectivity[19,20]. Indeed, LPL lipolytic activity in clinical samples has been reported to be inversely correlated with HCV viremia[21].

More than 40 cellular proteins were found in the HCV particles recently using proteomics analyses, including heat shock cognate protein 70 (HSC70) and nucleoporin 98 (Nup98); both proteins play a role in virus assembly/release[22,23].

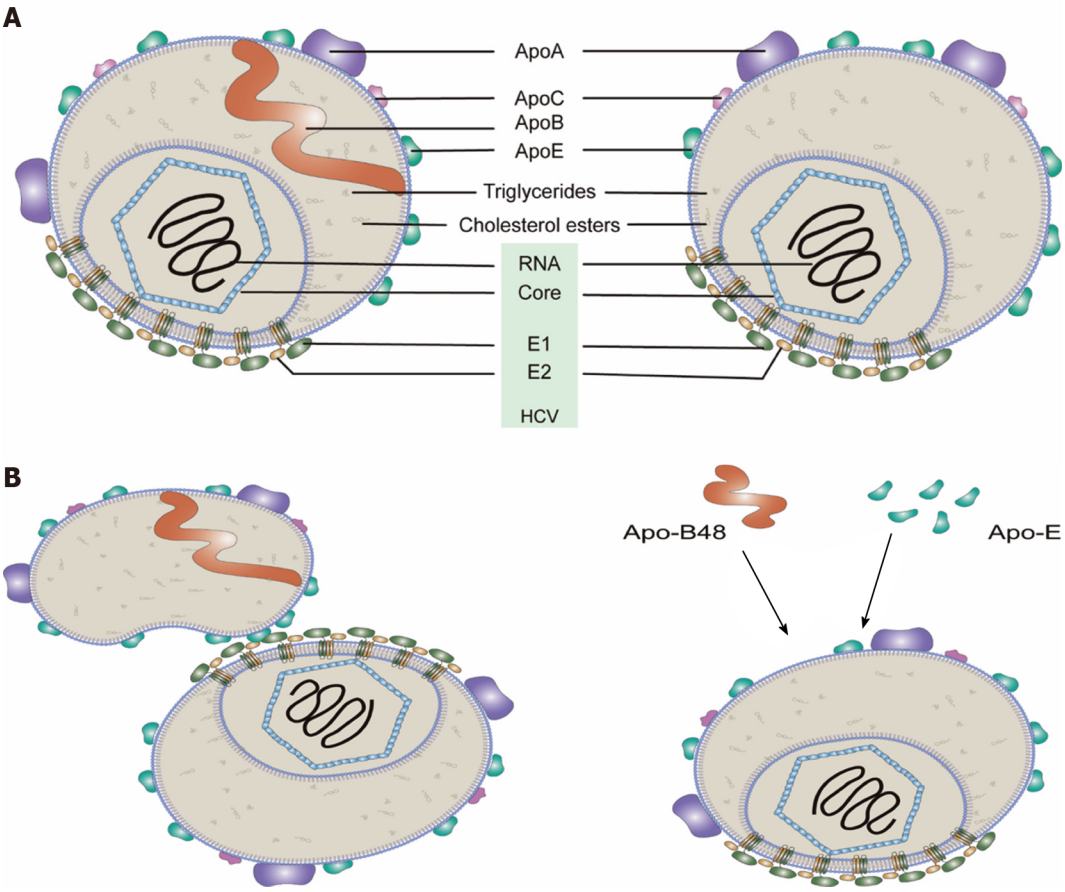

Figure 1 Model of hepatitis C virus particles (lipo-viral particles) secreted from cells. A: Most of the lipo-viral particles (LPV)'s membrane is a lipid monolayer. A bilayer-containing region is where the viral envelope proteins (*i.e.*, E1 and E2) are inserted. Viral envelope proteins may also exist in the phospholipid monolayer membrane. Though the precise structure has not yet been determined, LVPs are believed to have multiple copies of Apo-E and less Apo-A1 molecules but only one Apo-B100 molecule (left). Some LPVs may not have Apo-B (right). Within the phospholipid monolayer, there are the core proteins wrapping the viral RNA genome and neutral lipids (*e.g.*, cholesterol esters and triglycerides); B: Serum lipoproteins are possibly associated with hepatitis C virus particles in different ways. HCV: Hepatitis C virus.

Association of HCV particles with host lipoproteins has advantages for the virus: (1) Lipoproteins likely mask viral epitopes of viral E1 and E2 proteins thus helping the virus escape from the humoral immune response; and (2) Lipoproteins contribute to the hepatotropism of HCV, *e.g.*, HCV attachment to hepatocytes involving Apo-E (and/or Apo-B) binding with the cellular factors [*e.g.*, low-density lipoprotein receptor (LDLR), highly sulfated heparan sulfate proteoglycans (HSPGs) and scavenger receptor class B type 1 (SR-B1)] for viral entry[24].

VIRAL ENTRY

HCV can infect hepatocytes and other cells (*e.g.*, lymphocytes). In general, HCV infects hepatocytes through two distinct routes: Cell-free virus entry and cell-to-cell transmission. Viral entry requires interactions between the components of LPVs (particularly Apo-E and viral envelope proteins) and those of cells (particularly entry factors). Alternatively, HCV may infect cells through exosomes (for a review see Reference[25]).

Cell-free virus entry into hepatocytes

HCV transmission is through the parenteral route, and it needs to reach the liver by crossing the endothelium. Before attachment to the hepatocytes, HCV particles may be captured by DC-SIGN on dendritic cells or L-SIGN on endothelium[26,27] (Figure 2).

Cellular factors responsible for HCV entry into hepatocytes are divided into three groups based on their functions[25,28]: Attachment factors, entry factors (or receptors) and entry cofactors (or facilitators). Attachment factors help dock the virus on the cell's surface, mostly through non-specific interactions. Entry factors mediate specific

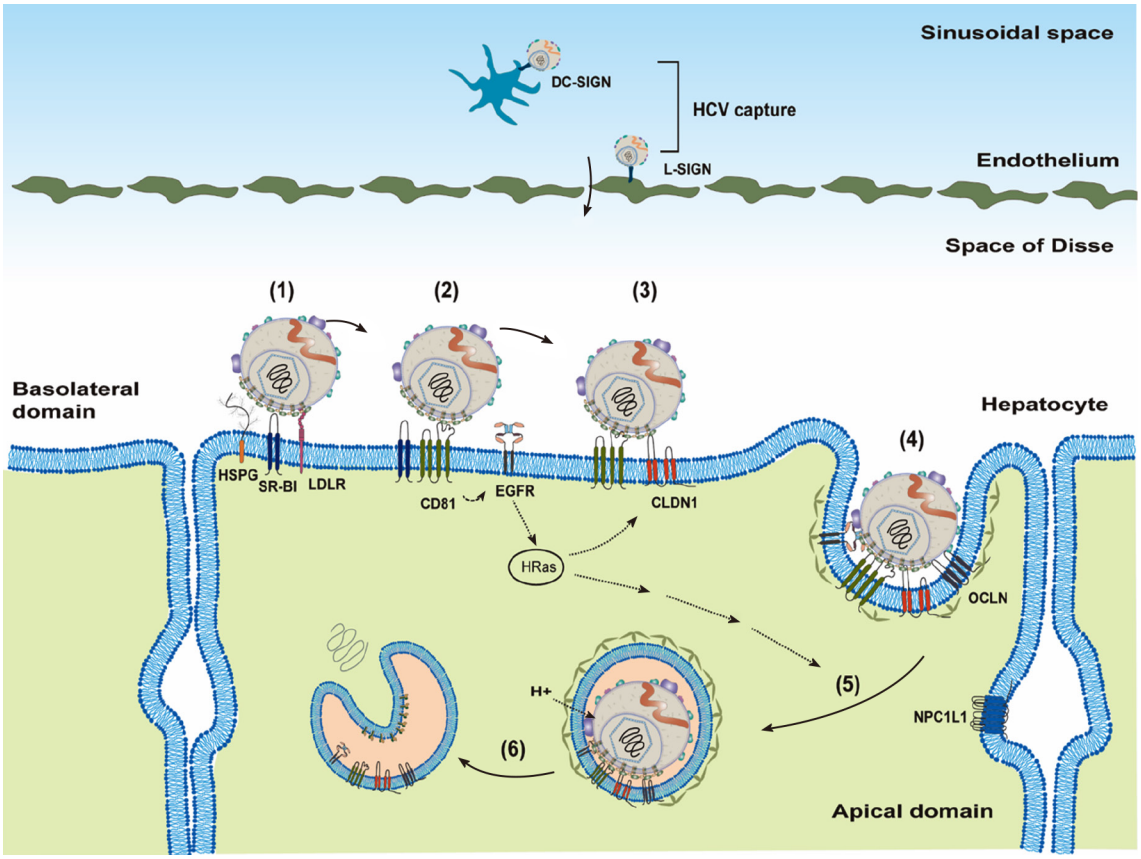

Figure 2 Model of cell-free virus entry into hepatocytes. Hepatitis C virus (HCV) lipo-viral particles (LPVs) may be captured by DC-SIGN on the dendritic cells or L-SIGN on the endothelium in the sinusoidal space. After transfer to Space of Disse, HCV LPVs could attach to the hepatocytes through interacting with highly sulfated heparan sulfate proteoglycans, low-density lipoprotein receptor and scavenger receptor class B type 1 (1). This attachment allows the engagement of LPVs to cluster of differentiation 81 (CD81) and then induces the epidermal growth factor receptor receptor signaling (2). Lateral diffusion of the CD81–HCV complexes results in the association of CD81–HCV with Claudin-1 (3) and then OCLIN (4). Formation of the HCV–CD81–CLDN1–OCLIN complex allows viral particles internalized through clathrin-dependent endocytosis (5). Endosomal acidification induces the fusion of viral particles possibly through E1 and leads to the release of the viral genomic RNA into cytosol (6). HSPGs: Heparan sulfate proteoglycans; HCV: Hepatitis C virus; EGFR: Epidermal growth factor receptor; LDLR: Low-density lipoprotein receptor.

interactions with viral glycoproteins. Entry cofactors, although not interacting directly with the virus, play an important role in supporting viral entry.

To infect a new hepatocyte, the HCV needs to interact with the attachment factors on the basolateral side of hepatocytes first (Figure 2). The well-known attachment factors include HSPGs, (particularly syndecans: SDC-1 and SDC-2), LDLR and SR-B1 [29-32]. Attachment of HCV LPVs to host cells is mediated mainly through the virus-associated lipoprotein components (particularly Apo-E[33]) and viral glycoproteins (E1 and E2, particularly E2)[32,34,35]. In addition to the binding of Apo-E with attachment factors, Apo-B100 could also interact with LDLR[36] and Apo-AI with SR-B1[37]. Recently, the redundant functions of Apo-C1 and Apo-E in the HCV infection have been demonstrated[38]. Attachment to SR-B1 may bring HCV particles to entry factor cluster of differentiation 81 (CD81)[39]. SR-B1, as both an entry factor and an attachment factor, has been shown to bind viral envelope proteins[29,40]. Interaction of HCV with CD81 activates epidermal growth factor receptor (EGFR) signaling and also facilitates CD81 diffusion and formation of the HCV–CD81–CLDN1 complex[39, 41-43]. The HCV–CD81–CLDN1 complex then interacts with OCLN, which is believed to mediate the clathrin-dependent internalization through interacting with GTPase dynamin[44-46]. SR-B1, CD81, CLDN1 and OCLN are four well-characterized entry factors for HCV entry[28]. In addition, LRL-R could interact with both HCV and E2 proteins and, thus, function as an entry factor[47].

HCV particles are then internalized, mature in the acidic endosomes that promote low pH-dependent HCV fusion and, ultimately, release HCV genomic RNAs (uncoating) into cytosol[48-50] (Figure 2). Low endosomal pH and interactions of viral glycoproteins with CD81 are thought to induce conformational rearrangements of viral glycoproteins for HCV fusion[51], which is controlled by E1 protein[52]. Recently, cell death-inducing DFFA-like effector B (CIDEB) protein was identified as an entry

cofactor to act at a late membrane fusion event[53].

Both HCV and coronavirus [*e.g.*, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)][54] are positive-strand RNA viruses. These two viruses enter their target cells through receptor-mediated endocytosis and release their genomic RNAs for translation in the cytosol. However, unlike HCV, coronavirus fusion for viral entry is unusual in that it is often biphasic and can occur at or near the cell's surface or in late endosomes[55].

In addition to HSPGs, LDLR, and SR-B1, interferon receptor IFNAR2 was found as a novel attachment factor to facilitate HCV entry through interacting with Apo-E[56]. VLDL receptor (VLDLR), similar to LDLR, could also serve as an attachment factor for HCV entry[57]. Niemann–Pick C1-like 1 (NPC1L1) contributes to HCV entry possibly through its role as a cholesterol receptor, thus functioning as an HCV entry cofactor [58]. Similarly, PS receptor (TIM-1/human hepatitis A virus cellular receptor 1/CD365) has also been identified as an attachment factor through binding with PS on HCV LPVs[59,60]. It should be noticed that only tiny amounts of PS were detected in the HCV particles[12]. On the other hand, LPLs, hepatic triglyceride lipase and long-chain fatty acyl-coenzyme A can inhibit HCV attachment by targeting virus-associated lipoproteins[17,18,20,61].

In addition to CLDN1, other CLDNs (*e.g.*, CLDN6, CLDN9 and CLDN12) have also been reported as HCV entry factors for some genotypes[62-64]. Recently, CD63 (binding directly with HCV) and CD36 (interacting directly with HCV E1 protein) were demonstrated to be entry factors[65,66]. Under hypoxic conditions, VLDLR could serve as an entry factor independent of canonical CD81-mediated HCV entry[67].

Most cellular factors, not directly interacting with the virus, involved in viral entry are served as the function of entry cofactors[25]. Some entry cofactors were identified to interact with SR-B1 [*e.g.*, PDZK1 and UDP-glucose: Glycoprotein glucosyltransferase 1 (UGGT1)]. The scaffold protein PDZK1 may be involved in linking SR-B1 to the actin cytoskeleton and the endocytic network[68], while UGGT1, a key component of the calnexin cycle involved in protein glycosylation, may stabilize SR-B1[69].

In addition to EGFR signaling, the association of CD81–CLDN1 is also regulated by protein kinase A (PKA)[70], ephrin receptor A2[71] and phosphatidylinositol 4-kinase type III-alpha/beta[72]. These are also entry cofactors supporting viral entry. Several other entry cofactors were identified as CD81-associated factors including HRas[39], integrin 1 (ITGB1)[39], Ras-related protein Rap2B[39], calpain-5[73], ubiquitin ligase Casitas B-lineage lymphoma proto-oncogene B[73] and serum response factor binding protein 1[74]. The membrane lipid composition has been shown to affect CD81 expression on the cell's surface and, in turn, modulate HCV entry[75]. Indeed, depleting cholesterol from the plasma membrane has been shown to decrease viral entry owing to reduced CD81 on the cell's surface[76]. In agreement with these findings, lipid-free Apo-E was demonstrated to induce adenosine triphosphate-binding cassette subfamily G member 1 protein-dependent cholesterol efflux and inhibit HCV replication[77].

Several other entry cofactors affecting CLDN1 and/or OCLN localization are also important in the HCV entry. E-cadherin, tumor-associated calcium signal transducer 2 (TACSTD2) and possibly Rab13 could regulate the localization of CLDN1 and OCLN [78-80]. Cell surface localization of CLDN1 is also regulated by vesicular transport proteins (such as Sec24C)[81]. Serotonin 2A receptor (5-HT2AR) is shown to control CLDN1 localization through PKA-mediated phosphorylation[82].

Several cellular factors involved in the process of HCV internalization have been identified: the expression level of SR-B1[83,84], EGFR–MKNK1 signaling[85,86], Abl tyrosine kinase[87], signaling pathways of Rac/Rho/CDC42/mitogen-activated protein kinase[41], actin[50], transferrin receptor 1[88], adaptor proteins (AP)-2-associated protein kinase 1[89] and cyclin G-associated kinase[89].

Pim kinase[90], Ankyrin repeat domain 1[91] and solute carrier family 3 member 2 [92] proteins are required for HCV entry, though their exact roles are not yet defined. In addition to the clathrin-dependent internalization pathway, HCV could also use clathrin-independent mechanisms to enter different cells[93].

Viral cell-to-cell transmission

In addition to cell-free virus entry into hepatocytes, HCV particles can also transmit directly from an infected hepatocyte to an adjacent hepatocyte[94-96]. A recent study demonstrated that the HCV core, *E1*, *E2* and *P7* genes were essential for not only cell-free viral transmission but also cell-to-cell transmission[97]. Several cellular factors were reported to contribute to HCV cell-to-cell transmission, including CD81[98,99], SR-B1[95], CLDN1[98], OCLN[98], LDLR[98], SDC-1[98], SDC-2[98], TIM-1[98], Apo-E in mature HCV particles[33,98,100], AP-1B and AP-4[101]. However, SR-B1-

independent[102] or CD81-independent[103] HCV cell-to-cell transmission has also been reported. More studies are needed to clarify this issue.

Viral transmission through exosomes

Exosomes, small vesicles normally used for intercellular communication, have been reported containing HCV RNA[104-107]. HCV transmission through exosomes should be independent of any entry factor, and it is resistant to antibody neutralization. However, further investigation is required to understand the mechanisms of transmitting HCV genomic RNA through exosomes[108].

Infection of HCV into other cells

B7.2 (CD86)[109] enabling lymph-tropic HCV to infect memory B cells and CD5[110] important for HCV entry into human T lymphocytes were identified. HCV enters macrophages mainly through phagocytosis[111].

VIRAL PROTEIN TRANSLATION

After the fusion between the viral envelope and the endosomal membrane, HCV positive-strand RNA will be released into the cytosol (Figure 2). Translation of HCV genomic RNA is modulated by the viral RNA structure, cellular translational machinery [*e.g.*, 40S, translation initiation factors (eIFs)] and several cellular regulatory factors [*e.g.*, microRNA-122 (miR122) and internal ribosome entry site (IRES) trans-acting factors (ITAFs)] (for a review see Reference[112]).

The most important structures of the HCV genomic RNA for translational regulation reside in the IRES of the 5'-untranslated region (5'UTR), a short segment of the core gene sequence, the cis-acting replication element (CRE) in the NS5B coding region[113] and the entire 3'UTR[114] (Figure 3). Many long-range RNA–RNA interactions among different regions of the HCV genomic RNA are involved in translational regulation[115]. The HCV IRES could bind to the ribosomal 40S subunit directly[116-118]. Interaction between the viral IRES and cellular 18S rRNA consisting of a three-nucleotide base pairing of these two molecules is crucial for HCV translation [119].

When eIF2–Met–tRNAi Met is available, canonical eIFs, including eIF3, eIF2, eIF1A, eIF5 and eIF5B, can initiate HCV translation[120]. On the other hand, when eIF2–Met–tRNAi Met is limited, eIF2A[121], eIF2D[122], eIF5B[123], a combination of eIF2A and eIF5B[124], or MCT-1 and a DENR protein complex[125] could substitute for eIF2 to initiate the translation (for a review see Reference[112]). A single RNA loop in domain II of the HCV IRES controls the translation from initiation to elongation [126].

The most important cellular factor involved in HCV translation is miR122. The liver-specific miR122 is crucial for HCV production (for a review see Reference[127]). miR122 can bind to two adjacent recognition sites on the HCV 5' UTR with the help of human Argonaute protein 2 (hAgo2)[128-130]. The hAgo2/miR122 complex could alter the HCV 5'UTR structure and promote the IRES formation to enhance viral translation[131].

Several cellular proteins could bind to the HCV 5'UTR directly as ITAFs and enhance the viral protein translation such as La[132], heterogeneous nuclear RNA-interacting protein Q (hnRNP Q; NSAP1)[133], hnRNP L[134], hnRNP D[135], IGF2BP1 (insulin-like growth factor 2 mRNA binding protein 1; IMP-1)[136], poly(C)-binding protein 2 (PCBP2)[137], the LSm1-7 complex[138] and polypyrimidine tract binding protein (PTB)[139]. On the other hand, RNA binding protein 24[140] and Gemin5 would possibly suppress HCV translation[141].

Some proteins do not bind to HCV RNA directly but act through protein–protein interactions to help HCV translation, such as HuR (ELAVL1)[142], and the proteasome subunits[143].

Several other cellular proteins, identified as positive regulators of HCV translation through different mechanisms include MAP kinase interacting serine/threonine kinase 1 (MKNK1), phosphatidylinositol 4-kinase catalytical subunit beta (PI4K-beta) [144], ubiquitin-specific protease 15[145], NSAP1[146], RNA helicase DDX6 (RCK, p54) [147] and heat shock protein 70[148].

In addition to miRNAs and proteins, long non-coding RNA (lncRNA), such as HULC, could enhance HCV translation[149]. Moreover, the PI3K–Akt signal pathway could also upregulate HCV translation through the activation of SREBPs[150].

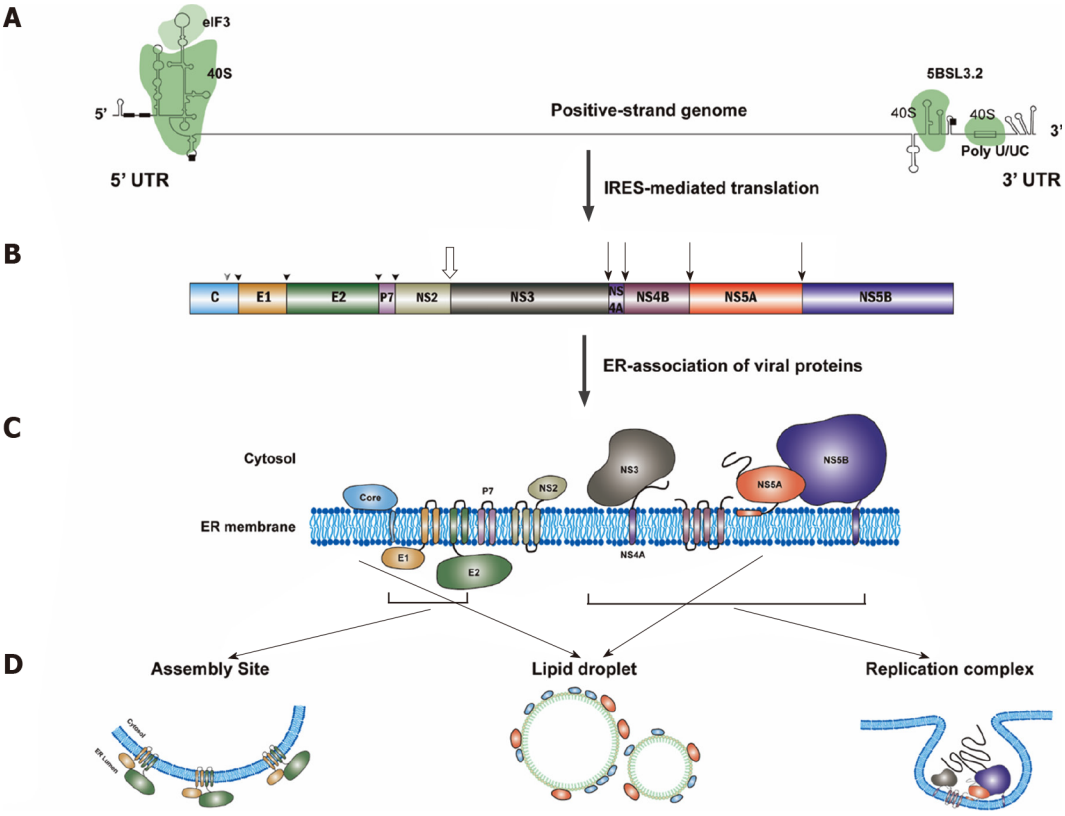

Figure 3 Hepatitis C virus protein translation. A: Translation of hepatitis C virus (HCV) genomic RNA is regulated by the internal ribosome entry site in the 5'-untranslated region (5'UTR) along with a short segment of the core gene sequence, the cis-acting replication element in the NS5B coding region and by the entire 3'UTR. Binding sites for eIF3 and 40S were marked. The start and stop codons for protein translation are marked by black squares, while two recognition sites on the 5'UTR for miR122 are marked by black rectangles; B: Polyprotein is co- and post-translationally cleaved by host or viral proteases to yield the structural proteins (core, E1 and E2) and the nonstructural proteins (p7, NS2, NS3, NS4A, NS4B, NS5A and NS5B proteins). Core, E1 and E2 are processed by cellular signal peptidase (filled arrowhead). Mature core protein will be generated after further cleavage by signal peptide peptidase (empty arrowhead)[317]. The NS2/NS3 junction site is cleaved by the NS2–NS3 auto-protease[318] (empty arrow), and the remaining nonstructural proteins are processed by the NS3/4A proteinase[319] (filled arrow); C: All of the HCV proteins are associated with endoplasmic reticulum directly or indirectly[320]; D: Then, NS3, NS4A, NS4B, NS5A and NS5B proteins will form the replication complex. Core and NS5A proteins will be transferred to lipid droplets, while E1 and E2 proteins will stay in the assembly sites. IRES: Internal ribosome entry site; 5'UTR: 5'-untranslated region.

Expression of the alternative reading frame/core+1 protein

In addition to the synthesis of HCV polyprotein, another viral protein is produced through the core+1 reading frame (for a review see References[151,152]). Recently, the conserved RNA stem loops (SLs) SL47 and SL87 of the HCV core gene were identified to possess a novel cis-acting element and direct the internal translation initiation of the alternative reading frame (ARF)/core+1[153].

RNA REPLICATION

HCV genomic RNA replication, tightly linked to ER membrane alterations designated the MW[154,155], occurs in the replication organelles (ROs)[156], mainly consisting of double membrane vesicles (DMVs)[157]. The HCV RNA replication requires at least viral genomic RNA and viral RNA-dependent RNA polymerase (NS5B protein) in the ROs. Thus, HCV RNA replication could be modulated by the viral RNA structure (*i.e.*, CREs), viral proteins (particularly, NS5B) and the biogenesis of ROs. Many cellular factors play important roles in the modulation of HCV RNA replication (for a review see References[158,159]).

The CREs of HCV genomic RNA were identified close to the 5'UTR and 3'UTR of the genome[160]. Several cellular proteins could bind to the 5'UTR and the 3'UTR of the viral RNA, facilitate the genome circularization and enhance RNA replication. These proteins include La[161], hnRNP L[162], the NFAR protein complex (NF90, NF45, and RHA)[163], PTB[164], PCBP2[137], and RNA binding protein 24[140]. High-mobility group box 1 interacting with SL 4 of 5'-UTR[165], Src-associated in mitosis 68 kDa protein binding with SL2 of 5'-UTR[166] and HSC70 with poly U/UC in the 3'-

UTR[167] could also promote HCV replication.

In addition to cellular proteins, liver-specific miR122 could bind to the two adjacent sites of HCV 5'UTR[168], forming a ternary complex[169]. Through this interaction, in addition to stimulating translation[128], miR122 could protect the genome from cellular DUSP11 pyrophosphatase activity[170] and subsequent degradation by the exonucleases Xrn1[171,172] and Xrn2[172,173] to facilitate RNA replication. Cellular proteins involved in HCV RNA replication through the regulation of miR122 include DDB1-Cul4 associate factor 1[174], glycogen synthase kinase 3b[175], GTPase Rab27a [176], heterogeneous ribonucleoprotein K (hnRNP K1)[177] and DEAD-box RNA helicase (DDX6)[178]. Interestingly, various miRNAs were found to compensate for the role of miR122 on HCV replication in non-hepatic cells[179].

The HCV nonstructural proteins, NS3 to NS5B, are required for RNA replication, and NS5B constitutes the catalytic core of the HCV replication complex[180,181]. Cellular protein kinase C-related kinase 2 could phosphorylate NS5B to regulate HCV RNA replication[182]. Several cellular factors were identified to enhance HCV RNA replication through interacting with NS5B, including cellular chaperonin TRiC/CCT [183], ribonucleotide reductase M2[184], sphingomyelin[185], HuR[186], VAPB-MSP [187] and CYP4F12[188].

In addition to NS5B, NS5A is also essential to HCV RNA replication. DDX3[189], Y-box binding protein 1[189] and FKBP6[190] could interact with NS5A to facilitate HCV RNA replication. Cellular cyclophilin A (CypA)[191,192] and human replication protein A[193] could bind to NS5A and stimulate the binding of NS5A to NS5B and viral RNA to facilitate HCV RNA replication. Three domains in NS5A protein were identified using biochemical analyses: Domain I (a.a. 1–213), domain II (a.a. 250–342) and domain III (a.a. 356–448) in NS5A[194]. Domain I, with RNA-binding ability, is essential for RNA replication[195], while domain III is required for assembly[196]. A critical ratio between the different phospho-forms of NS5A protein must be maintained for productive HCV RNA replication[197]. Several cellular kinases could phosphorylate HCV NS5A, including casein kinase II (CKII)[198] and CK1a[199], lipid kinase PI4KIIIα[200] and c-Abl tyrosine kinase[201]. These kinases control the switch between virus replication and assembly by phosphorylating NS5A[202]. Vinexin b also regulates HCV replication *via* modulating the phosphorylation status of NS5A in a CK1a-dependent manner[203]. Notably, association of vesicle-associated membrane protein A (VAP-A) with NS5A depends on the phosphorylation status of NS5A[204]: VAP-A binds to hypophosphorylated NS5A and contributes to HCV RNA replication [202]. F-box/LRR-repeat protein 2, when geranylgeranylated, could also interact with NS5A and promote HCV replication[205]. On the other hand, proprotein convertase subtilisin/kexin type 9 interacts with NS5A and inhibits HCV replication, possibly through preventing the dimerization of NS5A[206]. SPRY domain- and SOSC box-containing protein 2 induces NS5A ubiquitination and degradation to suppress HCV replication[207].

Viral NS3 protein is also an important component of HCV replication complex. Rad51[208] and GBF1[209] could interact with NS3 and promote HCV RNA replication.

HCV NS3–NS5B proteins, in collaboration with cellular factors, could induce MW formation. Among these viral proteins, NS5A and NS4B play a major role in the induction of MW[210,211]. Cellular factors could modulate HCV replication through affecting MW biogenesis. For example, CypA plays a role in the formation of DMVs through interacting with NS5A, in addition to its role in facilitating HCV RNA replication[212]. Similarly, receptor for activated protein C kinase 1 and ATG14L were found to participate in the DMV formation through interacting NS5A[213].

Proline–serine–threonine phosphatase interacting protein 2, a protein with membrane-deforming activity, is critical for MW formation through directly interacting with NS4B and NS5A[214]. Cytosolic phospholipase A2 gamma group IVC (PLA2G4C) is also required in the biogenesis of the MW. PLA2G4C expression was upregulated after HCV infection, contributing to HCV replication and assembly through interacting with NS5A and NS4B[215].

The cellular protein Surf4, maintaining ER-Golgi intermediate compartments and the Golgi compartment, was recruited into ROs by NS4B and was involved in the formation of DMVs[216]. Another cellular protein prolactin regulatory element binding could promote HCV RNA replication by interacting with NS4B and participating in the formation of DMVs[217].

HCV replication also depends on the GBF1-Arf1-COPI complex[218,219] and phosphatidic acid phosphatase lipin1[220], possibly due to their involvement in the MW biogenesis. Sphingomyelin and ceramide transfer protein (CERT), which is in the sphingomyelin biosynthesis pathway, are also essential for the biosynthesis of DMVs

[221].

Several Rabs (the Ras superfamily of small GTPases) are involved in the formation of HCV RNA replication machinery: (1) Rab5 can be recruited by NS4B and involved in HCV genome replication[222]; (2) Rab5 and 7 co-localize with NS4B and Rab2, 5 and 7 are required for HCV RNA replication[223]; (3) Rab1b and its negative regulator TBC1D20 are involved in the HCV replication[224,225]; and (4) Rab18, through associating with NS5A directly, is believed to promote the physical interaction between LDs and Ros[226].

Proteins in the nuclear transport machinery [including soluble nuclear transport factors, *e.g.*, karyopherins (Kaps)] and nucleoporins (Nups) in the nuclear pore complexes are involved in the HCV life cycle[227,228]. Interaction of various HCV proteins with Nups and Kaps could potentially alter host cell nucleocytoplasmic transport to facilitate HCV replication[229].

Several studies have demonstrated that autophagy plays an early role in establishing HCV re-plication[230,231]. Indeed, DMVs induced by HCV accumulate at the MW and morphologically resemble autophagosomes[232]. Thus, autophagy may help to induce the MW formation during HCV replication[233]. However, the role of autophagy in HCV replication is still a matter of controversy[234] (for a review see Reference[235]).

To shape an ER membrane into an RO requires not only viral and cellular proteins but also lipid synthesis (for a review see Refenence[236]). Many studies have shown that HCV could modulate lipid metabolism (*e.g.*, cholesterol and fatty acid biosynthesis) to promote viral replication[237-239]. Furthermore, to achieve robust HCV replication, it is necessary to limit the oxidative degradation of lipids[240]. Sphingolipid is also required for HCV replication and might contribute to detergent resistance of HCV replication sites[241]. Modulation of the lipid environment of RO by HCV includes the recruitment and activation of the lipid kinase PI4KIIIα by NS5A and NS5B proteins to generate enhanced levels of phosphatidylinositol 4-phosphate (PI4P) at the RO[200]. PI4P could attract lipid transport proteins [oxysterolbinding protein (OSBP), four-phosphate adaptor protein 2 and CERT)] to deliver glycosphingolipids, cholesterol and ceramide respectively to the RO[242,243]. OSBP and CERT could interact with the human VAP residing in the ER[244]. Both VAP-A and VAP-B, enriched in purified DMVs[245], interact with NS5A and NS5B and assist in the formation of the replicase complex[204,245]. Two types of lncRNAs, lin-IGF2-AS and lnc-7SK, are involved in HCV replication through regulating PI4P[246]. Recently, HCV NS3/4A protease was reported to control the activity of 24-dehydrocholesterol reductase, catalyzing the conversion of desmosterol to cholesterol, to regulate the lipid environment for HCV RNA replication[247].

FUSE binding protein 1 is reported to be an essential cellular factor required for HCV replication through inhibiting the function of tumor suppressor p53[248]. Several other cellular factors were involved in the HCV RNA replication, mTORC1[249] and chloride channel[250], but their exact roles are not yet defined.

VIRAL ASSEMBLY AND RELEASE

Assembly of HCV particles requires a viral genomic RNA, core proteins (for the capsid formation) and the viral envelope glycoproteins (E1 and E2). In addition to these viral factors, other viral nonstructural proteins and cellular factors, especially VLDL synthesis and secretion, are essential for the HCV assembly (for a review see Reference [251]).

Cleavage at the HCV core protein C-terminus by the intramembrane signal peptide peptidase is required for its maturation and targeting to LDs[252]. The mature core protein, forming the viral capsid, comprises two domains: The amino-terminal domain (D1; a.a. 1–118) and a central domain (D2; a.a. 119–177)[253]. D1 harbors basic aa residues that interact with viral RNA[254], while D2 is hydrophobic and associated with LDs[252]. LDs are important for the production of infectious HCV particles[255]. As expected, a reduction in the volume of LDs by the suppression of HSC70 expression[23] or disruption of LDs by the inhibitor of aryl hydrocarbon (AhR)[256] would inhibit HCV production. Thus, ADP-ribosylation factor-related protein 1 essential for LD growth is required for HCV propagation[257], while N-Myc Downstream-Regulated Gene 1 restricts HCV assembly by limiting LD formation[258].

Several cellular factors are involved in the association of the core with LDs. Diacylglycerol acyltransferase-1 (DGAT1) interacts with both the core and NS5A proteins and is required for the trafficking of these two proteins to LDs[259]. PLA2G4A also

plays a role in recruiting core to LDs, and its specific cleavage of lipids containing arachidonic acid is essential for the production of infectious viral particles[260]. Interaction of core and Nup98 in LDs is important for HCV propagation[22], while heterogeneous nuclear ribonucleoprotein K is recruited to sites in close proximity to LDs and suppress HCV production[261].

HCV genomic RNAs synthesized by the HCV replication complex (NS3–NS5B proteins) in the DMVs will be transferred by NS5A and NS3-4A proteins and encapsidated by the viral capsid to form the nucleocapsid. The HCV RNA structure [262] responsible for its encapsidation by core proteins has been suggested to be (1) a highly conserved secondary structure within the core D2 region[263]; (2) the conserved apical motifs of the 3'X region[264]; or (3) multiple RNA motifs with a secondary structure[265].

Lipid mobilization from cytoplasmic LDs favors the morphogenesis and secretion of HCV particles[266,267]. HCV infection suppresses the cellular lysophosphatidylcholine acyltransferase 1 expression resulting in altered lipid metabolism and, in turn, increases the production of infectious viral particles with low density[267]. α/β hydrolase domain-containing protein 5/CGI-58[266] and ATGL lipase[268] also mobilize lipids in LDs for the production of HCV particles.

PLA2G4C[215] and AAM-B[269] recruit the NS4B protein to LDs. Thus, these two proteins may bridge the steps of HCV RNA replication and assembly by translocation of RCs to LDs. In addition to DGAT1, CD2AP also participates in the transfer of NS5A to LDs[270]. Interactions between NS5A and core proteins are crucial for productive HCV infection[271]. Protein kinase C and CK substrate in neurons protein 2[272] and cortactin[273] promote interactions between HCV core and NS5A in the LDs. HCV NS5A protein domain I interacts with the D1 region of core protein[274]. Indeed, core and NS5A proteins are found associated with LDs at 12 h post-infection[275]. The LDs associated with core and NS5A proteins are close to the DMVs and the assembly sites on the ER membrane (Figure 4). Several studies suggested that the NS5A protein might link DMVs with assembly sites. Two LD-associated proteins, Rab18[226] and TIP47[276,277], were found to interact with NS5A and might help the juxtaposition of replication and assembly sites.

Formation of HCV nucleocapsid may occur in the LDs and/or assembly sites (Figure 4). Then, HCV nucleocapsid will move to the assembly sites and interact with viral E1/E2 proteins (envelopment) and bud into the ER lumen (egress) (Figure 4). All viral proteins are involved in HCV assembly[278,279]. The core and E1/E2 proteins are the integral protein components of an HCV particle. The other viral proteins do help viral assembly and egress, especially NS5A, p7, and NS2[278-281]. NS2, ubiquitinated by MARCH8[282], is a key regulator of viral assembly by bringing together the structural and nonstructural proteins required for particle formation. The cellular signal peptidase complex subunit 1 interacts with both NS2 and E2 proteins and mediates membrane association of the NS2–E2 complex to control HCV assembly [283]. Then, PLA1A plays a role in bridging NS2–E2 complex and NS5A-associated replication complex through its interaction with E2, NS2 and NS5A[284,285]. It is likely that NS2 protein brings E1, E2, NS3, NS5A and core proteins together to form a complex within the detergent-resistant membranes in the ER as an assembly platform to initiate HCV assembly[286]. Meanwhile, the clathrin Adaptor Related Protein Complex 2 Subunit Mu 1[287] and a small GTPase, Rab32[288], may transfer nucleocapsids to the sites of envelopment. HRS (hepatocyte growth factor-regulated tyrosine kinase substrate), an endosomal-sorting complex required for transport (ESCRT)-0 complex component, is involved in the viral envelopment[289].

HCV assembly and envelopment are linked to the VLDL synthesis and secretion [290]. Indeed, CIDEB, an important regulator of the VLDL pathway, contributes to the HCV assembly through interacting with NS5A[291]. However, inhibitors of microsomal triglyceride transfer protein (MTTP) affect secretion of HCV more severely than that of VLDL[292]. HCV is also reported to modify VLDL secretion[293,294]. These results suggest that HCV assembly occurs possibly through modification of the VLDL secretion. Indeed, colocalization of the core with Apo-E but not with Apo-B was demonstrated[295]. Therefore, it is more likely that HCV suppresses VLDL secretion and then uses the excess lipid to produce lipid-rich viral particles. Components of VLDL synthesis, such as MTTP[290], Apo-B[296] and especially Apo-E[10], have been implicated in HCV assembly. HCV production in HuH7 cells with double knockout of Apo-B/Apo-E was reduced significantly compared to that of single knockout cells, and ectopic expression of Apo-E in cells with double knockout of Apo-B/Apo-E restored production of infectious viruses. Furthermore, ectopic expression of Apo-E or MTTP in cells with double knockout of Apo-B/MTTP could restore infectious virus production[297]. These studies suggested that there are Apo-B-dependent and -

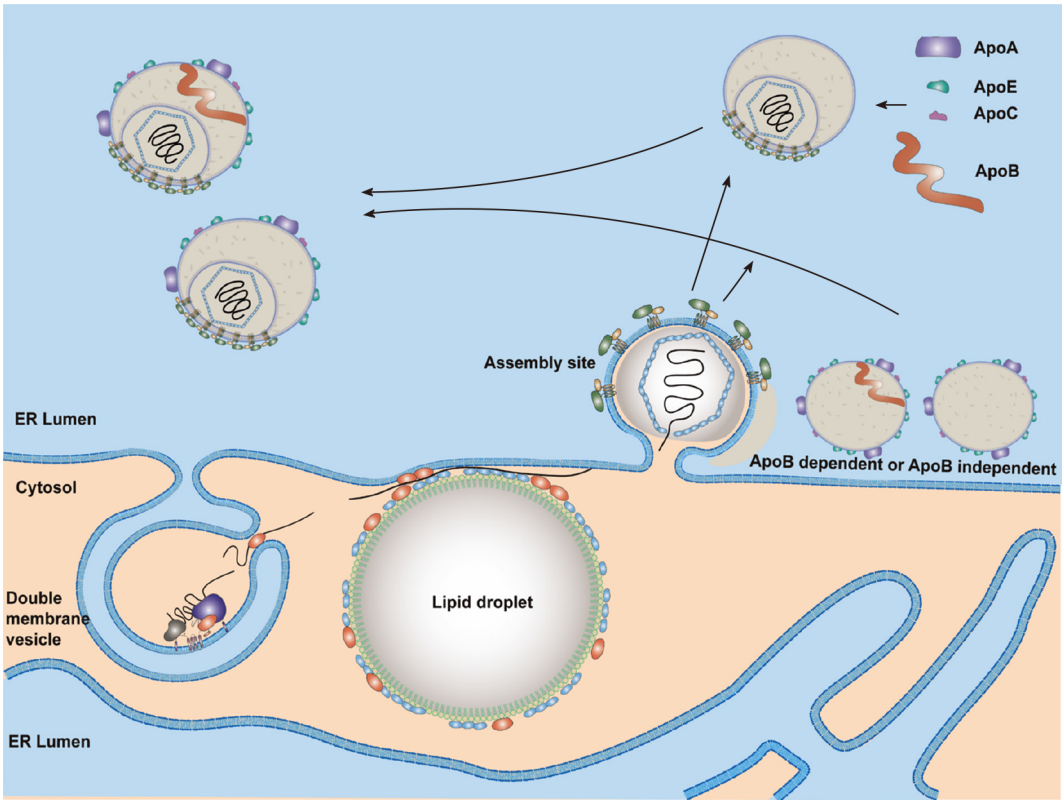

Figure 4 A proposed model for hepatitis C virus assembly. Lipid droplets (LDs) are surrounded by endoplasmic reticulum (ER)[321]. LDs with a hepatitis C virus (HCV) core and NS5A proteins are close to replication sites [double membrane vesicle (DMV)] and assembly sites. HCV genomic RNA synthesized by the replication complex (NS3–NS5B proteins) in the DMVs will be transferred by NS5A and NS3-4A proteins and encapsidated by the core proteins to form the nucleocapsid. Then, the HCV nucleocapsid will interact with glycoproteins E1/E2 in the assembly sites and bud into the ER lumen. Both Apo-B-dependent and -independent mechanisms are possibly involved in HCV particle assembly. One model shows the production of a fused form of HCV with very-low-density lipoproteins. Another model shows the budding of HCV particles with several apolipoproteins but not Apo-B. Nascent viral particles may be further lipidated by luminal lipoproteins and incorporated with exchangeable apolipoproteins. ER: Endoplasmic reticulum.

independent virus assembly pathways (Figure 4). Similar to the effect of ectopic expression of Apo-E in Apo-B/Apo-E double knockout cells, expression of exchangeable apolipoproteins (*e.g.*, Apo-A1, A2, C1, C2 and C3), the peptides of amphipathic α-helices containing the amino-terminal domain of Apo-E[297] or even human cathelicidin antimicrobial peptide[298] also restored infectious virus production. These results suggest that infectious virus production is regulated redundantly by exchangeable apolipoproteins expressed in the liver. Annexin A3 (ANXA3) through facilitating the incorporation of Apo-E[299] and Golgi protein 73, a resident Golgi membrane protein, through facilitating the interaction of HCV NS5A with Apo-E[300], promote HCV virion maturation. Recently, Apo-M, interacting with E2, was reported to be a novel virus particle-associated protein[301].

After envelopment, HCV particles then traffic to Golgi likely within COPII secretory vesicles[295,302]. Secretion of infectious HCV particles relies in part on components of the ESCRT pathway[303]. HCV egress but not VLDL secretion is blocked by silencing Rabs and the transGolgi network (TGN)-associating adaptors[304]. Moreover, inhibition of Apo-E secretion using monensin does not impair HCV release. These results suggested that HCV and VLDL use distinct secretion pathways[305]. Altogether, these results suggest that the release of HCV particles occur *via* a TGN-endosomal secretion pathway that is different from that of VLDL. The lipid-associated TM6SF2 (transmembrane 6 superfamily 2) has been demonstrated to promote lipidation and secretion of HCV particles[306]. The secreted HCV particle is likely a single particle fusion of viral structural proteins with various apolipoproteins and lipids (Figure 1).

Autophagy triggered by HCV-induced oxidative stress favors the release of HCV particles[307]. Thus, autophagy may play a role not only in the induction of DMVs but also in the secretion of HCV particles (for a review see Reference[235]).

HCV particles from the sera of HCV-infected patients harbor higher amounts of Apo-E than those derived from cell culture[308]. The interaction of Apo-E and HCV enhances specific infectivity and may aid HCV in evading neutralizing antibodies

[309]. HCV particles from the blood of HCV-infected patients contain Apo-B100 or Apo-B48, indicating that a significant fraction of HCV particles in blood is also associated with Apo-B48-containing lipoproteins[310]. These results suggested that the interactions between HCV particles and lipoproteins (*e.g.*, Apo-E and Apo-B48) in the blood of HCV patients (Figure 1B). Besides lipoproteins, specific serum factors, including albumin, also promote extracellular maturation of HCV particles[311].

Several cellular factors were involved in the assembly and secretion of HCV particles, such as ANXA2[312], sorcin (soluble resistance-related calcium-binding protein)[313], AP-1A, AP-1B, AP-4[101] and O-linked N-acetylglucosamine transferase [314], but their exact roles are not yet defined.

CONCLUSION

Study on the life cycle of the HCV has progressed tremendously after the development of *in vitro* HCV culture systems[315]. Understanding the HCV replication cycle led to the huge success of direct-acting anti-virals (DAAs) targeting NS3, NS5A, and NS5B. Hundreds of cellular factors involved in various stages of the HCV's life cycle have also been identified after more than 30 years of research on HCV–host cell interactions. Some of these cellular factors have been selected as targets for anti-HCV therapy (*e.g.*, SR-B1, EGFR, NPC1L1, miR122, CypA)[7]. Inhibitors against these cellular factors may complement existing DAAs. A successful vaccine for HCV is still a challenge in the near future. Understanding the mechanisms of viral entry, especially E2–CD81 interactions, should help in the development of a vaccine.

HCV particle, a hybrid lipo-viro-particle, does not look like a canonical enveloped virus. Thus, HCV has become a unique model for studying virus–host interactions, *e.g.*, between HCV and cellular lipid metabolisms. Furthermore, all positive-strand RNA viruses, including coronaviruses and picornaviruses, induce the reorganization of cellular membranes to replicate their genomes, similar to HCV[316]. Using HCV as a paradigm to study how HCV induces cellular membrane re-organization may lead to identification of broad-spectrum antivirals targeting cellular factors commonly used by these viruses.

Despite the impressive advances, many issues are still far from being clarified regarding HCV–host cell interactions. More studies are needed to understand the detailed mechanisms.

Abstract

In solid tumors, the development of vasculature is, to some extent, slower than the proliferation of the different types of cells that form the tissue, both cancer and stroma cells. As a consequence, the oxygen availability is compromised and the tissue evolves toward a condition of hypoxia. The presence of hypoxia is variable depending on where the cells are localized, being less extreme at the periphery of the tumor and more severe in areas located deep within the tumor mass. Surprisingly, the cells do not die. Intracellular pathways that are critical for cell fate such as endoplasmic reticulum stress, apoptosis, autophagy, and others are all involved in cellular responses to the low oxygen availability and are orchestrated by hypoxia-inducible factor. Oxidative stress and inflammation are critical conditions that develop under hypoxia. Together with changes in cellular bioenergetics, all contribute to cell survival. Moreover, cell-to-cell interaction is established within the tumor such that cancer cells and the microenvironment maintain a bidirectional communication. Additionally, the release of extracellular vesicles, or exosomes, represents short and long loops that can convey important information regarding invasion and metastasis. As a result, the tumor grows and its malignancy increases. Currently, one of the most lethal tumors is pancreatic cancer. This paper reviews the most recent advances in the knowledge of how cells grow in a pancreatic tumor by adapting to hypoxia. Unmasking the physiological processes that help the tumor increase its size and their regulation will be of major relevance for the treatment of this deadly tumor.

Core Tip: Pancreatic ductal adenocarcinoma is characterized by high aggressiveness, therapeutic resistance, and mortality. The cells included in the mass, both tumor and those forming the stroma, have a high proliferative rate that leads to the rapid growth of the tumor. Because of this, the distribution of blood vessels is insufficient to supply oxygen to the cells, and hypoxia is a consequence. Cells escape from death and adapt by undergoing critical changes in intracellular pathways involved in energy supply, proliferation, and cell-to-cell communication.

INTRODUCTION

World Health Organization estimates that about 465.000 people died from pancreatic cancer (PC) in 2020, which was the seventh leading cause of cancer deaths[1]. Various studies point toward recent increases in the incidence of PC and in the number of PC-related deaths[2,3]. The causes of high mortality are late diagnosis and few and ineffective therapeutic strategies. Of the various types of PC, pancreatic ductal adenocarcinoma (PDAC) accounts for 90% of the diagnoses[4].

Tumors conditions include the development of hypoxic areas of varying extent, in which the growing cell population is subjected to low O_2 availability[5]. This condition derives from the high rate of cell proliferation and the rapid growth of the tumor mass, which is accompanied by an abnormal distribution of blood vessels that limits blood flow and, hence the O_2 supply[6]. An ongoing hypoxic state has been well documented in PC. The average of O_2 level in the healthy pancreas is 6.8%, whereas in PC it is 0.4%. This 17-fold decrease in O_2 availability is high compared with other tumors[7]. Extensive fibrosis and hypovascularization are characteristic of PDAC, and lead to significant tissue hypoxia and the aggressiveness, therapeutic resistance, and high mortality that are characteristic of this type of cancer[8].

Not less important, the stroma that forms part of the tumor mass contributes to the creation of a tumor microenvironment that contributes to conditions that determine tumor growth, invasion, and metastasis[9]. The tumor microenvironment is composed of structural elements, which include extracellular matrix proteins and cells, such as macrophages, endothelial cells, fibroblasts, and stellate cells[9,10]. Pancreatic stellate cells (PSC) interact closely with cancer cells and set up a close relationship that favors tumor growth[11]. Additionally, PSC are considered major contributors to the fibrosis that forms part the stroma[12]. Increased hypoxia promotes collagen deposition and tumor progression, *i.e.* hypoxia contributes to the development of fibrosis in PC and in other types of tumors[13]. Hypoxia promotes PSC activation, increased proliferation, and invasiveness, confirming their participation in the formation of fibrotic tissue[14].

Hypoxia-inducible factor (HIF) plays a pivotal role in the development of cellular responses to hypoxia[15]. Usually, this factor promotes or represses the transcription of many of genes that are involved in cellular homeostasis. HIF is degraded, and hence is nonfunctional when O_2 is available to the cells, but becomes active under specific conditions, including low-O_2 (hypoxic) stress. The genes targeted by HIF allow cells to adapt to hypoxic conditions and survive. The genes involved code for vascular endothelial growth factor (VEGF), erythropoietin, and glucose transporter-1[16]. In order to adapt to O_2 deprivation, energy metabolism switches to glycolysis[17]. Concomitantly, regulation of the transcription of certain metabolic enzymes, including pyruvate dehydrogenase kinase 1, lactate dehydrogenase A, glycogen phosphorylase L, and others occur. The result is the improvement of adenosine triphosphate (ATP) production at the expense of increases of glucose uptake, glycolysis, and generation of lactate[18].

Several isoforms of HIF have been identified. HIF-1α and HIF-2α are closely related, and HIF-1α is the first isoform that was described. Both activate the transcription of genes associated with hypoxia. HIF-3α is more distantly related. Current evidence indicates that HIF-1α, and not HIF-2α, is active in regulating the transcription of genes that encode the enzymes that coordinate the activation of cellular pathways related to

ATP support[19]. HIF-1 is a major activator of pathways that play crucial roles in tumor development by upregulating pivotal genes. The genes thereafter regulate energy metabolism, angiogenesis, survival, invasion, metastasis, and drug resistance of cancer cells[20]. The HIF-1α subunit is regulated by O_2-dependent hydroxylation, ubiquitination, and degradation. In general, it is accepted that HIF signaling is activated in all types of cancer, including PC. Its activation will provide the tumor cells with tools to support survival. Therefore, HIF has been described as a key molecular target for cancer therapy. therapy[5,21]. To cite some examples, Xiao *et al*[22] showed that silencing the expression of HIF-1 diminished the invasiveness of Panc-1 and MiaPaca-2 cells. The enzyme prolyl hydroxylase domain 3 (PHD3) regulates the degradation of HIF and is the rate-limiting in that process. PHD3 is deregulated in PC cells. It has been shown that HIF-1α expression was suppressed in MiaPaca2 PC cells that overexpressed PHD3, which inhibited cell growth and colony formation under hypoxic conditions[19,23]. Another study showed that PHD3 expression regulated the secretion of VEGF evoked by hypoxia and inhibited tumor growth *in vivo* by abrogation of angiogenesis[24].

Along with cancer cells, the fibrotic tissue also undergoes adaptation to hypoxia by terms of HIF signaling. HIF-1α expression was found in the stroma adjacent to the PDAC cells[25]. HIF-1 and HIF-2 were expressed in cultured PSC subjected to hypoxia [14]. HIF-1 expression induced changes in PSC that promoted invasion and epithelial-mesenchymal transition and inhibited death of PC cells[22]. HIF-1α induced secretion of collagen in PSC. Accumulation of collagen together with other extracellular matrix components promotes fibrotic stroma formation[26]. Another study showed that HIF-1 α promoted the activation of PSC through recruitment of macrophages in PDAC[27].

The growth of fibroblasts was accelerated by the release of sonic hedgehog protein (SHH) in PC cells that were subjected to hypoxia, and that situation contributed to increased deposition of fibrous tissue[28]. PC stromal fibroblasts subjected to hypoxia were found to be associated with aggressive invasion and liver metastasis and increased processing and release of hepatocyte growth factor activator[29]. Moreover, fibroblasts have been found to contribute to vascular remodeling under hypoxia by influencing VEGF expression[30]. Figure 1 is a depiction of all the cell types that can be included in tumor tissue. Depending on their location in the mass, all cells are subjected to hypoxia to different extents.

OXIDATIVE STRESS AND ANTIOXIDANT RESPONSE UNDER HYPOXIA IN PC

Cancer cells have high proliferation rates, altered metabolism, and increased oxidative stress. The generation of reactive oxygen species (ROS) leads to genomic instability and the impairment of gene expression that underly cancer development[31]. ROS are produced in the mitochondria[32] and production is increased in tumor cells[6]. In healthy cells, uncontrolled overproduction of ROS is usually accompanied by cell death[33]. However, that does not necessarily happen in tumor cells, which can adapt to survive. Local expression of renin-angiotensin system has been signaled to play an important role in the regulation of blood pressure and fluid homeostasis in the pancreas[34]. Interestingly, hypoxia could upregulate the mentioned system that could then contribute to the modulation of local blood flow in a growing tumor and help the tissue to manage oxidative stress. Along this line, angiogenesis is a process that attempts to counter the lack of nutrients and oxygen shortage that develops in tumors [35]. However, in spite of the development of new microvasculature, vascular access is still poor and O_2 supply is compromised in the majority of tumors[36]. In PDAC for example, a low microvessel density and collapsed vasculature are observed[37].

To adapt to the adverse pro-oxidative conditions derived from uncontrolled cell proliferation and a limited blood supply, cancer cells increase their antioxidant defenses[38]. The redox signaling protein apurinic/apyrimidinic endonuclease 1/Redox effector factor 1 (APE1/Ref-1) modulates the redox activity of PC cells and is involved in cell proliferation and migration through the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and HIF-1 pathways[39]. The transcription factor nuclear factor erythroid-related factor 2 (Nrf2) regulates a wide range of cytoprotective genes in response to oxidative stress and various stressors present in the extracellular environment. The glutathione system is key among the antioxidant systems that are regulated by this transcription factor[40]. Chronic hypoxia is known to increase glutathione-dependent antioxidant capacity, which avoids damage to the cell membrane because of concomitant oxidative stress[41]. Indeed, glutathione

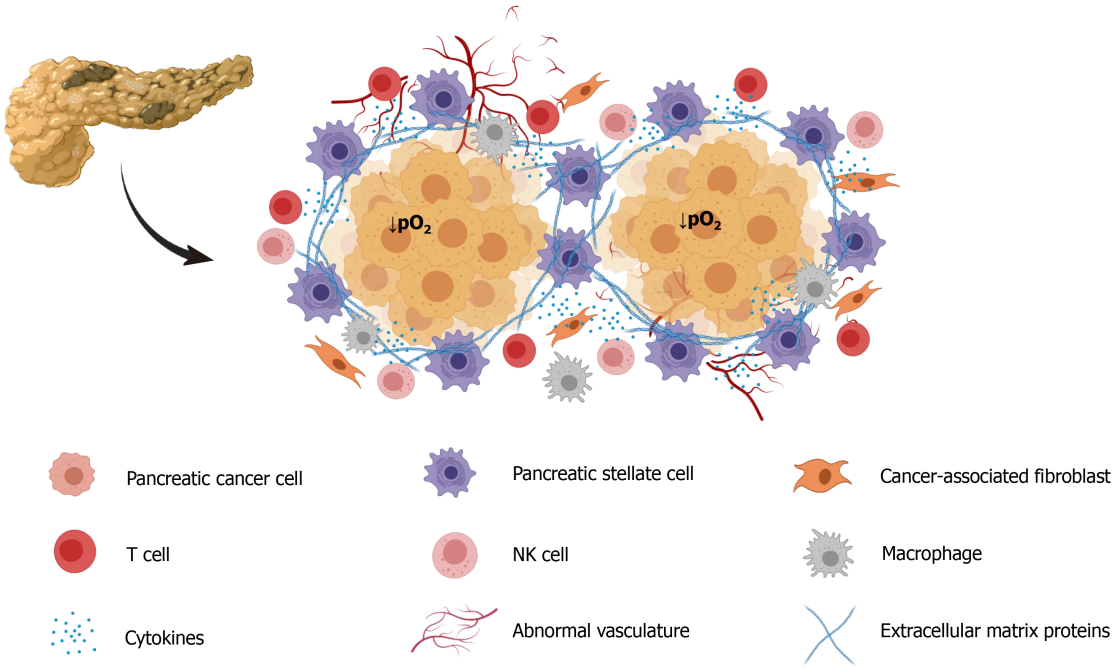

Figure 1 Illustration of the cells that form tumor tissue. Both tumor cells and the stroma contribute to the formation of tumor tissue. The latter comprises fibroblasts, stellate cells, immune cells, secreted components such as cytokines or extracellular matrix proteins, and the vasculature. Depending on their location in the mass, all cells are subjected to hypoxia to differing extents. Created with BioRender.com.

peroxidase maintains redox homeostasis in Panc1 cells, a pancreatic tumor cell line [42]. Heme oxygenase-1, an antioxidant enzyme regulated by Nrf2, has been shown to provide a survival advantage to PDAC cells subjected to hypoxia, and its inhibition induced an increase of the production of ROS and increased cell death[43]. Superoxide dismutases (SODs) are antioxidant enzymes that protect cells against ROS. The family consists of three isoforms, cytoplasmic Cu/ZnSOD (SOD1), mitochondrial MnSOD (SOD2), and extracellular Cu/ZnSOD (SOD3)[44]. A decrease in the expression of SOD1 has been related to a decrease in the viability of the pancreatic tumor cell lines Panc-1 and MiaPaCa2 cells when they were subjected to hypoxia[45]. SOD2 was shown to protect KP4 human pancreatic carcinoma cells against oxidative stress evoked by hypoxia/reoxygenation. The evidence thus supports the involvement of antioxidant enzymes in PC cell survival[6].

Interestingly, PSC undergo oxidative stress under hypoxia, and increased oxidation of lipids and proteins have been reported in PSC subjected to hypoxia. Moreover, PSC can adapt to hypoxia by increasing their antioxidant defenses by upregulated expression of SOD1 and SOD2 associated with increased phosphorylation of the Nrf2 transcription factor[14]. Figure 2 summarizes the involvement of the pathways involved in hypoxia-evoked antioxidant responses. In general, both the tumor cells and the other cells that grow in the mass adapt to varying extents. The overall success achieved by cellular responses determines the growth of the tumor and the probable concomitant migration, invasion, and metastasis[46].

HYPOXIA AND MITOGEN-ACTIVATED PROTEIN KINASE SIGNALING IN PC

Mitogen-activated protein kinases (MAPKs) comprise a family of proteins that regulate various physiological processes. Among them, cell proliferation, differentiation and survival play major roles in cancer development and progression[47]. Participation of extracellular signal-regulated kinases 1 and 2 (ERK1/2) and c-Jun amino-terminal kinases (JNK) in the growth of PC was demonstrated in KP-1N human pancreatic carcinoma cells that had been incubated with the secretagogue cholecystokinin[48]. Glucose deprivation, which was used to mimic hypoxia, induced the activation of JNK in the PC cells. Inhibition of the kinase led to a decrease of cell sensitivity to glucose deprivation-induced apoptosis[49]. JNK was also activated by

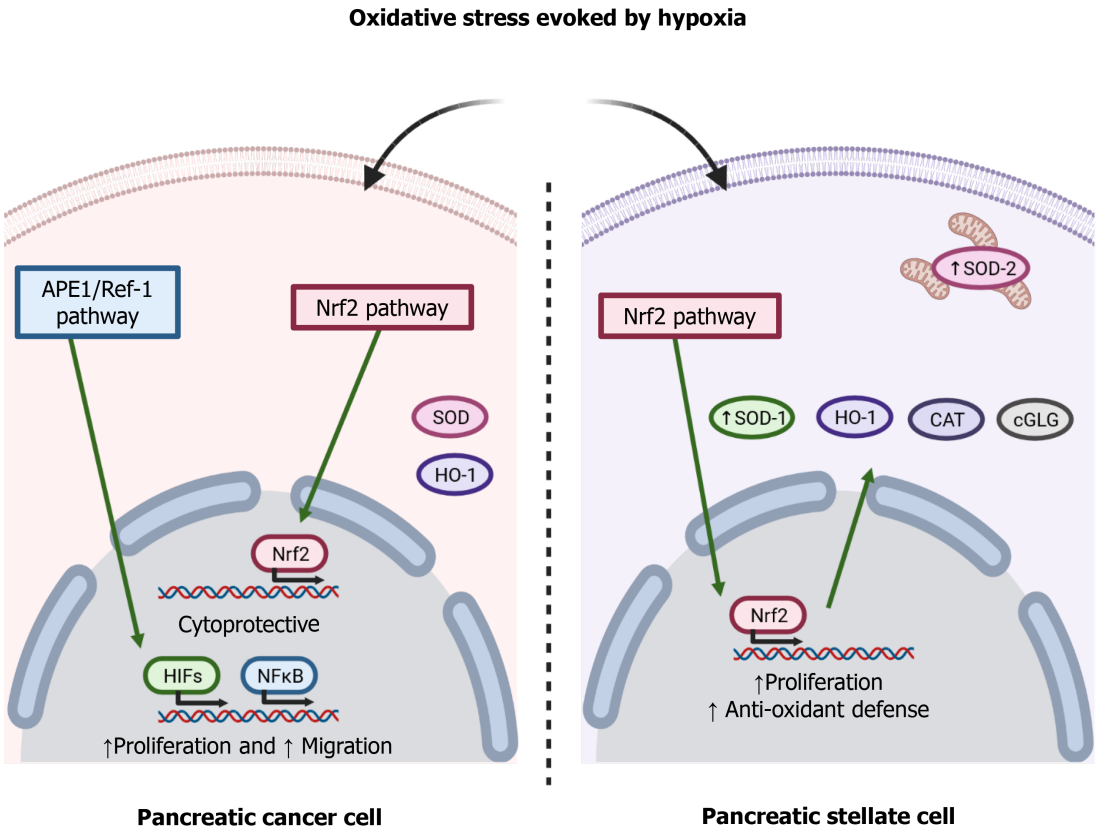

Figure 2 Hypoxia-evoked antioxidant response. In response to the increase in the generation of reactive oxygen species under hypoxia, cells activate intracellular pathways that provide antioxidant protection. Among them, the Nrf2 pathway plays a critical role by coordinating the activation of cytoprotective genes that lead to the expression of major antioxidant enzymes. Created with BioRender.com. APE1/Ref-1: AP endonuclease1/Redox effector factor 1; HIFs: Hypoxia-inducible factors; NF-B: Nuclear factor kappa-light-chain-enhancer of activated B cells; Nrf2: Nuclear factor erythroid-related factor 2; SOD: Superoxide dismutases.

interferon-induced protein with tetratricopeptide repeats 3, a group of genes that are stimulated by interferon and upregulated in aggressive PC cells[50]. Pro-survival and proliferation pathways regulated by ERK1/2 have been reported in Panc-1 cells[51]. In Capan-2 cells, another human PC cell line, hypoxia upregulated ERK1/2 and activated HIF-1α, which conferred chemoresistance of cells to gemcitabine[52]. On the contrary, a decrease in the phosphorylation of ERK1/2 was accompanied by a drop in the proliferation of L3.6pl human PC cells[53]. ERK1/2 were also involved in the malignant transformation and development of PDAC under hypoxia; and as has been shown in other pancreatic tumor cell lines, implication of HIF-1α expression was also reported [54].

Involvement of p38 MAPK in the modulation of cancer cell survival has also been shown. Its inhibition protected of MiaPaCa2 cells from death in response to 15-deoxy-delta-prostaglandin J2[55]. Conversely, p38 was activated in MiaPaCa2 cells subjected to simulated ischemia, and led to activation of HIF-1α[56]. Moreover, inhibition of p38 in MiaPaCa2 cells subjected to hypoxia-induced sensitization of cells to 2-deoxy-glucose and D-allose and decreased their viability. Involvement of HIF-1α was probably responsible for the antiproliferative activity because the inhibitor decreased HIF-1α protein accumulation and transcriptional activity[57]. Participation of MAPKs in the development of stromal tissue in cancer has also been proposed[58,59]. In a recent study it has been shown that PSC subjected to hypoxia exhibited an increase in the phosphorylation of JNK, whereas that of p44/42 and p38 was decreased. PSC survival under hypoxia was dependent on JNK activation because incubation of cells with the specific inhibitor SP600125 decreased cell viability[14]. Another member of the MAPK family, extracellular-signal-regulated kinase 5 (ERK5), is required for the prevention of apoptosis, regulation of hypoxia, tumor angiogenesis, and cell migration [60]. Inhibition of ERK5 diminished proliferation and migration of HepG2 and Huh-7 human hepatocellular carcinoma cells[61]. Implication of ERK5 in other types of cancer, including renal cancer[62], prostate cancer[63], and leukemia[64] has also been reported.

The ERK-5 inhibitor XMD8-92 inhibited pancreatic tumor growth *via* downregulation of doublecortin-like kinase 1 and several of its downstream targets that are involved in oncogenic pathways, including c-Myc, KRAS, NOTCH1, ZEB1, ZEB2, SNAIL, SLUG, OCT4, SOX2, NANOG, KLF4, LIN28, VEGFR1, and VEGFR2)[65]. Inhibition of p44/42 and ERK5 synergistically caused loss of Myc protein, which is a key transcriptional factor with a key role in cell growth, differentiation, and tumor development. Inhibition of both MAPKs suppressed PDAC growth[66]. However, additional studies on the participation of ERK5 in the development of PC are currently lacking.

To our knowledge, little is known about the involvement of MAPK signaling in PC under hypoxia because of a lack of published studies. The available evidence indicates that differential inhibition of protein kinases might be used to attenuate the progression of the disease, but it is not conclusive. Therefore, additional research should be conducted in to unravel how this important signaling pathway is affected by hypoxia and to elucidate whether the targeting of MAPKs could be used in cancer therapy. The putative involvement of MAPK signaling under hypoxia is summarized in Figure 3.

HYPOXIA AND APOPTOSIS IN PC

Apoptosis is a regulated cellular process that occurs both in physiological and pathological conditions. It is designed to control the cell population within a tissue or organ[67]. The pathways involved in apoptosis can undergo defects that might lead to the transformation of damaged cells. This commonly occurs in cancer and has been reported as responsible for development, growth, metastasis, and chemoresistance in different types of tumors[68]. Bcl-2 is a major protein in the apoptosis pathway. It is considered a gene that suppresses the pathway in the sense that overexpression of Bcl-2 blocks or delays the onset of apoptosis in cancer cells[69]; conversely, inhibition of Bcl-2 may lead cell death in some cancers that are resistant to apoptosis, for example breast cancer and PC[70]. Hypoxia has been associated with treatment resistance in various cancers, and apoptosis is among several signaling pathways that are thought to be involved. Many studies conducted in different cellular models of tumors have reported that the antitumor, and hence beneficial, effects of a variety of drugs depend on their ability to activate apoptosis[71]. However, few studies have focused on how the pathways that control apoptosis are modulated by hypoxia.

Cells with constitutive expression of HIF-1α have been shown to be more resistant to apoptosis than those without constitutive expression of the transcription factor, and the lack of expression was associated with increased *in vivo* tumorigenicity[72]. The expression of a regulator of hypoxia-induced cell death, Bcl-2/adenovirus E1B 19 kDa interacting protein 3 (BNIP3), was downregulated in PC cells and was associated with adaptation of the tissue to hypoxia and tumor resistance. Restoration of BNIP3 expression increased cell sensitivity to death[73]. Decreased expression of thioredoxin 1 has been reported in human PC tissues and was associated with decreased apoptosis and increased cell survival. The induction of thioredoxin-interacting protein, a tumor suppressor gene, resulted in increased apoptosis of Panc-1 cells even in cells with activation of HIF-1α[74].

In a mouse pancreas endocrine tumor model, it was shown that increased invasion into surrounding exocrine tissue was associated with decreased the expression of caspase-3, and occurred in areas were high levels of HIF-1α were noted[75]. In a related study, cleaved caspase-3 staining was increased in viable tumor tissue of hypoxic models. That was considered as indicating a remodeling process of the growing tissue by a counterbalanced cell loss by apoptosis in response to rapid cell proliferation[76]. Another study showed that MiaPaca2 cells exhibited increased levels of caspase-3 when cells were transfected with HIF-1α siRNA. That resulted in a decrease of cell proliferation and in an increase of chemosensitivity[77]. Overexpression of HIF evoked the expression of hypoxia-induced gene domain family-1a (Higd-1a), a mitochondrial inner membrane protein. The gene expression was believed to promote cell survival under hypoxia, because apoptosis was decreased. The antiapoptotic effect of the genes resulted from the inhibition of cytochrome C release and from the reduction of caspase activity[78]. Another study showed that hypoxia and serum-free media, which were used to mimic tumor hypoxic-ischemic microenvironment, reduced apoptosis and stimulated proliferation of MiaPaCa2 cells[79].

With respect to the tumor microenvironment, it is well accepted that it contributes to resistance to cancer therapy and to the evolution of the disease by regulation of

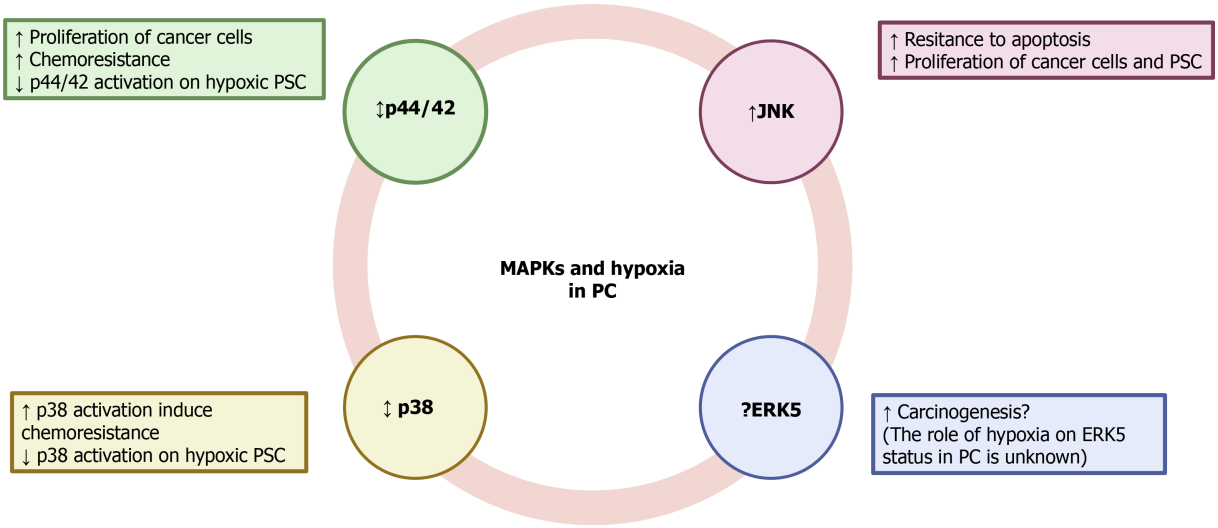

Figure 3 Contribution of mitogen-activated protein kinase signaling to cell responses under hypoxia. Mitogen-activated protein kinases comprise of a family of proteins that regulate physiological processes such as cell proliferation, differentiation, and survival, which play major roles in cancer development and progression. Differential inhibition of protein kinases might be used to attenuate the progression of the disease. Created with BioRender.com. ERK5: Extracellular-signal-regulated kinase 5; JNK: c-Jun amino-terminal kinase; MAPKs: Mitogen-activated protein kinases; PC: Pancreatic cancer; PSC: Pancreatic stellate cells.

apoptosis[80]. Hypoxia has been shown to regulate the viability of PSC through p21-activated kinase 1. The inhibition of this kinase decreased the activation, inhibited proliferation, and increased apoptosis of human PSC[12]. TH-302, a hypoxia-activated prodrug, was assayed in MiaPaCa2 and PANC-1 cell lines, and in BxPC-3 PDAC xenograft models in mice. The compound helped to reduce stromal density and intratumoral hypoxia, and hence, increased the effectiveness of anticancer drugs[81]. The expression of fibulin-5 (Fbln5) is abundant in the stroma of PDAC[82]. This matricellular protein supports PDAC progression by blocking fibronectin-integrin interaction. Compared with normal pancreatic tissue, Fbln5 content was increased in mouse embryonic fibroblasts and 3T3 fibroblasts subjected to hypoxia. This involved transforming growth factor β (TGF-β)- and PI3K-dependent mechanisms, because inhibition blocked hypoxia-induced Fbln5 expression[83]. The balancing of apoptosis pathways could be a maneuver of PC cells to support the growth of tumor tissue[84]. Moreover, the modulation of HIF expression might be a valuable tool to control tumor cell proliferation under hypoxia[85].

AUTOPHAGY AND ADAPTATIONS OF CELLULAR BIOENERGETICS UNDER HYPOXIA IN PC

Autophagy is a metabolic pathway that is used by the cell for degradation of cytoplasmic proteins, macromolecules, and organelles in the lysosomes. It serves as a mechanism for protection of the cell and represents a major survival pathway that is activated in the presence of environmental and cellular stress[86]. However, is relationship to cancer development is contradictory. Both cell survival and cell death have been associated with autophagy because defects or partial reduction in autophagy transmit oncogenic stimulus and have been associated with cancer cell survival[70]. Autophagy is also activated under hypoxia and has been reported as potential contributor to the resistance of various types of cancer to therapy[71].

Inhibition of the pAkt/mTORC1 pathway, one of the critical regulators of autophagy, was observed in PC cells incubated under hypoxia, was found to promote autophagy, and was associated with enhanced cell survival[87]. Autophagy induction in response to hypoxia was detected in the PANC-1, BxPC-3 and AsPC-1 pancreatic cell lines, in which inhibition of AMP-activated protein kinase induced cytotoxicity and enhanced apoptosis. This suggested the involvement of this pathway in cell survival under hypoxia[88]. Serum-free media and hypoxic conditions protected MiaPaCa2 cells against death by stimulating autophagy. In that study, the ratio of LC3-II to LC3-I expression was increased, and treatment with the inhibitor of autophagy 3-MA decreased cell viability[79]. Autophagy was inhibited by chloroquine in MiaPaCa2 and S2VP10 cells that had been subjected to hypoxia, suggesting that the

pathway was responsible for tumor cell survival[89]. Autophagy was also involved in the survival of PDAC cells in spite of the deprivation of nutrients and O_2 that derived from the hypoxic tumor microenvironment[90]. In the aforementioned study, LC3 was converted to the active LC3-II form, formation of autophagic and acid vesicles was detected, and PC cell survival and migration increased. Similarly, intermittent hypoxia increased the levels of HIF-1α. Enhanced autophagy was associated with increases in the levels of LC3-II and Beclin. As a consequence, hypoxia-induced stem-like properties of non-stem PC cells, which influenced tumor development and growth [91]. Analysis of the expression of LC3 in different PC tissue samples revealed strong LC3 expression in the peripheral areas, which was related to poor outcome. It was concluded that activation of autophagy was associated with the responses of cells to factors in the cancer microenvironment, including hypoxia[92].

Changes in metabolism related to mitochondrial and bioenergetics adaptations also occur in response to hypoxia. It has been demonstrated that tumor cells survive and proliferate under hypoxic and glucose-deprived conditions that develop in PCs that are caused by a lack of vasculature that leads to a low blood supply to the growing tissue and to changes in energy metabolism[49]. In the same study 63 genes were identified, whose expression was increased under conditions that mimicked hypoxia. Thus, the expression of certain genes may determine the survival of cancer cells when the blood supply of O_2 is compromised[49]. Mitochondria are the major organelles responsible for supplying energy to the cell in the presence of O_2[93]. It has been suggested that mitochondria undergo changes in dynamics and distribution that are an adaptive response for survival and metastasis[94]. Along this line, PDAC cell lines are able to grow even when O_2 tension is as low as 0.1%. Under such conditions, the cells maintain the mitochondrial parameters and oxidative metabolism needed for the synthesis of metabolites that maintain proliferation[8].

Glycolysis is of major relevance to tumor survival and proliferation because is the main provider of energetic substrates[95]. MUC1 is a large type I transmembrane protein that is overexpressed in several carcinomas including PDAC. It regulates, through interaction with HIF-1α, the expression of genes involved in glucose metabolism and enhances glycolytic activity[96]. Hypoxia has been shown to induce adaptive metabolic responses, such as a high glycolytic rate and activation of the hexosamine biosynthetic pathway, which favor hypoxic and normoxic cancer cell survival[97]. Hypoxic glycolysis, with increases in glucose uptake and lactate production, was found to be governed by ERK2 in PDAC cells and was associated with malignant progression[54]. Phosphoglycerate kinase 1, an enzyme that is involved in the generation of ATP in glycolysis, is involved in the energy supply in PDAC cells *via* Nuclear Factor of Activated T Cells 5[98]. Activation of glycolysis was shown in another study carried out using PDAC cells subjected to hypoxia. The authors showed that carbonic anhydrase 9 (CA9), an enzyme that is involved in the regulation of cellular pH, was upregulated. It functions as a part of the cellular response to hypoxia to promote cell survival. The inhibition of CA9 reduced the cellular pH, decreased glycolysis, and increased cellular sensitivity to gemcitabine[99]. The use of inhibitors of CA9 was also suggested by Logsdon *et al*[100], who showed that inhibition of APE1/Ref-1 decreased HIF1α-mediated induction of CA9 and might reduce PDAC cells viability.

The expression of the enzymes 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase-3 and -4 (PFKFB-3 and PFKFB-4) was increased in different cancer cell lines, including PC, in response to HIF[101]. It is known that those enzymes play a major role in the regulation of glycolysis in cancer cells to support proliferation and survival. Correlation with the enhanced expression of VEGF and glucose transporter-1 (Glut-1) was observed[101]. The M2 isoform of pyruvate kinase (PKM2), a molecule involved in glycolysis, was shown to participate in the metabolic reprogramming of cancer cells and regulated cell cycle progression. Impairment of PKM2 expression decreased cell proliferation and augmented apoptosis and, hence, impaired tumor growth[102]. Another study showed that the activity of aldehyde dehydrogenase 1 was increased in cells subjected to hypoxia and was associated with the induction of colony and spheroid formation[103].

Glucose enters the cell *via* glucose transporters (GLUTs), of which various classes exist[104]. Targeting GLUTs might be a valuable tool to help anticancer drugs to exert their effects[105]. Increased expression of Glut-1 in cancer cells can maintain the energy supply needed for development and growth[106]. Expression of the genes Glut-1 and aldolase A, which are associated with the regulation of anaerobic metabolism, was found to be increased in cells with constitutive expression of HIF-1α compared with cells without it. It was assumed that expression of HIF-1α was associated with increased survival and proliferation of PC cells, and that cells undergo

activation of anaerobic metabolism under conditions of hypoxia and glucose deprivation[72].

Adaptation responses to glucose deprivation and hypoxia are also necessary for the survival of cells in the tumor microenvironment[107]. A number of genes, including Glut-1, Glut-3, and Hexokinase-2, were expressed at high levels in human PC tissue specimens where hypoxic conditions were detected[108]. Guillaumond *et al*[97] reported that hypoxic PDAC tissue was comprised of abundant epithelial cells harboring epithelial-mesenchymal transition features and expressing glycolytic markers. Hypoxia led to a change in the glycolytic metabolism of PC cells from oxidative phosphorylation to lactate production. As a consequence, the growth of normoxic cancer cells was favored[109]. Interestingly, PDAC cells might use PSC-derived alanine to increase their biochemical flexibility in order to adapt to the austere conditions resulting from hypoxia[110]. Finally, Munc18-1-interacting protein 3 (Mint3) was found to promote ATP production *via* glycolysis by activating HIF-1α in cancer fibroblasts[58].

HYPOXIA AND ENDOPLASMIC RETICULUM STRESS IN PC

Specific conditions and factors within tumor masses, for example hypoxia, nutrient starvation, low pH, and increased levels of free radicals, induce a situation that has been termed "endoplasmic reticulum (ER) stress". It is also known as unfolded protein response[111]. In tumors, this response is found in malignant cells and other cell types present in the stroma[112]. In general, ER stress works in favor of cell survival and adaptation to hostile environmental conditions. Nevertheless, the ER stress can also induce cell death if it is unresolved. It can also be connected to inflammation and immune suppression within tumors[113]. For information about the branches operating ER stress see Chern and Tai[114].

As mentioned above, glucose deprivation and hypoxia often occur in solid tumor cells, including PC cells. A study showed that with glucose deprivation, ER stress was activated in cancer cells and upregulated glucose-regulated protein 78 (GRP78), which protects cells from death. Inhibition of ER stress by pancastatin A (PST-A) and B (PST-B), which are glabretal triterpenoid moieties, suppressed the accumulation of GRP78, and exhibited selective cytotoxicity in Panc-1 cells[115]. Hypoxia and ER stress contributed to the overexpression of endoplasmic reticulum oxidoreductase 1 alpha (ERO1L) in PDAC. ERO1L is an ER luminal glycoprotein that participates in the formation of disulfide bonds in secreted and membrane proteins. This oxidoreductase has been associated with the proliferation of PDAC cells *in vitro*[116]. To our knowledge, little is known about how ER stress evolves under hypoxia. Further studies need to be carried out in order to better understand how this dual-sided pathway determines cell fate under hypoxia.

HYPOXIA AND INFLAMMATION IN PC

PDAC is characterized by a significant inflammatory response[103]. During malignant progression, cancer cells acquire various features that include increased secretion of VEGF and interleukin 6 (IL-6), to which inflammation contributes to a certain extent and confers chemoresistance[50]. Hypoxia induces the accumulation of metabolites that can enter signaling cascades and contribute to the inflammatory response[117]. The expression of IL-6 was enhanced by hypoxia and proteins involved in PC development like Kras, mesothelin or ZIP4. The cytokine contributed to the generation of a pro-tumorigenic microenvironment and was probably involved in angiogenesis [118]. The expression of IL-6 was also reported as responsible for the aggressiveness of PC cells under hypoxia[119]. PC cell lines expressed higher levels of IL-6 than normal human pancreatic tissue. Moreover, exogenous application of IL-6 in Panc-1, MIA PaCa-2, and BxPC-3 cells increased the secretion of multiple Th2-type cytokines. In addition, IL-6 activated ERK2 signaling pathways[120]. Under hypoxia, involvement of downstream elements of the pathways regulated by VEGF and tumor necrosis factor has been suggested[121].

Human IL-37 possesses anti-inflammatory and immunosuppressive properties. It also suppresses tumor growth and progression[122]. A study by Zhao *et al*[123] showed that HIF-1α attenuated IL-37 transcription. A decrease in the expression of IL-37 was observed in PDAC this was associated with increased histological grade, tumor size, metastasis, and vessel invasion. On the other hand, IL-37 suppressed the

expression of HIF-1α through the inhibition of Stat3. Stat3 exhibits a range of oncogenic functions that include suppression of antitumor immune responses and promotion of inflammation. Another found showed that PC cell death was induced by blockade of the expression of Stat-3-related genes[124]. It has been suggested that IL-1β was involved in cell proliferation after Myc-induced cell cycle entry. Following Myc activation, cells rapidly exhibited expression and release of the proinflammatory cytokine IL-1β, which could be the reason why pleiotropic Myc oncoproteins contributed to the expansion of the vascular compartment during tumor progression [124].

In PDAC the abundant stroma participates in the recruitment of immunosuppressive cells through the activation of cancer-associated fibroblasts and the secretion of TGF-β[125]. It has been proposed that PSC and myofibroblasts subjected to hypoxia contribute to the recruitment of myeloid-derived suppressor cells and B cells in PDA caused by the release of cytokines[26]. Recruitment of macrophages in PDAC was found to induce the activation of PSC that was associated with a certain degree of inflammation in the tumor region. The process was dependent on HIF-1α[27]. In a study by Maruggi *et al*[126], it was shown that hypoxic cancer cells secreted the inflammatory chemokines IL-1β and IL-8. Moreover, analysis of the tumor stroma revealed enrichment of myeloid dendritic cells 1 and 2, which secreted proangiogenic cytokines. Another study showed that IL-8 was significantly overexpressed in regions surrounding necrotic areas of PC tissue in which the cells were exposed to hypoxia and an acidic pH. IL-8 was reported to participate in the growth and metastasis of variants derived from COLO 357 human PC cells[127]. Additionally, IL-8 increased tumorigenesis by promoting angiogenesis and metastasis *via* VEGF and neuropilin expression. IL-8 also stimulated ERK1/2 signaling in the human PC cell line BxPC-3 [128]. It may be possible that controlling the inflammatory response and the release of cytokines by cells within the tumor mass would facilitate treatment and restrain tumor growth[129].

EXTRACELLULAR VESICLES AND HYPOXIA IN PC

Extracellular vesicles, also known as exosomes, consist of diverse types of membrane vesicles of endosomal and plasma membrane origin that are released by the cells into the extracellular milieu[130]. They are considered as an important mode of cell-to-cell communication because they function as vehicles to transfer membrane and cytosolic proteins, lipids, and RNA between cells[131]. The hypoxic microenvironment promotes tumor cells to release exosomes, which is an activity of solid tumors that allows invasion and metastasis[132]. As in other types of cancer, exosomes have a key role pancreatic tumor pathobiology by facilitating intercellular communication. Exosome, are considered as important mediators of the crosstalk between tumor cells and the microenvironment[133].

Hypoxia was found to stimulate the release of exosomes in MiaPaCa2 and AsPC1 cells and to promote the survival of cells subjected to hypoxia. HIF-1α was involved in exosome release[134]. Another study showed that exosomes derived from PC cells subjected to hypoxia-activated macrophages, a process that was dependent on HIF-1α or HIF-2α. Following release, the exosomes facilitated the migration, invasion, and epithelial-mesenchymal transition of PC cells, thereby worsening the prognosis[133]. Regarding the stroma, feedback loops are established between stromal elements and tumor cells in the cancerous tissue. Along this line, PSC are responsible for direct nutrient transfer *via* vesicles[135]. As with other aspects that have been reviewed above, modulation of exosome signaling under hypoxia deserves further study.

MICRORNA AND HYPOXIA IN PC

Micro (mi)RNAs are noncoding RNAs comprising of a single-stranded chain of 18 to 22 nucleotides, and they play major roles in the regulation of gene expression. Extracellular miRNAs function as chemical messengers to mediate cell-to-cell communication[136]. Synthesized miRNAs can be released from the cell into the extracellular space by (1) selective incorporation in the exosomes, (2) being coupled with Ago2 protein, and (3) by release attached to high-density lipoproteins. Once in the extracellular medium miRNAs will reach other cells to alter their functions[133, 137].

Hypoxia was found to decrease the expression of miR-519 in Panc-1 and SW1990 cells[138], and was regarded as a survival mechanism because transfection with miR-519 mimics inhibited cell growth and invasiveness and induced apoptosis. Similarly, HIF-1α induced the downregulation of miR-548an in PC cells during hypoxia. The vimentin content was inversely correlated with miR-548an expression and was associated with facilitation of pancreatic tumorigenesis[139]. miR-454 was found to be present in low levels in PDAC and it was associated with cell growth because overexpression of the miRNA led to slower cell growth[140]. The expression of other miRNAs has been associated with increased cell proliferation and cancer malignancy [141]. miR-210, which is induced by HIF-1α, was reported to have many targets within cells that can regulate the cell cycle, mitochondrial oxidative metabolism, angiogenesis, DNA damage response, and thus, cell survival[142]. A regulatory mechanism of HIF-1α on miR-191 expression was detected in MiaPaCa2 and Aspac1 cells subjected to hypoxic conditions. The expression of miR-191 in tissues from PC patients was closely associated with tumor size, stage, lymph node metastasis, and perineural invasion [143]. Similarly, miR-212 was associated with increased tumor size, lymph node metastasis, and vessel invasion in PDAC. A positive correlation between this miRNA and the expression of HIF-1α was noted, indicating that the miRNA was induced by hypoxia[144]. Hypoxia also increased the detection of miR-21 in BxPC-3 and AsPC-1 PC cells. Antisense constructs targeting miR-21 diminished cell proliferation by activating apoptosis[145]. Similarly, a study by Bao *et al*[119] reported that miR-21 and miR-210 were associated with increased cell migration, invasion, and angiogenesis.

The long noncoding (lnc)RNA UCA1 released from hypoxic PC cells and was shown to promote angiogenesis and tumor growth both *in vitro* and *in vivo* by regulation of miR-96-5p[132]. The synthesis and release of circ_0000977 was induced by hypoxia and conferred resistance to natural killer (NK) cells by Panc-1 cells. Inhibition of miR-153-mediated repression of HIF-1α and ADAM10 allowed the immune escape of the cancer cells[146].

Another hypoxia-induced microRNA, miR-646, blocked the expression of migration and invasion inhibitory protein (MIIP), which has been identified as an inhibitor of tumor development. MIIP acted to suppress the activity of histone deacetylase 6 and promote the degradation of HIF-1α, therefore impairing HIF-1α accumulation[147]. Inhibition of MIIP by miR-646 led to increased proliferation and invasion of PC cells. miR125a, the content of which was regulated by HIF-1α, inhibited mitochondrial fission and contributed to cellular survival in PDAC by preventing apoptosis[148].

The existing evidence signals that miRNAs differentially participate in regulating cell fate. Whereas certain types are downregulated in cancer cells, others have increased expression compared with healthy cells[149,150]. The expression of miRNAs is regulated by HIF-1α when hypoxic conditions are established, and that confers the tumor cells with adaptations that allow cancer growth. A summary of the roles of miRNAs in PC under hypoxia is provided in Table 1. Fewer studies have investigated miRNAs in the pancreatic stroma. Along this line, Bynigeri *et al*[151] reported that miRNAs were involved in the inflammatory and profibrogenic functions of PSC. Within the stroma, the interaction of PSC and tumor cells that include signaling through miRNAs can promote tumor progression, metastasis, immune evasion, and drug resistance, which impact the evolution and prognosis of PC[152].

POTENTIAL TREATMENTS DIRECTED AGAINST HYPOXIA

As noted earlier in this review, cells growing within the tumor mass make key adaptions and changes in intracellular pathways that might convey resistance to death and to treatment. In fact, the most frequent treatment of PDAC is radical surgery and chemotherapy, and they are the only treatments that seems to work in a only a few patients. Despite treatment, PDAC remains a highly lethal disease. In addition to surgery, various combinations of drugs of different types have been evaluated as chemotherapy and remains as the standard adjuvant therapy[153]. For example, the combination of FOLFIRINOX and nab-paclitaxel plus gemcitabine as found to improve the survival of patients with metastatic disease[154] and to improve surgical and clinicopathologic outcomes following pancreatic resection[155].

It must be noted that failure of chemotherapy, targeted therapy, and immunotherapy have all been attributed to the PDAC microenvironment[156]. Dysregulation of the tumor microenvironment promotes an intense fibrosis and immune suppression that plays a key role in drug resistance[157]. Therefore, targeting the extracellular tumor microenvironment *via* inhibition of signaling pathways, alteration of DNA

Table 1 List of oncogenic and tumor suppressor microRNAs in pancreatic cancer cells under hypoxia

MicroRNA	Oncogenic activity	Function	Ref.
miR-519	Anti-tumor	Inhibits cell growth and invasiveness	[138]
miR-58an	Anti-tumor	Reduces tumorigenesis	[139]
miR-454	Anti-tumor	Decreases cell proliferation	[140]
miR-210	Pro-tumor	Regulates cell cycle and promotes angiogenesis	[142]
miR-191	Pro-tumor	Promotes tumor growth, invasion, and metastasis	[143]
miR-212	Pro-tumor	Promotes tumor growth, vessel invasion, and metastasis	[144]
miR-21	Pro-tumor	Induces cell proliferation, invasion, and metastasis	[119,145]
miR-210	Pro-tumor	Increases migration, invasion, and angiogenesis	[119]
miR-646	Pro-tumor	Promotes proliferation and invasion	[147]
miR-125a	Pro-tumor	Increases tumor cell viability	[148]
miR-96-5p	Anti-tumor	Inhibits angiogenesis	[132]
miR-153	Anti-tumor	Avoids immune escape of tumor cells from natural killer cells	[146]

repair pathways, immunotherapy and/or modulation of cell metabolism, might serve as novel tools for PDAC treatment. Treatments under study include vaccines, oncolytic viruses, MEK inhibitors, cytokine inhibitors, and targeting hypoxia[125]. Recently, intense efforts have been carried out to evaluate the effectiveness of therapies aiming to increase tumor immunogenicity and promote the recruitment and activation of effector T cells[125]. Along this line, it has been suggested that challenging the immunosuppression occurring within pancreatic immune infiltrate might diminish tumor aggressiveness[154]. Because hypoxia contributes to aggressive tumor behavior, mainly involving tumor progression, malignancy, and promoting resistance to conventional and targeted therapeutic agents[158], finding drugs that are effective in the modulation of cell proliferation under hypoxia is a major challenge. HIF has been seen as a potential therapeutic target in the pathobiology of PDAC. Interestingly, HIF might exert its oncogenic influence through the modulation of the stroma rather than the modulation of cancer cells[159]. Cyclopamine, a hedgehog inhibitor plus paclitaxel in a polymeric micelle formulation, exhibited effects on the stroma by increasing microvessel density, alleviating hypoxia, and reducing matrix stiffness while maintaining the tumor-restraining function of extracellular matrix. As a result, tumor growth was suppressed and animal survival was prolonged[160]. Targeting HIF by siRNAs delivered to cancer cells might be an effective cancer treatment. Indeed, recombinant adeno-associated virus has been employed to deliver siRNA targeting HIF-1α into MiaPaCa2 human PC cells subjected to hypoxia. As a consequence, cell proliferation and migration decreased and apoptosis was induced [85]. siRNA targeting of HIF-1α in MiaPaCa2 cells subjected to hypoxia-induced apoptosis through both NF-kB-independent and -dependent mechanisms[161].

Additionally, hypoxia-activated prodrugs designed to overcome the resistance of cancer cells have shown clinical efficacy[162]. TH-302 is an investigational hypoxia-activated prodrug. Its combination with gemcitabine and nab-paclitaxel was effective in PDAC xenograft models in mice[81]. Moreover, TH-302 significantly decreased *in vivo* tumor growth, increased survival in a MiaPaCa cancer model and improved survival in Hs766t tumors[162]. Recently, we showed that PSC adapted to pro-oxidant conditions under hypoxia, and that the adaptations may have been responsible for increased cell viability and proliferation[14]. Interestingly, melatonin modulated the antioxidant responses and signaling by inflammatory regulators. Therefore, this indoleamine is emerging as another potential treatment of PDAC[163].

CONCLUSION

Hypoxia is a common condition that is created in solid tumors and it results from rapid, uncontrolled growth of the tissue that is accompanied by insufficient development of blood microcirculation. Along with tumor cell proliferation, a fibrotic reaction is established that involves the parallel growth of several types of cells

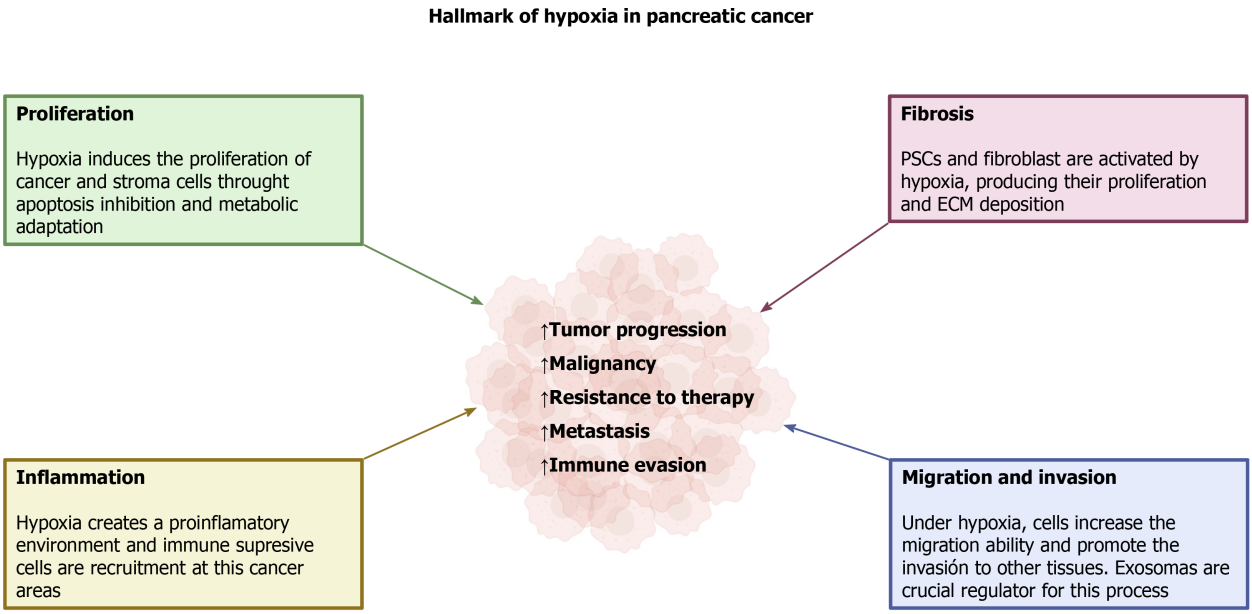

Figure 4 Hallmarks of hypoxia in pancreatic cancer. The figure summarizes the major adaptive features of pancreatic tumor cells in response to hypoxia. In general, low O_2 availability worsens the prognosis of pancreatic cancer by promoting increases in tumor progression, drug resistance, immune evasion, and metastatic ability. Created with BioRender.com. ECM: Extracellular matrix; PSC: Pancreatic stellate cells.

different from tumor cells, and the deposition of extracellular components, which comprises a stromal component. As a consequence of the low O_2 availability that develops, all the cells included in the mass adapt in order to survive. HIF is the major regulator of cell responses to hypoxia. Activation of different intracellular pathways and changes in cellular energy metabolism take place, and are all modulated by hypoxia. These conditions are responsible for tumor progression, malignancy, and resistance to therapy, which are major features of PC. Additionally, capabilities of invasion of neighbor tissues, organs, and metastasis are acquired, all of which are critical determinants of the extreme malignancy of PC. A summary of the major adaptations of pancreatic tumor to hypoxia is shown in Figure 4.
