Abstract

In this review the current overall knowledge on hepatitis A, B, C, D, and E will be discussed. These diseases are all characterized by liver inflammation but have significant differences in distribution, transmission routes, and outcomes. Hepatitis B virus and hepatitis C virus are transmitted by exposure to infected blood, and in addition to acute infection, they can cause chronic hepatitis, which in turn can evolve into cirrhosis. It is estimated that more than 300 million people suffer from chronic hepatitis B or C worldwide. Hepatitis D virus, which is also transmitted by blood, only affects hepatitis B virus infected people, and this dual infection results in worse liver-related outcomes. Hepatitis A and E spread *via* the fecal–oral route, which corresponds mainly to the ingestion of food or water contaminated with infected stools. However, in developed countries hepatitis E is predominantly a zoonosis. Although hepatitis A virus and hepatitis E virus are usually responsible for a self-limiting hepatitis, a serious, rarely fatal illness is also possible, and in immunosuppressed patients, such as organ transplant recipients, hepatitis E virus infection can become chronic. The description of goals achieved, unresolved issues, and the latest research on this topic may make it possible to speculate on future scenarios in the world of viral hepatitis.

Key Words: Viral hepatitis; Hepatitis A; Hepatitis B; Hepatitis C; Hepatitis D; Hepatitis E

INTRODUCTION

Hepatitis viruses are a leading cause of morbidity and mortality as the consequences of their acute or chronic infections. The World Health Organization (WHO) estimated 1.4 million deaths per year due to viral hepatitis worldwide, most of which are a consequence of hepatitis B or C. Significant progress has been made in the prevention and treatment of hepatitis B, C, and D viruses (HBV, HCV, and HDV) infections, but chronic hepatitis by these viruses still represents the most common etiology of cirrhosis and hepatocellular carcinoma (HCC). Hepatitis A virus (HAV), HBV, HDV, and hepatitis E virus (HEV) are a frequent cause of clinical hepatitis and acute liver failure. Although it is rare, the latter is a life-threatening condition. In 2016, the WHO Global Health Sector Strategy established the goal of eliminating viral hepatitis "as a major public health threat" by 2030. However, great efforts are still needed to bridge the gap between the current situation and this ambitious goal.

HEPATITIS C

HCV is a single strand positive sense RNA virus of the Flaviviridae family (Hepacivirus genus) discovered in 1989 by Michael Houghton and colleagues[1,2]. This discovery, which was awarded the 2020 Nobel Prize in Physiology or Medicine, shed light on blood-transmitted chronic non-A, non-B hepatitis cases, and through the subsequent advent of specific therapies is estimated to have saved millions of lives. HCV is blood-borne transmitted[3], and currently eight viral genotypes are recognized [4,5]. In 15% of cases HCV infection is responsible for acute hepatitis[6], while approximately 80% of infected patients progress to chronic infection; 20% of chronically infected patients develop cirrhosis within 25 years, and among patients with cirrhosis 25% develop HCC and/or decompensated liver disease[7].

EPIDEMIOLOGY

HCV is widespread all over the world, with different prevalence of viral genotypes within different geographical areas. Genotype 1 is the most common, especially in North America, Europe, and Asia. Genotype 2 is endemic in parts of West Africa and Latin America. Genotype 3 is present in Southeast Asia and Eastern Europe. Genotype 4 is endemic in North Africa and Sub-Saharan Africa. Genotype 5 is particularly common in Southern Africa[8]. This virus, whose only host is humans, is transmitted by blood. In high-income countries this infection occurs particularly in "at risk" populations, such as people who inject drugs who may share infected needles, men who have sex with other men, and prisoners. In low-middle-income countries, healthcare associated transmission (*e.g.*, during invasive procedures or the execution of blood transfusions with infected blood) is still an important problem[9,10]. Perinatal transmission from infected mothers occurs in 3%-10% of cases[11].

CLINICAL MANIFESTATION

Acute HCV infection is usually asymptomatic and characterized by increased transaminases usually occurring between 6 wk and 8 wk after exposure[12]. Symptoms such as nausea, asthenia, and weight loss appear in less than 30% of patients, and in most cases they do not interfere with normal daily activities[13]. The presence of jaundice is also infrequent, occurring in less than one third of patients[14]. Acute liver failure due to HCV infection is unusual[12].

About 30% of people who contract the infection spontaneously eliminate the HCV within 6 mo. On the contrary, at least 60% to 70% of infected people develop chronic infection, defined as the presence of anti-HCV immunoglobulin in the blood and the persistence of HCV-RNA for at least 6 mo[12,15]. In these cases, transaminases are

usually moderately increased but can also be normal[16]. Most patients with chronic hepatitis C are asymptomatic, but some may experience asthenia, anorexia, and weight loss. Jaundice occurs only in the case of advanced liver cirrhosis. Physical examination can reveal hepatomegaly and splenomegaly (this latter in case of cirrhosis or blood malignancies)[12]. Chronic HCV infection could induce liver fibrosis, which can progress to the development of cirrhosis, decompensation, and HCC[17]. In HCV patients, HCC usually appears in patients with liver cirrhosis, but it can also occur in the absence of such condition[12]. The proportion of patients who develop liver cirrhosis after 20 years of infection is quite varied, ranging between 2%-3%[18,19] and 51%[20], depending on the study population and various risk factors, such as male gender, alcohol consumption, older age at the time of infection, coinfection with other viruses [human immunodeficiency virus (HIV) and HBV], and others[7].

EXTRAHEPATIC MANIFESTATIONS

The HCV primarily affects the liver, but a high percentage of HCV patients (up to 74%) was observed to have at least one extrahepatic manifestation[21]. For some extrahepatic manifestations the link with HCV was strongly demonstrated by epidemiological and pathogenetic data (mixed cryoglobulinemia/cryoglobulinemic vasculitis and B-cell non-Hodgkin's lymphoma), while others have a less close connection with this virus[22,23]. Mixed cryoglobulinemia is a small vessel vasculitis that predominantly affects the skin, joints, peripheral nerves, and kidneys, and in 80% of cases is caused by HCV. Clinical manifestations are variable, ranging from mild manifestations (purpura or arthralgia) to more serious conditions such as glomerulonephritis or generalized vasculitis[24]. B-cell non-Hodgkin's lymphoma is particularly common in HCV infected patients[25,26], and over the last years the association between these two diseases has been confirmed in some meta-analyses[27,28]. The association between HCV infection and lymphoma seems to be greater in Mediterranean countries, Japan, and Brazil[29], while it seems less strong in the United Kingdom, Northern Europe, and Canada[30]. In the United States, two extensive studies showed a modest increased risk of developing B-cell non-Hodgkin's lymphoma in infected HCV patients compared to negative controls[31,32].

Other pathological conditions that have been associated with chronic HCV infection include autoimmune disorders (such as arthritis, Sjogren's syndrome, hemolytic anemia, autoimmune thrombocytopenia)[33], chronic kidney failure secondary to the onset of glomerulonephritis[24], cardiovascular diseases[34], endocrine disorders (such as thyroiditis), and type 2 diabetes mellitus[35].

THERAPY FROM INTERFERON MONOTHERAPY TO INTERFERON-FREE REGIMENS: BEGINNING OF A NEW ERA

The discovery of second-generation direct-acting antiviral agents (DAAs) was a real revolution in the treatment of hepatitis C (Figure 1). In the early 1990s, the use of alpha interferon (IFN) (3 million units three times a week for 6 mo) gave rather unsatisfactory results, with a sustained virological response rate (SVR) of about 25%[36]. The addition of ribavirin (RBV) combined with IFN 2α for 48 wk provided a good increase in the SVR rate, showing an efficacy of 43% compared to 19% of SVR in patients treated with IFN in monotherapy for 48 wk. However, patients receiving combination therapy showed a higher rate of adverse events (19% *vs* 13%) than patients in monotherapy, particularly anemia and leukopenia[37]. In the early 2000s, the use of pegylated IFN (peg-IFN) with the addition of RBV further improved viral eradication rates, with an SVR greater than 50%[38,39].

In 2011 the addition of protease inhibitors, such as boceprevir and telaprevir, to the standard therapy with peg-IFN + RBV allowed the achievement of eradication rates higher than 60% in the treatment of genotype 1 chronic HCV infection[40-43]. This triple therapy was, however, burdened by a greater number of adverse events than the standard therapy, particularly anemia, dysgeusia, and skin rash for boceprevir[41,44]. The use of telaprevir was more associated with the onset of skin rash, itching, anemia, nausea, and diarrhea[40,42]. In 2013 a new protease inhibitor, simeprevir, was used in combination with peg-IFN and RBV, which allowed a further increase in the success rate of antiviral therapy (86%) and a reduction of adverse events associated with previous regimens[45,46].

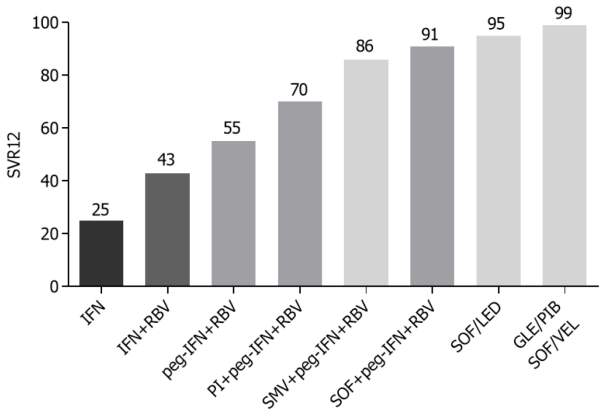

Figure 1 Sustained virological response rate of hepatitis C virus antiviral treatment, from interferon to direct-acting antiviral agents' regimens. SVR12: Sustained virologic response 12 wk post-treatment; IFN: Interferon; RBV: Ribavirin; peg-IFN: Pegylated interferon; PI: Protease inhibitor; SMV: Simeprevir; SOF: Sofosbuvir; LED: Ledipasvir; GLE: Glecaprevir; PIB: Pibrentasvir; VEL: Velpatasvir.

The big breakthrough came with the commercial introduction of sofosbuvir, a polymerase nucleotide inhibitor. Initially, it was used in combination with peg-IFN and RBV, obtaining a SVR rate of 90% and allowing a reduction of the treatment period to 12 wk[47-49]. It subsequently became the fundamental drug for the first IFN-free regimens[50], exceeding 95% of SVR in combination with ledipasvir in the treatment of genotype 1 HCV chronic infection[51]. Finally, a further step in the treatment of chronic HCV infection was the advent of pangenotypic regimens, such as sofosbuvir/velpatasvir and glecaprevir/pibrentasvir that guarantee an SVR rate close to 100% in all HCV genotypes[52-55]. The glecaprevir/pibrentasvir combination allowed a further reduction in the treatment period by showing a 99% of SVR in non-cirrhotic patients treated for 8 wk[56,57] (Table 1).

DAAS IN CIRRHOTIC PATIENTS

The second generation DAAs, thanks to their effectiveness and high safety profile, have allowed the treatment of patients once considered difficult to treat. In patients with compensated cirrhosis DAAs showed a 95% eradication rate, slightly lower (86.1% and 88.3%) in patients with Child Pugh score B[58,59]. Even in cirrhotic patients the treatment period has been further reduced. In a recent trial, the administration of glecaprevir/pibrentasvir for 8 wk in treatment-naïve patients with compensated cirrhosis showed efficacy and safety comparable to the 12 wk regimen [60]. A recent study of 667 patients with advanced/decompensated cirrhosis treated with DAAs showed an improvement of at least 3 points in the MELD score in 29% of patients at a long-term follow-up. This improvement was more frequent in patients with MELD score ≥ 16 at baseline (45%)[61]. In addition, DAA treatments reduced the hospitalization rate of patients with HCV-related liver cirrhosis[62] and allowed a reduction of liver transplantation for related HCV diseases in Europe from 22.8% in the IFN/RBV era to 10.6% in the first half of 2017[63]. Therefore, treating patients with compensated or decompensated cirrhosis with DAAs not only allows viral eradication, but also an improvement in the natural history of this disease.

IFN-free therapies have shown efficacy and safety even in patients with HCC. In a recent meta-analysis by He *et al*[64], 3126 patients with a prior history of HCC or with present HCC were compared with 49138 cirrhotic patients without HCC showing a percentage of SVR of 88.2% and 92.4%, respectively ($P > 0.001$). After initial controversy over the possibility that the DAAs could increase the occurrence or recurrence of HCC[65], in recent years several studies have denied this possibility. In a large cohort study of about 60000 patients, Ioannou *et al*[66] compared the incidence of HCC in patients treated with IFN-only, DAA + IFN, and DAA-only. Authors showed that SVR was associated with a significantly decreased risk of HCC in multivariable models irrespective of whether the antiviral treatment was DAA-only, DAA + IFN, or IFN-only. Particularly, DAA-induced SVR is associated with a 71% reduction in HCC risk.

Table 1 Direct-acting antiviral agents currently available in Italy and clinical indications (from Italian Association for the Study of the Liver[253])

DAAs	Clinical indications
Glecaprevir/Pibrentasvir	Pangenotypic regimen
	8 wk treatment in naïve/experienced (except GT3) non-cirrhotic pts and naïve CPT A5 cirrhotic pts
	12 wk treatment in experienced (except GT3) CPT A5 cirrhotic pts
	16 wk treatment in experienced GT3 non-cirrhotic or CPT A5 cirrhotic pts
	ESRD and/or hemodialysis (same treatment duration of pts without CKD)
	Contraindicated in decompensated cirrhosis
Grazoprevir/Elbasvir	GT1b, GT4
	12 wk treatment in GT1b or GT4 with HCV-RNA < 800000 IU/mL, naïve/experienced, CPT A5 cirrhotic or non-cirrhotic pts
	ESRD and/or hemodialysis (same treatment duration of pts without CKD)
	Contraindicated in decompensated cirrhosis
Sofosbuvir/Velpatasvir	Pangenotypic regimen
	12 wk treatment in naïve/experienced, cirrhotic or non-cirrhotic pts
	Indicated in decompensated cirrhosis
	Add RBV (if tolerated) in GT3 cirrhotic pts or in decompensated cirrhosis
	Optimal profile for drug interactions
	Contraindicated in pts with eGFR < 30 mL/min
Sofosbuvir/Velpatasvir/Voxilaprevir[1]	Pangenotypic regimen
	8 wk treatment in naïve/experienced non cirrhotic pts or GT3 naïve/experienced CPT A5 cirrhotic pts
	12 wk treatment in GT1, 2, 4, 5, 6 naïve/experienced CPT A5 cirrhotic pts
	First line therapy for retreatment after DAAs failure
	Contraindicated in pts with eGFR < 30 mL/min
	Contraindicated in decompensated cirrhosis

[1]In Italy, this regimen is currently refundable only for retreatment after direct-acting antiviral agent failure. DAAs: Direct-acting antiviral agents; GT: Genotype; pts: Patients; CPT: Child Pugh Turcotte Score; ESRD: End stage renal disease; CKD: Chronic kidney disease; RBV: Ribavirin; eGFR: Estimated glomerular filtration rate; HCV: Hepatitis C virus.

In a study involving 18076 patients treated with DAAs, with a follow-up of about 3 years, Kanwal *et al*[67] showed a cumulative incidence of HCC occurrence at 1, 2, and 3 years of 1.1%, 1.9%, and 2.8%, respectively. In patients with cirrhosis the cumulative incidence was 2.2%, 3.8%, and 5.6% at 1, 2, and 3 years, respectively. Two recent prospective Italian studies showed an incidence of HCC in patients treated with DAAs less than 3%, and in both studies the lack of SVR was a risk factor for the development of HCC[68,69].

Careful screening for hepatic nodules is essential before starting treatment with DAAs as the presence of undefined/benign hepatic nodules is significantly associated with HCC occurrence during or after treatment with DAA[70,71]. The recurrence rate of HCC in patients treated with DAAs is quite varied in literature, ranging from 2.2% in a cohort of liver transplant recipients for HCC and then treated with DAAs to 45.1% in cirrhotic patients[72]. In a broad, retrospective cohort study, patients treated with DAAs were compared with HCV-infected, cirrhotic patients that had not received any antiviral treatment, showing a lower early recurrence rate of HCC in the group of patients treated with DAAs (42.1% *vs* 58.9%)[73]. Finally, treatment with DAAs showed an improvement in survival in cirrhotic patients with HCC compared to patients with HCC and chronic HCV infection not treated with DAAs, thus resulting in effective, safe and beneficial treatment for patients[74-76].

IFN-FREE REGIMEN IN EXTRAHEPATIC MANIFESTATIONS

DAA regimen has been shown to be highly effective in treating patients with chronic HCV infection and the concomitant presence of extrahepatic manifestations, such as mixed cryoglobulinemia and/or lymphoma. The SVR rate is similar compared to patients with no extrahepatic symptoms, exceeding 90%[77]. In a study by Passerini *et al*[78], 93 patients with chronic HCV infection and mixed cryoglobulinemia treated with DAAs were enrolled and compared with a control group of 89 HCV infected without mixed cryoglobulinemia also treated with an IFN-free regimen. The SVR rate was superimposable between the two groups, and the percentage of adverse events was similar. The authors demonstrated the high efficacy and safety of DAA treatment in patients with mixed cryoglobulinemia.

Conflicting data have been collected on the effectiveness of DAA regimen in the treatment of mixed cryoglobulinemia. In a study involving 148 patients with HCV infection and secondary mixed cryoglobulinemia vasculitis treated with DAAs with an average follow-up of about 15 mo, it was observed that 72.6% of patients obtained a complete response (defined as improvement of all organs involved at baseline without subsequent relapse), 22% a partial response, while 5% had no clinical response. Cryoglobulins were eliminated in the blood in about 50% of patients, while in over 90% of patients vasculitic and renal manifestations were eliminated; in 86% of patients an improvement of arthralgia was observed. Factors associated with a partial or absent response were a severe form of vasculitis and peripheral neuropathy[79]. In a recent work by Colantuono *et al*[80], 70 patients with HCV and mixed cryoglobulinemia vasculitis treated with DAAs were compared with 39 patients with the same clinical condition treated with IFN. The percentage of patients achieving at any time point of follow-up (more than 2 years) a complete or partial response was similar in the two groups, but patients treated with an IFN-free regimen had less effectively eliminated cryoglobulins and B-cell clones in the blood. Most importantly, they had a significantly higher percentage of vasculitis relapse (18% *vs* 3%, $P = 0.028$) and a greater need for treatment with rituximab.

In 2017, our group demonstrated that DAA therapy was safe and effective in patients with chronic HCV infection and with diffuse large B cell non-Hodgkin lymphoma (DLBCL) in current chemotherapy. In this small cohort of patients the SVR rate was 100%, and it emerged that patients treated with DAAs had a greater disease-free survival than HCV+ patients with DLBCL not treated with antiviral therapy (historical cohort). In multivariate analysis, DAAs have proven effective ($P = 0.012$) in improving remission of aggressive lymphoma in HCV+ patients[81]. Our data were subsequently confirmed in a study by Pellicelli *et al*[82], in which they demonstrated how HCV+ patients with DLBCL treated with DAAs or with peg-IFN + RBV who had not obtained SVR showed a greater relapse of DLBCL after chemotherapy than patients who reached a SVR. Furthermore, an Italian-French cohort of 47 HCV+ patients with DLBCL showed an SVR rate of 96% and a progression of lymphoproliferative disease in only three patients who had obtained SVR[83].

In a recent paper by Frigeni *et al*[84], 100 HCV+ patients with indolent non-Hodgkin lymphoma treated with an IFN-free regimen were enrolled. They showed an SVR rate of 99%, with an overall hematological response rate of 66%, with 23% of complete response and 43% of partial response; a higher overall hematological response rate was observed in marginal zone lymphoma than in non-marginal zone lymphoma (73% *vs* 48%, $P = 0.021$). Moreover, in this study a comparison between patients treated with DAAs alone as first-line therapy for indolent non-Hodgkin lymphoma (excluding patients previously treated with IFN) and a historical cohort of HCV+ patients with indolent non-Hodgkin lymphoma treated with IFN was performed. Although the SVR rate was higher in patients treated with DAAs, IFN therapy had a higher percentage of complete response and a higher median duration of response than DAAs, thus demonstrating a greater anti-lymphoma action than IFN-free regimens, secondary to the well-known antiproliferative activity of IFN. The hematological outcomes in terms of overall survival and progression-free survival (PFS) were overlapping[84]. Finally, a recent meta-analysis of our group comprising 317 HCV+ patients with non-Hodgkin lymphoma treated with DAAs and/or an IFN-based regimen and 250 controls not treated with antiviral therapy showed how the achievement of an SVR, regardless of the antiviral treatment performed, has a strong positive effect on the non-Hodgkin lymphoma outcome in terms of progression-free survival[85].

DAAS IN PATIENTS WITH CHRONIC KIDNEY DISEASE

DAAs are effective and safe in patients with chronic kidney disease (CKD) and/or hemodialysis. Antiviral treatments containing sofosbuvir are currently not recommended as first-line therapy in patients with CKD and or end stage renal disease due to its renal metabolism and possible adverse events on kidney function[86]. The first combination to be used was ombitasvir/paritaprevir/ritonavir + dasabuvir in the treatment of patients with genotype 1 and 4[87]. Subsequently, the combination grazoprevir/elbasvir showed efficacy and safety in patients with CKD and HCV chronic infection genotypes 1 and 4[88,89]. The pangenotypic regimen glecaprevir/pibrentasvir showed high SVR rates and satisfactory safety profile in the treatment of moderate/advanced CKD and/or hemodialysis patients with HCV chronic infection genotype 1-6 for 12 wk of treatment[90]. In a recent trial, the administration of glecaprevir/pibrentasvir for 8 wk in non-cirrhotic patients with moderate/advanced CKD and/or in hemodialysis with chronic HCV infection (all genotypes) showed SVR rates comparable to the 12 wk, thus allowing a significant reduction in the treatment period[91]. The effectiveness and safety of glecaprevir/pibrentasvir in patients with CKD or end stage renal disease has also been tested in real life settings[92,93], showing data superimposable with controlled trials. The efficacy and safety of sofosbuvir/velpatasvir has recently been tested in patients with CKD and/or hemodialysis. Although the two cohorts are limited (51 and 59 patients, respectively), the SVR rate was high (96% and 95%) with an acceptable safety profile[94,95]. Studies with larger populations will be needed to confirm these data.

NEW TARGET: ELIMINATION OF HCV INFECTION. A PATH INTERRUPTED BY THE GLOBAL PANDEMIC

In 2016, the WHO set the challenge of eliminating HCV infection and blocking its spread worldwide by 2030[96]. In order to achieve this objective, the European Association for the Study of the Liver has proposed to strengthen the measures of case finding and treatment in populations at greater risk of infection, such as people who inject drugs, prisoners, the homeless, and men who have sex with other men, so as to obtain a microelimination in these populations and subsequently the macroelimination of HCV infection[97]. In a recent study of our group in which 160 people who inject drugs with HCV infection, afferent to drug addiction centers were treated, the SVR rate was 98.5% without significant side effects[98]. Furthermore, the concomitant opioid substitution therapy does not affect the efficacy and safety of DAAs[99]. Even in a complicated context such as prison, therapy with DAAs has proved highly effective, with a 100% SVR in 46 convicts in southern Italy. This study highlights how difficult it is to reach these patients not to treat them[100].

The conditions for achieving microelimination in 2030 were quite satisfactory, but the recent global pandemic caused by severe acute respiratory syndrome coronavirus 2 infection has suddenly interrupted this process. Indeed, the national health systems have had to concentrate all their resources (human, structural, and economic) on the fight against this infection, temporarily putting aside the activities of screening and treatment of chronic diseases, such as chronic HCV infection. In a study conducted at the Boston Medical Center, it was shown that between March and June 2019, there was a 49% reduction in the performance of HCV tests and a 42% reduction in new HCV+ patient identification hospital wide. These numbers are even higher in ambulatory clinics connected to this center for screening programs for HCV infection with a reduction of 72% and 63% in the number of HCV tests performed and in the new HCV+ patient identification, respectively[101].

In Italy, a recent survey proposed by the Italian Association for the Study of the Liver showed that outpatient activities concerning viral hepatitis were reduced in 99% of hospitals involved in the study, and the start of antiviral treatment has been postponed in 23% of centers, even for patients considered at risk of disease evolution [102]. In Germany between March and May 2020 there was also a sharp reduction in outpatient hepatological activities and in the prescription of anti-HCV treatments [103]. The consequences of this reduction in the screening and treatment of hepatitis C could be serious in the near future. In a study by Blach *et al*[104], it was estimated that in the decade 2020-2030 there could be 900000 missed new diagnoses of HCV infection and a reduction of about 750000 treatments due to the global pandemic. This could result in an increase in end-stage disease outcomes, with 44800 excess HCC cases and 72300 excess liver-related deaths predicted over 2020-2030.

HEPATITIS B

HBV, the pathogen responsible for hepatitis B, is a major public health problem, as both its acute and chronic infections are still responsible for numerous cases of morbidity and mortality. International guidelines provide specific indications (with few differences from one another) on antiviral therapy against HBV, but this field still represents an open challenge because despite the increasing effectiveness of anti-HBV drugs approved over the years, a definitive cure for hepatitis B does not yet exist.

EPIDEMIOLOGY

In 2016, a worldwide prevalence of hepatitis B surface antigen (HBsAg) positivity of about 292 million people was estimated and that in the same year only 10% of these were identified[105]. Moreover, it was calculated that this virus caused 887000 deaths in 2015, mainly from cirrhosis or HCC. Africa and the Western Pacific are the areas with the higher prevalence of infection, and the WHO African Region was estimated to have the lowest vaccine birth dose coverage[105,106]. Despite the open challenges, important results have already been achieved, such as the reduction in chronic hepatitis B (CHB)[106-108], HCC[109], extrahepatic manifestations, and decreased mortality for fulminant hepatitis[110] due to vaccination against this virus.

HBV can spread in different ways. In high prevalence areas, transmission during the first years of life is the most common. In this age group, they can be distinguished by perinatal transmission (from infected mother to newborn), that is the most widespread worldwide and occurs at the time of birth, shortly after, or rarely in the intrauterine life and horizontal transmission during childhood that is prevalent in certain countries and can occur *via* small lesions through contaminated environmental surfaces[106,108]. Horizontal infections in adulthood occur mainly through the parenteral route in both health care settings (due to the use of contaminated blood derivatives or contaminated instruments) or in the context of intravenous drug use, such as opioids. Getting tattooed and performing piercings are other procedures that can allow HBV spread [106]; sexual intercourse is a consistent risk factor for certain categories of people, such as male homosexuals or people who have multiple partners[106,108]. In addition to blood, HBV is found in saliva, seminal, vaginal, or menstrual fluids[106,111].

HISTORY, CLASSIFICATION, AND VIROLOGY

In 1965, Blumberg *et al*[112] described the formation of precipitins (precipitating antibodies) after contact between serum from two hemophilic patients and that of an Australian aborigine. Since this antigen (called "Australia antigen") was subsequently found also in the serum of patients suffering from acute hepatitis, it was hypothesized that it could be linked to a hepatitis virus[113]. Following observations through electron microscopy, in 1970 David Dane made it known for the first time that the agent responsible for the "Australian antigen-associated hepatitis" was a virus of 42 nm in diameter[114], therefore called "Dane particles." The term "hepatitis B virus," however, appeared several years before identification of this virus (in 1947) and was proposed to distinguish the two different types of hepatitis that were known at the time[115,116].

HBV belongs to a family of hepatotropic, DNA viruses named Hepadnaviridae. This family includes five genera: Avihepadnavirus, Herpetohepadnavirus, Metahepadnavirus, Orthohepadnavirus, and Parahepadnavirus. The genus Orthohepadnavirus comprises 12 species (which can be hosted by a wide range of mammals) among which there is the HBV species that infects humans and apes[117,118]. HBV is divided into four serotypes (adw, ayw, ayr, and adr) based on HBsAg and depending on nucleotide sequences in ten different genotypes (A, B, C, D, E, F, G, H, I, J)[118,119]. There are some subtypes of the different genotypes. The various genotypes have a different geographical distribution, are associated with different responses to therapies (genotypes A and B have a better response to IFN than C and D), and outcomes (genotype C is associated with an increased risk of advanced fibrosis and HCC)[119].

The HBV genome consists of a 3.2 kb long, partial double stranded, relaxed circular DNA molecule, formed by a complete coding negative strand, linked to the viral polymerase, and an incomplete noncoding positive strand. The minus strand contains four open reading frames (ORF) that partly overlap: preC/C, P, preS/S, and X[117,119,120].

PreC region (pre-core) encodes the E antigen (HBeAg) which unlike HBc (that remains in the cell) is secreted into the circulation; this protein has immunomodulatory/tolerogenic functions, and it is believed to give the virus an evolutionary advantage (in fact it is found in all Orthohepadnaviruses). It is still unclear if it could also have other roles[121,122]. ORF C encodes the highly antigenic and self-assembling core protein HBc, which constitutes the structural protein (HBcAg) that covers the HBV DNA forming the nucleocapsid. It also participates in other steps of the HBV life cycle, including viral replication[123]. ORF P encodes the viral polymerase (P protein), a multifunctional protein responsible for viral replication; this latter is divided into four (TP, spacer region, RT, and RNase H) domains that allow the DNA or RNA reverse transcription and the ribonuclease activity[124]. Pre-S (1 and 2)/S ORF encode the HBsAg that form the viral envelope; they are distinguished in small, medium, and large surface proteins. Small surface proteins are the most abundant envelope protein and includes the "a" determinant, which is the main target of the neutralizing anti-HBs response. HBV results in an icosahedral shaped, enveloped particle of about 42 nm in diameter[125]. ORF X encodes the HBx protein, whose functions have long been unclear; it can transactivate several viral and cellular gene promoters and cause epigenetic modifications of covalently closed circular DNA (cccDNA)[126].

HBV LIFE CYCLE

The life cycle of HBV has been described in detail. Briefly, the virus initially attaches to the hepatocyte surface through a low affinity binding of S-HBsAg with heparan sulfate proteoglycans. Glypican-5 was recently found to be involved in the early stages of HBV attack on the host cell. Hence, a highly specific bond between L-HBsAg and sodium-taurocholate cotransporting polypeptide takes part, and this is followed by entry *via* endocytosis[120,127,128]. Once inside the cell, the fusion of the envelope with the endosome membrane causes the release of the nucleocapsid into the cytoplasm, and subsequently the HBV relaxed circular DNA is transported to the nucleus. After completion of the positive strand, the HBV DNA is converted into a cccDNA molecule that remains stable in the nucleus in the form of a chromatin-like minichromosome [120,129]. Here it can undergo epigenetic modifications that modify its expression. The cccDNA probably persists for the entire life of the hepatocyte and explains the persistence of this virus and the viral reactivations that occur in certain patients, such as immunosuppressed or those who stop antiviral therapy[128]. The cccDNA serves as a template for the transcription of viral mRNAs by the host's RNA polymerase II. The envelope and the HBx proteins originate from the subgenomic RNAs, while the core protein and viral polymerase derive from pregenomic RNA (pgRNA). This latter is also encapsulated together with HBV polymerase by core proteins to form immature particles. After encapsulation, the pgRNA will serve as a template for the reverse transcription of HBV DNA that is first synthesized in its minus strand[120,128,129]. The latter acts as a template for the synthesis of the positive HBV strand, which will result as partially incomplete. These nucleocapsids are supplied with envelope proteins in the endoplasmic reticulum (ER), and further modifications occur in the Golgi complex[120]. Finally, complete particles and sub-viral particles (including "S" antigen) are released from the host cell. Other nucleocapsids, on the other hand, recirculate in the nucleus to supply it with viral genome. HBV is not cytopathic, and liver damage is mediated by the immune system[107].

CONVENTIONAL AND NEW MARKERS

In the acute HBV infection, the appearance of HBV DNA is followed by HBsAg and HBeAg (the latter, as well as HBV DNA, is a marker of viral replication). HBsAg appears and increases approximately by 1-10 wk after contact with HBV, and anti-HBc IgM and then IgG are found in the serum about 2 wk after the appearance of HBsAg [130,131]. HBV DNA and HBsAg persist for the time of duration of clinical manifestations, while HBe seroconversion usually coincides with the peak of clinical illness [131]. Following the disappearance of HBsAg, anti-HBc IgM may be the only detectable marker. In those who develop them, anti-HBs appear during or after recovery from the disease; they are a marker of immunity against HBV and are found together with anti-HBc IgG in those who had a past infection or alone in vaccinated people[131].

An occult HBV infection (OBI) is defined by the combination of HBsAg absent/HBV DNA present in the liver (*e.g.*, cccDNA) and HBV DNA absent or present in the serum. This phase is distinguished in seropositive OBI [(anti-HBc and/or anti-HBs positive) that may occur both after overcoming an acute infection or following a chronic infection/hepatitis] and seronegative OBI [(anti-HBc and anti-HBs negative) that may result from the progressive loss of antibodies against HBV or because they never developed][132]. It is of crucial importance to recognize an OBI because of the high risk of viral reactivation that exists for such patients in certain circumstances (*e.g.*, anti-CD20 chemotherapy regimens for hematological malignancies)[133].

HBsAg persistence for at least 6 mo is defined as chronic hepatitis B[108,131]. In this case, the HBeAg and HBV DNA persist for a long time. Levels of HBsAg vary in the different phases of the disease and as well as the values of HBV DNA correlate with the risk of developing cirrhosis and HCC[134,135]. As discussed below, HBsAg loss is associated with a reduction (but not abolition) in the occurrence of HBV related complications, but it is a rare event. Furthermore, it is not yet known whether the appearance of anti-HBs confer greater advantages in terms of clinical outcomes than the disappearance of HBsAg alone[135]. In recent years, new biomarkers have been studied to overcome the limitations offered by those currently in use.

HBcrAg is made up of three related viral proteins (HBcAg, HBeAg, and p22cr; the latter is a 22-kDa pre-core protein) that share a 149 amino acids long identical sequence. HBcrAg measurement is not redundant to that of HBsAg, and this marker can also be detected in HBsAg negative patients. It showed an association with intrahepatic cccDNA, intrahepatic pgRNA, HBV translational activity, and serum HBV DNA[136]. From a practical point of view, higher levels of HBcrAg were found to be associated with an increased risk of HCC onset [in nucleos(t)ide analogues (NAs) treated or untreated patients] and recurrence. Moreover, this marker was linked to the risk of viral reactivation, response to treatment, and relapse after therapy withdrawal [136-138]. The latest guidelines for the management of HBV infection of the Japan Society of Hepatology recommend HBcrAg dosage to predict the risk of relapse after cessation of therapy, while in Europe and the United States it has not yet entered into daily practice. Other tools that have been explored in the context of HBV infection include circulating HBV RNA (prediction of response to treatment and relapse after the end of treatment), anti-HBc titers, and HBeAg levels[138].

CLINICAL MANIFESTATIONS OF HBV INFECTION

This virus causes acute and chronic infections. After contact with HBV, the incubation period is approximately 75 d, but it can be very variable[106]. Acute hepatitis B can be asymptomatic or symptomatic, with varying severity. Newborns and children usually have an asymptomatic and anicteric course, while adults can develop a symptomatic hepatitis in 30%-50% of cases. Fulminant hepatitis occurs in about 0.1%-0.5% of infected patients[131,139]; it is probably due to an abnormal response of the immune system and has a very high rate of mortality. In symptomatic patients, the disease can run through the typical course of acute hepatitis (incubation, prodromal, icteric, and resolution periods). A few weeks after the appearance of viral markers in the serum, abnormalities of liver biochemistry can be found[131]; transaminases can exceed 1000 IU/L [with alanine aminotransferase (ALT) greater than aspartate aminotransferase], bilirubin increase can be of varying degrees depending on the severity of the disease, whilst an increase in international normalized ratio (> 1.5) is typical of severe forms [107]. Clinical and laboratory resolution occur in highly variable timescales, depending on the severity of the disease. In adults, the disease spontaneously resolves itself in more than 95% of cases, and this is followed by the appearance of anti-HBs.

Progression to chronic hepatitis mainly depends on the age at which the infection is acquired. It occurs in about 90% of cases if the infection is acquired in the perinatal or infantile period, 30%-50% if acquired by children up to 6-years-old, and less than 5% if acquired in adulthood[106,139]. Chronic hepatitis B proceeds through various phases characterized by different laboratory findings, and chronically HBV infected and untreated people have a 5-year cumulative incidence of cirrhosis of 8%-20%. Therefore, the disease can further progress to the onset of complications and HCC. The latter was found to arise with an incidence rate of 2%-5% per year in HBV cirrhotic patients[106,107]. Viral, host, or environmental related factors (genotype C, older age, male gender, coinfection with HDV, HCV, and HIV, alcohol, diabetes, and others) can increase the probability of worse outcomes, including HCC[107,139]. Several extrahepatic manifestations can be observed in the context of HBV infection and are

thought to be due to the formation of immune complexes with HBsAg or HBeAg. Among these, there are systemic syndromes (serum sickness-like or flu-like), vasculitis (*e.g.*, polyarteritis nodosa), glomerulonephritis, skin manifestations (*e.g.*, purpura and lichen planus), polyarthritis, neurological disorders (*e.g.*, Guillain-Barré syndrome), cryoglobulinemia, and increased inflammatory indices[107,140]. It has also been found that HBV infected people have a higher risk of developing B-cell lymphoma[141].

PHASES OF CHRONIC INFECTION

HBV chronic infection is a dynamic condition, and its course depends on the virus-host relationship. To characterize the disease and choose whether to start the treatment, viral (HBsAg, HBeAg, anti-HBe, HBV DNA) and liver damage (ALT, fibrosis, or necroinflammation through non-invasive tests such as liver elastography or score results or with liver biopsy) markers must be evaluated. Based on the results of these tests, various phases (Table 2) of CHB can be identified[107,142].

The last phase, described above, is the occult phase (also named HBsAg loss phase, resolved CHB, or phase 5)[109,143,144]. Gish *et al*[144] also proposed two theoretical phases: "clearance of cccDNA" and "clearance of cells that have integrated HBV." Progression from one phase to another is not necessarily sequential (*e.g.*, the phase 2 can be followed by phase 3 or directly by phase 4), and the return to a previous phase is also possible. Moreover, in daily practice, several cases of CHB may not belong to any of these phases (for example during transition between phases or in the presence of concomitant liver diseases)[107,143].

HBV AND HCC

HCC has variable incidence rates worldwide, depending on the prevalence of the various risk factors around different geographical areas. Most cases, however, are documented in the Asian regions[145]. In 2015, there were about 854000 incident cases of HCC, and this cancer caused 810000 deaths worldwide; these numbers are expected to increase in the coming years[146]. In most cases, HCC develops in the context of cirrhosis, but it is well known that many HCCs arise in the absence of such disease. Although the prevailing causes of HCC vary by region, HBV is the overall leading cause. Despite an observed increase in the overall number of cases in the 1990–2015 time frame, a deflection of incidence rates of liver cancer due to HBV was also reported during the same period[146]. This virus can cause HCC in the absence of cirrhosis and at a younger age compared to other etiologies[147]. In addition to viral, host, and environmental risk factors mentioned above, several conditions have been associated with the onset of HBV-related HCC[148]: host genetic predisposition (*e.g.*, single nucleotide polymorphisms). Immune response to HBV, cell death, hepatic inflammation, and liver fibrosis create an optimal substrate for the onset of HCC. Mutations in the HBV preS1/S2 domain cause an accumulation of altered large surface proteins in the ER, resulting in the development of oxidative stress. Integration of HBV-DNA into the host genome causes genomic instability or direct involvement (insertional mutagenesis) of cancer-associated genes (*e.g.*, *TERT*, *MLL4*, *CCNE1*).

Viral proteins (HBx, preS and HBc) interfere with critical steps of cell life cycle.

The HBx protein can have a procarcinogenic role as it causes reactive oxygen species production in mitochondria and ER stress. It can interfere in cancer-related pathways (*e.g.*, Jak/STAT, RAS/RAF/MAPK, or Wnt/β-catenin; moreover HBx is able to inactivate p53) and can cause epigenetic modifications of the host DNA. It alters the expression of microRNAs and long noncoding RNAs, and it interferes with processes involved in DNA repair. It was proposed to promote the "stemness" of HCC cells[147-149]. Much knowledge on HBV-related HCC has been accumulated, but there is still a gap compared to what is clinically useful.

CURRENTLY AVAILABLE THERAPIES, GOALS, AND UNRESOLVED ISSUES

The aim of antiviral therapies against HBV is to increase the survival of people suffering from CHB by reducing cases of liver failure, cirrhosis, and HCC and prevent the transmission of the infection. Specific terms are used to indicate the goals of

Table 2 New classification of chronic hepatitis B phases

HBsAg+ ≥ 6 mo	
HBeAg-positive chronic infection (1)	
HBe: HBeAg+; HBV DNA: very high; ALT: persistently normal; Liver disease: minimal or absent	Ex "immune-tolerant;" Typical of children and young adults infected at birth; HBV DNA: > 1 million IU/mL; highly contagious people; Low rate of spontaneous HBeAg loss.
HBeAg-positive chronic hepatitis (2)	
HBe: HBeAg+; HBV DNA: high; ALT: elevated; Liver disease: moderate or severe	Ex "immune reactive HBeAg-positive;" People infected in adulthood are likely to enter this phase; HBV DNA > 20000 IU/mL; rapid progression to fibrosis; Frequent HBe seroconversion.
HBeAg-negative chronic infection (3)	
HBe: HBeAg-, anti-HBe+; HBV DNA: low or undetectable; ALT: normal; Liver disease: low	Ex "inactive HBV carrier;" HBV DNA: < 2000 IU/mL; it can also be > 2000 IU/mL but usually < 20000 IU/mL; Low risk of progression to cirrhosis or HCC; HBsAg loss in 1%–3%/yr.
HBeAg-negative chronic hepatitis (4)	
HBe: HBeAg-, anti-HBe+; HBV DNA: moderate or high; ALT: elevated (variable); Liver disease: moderate or severe	HBV DNA: 2000-20000 IU/mL; Older people, frequent mutant precore HBV; Fluctuating levels of HBV DNA and ALT; Rare spontaneous remission and rapid progression to cirrhosis.

HBV: Hepatitis B virus; HBeAg: Hepatitis B E antigen; HBsAg: Hepatitis B surface antigen; ALT: Alanine aminotransferase; HCC: Hepatocellular carcinoma.

antiviral therapy. With the currently available drugs a "definitive," "sterilizing," or "true" cure for hepatitis B (defined by HBsAg/serum HBV DNA/hepatic cccDNA/integrated HBV DNA not detected) is not possible, given the persistence of HBV DNA in the nucleus[107,150]. The "functional cure" corresponds to HBsAg loss, with or without seroconversion, and undetectable HBV DNA following a course of antiviral therapy. This event, related to both therapy and disease factors, is associated with reduced risk of HCC, liver failure, and other liver-related adverse outcomes[151]. This "ideal endpoint" is uncommon with currently available drugs, but after HBsAg disappearance (both after therapy with NAs or peg-IFN or spontaneous) this result is generally stable and allows patients to stop the therapy[107,135,143]. Experts believe that near-future therapies will have to achieve this goal rather than others (that however may appear more radical), and it is believed that HBsAg loss should be the primary endpoint of phase III trials[150]. In a recent meta-analysis that included 42588 CHB adult patients, it was observed that HBsAg loss occurred in 3194 of them, with an annual pooled seroclearance rate of 1.02%. This event was more likely in patients who were HBeAg negative and those who had lower HBsAg and HBV DNA levels at baseline. On the other hand, the treatment did not have a major effect in achieving this goal[151]. Other studies also obtained similar results regarding the rate of spontaneous or post therapy HBsAg loss. In any case, even after HBsAg loss, the risk of HCC is not eliminated[107,143].

Therefore, the main and "realistic" endpoint that current therapies can offer correspond to suppression of HBV DNA or virological response, defined in different ways depending on type and timing of therapy. Normalization of ALT (biochemical response), loss of HBeAg ± seroconversion, or reduction in necroinflammatory activity (histological response) are other surrogate but important endpoints. The indications for treatment (Figure 2) derive mainly from ALT, HBV DNA values, and from the severity of liver damage defined by liver biopsy or non-invasive tests such as transient elastography or scores such as FIB-4 and FibroTest[107,142]. A recent meta-analysis that included 162 studies and 145789 people with chronic HBV infection from all WHO regions estimated that 19% of infected people were eligible for treatment according to current indications[152].

Antiviral therapy is usually not indicated in those who have HBeAg-positive (ex-immunotolerant phase, IT) or negative (ex-inactive carrier phase) chronic infection [107,150]. IT patients who remain in this phase showed a minimal or no progression of liver disease[153]. Some studies seemed to provide evidence against such indications, showing, for example, a greater risk of worse outcomes in untreated IT patients than those in immune-active phase on NAs[154]. However, these and conflicting results from other studies were partly attributed to patient inclusion criteria[155]. Anyhow, it is not excluded that despite current statements IT patients may benefit in the future from more effective therapies to reduce the viral replication (and the risk of HBV

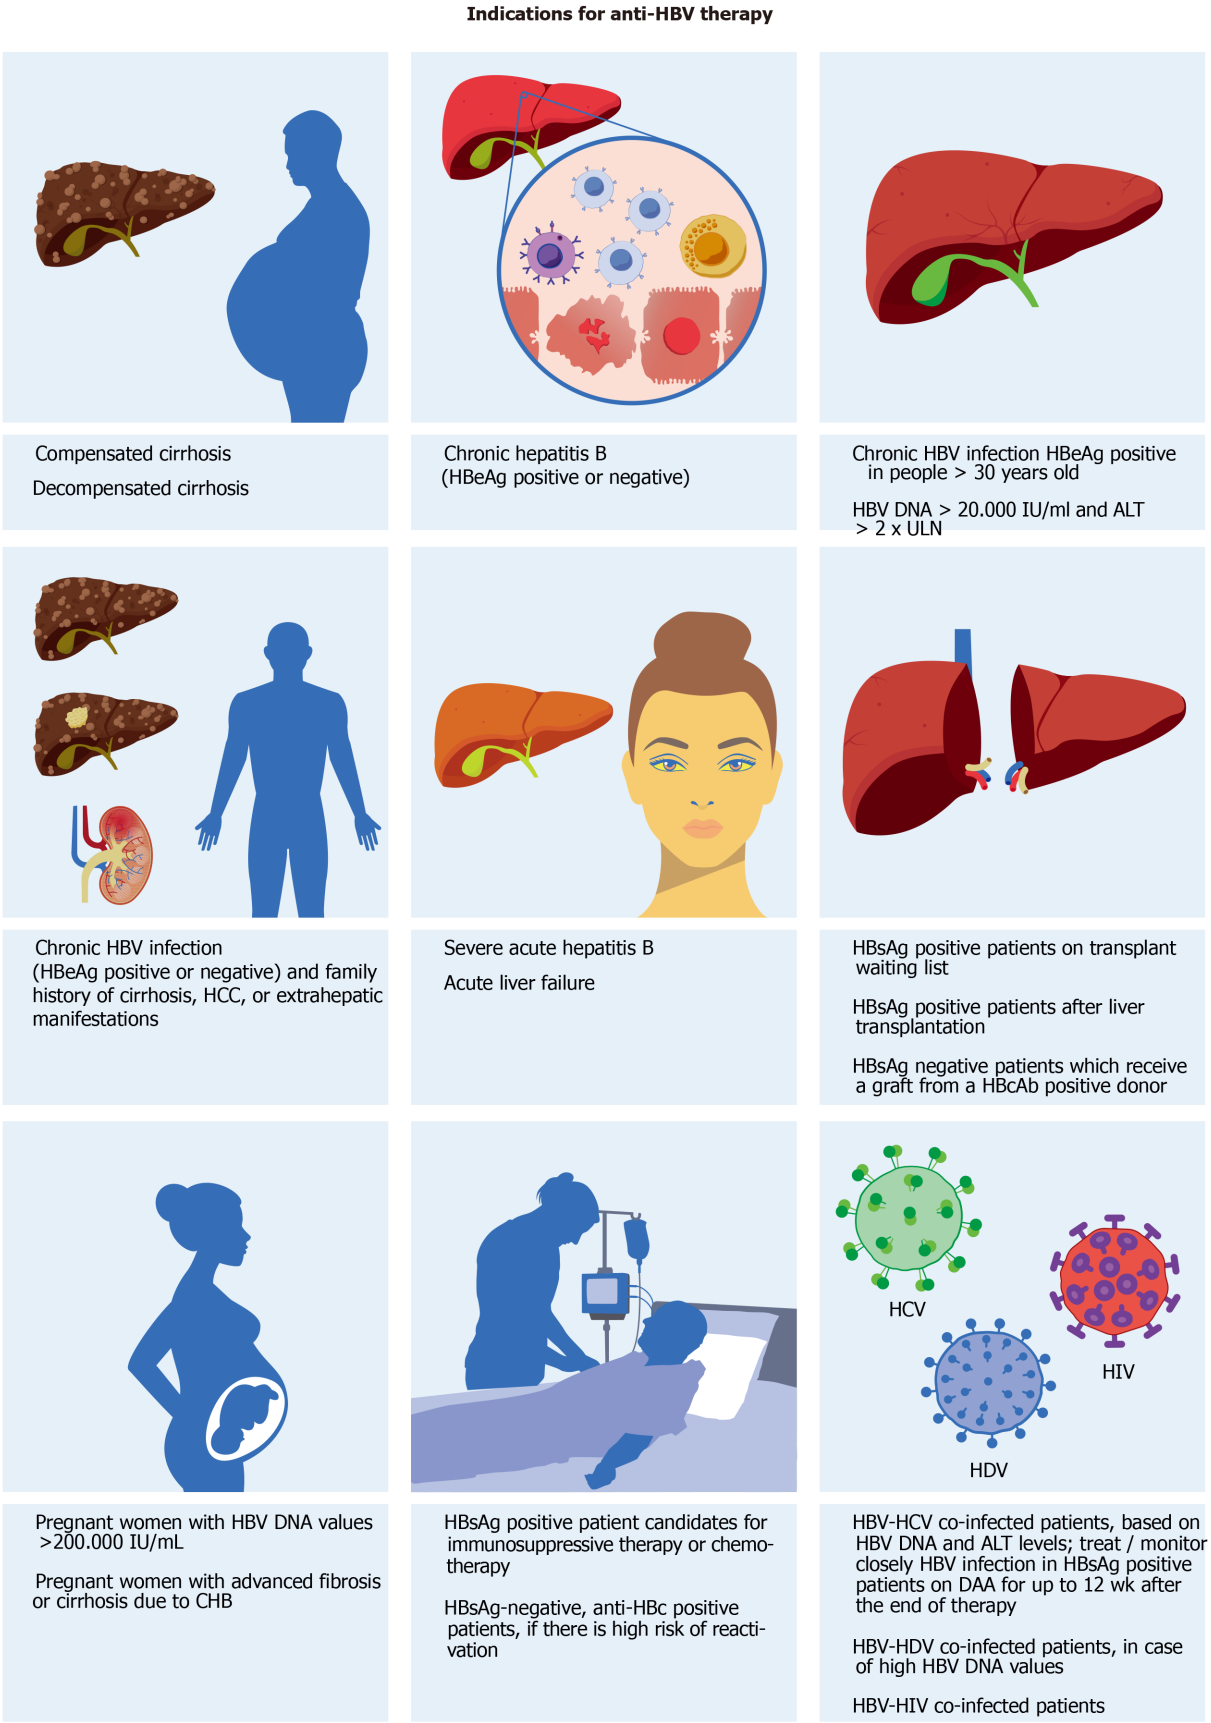

Figure 2 Indications for anti-hepatitis B virus therapy according to international guidelines. HBV: Hepatitis B virus; HCV: Hepatitis C virus; HDV: Hepatitis D virus; HCC: Hepatocellular carcinoma; HBeAg: Hepatitis B E antigen; HBsAg: Hepatitis B surface antigen; CHB: Chronic hepatitis B; ALT: Alanine aminotransferase; ULN: Upper limits of normal; DAA: Direct-acting antiviral agents.

transmission) and potential complications[150].

The drugs currently used for the treatment of HBV infection are: NAs: nucleoside analogues [lamivudine, telbivudine, entecavir (ETV)]; nucleotide analogues [adefovir dipivoxil, tenofovir disoproxil fumarate (TDF), tenofovir alafenamide fumarate; besifovir dipivoxil maleate was recently approved in Korea]; and peg-IFNα.

Between these options, the most used are NAs[107,119]. This class of drugs inhibits reverse transcription activity of HBV DNA polymerase; NAs compete with natural substrates, and their integration in the nascent viral DNA chain interrupts its formation[156]. Lamivudine, adefovir dipivoxil (the first two approved NAs for the treatment of hepatitis B), and telbivudine have a low barrier to resistance and therefore are characterized by a high percentage of cases of resistance during therapy (70% for lamivudine and 29% for adefovir dipivoxil after 5 years of therapy)[107,157]. Despite this, these drugs are still used in some countries mainly for their low cost[157].

On the other hand, ETV, TDF, and tenofovir alafenamide fumarate, the most powerful NAs available today, have a high barrier to resistance. They are associated with higher HBV DNA suppression rates and are the recommended first-line drugs for treatment of CHB. These NAs have a high tolerability and can be used regardless of the severity of the liver disease (even in decompensated cirrhosis) and comorbidities [107]. The occurrence rate of resistance to ETV after 5 years of therapy was shown to be approximately 1% in nucleoside naïve CHB patients, while no cases of resistance were recorded in a 7 year-long study in which 437 CHB patients received TDF monotherapy[158] and in other long-standing studies[107]. Accordingly, the discovery of tenofovir resistant strains would be of considerable impact.

Two cases of viral breakdown addressed to a quadruple mutation (CYEI) were recently reported in CHB patients and linked to the ongoing therapy, which included TDF. It was therefore emphasized that in these cases there would be no consolidated possibilities of therapy[159]. In a response study, however, it was pointed out that CYEI mutation was already documented before the availability of TDF, suggesting that it could (rarely) arise in therapy naïve people. Other evidence behind the reduced susceptibility/resistance to tenofovir has recently been claimed, but currently the clinical impact of this phenomenon is limited[160,161].

Although NAs have been shown to effectively suppress HBV DNA and reduce the progression of liver disease, the disappearance of HBsAg, as already mentioned, rarely occurs, and they have no direct effect on cccDNA. Nevertheless, a study on patients on long-term therapy with NAs showed that they can achieve a reduction in intrahepatic HBV DNA and cccDNA and that the latter can also become not detectable[162]. It was recently observed, however, that among patients that were part of the same study who had undetectable cccDNA, all those who discontinued antiviral therapy (n = 13) experienced an HBV DNA rebound, unlike those who continued treatment. These results suggested that even small, not detectable amounts of cccDNA may allow the virus to reactivate[163]. NAs require frequent monitoring, and usually they must be assumed for an indefinite period. Moreover, the risk of HCC is not eliminated, and long-term therapy is associated with some adverse events. To reduce renal or bone toxicity, ETV or tenofovir alafenamide fumarate should be preferred over TDF[107,142].

Conversely, peg-IFNα is administered for a finite period, generally 48 wk, but longer durations are also recommended in certain cases[107]. The choice between peg-IFNα and the NAs depends on the patient and his preferences, previous treatments, virological factors, and the liver disease. However, it requires subcutaneous injection, and it is associated with well-known side effects. Moreover, due to its non-optimal safety profile, it is contraindicated in patients with decompensated cirrhosis, in cases of other co-morbidities (*e.g.*, autoimmune diseases, psychiatric disorders, cytopenias), during pregnancy, and in severe acute hepatitis B or liver failure, and it is not recommended in some patients with compensated cirrhosis (*e.g.*, those with portal hypertension)[107,142]. Combination therapy (NA-IFN) increased response rates but is currently not recommended as further confirmations are needed[107,119]. The response to anti-HBV therapy and its effect on liver-related outcomes, such as the onset of HCC, were found to vary also by ethnicity (*e.g.*, Asian patients are less likely to experience HBsAg loss following NA therapy than Caucasian ones)[107,119,150].

FUTURE PERSPECTIVES

Many molecules are being studied as a therapy for hepatitis B to improve the results obtainable with the drugs currently available. Among the various approaches, some aim to strengthen the immune response against HBV, while others interfere with

specific steps in its life cycle. Direct elimination of the HBV genome is not yet close to clinical practice[119,164].

HBV entry inhibitors: Bulevirtide binds and inhibits the sodium-taurocholate cotransporting polypeptide, preventing the intrahepatic entry of HBV. The same mechanism of action is shared by Cyclosporin A and its analogues, but the block of bile acids transport should be considered. Other strategies to block cell entry include attack inhibition and antibodies against HBV antigens.

cccDNA inhibitors: TALENs and CRISPR/Cas9 can lead to genome rearrangement by acting in specific sites and are under investigation to evaluate their efficiency in targeting cccDNA. In these cases, the potential risk of making changes to non-target genes has to be considered.

Core protein assembly/allosteric modulators: these molecules interfere with the formation of viral capsid. The class I core protein assembly/allosteric modulators lead to the appearance of abnormal, misassembled, capsid structures, while the class II core protein assembly/allosteric modulators accelerate the formation of morphologically intact but empty capsids (without pgRNA).

RNAi-based agents: in this case HBV transcripts are recognized and degraded by small RNA molecules, resulting in post-transcriptional silencing.

HBsAg release inhibitors: REP 2139 inhibits the release of HBsAg by targeting sub-viral particles, with the aim of counteracting its tolerogenic effect.

RNaseH inhibitors: they inhibit the RNase activity of DNA polymerase, an important step for viral replication. Other options under study include new NAs, innate response stimulating drugs (TLR-7, TLR8, or STING agonists, RIG-1 activator), and therapeutic vaccines.

HBV/HDV INFECTION

Hepatitis D, or delta, is the liver disease caused by HDV that was discovered by Rizzetto *et al*[165] in 1977. A recent review and meta-analysis estimated a 4.5% prevalence of anti-HDV among HBsAg-positive people, corresponding to about 12 million HDV infections worldwide. Other recent estimates, however, provided much larger numbers[166,167]. Its real spread remains elusive probably due to the non-systematic and universal screening in HBsAg positive patients[166,167]. Over recent years a drop in the prevalence and incidence of HDV infection in developed countries, such as Italy, was recorded as presumably the result of HBV vaccination and the increased sensitivity and precautionary measures to counteract risk factors for parenteral and sexually transmitted infections[167-169]. A current issue is delta hepatitis cases due to immigration from high prevalence countries. Nowadays, this infection is highly prevalent in several Asian countries (*e.g.*, Mongolia), West and central Africa, Moldova, and the Amazon region[167-169].

HDV is a defective, satellite virus, 36-43 nm in diameter, which belongs to the Deltaviridae family that in turn includes a single genus (Deltavirus). The latter contains a single species, the hepatitis delta virus. Eight distinct genotypes, with different geographical distribution, have been identified[167]. Its genome consists of a single-stranded negative circular RNA molecule ~1.7 kb long, and encodes only the hepatitis delta antigen (HDAg, distinct in HDAg-S, small, and HDAg-L, large), which together with viral RNA form the HDV ribonucleoprotein[170,171]. HDV exploits the host RNA polymerase II for the replication of its genome. HDV envelope is formed by the S, M, and L proteins of HBV, and the latter is necessary for HDV to enter the host cell as well as in the assembly and exit phases[171]. However, replication within the hepatocyte can occur in the absence of HBV components, and it is thought that in addition to the extracellular propagation pathway, HDV can also spread by a cell-division mediated pathway[172]. This virus has the same modes of transmission as HBV (parenteral, inapparent parenteral, sexual, and rarely vertical)[168,171].

Only HBV infected people can contract delta hepatitis. Coinfection that occurs when HBV and HDV are acquired simultaneously usually manifests itself as an acute hepatitis B, with varying severity up to fulminant hepatitis and has a chronicization rate of 2%-5% in adults. Superinfection refers to an HDV infection in a chronically HBV infected person. In this case, there is a higher risk of severe acute hepatitis and the probability of chronicity is about 80%-90%[168,171-173]. Chronic hepatitis D evolves rapidly towards cirrhosis and its complications[173]. The diagnosis consists in the detection of anti-HDV IgM or IgG and HDV RNA in the serum[168,171]. Current guidelines recommend looking for this infection systematically in HBV infected patients (European Association for the Study of the Liver, Asian-Pacific Association for

the Study of the Liver) or preferentially in certain categories of people (American Association for the Study of Liver Diseases).

Until recently, there were no specific approved therapies for hepatitis D. The latest international guidelines recommend using peg-IFNα to treat this infection (in association with NAs if patients have high HBV DNA levels). This drug demonstrated HDV RNA suppression in 19%-57% of treated patients at the end of the treatment but is characterized by high rates of post-therapy relapse[169]. In addition to the well-known side effects, it should not be used in patients with decompensated disease. Recently, 24 wk of peg-IFN-lambda showed similar antiviral effect but better tolerability compared to peg-IFNα[174].

Bulevirtide acetate (Hepcludex®, previously known as Myrcludex B, MyrB) was approved in 2020 in the European Union for the treatment of chronic HDV infection in adults with compensated liver disease[175]. The recommended dosage is 2 mg s.c. once daily, but the optimal duration of therapy is currently not specified. This drug blocks the entry of HBV and HDV into cells by binding sodium-taurocholate cotransporting polypeptide[175]. The results of a phase 2b clinical trial with primary endpoint HDV RNA reduction by 2 log or HDV negativity showed that 24 wk of treatment with MyrB in combination with TDF allowed patients to reach the endpoint in a significantly higher percentage of cases compared to those on TDF monotherapy (46.4% in the MyrB at 2 mg/die plus TDF arm *vs* 3.3% in the TDF in mono one) and that HDV RNA was suppressed in a dose-dependent manner. Twelve weeks after the end of therapy, however, the relapse was a frequent event[176]. Currently, some studies on bulevirtide are evaluating mono or combination therapies, different dosages, and durations, and the effect on patients with liver disease of varied severity.

Prenylation inhibitors block the prenylation of HDAg-L mediated by farnesyl transferase, preventing the bond of HDAg-L to HBsAg. Oral lonafarnib (LNF) inhibits the farnesyl transferase and makes it impossible for HDV particles to form. It reduced HDV RNA significantly more than the placebo in a study where it was used for 28 d; this therapy was associated with the appearance of some side effects, including gastrointestinal that were the most frequent[177]. Subsequently, LNF was tested in combination with ritonavir (ritonavir inhibits the CYP3A4 that metabolizes LNF, allowing the LNF dosage to be lowered), peg-IFNα, or lambda. The combination peg-IFN-lambda/LNF/ritonavir taken for 24 wk recently showed that it lowered HDV RNA > 2 log in most (25/26) treated chronic HDV patients and led to undetectable or "below the lower limit of quantification" HDV RNA in more than 50% of them at the end of treatment[178].

Among HBsAg secretion inhibitors, there is REP 2139, which in combination with peg-IFNα 2α (REP 301 study) was safe and was associated with HBsAg suppression in 5/12 patients and HDV RNA control in 7/12 patients after 1 year from the end of treatment[179]. This protocol showed persistence of the results in terms of safety and virological control of HBV and HDV over an extended follow-up period of 3.5 years [180].

Liver transplant is a therapeutic option for HDV patients who have not benefited or cannot use medical therapy[169].

HEPATITIS A

HAV is a single-strand RNA virus belonging to the Hepatovirus genus of the Picornaviridae family that was discovered by Feinstone *et al*[181] in 1973. HAV is able to withstand moderate temperatures and to survive in the environment. Therefore, it is transmitted through the orofecal route[182]. The clinical manifestations of HAV infection depend on the age at which the infection is contracted. In children, it occurs in less than 30% of cases with symptomatic hepatitis, while 80% of infected adults have a severe hepatitis with jaundice and a significant increase in transaminases[183].

EPIDEMIOLOGY

HAV infection is widespread worldwide, with a higher prevalence in low- and middle-income countries[184] where the hygienic-sanitary conditions are scarce. Most of the children (90%) contract the infection before the age of 10, often without clinical manifestations. Epidemics rarely occur as older children and adults are generally immune. Intermediate endemicity is observed in North Africa, Eastern Europe, the Middle East, Latin America, and middle-income regions in Asia[185]. High-income

countries such as the United States and West European countries have lower rates of HAV infection, but most of their adult population is not immune to this virus, resulting in a higher probability for this category of developing clinical manifestations due to HAV infection than in the low-income countries[186]. In areas with high endemic and poor hygienic and sanitary conditions, HAV infection is transmitted mainly by contaminated water. In intermediate endemic areas HAV is mainly transmitted through contaminated food and water[187], while in non-endemic countries, risk factors are travel to endemic areas and oroanal sex[188,189].

CLINICAL MANIFESTATIONS

Clinical manifestations of HAV infection range from the total absence of signs and symptoms to acute hepatitis. Acute liver failure (ALF) is also possible, but it is a rare event. This infection usually resolves itself spontaneously and is not responsible for chronic hepatitis. After a period of 2-7 wk from the time of infection, the patient may develop typical symptoms of acute hepatitis, such as jaundice, asthenia, vomiting, dark urine, clay-colored stools, fever, or general malaise[190]. Blood tests show a severe increase in transaminases (also 100 times the upper limit of normal), usually with ALT > aspartate aminotransferase, increased total bilirubin, and increased alkaline phosphatase. It is important to monitor PT and the onset of portosystemic encephalopathy to assess the presence of ALF[191], although this is a very rare occurrence (less than 1%)[192]. Atypical manifestations may also be present, including relapse hepatitis, autoimmune hepatitis, prolonged cholestasis, and acute kidney failure[193]. Considering that the clinical presentation of hepatitis by HAV is similar to any other hepatitis, the diagnosis of HAV infection requires the dosage of IgM anti-HAV. IgM anti-HAV becomes detectable in the blood about 5 d after the onset of the disease and remains positive for a short period after healing. The recent execution of the HAV vaccine can determine a positive test result for IgM anti-HAV. The presence of IgG anti-HAV indicates a previous HAV infection[194].

THERAPY AND PREVENTION

There is no specific cure for HAV acute hepatitis. Therefore, supportive therapy is indicated, trying to alleviate the symptoms of the infection (fever, nausea, vomiting) and intervening on any other complication (dehydration, electrolytic abnormalities, *etc.*). IFN has been evaluated in the past for the treatment of hepatitis A. This drug has been shown to reduce viral replication in cell cultures[195] and has been administered in sporadic cases of patients with severe or fulminant hepatitis secondary to HAV infection[196]. Sofosbuvir showed the ability to inhibit replication of HAV *in vitro* [197], but there are no reported cases in literature where this drug was administered *in vivo*. Viral hepatitis are responsible for 12% of acute liver failure, and of these only in 0.35% of cases the causative agent is HAV[198]. HAV infection is the main cause of ALF in the pediatric population in some countries[199-201]. Liver transplantation is necessary in 30% of ALF due to HAV infection, therefore it is a rare indication[198]. In some case reports, the effectiveness of plasma exchange in ALF therapy due to HAV infection is reported[202,203], while the use of corticosteroids in a small cohort of children was associated with reduced hepatocyte destruction and with higher survival rates compared to controls[204]. N-acetyl cysteine, although very effective in ALF secondary to paracetamol abuse, does not appear to provide any benefit in the treatment of HAV related ALF[205]. In the case of worsening liver function, liver transplantation is required[206]. Liver transplantation in ALF secondary to HAV infection is burdened with a high mortality[207] and is rarely complicated even by a post-transplant HAV reinfection[208].

The improvement of sanitary conditions and vaccination play a fundamental role in the prevention of HAV infection[209,210]. Available vaccine formulations for hepatitis A (inactivated and attenuated) have proven effective and safe in immunizing in large trials involving nearly 750000 patients worldwide[211]. The vaccine can be administered in one or two doses 6 mo apart to obtain long-term immunization[212]. Lower protection rates following vaccination are observed in immunosuppressed patients, (HIV-infected patients, transplant recipients) and in elderly people[213,214]. The administration of the vaccine is particularly recommended in patients with concomitant chronic HCV and/or HBV infection[215] and in non-immune people traveling in areas of high endemia[216,217]. The vaccine may also be administered in

secondary prophylaxis, single-dose, 14 d after contact, after the exposure to a patient with known HAV infection, showing the same efficacy as immunoglobulins[218].

HEPATITIS E

Hepatitis E, the liver disease caused by HEV, is a health problem that is receiving increasing attention over the years, although many aspects concerning this infection are still lacking. It has a self-limiting and benign course in most people, but some categories are particularly at risk of serious outcomes, such as pregnant women who have a mortality risk of about 25%, immunocompromised patients who can develop a chronic hepatitis (and its consequences), and patients with previous liver disease who are at risk of acute-on-chronic liver failure.

EPIDEMIOLOGY

The strong negative impact of HEV on human health can be deduced from data estimating that in 2005 there were about 20.1 million cases of hepatitis E (genotypes 1 and 2) infections and 70000 deaths worldwide[219]. A recent study[220] estimated that more than 900 million people have had contact with this virus; moreover, in many regions of the world HEV is the leading cause of acute viral hepatitis[221]. While in some countries HEV infections appear to have remained stable, in others, including European ones, there has been an increase over time (data probably explained also by an increase in identifications)[221,222]. However, the real burden of hepatitis E on human health is not yet fully known[220].

The transmission mode and diffusion of HEV infection vary greatly depending on the countries, and in the same country there are some epidemiological differences depending on the areas (*e.g.*, southwest compared to other regions in France)[221,223]. The most frequent transmission mode in areas of the world with poor hygiene standards is the oral-fecal route, mediated by water (genotypes 1 and 2), while in developed countries is zoonosis (genotypes 3 and 4)[223].

DISCOVERY AND VIROLOGY

The existence of an enterically transmitted non-A, non-B hepatitis virus was first hypothesized in 1978 by Khuroo[224], while identification under microscope occurred in 1983. The name "hepatitis E virus" was proposed for the first time in 1988[225].

HEV is a non- or quasi-enveloped icosahedral virus, 27-34 nm in size that contains a single strand, positive-sense RNA 7.2 kb long. The quasi-enveloped variant that exists in circulation is due to the lipid membrane originating from infected cells. The HEV RNA genome contains three ORF: ORF1 encodes a polyprotein that includes an RNA-dependent RNA polymerase; ORF2 encodes the capsid protein; and ORF3 encodes a protein involved in the viral egress[221,225]. ORF 4, recently described for HEV-1, has a supporting role for viral polymerase[226]. Despite the advances in knowledge of this virus, several aspects of the HEV life cycle are not yet known, including the exact mechanism by which the virus enters the host's cells (*e.g.*, entry receptors), some aspects of the relationship between host components and virus, and many processes concerning assembly and cell exit[227].

It is likely that, as well as other major hepatotropic viruses, HEV causes liver damage mainly through an immune-mediated mechanism[228]. Briefly, the host response starts with an initial phase in which the innate immune system detects the virus through pathogen recognition receptors such as TLR3, TLR7, RIG-I, and MDA5 [229,230]. Subsequently, the production of IFN and other cytokines or chemokines that amplify the response against HEV take part[229,230]. Liver migration and activation of innate cells such as natural killer and neutrophils and then recruitment of T lymphocytes determine the antiviral response and contextually the immune-mediated liver injury[228,231]. The immune response (including antibodies) against specific regions of the ORF2 protein is critical in the fight against the virus. Although the HEV can hinder some steps of both innate and adaptive responses[228,229,232], the combination of these events usually leads to the clearance of the virus. Anyhow, the role of anti-HEV antibodies in the resolution of the infection[232] as well as the specific role of other elements of the immune system in the host-HEV relationship is not yet

fully understood.

DIFFERENT GENOTYPES AND TRANSMISSION ROUTES

HEV is part of the Herpesviridae family that is divided into two genera, Orthohepevirus and Piscihepevirus. The genus Orthohepevirus includes four species (A-D), while the genus Piscihepevirus has only the Piscihepevirus A species. Eight distinct genotypes belong to the Orthohepevirus A species, and some viral subtypes of these genotypes have been recognized[225,233].

Orthohepevirus A genotypes 1, 2, 3, and 4 (HEV-1, HEV-2, HEV-3, and HEV-4) infect humans differently from the other genotypes of this species[225,226]. However, a case of a middle-aged liver transplanted Somalian man who regularly consumed camelid meat and milk infected with dromedary HEV (HEV-7) was also described [234].

HEV-1 and HEV-2 are restricted to higher primates (humans and several species of monkeys), but the finding of HEV-1 in the serum of Egyptian horses suggested that in rare circumstances transmission of these genotypes to other animals is also possible [233].

HEV-1 and HEV-2 spread among the human population mainly by the oral-fecal route that consists in ingestion of water contaminated with human feces[221,223,225, 235]. This phenomenon typically occurs in regions of the developing world with poor hygiene standards, such as those in which untreated water, for example of a river, is drunk or used for cooking, bathing, and waste disposal. In such contexts, climatic changes (*e.g.*, heavy rainfall or monsoons) can increase the risk of HEV infection spreading[235,236]. These genotypes are responsible for the occurrence of epidemics and outbreaks. The first one to be retrospectively documented broke out in Delhi (India) in 1955[225]. Today HEV infection is considered hyperendemic and associated with the development of outbreaks in various parts of north, east, and west Africa, south and central Asia, the Middle East, and Latin America[223,236]. In such areas, a high percentage of inhabitants were found to be anti-HEV IgG positive[220]. The typical route of transmission of these genotypes makes it conceivable that an improvement in hygiene conditions could result in a containment of the spread of infection[221,225]. In addition to the orofecal route, vertical *via* blood transfusion and person-to-person transmissions were documented[225,236]. In developed countries, where a better level of sanitation is guaranteed, HEV infection is sporadic and it is acquired as zoonoses, by travelling to endemic areas, or by blood transfusion[221,225].

HEV-3 and HEV-4 infect animals (including pigs that are the main reservoir and source of contagion for humans, wild boars, and deer) and humans and are responsible for the zoonotic form of the disease. They can be transmitted to humans in several ways: consumption of undercooked or raw meat (a recurring example in literature of a source of infection are the Corsican sausages "figatelli" that contain pork liver) or milk from infected animals; consumption of fruits, vegetables (strawberries, raspberries, lettuce, *etc.*), or seafood contaminated with feces of infected animals, and direct contact with infected animals (farmers, veterinarians, slaughterhouse workers) [221,223,225,236]. Today it is known that in addition to the most often mentioned animals (pig, wild boar, and deer), many others can serve as reservoirs for HEV-3 and HEV-4 (*e.g.*, rabbits, cattle, rats, goats, sheep, dogs, horses, Java mongoose, dolphins, clouded leopard, Asiatic black bear, and others)[233]. An aspect not yet well known is which animals are "true hosts" for HEV and which others host it transiently. Blood transmission is also possible for HEV-3 and HEV-4[221].

The other Orthohepevirus A genotypes were identified in animals: HEV-5 and HEV-6 in wild boar, HEV-7 and HEV-8 in camelidae (dromedary and bactrian camel, respectively)[233].

Orthohepevirus B, of which four genotypes are known, has been isolated mainly in chickens but also in turkeys, ducks, and other birds. However, the possibility that some of its strains can infect mammals cannot be ruled out[233]. In the Orthohepevirus C species there are two different genotypes (HEV-C1, HEV-C2), whose presence has been documented in different types of rodents (rats, mice, shrews, ferrets, minks, and others). Some cases of human infections from rat HEV have been recently discovered in patients from Hong Kong and in a man suffering from acute hepatitis, who probably contracted the infection in central Africa[233,237,238]. Orthohepevirus D species was isolated in the bat. The Piscihepevirus genus includes only the Piscihepevirus A species that infects the cutthroat trout and other fish[233]. An illustration of the link between HEV genotypes, hosts, and routes of transmission is provided in Figure 3.

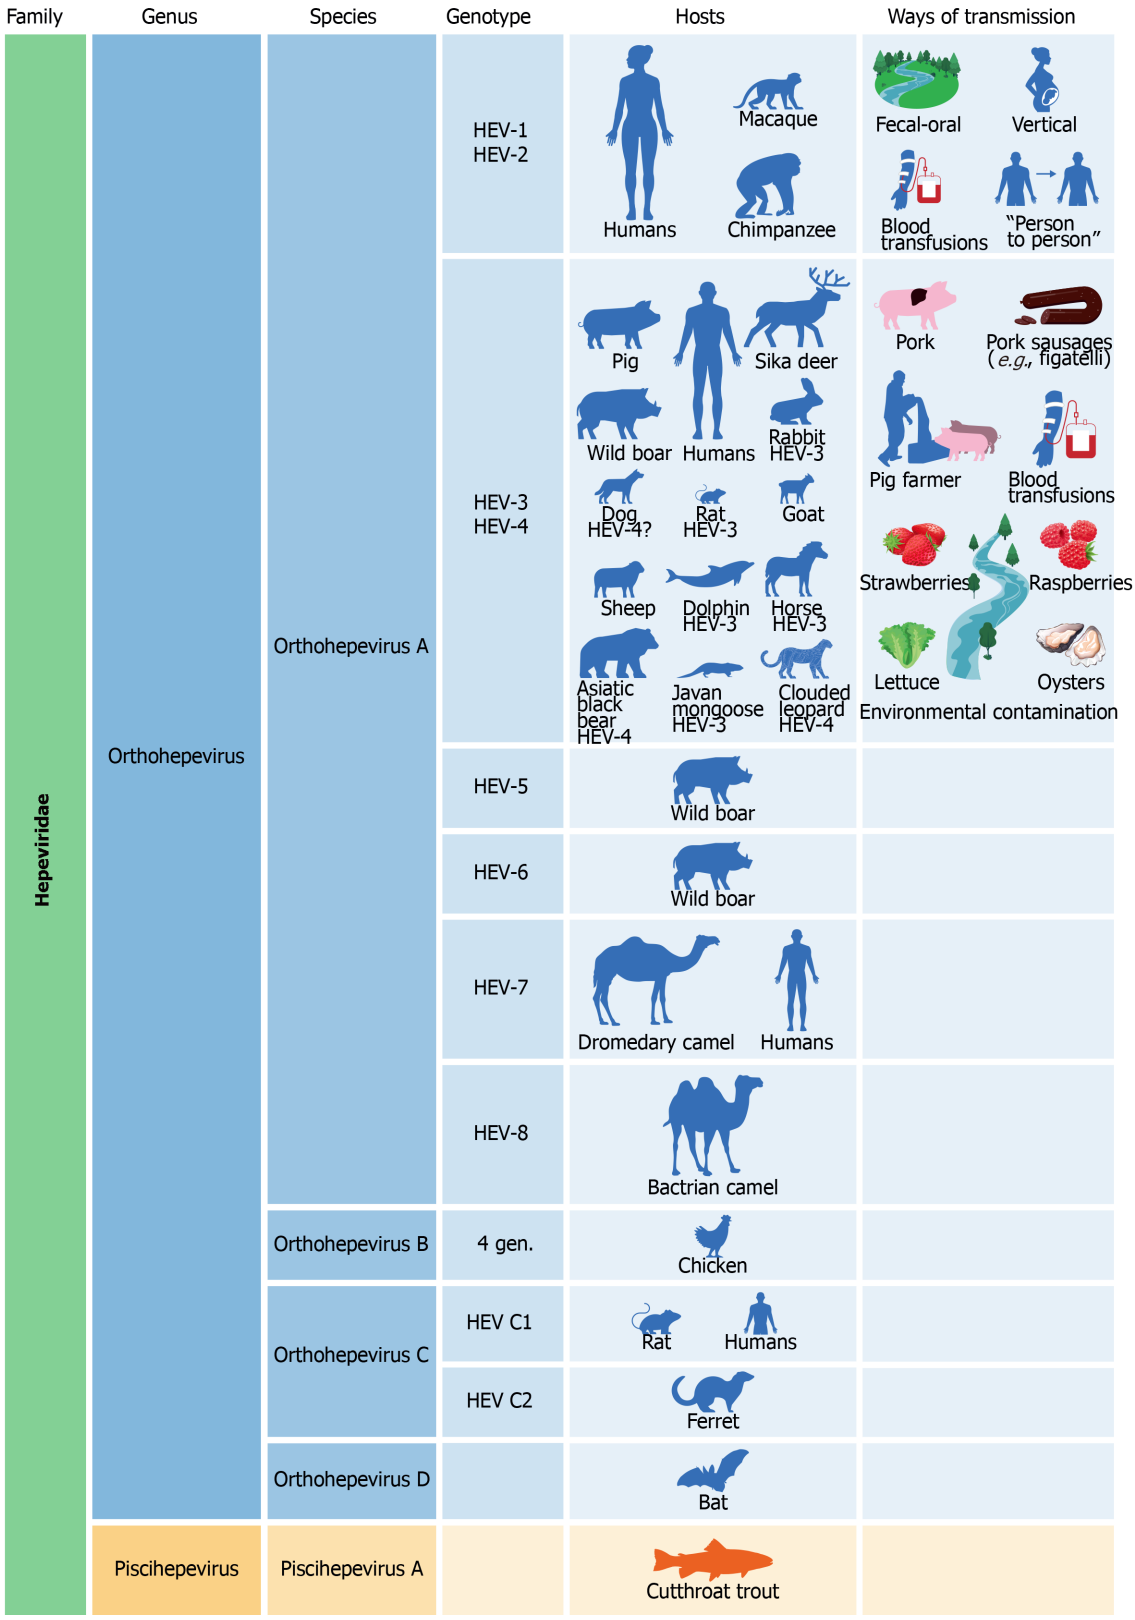

Figure 3 Classification, hosts, and ways of transmission of the hepatitis E virus. HEV: Hepatitis E virus.

DIAGNOSTIC TESTS

Anti-HEV IgM appear about 4 wk after infection, approximately with the onset of symptoms, and their persistence in the serum is variable (they usually last 3 or 4 mo, but cases in which they were detectable after a longer time were also described). Given their kinetics, they reveal a recent infection and can be considered a marker of acute hepatitis E[221,239,240]. In addition to anti-HEV IgM, anti-HEV IgA antibodies are

considered markers of acute hepatitis E, but it is not a widely used test[221].

Conversely, anti-HEV IgG appear after anti-HEV IgM and last several years. They are used to diagnose a past infection and are indispensable for seroprevalence studies of such disease. Because anti-HEV IgG appear quite early in the course of the disease they can be detected together with IgM in the acute phase; in this way they help to reduce the misdiagnosis rate that occurs if IgM are considered alone[221,240]. The antibodies against HEV are determined by enzyme immunoassays[239,240]. For diagnostic purposes, due to the non-optimal reliability of antibody assays, guidelines of the European Association for the Study of the Liver recommend using the anti-HEV IgM (or anti-HEV IgG) in combination with the HEV RNA, or antibodies in combination with each other, or HEV RNA (in blood or stool) alone to reveal a current infection[221].

HEV RNA is detectable soon after infection before symptoms appear and generally lasts a maximum of 6 wk; it confirms the diagnosis of infection. To improve comparability of nucleic acid amplification test results and ensure a correct genotype identification, the WHO defined international standard and an international reference panel for HEV genotypes 1-4. Another direct test consists of the search for the HEV capsid antigen, but its role in the diagnosis is still unclear[221,240]. Currently it is difficult to know how widespread screening is for HEV, but the raising awareness of the spread of hepatitis E even in high-income countries over the years will likely result in a reduction of undiagnosed cases in the near future.

CLINICAL MANIFESTATIONS

After HEV contact, the incubation period is about 2-6 wk, but it can be very variable. HEV infection is generally asymptomatic or with very few symptoms and self-limiting. This aspect also contributes to the non-definitive knowledge on the real diffusion of the disease. In about 5%-30% such infection is symptomatic and has a similar course to that of other acute hepatitis. In these cases, the infection is responsible for nonspecific symptoms, such as asthenia, nausea, vomiting, fever, muscle, and joint pains and then jaundice, itching, dark urine, and light-colored stools. Contextually, blood tests can show alterations in liver biochemistry such as high transaminases (ALT often exceeds 1000 IU/L), bilirubin, gamma glutamyl transferase, and alkaline phosphatase. It was observed that HEV-3 and HEV-4 tend to be associated with clinically more severe hepatitis in older males, but the underlying reasons are still unclear. Rarely can HEV infection result in ALF[219,223,225,239,240].

While healthy, immunocompetent people usually have a benign course, there are some categories for whom HEV is more dangerous. Patients with pre-existing chronic liver disease can develop acute-on-chronic liver failure due to hepatitis E virus infection[223,226]. Nowadays it is estimated that many cases of liver damage of undetermined etiology or suspected drug origin are caused by HEV. For this reason, it is recommended to test patients with liver biochemistry compatible with hepatitis or diagnosed with ALF or acute-on-chronic liver failure of still undetermined etiology for HEV infection in addition to other causes of liver injury.

Immunosuppressed patients, including organ or stem-cell transplant recipients, HIV infected patients, patients receiving chemotherapy for hematological diseases, or long-term therapy for autoimmune disorders are another category at risk of worse outcomes[221,226,240-242]. In these patients the risk of developing chronic hepatitis E is consistent, given the inability of their immune system to eliminate the virus. Studies on organ transplant patients infected with HEV showed a chronicization rate of more than 60%[243]. In this group, it is debated whether to consider "chronic" an infection from HEV when the RNA has been identifiable for at least 6 mo, or if it is detectable for more than 3 mo after infection[221,244]. Chronic HEV infection has been described mainly for genotype 3, but chronic infections from HEV-4 were also reported, and one case of chronic infection by HEV-7 (as reported above) was described.

Some cases of chronic hepatitis E by HEV-1 have recently been claimed[245,246]. Chronic hepatitis E generally has a slightly symptomatic or asymptomatic course, with only mild alterations of liver biochemistry[240,241,243]. Moreover, anti-HEV antibodies can often give false negative results, and therefore the search for HEV RNA is particularly useful in these people[240]. This form can progress through the development of increasingly severe fibrosis up to decompensated cirrhosis. Liver injury, as has already been observed for other viral hepatitis, can regress after the elimination of the virus[221,240].

HEV-1 and HEV-2 are responsible for a high percentage of liver failure and mortality (25%-30%) in pregnant women during the third trimester, and HEV infection during pregnancy was also associated with increased neonatal morbidity (*e.g.*, preterm birth) and mortality[223,247]. Several factors have been hypothesized to explain the high severity of HEV infection in pregnancy, including host (hormonal and immune changes) and virus-related factors, but the exact causes are not known[247]. Another noteworthy aspect is that there are considerable geographical differences regarding the severity of the course of HEV infection in pregnancy[223].

The hepatitis E virus is responsible for several extrahepatic manifestations. The pathophysiology of these events is not yet fully understood, but direct damage by the virus is not excluded[221,226,240]. It has been observed that HEV can replicate in many other locations besides the liver, and these findings raised the hypothesis that the entry receptors of HEV are not limited to hepatocytes. Among the extrahepatic manifestations there are neurological disorders (Guillain–Barré syndrome, neuralgic amyotrophy, Bell's palsy, meningoencephalitis, peripheral neuropathy, mononeuritis multiplex), kidney injury (membranoproliferative and membranous glomerulonephritis, IgA nephropathy), hematologic disturbances (thrombocytopenia, hemolysis, aplastic anemia, monoclonal immunoglobulin, cryoglobulinemia), acute pancreatitis, and some reports of thyroiditis, arthritis, and myocarditis[221,240].

THERAPY AND VACCINE

Antiviral therapy is usually not necessary for acute hepatitis E, and in any case, there are no specific or extensively tested treatments. In cases of severe forms of hepatitis E and liver failure, RBV was successfully used and resulted in improvement of liver biochemistry and clearance of HEV RNA; corticosteroids have also been shown to be effective in some patients[221,240].

For patients diagnosed with a chronic form of hepatitis E in the context of transplant recipients, it is recommended to reduce immunosuppressive therapy as a first step. This measure alone proved to cause HEV clearance in a consistent percentage of patients (nearly one-third)[221,243]. Currently, RBV represents the therapy of choice for chronic hepatitis E, but its mechanism of action against this virus remains unknown. In a retrospective study on 59 organ transplant patients suffering from chronic hepatitis E treated with RBV, the SVR rate was 78% after a first course, and 85% if re-treatments are considered[248]. In another study of 255 organ transplant patients with chronic HEV infection, 81.2% of them reached SVR after the first course [249]. In these studies, RBV was used with a median dose of 600 mg/d for a median duration of 3 mo, and this is the most used protocol. As known, RBV treatment can be associated with the onset of side effects including hemolytic anemia, skin reactions, or a dry cough. Furthermore, due to its teratogenic potential, the use of RBV is not recommended in pregnancy, and for this category careful monitoring and supportive care must be provided; therefore, prevention of infection is a key point[221,247].

Peg-IFNα is another drug used for hepatitis E in liver transplanted patients and people undergoing hemodialysis, but it is contraindicated in kidney, heart, lung, and pancreas transplant recipients due to the risk of rejection[221,240]. In cases of non-response or intolerance to RBV and the patient is not eligible for IFN, there are no options to continue therapy[221,249,250]. A recent study in which sofosbuvir in monotherapy was used in nine chronic hepatitis E patients showed the ineffectiveness of this drug in eliminating HEV[250]. For these reasons, there is a need for new effective drugs with specific anti-HEV activity[250,251].

An HEV vaccine (Hecolin®) has been available in China since 2011; this vaccine was designed based on the ORF2 region of HEV-1 and showed very high efficacy in preventing symptomatic hepatitis E in a randomized placebo-controlled trial[252]. It proved to be effective for several years, but the overall duration of protection is yet to be known. The vaccine looks safe in pregnant women, but further concrete data is needed. The other open questions are efficacy and safety in specific categories of patients (such as those suffering from chronic liver diseases) and effectiveness against other genotypes[221].

CONCLUSION

In conclusion, although viral hepatitis still represents a major public health problem and a leading cause of mortality, important milestones have been achieved in this

field. Nowadays, hepatitis C is curable in almost all patients by simple, safe, and short-course therapies. To eradicate it, it is crucial to focus on case-finding and linkage to care initiatives. The scenario of hepatitis B and D is changing, with a reduction in their prevalence largely due to the anti-HBV vaccination. Currently available anti-HBV therapies are effective in suppressing viral replication, but they do not eradicate HBV. However, several new therapeutic approaches are being studied for HBV and HDV infections, and in 2020 an entry inhibitor for the treatment of chronic hepatitis D was approved in the European Union. Improvements in hygiene conditions and vaccination can prevent hepatitis caused by HAV and HEV, but the vaccine against the latter virus is not available in all countries. Hepatitis E still represents a challenge as its pathophysiology and real spread are not fully known. Moreover, currently available treatment options are not feasible in all patients.

Abstract

This review summarizes the safety and efficacy of statins in patients with cirrhosis. Due to concerns about the safety of statins in patients with impaired liver function, they have recently been investigated as a potential treatment option in cirrhosis. The most clinically significant adverse event is statin-related myopathy, and this may be related to the high serum statin concentrations in the setting of severely impaired liver function. Rhabdomyolysis is the most serious and potentially life-threatening manifestation. It has recently been demonstrated that the recommended dose of simvastatin in patients with decompensated cirrhosis would be 20 mg/d because higher values, such as 40 mg/d, are associated with many adverse events, especially muscle injury. Likewise, simvastatin should not be administered to patients with Model for End-stage Liver Disease score > 12 and/or Child-Pugh class C because of the high risk of severe muscle injury. Due to the pleiotropic effects, the focus on statins has shifted from being considered harmful to something useful. Through these effects, statins could prevent liver-related morbidity and mortality in cirrhotic patients. Observational studies in large populations of patients with cirrhosis have shown that treatment with statins to decrease high cholesterol levels was associated with a reduced risk of hepatic decompensation, hepatocellular carcinoma development and death.

The few randomized controlled trials in patients with cirrhosis and portal hypertension showed that statins lower portal pressure, quite likely through a reduction in hepatic resistance. Another large randomized controlled trial in patients with variceal bleeding showed that simvastatin in addition to standard of care did not prevent rebleeding but improved survival rate. Despite these encouraging outcomes, the quality of the evidence regarding the use of statins is low or very low due to the observational characteristics of most of the studies involved. Therefore, it is advisable to perform further randomized controlled trials on a large series of patients with hard clinical endpoints, using different statin types and varying doses. The objectives would be to prevent liver-related morbidity and mortality rather than treating cirrhosis complications to take additional information that makes it possible to add statins to the standard of care of these patients.

Key Words: Cirrhosis; Liver disease; Statins; Safety; Efficiency

Core Tip: Several observational studies of statins in patients with liver disease were published, but they were highly biased. On the other hand, only one randomized controlled trial improved survival in Child-Pugh class A/B patients but did not reduce variceal rebleeding. Finally, the dose and type of statin to be used should be defined. This review concludes that new randomized controlled trials are necessary before endorsing statin use in patients with chronic liver disease.

INTRODUCTION

The 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors, "statins," have been used for more than three decades to treat the increase of serum cholesterol by inhibiting its synthesis *via* the competitive inhibition of the hepatic enzyme HMG-CoA reductase [1]. They represent a breakthrough in the treatment and prevention of atherosclerotic cardiovascular disease. High-quality evidence from large randomized controlled trials (RCTs) supports the use of statins in primary and secondary prevention of atherosclerotic cardiovascular disease[2-5]. Nevertheless, no patients with liver disease were included in these trials, and consequently there is limited data regarding the therapeutical role of statins over this population.

Atherosclerosis has been widely recognized as an inflammatory process[6]. Statins prevent inflammatory atherosclerotic cardiovascular disease by two mechanisms: the first one is direct and acts by reducing the plasma cholesterol levels, and the second one is indirect and independent of cholesterol levels, also known as the pleiotropic effect. This effect reduces atherosclerotic inflammation independently of the serum cholesterol levels and any cholesterol levels variation[7,8]. The isoprenoid intermediates, such as farnesyl-PP and geranylgeranyl-PP, are essential in the biosynthetic pathway of cholesterol. These isoprenoid intermediates lead to isoprenylation, adding lipophilic molecules to various proteins, including the small guanosine triphosphate binding proteins Rho, Ras, and Rac (also known as small GTPases), which are activated and translocated from the cytoplasm to the cellular membrane. The inhibition of isoprenylation of Rho, Ras, and Rac by statins keeps them inactive in the cytoplasm, as shown in Supplementary Figures 1 and 2. The inhibition of isoprenoid intermediates favors the pleiotropic effects of statins by preventing small GTPase protein isoprenylation, implicated in intracellular signaling pathways[8].

Moreover, the activity of Rho kinase is reduced by the inhibiting effect of statins upon both hepatic stellate cells (HSC) and liver sinusoidal endothelial cells[9]. In experimental models, these effects seem to reduce collagen production and the activation of HSC in early fibrosis and proliferation, cytokine production and contraction of activated HSCs in cirrhosis[9,10]. Additionally, statins might decrease the turnover of HSCs inducing the senescence of these high activity cells[9-11]. On the other hand, in cirrhotic livers, statins improve endothelial dysfunction by the upregulated activity of endothelial nitric oxide synthase and nitric oxide availability and lower portal pressure[9,12]. Krüppel like factor 2 mediates statin-induced upregulation of endothelial nitric oxide synthase to decrease HSC activation and produce a further decrease of portal pressure[13,14]. These data deliver the rationale for statin use in patients with cirrhosis and portal hypertension[15,16].

This review will discuss available evidence about the safety and efficacy of statins in patients with cirrhosis.

SAFETY

The most commonly reported adverse events during treatment with statins are relatively mild and often described as transient gastrointestinal symptoms (diarrhea, abdominal pain, flatulence and constipation), headache and rash[17]. Muscle injury, liver injury and new-onset diabetes mellitus are proven adverse events of statin therapy[18]. Statin plasma levels have been regarded as an index of these potential adverse events[19], and they depend on several factors[20]:

(1) Statin dose: High-intensity statin therapy reduces cardiovascular events more than lower intensity equivalent treatment, but the safety impact of using the first one is unknown. On that subject, a meta-analysis showed that high-intensity statin therapy augmented the incidence of increased aminotransferase levels [relative risk = 3.10; 95% confidence interval (CI): 0.88-7.85] compared with lower intensity statin therapy. Based on clinical trials, the authors conclude that an aggressive statin therapy increases aminotransferase levels more than a lower intensity one[21].

(2) Statin type: In a rat model, Nezasa *et al*[22] showed that rosuvastatin was taken up by hepatocytes more selectively and more efficiently than simvastatin. A possible reason for this finding is that rosuvastatin requires an anion transporter to enter into the cells in the same way as pravastatin, another hydrophilic statin. On the other hand, simvastatin does so by passive diffusion. This possibly happens due to its greater lipophilicity, and in this way, it is similarly taken up by the liver and by extrahepatic tissues as other lipophilic statins do, such as atorvastatin and fluvastatin. These different mechanisms of entry into the cells may be consistent with specific organ toxicity.

In the meta-analysis mentioned above, when evaluating the different effects of hydrophilic and lipophilic statins were studied, higher intensity therapies based on the first ones showed an increased risk for raising aminotransferases levels, whereas those using lipophilic statins did not. Regarding creatine kinase (CK) levels, these were not increased during evaluating hydrophilic statins, whereas lipophilic statins revealed an increased risk with higher intensity treatment[21]. Therefore, the increase in aminotransferase levels is likely to be more troublesome when high doses of hydrophilic statins are prescribed, whereas CK elevations become problematic with equally aggressive lipophilic statin treatment.

(3) Drug-drug interactions: Drug interactions that involve statins may be enhanced in the setting of cirrhosis, given the altered statin pharmacokinetics[23]. In this sense, the total body clearance of statins is very high due to the important hepatic first-pass effect. Except for pravastatin metabolized enzymatically in the liver cytosol, all statins undergo extensive microsomal metabolism by the cytochrome P450 isoenzyme systems[20]. The cytochrome 4503A4 isoform commonly has a competitive inhibition with drugs at the enzymatic level and may alter statin disposition, leading to increased plasma levels and greater risk of adverse events[24]. Since 2011, the United States Food and Drug Administration is assuming a more significant role in post-marketing surveillance and keeping package labeling of statins with current contemporary literature[25]. In Supplementary Table 1 are shown simvastatin-drug interactions[26]. This information is deemed incomplete, therefore an updated bibliography and other tools for evaluating the interaction with each drug are needed. It is important to note that there are no simvastatin interactions with drugs commonly used in cirrhosis, such as non-selective β-blockers (NSBBs), diuretics, quinolones, rifaximin and anticoagulants.

Also, the consumption of grapefruit juice, at more than 1 quart per day (approximately 1 L/d), is known to inhibit cytochrome 3A4 isoenzyme activity in the enterocyte[27]. Likewise, gemfibrozil therapy reduces glucuronidation and consequently the elimination of statins[28]. Therefore, the effect of both could increase statin availability and in turn potentially raise their systemic exposure and side effect occurrence.

(4) Reduced statin metabolism and/or transport activities: It is well known that cirrhosis significantly affects statin pharmacokinetics[29]. However, although no study has so far evaluated the pharmacokinetics of simvastatin in cirrhotic patients, there are data with other statins in Child-Pugh (CTP) class A and class B patients[30-32]. So far, there are no reports about the pharmacokinetics of statins in CTP class C patients. It is known that the maximum plasma concentration increases with rosuvastatin, the area under the curve becomes larger with fluvastatin and both parameters increase with atorvastatin in cirrhosis[30-32]. Furthermore, another mechanism could be a single nucleotide polymorphism in SLCO1B1, which encodes the OATP1B1 that regulates the hepatic uptake of statins[33]. Recent studies have shown that a diminished expression of SLCO1B1 is associated with progressive alcoholic liver disease[34,35]. This last mechanism reduces the hepatic uptake and increases the blood levels of statins and enhances the risk of adverse events[19].

Proven adverse events

Muscle injury: Statins have been associated with a broad spectrum of muscle injury ranging from asymptomatic serum CK elevations to rhabdomyolysis[36]. Statin-associated muscle adverse events ranged from 1% to 5% in controlled clinical trials and 11% to 29% in observational ones[36]. Much of the concern about statin's potential side effects arise from the results of these observational studies.

There are well-established risk factors for statin-related muscle injury[36]. Mounting evidence suggests that higher-dose statin therapy confers a greater risk of muscle injury (see Safety, Statin dose). Statin-related muscle injury is also related to interactions between drugs that increase serum statin levels (see Safety, Drug-drug interactions).

Many patients experience the onset of symptoms in a temporary relationship when starting statin therapy. These symptoms often carry patients and physicians to claim that statins are the cause for them, even when there are very few randomized data to support these assertions. The N-of-1 trial in a group of eight patients experiencing myalgia while being treated with statins demonstrated that data on subjective side effects from observational studies are heavily loaded with bias. Patients were randomly assigned to receive either placebo or the same statin; each patient served as their self-control, and statin and placebo were alternated between them. Pain and interference with life activity were assessed using a weekly visual analog scale. The authors observed no significant difference between statin and placebo in myalgia score in each patient, with five patients resuming statin therapy[37].

Muscle safety in patients with cirrhosis was assessed in three RCTs that evaluated the effect of simvastatin on portal pressure and gastrointestinal bleeding occurrence [16,38,39]. These studies included patients from all CTP classes, but the proportion of CTP class C patients was low. Abraldes *et al*[16] reported a 2-fold increase — or higher — in CK levels for 1 out of 29 placebo patients and 2 out of 30 simvastatin patients. They concluded that the simvastatin safety profile was excellent. Pollo-Flores *et al*[38] reported a 7% incidence of myalgia in the simvastatin group and a 10% in the placebo group. Finally, in BLEPS (Bleeding Prevention with Simvastatin) trial, when evaluating the addition of simvastatin to standard therapy for preventing variceal rebleeding, 2 out of 69 patients on simvastatin developed rhabdomyolysis (2.9%)[40], which was a concerning issue considering an incidence of 0.009% to 0.1% in the general population [41]. The authors observed that both patients had a more advanced liver disease with bilirubin levels greater than 5 mg/dL. Therefore, Abraldes *et al*[16] concluded that severely deteriorated liver function patients might develop muscle injury at lower doses than the general population.

The LIVERHOPE-SAFETY trial was a double-blind, randomized, placebo-controlled, phase 2 trial in patients with decompensated cirrhosis and moderate-to-severe liver failure from nine university hospitals in six European countries[42]. Patients older than 18 years with CTP class B or class C disease were eligible and randomly assigned to receive for 12 wk (in a 1:1:1 proportion) either: Simvastatin 40 mg/d plus rifaximin 1200 mg/d (SVT40 + RFX), simvastatin 20 mg/d plus rifaximin 1200 mg/d (SVT20 + RFX) or placebo of both drugs. Randomization was stratified according to CTP class (B *vs* C). The main endpoint was the appearance of liver or muscle injury, as defined by changes in aspartate aminotransferase (AST) and alanine aminotransferase

(ALT), alkaline phosphatase and CK. The full analysis set included 44 patients: 16 in the SVT40 + RFX group, 14 in the SVT20 + RFX group and 14 in the placebo group. Patients in the first group showed an increase in CK at the end of treatment compared with patients in the placebo group (1060 IU/L *vs* 106 IU/L, $P = 0.014$). It was also observed that there were no significant changes in CK levels in the second group *vs* the placebo group (106 IU/L *vs* 67 IU/L, $P = 0.992$). Three patients (19%) from the SVT40 + RFX group developed liver and muscle toxicity consistent with rhabdomyolysis. See Safety, Reduced activities in statins metabolism and/or transport.

Liver injury: An electronic PubMed search of reported statin hepatotoxicity cases identified 40 patients in 26 publications[43]. The small number of reported cases is a testimony of the supposed hepatic safety of statins given many recipes for this class of drugs, *e.g.*, 142 million in 2008 in the United States alone[44]. Of the 40 cases, 17 patients were men, and most in the sixth or seventh decade of life. The initial symptoms were jaundice, anorexia, nausea, abdominal pain, adynamia and pruritus, similar to acute hepatitis. Mortality due to statins was exceptionally infrequent because only two cases were reported[45,46]. The time elapsed since the drug administration and the development of hepatotoxicity is highly variable: between 5 d and 4 years. However, in more than half of the cases, it occurred within 4 mo from the start of therapy. The interval between the discontinuation of the statin and drug-induced liver injury resolution ranges from a few weeks to 6 mo. The most frequent liver damage pattern is hepatocellular; however, a mixed pattern was also reported, with prolonged symptomatic cholestasis[47].

Based on this data, the Food and Drug Administration in 2012 issued a report on significant changes in the safety of the statin packet insert; all statins currently marketed appear to be associated with a shallow risk of severe hepatic injury[48]. Furthermore, continuous periodic monitoring with ALT does not help detect or prevent drug-induced liver injury and removes the need to perform it. Packet inserts now recommend performing liver function tests before starting statin therapy and then when clinically indicated.

Three RCTs that appraised the effect of simvastatin on portal pressure and gastrointestinal bleeding frequency assessed the liver safety of statins in patients with cirrhosis[16,38,40]. Pollo-Flores *et al*[38] did not report any patient with liver injury. Abraldes *et al*[16] observed a patient with aminotransferase increase in each trial. In 2009, with AST > 2 times the upper limit of the normal, simvastatin was continued, whereas in 2016, with ALT > 3 times the upper limit of the normal, simvastatin was stopped[40].

In the LIVERHOPE-SAFETY trial, due to advice from the data safety monitoring board, the SVT40 + RFX group was stopped prematurely when the first 10 patients completed treatment because of severe liver adverse events (grade 3)[42]. Patients within the SVT40 + RFX group showed a significant increase in AST and ALT than the placebo group (AST 191 IU/L *vs* AST 62 IU/L, $P = 0.0009$ and ALT 96 IU/L *vs* ALT 35 IU/L, $P = 0.0025$). They observed no significant differences at 12 wk in AST and ALT between the SVT20 + RFX and placebo groups (AST 48 IU/L *vs* AST 62 IU/L, $P = 0.728$ and ALT 27 IU/L *vs* ALT 35 IU/L, $P = 0.698$, respectively). There were no significant differences in alkaline phosphatase levels between the SVT40 + RFX or the SVT20 + RFX groups compared with the placebo group. The number of patients who stopped treatment because of adverse events was significantly higher in the SVT40 + RFX group [9 (56%) of 16 patients] compared with the other two groups [2 (14%) of 14 for both groups, $P = 0.017$]. In conclusion, in patients with decompensated cirrhosis, SVT40 + RFX was associated with a significant increase in adverse events requiring treatment withdrawal, specifically liver and muscle toxicity, compared with SVT20 + RFX. In future trials evaluating the role of statins in patients with decompensated cirrhosis, simvastatin 20 mg/d should be preferred to 40 mg/d. See, Safety, Reduced activities in statins metabolism and/or transport.

EFFICACY

Statins and risks of cirrhosis decompensation and death

Cirrhosis is a worldwide public health problem, together with its complications and hepatocellular carcinoma (HCC). In this regard, evidence from preclinical and clinical research of drugs such as statins showed a potentially positive effect on the natural history of cirrhosis[49].

The evaluation of these issues was performed based on large-sized national registries. These trials were derived from detailed patient databases in which the International Classification of Diseases, 9th version codes identified variables of interest. Patients treated with statins during follow-up were compared with those not treated with them, and endpoints were adjusted for the most important confounding variables. Simvastatin was the most frequent statin used in all studies. The majority of studies carried out unmatched analysis together with propensity score (PS)-matched analysis. Statins consistently reduced the risk of cirrhosis decompensation and death (Table 1).

Supported by data taken from the Veteran Affairs Clinical Case Registry, the use of statins within patients with hepatitis C virus (HCV) and compensated cirrhosis is related to a 40% or higher reduction in the risk of cirrhosis decompensation and death [50]. Huang *et al*[51] showed that patients with chronic hepatitis B who received statin had a dose-dependent reduction in the risk of cirrhosis complications. Patients with hepatitis B virus (HBV)-, HCV- and alcohol-related cirrhosis were identified from a Taiwan National Health Insurance[52]. Statins, in a dose-dependent manner, decrease the decompensation rate in both HBV- and HCV-related cirrhosis. For patients with alcohol-related cirrhosis, a decreased decompensation rate has a borderline significance. In a low number of patients with biopsy-proven cirrhosis, Kumar *et al*[53] demonstrated that statins delay cirrhosis complications and reduce mortality. For patients with alcoholic cirrhosis, the use of statins showed an association with a reduced risk of decompensation and death. This association was stronger in patients with cirrhosis than in those with non-cirrhotic controls[54]. Statins consistently reduced the risk of decompensation and death in all studies, with hazard ratios ranging from 0.29 to 0.58 and 0.46 to 0.66, respectively[55].

Statins and portal hypertension

In the first RCT on the matter, Abraldes *et al*[16] assumed that pleiotropic effects are the rational basis for statin use in patients with cirrhosis and portal hypertension, which led them to conduct a proof-of-concept study, as shown in Table 2. A multicenter RCT evaluated simvastatin or placebo administration to patients with cirrhosis and severe portal hypertension for a month. The decrease in hepatic venous pressure gradient (HVPG) by simvastatin was significantly greater than the placebo changes. In the simvastatin group, 9 out of 28 patients (32%) *vs* in the placebo group, 3 out of 27 patients (11%) reached a target hemodynamic response defined as a reduction in HVPG of at least 20% of baseline values or to less than 12 mmHg (P = 0.054). The decrease in portal pressure observed with simvastatin was not associated with changes in hepatic blood flow. Simvastatin significantly decreased the HVPG in both sets of patients: those who received NSBBs and those who did not receive them. The portal pressure-reducing effect of simvastatin was slightly higher in patients receiving NSBBs than those who were not. Finally, simvastatin administration but not placebo markedly increased indocyanine green clearance, fractional clearance and intrinsic clearance, suggesting that simvastatin increased effective liver perfusion and improved liver function. In summary, this proof-of-concept study has shown that simvastatin lowers portal pressure in patients with cirrhosis and portal hypertension, most likely through a reduction in hepatic vascular resistance without adverse effects on the systemic circulation and consistent with the theory that hemodynamic effects of simvastatin are liver-selective. Whether the patients are taking NSBBs or not, simvastatin decreases HVPG. This suggests that its effect on portal pressure is additive with the NSBBs. Besides, simvastatin improves liver function tests by enhancing effective liver perfusion and providing potential additional benefits to NSBB therapy.

The BLEPS trial is the largest RCT that assessed the effects of statins in cirrhosis. In patients with variceal bleeding, simvastatin was added to standard prophylaxis to prevent rebleeding — NSBBs and band ligation[40]. Within 10 d of bleeding, patients were randomly assigned to receive simvastatin 20 mg/d (n = 69) or placebo (n = 78) for the first 2 wk, followed by 40 mg/d or placebo for 2 years and stratified by CTP class A/B *vs* class C. The main endpoint was a composite of rebleeding or death. During a median follow-up of approximately 1 year, 30 out of 78 patients (39%) in the placebo group and 22 out of 69 patients (32%) in the simvastatin group reached the primary endpoint [hazard ratio (HR) = 0.82; 95%CI: 0.47-1.43, P = 0.420]. Nonetheless, when only death was evaluated, mortality was 22% in the placebo group compared to 9% in the simvastatin group (HR = 0.39; 95%CI: 0.15-0.99, P = 0.030). Therefore, treatment with simvastatin was associated with a 61% reduction in the relative death risk than placebo. Rebleeding, spontaneous bacterial peritonitis, and progression of liver disease were the most frequent cause of death in the placebo group (5, 3 and 3 patients, respectively), and in the simvastatin group, only one patient died by re-

Table 2 Statins and portal hypertension

Ref.	Groups	*n*	Endpoints	Outcomes
Abraldes *et al*[16], 2009	SVT; Placebo	27; 28	Change in HVPG	HVPG decreased in SVT from 18.5 to 17.1, $P = 0.003$; no decrease in placebo
Pollo-Flores *et al*[38], 2015	SVT; Placebo	14; 20	Change in HVPG	HVPG decreased in SVT *vs* placebo: -2 *vs* 0 mmHg, $P = 0.02$
Bishnu *et al*[39], 2018	ATV + NSBBs; NSBBs	11; 12	Change in HVPG	HVPG decreased in ATV + NSBBs -4.8 *vs* NSBBs -2.6 mmHg, $P = 0.041$
Abraldes *et al*[40], 2016	SVT; Placebo	69; 78	Composite endpoint (rebleeding or death)	Non-significant decrease in risk of rebleeding or death; decrease in mortality HR = 0.39, $P = 0.030$ in SVT *vs* placebo
Wani *et al*[56], 2017	CVL; CVL + SVT	101; 35	Change in HVPG	HVPG decreased 62% in CVL and 16% in CVL + SVT (CVL non-responders)

ATV: Atorvastatin; NSBBs: Non-selective β-blockers; CVL: Carvedilol; HR: Hazard ratio; HVPG: Hepatic venous pressure gradient; SVT: Simvastatin.

bleeding, none by spontaneous bacterial peritonitis and three by a progression of liver disease. An exploratory analysis showed that mortality improvement was mainly related to decreased liver-related deaths [14 in placebo and 6 events in simvastatin; absolute risk reduction = 10.39% (95%CI: 0.26-20.51]. In the subgroup analysis, the effects of simvastatin on survival were quantitatively different in CTP class A/B patients from CTP class C patients. In CTP class A/B patients, an important outcome was the significant decrease in mortality with simvastatin, which was not observed in CTP class C patients (HR = 0.16; 95%CI: 0.05-0.27, $P = 0.006$), as shown in Table 2. The other major secondary outcome was rebleeding. In the placebo group, 22 patients developed rebleeding (28%) and 17 patients in the simvastatin group (25%). The rebleeding rate was not significantly decreased by the addition of simvastatin to standard therapy. Neither difference was observed in the rate of other secondary outcomes, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, portal vein thrombosis and need for rescue shunting, need for transfusion, liver transplantation and Model for End-stage Liver Disease (MELD) score between the two groups during the study period. The BLEPS trial demonstrated that the effect of adding simvastatin to the standard of care in patients who recover from an acute variceal bleeding episode improves survival without reducing the rate of other complications of cirrhosis.

Shortly after, two RCTs on small groups of patients reported the effects of statins on portal hypertension. Most of the patients, CTP class A and class B, had compensated cirrhosis, and very few were CTP class C. In one of these trials, simvastatin (at 40 mg/d for 3 mo) was evaluated *vs* placebo, whereas for the other trial, atorvastatin (20 mg/d for 1 mo) plus propranolol was tested *vs* propranolol alone on portal pressure estimated by HVPG[38,39] (Table 2).

In the first place, Pollo-Flores *et al*[38] showed that simvastatin therapy was associated with a decrease in HVPG, whereas no change was noted in the placebo group. Likewise, in 55% of patients treated with simvastatin, a clinically significant reduction in portal pressure was achieved because the decrease in HVPG was greater

than 20% *vs* no decrease in HVPG for patients with placebo (P = 0.030). Furthermore, they observed a slight improvement in liver function by CTP score, at baseline 6.6 *vs* at the end of the trial 6.2, P = 0.080. They concluded that simvastatin lowers portal pressure and may improve liver function.

Secondly, Bishnu *et al*[39] demonstrated that atorvastatin plus propranolol *vs* propranolol alone was associated with a greater decrease of HVPG mean. Likewise, the combined treatment compared with propranolol alone achieved more frequently a clinically significant reduction in portal HVPG (91% *vs* 50%, P = 0.069). However, they did not observe differences between the groups in cirrhosis complications and death after a 1 year follow-up. They concluded that the addition of atorvastatin to propranolol leads to a more significant reduction of portal pressure in patients with cirrhosis, likely through a reduction in hepatic vascular resistance.

In 2017, Wani *et al*[56] carried out a sequential trial in carvedilol non-responders to analyze if adding simvastatin could be a medical rescue therapy in these patients. One hundred and two consecutive patients with cirrhosis and significant portal hypertension were included. Forty-three were CTP class A, 32 were CTP class B and 27 were CTP class C. HVPG was measured at the baseline and after 3 mo of carvedilol treatment. Sixty-four patients (63%) responded to carvedilol. The other thirty-eight were classified as carvedilol non-responders. In these patients, simvastatin 20 mg/d was added for 2 wk, and after the adverse events were evaluated, 3 patients were discontinued. Thirty-five continued carvedilol and simvastatin 40 mg/d for up to 1 mo, and a new measurement of HVPG was performed. There were 16 responders (42%) and 19 non-responders. Thus, the overall carvedilol response was 79% (63% with carvedilol alone and 16% with carvedilol plus simvastatin), as shown in Table 2. In conclusion, this is the first time it has been clearly shown that a sequential treatment is an excellent strategy in the medical therapy of portal hypertension.

Statins and risk of infections

Infections are common in cirrhotic patients, and their presence causes a four-fold increase in mortality[57]. Motzkus-Feagans *et al*[58] assessed the consequence of including statins on the occurrence of infections. This trial was carried over 19379 compensated cirrhosis patients from the United States Veterans Health Administration database. Statins were administered to 2468 patients, simvastatin being the most common one. Infection was diagnosed in 200 statin users and 2153 nonusers during follow-up. The most frequent infections were pneumonia and skin infections. Statin treatment was associated with a reduction of infection rate and of mortality rate in the whole cohort (adjusted HR = 0.42; 95%CI: 0.36-0.48), and the PS-matched sample included 503 statin users and 1760 statin nonusers (adjusted HR = 0.67; 95%CI: 0.47-0.95). They concluded that statin use might potentially reduce the morbidity and mortality by infections in patients with cirrhosis.

Statins and risk of HCC

The World Health Organization (globacan.iarc.fr) estimated that HCC globally speaking is now the fifth most common type of cancer and the third cause of cancer-related mortality. Back in 2012, there were approximately 782000 cases, of which 83% were from the underdeveloped regions of the world[59]. Pre-existing cirrhosis was present in more than 80% of participants diagnosed with HCC[60].

The Electronically Retrieved Cohort of HCV Infected Veterans for the first time has shown that statin addition to pegylated interferon-based therapy for chronic HCV infection, decreases the incidence of HCC in those who received statin therapy compared to those who did not. Statins remained significantly associated with a lower risk of HCC incidence (HR = 0.51; 95%CI: 0.34-0.76)[61]. In an extension of their previous study, the authors showed that the decrease in HCC was dose-dependent. For subjects with 90-180 cumulative defined daily dose and cumulative defined daily dose > 180, adjusted HRs of incident HCC were 0.48 (95%CI: 0.27-0.88, P = 0.02) and 0.51 (95%CI: 0.36-0.72, P = 0.0001), respectively. Increasing statin dose was also associated with a significant delay in the time taken for the development of HCC. In two sensitivity analyses, it was shown that the incidence of HCC was independent of statin antifibrotic effect and sustained virological response[62].

Hsiang *et al*[63] ran a hospital-based population trial on HBV patients taken from the Hospital Authority database in Hong Kong. They defined statin use by landmark analysis to abrogate "immortal time bias" and PS to minimize baseline confounders and "indication bias." The 2-year landmark analysis entered 73499 patients with a crude HCC incidence of 1.75 per 100 patient-years. After landmark analysis and PS weighting of baseline covariates, statin users had a 32% risk reduction of HCC than nonusers. In subgroup analysis, a reduction of 59% in the HCC risk was associated

with concomitant statin and nucleos(t)ide analogues use compared to nucleos(t)ide analogues use alone. In conclusion, after adjustment for confounders and biases in this HBV cohort, statin use was associated with reduced HCC risk by 32%. The authors were able to see the additive HCC chemopreventive effect with the concomitant use of nucleos(t)ide analogues and statins. In 2018, Kim *et al*[64] investigated the risk of HCC after statin use in the whole population and patients at high risk for pre-existing diabetes or cirrhosis. A nationwide, nested case-control study was conducted with data from the National Health Insurance Service-Physical Health Examination Cohort 2002-2013 in the Republic of Korea. Individuals diagnosed with HCC, over 514000 participants, were matched with controls based on the follow-up, their sex and their age. Statin use was associated with a reduced risk of HCC development [adjusted odds ratio (aOR) = 0.44] than nonusers. The reduction in patients at risk was more significant in the presence of diabetes (aOR = 0.28) than in the absence of it (aOR = 0.53) and the presence of cirrhosis (aOR = 0.39) than in the respective absence (aOR = 0.42). In conclusion, statin use may have a beneficial inhibitory effect on HCC development, particularly in patients at high risk for pre-existing diabetes or cirrhosis.

Statins have also been tried as concomitant therapy in patients with confirmed HCC. Two RCTs evaluated the role of statins in the treatment of advanced HCC. Japanese authors randomized 83 patients with non-resectable HCC undergoing transarterial chemoembolization (TACE) into pravastatin 40 mg/d group and control group. The mean survival rate resulted significantly longer in the pravastatin plus TACE group *vs* control group, over 18 mo *vs* 9 mo, respectively (relative risk = 0.35; 95%CI: 0.17-0.61, P = 0.005)[65]. These results were confirmed in a similarly designed German RCT that included 131 patients. Survival in the pravastatin plus TACE group was 20.9 mo compared to TACE alone group 12.0 mo, P = 0.003[66].

OUR EXPERIENCE

A safety prospective, open, uncontrolled phase IIa trial was recently published online ahead of print about chronic simvastatin treatment in patients with decompensated cirrhosis. This trial included 30 patients, CTP class A (n = 6), B (n = 22) and C (n = 2). The patients received standard treatment plus simvastatin 20 mg/d for 2 wk and after that simvastatin 40 mg/d up to 1 year[67].

Muscle injury was assessed according to the National Lipid Association Safety Expert Panel of the United States[36]. In total, 11 out of 30 patients (36%) developed muscle injury, of which 7 were classified as myalgia (23.4%) and the remaining 4 myonecrosis (13.3%). All of them were related to simvastatin. On the other hand, a significantly greater baseline MELD score was observed within the group with muscle injury (14.0 ± 3.6) than the group without muscle injury (11.4 ± 2.8) (P = 0.035). The receiver operating characteristic analysis revealed a cutoff value > 12 for baseline MELD score to differentiate patients with muscle injury from those without muscle injury. Moreover, the only two CTP class C patients included in the study developed myonecrosis.

No patient developed drug-induced liver injury according to the criteria proposed by Aithal *et al*[68]. One patient developed diabetes mellitus (3.3%). This rate is more significant than for the first time reported in the JUPITER trial (0.6%)[69]. Gastrointestinal symptoms were recorded in 53.3% of patients. The rate of each of them was from 7% to 40%. This figure is more significant than reported with simvastatin in subjects without liver disease for all digestive symptoms (10% and each one of them from 0.7% to 2.5%)[17]. Simvastatin dosage was reduced exclusively by myalgia and transiently interrupted due to myonecrosis; thus, muscle injury was considered the only clinically significant adverse event.

In conclusion, chronic treatment with simvastatin 40 mg/d in patients with decompensated cirrhosis up to 1 year was associated with several adverse events, although no liver injury was registered. Moreover, muscle injury was the only clinically significant adverse event, which appears to be related to the simvastatin dosage and the degree of cirrhosis severity. Consequently, simvastatin 40 mg/d should not be prescribed in patients with cirrhosis MELD score > 12 because of a high rate of adverse muscle events and CTP class C patients due to potential severe muscle injury.

META-ANALYSIS AND EDITORIAL

A recent systematic review and meta-analysis discussed the impact of statins on fibrosis progression, hepatic decompensation and death in patients with chronic liver disease[70]. Ten trials spanning over 259453 patients were evaluated; most of the aforementioned studies were discussed in this review. Subjects receiving statins *vs* statin nonusers were associated with a reduction of all the previous endpoints mentioned. However, the quality of the evidence for these results was low or very low because nine out of ten studies were observational.

An editorial about this article highlights that the quality of these outcomes arises from the weakness of observational studies, selection or channelings bias, residual confounding, heterogeneity in the methods used to estimate fibrosis progression, the underlying population, lack of granularity regarding specific statin use, dose and the absence of information on adverse events of statins[71].

Finally, the authors proposed if the time has arrived to consider approving the use of statins in patients with liver disease to prevent liver-related morbidity and mortality. There are now experimental studies supporting the biological plausibility of hepatic protection, observational evidence of a beneficial effect and a limited number of RCTs demonstrating benefits. However, many unknowns remain, including the optimal statin to select and its dosing, particularly in patients with impaired liver function, and the risk of severe non-hepatic adverse events, such as rhabdomyolysis [71]. After Kamal *et al*[70]'s study in 2017, only the LIVERHOPE-SAFETY trial[42] and our safety study[67] provided some security data, as we will refer to in the Discussion and Conclusion. Nevertheless, the study by Kamal *et al*[70] encourages and supports the need for well-designed clinical trials to assess the benefits and safety of statins in this population.

CONCLUSION

In patients with cirrhosis, the most significant adverse event is statin-related myopathy, and it may be associated with high serum statin concentrations in the setting of severely impaired liver function. According to the LIVERHOPE-SAFETY trial findings, patients with decompensated cirrhosis should be treated with a lower dose of simvastatin, maybe 20 mg/d rather than 40 mg/d dose. For this reason, statins could be unsafe in CTP class C patients. Likewise, and based on the safety trial, we advise that a simvastatin dosage of 40 mg/d should not be prescribed in patients with cirrhosis MELD score > 12 and/or CTP class C patients due to potential severe muscle injury. In observational studies over large populations of cirrhosis patients, statins were associated with a reduced risk of hepatic decompensation, HCC development and death. However, the quality of the evidence of these studies is considered low or very low. The few RCTs in patients with cirrhosis and portal hypertension showed statins lower portal pressure, likely reducing hepatic resistance. The largest RCT demonstrated that the addition of simvastatin to standard therapy improved survival but did not prevent variceal rebleeding. For these reasons, before endorsing statins in patients with CTP class A/B cirrhosis to prevent liver-related morbidity and mortality, further RCTs should be performed over a larger number of patients with hard clinical endpoints using different statins and dosage[72,73].

Abstract

Gastric cancer accounts for the majority cancer-related deaths worldwide. Although various methods have considerably improved the screening, diagnosis, and treatment of gastric cancer, its incidence is still high in Asia, and the 5-year survival rate of advanced gastric cancer patients is only 10%-20%. Therefore, more effective drugs and better screening strategies are needed for reducing the incidence and mortality of gastric cancer. Cyclooxygenase-2 (COX-2) is considered to be the key inducible enzyme in prostaglandins (PGs) synthesis, which is involved in multiple pathways in the inflammatory response. For example, inflammatory cytokines stimulate innate immune responses *via* Toll-like receptors and nuclear factor-kappa B to induce COX-2/PGE2 pathway. In these processes, the production of an inflammatory microenvironment promotes the occurrence of gastric cancer. Epidemiological studies have also indicated that non-steroidal anti-inflammatory drugs can reduce the risk of malignant tumors of the digestive system by blocking the effect of COX-2. However, clinical use of COX-2 inhibitors to prevent or treat gastric cancer may be limited because of potential side effects, especially in the cardiovascular system. Given these side effects and low

treatment efficacy, new therapeutic approaches and early screening strategies are urgently needed. Some studies have shown that genetic variation in *COX-2* also play an important role in carcinogenesis. However, the genetic variation analysis in these studies is incomplete and isolated, pointing out only a few single nucleotide polymorphisms (SNPs) and the risk of gastric cancer, and no comprehensive study covering the whole gene region has been carried out. In addition, copy number variation (CNV) is not mentioned. In this review, we summarize the SNPs in the whole *COX-2* gene sequence, including exons, introns, and both the 5′ and 3′ untranslated regions. Results suggest that *COX-2* does not increase its expression through the CNV and the SNPs in *COX-2* may serve as the potential marker to establish risk stratification in the general population. This review synthesizes emerging insights of COX-2 as a biomarker in multiple studies, summarizes the association between whole *COX-2* sequence variation and susceptibility to gastric cancer, and discusses the future prospect of therapeutic intervention, which will be helpful for early screening and further research to find new approaches to gastric cancer treatment.

Key Words: Cyclooxygenase-2; Inflammation; Genetic variant; Gastric cancer; Prostaglandin E2

INTRODUCTION

Gastric cancer is the fifth most commonly diagnosed cancer and the third leading cause of cancer-related deaths worldwide. The incidence of gastric cancer remains high in Eastern Asian despite its global decrease in the last few years[1,2]. Approximately 75% of patients with gastric cancer are diagnosed at advanced stage and the median survival is 7-10 mo[3]. Therefore, individualized prevention and early detection and treatment are of clinical significance in improving the survival time and reducing the mortality of gastric cancer.

Environmental factors including smoking, drinking, and *Helicobacter pylori* (*H. pylori*) infection and genetic alterations such as susceptible genetic variants and epigenetic alterations have been associated with gastric carcinogenesis[4,5]. Cyclooxygenase-2 (COX-2) has been extensively studied in carcinogenesis, and its participation in chronic inflammation and various infections (such as *H. pylori* infection and chronic viral hepatitis) significantly increases the risk of cancer[6,7]. In this review, we will summarize the association between whole *COX-2* sequence variation and susceptibility to gastric cancer. We will also discuss the crucial role of *COX-2* in the occurrence of gastric cancer and its mechanisms.

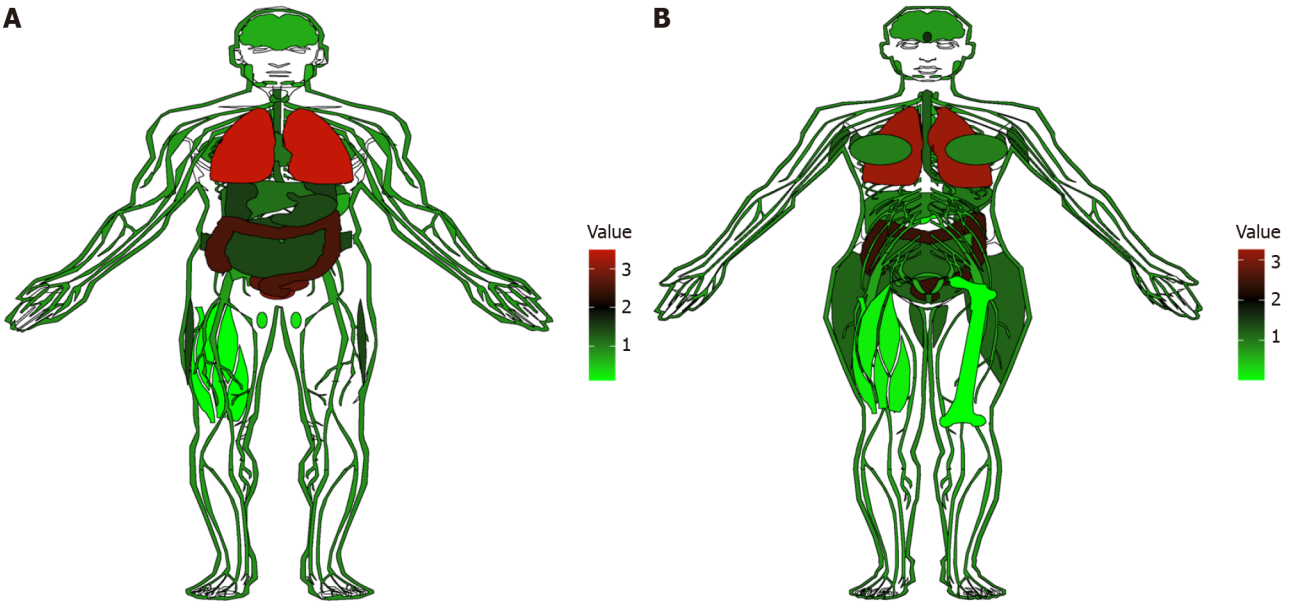

Figure 1 Visualization of cyclooxygenase-2 expression in normal tissues from the genotypic tissue expression database. The red parts indicate the organs with more cyclooxygenase-2 distribution, while the green parts indicate less distribution. A: Distribution of expression in males; B: Distribution of expression in females.

MOLECULAR CHARACTERISTICS OF COX-2

COX-2 is known as the key inducible enzyme in prostaglandins (PGs) synthesis, and the *COX-2* gene is located at chromosome 1q25.2-25.3 and composed of 9 introns and 10 exons[8]. The 5′ region of the *COX-2* gene has binding sites for several activated transcriptional factors, such as nuclear factor-kappa B (NF-κB), stimulatory protein 1 (SP1), activator protein-2 (AP-2), and transforming growth factor. In order to explore the expression of *COX-2* in normal tissues, the expression data of *COX-2* were downloaded from the genotypic tissue expression (GTEx) database (https://xenabrowser.net/datapages/) and the distribution of *COX-2* expression in different tissues was visualized by plotting an anatomical map with R-3.5.3 software. Detailed data are shown in Supplementary material 1. Previous studies have shown that *COX-2* has negative expression in normal tissues and organs under physiological conditions, though it is constitutively expressed in the brain and kidney. We also found that *COX-2* gene was rarely expressed in normal tissues (including the stomach), but distributed more in the colon and lungs, both in males and females (Figure 1). However, its expression is increased dramatically in response to certain inflammatory stimuli such as cytokines, oncogenes, and tumor inducers[9]. COX-2 have been shown to play crucial roles in tumorigenesis[10]. The COX-2/PGE2 pathway activates macrophage infiltration and further induces cytokine signaling to activate the transcription factors NF-κB and signal transducer and activator of transcription 3 (Stat3)[11,12], which can change the tumor microenvironment and affect the occurrence of cancer.

GENETIC VARIANTS OF COX-2 IN TUMORIGENESIS

COX-2 has been implicated in the etiology of cancer and its expression has been confirmed to be increased in gastric cancer. Genetic variants may lead to an increase in expression and change in the function of *COX-2*, which may affect the occurrence of cancer. Studies have suggested that *COX-2* single nucleotide polymorphisms (SNPs) may affect the gastric tumorigenesis. However, these studies only focused on a few or particular region SNPs, and lacked an overall description of the whole sequence variation of *COX-2*. In this review, we summarize the SNPs in the whole *COX-2* gene sequence, including exons, introns, and both the 5′ and 3′ untranslated regions (UTR). In addition, we also analyze the copy number variation (CNV) information of *COX-2* in gastric cancer.

CNV of COX-2 in gastric cancer

The SNPs of *COX-2* have been widely studied, but its CNV was rarely mentioned. We downloaded the copy number data of the *COX-2* gene in gastric cancer from The Cancer Genome Atlas (TCGA) database (https://www.cancer.gov/about-nci/organization/ccg/research/structural-genomics/tcga), and then visualized the data with R-3.5.3 software (detailed data in Supplementary material 2). The genes displayed are all genes with CNV, but no CNV of the *COX-2* gene was found.

Association between COX-2 SNPs and gastric cancer

The SNPs of *COX-2* may have a functional effect on *COX-2* transcription and cause *COX-2* overexpression to change the response to various inflammatory stimuli. However, only a single locus of SNP can explain the occurrence of cancer very little, which is not enough to fully demonstrate the association between *COX-2* SNPs and gastric cancer. We combined data from the TCGA (https://portal.gdc.cancer.gov/repository; downloaded data in Supplementary material 3) and Ensembl (http://grch37.ensembl.org/Homo_sapiens/Tools/VcftoPed?db=core) using Haploview 4.2 software to screen SNPs. The criteria for screening SNPs were minor allele frequency ≥ 0.05 and pairwise $r^2 < 0.8$. All obtained SNPs are shown in Figure 2. At the same time, we retrieved the SNPs that have been studied. The results showed that 14 SNPs were associated with cancer in the whole sequence of *COX-2*, including 9 SNPs associated with gastric cancer (Table 1). At present, five *COX-2* polymorphisms have been extensively studied, including rs5275 and rs689470T>C that are located in the 3′ UTR, as well as rs689466G>A and rs20417G>C mutations that are located in the promoter region with multiple enhancers and transcriptional regulatory elements. SNPs in the *COX-2* promoter region may change the activity of the promoter and C-reactive protein (CRP), which may be related to acute or chronic inflammation[13]. Although SNPs may have functional effects, there are still a large number of functional features of SNPs that have not been discovered, and their mechanism needs to be further studied. Meanwhile, risk estimates of previous studies have been inconsistent. Therefore, we made a summary and pooled analysis of the extracted data. The results showed that rs689466G>A, rs20417G>C, and rs3218625G>A in the promoter region conferred a higher risk of gastric cancer [A *vs* G: odds ratio (OR) = 1.19, 95% confidence interval (CI): 1.10-1.29; C *vs* G: OR = 1.26, 95%CI: 1.12-1.41; and A *vs* G: OR = 1.62; 95%CI: 1.02-2.56]. Similarly, rs5275T>C and rs689470T>C in the 3′UTR were significantly associated with gastric cancer (C *vs* T: OR = 1.14, 95%CI: 1.01-1.29 and TC *vs* TT: OR = 7.49; 95%CI: 1.21-46.2). As to the rs2066826 G>A polymorphism, a significant association was detected in pancreatic cancer (A *vs* G: OR = 1.60, 95%CI: 1.06-2.40, $P = 0.026$). However, rs5279 T>C in the exon region and rs4648298A>G in the 3′ UTR may reduce the risk of gastric and colorectal cancers (TC *vs* TT: OR = 0.24, 95%CI: 0.08-0.73 and G *vs* A: OR = 0.24; 95%CI: 0.10-0.56).

In our previous study of 296 gastric cancer patients and 319 control family members in the Chinese Han population, an increased risk was observed in individuals with the *COX-2* rs689466AA genotype (OR = 2.03; 95%CI: 1.27-3.22), and the association decreased as the degree of relationship decreased[14]. Recently, we further performed genotyping in 660 gastric cancer cases form the First Affiliated Hospital of Zhengzhou University from 2013 to 2015 and 660 control individuals from a community-based cardiovascular diseases survey in the same time. Our results found that individuals with rs20417 GC genotype were more likely to develop gastric cancer (OR = 1.54, 95%CI: 1.08-2.19). Meanwhile, Zhang *et al*[15] found that rs689466 G>A enhanced the transcriptional activity and thus increased the expression of *COX-2* by creating a c-MYB binding site.

These results suggest that the SNPs of the *COX-2* gene plays an important role in the carcinogenesis of gastric cancer, especially the variation in the promoter region which may have functional consequences. In addition, SNPs in the promoter region could enhance *COX-2* gene transcription, affect the stability of mRNA, regulate the inflammatory response, and consequently lead to individual variation in susceptibility to gastric cancer[16,17]. Our study provides a basis for more thoroughly exploring the exact function of *COX-2* in the occurrence of gastric cancer. Further functional studies will be considered and be elaborated in another study.

INFLAMMATORY MECHANISM OF COX-2 IN GASTRIC CANCER

COX-2 overexpression has been found in a variety of cancers, including gastric cancer [18,19]. A large number of studies have shown that many factors (such as *H. pylori*

Table 1 Summary of single nucleotide polymorphisms in whole region of cyclooxygenase-2 and their association with risk of cancer

infection, NF-κB activation, K-ras expression, and the dysregulation of some trans-acting regulatory factors) can lead to overexpression of COX-2 and more inflammation in neoplasia[20-23].

H. pylori infection and COX-2 expression

It is generally accepted that *H. pylori* infection is an important risk factor for gastric cancer and *H. pylori* has been classified as a class I carcinogen. *H. pylori* infection may

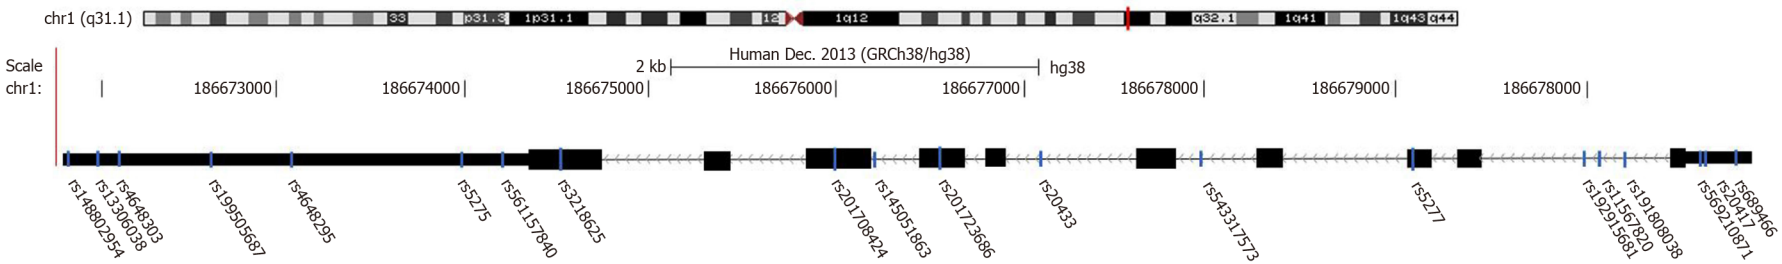

Figure 2 General location of cyclooxygenase-2 single nucleotide polymorphisms searched by bioinformatics (based on The Cancer Genome Atlas, NCBI, and UCSC).

trigger various inflammatory pathways to increase cancer risk. A study has shown that 24 h after *H. pylori* infection of the MKN 28 cell line, the level of *COX-2* mRNA transcription and PGE2 expression increased 5-fold and 3-fold, respectively[24]. However, the exact molecular mechanisms underlying the increased expression of COX-2 in gastric cancer patients with *H. pylori* infection remains unclear.

A study found that *H. pylori* infection stimulates Toll-like receptors (TLRs), to activate innate immunity and the COX-2/PGE2 pathway, which induces "infection-associated inflammation" [such as CXCL1, 2, and 5, CCL3 and 4, interleukin (IL)-11, IL-23, and tumor necrosis factor alpha (TNF-α)], to generate an inflammatory microenvironment and further lead to gastric tumorigenesis[25,26]. Another study using AGS gastric cancer cells showed that *H. pylori* (patient isolate) promotes *COX-2* transcription, which may be due to the activation of mitogen-activated protein kinase (MAPK) pathways (ERK1/2, p38, and JNK) and the activation of cAMP response element (CRE) and AP-1 on the *COX-2* promoter by TLR2/TRL9[27]. Jüttner *et al*[28] found that the binding of upstream stimulatory factor 1/2 (USF1 and 2) to the CRE/Ebox site of the *COX-2* promoter promotes the upregulation of *COX-2* after *H. pylori* infection. Another study demonstrated that *H. pylori* infection may lead to the phosphorylation of p38 MAPK and its downstream activating transcription factor 2 (ATF-2), which affects the expression of COX-2[29]. Some studies have pointed out that the expression of COX-2 is induced by NF-κB, which is recognized and activated by c-Src or TLR2/TLR9 and MAPK kinase kinase 14 (MAP3K = NIK)[30]. In addition, *H. pylori* infection promoted the secretion of gastrin, which extended the half-life of *COX-2* mRNA and increased the expression of COX-2[31]. Semple *et al*[32] reported that gastrin upregulates the expression of COX-2 by CCK-2R-mediated JAK2/Stat3 and subsequent PI3K/Akt activation in gastric cancer cell lines. Meanwhile, *H. pylori* infection may also activate NF-κB, which can induce COX-2 expression[33]. Moreover, another study showed that eradication of *H. pylori* infection significantly reduced COX-2 expression[34].

Table 2 Application of cyclooxygenase-2 inhibitors in cancer

Drug	Cancer type	Effect(s)	Mechanism	Ref.
Celecoxib	Gastric	Inhibits tumor growth	Increases CD206 and activates macrophages	Thiel *et al*[46]
Aspirin	Gastric	Induces apoptosis; inhibits proliferation; inhibits angiogenesis	Acetylates the active site of COX-2;inhibits PG synthesis; activates caspase-8/Bid and caspase-3	Liu *et al*[57], and Niikura *et al*[78]
Oxadiazole 10c	Colon	Increases antitumor activity; increases sensitivity	Docked into the COX-2 bind site	El-Husseiny *et al*[79]
Celecoxib and platinum	Gastric	Prolong overall survival and progression-free survival	-	Guo *et al*[80]
Celecoxib and rapamycin	Gastric	Increase sensitivity	Inhibit PI3K/AKT pathway	Cao *et al*[81]
Celecoxib and FOLFOX4	Gastric	Inhibit angiogenesis	Down-regulate VEGF level	Tołoczko-Iwaniuk *et al*[82]
Celecoxib and erlotinib	Colorectal	Reduce angiogenesis; inhibit formation; inhibit expansion	Inhibit EGFR signaling	Roberts *et al*[83]
Celecoxib and Curcumin	Hepatocellular	Inhibit angiogenesis; inhibit proliferation; induce apoptosis	Inhibit Akt/NF-κB/PGE2/ROS pathway; inhibit COX-2/PGE2 pathway	Abdallah *et al*[84]
Sorafenib and meloxicam	Hepatocellular	Inhibit tumor cell growth; inhibit proliferation; enhance apoptosis	Activate endoplasmic reticulum stress; enhance the cytotoxicity	Zhong *et al*[85]
Ferrocene derivatives	Breast/cervical	Suppress tumor growth; increase antiproliferative activity; induce apoptosis	Increase the levels of cytotoxicity and reactive oxygen species; reduce the level of PGE2	Ren *et al*[86], and Farzaneh *et al*[87]

COX-2: Cyclooxygenase-2; PGs: Prostaglandins; PI3K: Phosphatidylinositol 3 kinase; Akt (PKB): Protein kinase B; VEGF: Vascular endothelial growth factor; PGE2: Prostaglandin E2; ROS (MDA): Reactive oxygen species measured as malondialdehyde.

Noteworthy, COX-2 is overexpressed not only in *H. pylori* positive gastritis and gastric cancer, but also in precancerous lesions such as intestinal metaplasia and atrophic gastritis, suggesting that COX-2 plays a key role in the early gastric carcinogenesis[35,36]. These may be associated with individual genetic susceptibility, especially inflammatory genes, such as *COX-2*, *IL-1b*, and *TNF-α* gene polymorphisms in our previous reports[14,37].

Inflammatory pathway of COX-2

COX-2 is regulated by multiple pathways in gastric cancer cell lines. The pathway of COX-2/PGE2 has been shown to play crucial roles in tumorigenesis by triggering the production of an inflammatory microenvironment[10,38,39]. However, the exact tumor-promoting mechanism of PGE2 remains unclear. It has been reported that TLR signaling through the adaptor molecule MyD88 induces the COX-2/PGE2 pathway to promote the occurrence of gastritis and gastric cancer[26]. Meanwhile, the expression of COX-2 was significantly reduced when NF-κB signal was blocked by chondroitin sulfate[40]. Some inflammatory cytokines, such as IL-6, IL-8, and TNF-α, can activate NF-κB to induce overexpression of COX-2[41].

It has also been reported that the expression of K-ras and the activation of matrix metalloproteinase-2 (MMP-2) and MMP-9 are significantly related to the increased expression of COX-2[42]. They may jointly promote the occurrence of gastric cancer, but the mechanism is not clear.

Recent studies suggest that the cooperation of the COX-2 /PGE2 pathways and TLR/MyD88 signaling through NF-κB activation is crucial in tumorigenesis[26]. Some genetic studies have shown that the activation of carcinogenic Wnt is related to the occurrence of gastric tumors induced by COX-2[10,38]. In the TCGA database, the Wnt signal and the NF-κ B and COX-2 inflammatory pathways were observed to be activated simultaneously in intestinal gastric cancer[26]. The adenomatous polyposis coli (APC) regulates the expression of COX-2 through a β-catenin-independent mechanism[43]. Inducible nitric oxide synthase (iNOS) can increase the activity of COX-2 to upregulate the production of PGs[44].

These results suggest that COX-2 promotes the occurrence of cancer through induction of various inflammatory pathway signaling and generation of an inflammatory microenvironment (Figure 3).

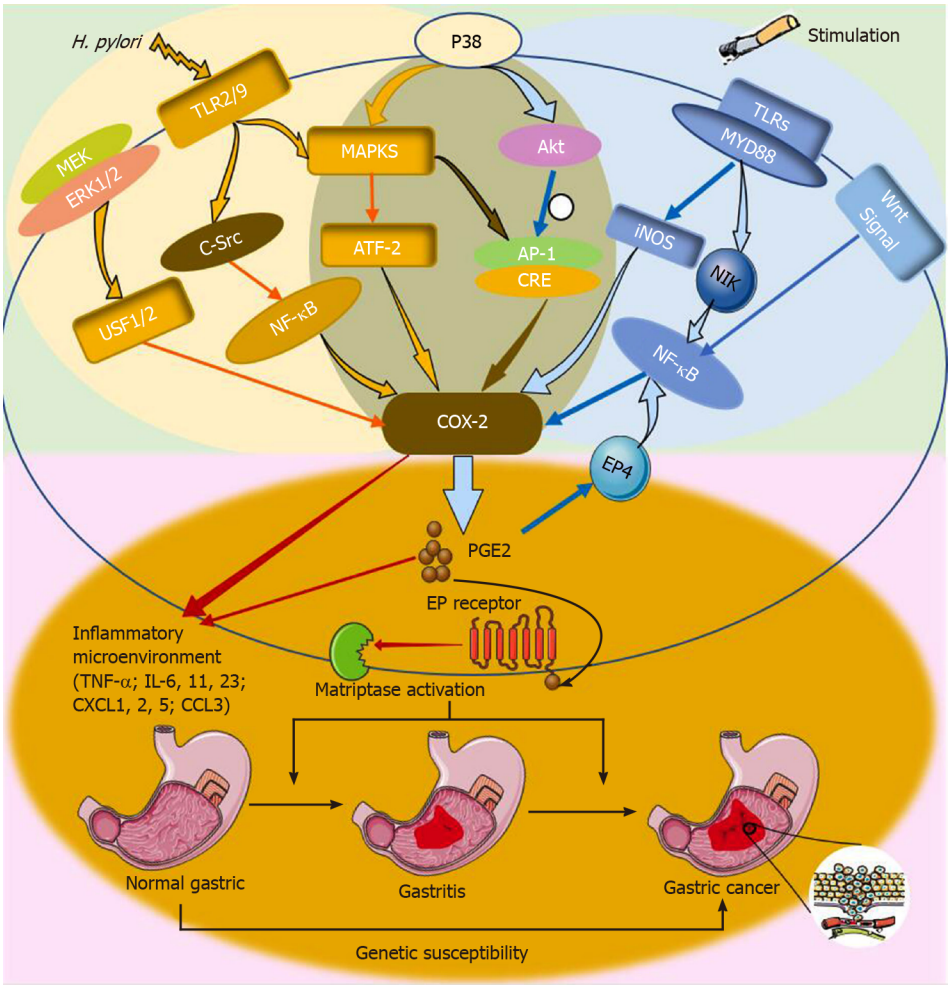

Figure 3 Schematic representation of interactions in regulation of cyclooxygenase-2 to generate an inflammatory microenvironment that has been described in the review. The active pathway of *Helicobacter pylori* infection is shown on the right. TLR: Toll-like receptor; NF-κB: Nuclear factor κB; PGE2: Prostaglandin E2; EP4: Prostaglandin E receptor subtype 4; C-Src: Cellular src; Akt: Protein kinase B; AP-1: Activator protein 1; MEK1: MAP kinase kinase 1; USF: Upstream stimulatory factor; NIK: Mitogen-activated protein kinase kinase kinase 14; Inos: Inducible nitric oxide synthase; MAPK: Mitogen-activated protein kinase; ATF-2: Activating transcription factor 2; TNF-α: tumor necrosis factor-α; IL: Interleukin; CXCL: Chemokine (CXC motif) ligand; CCL: Chemokine (C-C motif) ligand; COX-2: Cyclooxygenase-2.

ROLE OF COX-2 IN CANCER PREVENTIONS AND THERAPEUTICS

Epidemiological studies have indicated that the application of COX-2 inhibitors can reduce the inflammatory response and suppresses gastrointestinal cancerization. It may be an effective and crucial target to treat patients with atrophic gastritis and reduce the risk of *H. pylori*-related gastric cancer[22,45]. The use of non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin can reduce the risk of malignant tumors of the digestive system by blocking the effect of COX-2[46].

NSAIDs can reduce the number and size of colorectal carcinomas in patients with familial adenomatous polyposis. Celecoxib, an selective COX-2 inhibitor, and NSAID can also reduce the occurrence of digestive system cancers, such as inhibiting the proliferation of gastric, esophageal, and colorectal cancer cells[47,48]. It is estimated that long-term use of NSAIDs can reduce the incidence of colon cancer by 40%-50% [49]. However, studies have shown that the use of NSAIDs is not an effective chemoprophylaxis for all cancer patients, as aspirin has no effect on the incidence of colorectal adenoma or cancer in patients with Lynch syndrome[50]. Therefore, the combined use of COX-2 inhibitors and the development of new inhibitors have gradually emerged and have better antitumor activity. More detailed results are shown in Table 2. Moreover, clinical use of COX-2 inhibitors to prevent or treat gastric cancer may be limited because of potential side effects, especially in the cardiovascular system, such as elevated blood pressure and myocardial infarction[51,52]. Recently, a systematic review of 329 studies suggested that in addition to COX-2-selective inhibitors, NSAIDs also increase the risk of cardiovascular morbidity[53]. These side effects and low

treatment efficacy hinder the application of NSAIDs and COX-2 selective inhibitors as chemopreventive drugs to prevent cancer. At the same time, a study indicated that the combined regulation of the inflammatory microenvironment by inhibiting the COX-2/PGE2 and TLR/MyD88 pathways may be an effective strategy to prevent or treat the development and malignant progression of gastrointestinal cancer, especially those with p53 gain-of-function mutations[54]. Therefore, targeting the COX-2/PGE2 pathway combined with TLR/MyD88 signal pathway may inhibit the inflammatory microenvironment and the stemness of gastric tumor cells, which may be an effective strategy for the prevention and treatment of gastric cancer and needs further clinical evaluation[26]. In addition, as the information of genetic susceptibility and *COX-2* SNPs may have the potential to establish risk stratified markers in the general population, it is helpful for early screening and treatment of precancerous lesions in high-risk population groups to reduce the incidence of gastric cancer and avoid unnecessary treatment.

CONCLUSION

It has been established that the expression of COX-2 in gastric cancer cells is induced by various pathways including *H. pylori* infection and COX-2 overexpression results in the generation of an inflammatory microenvironment to promote the occurrence of gastric carcinomas. The polymorphisms including rs689466G>A, rs20417G>C, rs3218625G>A, rs5275T>C, and rs689470T>C in *COX-2* confer individuals a higher susceptibility to gastric cancer. NSAIDs can reduce the risk of digestive system malignant tumors. In addition, the combined regulation of the COX-2/PGE2 and TLR/MyD88 signaling pathways may be an effective strategy to prevent or treat the occurrence and development of gastrointestinal tumors. However, these treatments may increase the incidence of cardiovascular diseases. The above results encourage further functional research to find more accurate individualized prevention strategies and better therapies for gastric cancer.

ACKNOWLEDGEMENTS

The authors express their gratitude to Dr. Liu M and Dr. Zhang X for giving excellent advice for modification.

Abstract

BACKGROUND

Sorafenib is the first-line treatment for patients with advanced hepatocellular carcinoma (HCC). Y-box binding protein 1 (YB-1) is closely correlated with tumors and drug resistance. However, the relationship between YB-1 and sorafenib resistance and the underlying mechanism in HCC remain unknown.

AIM

To explore the role and related mechanisms of YB-1 in mediating sorafenib resistance in HCC.

METHODS

The protein expression levels of YB-1 were assessed in human HCC tissues and adjacent nontumor tissues. Next, we constructed YB-1 overexpression and knockdown hepatocarcinoma cell lines with lentiviruses and stimulated these cell lines with different concentrations of sorafenib. Then, we detected the proliferation and apoptosis in these cells by terminal deoxynucleotidyl transferase

dUTP nick end labeling, flow cytometry and Western blotting assays. We also constructed a xenograft tumor model to explore the effect of YB-1 on the efficacy of sorafenib *in vivo*. Moreover, we studied and verified the specific molecular mechanism of YB-1 mediating sorafenib resistance in hepatoma cells by digital gene expression sequencing (DGE-seq).

RESULTS

YB-1 protein levels were found to be higher in HCC tissues than in corresponding nontumor tissues. YB-1 suppressed the effect of sorafenib on cell proliferation and apoptosis. Consistently, the efficacy of sorafenib *in vivo* was enhanced after YB-1 was knocked down. Furthermore, KEGG pathway enrichment analysis of DGE-seq demonstrated that the phosphoinositide-3-kinase (PI3K)/protein kinase B (Akt) signaling pathway was essential for the sorafenib resistance induced by YB-1. Subsequently, YB-1 interacted with two key proteins of the PI3K/Akt signaling pathway (Akt1 and PIK3R1) as shown by searching the BioGRID and HitPredict websites. Finally, YB-1 suppressed the inactivation of the PI3K/Akt signaling pathway induced by sorafenib, and the blockade of the PI3K/Akt signaling pathway by LY294002 mitigated YB-1-induced sorafenib resistance.

CONCLUSION

Overall, we concluded that YB-1 augments sorafenib resistance through the PI3K/Akt signaling pathway in HCC and suggest that YB-1 is a key drug resistance-related gene, which is of great significance for the application of sorafenib in advanced-stage HCC.

Core Tip: Y-box binding protein 1 (YB-1) was significantly increased in hepatocellular carcinoma (HCC), and it could increase the IC_{50} values of sorafenib in HCC cell lines. Meanwhile, YB-1 suppressed apoptosis and cell proliferation inhibition induced by sorafenib. Furthermore, we screened the phosphoinositide-3-kinase (PI3K)/protein kinase B (Akt) signaling pathway to explore the molecular mechanism of sorafenib resistance by the KEGG pathway enrichment analysis of the digital gene expression profiling-seq. And the blockade of PI3K/Akt signaling pathway by LY294002 mitigated YB-1-induced sorafenib resistance. Given that sorafenib is the first-line treatment for patients with advanced HCC, we proposed that the down-regulation of YB-1 is of great significance for the application of sorafenib in advanced HCC.

INTRODUCTION

Approximately 90% of liver cancer cases are hepatocellular carcinoma (HCC)[1,2]. Approximately 420,000 people die of HCC every year in China, a region with a high HCC incidence[3,4]. Although studies have tried to clarify the pathogenesis of HCC, our understanding of HCC remains limited[5,6], and treatments including resection, ablation or transplantation are only feasible for patients diagnosed early[2,7]. For those with advanced HCC, the best treatment options are still lacking. The Food and Drug Administration (FDA) has approved sorafenib, which is a multitarget tyrosine kinase inhibitor, as a first-line drug for patients with advanced HCC and provides circumscribed survival benefits[8-10]. Additionally, because HCC is prone to relapse and

metastasis, the prognosis of this refractory disease remains frustrating[11]. Therefore, further deepening our understanding of the molecular mechanisms of HCC and developing new intervention strategies are critical.

Y-box binding protein 1 (YB-1) is a multifunctional protein of the Y-box binding protein family that is distributed in both the cytoplasm and nucleus[12]. Current research on the function of YB-1 mainly involves the following three aspects: (1) YB-1 promotes the proliferation of hepatoma cells *via* the Wnt (wingless/integrated)/β-catenin signaling pathway[13] and promotes human breast epithelial tumor cell proliferation by activating the endothelial growth factor receptor (EGFR)/protein kinase B (Akt) signaling pathway[14]; (2) YB-1 effectively inhibits the gene expression of fatty acid synthase (Fas), thereby preventing the occurrence of apoptosis[15], and binds to the key apoptotic factor p53 to form protein complexes, which also exert anti-apoptotic effects[16,17]; (3) YB-1 activates the expression of multidrug resistance (MDR) genes in multiple cancers, such as kidney cancer, breast cancer and colorectal cancer[18]. Additionally, the most recent research indicates that YB-1 augments gefitinib resistance by activating the Akt signaling pathway and epithelial-mesenchymal transition (EMT) by targeting major vault proteins in lung adenocarcinoma cells[19]. Furthermore, YB-1 is significantly increased in pancreatic cancer, breast cancer, colorectal cancer, melanoma and sarcoma[13,14,20]. Chao *et al*[13] proved that the YB-1 expression level is significantly elevated in HCC and closely related to drug resistance. However, the specific underlying molecular mechanism remains uncertain. Therefore, our study intends to elucidate the relationship between YB-1 and sorafenib resistance in HCC and further explore the specific molecular mechanism underlying sorafenib resistance.

MATERIALS AND METHODS

Patients and samples

HCC tissues and paired paracancerous tissues (normal) were surgically resected from 6 patients with HCC and were obtained from 09/2020 to 11/2020 at our hospital. Patients with HCC diagnosed according to clinical and histological diagnostic criteria for HCC in China[21] were included in this study, and patients with tumor recurrence or other organ tumors were excluded. The diagnosis of HCC and histological evaluation were performed by an experienced pathologist. After excision, the tissues were fixed with 4% paraformaldehyde (Shijiazhuang Huawo Kerui Biological Technology Co., Ltd., Hebei Province, China) or immediately placed at -80 °C. All the patients signed informed consent forms, and the Ethics Committee of the Second Hospital of Hebei Medical University approved our study (approval letter No. 2020-P025).

Cell culture

The human normal hepatic cell line (LO2) and human hepatocarcinoma cell lines (HepG2, Huh7, Bel7402, SMMC7721) were purchased from the American Type Culture Collection (ATCC; Manassas, VA, United States). Cells were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco BRL, Grand Island, NY, United States) supplemented with 10% fetal bovine serum (FBS, HyClone, South Logan, UT, United States), 100 μg/mL of streptomycin and 100 U/mL of penicillin (Gibco BRL). Overexpression was accomplished by transfection with lentivirus-YB-1 (Lv-YB-1) for 24 h (Shanghai GenePharma Co., Ltd., Shanghai, China, Supplementary Table S1). Sequences of the YB-1 siRNA are displayed in Supplementary Table S2. Lentiviral vectors harboring YB-1-specific shRNA (Lv-shYB-1) were used (Shanghai GenePharma Co., Ltd, Supplementary Table S1), and cells were transfected for 24 h. Hepatoma cells were then incubated with 2.5 or 5 μmol/L sorafenib (MedChemExpress, Monmouth Junction, NJ, United States) for 24-48 h. LY294002 [a broad-spectrum inhibitor of phosphoinositide-3-kinase (PI3K), 20 μmol/L, 24 h] (MedChemExpress) or vehicle was also used to incubate YB-1-overexpressing cells with sorafenib.

Cell viability assay

Cell Counting Kit-8 (CCK-8) assays (Shanghai Share-bio Biotechnology Co., Shanghai, China) were used to examine the half-inhibitory concentration (IC_{50}). Briefly, the cells were seeded into 96-well plates at a density of 5×10^3 cells/well and incubated with different concentrations of sorafenib. Next, CCK-8 (10 μL/well) was added (serum-free medium *vs* CCK-8 = 10:1) to a volume of 110 μL and incubated for 2 h. The optical density (OD) value was measured using a microplate reader (BioTek, Winooski, VT,

United States) at 450 nm. For the cell cycle distribution analysis, the cells were cultured in six-well plates and collected when the cells were transfected and incubated for 24 h. Hereafter, we washed the cells with precooled phosphate-buffered saline (PBS; Solarbio Science and Technology Co., Ltd., Beijing, China), fixed the cells in 70% ethanol (Tianjin YongDa Chemical Reagent Co., Ltd., Tianjin, China), and subjected them to staining with PI/RNase Staining Solution (Beyotime Biotechnology Co., Shanghai, China) at 37 °C in the dark for 30 min. A FACSVerse flow cytometer (BD Biosciences, San Jose, CA, United States) was used to analyze the samples, and ModFit 5.0 software (BD Biosciences) was used to process the data.

Apoptosis assays

Following treatment, we collected and washed the cells with precooled PBS and utilized the Annexin V Apoptosis Detection Kit (Invitrogen, Carlsbad, CA, United States) to detect apoptotic cells. Briefly, the cells were incubated with staining solution containing 2.5 μL of Annexin V-APC, 5 μL of propidium iodide (PI) buffer and 200 μL of binding buffer for 20 min in the dark at room temperature. A FACSVerse flow cytometer was applied to analyze the samples. Additionally, a one-step terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) apoptosis detection kit (Beyotime Biotechnology Co.) was employed to examine apoptosis according to the manufacturer's instructions. TUNEL-positive cells were recorded as the measurement of cell apoptosis. A laser scanning confocal microscope (Olympus, Tokyo, Japan) was used to acquire representative images.

Animal experiments

BALB/c nude mice were purchased from Beijing Vital River Laboratory Animal Technology Co., Ltd. Approximately 2 × 10^6 Huh7 cells transfected with Lv-shNC or Lv-shYB-1 were subcutaneously injected into male BALB/c nude mice aged 4 wk. We measured the tumors every 2 d, and (length × width^2)/2 was used to calculate the tumor volume. Next, we randomly divided the mice into designated groups (n = 6) when the average volume of the tumors reached approximately 100 mm^3. The nude mice in the Lv-shNC + sorafenib and Lv-shYB-1 + sorafenib groups were treated with sorafenib by gavage at a dosage of 30 mg/kg/d for 14 d. We sacrificed the nude mice when the treatment was completed, and the tissues were fixed with 4% paraformaldehyde or immediately placed at -80 °C. The animal protocol was designed to minimize pain and discomfort to animals. The nude mice were acclimatized to laboratory conditions for 1 wk prior our experiment. Intragastric gavage administration was conducted by using straight gavage needles (22 gauge). All the animals in our study received humane care, and the ethics committee of the Second Hospital of Hebei Medical University approved our study (approval letter No. 2020-AE002).

Histological and immunohistochemical analyses

We fixed human liver tissues and mouse xenograft tumors with 4% paraformaldehyde, embedded tissues in paraffin (Shanghai YiYang Instrument Co., Ltd., Shanghai, China), and sectioned them. The sections were then subjected to hematoxylin and eosin (HE, Beijing Legian Biotechnology Co., Ltd., Beijing, China) and immunohistochemical (IHC) staining using standard protocols as previously described[22]. YB-1 (diluted 1:200; catalog number: CY5462; Shanghai Abways Biotechnology Co., Ltd., Shanghai, China) and proliferating cell nuclear antigen (PCNA; diluted 1:200; catalog number: AB0051; Shanghai Abways Biotechnology Co., Ltd.) antibodies were used in our study, and IHC images were obtained using an upright microscope (Leica, Wetzlar, Germany). We utilized ImageJ software (National Institutes of Health, Bethesda, MD, United States) to morphometrically evaluate the percentage of positive areas on the micrographs.

Western blot analysis

Cells or tissues were lysed using radioimmunoprecipitation assay buffer [50 mmol/L Tris, 1 mmol/L ethylenediaminetetraacetic acid, 150 mmol/L NaCl, 0.1% sodium dodecyl sulfate (SDS), 1% Triton X-100, 1% sodium deoxycholate, 1 mmol/L phenylmethylsulfonyl fluoride] (Beyotime Biotechnology Co.) for total protein extraction after washing in PBS. Next, we quantified the protein concentrations by Coomassie blue staining (Solarbio Science and Technology Co., Ltd.) and denatured in SDS loading buffer (Beyotime Biotechnology Co.) by boiling for 10 min. The proteins from each sample were subjected to SDS-polyacrylamide gel electrophoresis (Shanghai Epizyme Biotechnology Co., Ltd., Shanghai, China) and transferred onto polyvinylidene difluoride membranes (Merck Millipore, Billerica, MA, United States). Next, 5%

milk (Solarbio Science and Technology Co., Ltd.) was used to block the membranes for 1 h, followed by incubation with the primary antibodies overnight at 4 °C. The next day, the membranes were incubated with fluorescence-conjugated secondary antibodies (LI-COR Biosciences, Lincoln, NE, United States) for 1 h at room temperature. We applied an Odyssey infrared imaging system (LI-COR Bioscience) to visualize the bands and quantified them using ImageJ software. GAPDH, PI3K or Akt was applied to normalize the desired bands, and the results were shown as relative density ratios. The primary antibodies used included YB-1 (diluted 1:500), p-PI3K (diluted 1:100; catalog number: AF3242; RRID: AB_2834668; Affinity Biosciences Ltd., Jiangsu, China), PI3K (diluted 1:100; catalog number: AF6242; RRID: AB_2835106; Affinity Biosciences Ltd.), GAPDH (diluted 1:1000; catalog number: AB0037; Shanghai Abways Biotechnology Co., Ltd.), p-Akt (diluted 1:100; catalog number: CY6569; Shanghai Abways Biotechnology Co., Ltd.), Akt (diluted 1:500; catalog number: CY5561; Shanghai Abways Biotechnology Co., Ltd.), PCNA (diluted 1:1000), and PARP (diluted 1:1000; catalog number: #9532; RRID: AB_659884; Cell Signaling Technology, Danvers, MA, United States).

Digital gene expression profiling

Two samples of HepG2 cell lines (Lv-shNC + sorafenib and Lv-shYB-1 + sorafenib) with stable YB-1 knockdown and sorafenib treatment were used, and each sample was repeated 3 times. Next, we submitted the samples to Beijing Novogene Technology Co., Ltd. (Beijing, China) for digital gene expression profiling (DGE) sequencing analysis to screen out DEGs. The analysis process mainly included data quality control, reference genome comparison, quantitative analysis, significance analysis of differences and functional enrichment analysis. The DESeq2 R package (1.16.1) was employed to perform the differential expression analysis between the groups (three biological replicates per group). The Benjamini and Hochberg approach to control the false discovery rate was adopted to adjust the resulting *P*-values (padj). A padj less than 0.05 and an absolute value of the log2 (fold change) more than 0 were utilized as the thresholds to recognize the differentially expressed genes[23,24].

Statistical analysis

All the experiments were repeated three times. Normally distributed data were expressed as mean ± SD, and nonnormally distributed data were expressed as medians with interquartile range. The difference between two groups was analyzed by Student's *t*-test. For differences among multiple groups, one-way ANOVA was performed. SPSS software version 19.0 (IBM, Armonk, NY, United States) was used to perform all statistical analyses. *P* values less than 0.05 were deemed statistically significant.

RESULTS

YB-1 is upregulated in HCC samples and cell lines

To determine the role of YB-1 in HCC, the expression of YB-1 in 6 paired HCC tissues and paracarcinoma tissues was detected by Western blot analysis. The YB-1 protein levels in HCC tissues were significantly elevated in all 6 patients (Figure 1A). To further verify the dysregulation of YB-1, we also performed IHC to detect YB-1 expression in the 6 paraffin-embedded HCC tissues and their paired adjacent liver tissues. The protein levels of YB-1 were also higher in HCC tissues than in nontumor tissues, and YB-1 was mainly located in the cytoplasm (Figure 1B, C). The expression of YB-1 was further detected in several hepatocarcinoma cell lines. Compared with the protein levels of YB-1 in LO2 cells, those in HepG2 and Huh7 cells were dramatically increased but slightly elevated in Bel7402 and SMMC7721 cells ($P < 0.05$) (Figure 1D). Taken together, YB-1 is elevated in HCC tissues and cell lines, implying that it might play a role in tumor progression.

YB-1 induces sorafenib resistance in hepatoma cells

Recent studies have shown that YB-1 is related to anticancer drug resistance in multiple tumor types. The IC_{50} of sorafenib in HCC cell lines was tested, and the IC_{50} values of Bel7402, SMMC7721, HepG2 and Huh7 cells were 4.47 μmol/L, 3.98 μmol/L, 5.01 μmol/L, and 2.51 μmol/L, respectively (Supplementary Figure S1A). We also found that YB-1 protein levels were upregulated in Bel7402, SMMC7721, HepG2 and Huh7 cells 24 h after sorafenib treatment (Supplementary Figure S1B). The transfection

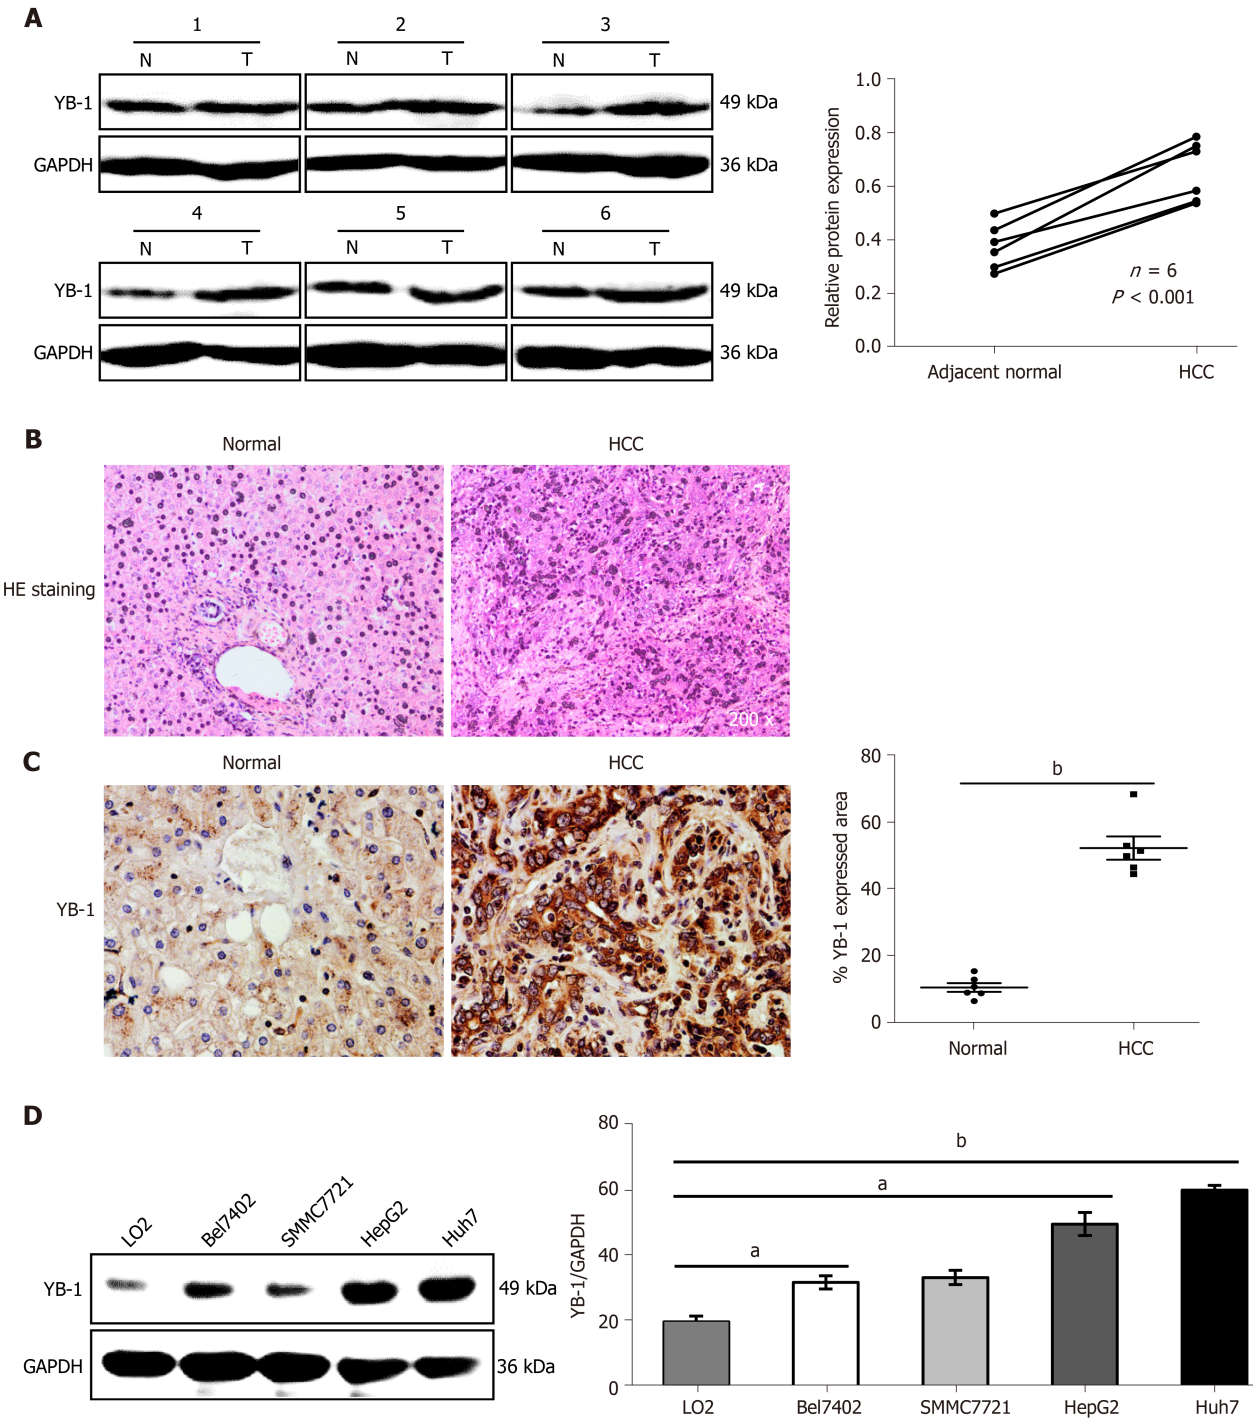

Figure 1 Increased expression of Y-box binding protein 1 in the liver tissues of hepatocellular carcinoma patients and cell lines. A: The protein expression levels of Y-box binding protein 1 (YB-1) in 6 pairs of hepatocellular carcinoma (HCC) liver tissues and their corresponding nontumor tissues were detected by Western blot analysis. Paraffin-embedded sections of liver tissues were stained with hematoxylin-eosin (HE) (B), and immunohistochemistry staining of YB-1 (C) was performed in the 2 groups; D: Western blot analysis showed YB-1 protein expression in one normal (N) liver cell line and four HCC cell lines. YB-1 protein levels (normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH)) were measured by scanning densitometry. $^{a}P < 0.05$, $^{b}P < 0.001$ *vs* the indicated groups. T: Tumor.

efficiency of the YB-1 siRNA and lentivirus is displayed in Supplementary Figure S2. We further tested the IC_{50} values of sorafenib in HepG2 and Huh7 cells with overexpressed or knocked down YB-1. The IC_{50} values were increased after YB-1 overexpression, whereas they were lower in the two cell lines with Lv-shYB-1 (Figure 2A).

Hereafter, we elucidated the effects of YB-1 and sorafenib on cell proliferation and apoptosis in HepG2 and Huh7 cells. Overexpressing YB-1 decreased the number of G1-phase cells and increased the number of S-phase cells, and sorafenib restrained the increase in G1-phase cells and reduced the number of S-phase cells (Figure 2B, C). Simultaneously, YB-1 silencing resulted in increased G1-phase and reduced S-phase

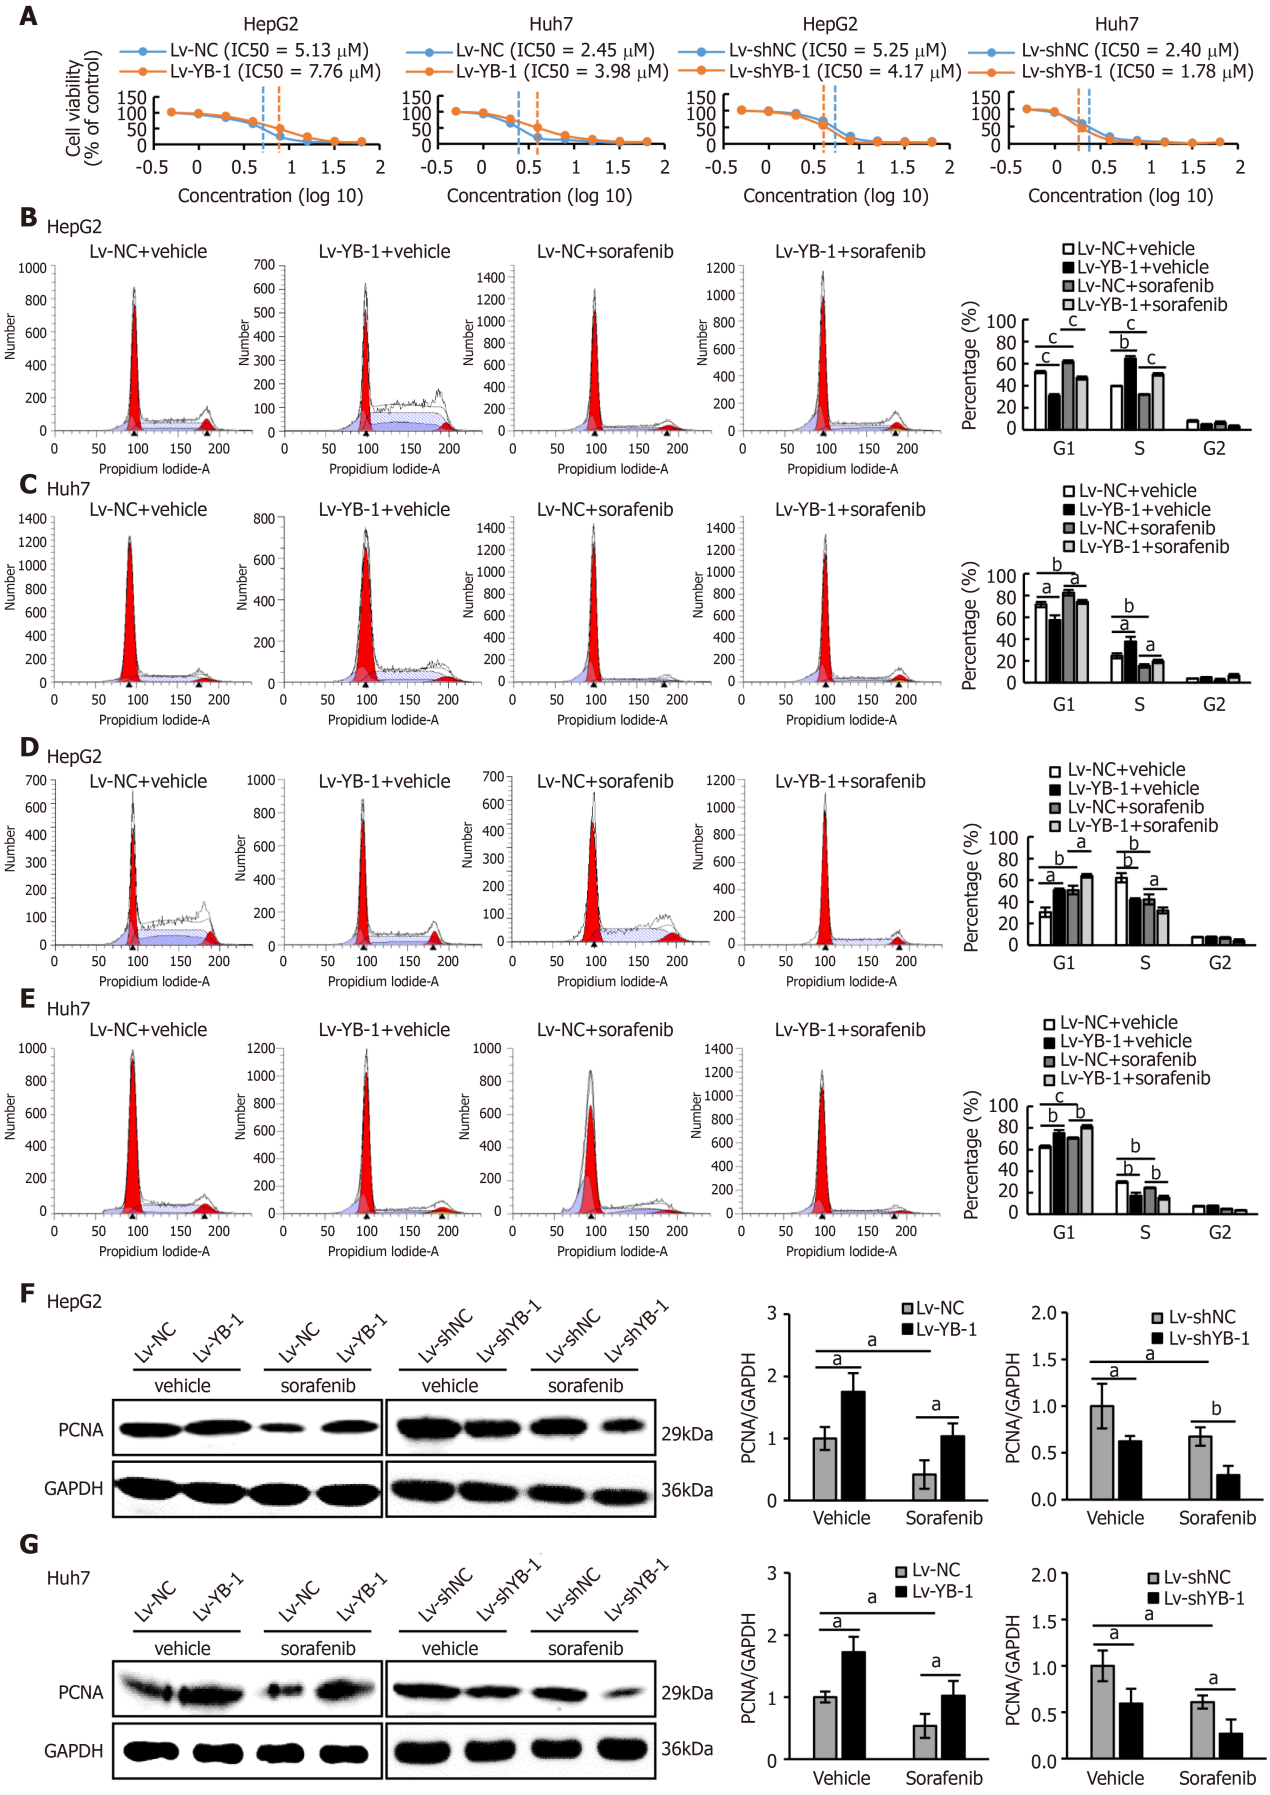

Figure 2 Y-box binding protein 1 offsets the effect of sorafenib on proliferation in hepatoma cell lines. A: The IC_{50} values of sorafenib in HepG2 and Huh7 cells infected with lentivirus encoding the Y-box binding protein 1 (lv-YB-1) or lentivirus encoding short hairpin RNA targeting YB-1 (Lv-shYB-1) were

detected by the Cell Counting Kit-8 (CCK-8) assay; B-E: Flow cytometry was conducted to perform cell cycle distribution analysis of the cells infected with the empty lentivirus vector as a negative control (Lv-NC) ± sorafenib *vs* Lv-YB-1 ± sorafenib groups (B, C) and lentivirus containing non-specific short hairpin RNA as a negative control (Lv-shNC) ± sorafenib *vs* Lv-shYB-1 ± sorafenib groups (D, E); F, G: Western blot analysis showed proliferating cell nuclear antigen (PCNA) protein expression in the Lv-NC ± sorafenib *vs* Lv-YB-1 ± sorafenib groups and Lv-shNC ± sorafenib *vs* Lv-shYB-1 ± sorafenib groups of HepG2 (F) and Huh7 (G) cells. PCNA protein levels (normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH)) were measured by scanning densitometry. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* the indicated groups.

cells and enhanced the effect of sorafenib on G1-phase and S-phase cells (Figure 2D, E). Additionally, we examined the levels of PCNA and found that it was increased in cells with YB-1 overexpression that the YB-1 overexpression offset PCNA reduction caused by sorafenib and that the knockdown of YB-1 had opposite effects in HepG2 (Figure 2F) and Huh7 cells (Figure 2G). These results indicated that YB-1 played a very important role in the G1/S transition in sorafenib-resistant HCC cell lines. Next, apoptosis was analyzed by TUNEL and flow cytometric analysis in HepG2 and Huh7 cells. YB-1 overexpression decreased cell apoptosis and reduced apoptosis induced by sorafenib (Figure 3A-D), while YB-1 knockdown strengthened the effect of sorafenib in HepG2 and Huh7 cells (Figure 4A-D). Furthermore, the protein levels of cleaved PARP decreased after YB-1 overexpression, which reduced the sorafenib-induced protein expression of activated PARP (Figure 3E, F). However, YB-1 knockdown played an opposite role in HepG2 and Huh7 cells (Figure 4E, F). Overall, these data proved that YB-1 mediated sorafenib resistance in liver cancer cell lines.

YB-1 knockdown ameliorates the efficiency of sorafenib in vivo

Xenograft tumor models were constructed using Huh7 cells with stable YB-1 knockdown. Tumor growth was suppressed both by YB-1 knockdown and sorafenib treatment. Nevertheless, the most obvious suppression was achieved by the amalgamation of YB-1 knockdown and sorafenib therapy (Figure 5A, B and Supplementary Figure S3). Additionally, YB-1 knockdown notably promoted the efficiency of sorafenib by examining tumor weights (Figure 5C). IHC staining also showed that the protein expression levels of PCNA in cells of the Lv-shYB-1 + sorafenib group were the lowest compared with those in cells with YB-1 knockdown or sorafenib treatment alone (Figure 5D). Furthermore, we extracted protein from xenograft tumors and found that the p-Akt and p-PI3K protein levels were downregulated after YB-1 knockdown or sorafenib treatment, and the most dramatic reduction occurred in the Lv-shYB-1 + sorafenib group (Figure 5E and F). Together, these results showed that YB-1 knockdown mitigated the resistance to sorafenib and reinforced the antitumor efficacy.

Identification of differentially expressed genes in the DGE-seq results of HepG2 cells

In total, 6254 significant differentially expressed genes were detected between the Lv-shYB-1 + sorafenib and Lv-shNC + sorafenib groups, among which 3317 were downregulated and 2937 were upregulated. The differentially expressed genes in the Lv-shYB1 + sorafenib and Lv-shNC + sorafenib groups were merged as the differential gene set. Mainstream hierarchical clustering was used to cluster the FPKM values (expected number of fragments per kilobase of transcript sequence per million base pairs sequenced) of the differential gene set to gather genes with similar expression patterns. The hierarchical clustering heatmap (Figure 6A) showed that the expression patterns of genes in the Lv-shYB1 + sorafenib group were distinguishable from those of the Lv-shNC + sorafenib group.

GO and KEGG pathway analyses

We identified the functional categories and signaling pathways using GO and KEGG pathway analyses[25]. The differentially expressed genes were categorized into three major GO categories: biological process (BP), cellular component (CC) and molecular function (MF). The top 30 GO categories are shown in Figure 6B. The differentially expressed genes were mapped to the reference canonical pathways using KEGG. The top 20 KEGG pathways were demonstrated in Figure 6C. Additionally, we searched the BioGRID (https://thebiogrid.org/) and HitPredict (www.hitpredict.org/) websites to explore the potential YB-1-interacting proteins. In the top 20 KEGG pathways, we found two key proteins that interact with YB-1 in the PI3K/Akt signaling pathway: (1) Akt1: activated Akt binds to the YB-1 cold shock domain at Ser102[26,27]; and (2) phosphoinositide-3-kinase regulatory subunit 1 (PIK3R1): PI3K is a critical regulator in

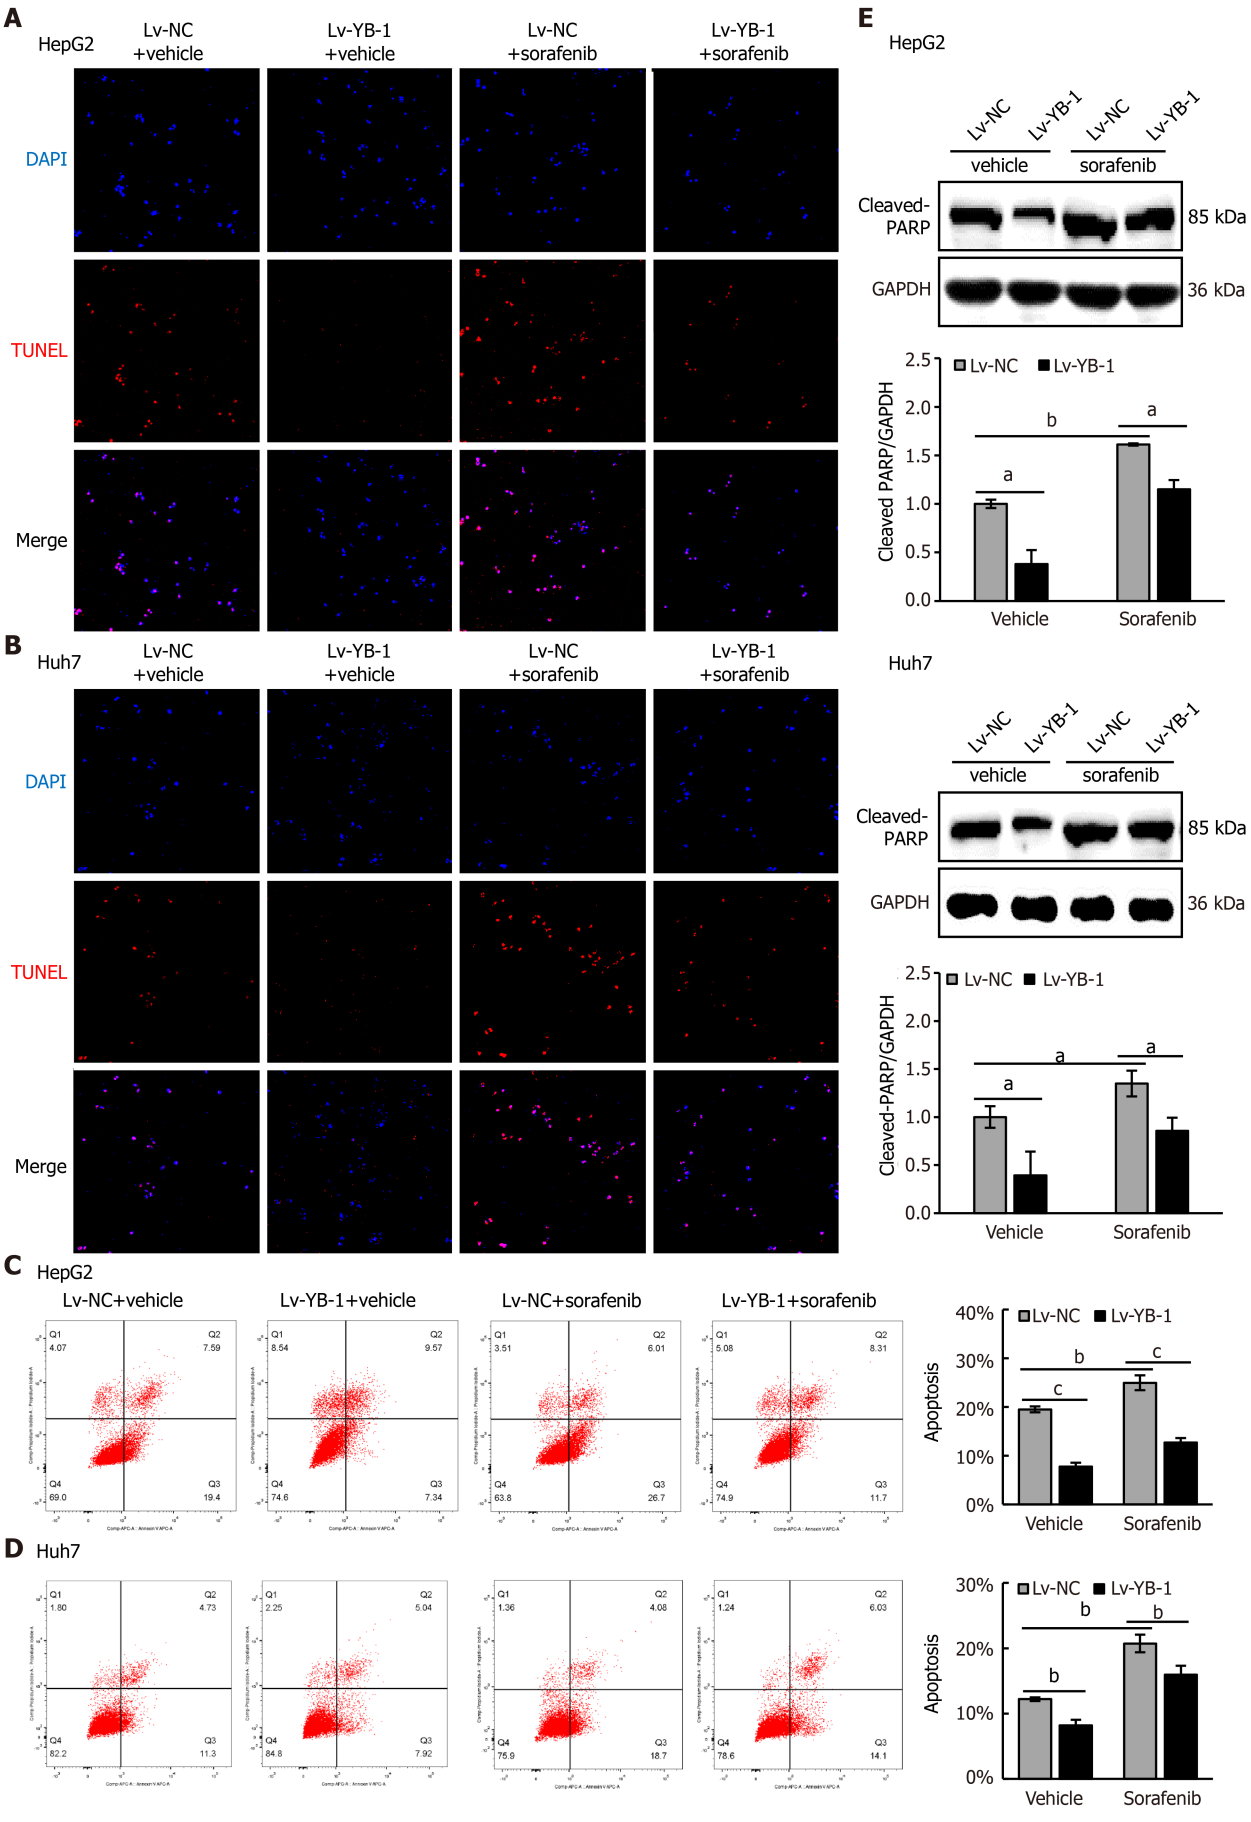

Figure 3 Y-box binding protein 1 suppresses apoptosis induced by sorafenib treatment in hepatocellular carcinoma cell lines. A-D:

Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) and flow cytometry were employed to analyze apoptosis in the cells infected with empty lentivirus vector as a negative control (Lv-NC) ± sorafenib *vs* lentivirus with Y-box binding protein 1 (Lv-YB-1) ± sorafenib groups; E, F: Western blot analysis showed cleaved poly ADP-ribose polymerase (PARP) protein expression in the Lv-NC ± sorafenib/Lv-YB-1 ± sorafenib groups. Cleaved PARP protein levels (normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH)) were measured by scanning densitometry. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* the indicated groups. DAPI: 4'6'-diamidino-2-phenylindole dihydrochloride.

the PI3K/Akt pathway, and YB-1 is one of the 49 cross-species PI3K binding proteins from Drosophila-human reciprocal blasts[28]. Pathway enrichment analysis indicated that 133 differentially expressed genes were annotated to the PI3K/Akt pathway. Additionally, our results suggest that the mRNA expression of Akt1 and Akt2 was significantly changed after YB-1 knockdown (Figure 6D). Furthermore, the Akt signaling pathway correlates with YB-1[29], sorafenib treatment[30] and HCC[31]. Therefore, we planned to further investigate the potential relationship of YB-1 and the PI3K/Akt pathway in HCC cell lines treated with sorafenib.

YB-1 promotes sorafenib resistance via the PI3K/Akt signaling pathway

Western blot analysis was consequently applied to detect the expression levels of key proteins in the PI3K/Akt signaling pathway in HepG2 and Huh7 cells. The expression levels of p-Akt and p-PI3K were increased in YB-1-overexpressing cells, and sorafenib decreased the protein expression; however, the association of YB-1 overexpression and sorafenib treatment neutralized the expression of the two proteins (Figure 7A-D). Simultaneously, either single knockdown of YB-1 or treatment with sorafenib inhibited p-Akt and p-PI3K expression. Furthermore, the most significant suppression of protein expression was accomplished by the combination of YB-1 knockdown and sorafenib incubation (Figure 7A-D).

Next, we explored whether blockade of the PI3K/Akt pathway would avoid YB-1-induced sorafenib resistance in Lv-NC + sorafenib and Lv-YB-1 + sorafenib-treated HepG2 and Huh7 cells. The phosphorylation of PI3K and Akt was obviously attenuated after the suppression of PI3K/Akt signaling by LY294002 in Lv-NC and Lv-YB-1 cells incubated with sorafenib (Figure 7E-H). Moreover, LY294002 led to increased G1-phase and reduced S-phase cells, inhibited YB-1-induced decreased G1-phase and increased S-phase cells (Figure 7I and J), and decreased PCNA expression (Figure 7K-M). Simultaneously, the suppression of PI3K/Akt signaling by LY294002 increased apoptosis in Lv-NC and Lv-YB-1 cells with sorafenib incubation (Figure 8A-D) and elevated the protein levels of cleaved PARP (Figure 8E and F). Taken together, YB-1 induced sorafenib resistance by activating the PI3K/Akt signaling pathway.

DISCUSSION

Researchers have mainly focused on the relationship between YB-1 and tumor proliferation, apoptosis, invasion, metastasis and other biological behaviors[32-36]. To date, few studies have investigated the correlation between YB-1 and drug resistance. In addition to YB-1 activating MDR in various tumors[18], YB-1 also induces the development of chemotherapy resistance by regulating the expression of P-glycoprotein and focal adhesion kinase and the characteristics of stem cells in various tumors[37-39]. Additionally, indirubin 3'-oxime inhibits the nuclear translocation of YB-1, thereby reducing MDR1 expression and exerting efficacy in treating liver cancer [40]. Sorafenib, a new type of multitarget antitumor drug, is a first-line systemic treatment option for patients with advanced HCC[41]. It has dual antitumor effects: (1) it blocks the signaling pathway mediated by RAF/MEK/extracellular regulated protein kinases (ERK) and directly inhibits tumor cell proliferation; (2) it inhibits vascular EGFR and platelet-derived growth factor receptor and then suppresses angiogenesis, indirectly inhibiting tumor cell growth[41]. Studies on the resistance mechanism of sorafenib have found that EMT, activation of the Akt signaling pathway, tumor stem cells, and abnormal regulation of proliferation and apoptosis induce sorafenib resistance[42].

The effect of sorafenib, which promotes cell apoptosis and inhibits cell proliferation, has been proven in previous studies[30,43,44]. A study on sorafenib resistance observed that β-catenin and its downstream target genes were elevated in hepatoma cells after incubation with sorafenib, and β-catenin overexpression inhibited apoptosis and promoted cell proliferation, while β-catenin knockdown enhanced the effect of sorafenib on apoptosis and proliferation. Additionally, the IC_{50} values of sorafenib

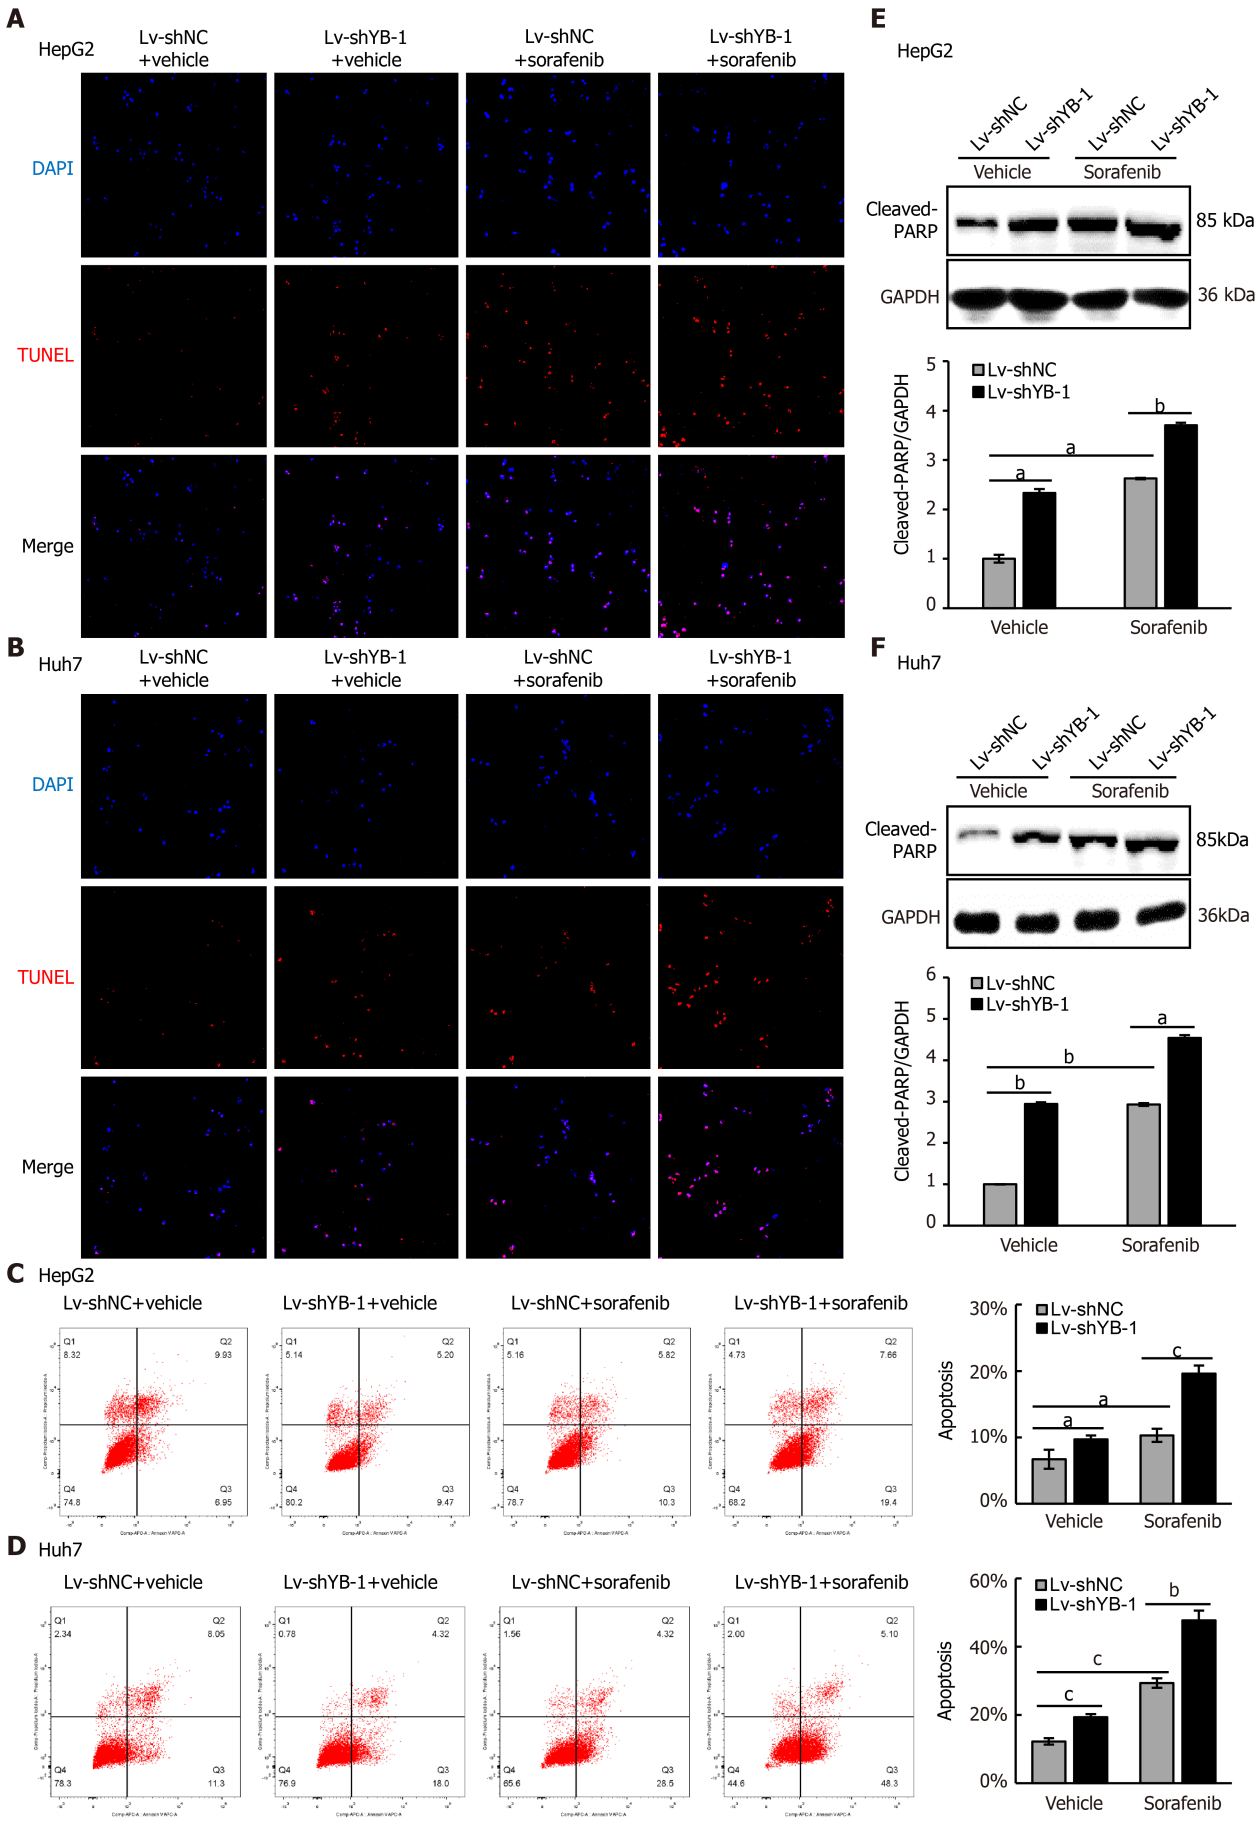

Figure 4 Y-box binding protein 1 suppresses apoptosis induced by sorafenib treatment in hepatocellular carcinoma cell lines. A-D:

Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) and flow cytometry were employed to analyze apoptosis in the cells infected with lentivirus encoding non-specific short hairpin RNA as a negative control (Lv-shNC) ± sorafenib *vs* lentivirus with short hairpin RNA targeting the Y box binding protein 1 (Lv-shYB-1) ± sorafenib groups; E, F: Western blot analysis showed cleaved poly ADP-ribose polymerase (PARP) protein expression in the Lv-shNC ± sorafenib/Lv-shYB-1±sorafenib groups. Cleaved PARP protein levels (normalized to glyceraldehyde-3-phosphate dehydrogenase (GAPDH)) were measured by scanning densitometry. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* the indicated groups.

were heightened in liver cancer cells overexpressing β-catenin, confirming that β-catenin is closely related to sorafenib resistance. The relationship between YB-1 and sorafenib resistance in HCC was first clarified in our study. First, YB-1 in liver cancer tissues showed dramatically higher expression than that in the corresponding adjacent tissues. Next, we constructed lentiviruses that overexpress or knock down YB-1 expression in two human liver cancer cell lines (HepG2 and Huh7) and simultaneously stimulated cells with different concentrations of sorafenib; YB-1 significantly elevated the IC_{50} of HCC cells. We proved that the effect of sorafenib on apoptosis and proliferation was suppressed by YB-1 overexpression, while YB-1 knockdown had opposite effects. Uniformly, the association of YB-1 knockdown and sorafenib treatment had the most significant effect on the efficacy of sorafenib *in vivo*. These results indicate that YB-1 leads to sorafenib resistance in HCC[43,44].

Next, we conducted digital gene expression profile analysis in HepG2 cells (Lv-shNC + sorafenib, Lv-shYB-1 + sorafenib) with stable YB-1 knockdown and sorafenib treatment. Akt1 and Akt2 in the Lv-shYB-1 + sorafenib group were notably lower than those in the Lv-shNC + sorafenib group, and KEGG pathway enrichment analysis revealed a significant difference in the PI3K/Akt signaling pathway between the two groups. At the same time, we searched for proteins that interact with YB-1 using the BioGRID and HitPredict websites. Among proteins that interface with YB-1, we identified two proteins, Akt1[26,27] and PIK3R1[28], which are essential proteins of the PI3K/Akt signaling pathway.

The PI3K/Akt signaling pathway, a well-known survival mechanism of cancer, is tightly correlated with cancer occurrence and growth. Presently, studies on the PI3K/Akt signaling pathway has mostly focused on the proliferation, apoptosis, migration and invasion of tumor cells, such as gastric cancer[45], breast cancer[46], cervical squamous cell carcinoma[47] and osteosarcoma[48]. Additionally, YB-1 was reported to promote the tumorigenesis and progression of spinal chordoma by activating the EGFR/Akt signaling pathway[29]. At the same time, the PI3K/Akt pathway is also involved in chemotherapeutic drug resistance; for example, suppressing the expression of Akt sensitizes cells to sorafenib-induced apoptosis[49], and blocking the PI3K/Akt signaling pathway induces increased sensitivity of hepatocarcinoma cells to sorafenib[50-52]. Regarding acquired sorafenib resistance, the PI3K/Akt signaling pathway is considered a compensation mechanism, and multiple studies have revealed that the phosphorylation level of Akt in HCC cells with acquired sorafenib resistance is higher than that in its parental cells. Inhibition of Akt by GDC0068, MK-2206 or LY294002 reverses the occurrence of acquired sorafenib resistance[53-55]. Fortunately, we verified that YB-1 activates the PI3K/Akt signaling pathway and inhibits the inactivation of the PI3K/Akt signaling pathway induced by sorafenib treatment. Additionally, the blockade of PI3K/Akt signaling pathway by LY294002 inhibited YB-1-induced sorafenib resistance in HepG2 and Huh7 cells. Thus, YB-1 stimulates sorafenib resistance by targeting the PI3K/Akt signaling pathway in HCC.

CONCLUSION

In conclusion, the absence of YB-1 effectively suppresses the occurrence of sorafenib resistance and promotes the deactivation of the PI3K/Akt signaling pathway caused by sorafenib. Given that sorafenib is the first-line treatment for patients with advanced HCC, we propose that downregulation of YB-1 may be a novel potential approach to treat advanced HCC and improve the efficacy of sorafenib in treating advanced HCC.

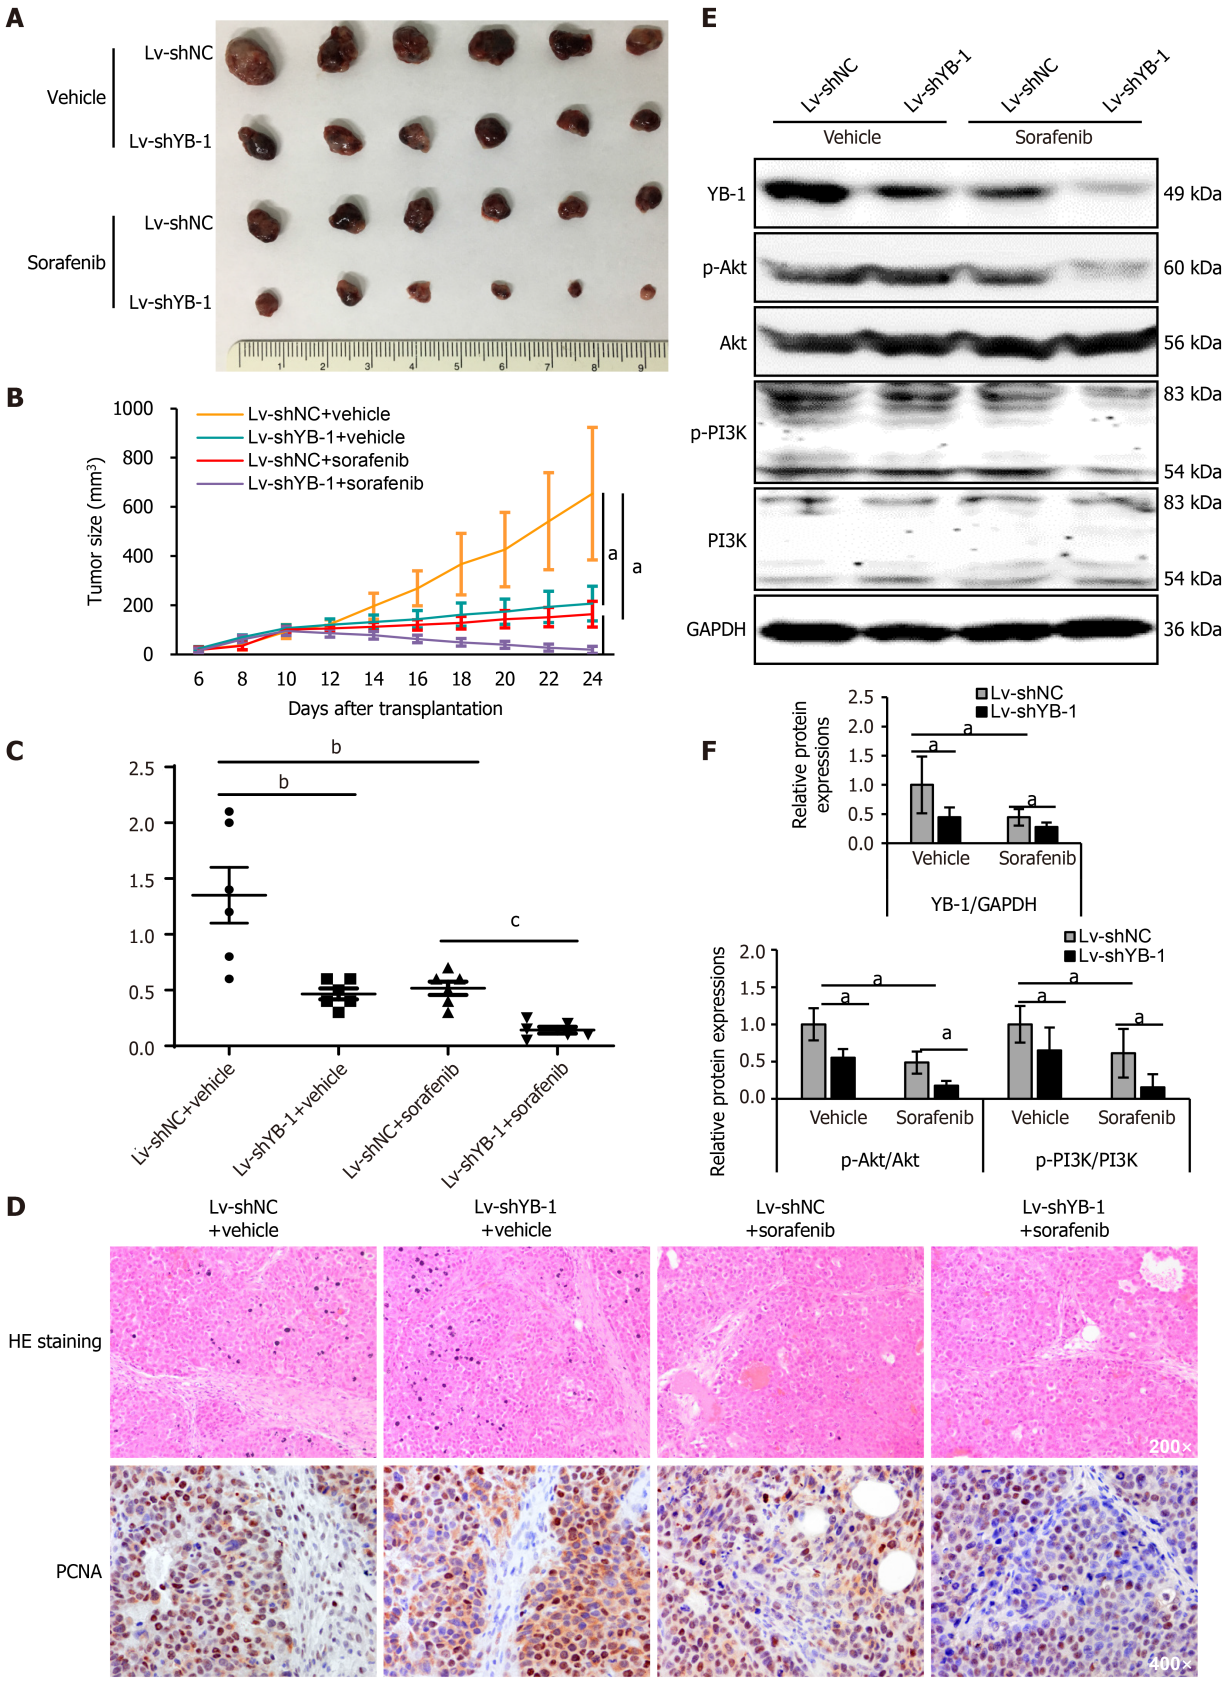

Figure 5 Sorafenib efficiency improves after Y-box binding protein 1 knockdown *in vivo*. A: The morphologies of collected tumors in subcutaneous Huh7 xenografts in nude mice; B: Tumor growth curves; C: Tumor weights were measured after collection; D: Hematoxylin-eosin (HE) and immunohistochemical staining for proliferating cell nuclear antigen; E, F: Western blot analysis showed Y-box binding protein 1 (YB-1), phosphorylated protein kinase B (p-Akt), protein kinase B (Akt), phosphorylated phosphoinositide-3-kinase (p-PI3K), and phosphoinositide-3-kinase (PI3K) expression in cells infected with lentivirus encoding non-specific short hairpin RNA as a negative control (Lv-shNC) ± sorafenib *vs* lentivirus containing short hairpin RNA targeting YB-1 (Lv-shYB-1) ± sorafenib groups. p-Akt (normalized to Akt) and p-PI3K (normalized to PI3K) protein levels were measured by scanning densitometry. Protein samples derived from the same experiment

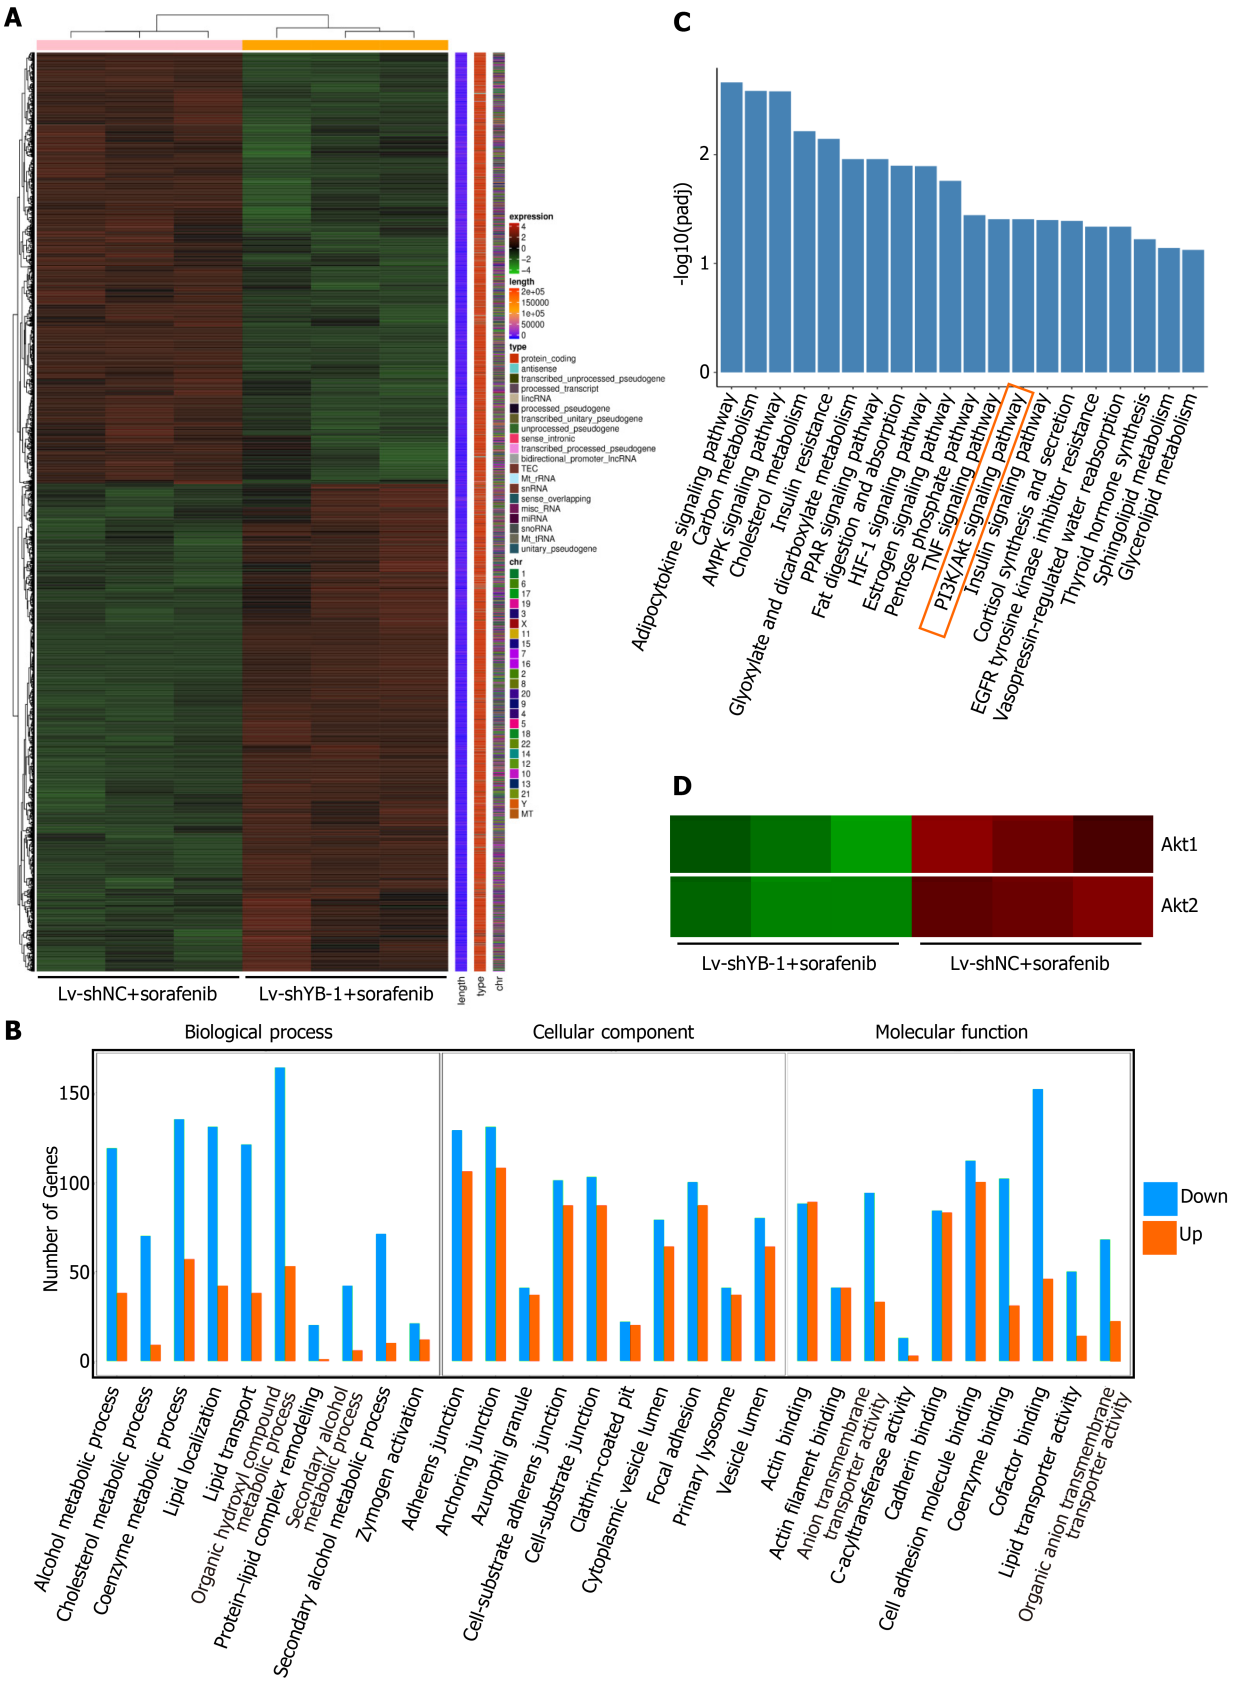
and gels were processed in parallel. [a]*P* < 0.05, [b]*P* < 0.01, [c]*P* < 0.001 *vs* the indicated groups. PCNA: Proliferating cell nuclear antigen.



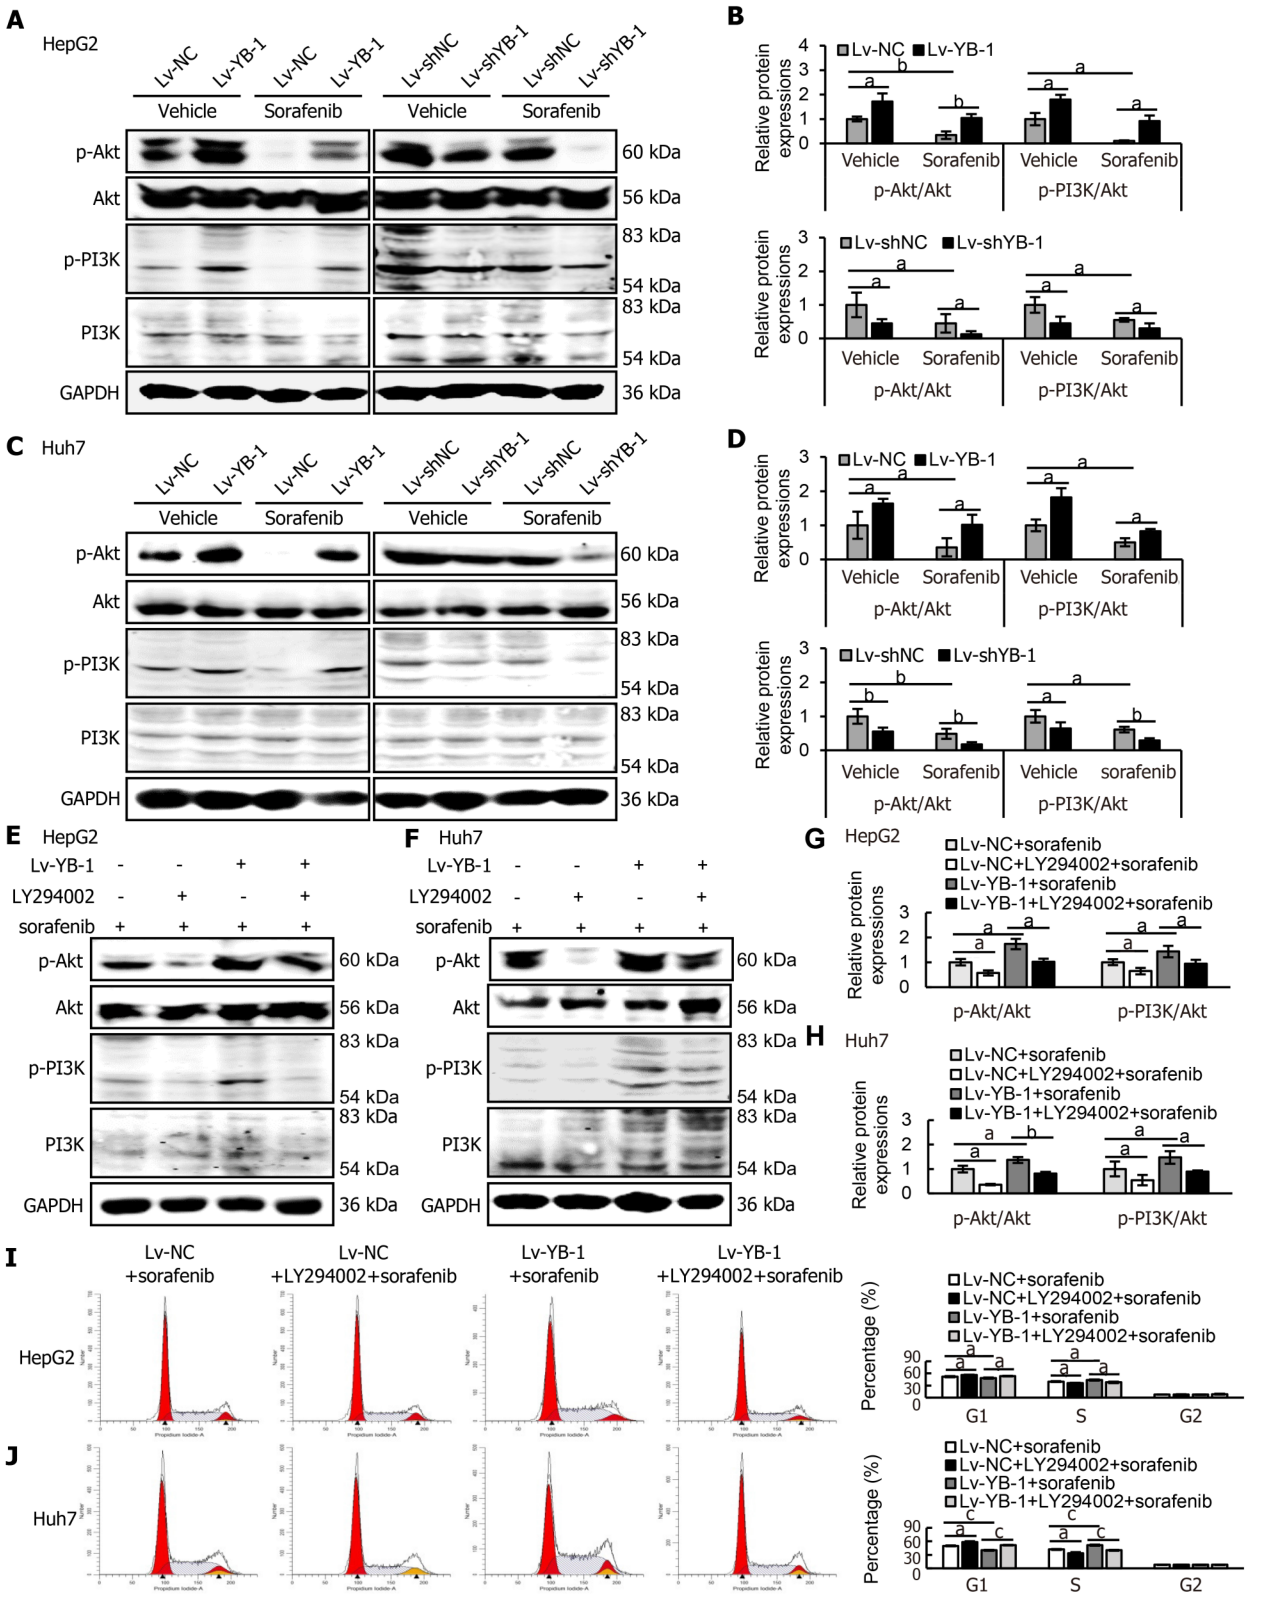


Figure 6 Digital gene expression profiling-seq analysis in HepG2 cells. A: Heat map of the results from the cluster analysis of the digital gene expression profiling (DGE)-seq data (cells infected with: lentivirus encoding non-specific short hairpin RNA as a negative control (Lv-shNC) + sorafenib *vs* lentivirus

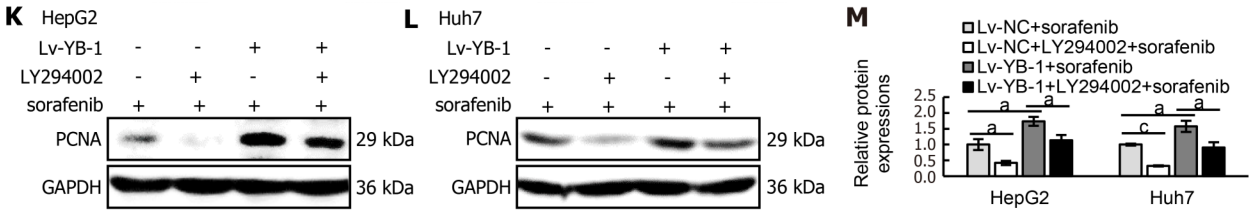
encoding short hairpin RNA against Y box protein 1 (Lv-shYB-1) + sorafenib). Each column denotes the DEGs identified in our study. Each row indicates a sample. For each gene, red represents a high level of expression relative to the mean, while green expresses a low level. The scale bar is the number of standard deviations from the mean; B: Histogram of GO functional analysis for the DEGs obtained from DGE sequencing. GO terms with padj < 0.05 were thought to be notably enriched by DEGs. The y axis represents the number of genes in a GO classification category. Red represents increased expression in the Lv-shYB-1 + sorafenib group, whereas green indicates decreased expression in that group; C: Pathway enrichment analysis showed the top 20 signaling pathways in KEGG (padj < 0.05); D: mRNA expression levels of protein kinase B1 (Akt1) and protein kinase B2 (Akt2) from the DGE-seq data (Lv-shNC + sorafenib, Lv-shYB-1 + sorafenib).



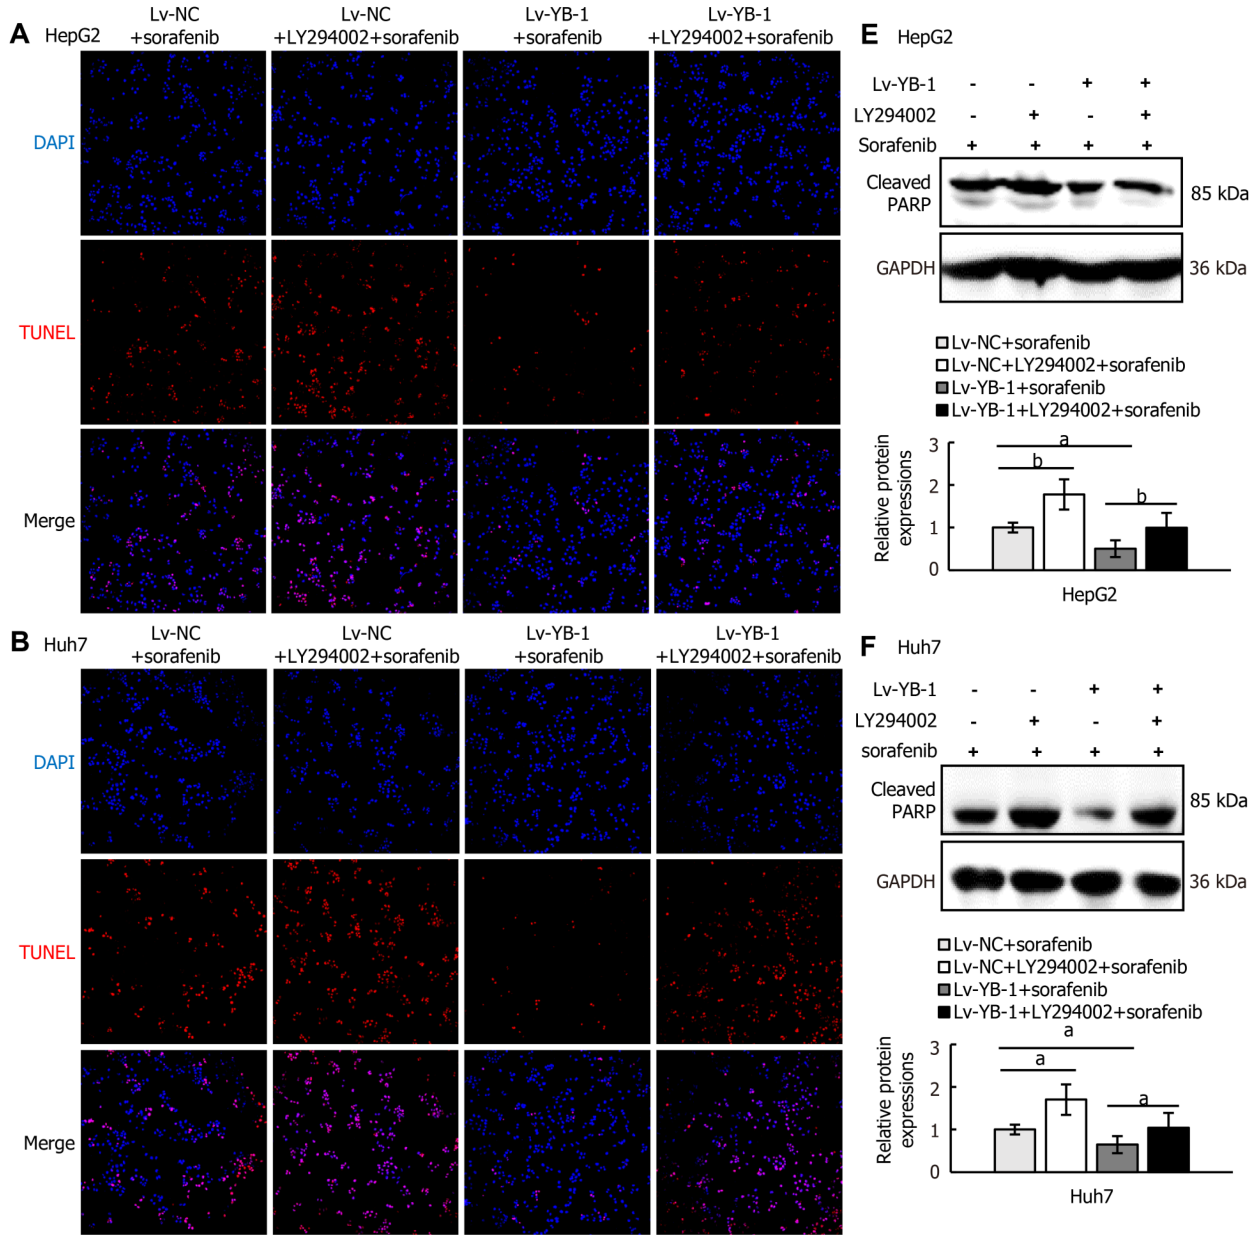


Figure 7 Y-box binding protein 1 suppresses the function of sorafenib in the PI3K/Akt signaling pathway, and blockade of the PI3K/Akt signaling pathway inhibits the promoting effect of YB-1 on proliferation. A-D: The protein expression levels of phosphorylated protein kinase B (p-Akt), protein kinase B (Akt), phosphoinositide-3-kinase (PI3K), and phosphorylated PI3K (p-PI3K) were detected by Western blot analysis in cells infected with lentivirus vector as a negative control (Lv-NC)±sorafenib *vs* cells infected with lentivirus encoding Y-box protein 1 (Lv-YB-1) ± sorafenib groups and lentivirus encoding non-specific short hairpin RNA as a negative control (Lv-shNC)±sorafenib *vs* cells infected with lentivirus encoding short hairpin RNA targeting Y-box binding protein 1 (Lv-shYB-1) ± sorafenib groups of HepG2 (A, B) and Huh7 (C, D) cells; E-H: Western blot analysis was also applied to evaluate the expression of p-Akt, Akt, p-PI3K and PI3K in the Lv-NC + sorafenib, Lv-NC + LY294002 + sorafenib, Lv-YB-1 + sorafenib, Lv-YB-1 + LY294002 + sorafenib groups of HepG2 (E, G) and Huh7 (F, H) cells. Protein samples derived from the same experiment and gels were processed in parallel; I, J: Flow cytometry was conducted to analyze the cell cycle distribution; K-M: Western blot analysis showed proliferating cell nuclear antigen (PCNA) protein expression, and its protein levels were measured by scanning densitometry. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$ *vs* the indicated groups.

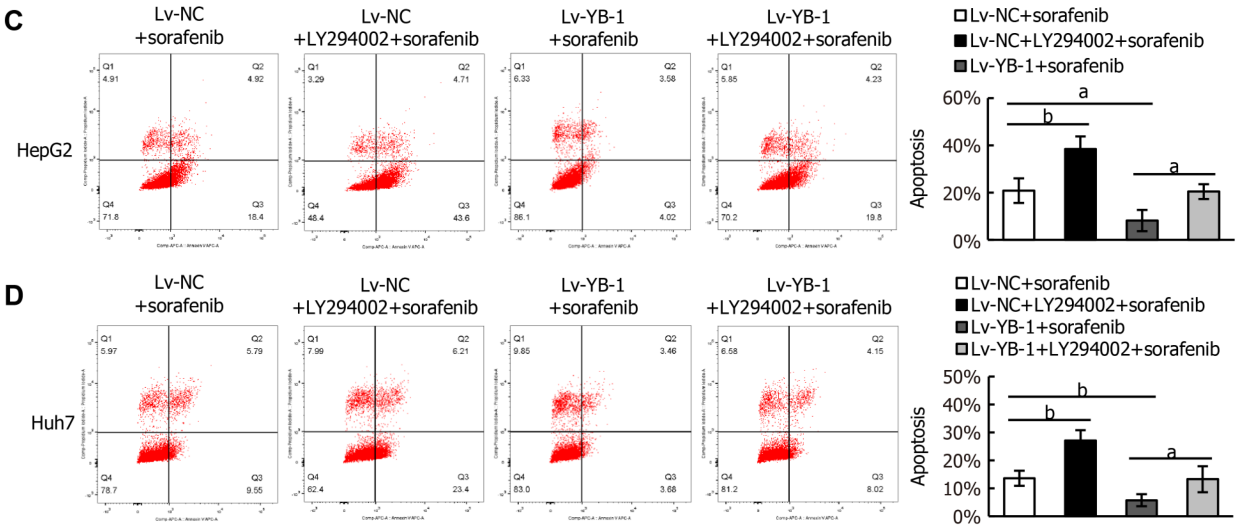

Figure 8 Blocking the PI3K/Akt signaling pathway suppresses the effect of Y-box binding protein 1 on apoptosis. A-D: Apoptosis analysis was conducted by terminal deoxynucleotidyl transferase dUTP nick end labeling staining (A, B) and flow cytometry with Annexin V-APC and PI staining (C, D); E, F: Western blot analysis showed cleaved poly ADP-ribose polymerase (PARP) protein expression. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* the indicated groups. Lv: Lentivirus; NC: Negative control; YB-1: Y-box binding protein 1; DAPI: 4'6'-diamidino-2-phenylindole dihydrochloride; TUNEL: Terminal deoxynucleotidyl transferase dUTP nick end labeling; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

ARTICLE HIGHLIGHTS

Research background

Y-box binding protein 1 (YB-1) promotes the proliferation of tumor cells, inhibits apoptosis, and activates the expression of multidrug resistance genes in breast cancer, kidney cancer and other cancers. It can also promote the resistance of gefitinib in lung adenocarcinoma cells. The specific molecular mechanism of YB-1 mediating drug resistance in hepatocellular carcinoma (HCC) is still unclear.

Research motivation

The study will provide a basis for the application of YB-1 in sorafenib resistance of HCC.

Research objectives

To detect the expression of YB-1 in HCC tissues and cells, and explore the role and the potential mechanism of YB-1 in sorafenib resistance of HCC.

Research methods

In this study, the authors examined the expression levels of YB-1 in cancer and corresponding paracancerous tissues of HCC patients, and clarified whether YB-1 was involved in sorafenib resistance in HCC by overexpressing and knocking down YB-1 in two kinds of hepatoma cell lines. Furthermore, a nude mouse liver cancer xenograft tumor model was established to verify the role of YB-1 in mediating sorafenib resistance in HCC *in vivo*. The signaling pathways involved in YB-1-mediated drug resistance in hepatocarcinoma cells were also screened and validated by digital expression profiling (DGE) technology.

Research results

YB-1 expression levels were significantly upregulated in both cancer tissues of HCC patients and human hepatoma cell lines. YB-1 could resist the effects of sorafenib on proliferation and apoptosis in hepatocarcinoma cells, which in turn mediated the resistance of HCC cells to sorafenib. YB-1 mediates sorafenib resistance in hepatocarcinoma cells through activating the phosphoinositide-3-kinase (PI3K)/protein kinase B (Akt) signaling pathway.

Research conclusions

Knockdown of YB-1 can effectively inhibit the occurrence of sorafenib resistance, and can also enhance the inactivation of sorafenib on the PI3K/Akt signaling pathway.

Therefore, YB-1 is a sorafenib resistance related gene.

Research perspectives

Downregulation of YB-1 may be a new potential method for the treatment of advanced HCC, and it is expected to improve the efficacy of sorafenib in the treatment of advanced HCC patients.

Abstract

BACKGROUND

Diagnostic accuracy of various tumor markers and their combinations for hepatocellular carcinoma (HCC) was not fully investigated.

AIM

To evaluate the diagnostic accuracy of alpha-fetoprotein (AFP), the *Lens culinaris* agglutinin-reactive fraction of AFP (AFP-L3), and protein induced by vitamin K absence or antagonist-II (PIVKA-II) and their combination for HCC diagnosis.

METHODS

Patients with newly detected liver mass or elevated serum AFP levels were considered eligible. Serum AFP level, AFP-L3 fraction, and PIVKA-II level were measured at the first visit.

RESULTS

In total, 622 patients were included; 355 patients (57.1%) had chronic liver disease, and 208 (33.4%) had liver cirrhosis. HCC was diagnosed in 160 patients (25.7%). The area under the receiver operating characteristics curves (AUROCs) of the serum AFP, AFP-L3 fraction, AFP-L3, and PIVKA-II levels for the diagnosis of HCC were 0.775, 0.792, 0.814, and 0.834, respectively. A novel diagnostic model was developed by classifying patients in a 1:1 ratio into training and validation sets. Using the binary regression analysis of the training cohort, the AFP, AFP-L3 fraction, and PIVKA-II (ALPs) score was calculated as follows: ALPs score = 3.8 × [serum AFP level (ng/mL) × AFP-L3 fraction (%) × 0.01] + 0.2 × PIVKA-II level (mAU/mL). The AUROC of the ALPs score for diagnosis of HCC was 0.878,

requirement for informed consent was waived owing to the retrospective nature of the study.

significantly higher than that of serum AFP level ($P < 0.001$), AFP-L3 fraction ($P < 0.001$), PIVKA-II level ($P = 0.036$), and AFP-L3 level ($P = 0.006$). The optimal ALPs score cut-off was 5.3 (sensitivity, 85.0%, specificity 80.1%). The validation cohort showed similar results.

CONCLUSION

The ALPs score calculated using serum AFP level, AFP-L3 fraction, and PIVKA-II level showed improved accuracy in HCC diagnosis.

Core Tip: The value of *Lens culinaris* agglutinin-reactive fraction of alpha-fetoprotein (AFP-L3) for improving diagnostic accuracy of hepatocellular carcinoma has not been fully evaluated. We investigated performance of AFP-L3 in patients with newly detected liver mass or elevated serum AFP level. In total of 622 patients, we observed significantly higher diagnostic accuracy of AFP-L3 level than with AFP level ($P < 0.001$). In addition, we developed a novel diagnostic model, AFP, AFP-L3 fraction, and protein induced by vitamin K absence or antagonist-II (PIVKA-II) score, derived from AFP level, AFP-L3 fraction, and PIVKA-II level, and it showed significantly higher area under the receiver operating characteristics curves of 0.878 than those of AFP level, AFP-L3 fraction, and PIVKA-II level (all $P < 0.05$).

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth most common tumor and the fourth significant cause of cancer-related death worldwide[1]. Although there have been many advancements in diagnosis of HCC, still, considerable number of patients are diagnosed as intermediate or advanced-stage HCC[2]. Therefore, improved diagnostics, especially for early-stage HCC where curative treatment is conceivable are warranted.

Imaging study plays a critical role in diagnosis of HCC, although limitations exist[3,4]. Furthermore, the imaging methods are not always applicable for certain patients, since the selection of imaging modality and contrast agent is subject to multiple factors, such as modality availability, scan time, throughput, technical capability of each institution, costs, radiologist expertise, patient preference, and safety considerations.

Therefore, although serum biomarkers usually have a minor role in the diagnosis of HCC, identifying biomarkers to better diagnose or predict HCC remains important priority in clinical research[5-7]. The American Association for the Study of Liver Diseases guideline suggests that alpha-fetoprotein (AFP) > 20 ng/mL and normal ultrasonography findings should alert recall procedures for possible HCC diagnosis, however, the routine use of novel biomarkers for HCC screening requires further evaluation[7-9]. The European association for the study of the liver guideline also indicate a lack of tumor markers for accurate and early detection of HCC owing to suboptimal previous data[5,9-11].

Various tumor markers including protein induced by vitamin K absence or antagonist-II (PIVKA-II), and novel blood parameter, the *Lens culinaris* agglutinin-reactive fraction of AFP (AFP-L3), have received considerable attention and were

L-Editor: A

evaluated in several studies[12,13]. AFP-L3 is AFP-isoform reflecting changes in the carbohydrate chain. Since AFP-L3 showed high specificity (92.0%–99.4%) and low sensitivity (18.8%–37.0%) for HCC[14-16], it is considered a more specific biomarker for HCC diagnosis. Recent studies evaluated the predictive performance of the combination of AFP, AFP-L3, and PIVKA-II, which showed improved HCC diagnostic ability than either AFP or PIVKA-II[17,18]. However, those results were inconclusive because of the small sample size and the specific characteristics of study population.

Hence, we conducted this retrospective study with a large number of patients, who were referred to our tertiary clinic for newly detected liver mass or elevated serum AFP level. We investigated and compared the predictive ability of AFP, AFP-L3, and PIVKA-II as well as their combination for HCC diagnosis and developed and validated a new diagnostic model for HCC.

MATERIALS AND METHODS

Subjects

Patients who were referred from the primary clinic to the Korea University Medical Center (a tertiary academic teaching hospital) for newly detected liver mass or elevated serum AFP level between 2015 and 2019 were enrolled (Supplementary Figure 1). The exclusion criteria were as follows: (1) Age < 18 years; (2) Insufficient laboratory findings or imaging data; (3) History of HCC; (4) Patients with liver failure; (5) History of liver transplantation or liver resection for reasons other than HCC; and (6) History of any malignancy other than HCC. This study protocol followed the ethical guidelines of the 1975 Declaration of Helsinki, and the institutional review board of Korea University Anam Medical Center. The requirement for informed consent was waived owing to the retrospective nature of the study.

Diagnosis of HCC

HCC diagnosis was based on non-invasive criteria or pathology or both in cirrhotic patients and pathology in non-cirrhotic patients. The non-invasive criteria were based on identification of typical hallmarks of HCC, obtained by multiphasic computed tomography or multiphase magnetic resonance imaging (nodule > 1 cm with arterial hypervascularity and portal/delayed-phase washout)[19,20]. Liver cirrhosis was diagnosed when typical ultrasonographic findings were found, with a low platelet count (< 100000/μL), varices, or overt complication of cirrhosis[21,22].

Measurements of tumor markers

Serum AFP level, AFP-L3 fraction, and PIVKA-II level were measured in patient blood samples collected at their first visit. We measured the AFP level and AFP-L3 fraction using the mTAS assay (Wako Pure Chemical Industries, Ltd., Osaka, Japan) and the PIVKA-II level using an enzyme immunoassay (Fujirebio Inc., Tokyo, Japan). Assay sensitivities were 0.3 ng/mL for AFP and 0.1 ng/mL for PIVKA-II. The percentage of AFP-L3 was determined in samples where both subfractions (AFP-L1 and AFP-L3) were > 0.3 ng/mL. The AFP-L3 level was calculated as follows: Serum AFP-L3 level = serum AFP level (ng/mL) × serum AFP-L3 fraction (%) × 0.01.

Statistical analysis

Data are presented as mean ± SD or numbers with percentages. The statistical significance of differences between continuous and categorical variables were compared using Student's *t*-test or Mann-Whitney *U* test and chi-square test, respectively. The predictive accuracies for the diagnosis of HCC were assessed using area under the receiver operating characteristics curves (AUROCs) as well as 95% confidence intervals. Optimal cutoff values were chosen to maximize the sum of the sensitivity and specificity. The sensitivity, specificity, positive predictive value (PPVs), and negative predictive value (NPVs) were computed for the optimal cutoff value. The AUROCs were compared using the Hanley-McNeil test[23]. Statistical analyses were conducted using IBM SPSS Statistics software (version 23.0.0.0., IBM Corporation, Armonk, NY, United States). Two-sided *P* values < 0.05 were considered significant.

RESULTS

Baseline characteristics of the study population

In total, 622 patients were finally included for the statistical analysis. The baseline characteristics of the study population are presented in Table 1**.** In the study population, chronic liver disease and liver cirrhosis were present in 355 (57.1%) and 208 (33.4%) patients, respectively. Among the 160 (25.7%) patients with HCC, BCLC stage was 0 in 35 (21.9%) patients, A in 50 (31.3%) patients, B in 32 (20.0%) patients, C (26.3%) in 42 patients, and D (0.6%) in 1 patients. The mean serum AFP, fraction of AFP-L3, AFP-L3 level and PIVKA-II level were significantly higher in patients with HCC than in those without HCC (all $P < 0.001$) (Table 1).

Diagnostic accuracy of tumor markers for HCC

For HCC diagnosis, AFP level, fraction of AFP-L3, level of AFP-L3 and PIVKA-II level had AUROC values of 0.775, 0.792, 0.814, and 0.834, respectively (Figure 1). The AUROC of the serum AFP level was similar to that of serum AFP-L3 fraction ($P = 0.321$), though significantly lower than that of the serum AFP-L3 level ($P < 0.001$) and PIVKA-II level ($P = 0.038$). The AUROCs of the serum AFP-L3 fraction, AFP-L3 level, and PIVKA-II level were similar (Figure 1). For diagnosis of HCC, The optimal cutoff values of the AFP level, fraction of AFP-L3, level of AFP-L3, and PIVKA-II level were 4.2 ng/mL, 5.7%, 0.3 ng/mL, and 35.0 mAU/mL, respectively.

Development of a novel diagnostic model

A novel HCC diagnostic model was developed by classifying all included patients into training and validation sets in a 1:1 ratio under stratifying them by presence or absence of HCC. The baseline characteristics did not differ significantly between the two datasets (Supplementary Table 1).

In the training set, the mean serum AFP, fraction of AFP-L3, AFP-L3 level and PIVKA-II level were significantly higher in patients with HCC than in those without HCC (all $P < 0.001$). The AUROCs of serum AFP level, AFP-L3 fraction, PIVKA-II level and AFP-L3 levels were 0.749, 0.786, 0.829, and 0.802, respectively. The AUROC of the serum AFP-L3 level was significantly higher than that of serum AFP level ($P < 0.001$), whereas no significant difference was observed in the other tumor marker comparisons (all $P > 0.05$).

Next, we performed binary regression analysis for the presence of HCC using the levels of two tumor markers, AFP-L3 level and PIVKA-II level (Table 2). Using the beta coefficients of each marker, we developed AFP, fraction of AFP-L3, and PIVKA-II (ALPs) score: ALPs score = 3.8 × [serum AFP level (ng/mL) × fraction of AFP-L3 (%) × 0.01] + 0.2 × PIVKA-II level (mAU/mL). In training set, mean ALPs score was significantly higher in patients with HCC than in those without HCC (10657.4 *vs* 11.9, $P < 0.001$). For the HCC diagnosis, ALPs score had significantly higher AUROC of 0.878, than those of serum AFP level ($P < 0.001$), fraction of AFP-L3 ($P < 0.001$), level of PIVKA-II ($P = 0.036$), and level of AFP-L3 ($P = 0.006$) (Figure 2A). The best cutoff value of ALPs score was 5.3 (sensitivity, 85.0%, specificity 80.1%, PPV 59.6%, and NPV 93.9%).

In the validation set, the mean serum AFP, fraction of AFP-L3, AFP-L3 level and PIVKA-II level were significantly higher in patients with HCC than in those without HCC (all $P < 0.001$). With an optimal ALPs score cutoff value of 5.3, the sensitivity, specificity, PPV, and NPV were 85.0%, 77.5%, 56.7%, and 93.7%, respectively. The AUROCs of the serum AFP level, AFP-L3 fraction, PIVKA-II level, AFP-L3 level, and ALPs score were 0.800, 0.798, 0.839, 0.825, and 0.897, respectively. The AUROC of serum AFP-L3 level was also significantly higher than that of serum AFP level ($P > 0.001$), whereas the ALPs score had higher AUROC than those of level of AFP ($P < 0.001$), fraction of AFP-L3 ($P < 0.001$), level of PIVKA-II ($P = 0.024$), and level of AFP-L3 ($P = 0.002$) (Figure 2B).

Diagnostic accuracy of the ALPs score and other tumor markers for very early and early-stage HCC

In total, 53 (8.5%) patients had very early and early-stage HCC. The baseline characteristic of these patients are presented in Supplementary Table 2. The predictive performance of the ALPs score and other tumor markers for very early and early-stage HCC was evaluated in all patients. The AUROCs of the level of AFP, fraction of AFP-L3, level of AFP-L3, level of PIVKA-II and ALP score for diagnosing very early and early-stage HCC were 0.631, 0.670, 0.679, 0.683, and 0.746, respectively. The AUROC of the serum AFP-L3 level was significantly higher than that of the serum AFP level ($P <$

Variables are expressed as mean ± SD or *n* (%). HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; AFP-L3: *Lens culinaris* agglutinin- reactive fraction of AFP; PIVKA-II: Protein induced by vitamin K absence or antagonist-II; ALPs: AFP, AFP-L3 fraction, and PIVKA-II.

Table 2 Binary regression analysis for the presence of hepatocellular carcinoma

	Beta coefficient	Standard error	*P* value
AFP-L3 level	0.038	0.017	0.021
PIVKA-II level	0.002	0.001	0.003

HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; PIVKA-II: Protein induced by vitamin K absence or antagonist-II.

0.001), whereas the ALPs score had higher AUROC than those of level of AFP (P < 0.001), fraction of AFP-L3 (P = 0.009), level of PIVKA-II (P = 0.015), and level of AFP-L3 (P = 0.010) (Figure 3). The optimal cutoff value of ALPs score was 6.7 (sensitivity 70.6%, specificity 85.5%, PPV 47.2%, and NPV 94.5%).

DISCUSSION

The ability of AFP-L3 alone or its combination with other markers for diagnosis of HCC has not been fully evaluated. In this large retrospective study of patients with newly detected liver mass or elevated serum AFP level, we observed a significantly higher diagnostic accuracy of AFP-L3 level than with AFP level (P < 0.001). In addition, we developed a novel diagnostic model for HCC, ALPs score, which is derived from the AFP level, AFP-L3 fraction, and PIVKA-II level. For HCC diagnosis, ALPs score had AUROC of 0.878, which was significantly higher than those of the AFP

Variables	AUROC (95%CI)	Cut-off value	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
AFP level	0.775 (0.740-0.807)	4.2 ng/mL	78.8	60.8	41.0	89.2
AFP-L3 fraction	0.792 (0.758-0.823)	5.7%	71.3	80.7	56.2	89.0
AFP-L3 level	0.814 (0.781-0.844)	0.3 ng/mL	71.3	80.7	56.2	88.8
PIVKA-II level	0.834 (0.802-0.862)	35.0 mAU/mL	62.5	95.7	83.3	88.0

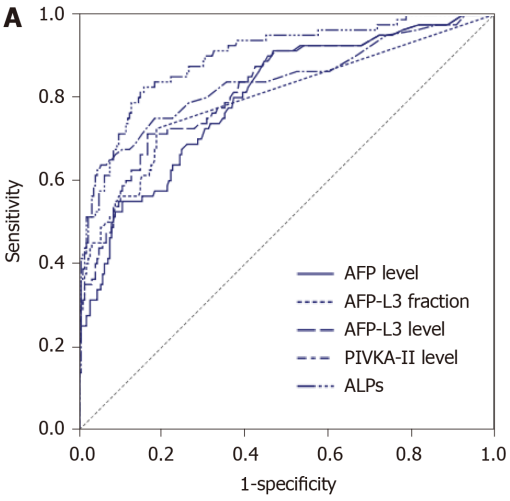

Figure 1 The area under the receiver operating characteristic curves of the tumor markers for hepatocellular carcinoma diagnosis in the total population. AUROC: Area under the receiver operating characteristic curve; HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; AFP-L3: *Lens culinaris* agglutinin-reactive fraction of AFP; PIVKA-II: Protein induced by vitamin K absence or antagonist-II; NPV: Negative predictive value; PPV: Positive predictive value.

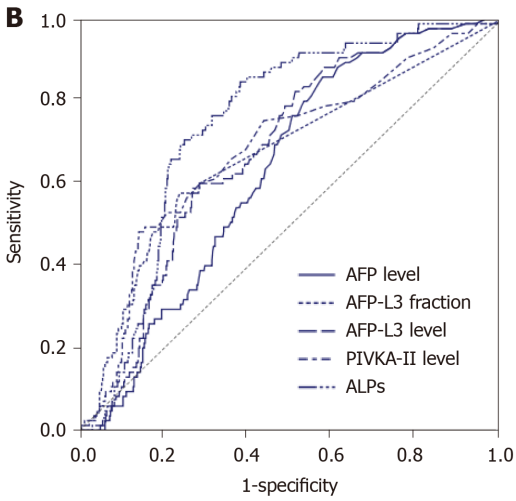
level, fraction of AFP-L3, and PIVKA-II level (all $P < 0.05$).

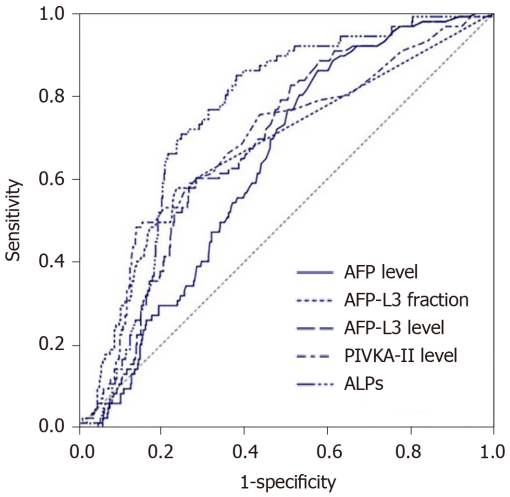


Our study has several strengths and clinical implications. First, we showed the significantly higher diagnostic accuracy of the AFP-L3 level in comparison with the AFP level for HCC diagnosis ($P < 0.001$). The AUROC of the serum AFP-L3 level was 0.814, and the optimal cutoff was 0.3 ng/mL with sensitivity of 71.3% and specificity of 80.7%. Although the AFP-L3 has been expected to compensate for low specificity of AFP level, previous studies showed conflicting results regarding the superiority of AFP-L3 over AFP for diagnosis of HCC[17,18,24,25]. However, in previous studies, the AFP-L3 fraction, and not the AFP-L3 level, was compared to the AFP level, thus leading to comparable results between the two variables. The present study also showed the comparable diagnostic accuracy between AFP-L3 fraction and the AFP level for HCC diagnosis ($P = 0.321$); however, the AFP-L3 level, calculated by multiplying the AFP level with the AFP-L3 fraction, showed consistent superiority over the AFP level for HCC diagnosis. Therefore, the use of AFP-L3 level rather than AFP-L3 fraction might be beneficial in future studies.

Second, we developed and validated a novel diagnostic model of HCC, ALPs score, derived from the combination of the AFP and PIVKA-II levels, and AFP-L3 fraction. The AUROC of the ALPs score for HCC diagnosis was 0.878, which was superior than those of the level of AFP, fraction of AFP-L3, AFP-L3 level, and PIVKA-II level (all $P < 0.05$) in both the training and validation sets. The optimal ALPs score cutoff for HCC diagnosis was 5.3 with sensitivity of 85.0% and specificity of 77.5%–80.1%. It seems that the high sensitivity and specificity of ALPs score, which could be easily obtained from simple blood tests has significant clinical implication. Lim *et al*[18] showed that the combined use of all three tumor markers improved the diagnostic accuracy compared to each marker alone in detecting HCC (AUROC of 0.877) and early-stage HCC (AUROC of 0.773). However, the specificity of the combination of three tumor markers for HCC diagnosis in Lim *et al*[18] was much lower than that of present study (60.1% *vs* 77.5%–80.1%), and this difference might be caused from the different patient population between two studies. In addition, our study derives its strength compared to the study by Lim *et al*[18] by developing a novel score with the diagnostic value of each marker, which was reweighted through binary regression analysis.

Recently, Best *et al*[17] introduced the GALAD score, derived from a combination of gender, age, AFP level, AFP-L3 fraction, and PIVKA-II level with an AUROC of 0.9242 (sensitivity of 85.6% and specificity of 93.3%), for detecting (very) early-stage HCC. However, such high AUROC for (very) early-stage HCC with only serum markers seems clinically unacceptable. In this study, the AUROC of ALPs score to predict very

Variables	AUROC (95%CI)
AFP level	0.800 (0.751-0.843)
AFP-L3 fraction	0.798 (0.750-0.841)
AFP-L3 level	0.839 (0.793-0.878)
PIVKA-II level	0.825 (0.778-0.866)
ALPs score	0.897 (0.857-0.928)



Variables	AUROC (95%CI)
AFP level	0.697 (0.643-0.751)
AFP-L3 fraction	0.728 (0.660-0.795)
AFP-L3 level	0.752 (0.698-0.806)
PIVKA-II level	0.756 (0.692-0.821)
ALPs score	0.836 (0.789-0.883)

Figure 2 The area under the receiver operating characteristic curves of tumor markers for hepatocellular carcinoma diagnosis in the training set and the validation set. A: Training set; B: Validation set. AUROC: Area under the receiver operating characteristic curve; HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; AFP-L3: *Lens culinaris* agglutinin-reactive fraction of AFP; PIVKA-II: Protein induced by vitamin K absence or antagonist-II; ALPs: AFP, AFP-L3 fraction, and PIVKA-II.

early and early-stage HCC was 0.746, which was significantly superior compared to other markers (all $P < 0.05$). Owing to the small number of patients with very early and early-stage HCC in our study (53 patients), we were unable to confirm the clinical validity of the ALPs score for the prediction of very early and early-stage HCC. Large multicenter cohort studies are required to evaluate the predictive ability of the ALPs score for diagnosing very early and early-stage HCC.

The use of AFP as a diagnostic marker for HCC has some shortcomings, including an increase in diseases other than HCC[26], large false-negatives, and missed diagnoses[27]. Although PIVKA-II is less likely to be elevated in other liver disease than AFP[26], the results of previous studies were restrictive to prove the sufficient role of PIVKA-II as a solitary biomarker for HCC diagnosis, since the superior ability of PIVKA-II over AFP was only shown in specific patient groups[14,28,29]. Therefore, recent studies investigated the ability of combined AFP and PIVKA-II in HCC diagnosis and showed the higher diagnostic ability of the combination of the two markers compared to that of either biomarker alone[10,30]. AFP and PIVKA-II complement each other's role, and similarly, AFP-L3 could act as a complementary biomarker for AFP and PIVKA-II in diagnosing HCC while improving the sensitivity and specificity.

We are also aware of several issues that remain unresolved. First, since this was a retrospective study, potential selection bias might be present. Second, 42.9% of the enrolled patients had no underlying liver disease, hence, the clinical implications of the ALPs score in patients with chronic liver disease could not be evaluated. However, because many patients without any underlying liver disease also have elevated AFP level or liver nodule, the result of our study could be beneficial in clinical practice. Further studies including patients with specific liver disease and studies for external validation are required. Third, the cost of using combination of tumor markers is another issue, therefore, further studies evaluating the cost-effectiveness are warranted.

Variables	AUROC (95%CI)
AFP level	0.631 (0.578-0.684)
AFP-L3 fraction	0.670 (0.605-0.736)
AFP-L3 level	0.679 (0.626-0.733)
PIVKA-II level	0.683 (0.621-0.746)
ALPs score	0.746 (0.698-0.794)

Figure 3 The area under the receiver operating characteristic curves of tumor markers for the diagnosis of very early and early-stage hepatocellular carcinom in the total population. AUROC: Area under the receiver operating characteristic curve; HCC: Hepatocellular carcinoma; AFP: Alpha-fetoprotein; AFP-L3: *Lens culinaris* agglutinin-reactive fraction of AFP; PIVKA-II: Protein induced by vitamin K absence or antagonist-II; ALPs: AFP, AFP-L3 fraction, and PIVKA-II.

CONCLUSION

In conclusion, AFP-L3 level, calculated by multiplying the AFP level with the AFP-L3 fraction, exhibited a considerably higher diagnostic ability than the AFP level for HCC diagnosis. The novel diagnostic model, ALPs score may be valuable compared to individual tumor markers for HCC diagnosis in patients with and without chronic liver disease.

ARTICLE HIGHLIGHTS

Research background

Identifying useful biomarkers to diagnose hepatocellular carcinoma (HCC) remains important priority in clinical research. Recently, various tumor markers including protein induced by vitamin K absence or antagonist-II (PIVKA-II), and novel blood parameter, the *Lens culinaris* agglutinin- reactive fraction of alpha-fetoprotein (AFP-L3), have been introduced and evaluated.

Research motivation

Several studies showed improved HCC diagnostic ability of the combination of AFP, AFP-L3, and PIVKA-II, than either AFP or PIVKA-II. However, because of the small sample size and the specific characteristics of the study population, conflicting results have been reported.

Research objectives

We aimed to investigate and compare the predictive ability of AFP, AFP-L3, and PIVKA-II as well as their combination for HCC diagnosis in this retrospective study with a large number of patients. Further, we developed and validated a new diagnostic model for HCC.

Research methods

Patients referred from primary clinics to the Korea University Medical Center for newly noted space occupying lesion in liver or elevated serum AFP level between 2015 and 2019 were enrolled. Their serum AFP level, AFP-L3 fraction, and PIVKA-II level were measured in blood samples collected at their first visit.

Research results

It was observed that AFP-L3 level exhibited a considerably higher diagnostic accuracy than with AFP level ($P < 0.001$). In addition, a novel diagnostic model for HCC, ALPs score, derived from the AFP level, AFP-L3 fraction, and PIVKA-II level showed highest area under the receiver operating characteristics curves of 0.878 for HCC diagnosis. It was significantly higher than those of the AFP level, AFP-L3 fraction, and PIVKA-II level (all $P < 0.05$).

Research conclusions

Finally, AFP-L3 level, calculated by multiplying the AFP level with the AFP-L3 fraction had a significantly higher diagnostic ability than the AFP level for HCC diagnosis. The novel diagnostic model, ALPs score was more valuable compared to individual tumor markers for HCC diagnosis.

Research perspectives

Further studies including patients with specific liver disease and studies for external validation and cost-effectiveness are required.

Abstract

BACKGROUND

There is little data available on the role of new anti-reflux plastic stents (ARPSs).

AIM

To compare the use of ARPSs with that of traditional plastic stents (TPSs) for patients with biliary strictures.

METHODS

Consecutive patients with biliary strictures who underwent first endoscopic biliary stenting between February 2016 and May 2019 were included. The onset of stent-related cholangitis, stent patency, clinical success, and other adverse events were evaluated.

RESULTS

Sixty-seven patients in the ARPS group and 66 patients in the TPS group were included in the final analyses. Fewer patients experienced stent-related cholangitis in the ARPS group than that in the TPS group (8 patients *vs* 18 patients; $P = 0.030$). The median time till the onset of first stent-related cholangitis was later in the ARPS group than that in the TPS group (128.5 d *vs* 76 d; $P = 0.039$). The cumulative median stent patency in the ARPS group was 185 d, which was significantly longer than that in the TPS group (133 d; $P = 0.001$). The clinical success rates and other adverse events did not significantly differ between both groups.

CONCLUSION

Placement of new ARPS might be a safe and effective optional therapeutic strategy to reduce the risk of stent-related cholangitis and prolong stent patency.

Core Tip: This is a retrospective study to compare the use of new anti-reflux plastic stents (ARPSs) with that of traditional plastic stents (TPSs) for patients with biliary strictures. Fewer patients experienced stent-related cholangitis in the ARPS group than in the TPS group (8 *vs* 18 patients; $P = 0.030$). The cumulative median stent patency in the ARPS group was 185 d, which was significantly longer than that in the TPS group (133 d).

INTRODUCTION

Endoscopic biliary stenting is an established procedure for either benign or malignant biliary strictures (BBSs or MBSs) that are not suitable for surgery. There are two stent categories available on the market: Plastic and metal stents. Plastic stents (PSs) are widely available, very effective, and inexpensive. PSs with a diameter of 10 Fr are usually used. However, the rather short stent patency (approximately 3 to 6 mo)[1] and the relatively high rate of stent-related cholangitis (about 3.5%-48.8%)[2-4] represent significant disadvantages. In contrast, self-expandable metal stents (SEMSs) are associated with significantly longer stent patency (approximately 9 to 12 mo)[5] compared to that of PSs. The rate of stent-related cholangitis, however, can reach as high as 45.8% (about 2.1%-45.8%)[3,6]. Most importantly, the higher costs of SEMSs limit their widespread application, especially in developing countries[7].

Both stent categories have complications of stent occlusion and stent-related cholangitis after stent placement, which may worsen the quality of patients' life. Since duodenobiliary reflux has been identified as a major cause of these problems[1,8-10], the design of biliary stents with an anti-reflux valve at the duodenal end has emerged as a potential solution for reducing duodenobiliary reflux over recent years. Previous studies[10-12] have shown that the use of anti-reflux SEMSs can effectively reduce the risk of stent-related cholangitis and prolong stent patency. Unfortunately, studies on anti-reflux PSs (ARPSs) have not yet yielded convincing results[7,13,14].

We designed an ARPS with a "duckbilled" valve attached to the PS. In the prior clinical trial, 19 patients with distal MBSs were successfully inserted with the new ARPSs, and the cumulative median stent patency of the ARPSs was significantly longer than that of traditional PSs (TPSs)[15]. However, the role of this new ARPS in reducing the onset of stent-related cholangitis compared with TPS remains unknown. In the present study, we aimed to determine whether placement of this new ARPS can reduce the risk of stent-related cholangitis in patients with biliary strictures compared to TPS.

MATERIALS AND METHODS

Study design

Consecutive patients with biliary strictures who underwent first endoscopic biliary stenting between February 2016 and May 2019 at West China Hospital, Sichuan University were included. We retrospectively reviewed the data of eligible patients from our prospectively collected database. Exclusion criteria were (1) Placement of SEMS; (2) Placement of multiple biliary stents; (3) Stents with a diameter other than 10Fr; (4) Simultaneous percutaneous transhepatic cholangial drainage and endoscopic

biliary stenting; (5) Temporary drainage for resectable MBS; (6) Patients died within 1 mo after stenting; and (7) Patients without available outcome data. Patient characteristics, endoscopic retrograde cholangiopancreatography (ERCP) procedures, stent details, liver function test results, adverse events, and stent patency duration were collected.

This study was approved by the Ethics Committee on Biomedical Research, West China Hospital of Sichuan University. Informed consent was waived by the Ethics Committee because of the retrospective nature of this study and anonymous data.

Plastic stents

The new ARPS (Tannenbaum design; Micro-Tech (Nanjing) Co. Ltd., Nanjing, China) with a diameter of 10 Fr was made of polytetrafluoroethylene, without any side holes (Figure 1A). A soft anti-reflux valve with a length of 1.5 cm, made of silicone rubber material, was attached to the PS. The antegrade flow of bile kept the valve open, whereas increased intestinal pressure made it close, thereby reducing duodenobiliary reflux. The TPS (Cotton-Leung Biliary Stent; Cook Ireland Ltd., Limerick, Ireland) used in this study was made of polyethylene (Figure 1B). Both types of stents were inserted into the bile duct using the same pull-back delivery system (Oasis; Cook Ireland Ltd.).

Endoscopic biliary stenting

Except for patients who were randomly assigned during the previous study period [15], other patients were advised to choose ARPSs during preoperative preparation, and TPSs were used for those who refused ARPSs. We did not administer prophylactic antibiotics and nonsteroidal anti-inflammatory drugs prior to ERCP. All ERCPs were performed by experienced endoscopists (experience of ≥ 300 ERCPs per year) using a standard duodenoscope (TJF-260V; Olympus Medical systems Corp., Tokyo, Japan). All patients were placed in the prone position with conscious sedation. After bile duct cannulation, the stricture was visualized by injecting contrast. A sphincterotomy was performed if necessary. Under the guidance of a guidewire (Jagwire; Boston Scientific, Natick, MA. United States), a single ARPS or TPS with an individually determined ideal length was inserted into the bile duct above the proximal end of the stricture for about 1-2 cm, and the distal end of the stent was kept outside of the duodenal papilla for about 1cm. The flow of bile was confirmed before the withdrawal of the duodenoscope (Figure 2). Patients received clinical evaluation and liver function tests within the first week after stent placement. Then, they underwent clinic visits or telephone follow-up every 1-2 mo until stent removal/exchange or death. The follow-up ended in December 2019.

Outcomes

The primary outcome was the onset of stent-related cholangitis. Stent-related cholangitis, including non-stent dysfunction cholangitis and stent dysfunction cholangitis, was considered if patients developed symptoms of acute cholangitis during the follow-up period and post-ERCP cholangitis was excluded. Non dysfunction cholangitis was diagnosed when acute cholangitis observed and when there was no definite finding of stent occlusion or migration[16]. Post-ERCP cholangitis was defined as cholangitis that developed within 2 wk after ERCPs[17] without definite findings of stent dysfunction, related to ERCP procedures,. The diagnostic criteria for acute cholangitis refer to Tokyo Guidelines 2018[18]. Stent dysfunction was confirmed by subsequent ERCP findings when patients presented with recurrent obstructive jaundice and/or cholangitis symptoms in combination with resolution of these abnormalities after insertion of a new stent.

Secondary outcomes were stent patency, clinical success, and other adverse events. The duration of stent patency was measured as the days from stent insertion until stent dysfunction requiring stent exchange. Clinical success was defined as a decrease in bilirubin levels of at least 50% within the first week after stent placement in patients with jaundice[19]. Other adverse events were defined according to American Society for Gastrointestinal Endoscopy guidelines[20], such as post-ERCP pancreatitis and stent migration. Stent migration included proximal and distal migration. Proximal migration was defined if the stent was visible in bile duct on fluoroscopy, but the distal end of the stent was not seen at duodenal papilla on endoscopy[21]. Partial distal migration was defined if the stent location was below the original position on fluoroscopy, and the distal end of the stent was seen at duodenum on endoscopy. Complete distal migration was defined if the stent was not present on fluoroscopy and endoscopy. Proximal biliary stricture was defined as stricture located in the common hepatic duct, while distal stricture was defined as stricture located in the common bile

duct.

Statistical analysis

Continuous variables were characterized using mean with standard deviation or

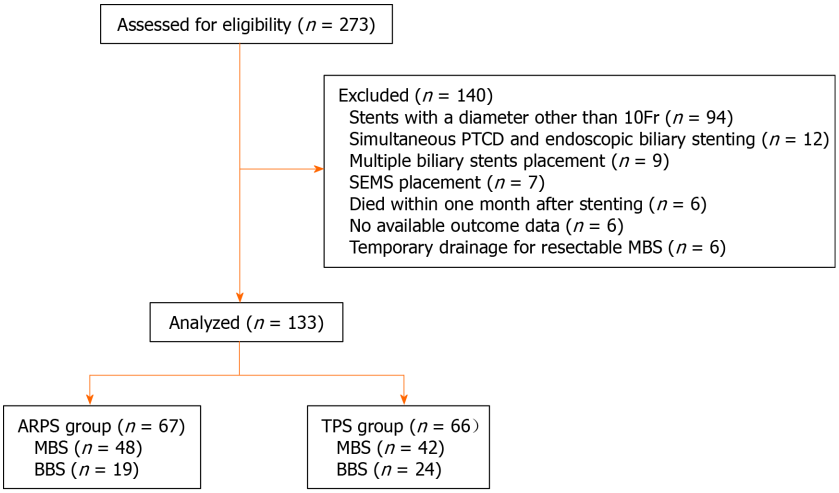

Figure 3 Flowchart. PTCD: Percutaneous transhepatic cholangial drainage; SEMS: Self-expandable metal stents; ARPS: Anti-reflux plastic stent; TPS: Traditional plastic stent. MBS: Malignant biliary stricture; BBS: Benign biliary stricture.

median with interquartile range (IQR), while categorical using frequencies or proportions. Exploratory subgroup analyses for MBS and BBS were performed. The differences of parametric variables between the two groups were compared using Student's *t* test, and nonparametric variables were compared using the Mann-Whitney *U* est. Chi-squared test or Fisher's exact test was used for comparison of differences in categorical variables as appropriate. The cumulative onset of stent-related cholangitis and stent patency of the two groups were plotted using the Kaplan-Meier method and were analyzed using Log-rank test. A P value of < 0.05 was considered statistically significant. All analyses were performed using SPSS v. 23.0 (IBM Corp., Armonk, NY, United States).

RESULTS

Patient characteristics and clinical outcomes

From February 2016 to May 2019, a total of 274 eligible patients who underwent first endoscopic biliary stenting were screened. Among these, 140 patients were excluded due to the presence of exclusion criteria; thus, 133 patients were included in the final analyses, including 67 patients in the ARPS group and 66 patients in the TPS group (Figure 3).

The baseline demographic data, liver function test results, cholecystectomy history, and comorbidities did not significantly differ between the two groups (Table 1). There were 90 (67.7%) patients of MBSs and 43 (32.3%) patients of BBSs in the two groups. Among patients with MBSs, 44 (48.9%) patients had pathological confirmation of malignancy through brush cytology, transpapillary biopsy, or fine needle aspiration sampling. Also, 46 (51.1%) patients with imaging-evidenced tumors were confirmed by clinical follow-up (Table 2). All ARPSs or TPSs were successful placement in an appropriate position as confirmed by fluoroscopy. Clinical success was achieved in 123 (92.5%) patients, while there was no significant difference between the ARPS (n = 62) and TPS groups (n = 61) (92.5% *vs* 92.4%; P = 1.000).

Stent-related cholangitis

During the follow-up period, 8 (11.9%) patients in the ARPS group and 18 (27.3%) patients in the TPS group developed stent-related cholangitis, and a significant difference was noted (P = 0.030). Among 8 patients with stent-related cholangitis in the ARPS group, 2 patients had pre-ERCP cholangitis, and 2 patients had non-stent dysfunction cholangitis. One patient had proximal stricture, and 7 patients had distal stricture. While 18 patients in the TPS group, 6 patients had pre-ERCP cholangitis, and 6 patients had non-stent dysfunction cholangitis. Three patients had proximal stricture, and 15 patients had distal stricture. The rates of pre-ERCP cholangitis (P = 0.657), onset of non-stent dysfunction cholangitis (P = 0.165), and distribution of stricture location (P = 1.000) did not significantly differ between both groups. In the MBS or BBS subgroup, no significant difference in the onset of stent-related cholangitis

[6]Fisher's exact test. ARPS: Anti-reflux plastic stent; TPS: Traditional plastic stent; ERCP: Endoscopic retrograde cholangiopancreatography; MBS: Malignant biliary stricture; BBS: Benign biliary stricture.

was observed between the two groups. The median time till the onset of first stent-related cholangitis in the ARPS group was later than that in the TPS group (128.5 d, IQR 197.5, range 65-347 d *vs* 76 d, IQR 72.8, range 5-337; $P = 0.039$), and there was also a similar trend in the cumulative median time between the two groups (Figure 4). In the ARPS group, 6 patients had stent-related cholangitis only once, 2 patients had it twice. In the TPS group, 12 patients had it once, 5 patients had it twice, and 1 patient had it three times. There was no significant difference in the frequency of stent-related cholangitis between the two groups ($P = 0.115$) (Table 3).

Stent patency

Up till the final follow-up, stent dysfunction was noted in 44 (65.7%) patients in the ARPS group and 52 (78.8%) patients in the TPS group, with median stent patency of 124 d (IQR 139, range 6-474) and 114 d (IQR 76.5, range 4-353), respectively. There were no significant differences in the occurrence of stent dysfunction ($P = 0.091$) and the median stent patency between the two groups ($P = 0.135$).

In the remaining patients, stent patency was maintained until stent removal/exchange or death. The cumulative median stent patencies were 185 d (SE 8.6; 95%CI: 168.2-201.8) in the ARPS group and 133 d (SE 16.9; 95%CI: 99.8-166.2) in the TPS group; the observed difference was statistically significant ($P = 0.001$). The cumulative median stent patency was 124 d (SE 26.2; 95%CI: 72.7-175.3) in patients with stent-related cholangitis in the ARPS group, while it was 96 d (SE 22.1; 95%CI: 52.7-139.3) in the TPS group ($P = 0.420$). In the MBS subgroup, the cumulative median stent patencies in the ARPS and TPS groups were 173 d (SE 32.0; 95%CI: 110.3-235.7) and 98 d (SE 11.6; 95%CI: 75.3-120.7), respectively; the observed difference was statistically significant ($P = 0.008$). In the BBS subgroup, the cumulative median stent patency in

the ARPS group was significantly longer than that in the TPS group (210 d, SE 23.8, 95%CI: 163.4-256.6 *vs* 155 d, SE 6.0, 95%CI: 143.3-166.8; $P = 0.049$) (Table 3, Figure 5).

Other adverse events

Post-ERCP pancreatitis occurred in 4 (6.0%) patients and 2 (3.0%) patients in the ARPS and TPS groups, respectively ($P = 1.000$), which were mild and improved after conservative treatment. Post-ERCP cholangitis occurred in 1 (1.5%) patient in the ARPS group and 1 (1.5%) patient in the TPS group ($P = 1.000$). They were mild and relieved after antibiotic therapy. No stent proximal migration was observed. Stent distal migration was noted in 3 (4.5%) patients in the ARPS group, including 2 patients of partial migration and 1 patient of complete migration. There were 4 (6.0%) patients of distal migration in the TPS group, including 2 patients of partial migration and 2 patients of complete migration. No significant difference was noted in the incidence of distal migration between the two groups ($P = 0.718$). All partial distal migrated stents were retrieved endoscopically, and complete distal migrated stents passed spontaneously. No stent migration-related intestinal injury was observed (Table 3).

DISCUSSION

Our study revealed that placement of new ARPS in patients with biliary strictures could reduce the onset of stent-related cholangitis and prolong stent patency. No serious procedures or stents related adverse events were observed. The use of new ARPS proved to be safe and effective.

Although placement of SEMS is recommended for patients with unresectable MBS [22], many patients in our institution prefer to PSs rather than SEMSs due to the costs, especially those with life expectancy less than 6 mo. Therefore, PSs were used in this study for patients with MBS. Considering the limited patency of PSs, we scheduled routine stent exchange every 3 to 6 mo. However, some patients only underwent stent removal/exchange when cholangitis or stent dysfunction occurred, due to the large number of patients and long waiting time for admission in our institution.

In the present study, the occurrence of stent-related cholangitis in the ARPS group was significantly lower than that in the TPS group. Moreover, the median time and cumulative median time till the onset of first stent-related cholangitis were significantly later than those in the TPS group, which may be attributed to the anti-reflux mechanism. The anti-reflux valve of the new ARPS, designed as "duckbilled", could simulate the opening and closing function of a duck's bill. This design allows antegrade bile flow into the duodenum, while it closes immediately when the intestinal pressure increases, thereby reducing the reflux of intestinal contents such as bacteria and food materials. However, the role of new ARPS in reducing the onset of cholangitis was not obvious in the subgroup analyses. The sample size in this study

may not be adequate for exploratory subgroup analyses. A small number of patients in both groups experienced 2 to 3 episodes of stent-related cholangitis. These patients usually presented with mild cholangitis symptoms, such as fever (temperature > 38 °C) and chills, accompanied by upper abdominal discomfort, and without obvious signs of stent occlusion, namely non-stent dysfunction cholangitis. In the early stage of stent occlusion, bacteria from the duodenum refluxed into the biliary tract and colonized, thus causing mild cholangitis. Although antibiotics could ameliorate symptoms, mild cholangitis were prone to recur owing to the existence of partial stent occlusion. Therefore, patients with recurrent cholangitis after stent placement should be considered for exchange a new one.

As the relatively short stent patency has always been an important issue in clinical practice, prolonging stent patency was another focus of this and previous studies. The actual mechanisms of PS occlusion remain unclear. The initial event of PS occlusion is the biofilm formation[1,23]. Several previous studies[24-26] have focused on the material of stents or the special coat that prevent bacterial adherence and biofilm formation, revealing somewhat discrepant results between *in vitro* testing and clinical studies. Food materials refluxed from the duodenum have been observed in occluded PSs, thus suggesting that duodenobiliary reflux may have an important role in stent occlusion[1,8]. It could theoretically prolong stent patency if we change the design of stent to eliminate retrograde flow from the intestine. Our study confirmed that new ARPS was superior to TPS in achieving relatively longer stent patency in either BBSs

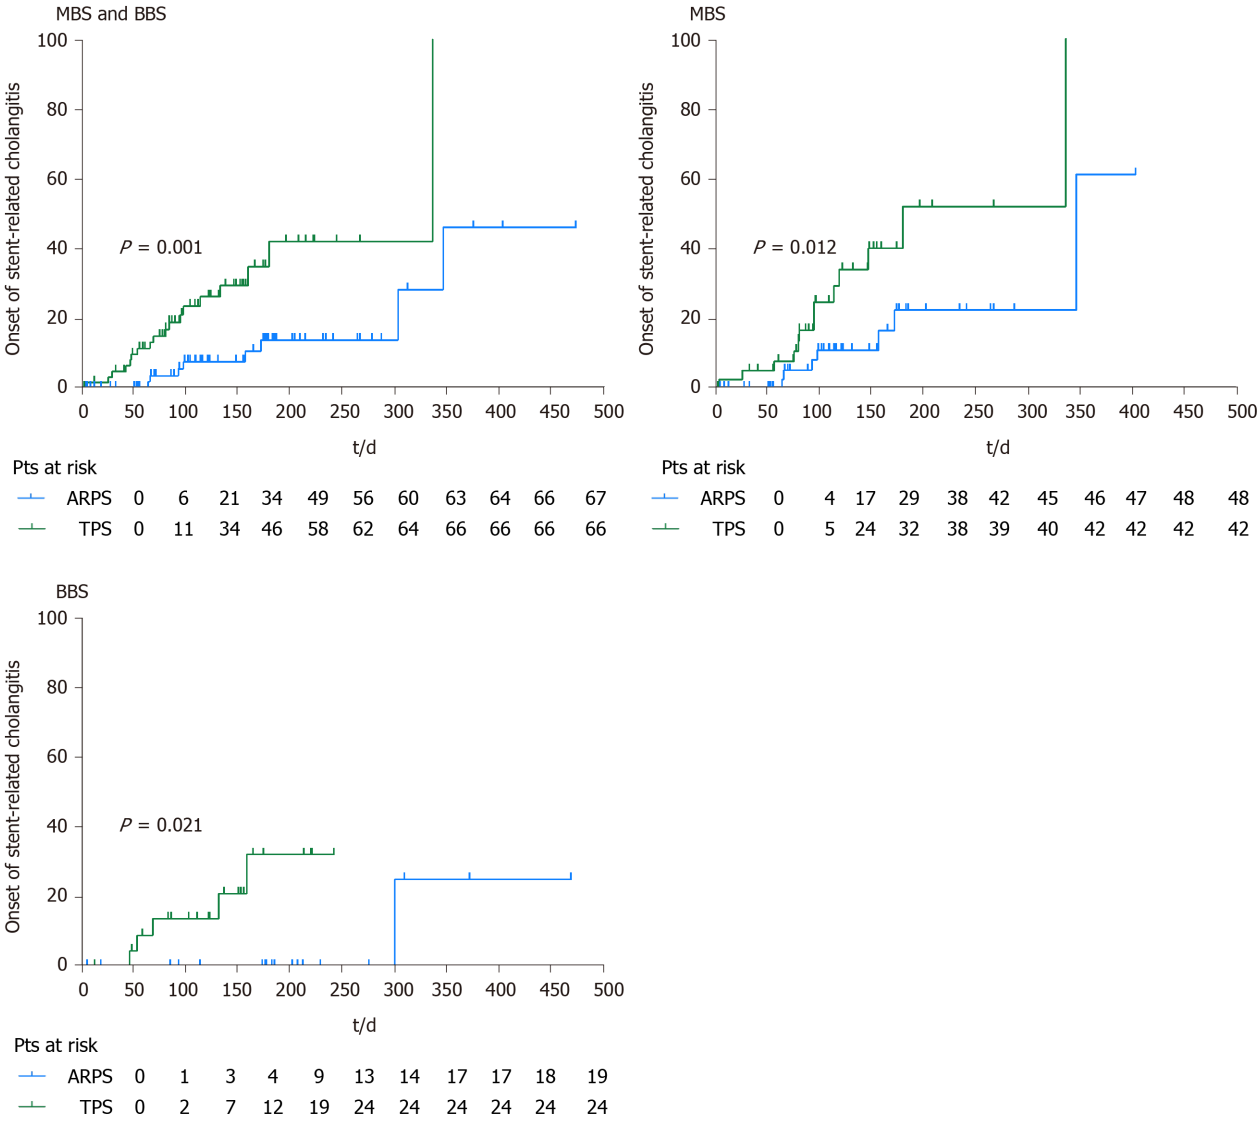

Figure 4 Kaplan-Meier curves of onset of stent-related cholangitis of anti-reflux plastic stent and traditional plastic stent (Log-rank test).
MBS: Malignant biliary stricture; BBS: Benign biliary stricture; Pts: Patients; ARPS: Anti-reflux plastic stent; TPS: Traditional plastic stent.

or MBSs. The ARPSs reported in prior studies[7,13,14] had a relatively large anti-reflux valve opening, which may diminish the effect on reducing duodenobiliary reflux. Moreover, the length of the anti-reflux valve was long (about 4cm), and the valve was easy to collapse or fold, resulting in poor bile drainage. Therefore, no ideal results were observed in their clinical trials. In the present study, the anti-reflux valve of the ARPS had a small opening, and its short length (about 1.5 cm) made it relatively hard to collapse or fold. It should be noted that the bile drainage gets blocked in the short term if the anti-reflux valve is not fully deployed during placement. This phenomenon occurred in 1 patient in our study; thus, complete expansion of the valve and sufficient bile flow are needed to be confirmed before the withdrawal of the duodenoscope.

Similar delivery systems were used in this study to deploy the investigated ARPS and TPS. Despite the valve, endoscopic placement of the ARPS was not difficult and did not increase the risk of biliary tract infection. The rates of post-ERCP cholangitis in the two groups were comparable to the rate (0.5-5%) previously reported[27-30]. European Society of Gastrointestinal Endoscopy guidelines[31] has shown that endoscopic sphincterotomy is a risk factor for post-ERCP pancreatitis; thus, endoscopic sphincterotomy was not routinely performed in this study. There was no significant difference in the incidence of post-ERCP pancreatitis between the two groups, neither this incidence was higher than the one (9.7%) reported in the latest meta-analysis[32]. Distal or proximal migration of PSs has been reported in 5%-10% of cases[21]. There was no proximal migration in our study. No significant difference was noted in the incidence of distal migration between the two groups, and our results were comparable to previous results (3%-6%)[21]. Previous studies[21,33] indicated

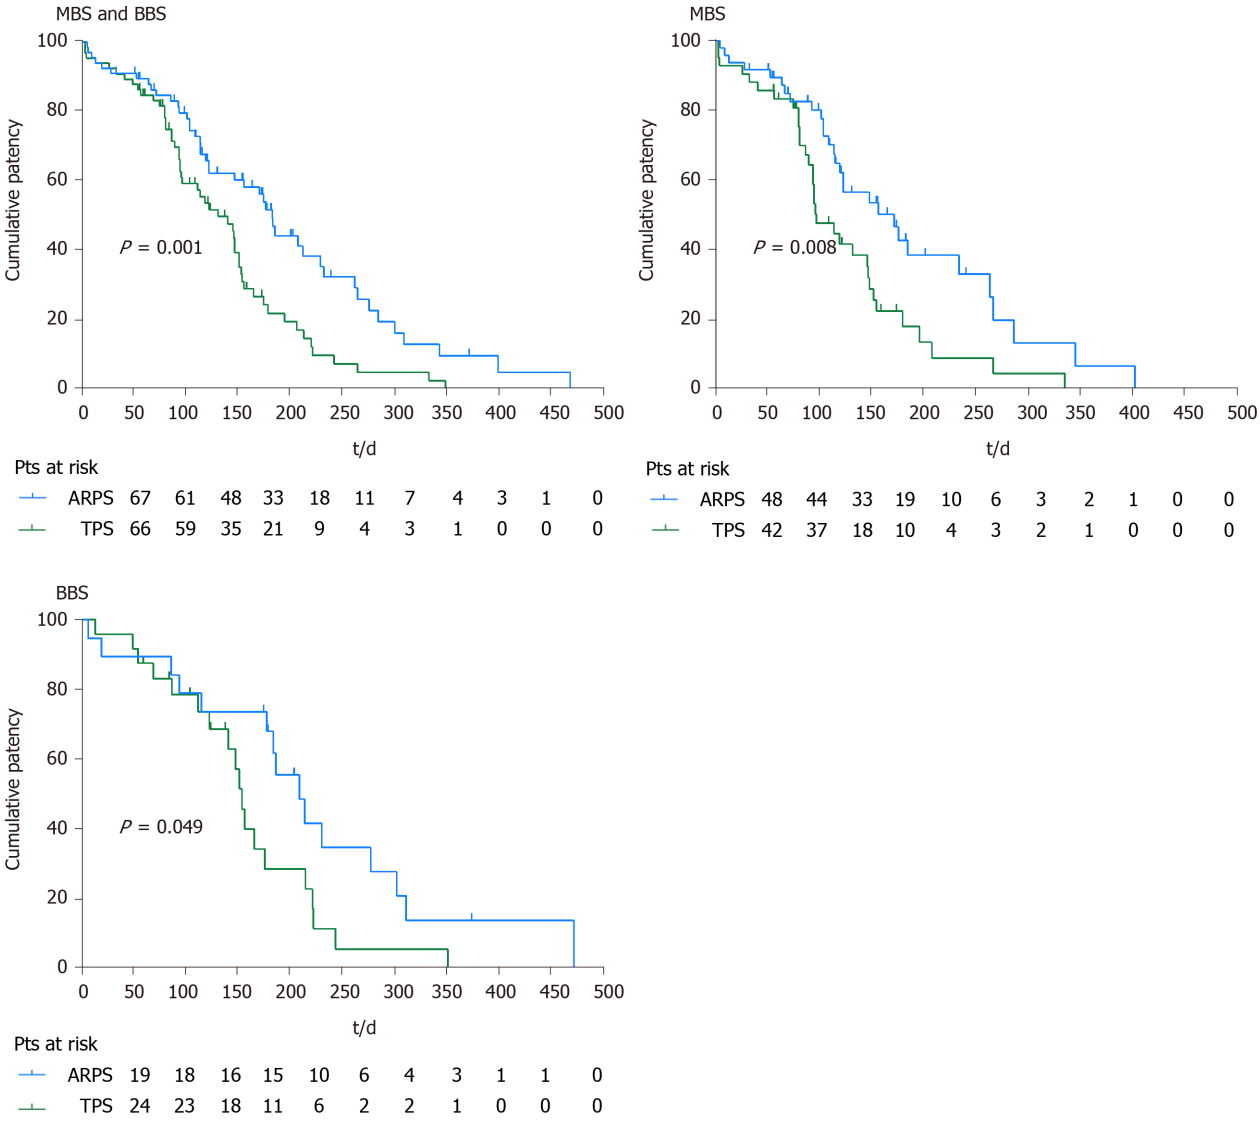

Figure 5 Kaplan-Meier curves of cumulative patency of anti-reflux plastic stent and traditional plastic stent (Log-rank test). MBS: Malignant biliary stricture; Pts: Patients; ARPS: Anti-reflux plastic stent; TPS: Traditional plastic stent.

that the most distal migrated stents can be retrieved endoscopically, and less than 1% of cases developed gut perforation caused by stent migration. No gut perforation was observed in our study. Therefore, the use of new ARPS in the treatment of biliary strictures does not increase the difficulty of procedures and the risk of adverse events related to the procedures or stents.

Some limitations of our study have to be mentioned. The first limitation was its retrospective design, but the data collected from a prospectively collected database supported the validity of the present results. The second limitation was that the ARPS and TPS used in this study exhibit different materials and antimigration designs. Previous studies have indicated that there were no significant differences in the rates of cholangitis and stent patency between stents made of different materials or stents with different antimigration designs[34-36]. Therefore, in the present study, the differences in the rates of stent-related cholangitis or stent patency between the two groups may not be attributed to those differences. However, further studies are needed to assess this hypothesis by comparing the same PS with or without anti-reflux valve. The third limitation was that macroscopic and microscopic examinations of dysfunctional stents were not performed, and the exact causes of stent dysfunction were unclear. The fourth limitation was the inadequate sample size for exploratory subgroup analyses. Further studies with large samples are needed to evaluate its safety and efficacy. The fifth limitation refer to potential selection bias in the inclusion of patients. Although patients with proximal biliary strictures or with pre-ERCP cholangitis were considered to have a higher risk of cholangitis, the distribution of these patients were comparable between the two groups in terms of baselines or

clinical outcomes.

CONCLUSION

In conclusion, our study suggests that it is safe and effective to use the new ARPS for the treatment of biliary strictures. This ARPS could reduce the risk of stent-related cholangitis and prolong stent patency. However, its role in reducing the onset of stent-related cholangitis is not obvious in the subgroup analyses. Studies with large samples are needed to evaluate further its safety and efficacy.

ARTICLE HIGHLIGHTS

Research background

Endoscopic biliary stenting is an established procedure for patients with biliary strictures. However, complications such as stent occlusion and stent-related cholangitis after stent placement may worsen the quality of patients' life. Since duodenobiliary reflux is a major cause of those complications, the design of stents with an anti-reflux valve is a potential solution for reducing duodenobiliary reflux.

Research motivation

The authors have previously developed a new anti-reflux plastic stents (ARPSs) and conducted a clinical trial to compare the patency of ARPSs with that of traditional plastic stents (TPSs), which showed this new ARPS had a significantly longer stent patency. However, the role of this new ARPS in reducing the onset of stent-related cholangitis compared with TPS remains unknown.

Research objectives

In this study, the authors compared this new ARPS with TPS in patients with biliary strictures.

Research methods

The authors retrospectively reviewed the data of consecutive patients with biliary strictures who underwent first endoscopic biliary stenting between February 2016 and May 2019 at West China Hospital, Sichuan University from our prospectively collected database. According to the inclusion and exclusion criteria, eligible patients were included for analysis. The onset of stent-related cholangitis, stent patency, clinical success, and other adverse events were evaluated.

Research results

During the study period, 67 patients in the ARPS group and 66 patients in the TPS group were included. There was a significant difference when comparing the onset of stent-related cholangitis, which was significantly lower in the ARPS group than in the TPS group. The cumulative median stent patency in the ARPS group was significantly longer than that in the TPS group. No significant differences were noted in the rates of clinical success and other adverse events between both groups.

Research conclusions

This new ARPS results in superior to TPS in reducing the risk of stent-related cholangitis and prolonging stent patency.

Research perspectives

Multicenter studies with large samples are expected to evaluate further the safety and efficacy of this new ARPS.

Abstract

BACKGROUND

Gastroesophageal reflux disease (GERD) has a high prevalence worldwide, and its incidence is increasing annually. Modified Xiaochaihu Decoction (MXD) could relieve the symptoms of GERD, but the effects of MXD on GERD manifestations and relapse prevention need to be further explained. Therefore, we performed a prospective, double-blind, and double-simulation study.

AIM

To verify the efficacy of MXD for GERD and its effect on esophageal motility.

METHODS

Using randomization, double-blinding, and a simulation design, 288 participants with GERD were randomized to the treatment group and control group and received herbs (MXD) plus omeprazole simulation and omeprazole plus herbs simulation, respectively, for 4 wk. The GERD-Q scale score and esophageal manometry were measured at baseline, after treatment, and at 1 mo and 3 mo follow-up visits when medication was complete to evaluate recurrence indicators.

RESULTS

The GERD-Q scale score in both groups decreased significantly compared to those before treatment ($P < 0.01$). However, no significant difference was observed

Clinical trial registration statement: This study is registered at: www.chictr.org.cn/; The registration identification number is ISRCTN17685397.

between the two groups ($P > 0.05$). Esophageal manometry showed that participants with lower esophageal sphincter pressure reduction and the proportion of ineffective swallowing (more than 50%) improved in both groups from baseline ($P < 0.01$), especially in the treatment group ($P < 0.05$). The percentage of small intermittent contractions, large intermittent contractions, and increased pre-phase contractions in the treatment group significantly improved compared with baseline ($P < 0.05$) but did not improve in the control group ($P > 0.05$). There was no significant difference between the groups after treatment ($P > 0.05$). The percentage of weak esophageal contractility (distal contractile integral < 450 mmHg·s·cm), improved in both groups ($P < 0.01$), but no significant difference was observed between the groups after treatment ($P > 0.05$). The relapse rate in the treatment group was lower than that in the control group at the 1 mo ($P < 0.01$) and 3 mo follow-up ($P < 0.05$).

CONCLUSION

MXD has a similar therapeutic effect to omeprazole in mild-to-moderate GERD. The therapeutic effect may be related to increased pressure in the lower esophageal sphincter and reduced ineffective swallowing.

Key Words: Gastroesophageal reflux disease; Traditional Chinese medicine; Esophageal sphincter pressure; Gastroesophageal reflux disease-Q scale score; Modified Xiaochaihu Decoction

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This multicenter, randomized, double-blind, double-simulation study proved that Modified Xiaochaihu Decoction has a similar therapeutic effect to omeprazole in the treatment of patients with typical symptoms of gastroesophageal reflux disease and reflux esophagitis grades A and B. Modified Xiaochaihu Decoction was superior to omeprazole in improving lower esophageal sphincter resting pressure and reducing ineffective esophagus swallowing. The recurrence rate of symptoms was significantly lower than that of omeprazole within 1 mo and 3 mo after completing treatment. Modified Xiaochaihu Decoction may be an alternative treatment to proton pump inhibitor maintenance in patients with gastroesophageal reflux disease.

INTRODUCTION

Gastroesophageal reflux disease (GERD) has a high prevalence worldwide, and its incidence is increasing annually[1]. Impaired esophageal and gastric motor function as well as reduced resting pressure of the lower esophageal sphincter are considered to be involved in the pathogenesis of GERD. Chemical drugs can help relieve the symptoms and eliminate inflammation, but the relapse rate is high. It is reported that esophagitis and other symptoms are 80% and 90%, respectively, 6 mo after proton pump inhibitor (PPI) withdrawal[2]; therefore, many patients require long-term maintenance medication. Our previous observations showed that Modified Xiaochaihu Decoction (MXD) could relieve the symptoms of GERD[3]. The present study aimed to evaluate the effects of MXD on GERD manifestations and relapse prevention and to determine its underlying mechanism, from the aspect of esophageal motion, using a prospective, double-blind, and double-simulation design compared with omeprazole.

MATERIALS AND METHODS

Patients

This is a prospective, double-blind, and double-simulation study, which was sponsored by Beijing Hospital of Traditional Chinese Medicine of Capital Medical University and conducted in Peking Union Medical College Hospital, Beijing Shijitan Hospital of Capital Medical University, and Shengjing Hospital of China Medical University from January 2015 to December 2019.

Ethical permission

The study was reviewed and approved by the Ethics Committee of Beijing Hospital of Traditional Chinese Medicine of Capital Medical University. The trial registration number is ISRCTN17685397.

Diagnostic criteria

Participants who met the standard of the "Chinese Experts Opinion on Gastroesophageal Reflux Disease"[2] were considered for inclusion in the study.

The inclusion criteria were: (1) patients aged 18-65 years; (2) satisfied the diagnostic criteria for GERD; and (3) GERD-Q score ≥ 8, with A-B esophagitis under gastroscopy.

Exclusion criteria were: (1) a history of gastric, esophageal, and duodenal surgery; (2) presence of Zollinger-Ellison syndrome or primary esophageal motility disease; (3) suspected or confirmed to have a malignant disease or have early warning symptoms; (4) use of PPI or H2 receptor blockers within 2 wk before enrollment; (5) serious primary heart, liver, lung, kidney, pancreas, or other serious diseases that would affect their survival; (6) disabled patients (blind, deaf, dumb, mentally retarded, mentally disabled, physically disabled) as required by law; (7) suspected or confirmed history of alcohol and drug abuse; (8) allergies, such as those with a history of allergies to two or more drugs or food; or known allergies to the ingredients of MXD; and (9) pregnant and lactating women.

Sample size estimation

The sample-size calculation in this design was based on a non-inferiority test with a 1:1 comparison principle. Using the one-sided test, according to previous literature reports and research results, the formula: [n1 = n2 = 2 (Z_α + Z_β) 2P (1-P)/δ2, Z_α = 1.645, Z_β = 0.845, P = 0.65, δ = -0.15; n1 = n2 approximately 125] was used. In this study, the expulsion rate was designed to be 15%, the sample content required for each group was 144, and a total of 288 samples were required.

Randomization and allocation concealment

Randomization into the treatment or control group was performed with a 1:1 allocation ratio. Balanced treatment assignments were achieved by block randomization. This process was performed using SAS 9.4 software to generate a random sequence. The block length was eight. Now that there were four units and a total of 288 subjects, each unit was assigned 72 connecting consecutive codes and the corresponding allocation to treatment or control.

Participants in the treatment group were given herbal granules (2 packets/d, one packet at a time with 200 mL water, before meals) combined with omeprazole simulation tablets produced by Jiangyin Tianjiang Pharmaceutical Co., Ltd. The traditional Chinese medicine (TCM) prescriptions were mainly composed of *Bupleurum* 10 g, *Codonopsis* 15 g, fried *Atractylodes* 12 g, *Coptis chinensis* 10 g, *Flos* insulae 10 g, and fried Raphani 15 g. Omeprazole placebo was produced by Lunan New Times Pharmaceutical Co., Ltd.) and was taken orally, 20 mg each time, once on an empty stomach in the morning.

Participants in the control group were given omeprazole enteric-coated tablets combined with an herbal granule placebo. The herbal granule placebo was produced by Jiangyin Tianjiang Pharmaceutical Co., Ltd. The simulated MXD placebo contained 2.5% of the dose of the original formula, with a color correction agent, seasoning agent, starch, dextrin, and other auxiliary materials added. After spray drying, crushing, screening, mixing, granulation, and packaging, the granule simulation agent was placed in bags. The appearance, characteristics, and odor were the same as those of the actual herbal medicine and contained 10.3 g/bag (produced by Jiangyin Tianjiang Pharmaceutical Co., Ltd.). Omeprazole enteric-coated tablets (Lunan New Times Pharmaceutical Co., Ltd., SFDA approval No. 008140505) were taken orally, 20 mg each time, once on an empty stomach in the morning.

All medications in both groups were administered for 4 wk, and all participants had a washout period of 2 wk before taking the medication.

Blinding

The blind codes were sealed separately and kept by those who were not directly involved in this clinical trial. Doctors and patients were blind to the medicine. The medicine and placebos were packaged in the same outer packaging, and their appearance, color, and characteristics were consistent. Both were made by the same manufacturer.

Esophageal manometry

The ManoScan360TM gastrointestinal dynamic high-resolution esophageal manometry system (Given Imaging, United States) and a solid-state surrounding pressure measuring electrode catheter with 36 pressure measuring channels was used. Adjacent channels were spaced 1 cm apart, and each channel had 12 surround pressure points. The recorded data were analyzed with ManoView Analysis software.

The patient underwent a high-resolution manometry test after fasting for at least 8 h, and the pressure-measuring catheter was inserted through the nasal cavity. The depth of the catheter was adjusted so that the display screen showed two high-pressure areas at the proximal and distal ends of the esophagus, the upper esophageal sphincter, and the lower esophageal sphincter (LES), and the catheter was fixed at the nasal wing. During the examination, the patient was placed in the supine position and adapted for 5 min. The basal pressure level in the esophagus was recorded, and the patient swallowed 10 times with 5 mL each time. The interval between two swallows was at least 30 s, and the patient remained awake throughout the recording.

Study endpoints

Primary endpoints: The primary endpoint of this study was the GERD-Q scale score. Positive symptom scoring may reflect the frequency of heartburn and reflux symptoms and scored 0, 1, 2, 3 points according to "0 d," "1 d," "2-3 d," or "4-7 d" with a maximum score of 6 points. Negative symptom scoring may reflect the frequency of central abdominal pain and nausea and scored 3, 2, 1, 0 points according to "0 d," "1 d," "2-3 d," or "4-7 d" with a maximum score of 6. Positive impact scoring may reflect the frequency of heartburn or reflux affecting sleep and the frequency of patients taking extra over-the-counter drugs such as antacids and scored 0, 1, 2, 3 points according to "0 d," "1 d," "2-3 d," and "4-7 d" with a maximum score of 6 points. The highest total score of the 6 questions was 18 points. Scores were recorded before medication and at the second and fourth weeks of medication, and follow-up scores were recorded at the first and third month after medication was complete.

Secondary endpoints: Lower esophageal sphincter pressure (LESP), the percentage of ineffective swallowing > 50%, percentage of small peristaltic interruption, percentage of large peristaltic interruption, distal contractile integral (DCI), and percentage of early contractions were the secondary endpoints. As not all participants in the study had abnormal esophageal manometry indicators, only those with abnormalities at baseline were measured before and after completion of medication. Indices of esophageal manometry were recorded before and 4 wk after treatment.

Follow-up

Follow-up was performed at 1 mo and 3 mo after completion of medication, and the number and percentage of patients who were not on medication, on maintenance medication, intermittent medication, and on-demand medication were recorded in the treatment group and the control group.

Statistical analysis

SAS9.4 software (Beijing Hospital of TCM Version, Order Number: 9C1XJD) was used for statistical analysis. mean ± SD were used to describe the continuous variables. Frequency and percentage were used to describe the categorical variables. Statistical tests were performed using the bilateral test, and a P value < 0.05 was considered statistically significant. Measurement data were analyzed using the t-test or Wilcoxon rank-sum test. For comparisons within groups, the paired t-test or Wilcoxon signed-rank test was used. For comparisons between groups, categorical variables were analyzed using the χ^2 test and Fisher's exact test, and continuous variables were analyzed using analysis of variance if normally distributed, or using the nonparametric test if non-normally distributed. For repeated measurements at several time

points between groups, the repeated measures analysis of variance or the generalized estimating equation was used.

RESULTS

Patient characteristics

A total of 288 patients were included in this study and were divided into the treatment group and the control group, with 144 cases in each group. Twenty-eight patients in the treatment group were excluded, including 1 patient with adverse reactions (systemic pruritus after taking the medicine, and the symptoms subsided after 2 d of withdrawal), 14 cases left the study due to personal reasons, and 13 cases left due to dissatisfaction with the treatment; of the 14 patients excluded in the control group, 9 patients left the study due to personal reasons, 5 patients left due to dissatisfaction, and a total of 246 patients completed the study (Figure 1).

One hundred and sixteen patients were included in the treatment group, 50 males and 66 females, aged 18-65 years, with an average age of 50.30 ± 10.38 years. Disease course ranged from 1 mo to 36.67 years. One hundred and thirty patients were included in the control group, 64 males and 66 females, aged 24-65 years, with an average age of 50.48 ± 11.71 years. Disease course ranged from 2 mo to 20 years. There were no statistically significant differences between the two groups of patients in terms of gender, age, and duration of illness.

GERD-Q scale scoring

There were significant differences ($P < 0.01$) within the treatment group in relation to withdrawal of medication before treatment and treatment at 2 wk, 4 wk, 1 mo, and 3 mo. In the control group there were significant differences ($P < 0.01$) in relation to withdrawal of medication before treatment compared with treatment at 2 wk, 4 wk, 1 mo, and 3 mo. There were no significant differences between the treatment group and the control group during treatment and follow-up visits (Table 1).

Indicators of esophageal manometry

With regard to post-treatment changes in patients with reduced LESP before treatment, post-treatment LESP was higher than pre-treatment LESP in both the treatment group and control group, and there was a significant difference between the groups ($P < 0.01$); there was also a significant difference between the two groups after treatment ($P < 0.01$) (Table 2 and Figure 2).

Changes in patients with small intermittent contractions

The post-treatment proportion of small intermittent contractions in the treatment group was reduced compared with that before treatment, and the difference was statistically significant ($P < 0.05$). There was no significant difference within the control group before and after treatment ($P > 0.05$), and there was no significant difference between the two groups after treatment ($P > 0.05$) (Table 3).

Changes in patients with increased large intermittent contractions

The post-treatment proportion of large intermittent contractions in the treatment group was reduced compared with that before treatment, and the difference was statistically significant ($P < 0.05$). There was no significant difference within the control group before and after treatment ($P > 0.05$), and there was no significant difference between the two groups after treatment ($P > 0.05$) (Table 4).

Changes in patients with ineffective swallowing > 50%

The post-treatment proportion of ineffective swallowing in the treatment group and control group was reduced compared with that before treatment. The difference was statistically significant in the two group ($P < 0.01$), and the difference was statistically significant in the two groups after treatment ($P < 0.05$) (Table 5).

Changes in patients with pre-phase contractions

The post-treatment proportion of pre-phase contractions in the treatment group was reduced compared with that before treatment, and the difference was statistically significant ($P < 0.05$). There was no significant difference within the control group before and after treatment ($P > 0.05$), and there was no significant difference between the two groups after treatment ($P > 0.05$) (Table 6).

Efficacy in reducing recurrence rate

Patients were followed up at 1 mo after completing treatment, and a significant difference was observed between the treatment group and the control group ($P < 0.01$) (Table 8).

Patients were followed up at 3 mo after completing treatment, and a significant difference was observed between the treatment group and the control group ($P < 0.05$) (Table 9).

DISCUSSION

This multicenter, randomized, double-blind, double-simulation study proved that MXD has a similar therapeutic effect to omeprazole in the treatment of patients with typical symptoms of GERD and reflux esophagitis grades A and B. MXD was superior to omeprazole in improving LES resting pressure and reducing ineffective esophagus swallowing. The recurrence rate of symptoms was significantly lower than that of omeprazole within 1 mo and 3 mo after completing treatment. MXD may be an alternative treatment to PPI maintenance in patients with GERD.

GERD-Q scale scoring has high diagnostic accuracy in GERD and can evaluate quality of life and treatment response[4-6]. The results of this study showed that the GERD-Q scale scores in the two groups revealed significant changes before and after treatment, while there was no significant difference between the two groups indicating that MXD and the PPI omeprazole had equivalent clinical efficacy in improving the

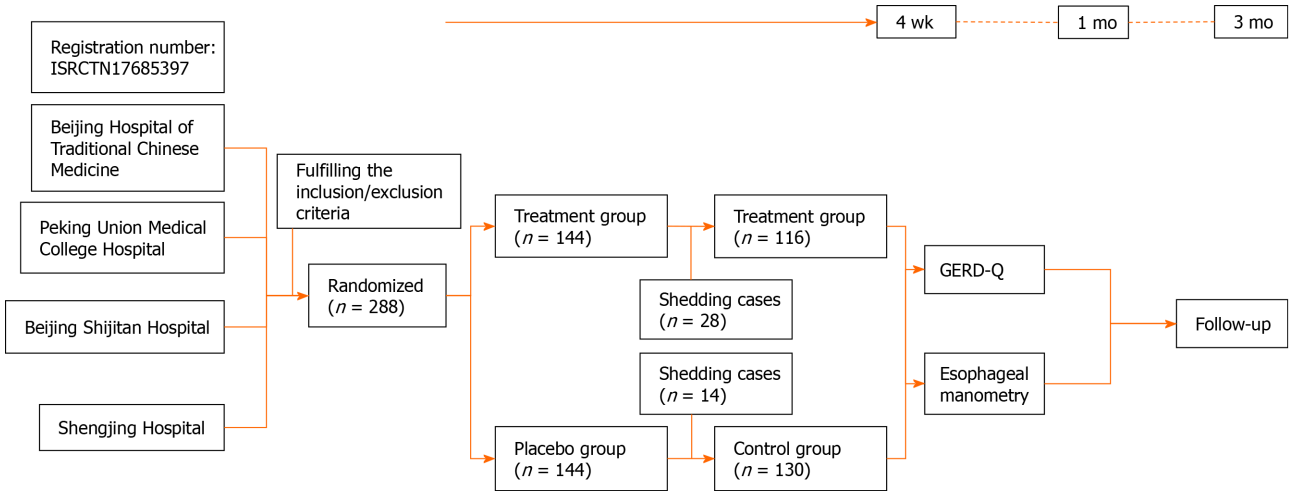

Figure 1 Study flow chart. GERD: Gastroesophageal reflux disease.

symptoms of GERD.

Esophageal dysfunction is a common cause of GERD. Abnormal dysfunction is mainly reflected in the weakened esophageal anti-reflux barrier function and esophageal clearance function. This study only compared abnormal esophageal motility indicators before and after treatment to explore the possible mechanism of MXD in the treatment of GERD. The results showed that MXD increased the LES resting pressure, enhanced the esophageal barrier effect, reduced ineffective contractions to improve esophageal clearance, reduced pre-phase contractions to adjust the coordination of esophageal movement, and improved esophageal clearance function. LES is an important component of the esophageal anti-reflux barrier, and its pressure is higher than that in the stomach to prevent the reflux of gastrointestinal content into the esophagus. It has been confirmed that LESP in GERD patients is significantly lower than in normal individuals[7]. When LESP decreases, the contents of the stomach and duodenum are more easily refluxed into the esophagus.

The research by Hu *et al*[8] showed that LES pressure decreases with the severity of acid reflux, and the decrease in LESP results in a significant increase in the incidence of hiatal hernia. Food in the esophagus is mainly propelled by peristalsis. When

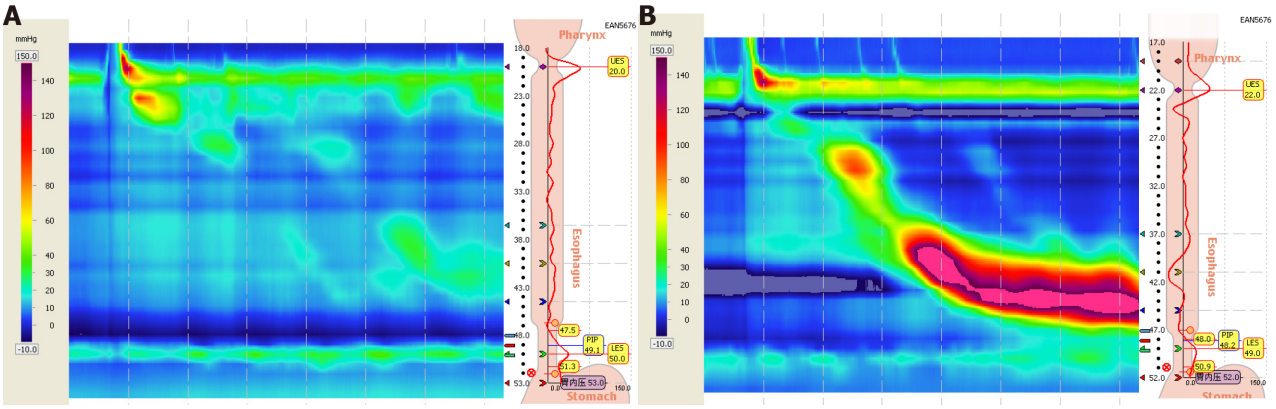

Figure 2 High-resolution esophageal manometry before and after treatment. The results in A and B were from the same patient in the treatment group. A: High-resolution esophageal manometry before treatment; B: High-resolution esophageal manometry 3 mo after treatment.

peristalsis is interrupted, the transmission and clearance functions of the esophagus in terms of the food bolus and reflux content are impaired, resulting in weakened clearance of the esophagus. Ribolsi *et al*[9] confirmed that esophageal peristalsis interruption in patients with GERD is associated with increased acid exposure in the supine position and increased reflux clearance time.

The Chicago esophageal dyskinesia classification released in 2015 defined swallowing with DCI < 450 mmHg·s·cm as ineffective swallowing and ineffective esophageal motility as > 50% of ineffective swallowing[10]. Frequent ineffective peristalsis of the esophagus can lead to impaired esophageal clearance and prolong the exposure duration of the food bolus and reflux content in the esophagus[11], thereby stimulating reflux symptoms. Liu *et al*[12] showed that GERD symptoms were closely related to DCI and ineffective esophageal peristalsis. With the widespread application of pH monitoring, the results of existing research show that ineffective esophageal peristalsis will lead to longer reflux time in both the supine and upright position and prolong average acid clearance time[8,13]. In addition, the pre-phase contractions of the esophagus will block passage of the food bolus and impair the peristaltic function of the esophagus. If the food bolus remains in the esophagus for an extended period, it will also increase stimulation of the esophageal mucosa. It can be inferred that MXD improved the patients' symptoms *via* the above effects.

The difficulty in the treatment of GERD lies in its high recurrence rate. Some studies have shown that in patients with GERD who take PPIs for 4-8 wk that the recurrence rate is 26.0%-47.8%, and the recurrence rate is 30.4% during the 1 year follow-up[14-16]. The follow-up visits in the present study were conducted at 1 mo and 3 mo after completing treatment. Patients not on medication, on maintenance medication, intermittent medication, and on-demand medication were assessed. It was found that the recurrence rate following TCM was low, and its ongoing efficacy was significantly better than omeprazole. The results of this study indicated that by increasing the resting pressure of the LES, improving ineffective swallowing, and reducing pre-phase contractions, the mechanism of reflux is partially corrected, and MXD can lower the recurrence rate.

It is generally accepted that the pathophysiology of GERD mainly involves inflammation and the immune response[17-19]. Modern pharmacological studies have shown that MXD has anti-inflammatory, antioxidant, and immunomodulatory activity. Saikoside, the active component of bupleurum has significant anti-inflammatory, immunoregulatory, and neuroregulatory effects[20]. Studies have shown that saikoside can significantly reduce the expression of tumor necrosis factor-α, interleukin-1, and interleukin-6 and can inhibit the production of nitric oxide, thereby contributing to its anti-inflammatory effects, and saikoside is an effective NF-κB channel inhibitor[21,22]. Studies have shown that inulin fructan extracted from the roots of Codonopsis has anti-inflammatory and anti-oxidant effects. Li *et al*[23] studied the protective effect of inulin fructan on ethanol-induced acute gastric ulcers in rats, and the results showed that inulin fructan significantly increased the activity of superoxide dismutase and glutathione peroxidase in gastric tissue in a dose-dependent manner and reduced the content of malondialdehyde and nitric oxide, thereby protecting the gastric mucosa. In addition, the active component Berberine from *Coptis chinensis* also has similar anti-inflammatory and antioxidant effects[24], and it has been shown that Berberine has a killing effect on *Helicobacter pylori*[25].

CONCLUSION

This study had the following limitations: the research only compared clinical symptoms, and pH monitoring before and after treatment was not carried out. In addition, the treatment duration was 4 wk, which was insufficient. It is considered that the course of treatment should be extended to 8 wk as this would be more conducive to symptom relief and resolution of inflammation. The next phase in this research is to extend the course of treatment and carry out in-depth observations on the effect of MXD on acid reflux.

In the present study, the number of drop-outs in the TCM group was higher, most of which were due to severe acid-refractory heartburn symptoms, and the TCM did not take effect quickly. Due to the double-blind and double-simulation design of the study, we believe that the results objectively demonstrate the effects of MXD and omeprazole on clinical symptoms and esophageal dynamics in GERD patients and provide evidence-based data for GERD patients to receive further treatment. Therefore, it is recommended that patients with reflux symptoms without serious or reflux esophagitis belonging to class A-B be treated with TCM, and for patients with severe symptoms of acid reflux and heartburn, which require quick relief, both Chinese and Western medicine is suggested to obtain more satisfactory efficacy.

ARTICLE HIGHLIGHTS

Research background

Gastroesophageal reflux disease (GERD) has a high prevalence worldwide, and its incidence is increasing annually. According to the preliminary experiment of the research group, Modified Xiaochaihu Decoction (MXD) could relieve the symptoms of GERD.

Research motivation

The effects of MXD on GERD manifestations and relapse prevention need to be further explained. Therefore, we performed a prospective, double-blind, and double-simulation study.

Research objectives

To verify the efficacy of MXD for GERD and its effect on esophageal motility.

Research methods

Using randomization, double-blinding, and a simulation design to compare the GERD-Q scale score and esophageal manometry between patients under the treatment of MXD (treatment group) and omeprazole (control group).

Research results

In total, 288 patients were divided into the treatment group and control group. The GERD-Q scale score in both groups decreased significantly compared to those before treatment ($P < 0.01$). However, no significant difference was observed between the two groups ($P > 0.05$). Esophageal manometry showed that participants with sphincter pressure reduction and the proportion of ineffective swallowing (more than 50%) improved in both groups from baseline ($P < 0.01$), especially in the treatment group ($P < 0.05$). The percentage of small intermittent contractions, large intermittent contractions, and increased pre-phase contractions in the treatment group significantly improved compared with baseline ($P < 0.05$) but did not improve in the control group ($P > 0.05$). The percentage of weak esophageal contractility (distal contractile integral < 450 mmHg·s·cm) improved in both groups ($P < 0.01$). The relapse rate in the treatment group was lower than that in the control group at the 1 mo ($P < 0.01$) and 3 mo follow-up ($P < 0.05$).

Research conclusions

MXD has a similar therapeutic effect to omeprazole in mild-to-moderate GERD. The therapeutic effect may be related to increased pressure in the lower esophageal sphincter and reduced ineffective swallowing.

Research perspectives

Our results supported that MXD has a similar therapeutic effect to omeprazole in mild-to-moderate GERD and could improve esophageal motility.

Abstract

BACKGROUND

Dysbacteriosis may be a crucial environmental factor for ulcerative colitis (UC). Further study is required on microbiota alterations in the gastrointestinal tract of patients with UC for better clinical management and treatment.

AIM

To analyze the relationship between different clinical features and the intestinal microbiota, including bacteria and fungi, in Chinese patients with UC.

METHODS

Eligible inpatients were enrolled from January 1, 2018 to June 30, 2019, and stool and mucosa samples were collected. UC was diagnosed by endoscopy, pathology, Mayo Score, and Montreal classification. Gene amplicon sequencing of 16S rRNA gene and fungal internal transcribed spacer gene was used to detect the intestinal microbiota composition. Alpha diversity, principal component analysis, similarity analysis, and Metastats analysis were employed to evaluate differences among groups.

RESULTS

A total of 89 patients with UC and 33 non-inflammatory bowel disease (IBD) controls were enrolled. For bacterial analysis, 72 stool and 48 mucosa samples were obtained from patients with UC and 21 stool and 12 mucosa samples were obtained from the controls. For fungal analysis, stool samples were obtained from 43 patients with UC and 15 controls. A significant difference existed between the fecal and mucosal bacteria of patients with UC. The α-diversity of intestinal bacteria and the relative abundance of some families, such as *Lachnospiraceae* and *Ruminococcaceae*, decreased with the increasing severity of bowel inflammation, while *Escherichia-Shigella* showed the opposite trend. More intermicrobial correl-

ations in UC in remission than in active patients were observed. The bacteria-fungi correlations became single and uneven in patients with UC.

CONCLUSION

The intestinal bacteria flora of patients with UC differs significantly in terms of various sample types and disease activities. The intermicrobial correlations change in patients with UC compared with non-IBD controls.

Key Words: Ulcerative colitis; Intestinal microbiota; Intermicrobial correlation; Bacteria; Fungi; Chinese

INTRODUCTION

Inflammatory bowel disease (IBD) is a group of chronic inflammatory disorders of the gastrointestinal tract that are divided into ulcerative colitis (UC), Crohn's disease, and IBD-unclassified[1]. The worldwide incidence rate of IBD varies greatly[2]. Among countries in the Asia-Pacific area, where the rate of IBD has rapidly increased, China has the highest incidence, with UC being the most common type[3]. The etiology of UC is still unclear, and it may be related to an abnormal epithelial barrier function and immune response driven by environmental factors in individuals with genetic susceptibility[1].

Disordered intestinal microbiota, or dysbacteriosis, is considered one of the crucial environmental factors for IBD[1]. Animal experiments have indicated the association between microbiota and UC. Some animal models, including mice with an immune deficiency, spontaneously develop chronic colitis resembling human UC[4]. However, under germ-free conditions or durative antibiotic therapy, the development of spontaneous colitis in these mice was prevented[4]. Dozens of studies found that bacterial strains derived from mice with colitis or patients with IBD could induce intestinal inflammation in mice with an immune deficiency and even in wild-type mice[4].

Existing evidence from animal experiments has stressed the necessity of a thorough understanding of the constitution and changes of the intestinal microbiota in patients with UC to elucidate the possible pathogenesis and investigate potential treatments. Numerous studies have focused on the variations in bacterial diversity and composition. Compared with non-IBD controls, there is a trend of decreased microbial α-diversity in patients with UC[5-7], although the total bacterial count decreased or increased in different studies[8,9]. Altered bacterial composition in patients with UC was discovered in almost all the related studies. The intestinal bacterial microbiota in the feces was different from that in the colon mucosa[10,11]. Differences were also found between patients with UC and non-IBD controls[6,7,12-16], among patients with UC of various severity[9,17,18] or disease types[11,19], between inflamed and noninflamed biopsies[6,16,19,20], among patients who accepted different therapies[10,

study participants provided informed written consent prior to study enrollment.

11], and between patients who responded or did not respond to certain therapies[13]. In recent years, studies have also focused on changes in intestinal fungi in IBD patients [5,17]. However, existing studies concerning the above areas have arrived at various conclusions, which may be attributed to the limited sample size, imprecise stratification of patients, or other factors. Therefore, further study is required to obtain more information about microbiota alterations in the gastrointestinal tract of patients with UC for better clinical management and treatment.

In this study, our main purpose was to characterize the intestinal microbiota of patients with UC by 16S rRNA gene amplicon sequencing and compare the differences between the fecal and mucosa samples of the same UC patient, among patients with active UC, those with UC in remission, and non-IBD controls, among patients with different degrees of disease activity or with different disease types, and between biopsy samples collected from inflamed and noninflamed sites. In addition, the fecal fungal microbiota in the patients and controls was also analyzed using internal transcribed spacer (ITS) rRNA gene amplicon sequencing. Finally, we compared the intermicrobial correlations in patients with UC and non-IBD controls.

MATERIALS AND METHODS

Patient selection and stratification

Patients with UC and non-IBD controls were recruited from patients admitted to Peking Union Medical College Hospital in Beijing, China from January 1, 2018 to June 30, 2019. The diagnosis of UC was determined by endoscopic and pathological findings. Only patients with regular follow-ups (more than 3 times in 1 year, outpatient and/or inpatient) were included, and all these patients orally took 1 g of mesalazine per time, 3-4 times per day. Patients with any history of colectomy, antibiotic use or probiotic application within 3 mo before sample collection, or other types of gastroenteric complications (including gastrointestinal tumor, gastroduodenal ulcer, and irritable bowel syndrome) were excluded. The clinical activity of disease was determined by the Mayo score/Disease Activity Index[21], and the patients were classified into UC in remission or active UC groups, with the latter further divided into mild, moderate, and severe groups. The patients were also classified into proctitis (type E1), distal colitis (type E2), or pancolitis (type E3) groups based on their disease types according to the Montreal classification[22]. The inflammatory status of the biopsy was confirmed by pathological evidence. The non-IBD controls were asymptomatic patients with colonic polyps.

This work was been approved by the ethical committees of Peking Union Medical College Hospital (No. JS-1488). All the patients included have signed an informed consent form.

Sample collection

Fecal samples were collected 1-2 d before bowel preparation and endoscopic examination, and were stored in stool tubes (Allwegene Company, Beijing) at -80 °C within 2 h after collection. Two biopsies were taken from each biopsy site during endoscopy. One of the biopsies was stored in formalin for standard histological staining, and the other was snap-frozen and then stored at -80 °C for sequencing.

DNA extraction and polymerase chain reaction amplification

DNA was extracted from samples using the DNeasy PowerSoil Kit (QIAGEN, Dusseldorf, GER) according to the manufacturer's protocol. The purity and quality of the genomic DNA were checked on 0.8% agarose gels. The V3-4 hypervariable region of the bacterial 16S rRNA gene was amplified with the primers 338F (ACTCCTACGGGAGGCAGCAG) and 806R (GGACTACHVGGGTWTCTAAT)[23]. The fungal ITS gene was amplified with the primers ITS3-F (GCATCGATGAAGAACGCAGC) and ITS4-R (TCCTCCGCTTATTGATATGC)[24]. For each mucosa or fecal sample, a 10-digit barcode sequence was added to the 5' end of the forward and reverse primers. Polymerase chain reaction (PCR) was carried out on a Mastercycler Gradient (Eppendorf, Germany) using a 25 μL reaction volume containing 12.5 μL of 2 × Taq PCR MasterMix, 3 μL of BSA (2 ng/μL), primers (5 μM), 2 μL of template DNA, and 5.5 μL of ddH_2O. The cycling parameters were 95 °C for 5 min, followed by 32 cycles of 95 °C for 45 s, 55 °C for 50 s, and 72 °C for 45 s with a final extension at 72 °C for 10 min. Three PCR products per sample were pooled to mitigate reaction-level PCR biases. The PCR products were purified using a QIAquick Gel Extraction Kit (QIAGEN, Germany), quantified using real-time PCR, and sequenced by Allwegene

Company (Beijing, China).

High-throughput sequencing and comparative sequence analysis

Deep sequencing was performed on the Miseq platform at Allwegene Company (Beijing). After the run, image analysis, base calling, and error estimation were performed using Illumina Analysis Pipeline Version 2.6. The raw data were first screened, and sequences were removed if they were shorter than 150 bp or longer than 500 bp, had a low-quality score (≤ 20), contained ambiguous bases, or did not exactly match the primer sequences and barcode tags. After screening, the qualified reads were separated using the sample-specific barcode sequences and trimmed with Illumina Analysis Pipeline Version 2.6. Then, the dataset was analyzed using Quantitative Insights Into Microbial Ecology (QIIME, Ver2.1, Rob Knight laboratory and Greg Caporaso laboratory, United States). After 16S rRNA amplicon sequencing and screening, an average of 59307 ± 4058 [mean ± standard error of mean (SEM)] qualified reads were obtained from the fecal samples, and an average of 54201 ± 3834 qualified reads were obtained from the mucosa samples. After ITS sequencing and screening, an average of 47051 ± 4675 qualified reads were obtained from the fecal samples. In the subsequent subgroup analysis, singletons were further removed from the qualified sequences and then the latter was subsampled and clustered into operational taxonomic units (OTUs) at a similarity level of 97% to generate rarefaction curves and to calculate the richness and diversity indices (the number of subsampled sequences and the corresponding OTUs for each subgroup analysis are described in Supplementary Table 1. The Ribosomal Database Project Classifier tool was used to classify all sequences into different taxonomic groups. Finally, the bacterial taxonomic groups were matched to specific genera based on Silva database (Ver. 128), and the fungal groups were based on the Unite database (Ver. 7.1).

Statistical analysis

A *t*-test was used to detect the difference in age among groups. The chi-square test was used to compare the distributions of sex, disease type, and disease activity among groups. The alpha diversity, principal component analysis (PCA), and analysis of similarities (ANOSIM) were performed based on the OTUs and the abundance acquired from the subsampled sequences of samples involved in the subgroup analysis. Alpha diversity was estimated using Shannon index metric, and one-way ANOVA (SPSS 19.0) was used to measure the difference among Shannon indices. To examine the similarity of the microbiota structure between different samples, PCA was performed using R software. PCA was used to reduce the high dimensionality of the intestinal microbiota structure, which contained numerous original variables, and to observe the relationship among samples in a rectangular coordinate. To further examine the similarity between different samples and to determine whether the between-group difference was greater than the inter-group difference, ANOSIM was performed in the R. The Metastats analysis using Mothur was employed to detect interindividual differences and the differences in microbiota composition among groups at the phylum and genus levels were measured. Only bacteria or fungi with relative abundances higher than 1% in either group were displayed in this study and were discussed with emphasis. Generally, the numerical value is shown as the mean ± SD. Under the condition of multiple comparisons, the *P* values were corrected to control for the false discovery rate by Benjamini-Hochberg method ($\alpha = 0.05$). Differences with a $P < 0.05$ were considered statistically significant. Moreover, Spearman correlation coefficient analysis was applied and inter-microbial correlations at the genus level with a *P* value less than 0.05 and an R value greater than 0.6 were selected and put into a correlation network using Cytoscape v3.7.0. The statistical methods of this study were reviewed by Dr. Tao-Tao Han from Chinese Academy of Medical Sciences and Peking Union Medical College.

RESULTS

Sample collection and microbiota analysis

Eighty-nine patients with UC and 33 non-IBD controls were included in the present study. Among the 89 patients with UC, 31 provided both stool and mucosa samples and 19 patients with UC at active stage provided mucosa samples from inflamed and noninflamed sites, and finally 72 stool samples and 67 mucosa samples were obtained. Twenty-one stool samples and 12 mucosa samples were obtained from non-IBD controls diagnosed with tubular adenoma, tubulovillous adenoma, or a hyperplastic

polyp according to histological evidence. The basic clinical characteristics of the subjects among the groups under different stratifications were compared (Supplementary Tables 2-4), including age, sex proportion, disease activity, and disease type distribution in patients with UC. Most of the characteristics showed little intergroup difference, except for the mean age of the non-IBD controls and patients with UC and the disease type distribution of active UC and UC in remission. Among the stool samples, the compositions of fungal flora in 15 non-IBD samples and 42 UC samples were detected by ITS sequencing. The rest of the samples (6 non-IBD controls and 30 UC patients) failed to undergo ITS sequencing due to the insufficiency of tissues. Although a difference existed in the results of OTUs clustering in different subgroup analysis, in both the fecal and the mucosa sample, *Firmicutes*, *Bacteroidetes*, *Proteo-bacteria*, and *Actinobacteria* were always the four chief components among the identified phyla, and the identified fecal fungi mainly consisted of *Basidiomycota* and *Ascomycota*.

Fecal and mucosal bacterial microbiota of patients with UC is different

The microbiota in the stool and mucosa samples of the same patient with UC were compared if collected within less than 3 d, and 31 pairs of samples were included. Compared with the mucosal sample (Shannon index, 5.04 ± 1.14), the α-diversity of the microbiota in the fecal sample (Shannon index, 4.08 ± 0.89) was significantly lower (P = 0.001) (Figure 1A). As directly assessed by PCA (Figure 1B), the flora structure of the mucosa sample and that of the stool sample showed obvious differences and ANOSIM indicated significant intergroup differences (Figure 1C). The microbiota compositions at the phylum and genus levels of the mucosa and fecal samples are shown in Figure 1D. At the phylum level, the relative abundance of mucosal *Proteobacteria* and unidentified phyla was higher than that of fecal *Proteobacteria*, while the relative abundances of *Bacteroidetes* and *Firmicutes* were lower in the mucosa sample. At the genus level, 16 types of bacterial genera differed significantly between the mucosa and stool samples (the relative abundance and the P value of each bacterium are described in Supplementary Table 5).

Comparison between patients with UC with different levels of disease activity and non-IBD controls–for stool samples

The α-diversity of intestinal bacteria decreases in patients with UC and the microbiota composition differs among UC patients in remission, patients with active UC, and non-IBD controls: As shown in Figure 2A, compared with the non-IBD controls (Shannon index, 4.71 ± 0.64), the α-diversity of the intestinal microbiota evaluated by the Shannon index significantly decreased in patients with UC in remission (Shannon index, 4.11 ± 0.74; P = 0.013), as well as in patients with active UC (Shannon index, 3.20 ± 1.04; P = 0.000). The α-diversity of patients with active UC was also significantly lower than that of UC patients in remission (P = 0.002). According to the PCA and ANOSIM results, the intergroup difference between the non-IBD controls and UC patients in remission group was significant (Figure 2B and C). The microbiota compositions of the different groups are shown in Figure 2D (the relative abundance and P value are listed in Supplementary Table 6). At the phylum level, the abundance of *Proteobacteria* significantly increased in patients with active UC but decreased in patients with UC in remission, while that of *Firmicutes* showed the opposite pattern. The abundance of *Bacteroidetes* significantly decreased in both the active UC and UC in remission groups. At the genus level, compared with the non-IBD controls, the relative abundances of *Alistipes*, *Bacteroides*, *Dialister*, and *Escherichia-Shigella* in patients with UC in remission significantly decreased, while that of *Lachnospira* increased. The relative abundances of *Escherichia-Shigella*, *Enterococcus*, and *Peptoclostridium* were significantly higher in the active UC group than in the non-IBD group, while those of *Alistipes*, *Subdoligranulum*, *Roseburia*, *Ruminococcus* 2, and *Ruminococcus torques* were significantly lower in patients with active UC. When comparing patients with active UC and UC in remission, the relative abundances of *Escherichia-Shigella*, *Enterococcus*, *Haemophilus*, and *Klebsiella* were higher in the former, while those of *Lachnospira*, *Faecalibacterium*, *Roseburia*, and *Blautia* were higher in the latter.

The α-diversity continuously decreases, and some bacteria show a consistently changing pattern with increasing disease activity in patients with active UC: As shown in Figure 3A, the α-diversity of the intestinal microbiota gradually decreased with increasing inflammation degree (the Shannon index of mild, moderate, and severe active UC was 3.74 ± 0.84, 3.08 ± 0.95, and 2.66 ± 1.14, respectively), and the difference between the mild and moderate groups (P = 0.025), and between the mild and severe groups (P = 0.003) was significant, though that between the moderate and

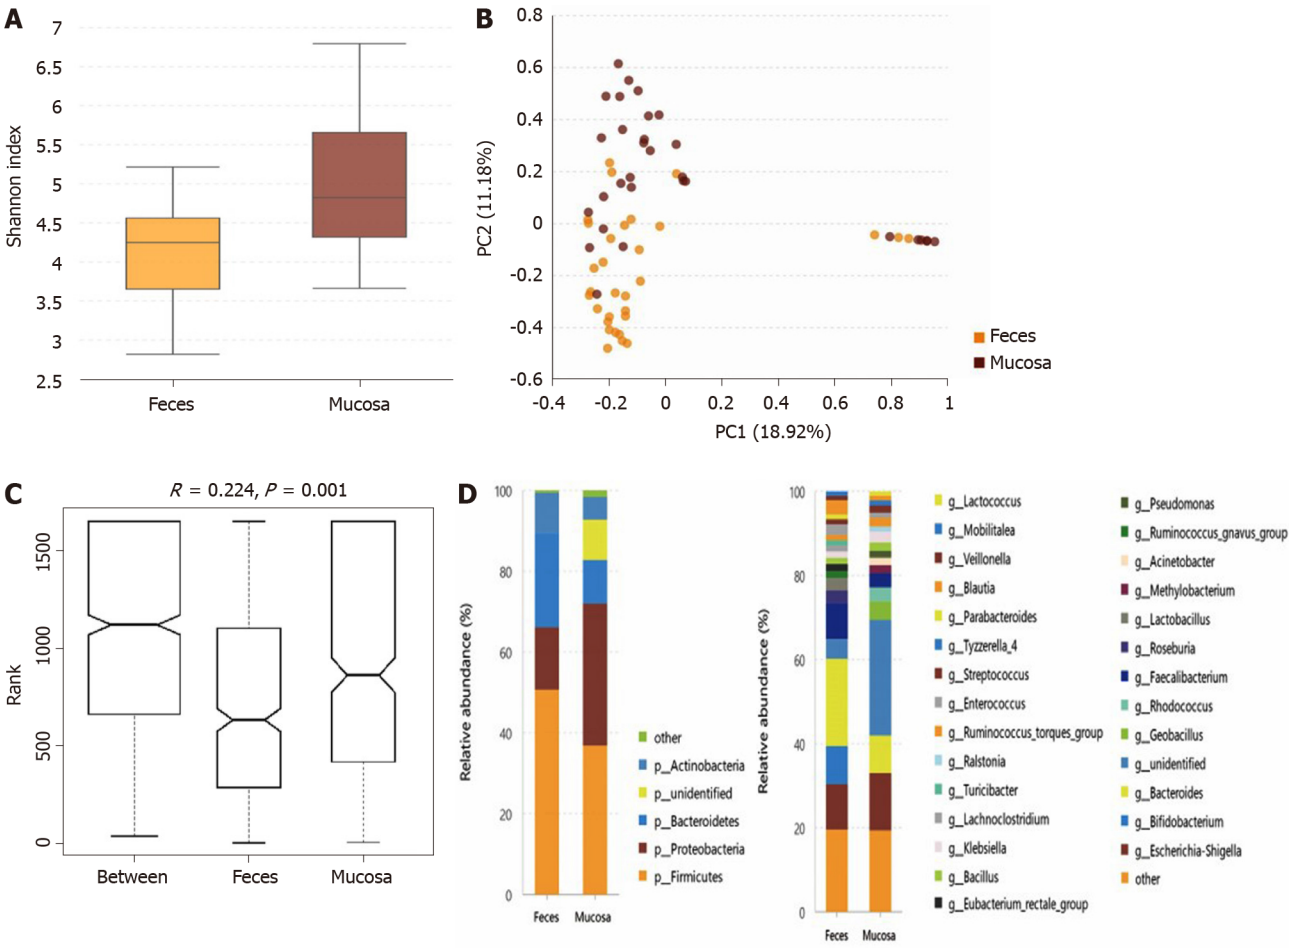

Figure 1 tatistical analysis of the sequencing results of the bacteria microbiota in stool and mucosa samples from patients with ulcerative colitis. A: The α-diversity of microbiota evaluated by Shannon index. The ordinate shows the Shannon index, and the abscissa shows the sample types. Compared with mucosa samples (Shannon index, 5.04 ± 1.14), the α-diversity of microbiota in fecal samples (Shannon index, 4.08 ± 0.89) was significantly lower (P = 0.001); B: Principal component analysis. The flora structure of mucosa samples and that of stool samples showed an obvious difference (with a PC1 of 18.92% and a PC2 of 11.18%, as showed in the abscissa and ordinate axis separately); C: The analysis of similarities. The intergroup difference (marked as Between) was greater than within group differences (marked as Feces and Mucosa for the two groups) and the result was significant (P = 0.001); D: The relative abundance of the bacteria at the phylum (the left bar graph) and genus (the right bar graph) levels. The ordinate shows the relative abundance (%), and the abscissa axis shows the sample types where the microbiota was sequenced from. At the phylum level, the relative abundance of mucosal *Proteobacteria* and the unidentified phyla was higher than fecal ones, while the relative abundance of *Bacteroidetes* and *Firmicutes* was lower in the mucosa samples. At the genus level, 16 kinds of bacteria genera differed significantly between mucosa and stool samples.

severe groups was not obvious (P = 0.235). Significant differences were observed through PCA (Figure 3B) and ANOSIM (Figure 3C). The microbiota compositions of different groups are shown in Figure 3D (the relative abundance and P value are listed in Supplementary Table 7). At the phylum level, the abundance of *Proteobacteria* showed a significantly increasing trend with deteriorating disease conditions, and that of *Bacteroidetes* gradually decreased, although only the difference between the mild and severe groups was obvious. At the genus level, some bacterial genera that differed significantly between the non-IBD controls and patients with active UC displayed consistently changing patterns when the disease condition worsened, including a further increase in *Escherichia-Shigella* in moderate-severe active UC and an obvious reduction of *Faecalibacterium*, *Roseburia*, and *Bacteroides* in severe active UC. The relative abundance of *Eubacterium rectale* group gradually decreased when the inflammation worsened, although this genus did not differ significantly between the non-IBD controls and patients with UC. Decreased *Blautia* in moderate active UC and reduced *Parasutterella* and *Lachnospira* in severe active UC compared with the mild UC group were also observed.

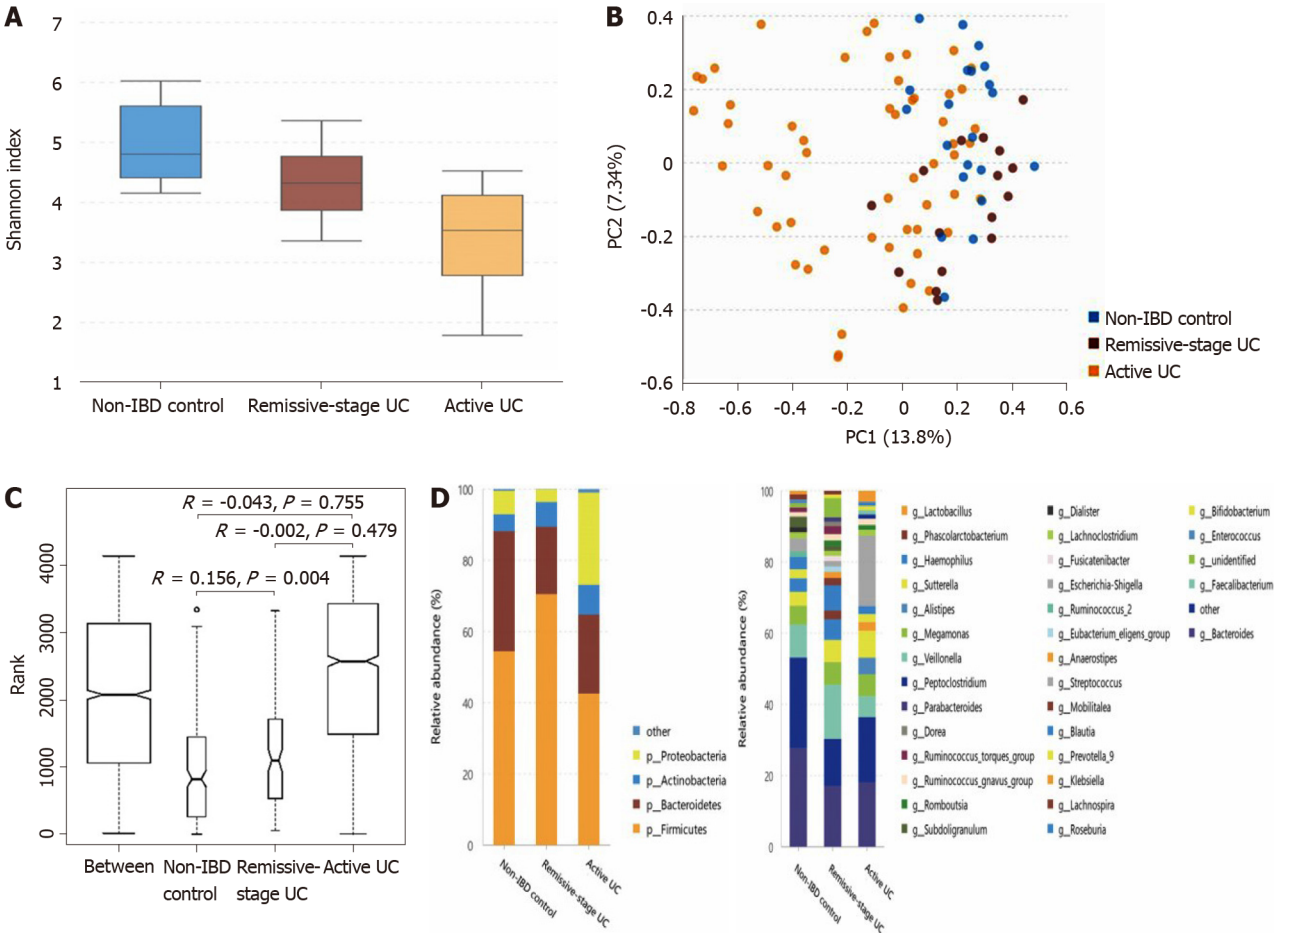

Figure 2 Statistical analysis of the sequencing results of the bacteria microbiota in stool samples from patients with ulcerative colitis and non-inflammatory bowel disease controls. A: The α-diversity of microbiota evaluated by Shannon index. The ordinate shows the Shannon index, and the abscissa shows the groups. Compared with non-inflammatory bowel disease (IBD) controls (Shannon index, 4.71 ± 0.64), the α-diversity of intestinal microbiota evaluated by Shannon index significantly decreased in the ulcerative colitis (UC) in remission (Shannon index, 4.11 ± 0.74; P = 0.013), as well as in the active patients with UC (Shannon index, 3.20 ± 1.04; P = 0.000). The α-diversity of active UC was also significantly lower than that of UC in remission (P = 0.002); B: Principal component analysis. The flora structure of non-IBD controls and UC in remission group showed an obvious difference (with a PC1 of 13.8% and a PC2 of 7.34%, as showed in the abscissa and ordinate axis separately); C: The analysis of similarities. The intergroup difference between non-IBD controls and UC in remission group was greater than within group differences, and the result was significant (P = 0.004); D: The relative abundance of the bacteria at the phylum (the left bar graph) and genus (the right bar graph) levels. The ordinate shows the relative abundance (%), and the abscissa axis shows the sample types where the microbiota was sequenced from. At the phylum level, the abundance of *Proteobacteria* significantly increased in active UC but decreased in UC in remission, while that of *Firmicutes* showed the opposite pattern. The abundance of *Bacteroidetes* significantly decreased in both active UC and UC in remission groups. At the genus level, compared with non-IBD controls, the relative abundance of *Alistipes*, *Bacteroides*, *Dialister*, and *Escherichia-Shigella* in UC in remission significantly decreased, while that of *Lachnospira* increased. The relative abundance of *Escherichia-Shigella*, *Enterococcus*, and *Peptoclostridium* was significantly higher in active UC group than in the non-IBD group, while that of *Alistipes*, *Subdoligranulum*, *Roseburia*, *Ruminococcus 2*, and *Ruminococcus torques* group was significantly lower in active patients with UC. When comparing active UC and UC in remission, the relative abundance of *Escherichia-Shigella*, *Enterococcus*, *Haemophilus*, and *Klebsiella* was higher in the former, while that of *Lachnospira, Faecalibacterium*, *Roseburia*, and *Blautia* was higher in the latter. IBD: Inflammatory bowel disease; UC: Ulcerative colitis.

Comparison between patients with UC with different levels of disease activity and non-IBD controls–for mucosa samples

The α-diversity of the mucosal microbiota decreases in patients with active UC, and the microbiota composition differs among groups: As shown in Figure 4A, the α-diversity of the mucosal microbiota in the non-IBD controls (Shannon index, 6.12 ± 0.70) was similar to that in patients with UC in remission (Shannon index, 5.63 ± 1.53; P = 0.682) but was significantly higher than that in patients with active UC (4.99 ± 1.02; P = 0.001). The α-diversity of patients with UC in remission and with active UC showed little difference (P = 0.453). Direct observation of the PCA rectangular coordinates (Figure 4B) indicated that the flora structure of the non-IBD controls was different from that of either UC group. ANOSIM indicated that the difference between the controls and patients with UC in remission was significant (Figure 4C). As shown in Figure 4D (the relative abundance and P value are listed in Supplementary Table 6), at the phylum level, compared with the non-IBD controls, the relative abundances of

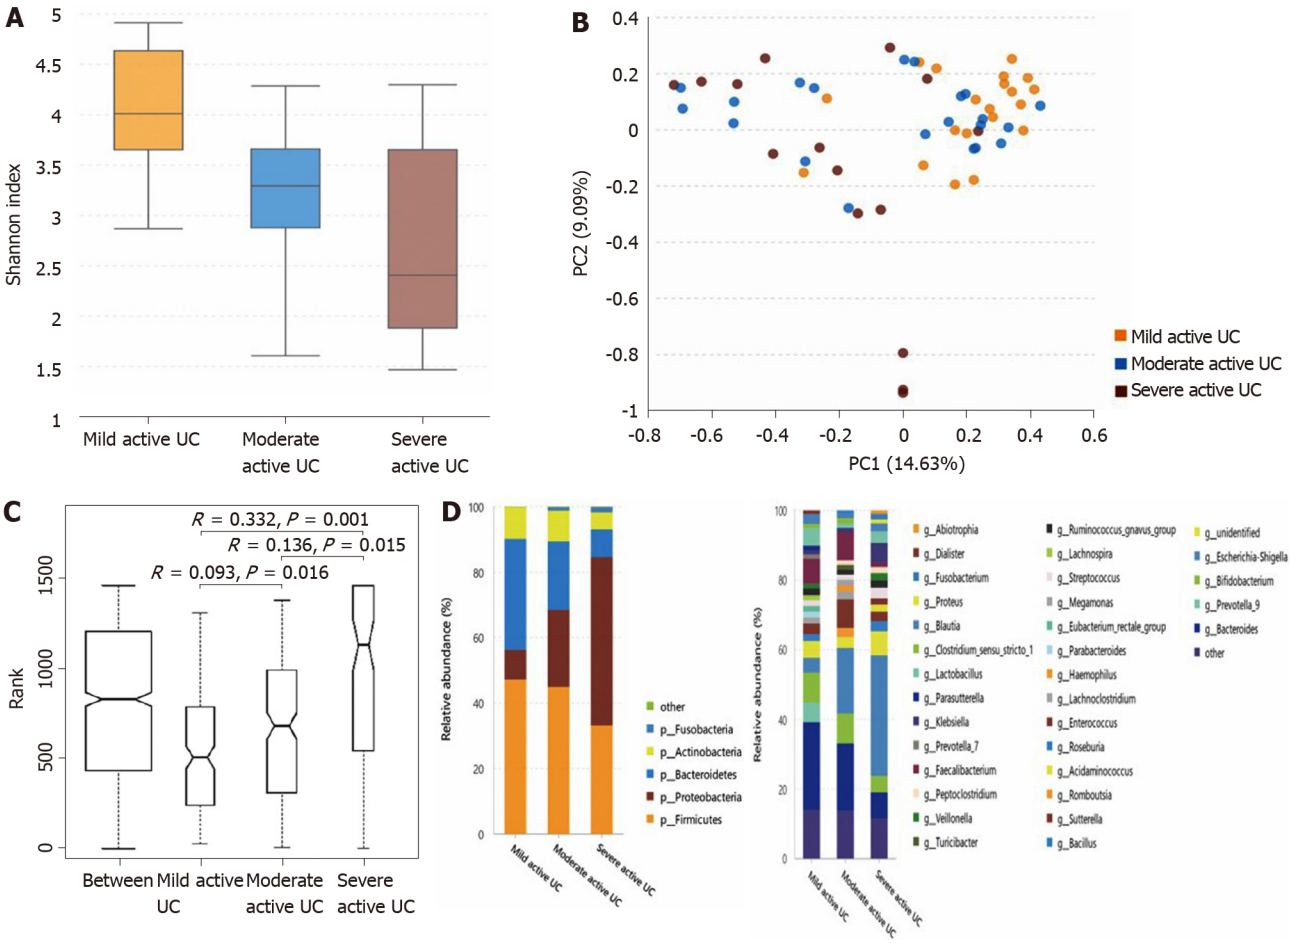

Figure 3 Statistical analysis of the sequencing results of the bacteria microbiota in stool samples from mild, moderate, and severe active ulcerative colitis groups. A: The α-diversity of microbiota evaluated by Shannon index. The ordinate shows the Shannon index, and the abscissa shows the groups. The α-diversity of the intestinal microbiota gradually decreased along with increasing inflammation degree (the Shannon index of mild, moderate, and severe active ulcerative colitis (UC) was 3.74 ± 0.84, 3.08 ± 0.95, and 2.66 ± 1.14, respectively), and the difference between the mild and moderate groups (P = 0.025), and between the mild and severe groups (P = 0.003) was significant, although that between it was not significantly between the moderate and severe groups (P = 0.235); B: Principal component analysis. The flora structure of mild, moderate, and severe active UC groups showed an obvious difference (with a PC1 of 14.63% and a PC2 of 9.09%, as showed in the abscissa and ordinate axis separately); C: The analysis of similarities. The intergroup differences between any two of these groups were significant (P = 0.016 between the mild and the moderate stage group, P = 0.015 between the moderate and the severe stage group, and P = 0.001 between the mild and the severe stage group); D: The relative abundance of the bacteria at the phylum (the left bar graph) and genus (the right bar graph) levels. The ordinate shows the relative abundance (%), and the abscissa axis shows the sample types where the microbiota was sequenced from. At the phylum level, the abundance of *Proteobacteria* showed a significant trend of increase with a deteriorating disease condition, and that of *Bacteroidetes* gradually decreased, though only the difference between mild and severe subgroups was obvious. At the genus level, some bacteria genera that differed significantly between non-inflammatory bowel disease (IBD) controls and active patients with UC displayed a consistent changing pattern when the disease condition was getting worse, including a further increase of *Escherichia-Shigella* in moderate-severe active UC and an obvious reduction of *Faecalibacterium*, *Roseburia*, and *Bacteroides* in severe active UC. The relative abundance of *Eubacterium rectale* group gradually decreased when the inflammation worsened though this genus did not differ significantly between non-IBD controls and patients with UC. Decreased *Blautia* in moderate active UC and reduced *Parasutterella* and *Lachnospira* in severe active UC compared with the mild group were also observed. UC: Ulcerative colitis.

Firmicutes and *Proteobacteria* significantly increased in patients with active UC, and that of *Actinobacteria* was significantly higher in patients with both active UC and UC in remission. The relative abundance of unidentified bacterial phyla obviously decreased in patients with UC in remission and further decreased in patients with active UC. At the genus level, the relative abundances of *Geobacillus*, *Lactococcus*, *Pseudomonas*, *Methylobacterium*, *Acinetobacter*, *Streptococcus*, *Bacillus*, and *Ralstonia* increased in the active UC group compared with the non-IBD controls, while those of *Ruminococcus torques* and the unidentified bacterial genera were reduced. When comparing the non-IBD controls and patients with UC in remission, the relative abundances of *Eubacterium rectale* and the unidentified genera were lower in the latter, while those of *Methylobacterium*, *Rhodococcus*, *Peptoclostridium*, and *Faecalibacterium* were higher. The difference between patients with active UC and UC in remission was also obvious, and more *Geobacillus*, *Lactococcus*, *Pseudomonas*, *Streptococcus*, *Bacillus*, *Ralstonia*, and *Prevotella group 9* were observed in patients with active UC.

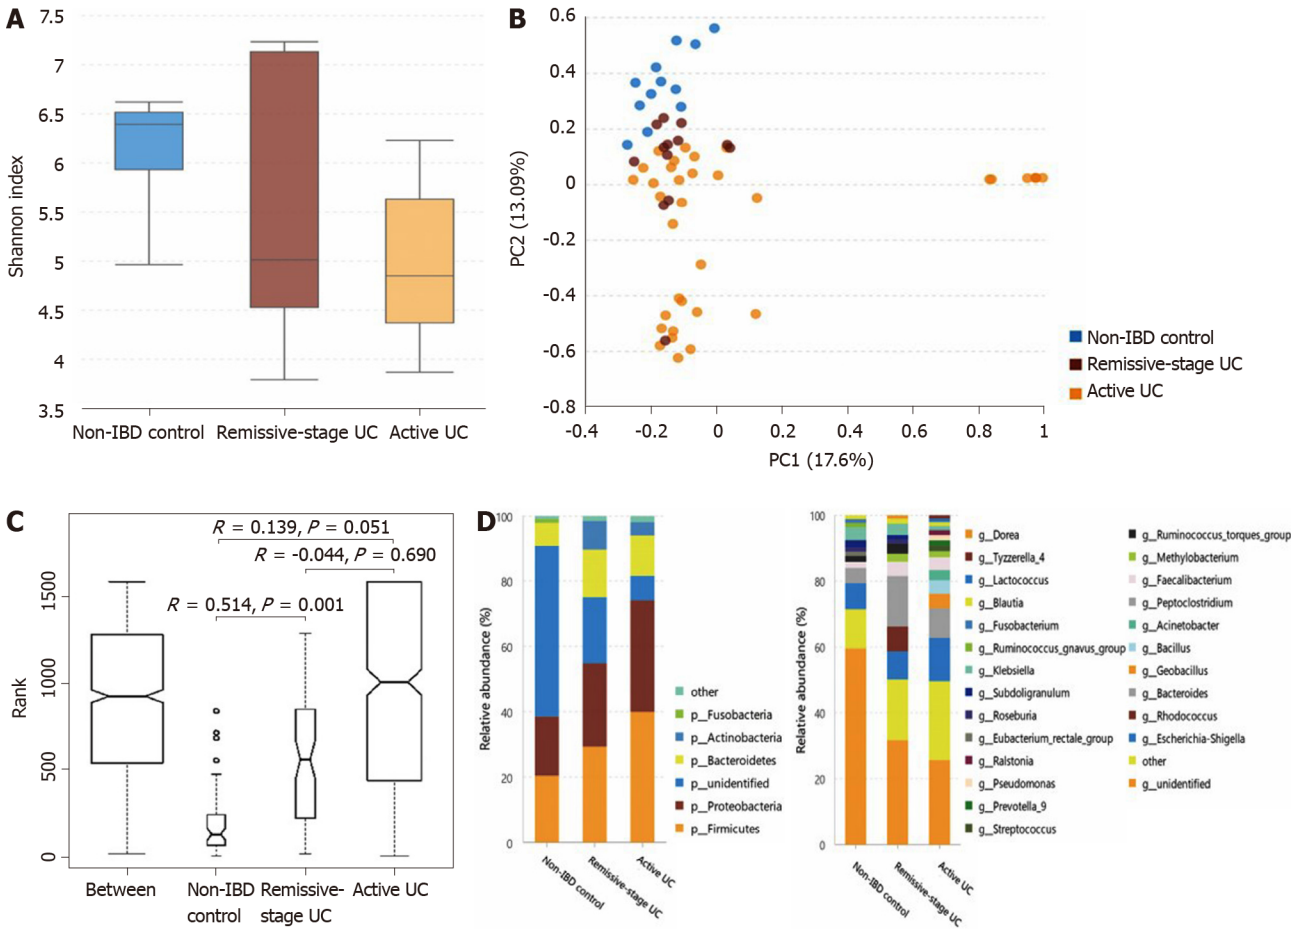

Figure 4 Statistical analysis of the sequencing results of the bacteria microbiota in mucosa samples from patients with ulcerative colitis and non-inflammatory bowel disease controls. A: The α-diversity of microbiota evaluated by Shannon index. The ordinate shows the Shannon index, and the abscissa shows the groups. The α-diversity of mucosal microbiota in non-inflammatory bowel disease (IBD) controls (Shannon index, 6.12 ± 0.70) was similar to that in ulcerative colitis (UC) in remission (Shannon index, 5.63 ± 1.53; P = 0.682) but significantly higher than that of the active UC group (4.99 ± 1.02; P = 0.001). And the α-diversity of UC in remission and active UC showed little difference (P = 0.453); B: Principal component analysis. The flora structure of non-IBD controls was different from that of either UC group (with a PC1 of 17.6% and a PC2 of 13.09%, as showed in the abscissa and ordinate axis separately); C: The analysis of similarities. The intergroup difference between controls and UC in remission was significant (P = 0.001); D: The relative abundance of the bacteria at the phylum (the left bar graph) and genus (the right bar graph) levels. The ordinate shows the relative abundance (%), and the abscissa axis shows the sample types where the microbiota was sequenced from. At the phylum level, compared with non-IBD controls, the relative abundance of *Firmicutes* and *Proteobacteria* significantly increased in active UC, and that of *Actinobacteria* was significantly higher in both the active UC and UC in remission groups. The relative abundance of unidentified bacterial phyla obviously decreased in UC in remission and further decreased in active UC. At the genus level, the relative abundance of *Geobacillus*, *Lactococcus*, *Pseudomonas*, *Methylobacterium*, *Acinetobacter*, *Streptococcus*, *Bacillus*, and *Ralstonia* increased in active UC compared with non-IBD controls, while that of *Ruminococcus torques* group and unidentified bacteria genera decreased. When comparing the non-IBD controls and UC in remission, the relative abundance of *Eubacterium rectale* group and unidentified genera was lower in the latter while that of *Methylobacterium*, *Rhodococcus*, *Peptoclostridium*, and *Faecalibacterium* was higher. The difference between active UC and UC in remission was also obvious and more *Geobacillus*, *Lactococcus*, *Pseudomonas*, *Streptococcus*, *Bacillus*, *Ralstonia*, and *Prevotella* group 9 were observed in active patients with UC. IBD: Inflammatory bowel disease; UC: Ulcerative colitis.

The α-diversity of mucosal bacteria further decreases in severe active UC, and the microbiota composition is slightly different among subgroups that vary in inflammation degree: The α-diversity of mucosal bacteria in patients with severe active UC (Shannon index, 3.67 ± 1.25) was significantly lower than that in patients with mild active UC (Shannon index, 5.40 ± 1.01; P = 0.017). However, little difference was observed between the mild and moderate subgroups (Shannon index, 4.80 ± 0.90; P = 0.100) or between the moderate and severe subgroups (P = 0.251) (Figure 5A). Only the flora structure of the mild and severe groups showed obvious differences according to PCA and ANOSIM (Figure 5B and C). As shown in Figure 5D (the relative abundance and P value are listed in Supplementary Table 7), at the phylum level, the relative abundance of *Actinobacteria* in patients with severe active UC was significantly lower than that in patients with mild/moderate UC, and fewer unidentified bacterial phyla were observed in patients with severe UC than in patients with mild UC. At the genus level, the relative abundance of *Methylobacterium* in patients with mild UC was significantly higher than that in patients with moderate/severe UC, and *Blautia*

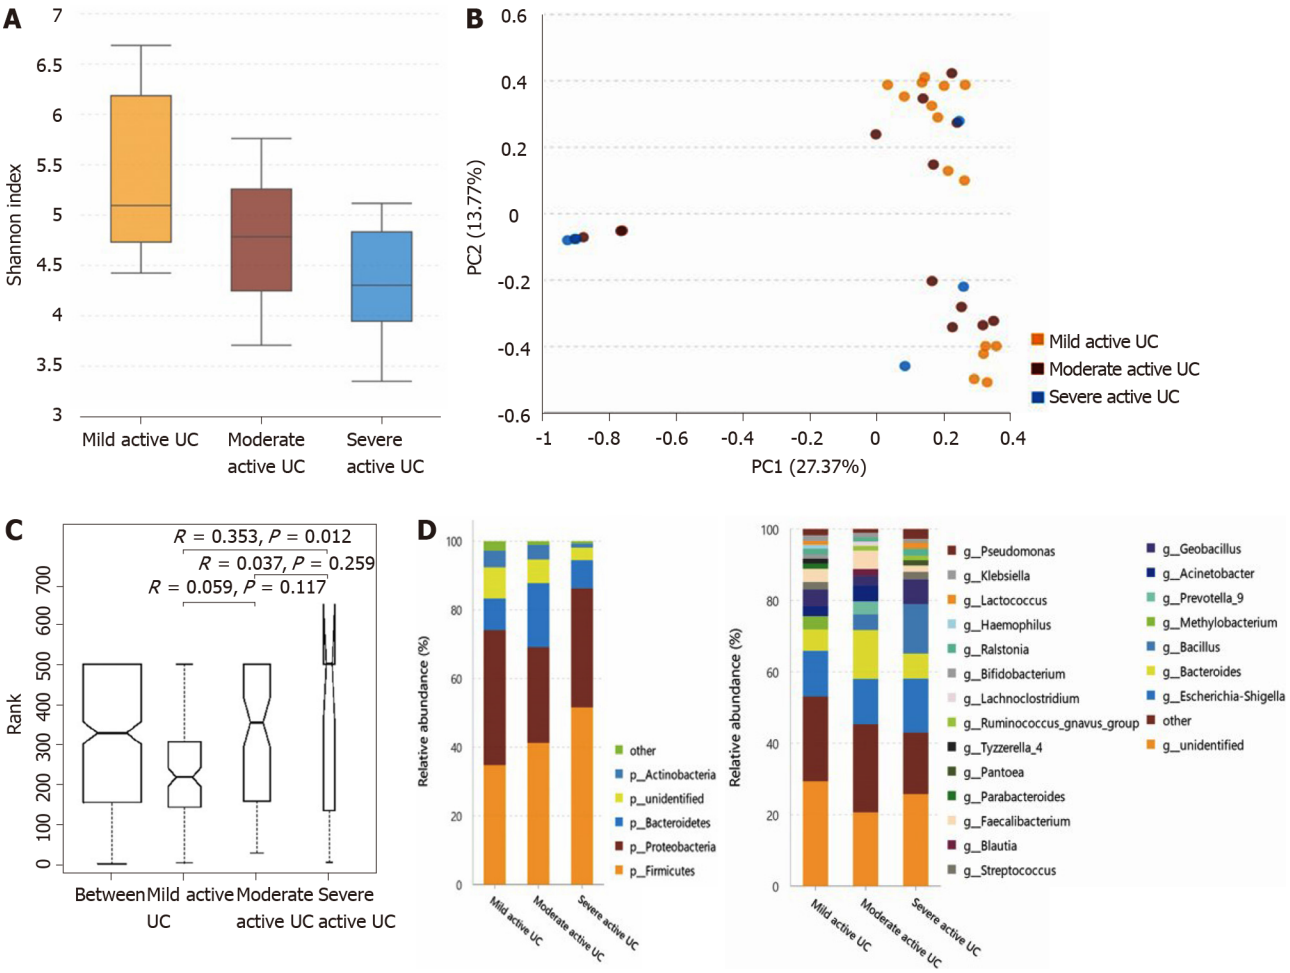

Figure 5 Statistical analysis of the sequencing results of the bacteria microbiota in mucosa samples from mild, moderate, and severe active ulcerative colitis groups. A: The α-diversity of microbiota evaluated by Shannon index. The ordinate shows the Shannon index, and the abscissa shows the groups. The α-diversity of mucosal bacteria in severe active ulcerative colitis (UC) (Shannon index, 3.67 ± 1.25) was significantly lower than that of mild active UC (Shannon index, 5.40 ± 1.01; $P = 0.017$). Little difference was observed between the mild and moderate groups (Shannon index 4.80 ± 0.90; $P = 0.100$), neither between the moderate and severe ones ($P = 0.251$); B: Principal component analysis. The flora structure of mild and severe subgroups showed a significant difference (with a PC1 of 27.37% and a PC2 of 13.77%, as showed in the abscissa and ordinate axis separately); C: The analysis of similarities. The intergroup difference between mild and severe groups was significant ($P = 0.012$); D: The relative abundance of the bacteria at the phylum (the left bar graph) and genus (the right bar graph) levels. The ordinate shows the relative abundance (%), and the abscissa axis shows the sample types where the microbiota was sequenced from. At the phylum level, the relative abundance of *Actinobacteria* of severe active UC was significantly lower than that of mild/moderate UC, and fewer unidentified bacteria phyla were observed in severe UC than in mild UC. At the genus level, the relative abundance of *Methylobacterium* in mild UC was significantly higher than that in moderate/severe UC, and *Blautia* significantly decreased in severe UC compared with the other two groups. UC: Ulcerative colitis.

significantly decreased in patients with severe UC compared with the other two subgroups.

Comparison between intestinal bacteria in patients with active UC with different disease extents or different biopsy sites

Patients with active UC with different disease extents show slight differences in bacterial α-diversity and composition: Based on the extent of colitis, patients with active UC were divided into two groups: Partial colitis (E1 and E2) and pancolitis groups (E3). The α-diversity of fecal bacteria in these groups was similar, while that of mucosal bacteria was higher in the pancolitis group. Regarding the bacterial composition in stool samples, only the relative abundance of the phylum *Fusobacteria* and its genus *Fusobacterium* was significantly higher in the stool of pancolitis patients. Regarding the mucosa sample, the relative abundance of unidentified phyla and the genus *Methylobacterium* in the "partial colitis" group was significantly lower than that in the pancolitis group (Supplementary Figures 1 and 2, and Supplementary Table 8).

Mucosa samples from inflamed and noninflamed sites have similar intestinal microbiota structures: Nineteen pairs of mucosa samples from inflamed and

noninflamed sites of one subject were collected. There was no significant difference between the microbiota of mucosa samples from the inflamed and noninflamed sites as evaluated by the α-diversity, PCA, ANOSIM, or microbiota composition at the phylum and genus levels (Supplementary Figure 3).

Analysis of fecal fungi and bacteria-fungi correlations

The α-diversity and composition of stool fungal microbiota slightly differ among groups: There was little difference between the fecal fungal microbiota of patients with UC and the non-IBD controls or among the active UC groups with different degrees of inflammation as evaluated by α-diversity, PCA, or ANOSIM. Regarding the fungal composition, only a few fungal genera differed significantly, including a higher relative abundance of *Mycosphaerella*, *Malassezia*, and/or *Suillus* in patients with active UC, more *Xeromyces* and *Yarrowia* in patients with severe active UC, and more *Rhizopus* in patients with moderate active UC (Supplementary Figures 4 and 5, and Supplementary Table 9).

The intestinal intermicrobial correlation changes in patients with UC compared with non-IBD controls: The intestinal intermicrobial correlations at the genus level in the non-IBD controls and the UC in remission and active UC groups are shown in a correlation network (Figure 6). In all of the groups, most of the bacteria-bacteria correlations existed in *Firmicutes*, the majority of the bacteria-fungi correlations occurred in *Firmicutes* and *Ascomycota*, and the *Ascomycota-Ascomycota/Basidiomycota* correlations were the major fungi-fungi correlations. Compared with the controls, the number of significant correlations increased in patients with UC in remission but decreased in patients with active UC. The most obvious change occurred in the number of bacteria-fungi correlations, while the number of fungi-fungi correlations was insignificant among the three groups.

To further investigate the change in bacteria-fungi correlations, we focused on the bacterium-fungus pairs in which at least one of the two genera had a relative abundance higher than 0.01, and the correlations with a *P* value smaller than 0.05 are shown in the heat map (Supplementary Figure 6). In the non-IBD controls, bacterial genera from nine bacterial phyla were correlated with fungal genera from four fungal phyla, while for patients with UC in remission, the number of involved bacterial phyla decreased to five, and for patients with active UC, the number of phyla was further reduced to three. In addition, the correlation intensity of the related bacterium-fungus pairs was distributed evenly among the controls, while the correlation intensity of some microbe pairs in patients with UC became prominent, indicating that the bacteria-fungi interaction became single and circumscribed in patients with UC.

DISCUSSION

In this study, the intestinal bacteria flora of patients with UC was analyzed, and three important results were acquired. First, the fecal bacteria and mucosal bacteria of patients with UC were different, and the former was characterized by a lower α-diversity, lower relative abundances of *Proteobacteria* and unidentified phyla, and higher proportions of *Bacteroidetes* and *Firmicutes*. Significant differences were also shown in 16 bacterial genera. This result agrees with a previous study showing that the sample origin (biopsy *vs* stool) is the single most influential factor on the microbial community structure in IBD patients[10]. Another study also reported fecal-specific bacterial species[11]. Bowel preparation impacted the mucosal microbiota α-diversity (mainly presented as decreased diversity) and the abundance of certain bacteria[25], which may partially contribute to the difference between biopsy and fecal samples. The vastly distinct environment for the colonization of microbes may be the principal factor.

Second, obvious distinctions were observed between the non-IBD controls and patients with UC. Notably, the intestinal bacteria in patients with UC in remission and active UC may be regarded as two dissimilar populations owing to their significantly different α-diversity and flora structure. The former was more similar to that of the non-IBD controls, as reflected by a smaller decrease in α-diversity and smaller changes in the bacterial composition. Moreover, the bacterial composition of the active and relieved UC groups even showed opposite changing patterns in some circumstances; for example, *Proteobacteria* and its genus *Escherichia-Shigella* increased in the feces of active UC but decreased in UC in remission, while *Firmicutes* and some of its members changed oppositely. Previous studies have confirmed a depletion of α-diversity in

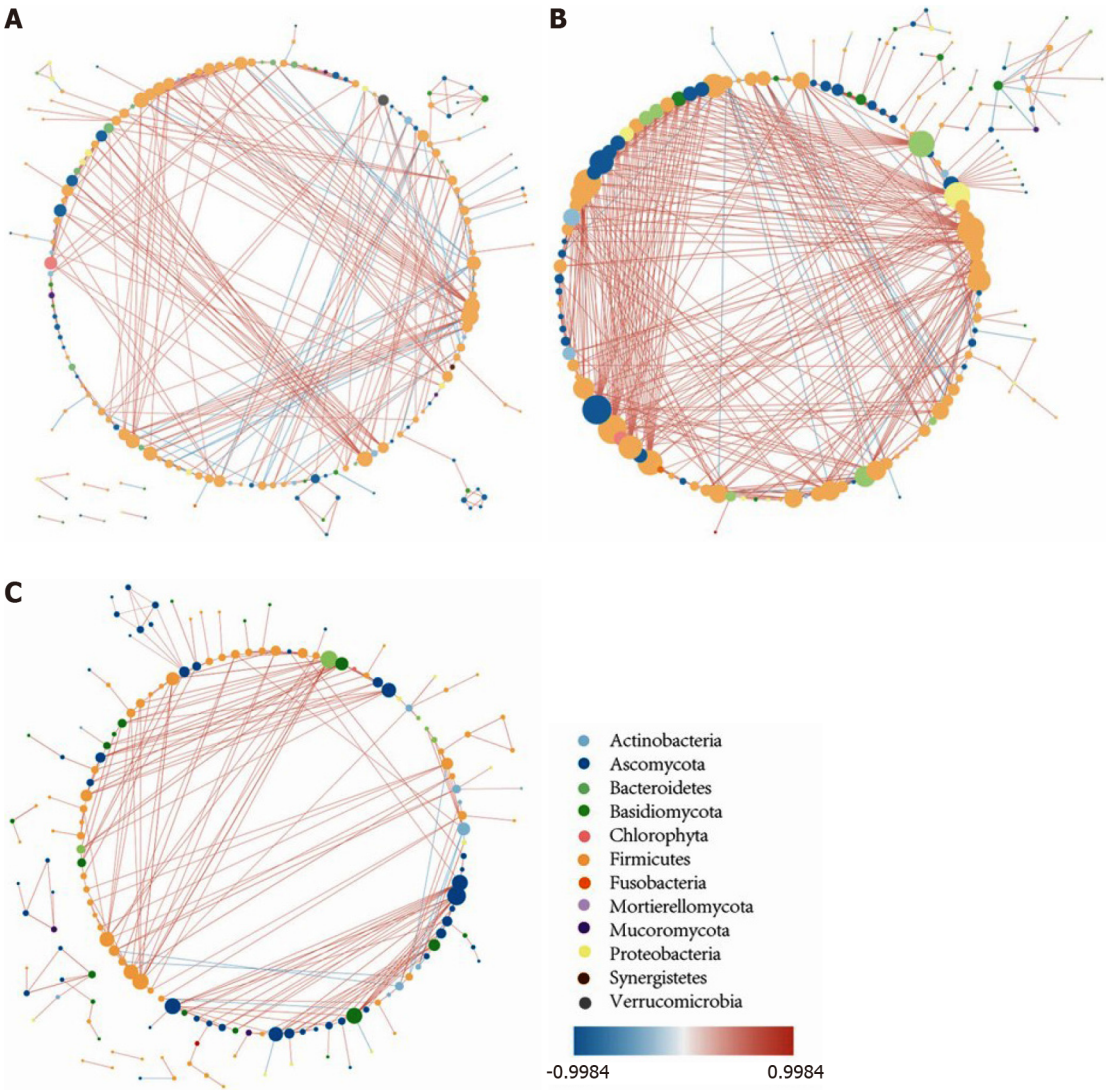

Figure 6 The intestinal microbiota correlation network. A: The intestinal microbiota correlation network of non-inflammatory bowel disease controls; B: The intestinal microbiota correlation network of ulcerative colitis (UC) in remission; C: The intestinal microbiota correlation network of active UC. The network was constructed based on Spearman correlation coefficient analysis and the software Cytoscape v3.7.0., and only the significant correlations are shown ($P < 0.05$). Each node represents one microbial genus and its color represents the phylum that it belongs to. The size of the node is equal to the number of correlated pairs that it evolves. The depth of color of the line connecting two nodes reveals the strength of the association. The red color indicates positive correlations and the blue color indicates negative correlations. Compared with controls, the number of significant correlations increased in UC in remission but decreased in active UC. The most obvious change occurred in the number of bacteria-fungi correlations, while the number of fungi-fungi correlations was insignificant among the three groups.

patients with UC, but the changes in bacterial composition were inconsistent. Some studies have reported a depletion of fecal *Firmicutes* and its members in patients with UC compared with non-IBD controls or co-habitation healthy partners[10,15,17,26,27], while others have reported opposite alterations[7]. The analysis of fecal *Bacteroids* and their members in patients with UC compared with non-IBD controls also reached different results[7,11,15,17,27]. The changes in mucosal bacteria in patients with UC are even more complicated and inconsistent than those in fecal ones[6,12,13,16]. Such confusing results may partially be attributed to the different sample sizes, ages, and races of subjects[14]; sampling biogeography; and the luminal pH values[10]. Another possible reason may be that many studies took the active and the quiescent patients with UC as a whole and analyzed them without distinction. This opinion was supported by our study as well as other studies that found different changing patterns of certain bacteria in active and quiescent UC[9,28]. Patients with UC even displayed different bacterial compositions before and after treatment, with the latter being more similar to non-IBD controls[8].

Third, the intestinal bacteria displayed a gradually decreased α-diversity and consistently changing pattern of certain bacteria when the inflammation state of active UC increased, which was represented by a gradual increase in *Proteobacteria* and *Escherichia-Shigella* and decrease in *Bacteroidetes*, *Faecalibacterium*, *Roseburia*, *Bacteroides*,

and *Eubacterium rectale group* in stool, as well as less *Methylobacterium* and *Blautia* in the mucosa. Previous studies also found that the patients with active UC with intestinal bacteria dominated by some kinds of bacteria (the members of *Proteobacteria*) exhibited more severe disease conditions than those enriched in other genera (*Blautia*, *Ruminococcus*, and other members belonging to *Firmicutes*)[17,18,29].

Despite the obvious alteration in intestinal bacteria along with the changed disease activity of UC, the bacterial composition only showed a slight or no difference when the disease type or biopsy site differed. These results agreed with most of the previous studies[11,16,19,20] except one finding that showed a significant difference between inflamed and noninflamed sites[6].

There were some commonalities among the changes of intestinal bacteria in this study. The bacteria with "protective effects" decreased while those with "deleterious effects" increased in active UC, especially in patients with moderate-severe inflammation, while in UC in remission, some of these bacteria changed in the opposite way, indicating a "correction effect" of some "protective" bacteria in recovering patients. The most representative change was the reduction of a series of genera affiliated with *Lachnospiraceae* and *Ruminococcaceae* in active UC. These are important bacteria for producing butyric acid, a substance beneficial to IBD in terms of anti-inflammation and intestinal barrier defense[30]. In addition, a decrease in the genus *Alistipes* in active UC was reported to produce bacterial sulfonolipids with potential anti-inflammatory effects[31]. Most of the genera that increased in the active UC and/or moderate-severe UC groups were opportunistic pathogens that may be harmful to gastrointestinal health. For example, *Escherichia-Shigella*[32] and *Prevotella*[33] promote inflammatory cytokine expression. In addition, *Fusobacterium*, which was more abundant in the feces of pancolitis patients, was enriched in patients with gut inflammation and was proportionally associated with colorectal cancer[34]. However, it is difficult to determine whether the change in microbiota is a cause or a consequence of UC since the bacteria depleted in patients were sometimes strictly anaerobic and failed to survive in the broken intestinal environment[30].

This study also detected fecal fungi and the intermicrobiota correlations. The diversity of fecal fungi was similar among groups, and the fungal composition only showed subtle differences at the genus level, which was in accordance with a previous study[17] but contrary to another[5]. The number of intermicrobiota correlations increased for UC in remission and decreased in active UC, with the most obvious change in the bacteria-fungi correlation, and the distribution of the correlations became uneven in patients with UC. The meaning of these results is still unclear, and more studies are needed to explore the complex changes in the intestinal fungi of IBD patients.

There were some limitations in this study. First, the sample size was insufficient, especially for the mucosa samples. Second, non-IBD controls were asymptomatic patients with colonic polyps rather than healthy people owing to ethical issues. Since the patients with colonic polyps generally had a higher onset age than patients with UC, the average ages of the controls and patients with UC were unmatched. It has been reported that age influences gut microbiota in adults, which is mainly manifested as decreases in the families of *Firmicutes* and *Bifidobacteria*, as well as an increase in *Proteobacteria* members, indicating a more proinflammatory gut microbiota phenotype in elderly people[35]. Therefore, the difference between non-IBD controls and patients with UC may be more obvious than that presented in this study. Third, many studies have implied that the gut fungal composition was significantly affected by lifestyle[36,37], but due to practical reasons, our study did not collect the information of the lifestyle in this population, which can be a confounding factor. Finally, the sequencing method in our study can only reach the genus level, and further research using the metagenomic sequencing is required to acquire more details at the species level.

CONCLUSION

Patients with active UC have a significantly different intestinal microbiota than non-IBD controls, while the difference between patients with UC in remission and non-IBD control is smaller. Disease degree of patients with active UC significantly affects the gut microbiota, and some bacteria show consistently changing patterns when the disease worsens. Some "beneficial" bacteria decrease while some "detrimental" bacteria increase in patients with active UC, especially in patients with moderate-severe inflammation. A difference was also observed in the intestinal bacteria flora collected from paired stool and mucosa samples of patients with UC. The fecal fungal

microbiota does not show evident changes compared with the controls. However, significantly different intermicrobial correlations and an unevenly distributed bacteria-fungi interaction were observed.

ARTICLE HIGHLIGHTS

Research background

The etiology of ulcerative colitis (UC) is still unclear, and dysbacteriosis may be a crucial environmental factor. Numerous studies have focused on the variations in intestinal microbiota diversity and composition of patients with UC.

Research motivation

Existing studies concerning UC and intestinal microbiota have arrived at various conclusions. A further understanding of the constitution and changes of the intestinal microbiota in patients with UC is necessary to elucidate the possible pathogenesis and investigate potential treatments.

Research objectives

To analyze the relationship between different clinical features and the intestinal microbiota, including bacteria and fungi, in Chinese patients with UC.

Research methods

Gene amplicon sequencing of 16S rRNA gene and fungal internal transcribed spacer gene was used to detect the intestinal microbiota composition. Alpha diversity, principal component analysis, similarities analysis, and Metastats analysis were employed to evaluate differences among groups.

Research results

A total of 89 patients with UC and 33 controls were enrolled. A significant difference existed between the fecal and mucosal bacteria, and the α-diversity of intestinal bacteria and the relative abundance of some families decreased with the increasing severity of bowel inflammation. More intermicrobial correlations in UC in remission than in active patients were observed, and the bacteria-fungi correlations became single and uneven in patients with UC.

Research conclusions

Patients with active UC have a significantly different intestinal microbiota in terms of various sample types and disease activities. Significantly different intermicrobial correlations and an unevenly distributed bacteria-fungi interaction were observed.

Research perspectives

There is still a need to collect subjects to expand the sample size and further include data from other parts of China. And metagenomic sequencing method may be needed for more details at the species level in future research.

ACKNOWLEDGEMENTS

We thank Dr. Tao-Tao Han for review of the statistical methods of this study.

Abstract

BACKGROUND

Adenocarcinoma originating from heterotopic pancreas tissue is a rare disease. Furthermore, to our knowledge, no HER2-positive cases in the duodenum have been reported in the scientific literature nor has the efficacy of trastuzumab treatment for the disease been reported.

CASE SUMMARY

A 65-year-old woman whose clinical diagnosis was unresectable advanced duodenal cancer with HER2 overexpression responded well to trastuzumab chemotherapy. The main tumor in the duodenum reduced drastically. The patient underwent pancreaticoduodenectomy and lymph node dissection. A small number of cancer cells remained in the submucosal layer of the duodenum and pancreas head. After histological and immunohistochemical examination, the patient was diagnosed with duodenal adenocarcinoma originating from heterotopic pancreas tissue.

CONCLUSION

Trastuzumab treatment is effective in HER2-positive adenocarcinoma originating from heterotopic pancreas tissue in the duodenum.

Core Tip: Adenocarcinoma that develops from heterotopic pancreas tissue in the duodenum is a very rare disease. Therefore, standard chemotherapy regimens to treat these patients have not been established. A 65-year-old woman presented with unresectable duodenal cancer with HER2 overexpression. Because the patient responded well to trastuzumab chemotherapy, pancreatoduodenectomy was performed. Histology and immunohistochemistry assessments revealed that the cancer developed from heterotopic pancreas tissue in the duodenum. The findings of this case suggest that HER2 status should be examined in duodenal adenocarcinoma to determine the indication for targeted therapy. Trastuzumab chemotherapy is effective for heterotopic pancreatic adenocarcinoma but not orthotopic pancreatic cancer.

INTRODUCTION

Heterotopic pancreas is a relatively rare event detected in 0.25% of gastrointestinal tract surgeries and in 0.6 to 13.7% of autopsy cases[1,2]. Malignant transformation was observed only in 0.7% to 1.8% of heterotopic pancreas cases[3,4]. In the literature, 16 reports of malignant tumors arising from duodenal heterotopic pancreas tissue were confirmed[5-7]. Some patients received chemotherapy, but information about the efficacy of the chemotherapy applied is limited. We describe the first case of HER2-positive adenocarcinoma originating from heterotopic pancreas tissue in the duodenum and the therapeutic effect of trastuzumab treatment in this patient.

CASE PRESENTATION

Chief complaints

The patient presented with epigastric discomfort that had persisted for 3 mo.

History of present illness

A 65-year-old woman complained of abdominal discomfort and had visited the hospital previously. Esophagogastroduodenoscopy revealed an advanced type 4 lesion in the pylorus of the stomach. The patient received a detailed medical examination and treatment at the current hospital.

History of past illness

The patient had an appendectomy due to acute appendicitis at the age of 15.

Personal and family history

The patient had no smoking or alcohol intake history. There was no family history of cancer.

Physical examination

The abdomen was soft and without tenderness.

Laboratory examinations

Initial laboratory data revealed a hemoglobin level of 7.2 g/dL, a white blood cell

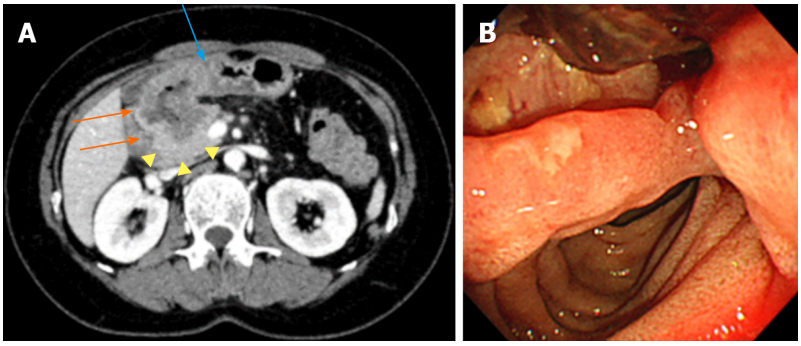

Figure 1 Abdominal computed tomography and gastroduodenoscopy. Images were obtained before the start of treatment. A: An axial image shows an irregular circumferential mass in the first portion of duodenum (orange arrows), with transmural extension to pylorus (blue arrow) and direct extension to pancreas head (yellow arrow heads); B: During gastroduodenoscopy, mass lesion with ulcer was visible in the first portion of duodenum.

count of 5700 cell/μL, and a platelet count of 3.95 × 10^5/μl. The creatinine level was 0.64 mg/dL, total bilirubin level was 0.44 mg/dL, aspartate aminotransferase level was 11 U/L, alanine aminotransferase level was 9 U/L, albumin level was 3.6 g/dL, and amylase level was 75 U/L (normal range 37 to 125 U/L). The level of the carcinoembryonic antigen tumor marker was 445.4 ng/mL, the cancer antigen 125 level was 317.3 U/mL, the squamous cell carcinoma antigen level was 4.1 ng/mL, and the carbohydrate antigen 19-9 level was less than 2 U/mL.

Imaging examinations

An abdominal computed tomography (CT) scan demonstrated wall thickening in the duodenal first portion extending toward the pylorus and pancreatic head (Figure 1A). Lymph node swelling in the common hepatic artery and in the portal vein and venous tumor thrombosis in the pancreatic head were also observed. There was no gross tumor mass in the orthotopic pancreas. The patient was referred for gastroduodenoscopy. The tumor was located in the first portion of the duodenum with ulcer formation (Figure 1B). The stomach pylorus was stenotic due to the extrinsic compression of the tumor. Histologic evaluation of the duodenum biopsy specimens revealed tubular adenocarcinoma, and HER2 overexpression was detected by immunohistochemistry (Figure 2). The clinical diagnosis of unresectable duodenal cancer was made based on cancer invasion of the pancreas and portal vein tumor thrombosis; thus, stomach bypass surgery and gastrojejunostomy were performed. Capecitabine and cisplatin plus trastuzumab chemotherapy was applied due to the potential efficacy of this treatment for HER2-overexpressing gastric cancer cells reported in the Trastuzumab for Gastric Cancer (ToGA) study. After 1 cycle of treatment, the patient developed renal impairment due to the side effects of cisplatin. The drug combination was changed to capecitabine and oxaliplatin plus trastuzumab. To assess the effects of treatment, a CT scan was performed after 2 cycles of capecitabine and oxaliplatin plus trastuzumab administration, and tumor size and lymph node swelling were dramatically reduced (Figure 3). The same chemotherapy was continued for two more cycles, and then pancreatoduodenectomy was conducted. No obvious tumor was visible in the duodenum or liver and there was no peritoneal metastasis.

Pathological examination

The histological evaluation of the biopsy specimens from the gastroduodenoscopy revealed an adenocarcinoma mass predominantly located in the duodenal submucosa (Figure 2). The cancer cells were strongly positive for HER2 membranous expression on immunohistochemical analysis (+3). On gross examination of the resected duodenum, no discrete mass lesion was visible, but a flat, slightly elevated mucosal fold was present in the first portion of the duodenum. On histological assessment, carcinoma cells were localized in the duodenal submucosal layer, forming small nodules, and in the pancreas head and pancreaticoduodenal lymph nodes (Figure 4A and B, data not shown). Heterotopic pancreas tissue was located close to the carcinoma cells within the submucosal layer and laminar muscularis mucosa of the duodenum, composed of acinar and duct structures (Figure 4C). In the immunohistochemical analysis, the cancer cells showed positive staining for cytokeratin (CK)7, CK20, MUC1 and MUC5AC and negative staining for MUC2 and CDX2 (Figure 5A-D and data not shown). Positive staining for MUC6, a specific marker for Brunner gland adenocar-

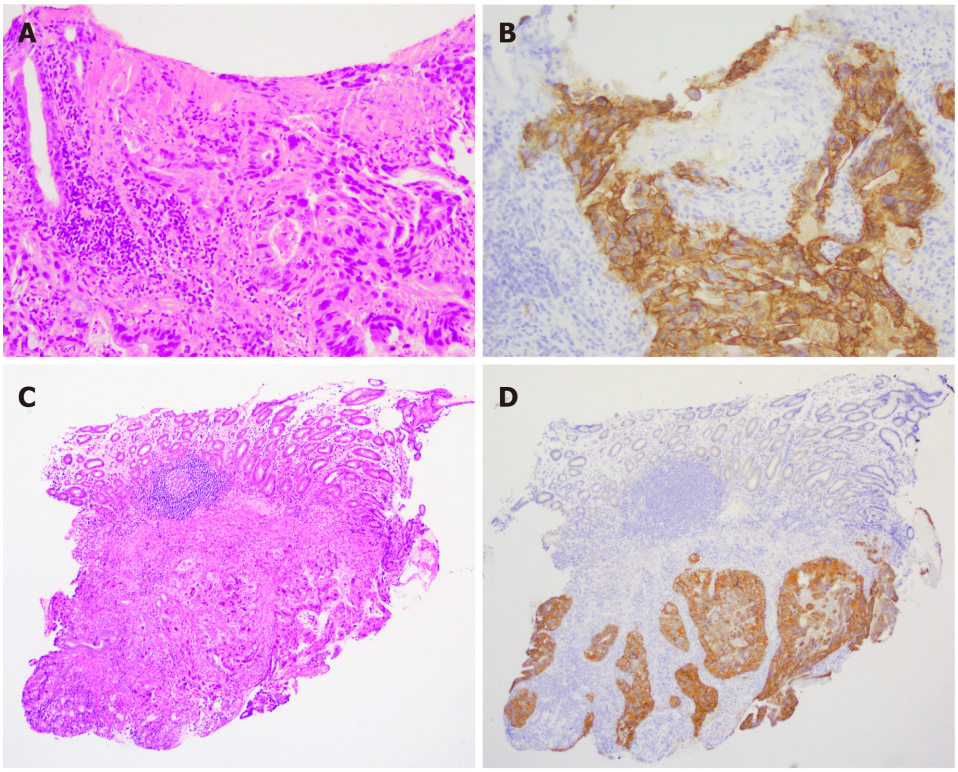

Figure 2 Histological findings of biopsy specimens from duodenal lesion. A: Adenocarcinoma cells proliferate in the proper mucosal and submucosal layer with ulcer formation (HE staining, × 200); B: Adenocarcinoma cells show strong HER2 membranous expression (× 200); C and D: Adenocarcinoma cells proliferate in the submucosal layer with strong HER2 protein expression (× 54).

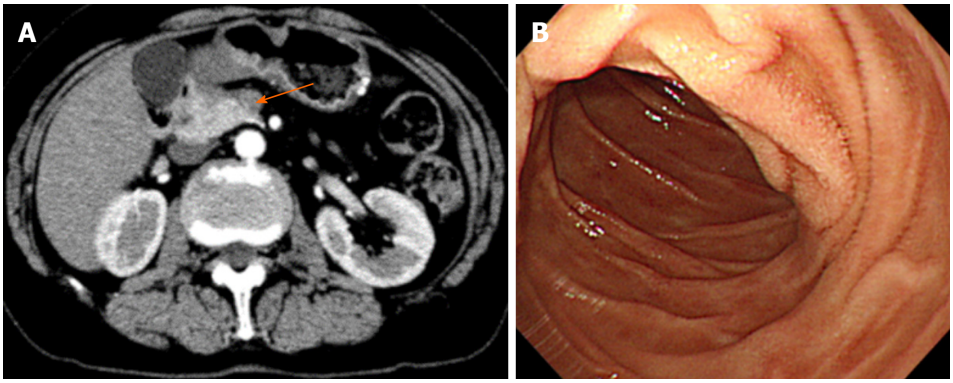

Figure 3 Abdominal computed tomography and gastroduodenoscopy. Images were obtained after 2 cycles of trastuzumab treatment. A: An axial image shows an irregular mass lesion in the pancreas head (orange arrows), duodenal and pylorus lesion are disappeared; B: During gastroduodenoscopy, mass and ulcer lesion were vanished in the first portion of duodenum.

cinoma, was positive in the Brunner glands but negative in the cancer cells (Figure 5E) [8].

FINAL DIAGNOSIS

These findings indicated that the carcinoma cells were of pancreatic duct origin[9-11] and are consistent with the diagnosis of adenocarcinoma arising from heterotopic pancreas tissue within the duodenum. The residual cancer cells were positive for HER2 on immunohistochemical analysis (Figure 5A).

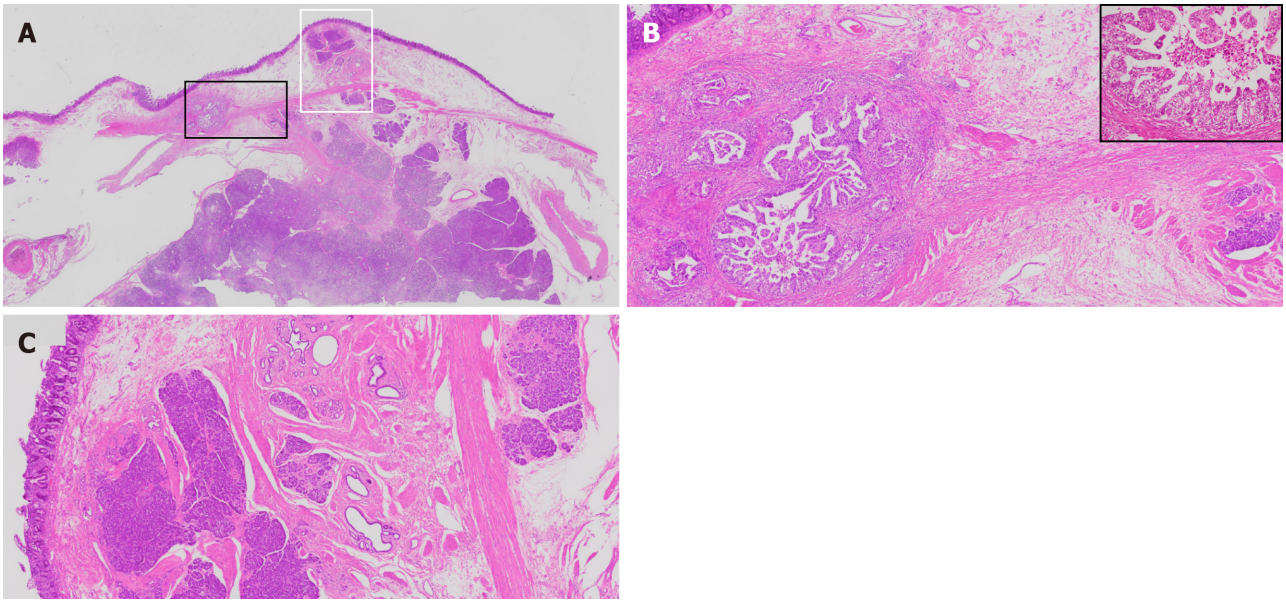

Figure 4 Histological findings of resected duodenum. A: Heterotopic pancreas tissues are located in the submucosal layer and the laminar muscularis mucosa (HE staining, x 0.08). Adenocarcinoma cells are positioned in closely to the heterotopic pancreas tissue (× 0.08); B: On magnified image of the black square in Panel A, papillary like growth of the adenocarcinoma is present in vicinity of the heterotopic pancreas tissue (HE staining, × 10 and inset × 200); C: On magnified image of the white square in Panel A, submucosal heterotopic pancreas tissue is composed of acinar and duct structure (HE staining, × 10).

TREATMENT

Various chemotherapies were given after surgery as follows: 1 cycle of capecitabine and oxaliplatin and 6 cycles of capecitabine. In the CT examination for evaluating chemotherapy, retroperitoneal lymph node enlargement, implying cancer metastasis, was revealed. Progressively, 3 cycles of paclitaxel, 4 cycles of S-1 and oxaliplatin plus trastuzumab, and 2 cycles of S-1 plus trastuzumab were administered. Thereafter, trastuzumab monoadministration was conducted. Chemotherapy-induced side effects guided the changes in drug selection.

OUTCOME AND FOLLOW-UP

Twenty-four months after the operation, the patient presented with enlarged retroperitoneal lymph nodes and was diagnosed with progressive disease according to the Evaluation Criteria in Solid Tumors. Due to the slow progression of the retroperitoneal lymph nodes, trastuzumab monoadministration was continued. When the retroperitoneal lymph nodes kept increase in size, nivolumab administration would be considered according to the gastric cancer chemotherapy regimens.

DISCUSSION

We describe a case of HER2-positive adenocarcinoma that developed in heterotopic pancreas tissue in the duodenum and outline the efficacy of HER2-targeting therapy for this disease for the first time in the English literature. Guillou *et al*[3] proposed the following three conditions for the definition of carcinoma arising from heterotopic pancreas tissue: (1) The tumor must be found within or close to the ectopic pancreatic tissue; (2) Direct transition between pancreatic structures and carcinoma must be observed; and (3) The nonneoplastic pancreatic tissue must comprise fully developed acini and ductal structures. In our case, the second condition, the transition between pancreatic structures and carcinoma, was not fulfilled completely; however, the desmoplasia of pancreatic cancer destroys the tissue architecture, making it impossible to identify the histological transition. Guillou *et al*[3]'s report included inconsistent statements; the term "close to" was used in the first condition and "direct transition" was used in the second. Furthermore, given the expanding knowledge within the field of pancreatic cancer immunohistochemistry since Gulliou *et al*[3]'s study was

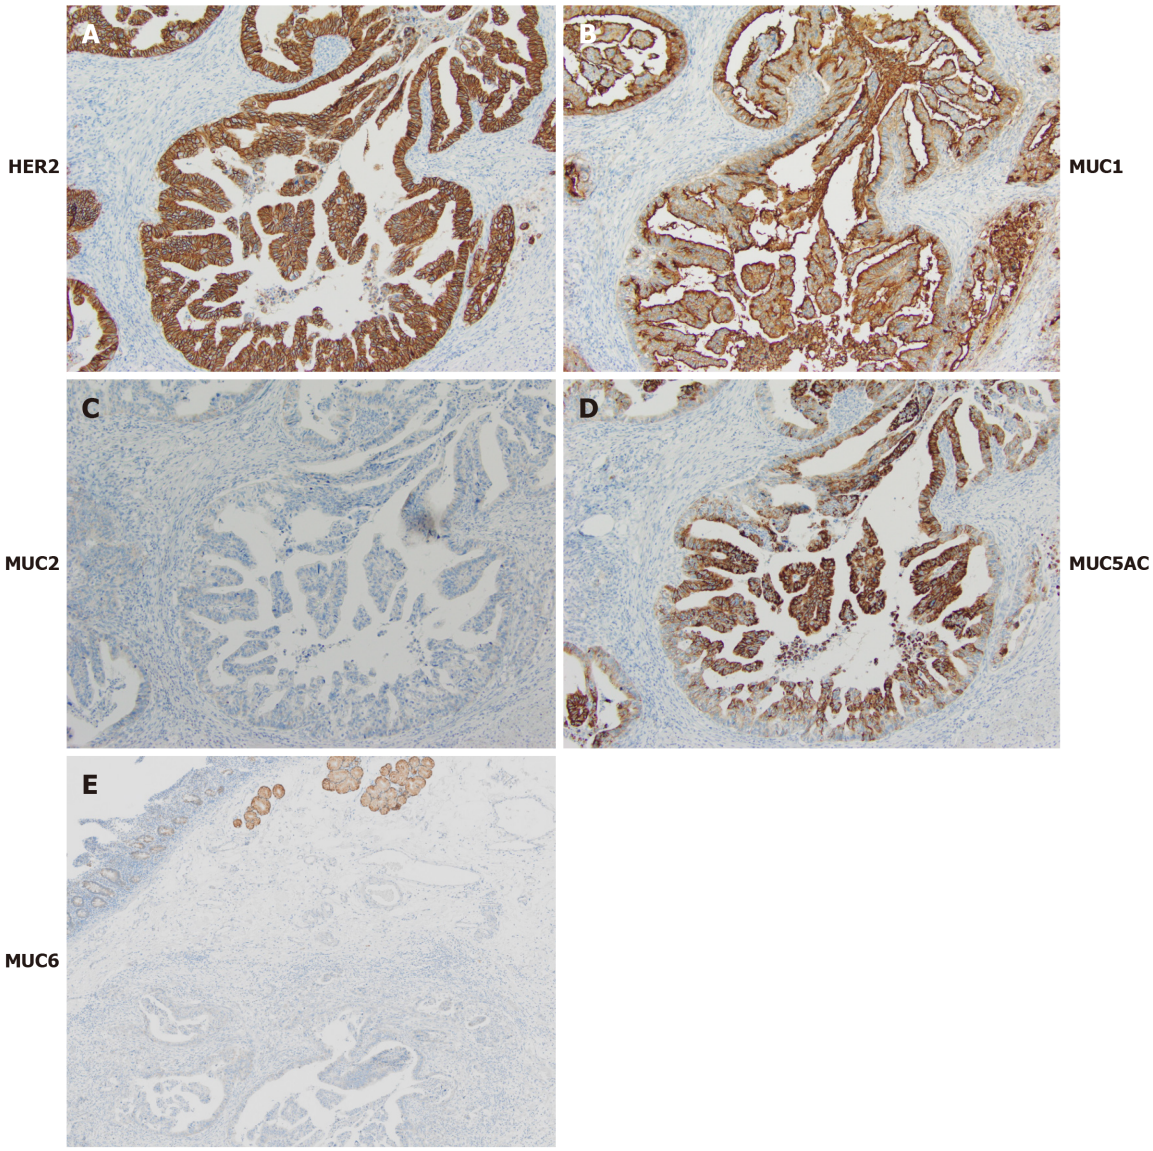

Figure 5 Immunohistochemical staining in adenocarcinoma cells in the submucosal layer. A: Strong HER2 expression is localized in the cell membrane (× 100); B-E: Adenocarcinoma cells express MUC1 and MUC5AC but no MUC2 or MUC6 protein (B-D: × 100; E: × 3.5).

published, we propose a replacement for the second Gulliou *et al*[3] criterion as follows: Direct transition between pancreatic structures and carcinoma is observed; alternatively, cancer cells express proteins indicating pancreatic origin.

Since chemotherapy against HER2-positive cancer improved the outcome of breast cancer patients, an extensive search was conducted to elucidate the incidence of HER2-expressing pancreatic cancer (ductal adenocarcinoma). The incidence of pancreatic cancer with +3 membranous HER2 protein expression ranges from 6% to 12% in the literature[12-14]. Using the same approach to investigate the use of Herceptin combined chemotherapy for metastatic pancreas cancer, Safran *et al*[13] reported modest a benefit to overall survival, but Harder *et al*[14] found no such beneficial results. Harder *et al*[14] conducted a phase II trial of trastuzumab and capecitabine, the same drug combination administered to our patient, for metastatic pancreatic cancer. The therapeutic efficacy of HER2 chemotherapy in the current case supports the theory that HER2 overexpression drives cancer progression. The mechanism of cancer cell proliferation might differ between heterotopic and orthotopic pancreatic cancer. Given that HER2 is one of the EGFR family receptors, HER2 shares the same two main downstream signaling pathways as other EGFR receptors, the RAS-MAPK and PI3K-AKT-mTOR pathways[15]. The most reliable explanation of the failure of HER2-targeted therapy is that many pancreatic cancers possess KRAS mutations, which lead to cancer cell proliferation regardless of HER2 inactivation. The cancer in the current case had no KRAS mutation, which supports the rationale for HER2-targeted chemotherapy (data not shown). However, the current case also revealed the

limitation of the therapy, since residual cancer was observed in the submucosal layer of the duodenum, lymph nodes and desmoplastic stroma in the pancreatic head. Similar to orthotopic pancreatic ductal adenocarcinoma, in the current case, the cancer cells penetrated the pancreatic parenchyma and developed a tumor microenvironment that supported cancer cell growth, invasion, and metastasis, which contribute to therapeutic resistance[16].

Trastuzumab therapy is the first-line treatment for patients with HER2-overexpressing cancer, but the mechanism of therapy resistance has not been completely established. Biological heterogeneity or clonal evolution could be the underlying mechanism. By analyzing the mechanism involved in trastuzumab resistance, targeted capture sequencing of the circulating tumor DNA (ctDNA) of advanced gastric cancer patients and a clone structure reconstruction approach were conducted[17]. Most of the gene mutation clones were concentrated in the MAPK and RAS pathways. This approach to identifying cancer gene mutations with ctDNA analysis could help to identify new targeted therapies for trastuzumab-resistant cancer patients.

CONCLUSION

HER2-positive unresectable adenocarcinoma that developed from heterotopic pancreas tissue in the duodenum was treated with trastuzumab. HER2-targeted treatment was effective for reducing the tumor volume sufficiently for surgical resection.

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Ischemic bowel disease (ISBODI) includes colon ischemia, acute mesenteric ischemia (AMI) and chronic mesenteric ischemia (CMI). Epidemiologically, colon ischemia is the most common type followed by AMI and CMI. There are various risk factors for the development of ISBODI. Abdominal pain is the common presenting symptom of each type. High clinical suspicion is essential in ordering appropriate tests. Imaging studies and colonoscopy with biopsy are the main diagnostic tests. Treatment varies from conservative measures to surgical resection and revascularization. Involvement of multidisciplinary team is essential in managing ISBODI. Although open surgery with revascularization plays an important role, recently there is an increasing interest in percutaneous endovascular treatment.

Key Words: Colon ischemia; Ischemic colitis; Acute mesenteric ischemia; Chronic mesenteric ischemia; Endovascular treatment of acute and chronic mesenteric ischemia

Core Tip: Ischemic bowel disease (ISBODI) includes a spectrum of diseases due to inadequate blood supply to the bowel wall. In this review, we will be discussing the epidemiology, risk factors, pathophysiology, clinical aspects, investigations, current management protocols and prognosis of each type of ISBODI.

INTRODUCTION

Ischemic bowel disease (ISBODI) is the most common vascular disorder of the gastrointestinal tract. ISBODI results from inadequate supply of oxygenated blood to any part of the bowel wall. ISBODI is a heterogenous group of disorders that can be divided into small intestinal ischemia or mesenteric ischemia, and large intestinal ischemia or colonic ischemia (CI) or ischemic colitis (IC). Clinically mesenteric ischemia is further classified as acute mesenteric ischemia (AMI) and chronic mesenteric ischemia (CMI). Although ISBODI is not that common in clinical practice, the morbidity and mortality can be high if this entity is not recognized and treated emergently.

ISBODI IN 2021

Epidemiology

CI is the most common entity of ISBODI. The exact epidemiology of ISBODI is not known. One study showed that the overall age-adjusted and sex-adjusted incidence of CI was about 6.1 cases *per* 100000 person-years in 1976-1980 and it increased by about 4-fold to 22.9/100000 person-years over the course of few decades (2005-2009)[1]. The prevalence of AMI is 1 in 1000 hospital admissions, whereas the prevalence of CMI is 1 in 100000 individuals[2]. The incidence of CMI is probably only 2-3 *per* 100000 persons *per* year[3]. AMI represents an uncommon cause of acute abdominal pain as the overall incidence of AMI is 0.09% to 0.2% of all acute surgical admissions[4].

Risk factors

ISBODI is commonly seen in the elderly population with mesenteric vascular atherosclerosis[5]. Other risk factors include diabetes mellitus, hypertension, coronary artery disease, peripheral artery disease, atrial fibrillation, congestive heart failure, recent myocardial infarction, shock, chronic renal failure requiring hemodialysis, severe dehydration, chronic obstructive lung disease, irritable bowel syndrome, sickle cell crisis with microvascular occlusion, rheumatic autoimmune diseases, substance abuse like amphetamine abuse or cocaine abuse, long distance running, hereditary and acquired thrombophilia[6]. Iatrogenic intestinal ischemia can occur post-surgically (abdominal aortic aneurysm surgery, colectomy, bypass surgery), due to dislodgement of intravascular devices, and secondary to use of certain medications–estrogen, digoxin, danazol, alosetron, pseudo ephedrine, vasopressin, Gold, psychotropic drugs, sumatriptan, serotoninergic agonists and anatagonists immunomodulators, laxatives and non-steroidal anti-inflammatory drugs[7,8]. Enterocolonic ischemia may also be due to systemic or infectious vasculitis, fibromuscular dysplasia, radiation and amyloidosis[9]. Colonic obstruction due to neoplasm, diverticular disease, adhesion, volvulus, intussusception, internal hernia with obstruction or fecal impaction may also contribute to CI although in most cases the precipitating cause remains unidentified. The CI usually occurs proximal to the obstruction[10].

There are several physiological factors which can make the colon more susceptible to ischemia. There is less blood flow to the colon (*per* 100 g of tissue) as compared to other parts of the gastrointestinal tract. Functional colonic motor activity further decreases colonic blood flow. The colon also depends on collateral circulation frequently. During hypotensive episodes, the colon cannot autoregulate well compared with the rest of the gastrointestinal tract[11].

Pathophysiology

It is important to have a clear knowledge of the vascular supply and venous drainage of the intestine to understand the pathophysiology of ISBODI. Small intestine and large intestine derive their blood supply mainly from the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA). Proximal part of the duodenum (up to the level of ampulla of Vater) receives its blood supply from the celiac artery (CA) *via* gastroduodenal artery (GDA) (a branch of hepatic artery) and superior pancreaticoduodenal artery (a branch of GDA)[12]. Rest of the small bowel and right two-third of the colon (up to splenic flexure) are supplied by SMA. Numerous branches arise from the SMA to supply the jeunum and ileum. These branches pass between the layers of the mesentery and form anastomotic arcades from which straight arteries called vasa recta arise to supply jejunal and ileal walls. Jejunal arterial arcades are less in number but they have long vasa recta. Ileal arterial arcades are more in number but they have short vasa recta (Figures 1 and 2)[13]. As a result, jejunum is more

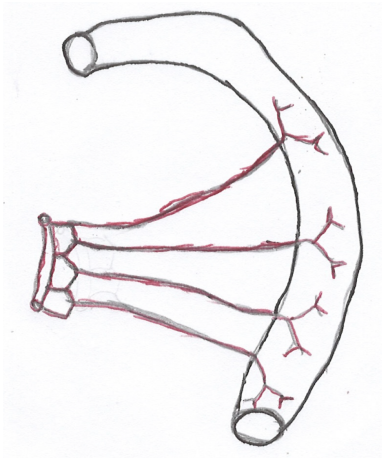

Figure 1 Jejunal arcades and long vasa recta.

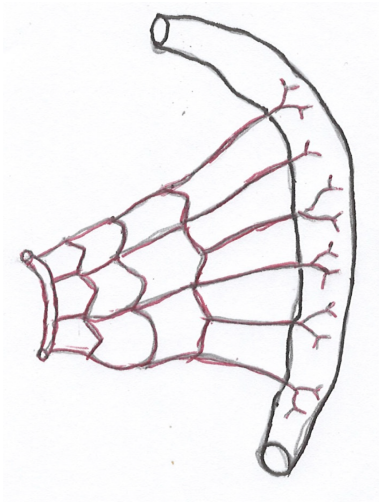

Figure 2 Ileal arcades and short vasa recta.

vulnerable to ischemic injury than ileum.

Left one-third of the colon and upper two-third of the rectum are supplied by IMA (most diminutive of 3 mesenteric arteries). Lower one third of the rectum is supplied by middle rectal artery (a branch of anterior division of internal iliac artery) and inferior rectal artery (a branch of internal pudendal artery). The transverse colon is mostly supplied by the middle colic artery which is a branch of the SMA. It may also receive blood supply from the marginal artery which is the anastomotic arcade between the left colic and right colic arteries. There are 3 watershed zones in the colon that receives blood supply from the distal branches of two large arteries. As they have the fewest vascular collaterals, they are prone to develop non-occlusive IC at the watershed zones when blood flow decreases. The watershed zones include the splenic flexure or Griffith's point, rectosigmoid region or Sudeck's point and the ileocecal region[14]. The small bowel mucosa is more sensitive to ischemia as compared to colonic mucosa but it has tremendous regenerative potential. On the other hand, colonic mucosa is less easily damaged by ischemia but once destroyed, slow recovery occurs[15].

Of 25% of resting cardiac output and 35% of post-prandial cardiac output go to the mesenteric circulation[16]. Mucosa and submucosa of the intestine receive 70% of mesenteric blood while muscularis propria and serosa receive the remainder (30%) of mesenteric blood. Mesenteric ischemia does not occur until the blood supply is reduced by more than 50%[17] or patient's mean arterial pressure does not go below 45 mmHg[18]. Significant injury to the intestine may not occur even if a 75% reduction in blood flow occurs for up to 12 h but complete occlusion of blood flow will cause bowel wall infarction within 6 h.

The venous drainage follows the arterial supply forming venae rectae and venous arcades so that duodenal venous drainage occurs *via* the splenic vein or superior mesenteric vein (SMV); jejunal, ileal and proximal (two-third) colonic venous drainage occurs *via* SMV, and distal (one-third) colonic venous drainage occurs *via* inferior mesenteric vein. Ultimately, these veins drain into the portal vein[19]. Atherosclerosis, thromboembolism, hypoperfusion (as a result of arrhythmia, heart failure, shock), hypercoagulable state, vasculitis, venous occlusion or any mechanical obstruction to the mesenteric blood vessels may to lead to ISBODI[20]. In most cases of SMA embolism, duodenum, proximal jejunum and transverse colon get spared as emboli lodge 6 to 8 cm beyond its origin, often beyond the origin of middle colic artery. Emboli lodge into the SMA more easily possibly because of its large diameter and its origin from the aorta at an acute angle[21]. On the other hand, SMA thrombosis generally occurs at the origin of SMA at the site of severe atherosclerotic narrowing [22]. Proximal colon may become ischemic because of involvement of ileocolic artery. Mesenteric venous thrombosis (MVT) generally involves the SMV but inferior mesenteric veinous (IMV) thrombosis can occur in up to 11% of all cases of MVT[23]. Venous thrombosis leads to intestinal edema and increased vascular resistance leading to bowel ischemia. Non-occlusive mesenteric ischemia (NOMI) results from mesenteric vasoconstriction associated systemic hypotension and low flow state in the splanchnic circulation. NOMI can cause small bowel as well as proximal CI and necrosis because of involvement of ileocolic artery.

AMI occurs due to sudden decrease in blood flow to varying portion of the small intestine and/or colon. The ischemic process can be severe enough to cause instant bowel wall infarction. The main mechanism of ischemic injury is hypoxia and cellular acidosis due to local accumulation of lactic acid and other cellular metabolic by-products secondary to anerobic glycolysis. Complete ischemia may result in infarction of the bowel wall supplied by the blood vessel whereas relative ischemia generally causes cellular dysfunction[24]. If the vascular obstruction is relieved soon after ischemic injury, reversibly injured cells may recover but if reperfusion occurs late, irreversibly damaged cells may not recover and this may lead to inflammation and bleeding due to release of reactive oxygen species and endothelial damage that occurred during the ischemic period. The restored blood flow to the ischemic area can cause further tissue damage called reperfusion injury as the white blood cells (WBC) in the blood release free radicals and interleukins; oxygen delivery to the ischemic tissue damages plasma membrane, DNA and cellular protein; and plasma membrane injury may release more free radicals. WBC can cause further ischemia if they bind to the endothelial cells of capillaries[25]. The pathophysiological process correlates well with the clinical scenario. In the first phase, patient feels abdominal pain because of bowel ischemia and hyperperistalsis. In the second phase (after 3 to 6 h), patient feels better as the intestine becomes aperistaltic and the intramural pain receptors become damaged by ischemia. In the third phase, mucosal necrosis occurs followed by infarction of the bowel wall. Bacterial translocation leads to gangrene of the intestine, diffuse peritonitis, sepsis and multi-organ failure[26].

CI can cause reversible damage or irreversible damage[27]. Reversible damage occurs in 50% of cases and this includes: (1) Reversible ischemic colopathy due to submucosal or intramural hemorrhage in two-third of cases; and (2) Transient segmental IC in one-third of cases. Irreversible damage may cause chronic ulcerative IC in 20%-25% of cases, ischemic colonic stricture in 10%-15% of cases, colonic gangrene in about 15% of cases, and fulminant universal colitis or pancolitis in only 1% of cases[28]. Old age, long duration of subjective symptoms and prolonged Laboratory (Lab) abnormalities (elevated white blood cell count or erythrocyte sedimentation rate) may predict the development of chronic ulcerative IC or ischemic colonic stricture. 85% of cases of CI are non-gangrenous, transient and self-limiting [29]. In 95% of cases, CI occurs due to sudden but transient reduction in blood flow to the colon due to non-occlusive causes and as a result, the watershed zones are affected [30]. Most of the time, the cause of non-occlusive ischemia remains unidentified and it is thought to be due to localized non-occlusive ischemia secondary to small-vessel disease (Type I disease). Rarely, episodes of non-occlusive ischemia secondary to systemic hypotension are identified (Type II disease). Occlusive ischemia due to atheromatous emboli or vasculitis affects short segment of the colon. CI can affect any part of the colon but the left colon is involved in two-third of cases[31]. Segmental involvement of the colon is commonly observed, particularly the splenic flexure, the descending colon and the sigmoid colon are the commonest sites of involvement. Isolated right colon ischemia can occur in about 10% of cases. Right colonic involvement generally occurs in patients with chronic renal failure requiring hemodialysis and is associated with severe IC[32].

Ischemic injury first occurs in the colon mucosa and it is most commonly seen on the antimesenteric side. Subsequently the ischemic changes may extend to the outer layers of the colon wall.

CMI occurs as a result of gradual decrease in blood flow to the intestine. As a result, numerous collaterals develop in the mesenteric circulation[33]. CMI is almost always associated with athererosclerosis. Although the prevalence of asymptomatic chronic stenotic mesenteric disease varied from 3% (below the age of 65 years) to 18% (above the age of 65 years) on doppler sonography in some studies[34], the incidence of CMI is low as mentioned before. Asymptomatic single vessel disease is more common in CA (81%) than in the SMA (19%). Generally, two out of the three major blood vessels (CA, SMA and IMA) need to be stenotic to produce ischemic symptoms. But patients may develop symptoms even with single vessel involvement[35] and many patients with two vessel disease may remain asymptomatic for many years because of extensive collaterals in the mesenteric circulation[36]. The most common cause of single vessel involvement is CA compression syndrome or median arcuate ligament syndrome where eccentric compression of the CA and/or celiac ganglion occurs by the median arcuate ligament and diaphragmatic crura[37]. The pancreaticoduodenal artery arcades, GDA, dorsal pancreatic artery and occasionally the arc of Buhler (embryonic anastomotic branch between 10th and 13th ventral segmental arteries) are the most common collaterals between the CA and the SMA[38]. On the other hand, the marginal artery of Drummond (anastomosis between the terminal branches SMA and IMA forming a continuous arterial arcade along the inner border of the colon) and arc of Riolan/meandering mesenteric artery (arterioarterial anastomosis between the middle colic branch of SMA and left colic branch of IMA running close to the root of the mesentery) are the most common collaterals between the SMA and IMA[39]. The exact association of severity of mesenteric arterial stenosis with collaterals formation and symptom development is not known.

Chronic NOMI is another entity found in 13% to 16% of all patients with CMI[40]. Its clinical presentation is similar to chronic occlusive mesenteric ischemia but vascular occlusion is not identified. The exact etiology is not known but possible pathophysiological mechanisms include vasospasm, micro-embolisms, shunting, cardiac or pulmonary insufficiency and autonomic dysfunction.

Clinical aspects

AMI is a life threatening potentially fatal abdominal and vascular emergency due to diminished blood flow in the superior mesenteric blood vessels. Patients are generally above the age of 60 and women are 3 times more commonly affected as compared to men. Although the clinical presentation is similar, the etiology could be occlusive or non-occlusive ischemia. SMA embolism is the most common cause (40%-50%) followed by SMA thrombosis (15%-25%) followed by MVT (5%-15%)[41]. NOMI occurs in about 5 to 15% of cases AMI[42].

Patients generally present with sudden onset of severe sharp abdominal pain that is generally accompanied by nausea and vomiting. The pain is out proportion to physical signs. In the early phase, abdomen is generally soft and non-tender but auscultation may reveal hyperactive bowel sound. Tenderness to palpation occurs when the entire bowel wall becomes ischemic. In late phase (within 12 h of onset) rebound tenderness (Blumberg's sign), rigidity and guarding indicate bowel wall infarction. At this stage, bowel sounds become hypoactive or absent, patient develops bloody diarrhea, fever and shock.

High degree of clinical suspicion is necessary to establish the diagnosis of AMI. A focused history is important to evaluate the underlying pathophysiology of AMI. Patients with atrial fibrillation, valvular heart disease, congestive heart failure, recent myocardial infarction and bacterial endocarditis are at increased risk of mesenteric embolism. About 50% of patients with embolic AMI have atrial fibrillation. Prior history of embolism is present in about one third of patients of embolic AMI[43]. The clinical triad of (1) Severe abdominal pain out of proportion to physical signs; (2) Spontaneous bowel movement (vomiting and/or non-bloody or bloody diarrhea); and (3) Obvious source of emboli such as atrial fibrillation or recent myocardial infarction may be present in 40% to 80% cases of SMA embolism[44]. History of chronic abdominal pain in the postprandial period, progressive weight loss and vascular procedures in the mesenteric arteries may be present in patients with mesenteric arterial thrombosis. Chronic and progressive symptoms appear in mesenteric arterial thrombosis is because of preexisting atherosclerosis plaque affecting mesenteric artery is the most common finding. NOMI should be considered in patients with hypotension and generalized (diffuse) abdominal pain. As NOMI generally occurs in critically ill patients on ventilator, the presentation can be silent. Gastrointestinal bleeding or

unexplained abdominal distention can be the only presentation of NOMI. MVT is suspected when patients with thrombophilia (hereditary or acquired) or coagulopathy present with abdominal pain (84% of cases), diarrhea (42% of cases), nausea/vomiting (33% of cases) or gastrointestinal bleeding (10% of cases)[45]. The author finds these clinical suspicions very useful in categorizing the pathophysiologic form of AMI that can guide the investigation and therapy.

CI is mostly a benign and self-limiting disease in most of the time although a minority of cases can be severe. Most of the patients with non-iatrogenic causes are older than 60 years old with a slight female predilection. Rarely, IC can also occur in young individuals due to substance abuse, vasculitis, long distance running, thrombophilia, sickle cell crisis with microvascular occlusion, irritable bowel syndrome and iatrogenic causes as mentioned before. Chronic constipation and prior history of abdominal surgery are common in both young and old patients with CI[46]. One study found that 6.8% of patients had a recurrence of CI with a mean follow-up of 4.5 years [47]. The recurrence is more common in patients with hereditary thrombophilia (deficiencies of protein C, protein S, antithrombin III, and factor V Leiden mutation), anti-phospholipid syndrome, active smoking, abdominal aortic aneurysm, coronary artery disease and elevated serum creatinine[48,49].

Patients with CI generally present with sudden onset of mild to moderate cramping pain over left lower quadrant of the abdomen or hypogastrium, and urgency to defecate followed by hematochezia within 24 h. The bleeding is not severe enough to require blood transfusion. Patients with right colon ischemia usually present with hypogastric pain rather than hematochezia[50]. Physical examination may reveal mild to moderate tenderness over the left lower quadrant or over the involved segment. The usual course of the disease is benign in non-gangrenous and non-fulminant CI. Patients feel better with resolution of abdominal pain and hematochezia in few days time. Persistent symptoms more than few days may indicate development of chronic CI *i.e.* chronic ulcerative IC or ischemic colonic stricture. Gangrenous colitis or fulminant pancolitis is generally recognized by marked abdominal tenderness, rebound tenderness, hypotension or shock. Absence of hematochezia and development of hypoalbuminemia may predict the development of gangrenous changes of CI[51].

CMI also called abdominal angina or intestinal angina or migraine abdominale is mostly seen in patients older than 60 years of old and is 3 times more common in females than in males[52]. Patients generally present with the triad of sharp post-prandial epigastric or mid-abdominal pain, sitophobia (fear of eating food) and chronic weight loss[53]. Patient starts feeling abdominal pain 15 to 30 min after a meal and the pain lasts for about half an hour to 2 h[54]. As the diseases progress, abdominal pain becomes dull-aching and chronic. Patients may also develop nausea, vomiting, diarrhea or constipation[55]. Physical examination may reveal abdominal bruit. But only 16% to 22% of patients with CMI have the classic triad of post-prandial abdominal pain, weight loss and abdominal bruit[56].

Investigations

AMI–At the present time, there is no specific Lab test which can identify AMI. But evidence of hemoconcentration, elevated white cell count, high anion gap lactic acidosis and positive D dimer test (fibrinolytic marker) in the presence severe abdominal pain disproportionate to physical sign may indicate AMI. Leucocytosis is the most common Lab finding seen in > 90% patients with AMI followed by lactic acidosis seen in 88% of cases of AMI[57]. But as the liver can metabolize large amount of L-lactic acid from the porto-mesenteric circulation and lactic acidosis can occur in dehydrated patients, it cannot reliably differentiate intestinal ischemia from infarction in the absence of appropriate clinical scenario. D-dimer can be considered as an exclusion test as in one study no patient with normal D-dimer had AMI[58]. Hyperamylasemia, hyperkalemia and hyperphosphatemia can occur when mesenteric ischemia progresses to mesenteric infarction[59,60]. Intestinal fatty acid binding protein (I-FABP) is a small, cytoplasmic, water soluble protein found abundantly in the epithelial cells of the small intestine. D-lactate has exclusive intestinal source and is produced by colonic bacterial metabolism. Glutathione S-transferase (GST) is a cytoplasmic enzyme and its alpha isoenzyme (alpha-GST) is almost exclusively located in the small intestine and liver. When binding of transition metals (copper, cobalt and nickel) to the N-terminal of Albumin is reduced in hypoxia or acidosis, it is called ischemia modified albumin (IMAL). I-FABP, D-lactate, alpha-GST and IMAL have been shown to be elevated in early AMI[61-63] but at the present time they are not being used in our clinical practice.

As neither symptoms nor Lab tests are specific for the diagnosis of AMI, imaging plays an important role. The recommended first line imaging study for the diagnosis of AMI is computed tomography angiography (CTA) or biphasic multidetector computed tomography of the abdomen and pelvis with IV contrast[64]. CTA is not only rapid, non-invasive, easily available and highly accurate (sensitivity 89%, specificity 99%) in diagnosing mesenteric ischemia but also helpful in detecting the underlying etiology of ischemia[65]. CTA can evaluate the bowel wall, vascular abnormalities and surrounding viscera. CTA may show bowel wall thickening, bowel wall hypoenhancement, intramural hemorrhage, fluid-filled dilated bowel loops, arterial or venous thrombus, decreased filling, narrowing, irregularity, spasm or engorgement of mesenteric vessels, pneumatosis intestinalis, portomesenteric venous gas, or infarction of other viscera[66]. Some of the findings may give a clue to the underlying cause of ischemia: Hypoenhanced bowel wall generally suggests arterial occlusion, bowel wall thickening may indicate MVT and patent SMA with diffuse narrowing of its branches (string of sausages sign) is seen in NOMI[67]. Considering serious and lethal consequences of missed diagnosis of AMI, CTA with intravenous contrast material should be done as soon as possible in patients with suspected AMI irrespective of renal function[68]. Traditional mesenteric angiogram or catheter-based angiogram is the gold standard considering its diagnostic and therapeutic potential but considering its invasiveness, expense and lack of wide availability it is now considered as the 2nd line modality in the evaluation of AMI[69].

Plain X-ray and ultrasound of abdomen have limited role in diagnosing AMI[70]. But plain X-ray abdomen may show free intraperitoneal air if bowel infarction and perforation occur. Mesenteric vessel duplex ultrasound scan (DUS) is useful in the evaluation of AMI. One multicenter study showed that DUS done at the Emergency Department can be helpful (sensitivity 100%, specificity 64%, negative predictive value 100%) in diagnosing and excluding occlusive AMI[71]. DUS is also very helpful in direct evaluation of MVT in the setting of AMI. Although it is specific and can be done at the bedside, it is not as sensitive as CTA or MRA[72]. DUS has also certain limitations that it is operator dependent, not useful in presence of dilated bowel with gas, cannot detect thrombus or embolus beyond the major vessels, and it cannot identify NOMI.

Contrast enhanced MRA is an excellent radiation-free non-invasive test with a sensitivity of 100% and a specificity of 91% in diagnosing AMI. But it is not considered as a practical test in diagnosing AMI considering its long time to do the test and high expense.

Once the diagnosis of MVT is made on imaging, the underlying cause of MVT should be investigated particularly for congenital or acquired thrombophilia. Patients should be evaluated for protein C, protein S and anti-thrombin III deficiency, factor V Leiden mutation, myeloproliferative disorders, homocystinuria, paroxysmal nocturnal hemoglobinuria as well as inflammatory bowel disease when more stable.

CI: There is no Lab test diagnostic of CI. Complete blood count, complete metabolic profile, serum lactate, lactate dehydrogenase (LDH), creatinine phosphokinase (CPK), amylase and coagulation studies are helpful assessing the severity of CI. Low hemoglobin may indicate the amount of colonic blood loss. Leucocytosis, lactic acidosis, hypoalbuminemia, elevated LDH, CPK and amylase may suggest colonic infarction[73]. Plain X-ray abdomen is normal in most of the time but rarely it may show 'thumbprinting' due to submucosal edema/hemorrhage, pneumatosis linearis due to necrosis of the colon wall, portal venous gas, colonic ileus or pneumoperitoneum due to perforation[74]. CT abdomen and pelvis with oral and intravenous contrast is the imaging study of choice to evaluate CI[75]. But as patients with right-sided CI (RSCI) can have large visceral artery occlusion, CTA should be done in case of suspected RSCI or when the diagnosis of AMI needs to be ruled out[76].

Colonoscopy with biopsy within 48 h is the next step to conform the diagnosis of CI. In non-gangrenous IC, colonoscopy may show a highly specific sign like a single linear ulcer running longitudinally along the antimesenteric colonic wall (colon single-strap sign) or non-specific signs like segmental erythema, fragile and edematous colon mucosa, scattered hemorrhagic erosions, scattered petechial hemorrhages with pale areas, bluish hemorrhagic nodules due to submucosal hemorrhage and sometimes mass-like lesions mimicking malignancy[77,78]. In gangrenous IC, colon mucosa will appear as black or gray-green. Histology is nonspecific most of the time. It may show focal crypt drop out, lamina propria and submucosal hemorrhage and edema, hemosiderin laden macrophages in the submucosa, fibrin thrombi in capillaries with infiltration of neutrophils, erosion and granulation tissue hyperplasia[79]. Necrosis and ghost cells *i.e.* preserved cellular outlines with empty cell contents are pathog-

nomonic but infrequently seen. Epithelial loss, presence of acute and chronic inflammatory cells and submucosal congestion can be seen in advanced ischemia.

CMI: Lab tests are generally non-specific but may show anemia, leukopenia, lymphopenia and hypoalbuminemia indicating underlying malnutrition due to CMI. There are various imaging studies available to diagnose CMI. According to American College of Radiology, CTA should be the first-line test to evaluate CMI[80]. Gadolonium-enhanced MRA is highly sensitive in detecting stenosis at the origin of CA, SMA and IMA. One disadvantage of MRA is that it may not be able to evaluate the IMA well[81]. Duplex ultrasound is cost-effective and may play an important role in the diagnosis of CMI. Fasting peak systolic velocity ≥ 275 cm/s in the SMA and ≥ 200 cm/s in the CA can reliably (sensitivity and specificity around 90%) indicate ≥ 70% stenosis[82]. But the study is time consuming and can be unsatisfactory due to bowel gas, obesity, body habitus, complex anatomy, post-operative changes and operator dependency[83]. Catheter-based angiography had been the gold standard for diagnosing CMI for many years[84]. Now-a-days it is done mainly for therapeutic intervention and also for diagnostic confirmation when the results of other imaging modalities are inconclusive.

Management

The main goal of managing AMI is not only prompt diagnosis but also resuscitation of the patient and revascularization of the bowel before irreversible damage occurs. As soon as AMI is suspected, the patient should be given supplemental oxygen and adequate hydration with crystalloid infusion (up to 100 mL/kg) to restore tissue perfusion. Hemodynamic monitoring including mental status and urine output should be done[85]. If the patient still remains hypotensive despite adequate fluid resuscitation, vasopressor pressor agents should be considered. But catecholamines should be avoided as they decrease splanchnic blood flow. Vasopressor agent like dobutamine, low dose dopamine or milrinone can be used to maintain blood pressure as they have less vasoconstrictive effect on mesenteric vessels. Many patients with atrial fibrillation/flutter will need medications to control the ventricular rate. In those cases, medications other than cardiac glycosides should be used as they can also reduce splanchnic blood flow. Any acid-base and electrolyte abnormalities (metabolic acidosis, hyperkalemia) should be corrected. Nasogastric tube should be placed for decompression. Broad spectrum antibiotics and heparin infusion should be started. Both general surgery and vascular surgery teams should be consulted and after resuscitation, laparotomy should be done promptly if the patient has signs of peritonitis (rebound tenderness) indicating bowel infarction. During laparotomy, the whole bowel should be inspected carefully and only the clearly defined infarcted bowel should be resected. According to Bulkley *et al*[86], signs of intestinal viability include normal looking bowl wall without bleeding, pulsatile artery and stimulation of intestinal peristalsis by mechanical factors or heat[86]. If there is any suspicion, intraoperative Doppler ultrasound should be done to find out the presence of Doppler flow over the distal branches of SMA in order to preserve all the viable bowels. Potentially viable bowel should be inspected for 30 min after revascularization. Revascularization technique depends on the underlying pathophysiologic form. In case of SMA embolism, a standard embolectomy is performed by doing a tranverse arteriotomy after clamping the SMA proximal and distal to the embolus[87]. The arteriotomy site is then closed with nonabsorbable interrupted sutures. In case of SMA thrombosis, a longitudinal arteriotomy is done followed by revascularization either by thromboendartectomy with a Fogarty catheter[88] or a bypass procedure. After thromboendartectomy, heparinized saline is used to flush the artery. If thromboartectomy restores blood flow, then the longitudinal arteriotomy is closed in a standard fashion or by patch angioplasty. Retrograde bypass from the iliac artery to the distal SMA using a synthetic graft or a femoral venous graft can also be considered. About 24 to 48 h after restoration of mesenteric blood flow, a second-look laparotomy or laparoscopy should be done to evaluate potentially viable bowel. Assessment can be done by inspection and palpation of the bowel and mesenteric vessels, Doppler ultrasound examination or intraoperative fluorescein administration[89]. Second-look surgery *i.e.* damage control surgery allows identification of necrotic bowel before perforation and contamination occurs, resection of any necrotic bowel, preservation of viable bowel preventing short bowel syndrome and primary anastomosis of viable parts of the bowel.

Over the last 15 years there has been tremendous interest in minimally invasive endovascular treatment of embolic or thrombotic AMI. This should be considered when there is no clinical, serological or imaging evidence of necrosis or infarction of

the bowel wall. Endovascular treatment involves less surgical trauma and less intensive unit care in the elderly patients with multiple comorbidities as compared to open surgical procedures. The endovascular interventions include endovascular embolectomy by transcutaneous mechanical aspiration, percutaneous aspiration thrombectomy, intraarterial pharmacological thrombolysis with infusion of urokinase for 2 to 12 h, and percutaneous transluminal angioplasty with or without stenting[90-93]. Intraarterial infusion of papaverine (30 to 60 mg/dL) is also considered when there is evidence of vasospasm in embolic or thrombotic AMI and the infusion is generally continued for 24 h. Intraarterial bolus followed by infusion of heparin is continued throughout the procedure. But heparin infusion should not be mixed with papaverine (a phosphodiesterase inhibitor) because of the risk of precipitation. After endovascular treatment, patient should receive low molecular weight heparin for 5 d and then anticoagulation should be continued with warfarin. In patients with stenting, in-stent restenosis and high symptom recurrence have been reported. So, if no contraindication exists, patients should be instructed to take daily antiplatelet indefinitely. Although the technical success rate of endovascular treatment in acute arterial mesenteric ischemia can be as high as 100%, intestinal necrosis can occur following the treatment requiring laparotomy and intestinal resection[94]. Other potential complications of endovascular treatment include vascular access-related bleeding, hematoma or pseudoaneurysm formation, and trauma to the vessels leading to arterial dissection or atheroembolization. One study compared endovascular treatment with open surgical treatment. Endovascular treatment group needed less laparotomy (33.3% *vs* 58.3%), had significantly shorter length of bowel resection (88 ± 44 cm *vs* 253 ± 103 cm) and less mortality (16.7% *vs* 33.3%)[95]. A completion angiogram is necessary following endovascular treatment to assess revascularization [96]. Revascularization is required in more than 70% of patients with occlusive AMI while bowel resection alone can be life saving in 30% of patients with occlusive AMI [97]. Hybrid technique (*i.e.* combination of endovascular surgery and open vascular surgery) is also widely used in the treatment of occlusive AMI. Intra-arterial catheter-directed thrombolysis following SMA recanalization by intraoperative retrograde balloon angioplasty, retrograde open mesenteric stenting or open embolectomy during laparotomy has been found to prevent necrosis of ischemic bowel and decrease the occurrence of short bowel syndrome[98].

The main principle of management of NOMI is reversal of mesenteric arterial spasm and restoration of mesenteric blood flow as fast as possible[99]. As soon as the diagnosis of NOMI is made by CTA, patients with NOMI should be resuscitated. The precipitating factors should be addressed to improve mesenteric perfusion. Measures should be taken to correct hypovolumia and hypotension, improve cardiac function in congestive heart failure, treat cardiac arrhythmias, correct metabolic acidosis, initiate broad-spectrum antibiotics, and place a nasogastric tube for gastric decompression. The next step of management depends on the stage of mesenteric ischemia. If the patient has developed signs of bowel infarction, surgical intervention should be done to resect the infarcted bowel and second look surgery should be done to save as much bowel as possible[100]. If there is no sign of bowel infarction, prompt catheter-based mesenteric arteriogram should be done to start continuous intra-arterial vasodilator infusion (papaverine 30-60 mg/h, prostaglandin PGE1 alprostadil 20 mcg bolus followed by infusion 60-80 mcg/24 h) for about 48 h by placing the catheter into the proximal SMA[101]. Frequently arterial vasospasm responds to this direct vasodilator treatment and occasionally within minutes[102]. One study showed that the shorter the time from CTA to direct vasodilator infusion, the better the chance of survival [103].

Treatment of MVT again depends on the presence or absence of bowel infarction. In the absence of bowel infarction, the main stay of treatment is anticoagulation with continuous heparin infusion which has been shown to cause frequent recanalization with better outcome[104]. Systemic thrombolysis with recombinant tissue–type plasminogen activator or transcatheter thrombolysis with urokinase can also be an initial effective treatment for acute superior MVT[105,106]. Anticoagulation with warfarin or direct oral anticoagulants (DOAC) should be continued for 3 to 6 mo in case of reversible causes, and for indefinite period in case of irreversible causes[107]. Patients with bowel infarction should have emergency surgery with resection of the infarcted bowel followed by second look surgery. Transjugular intrahepatic portosystemic shunt can be placed in case of extensive MVT to reduce the portal pressure and to increase the effectiveness of thrombolytic therapy[108].

CI is managed by supportive care in most of the cases in clinical practice. But risk stratification is extremely important in deciding whether supportive care only or surgical intervention is needed. Broadly, CI can be classified as non-gangrenous and

gangrenous forms. But CI can also be classified as mild, moderate and severe disease depending on the presence or absence of certain risk factors associated with poor outcome as proposed by the American College of Gastroenterology (ACG) in 2015 [109]. The risk factors include: (1) Male sex; (2) Abdominal pain without rectal bleeding; (3) Tachycardia (heart rate > 100/min); (4) Hypotension (systolic blood pressure < 90 mmHg); (5) Leukocytosis (white blood cell count > 15000/cmm; (6) Anemia (hemoglobin < 12 gm/dL); hyponatremia (< 136 meq/L); (7) Azotemia (blood urea nitrogen > 20 mg/dL; and (8) High serum LDH level (> 350 units/L). Mild CI: No risk factor associated with poor outcome. Moderate CI: Up to 3 risk factors associated with poor outcome. Severe CI: More than 3 risk factors associated with poor outcome or any of the following: (1) Signs of peritonitis on physical examination; (2) Pneumoperitoneum, portal venous gas or pneumatosis on imaging; or (3) Gangrenous colitis on colonoscopy.

Patients with mild to moderate CI should be managed conservatively with bowel rest, intravenous fluid infusion to improve colonic perfusion and nasogastric tube placement if there is ileus. Any precipitating condition like hypotension or cardiac arrhythmia should be treated. Offending medications like mesenteric vasospastic drugs should be discontinued immediately. Most of the patients with mild to moderate CI improve symptomatically in one to two days and recover completely in one to two weeks[110]. But if the patients continue to have symptoms (abdominal pain, hematochezia) with fever, leukocytosis or develop rebound tenderness, surgical exploration should be considered. Patients with severe CI without perforation or gangrenous colitis also need supportive care but they should have close clinical follow up for development of late complications like chronic IC presenting as chronic diarrhea or ischemic colonic stricture presenting as colonic obstruction. In those cases, patients may need elective segmental colonic resection with primary anastomosis. Patients with gangrenous colitis or colonic perforation should undergo surgical exploration for colectomy.

Patients with CMI should have mesenteric revascularization either surgically or endovascularly. Patient's comorbidities, nutritional status and renal function should be assessed before selecting the revascularization technique. Open surgical procedures include antegrade aorto-mesenteric or aorto-celiac bypass graft, retrograde bypass graft from infrarenal aorta and iliac arteries to distal SMA, endarterctomy and reimplantation of SMA directly into the infra-renal aorta[111-113]. The bypass graft can be synthetic (Polytetrafluoroethylene or Dacron grafts) or autologous (femoral vein or sephanous vein) graft and the type of surgery depends on the location of the stenosis[114]. Open surgical procedures for revascularization are highly successful in symptomatic improvement in 90% to 100% of cases[115] but associated with significant 30 d morbidity (21.1%) and mortality (5.8%)[116]. Percutaneous endovascular treatment (PEVT) involves percutaneous transluminal balloon angioplasty (PTBA) with or without stent placement. Matsumoto *et al*[117] found in a small study that PTBA plus stenting had better technical success and patency rate when compared with PTBA alone[117]. PEVT has high technical success (97%) as well as clinical success *i.e.* resolution of clinical symptoms (90%) in properly selected cases[118]. It is safe with less hospital length of stay, low 30 d mortality (3%) and low complication rate (9%) [119]. There is no prospective randomized control trial comparing open surgical revascularization *vs* PEVT. Experience at the Cleveland Clinic Foundation and Mayo Clinic showed that long term restenosis and recurrence of symptoms were higher in the PEVT group compared to open surgical revascularization group[120,121]. However, PEVT is now-a-days widely used as a first line treatment of choice in high risk patients considering the less invasiveness, morbidity, mortality and success rate. Open surgical revascularization is considered in patients with good clinical condition with acceptable surgical risk considering the less chance of recurrence. So patient selection is very important in deciding which modality of treatment is right for the treatment of CMI. Medical treatment with long-term anticoagulation warfarin is considered for patients who are not candidates for PEVT or open surgical revascularization.

Prognosis

AMI: Despite the advancement in diagnostic modalities and treatment options, the prognosis of AMI remains grave. Adaba *et al*[122] did a meta-analysis of observational studies in patients with acute mesenteric infarction and found that the pooled in-hospital mortality was 63%. Mortality was higher in acute arterial mesenteric infarction (73.9%) and NOMI (68.5% as compared to acute mesenteric venous infarction (44.2%)[122]. Risk factors for increased mortality include advanced age, leukocytosis, high arterial lactate level in the first 24 h of admission, metabolic acidosis, bandemia, sepsis, hypoxia, hyperamylasemia, intramural pneumatosis,

elapsed time between onset of symptoms and surgery more than 24 h, colon involvement, hepatic and renal impairment and multi-organ failure[123-125]. Mortality can be reduced substantially if diagnosis can be made and treatment given before the development of mesenteric infarction[126]. Patients who survive from extensive bowel resection suffer from short gut syndrome and become dependent on total parenteral nutrition. Klempnauer *et al*[127] did a long-term study on those patients and found that their 2-year and 5-year survival rates were 70% and 50% respectively[127].

CI: Most of the patients with CI recover quickly within 1 to 2 wk and the overall mortality is almost 10%. Bad prognostic factors include absence of hematochezia, signs of peritonitis (Blumberg's sign: Rigidity and rebound tenderness), tachycardia, anemia, hyponatremia, right sided colonic involvement and stenosis/stricture seen during colonoscopy[128,129].

CMI: Patients with CMI are at risk of developing acute mesenteric artery thrombosis or embolism that can cause increased morbidity and mortality. Patients with malnutrition due to sitophobia may have to stay at the hospital for prolonged period of time. There are certain prognostic factors associated with bad long-term outcome after open mesenteric revascularization. These include body mass index > 25 kg/m, smoking, peripheral artery disease, hypertensive chronic kidney disease, and open mesenteric bypass with a venous graft[130]. Blauw *et al*[131] did a retrospective study on the impact of revascularization in patients with CMI and found that mesenteric artery revascularization significantly improved their quality of life[131].

CONCLUSION

ISBODI is an important clinical entity we come across in our day-to-day clinical practice. Among the 3 forms of ISBODI (AMI, CMI, CI), CI is the most common form.

CI occurs as a result of non-occlusive ischemia due to small vessel disease in most of the time. Rarely, CI is due to systemic hypotension or vascular occlusion due to atheromatous emboli, vasculitis or vascular spasm. Although CI can occur in a well-known clinical setting, in a vast majority of cases, the risk factor remains unidentified. Patients with CI should be stratified into mild, moderate and severe cases depending on the presence or absence of the risk factors associated poor outcome as proposed by the ACG. Management will depend on the severity of the cases. Patients generally present with lower abdominal pain and hematochezia. Segmental involvements of the splenic flexure, rectosigmoid area and ileocecal region are most commonly seen. Imaging with CT followed by colonoscopy with biopsy clinches the diagnosis. Most of the patients belong to mild to moderate severity and CI carries a benign course in those cases. Surgical intervention is rarely required and indicated for fulminant, gangrenous or perforated CI, non-responders to conservative management, chronic ulcerative IC and ischemic colonic structure. Almost 10% of patients can die from CI. AMI is the most severe and devastating form of ISBODI. It has four pathophysiological forms which include SMA embolism, SMA thrombosis, MVT and NOMI. Irrespective of these pathophysiological forms, in the early phase, patients present with sudden onset of severe abdominal pain without much physical sign. As the mesenteric ischemia progresses to mesenteric infarction, patients develop Blumberg's sign. High clinical suspicion and a focused history are helpful in establishing the diagnosis and suspecting the underlying pathophysiologic form of AMI. Evidence of hemoconcentration, leukocytosis, lactic acidosis and positive D-dimer test may suggest the presence of AMI but the diagnosis is generally confirmed by contrast enhanced CTA. Resuscitation of the patient and revascularization of the bowel are the main aims of treatment of AMI. SMA embolism and SMA thrombosis can be treated by open surgery or PEVT. Combination of both treatments (hybrid technique) is also widely used. NOMI can be treated by intra-arterial vasodilator infusion therapy by placing a catheter into the SMA. In case of MVT, systemic anticoagulation or thrombolytic therapy followed by coumidine or DOAC should be given. If the patient has developed bowel wall necrosis in any form of AMI, open surgery should be done to resect the necrotic bowel and then revascularization should be done. Second look surgery should be done after 24 to 48 h to evaluate the potentially viable bowel and to preserve the bowel as much as possible to prevent short bowel syndrome. CMI occurs when patients develop ischemic symptoms due to stenosis of two of the three major mesenteric arteries. Almost always it develops slowly over the years due to atherosclerotic narrowing of those arteries. Patients generally present with post-prandial

intestinal angina. The classic triad of post-prandial upper or mid-abdominal pain, sitophobia and weight loss is present in less than one quarter of cases. CTA is the diagnostic investigation of choice. Revascularization can be done either surgically or by PEVT. Currently, PEVT is widely used as the first line treatment in high-risk patients and open surgical treatment is reserved for patients with less comoribidities. Revascularization can greatly improve the quality of life in patients with CMI.

Abstract

The emergence and rapid spread of novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has caused over 180 million confirmed cases resulting in over 4 million deaths worldwide with no clear end in sight for the coronavirus disease 19 (COVID-19) pandemic. Most SARS-CoV-2 exposed individuals experience mild to moderate symptoms, including fever, cough, fatigue, and loss of smell and taste. However, many individuals develop pneumonia, acute respiratory distress syndrome, septic shock, and multiorgan dysfunction. In addition to these primarily respiratory symptoms, SARS-CoV-2

can also infiltrate the central nervous system, which may damage the blood-brain barrier and the neuron's synapses. Resultant inflammation and neurodegeneration in the brain stem can further prevent efferent signaling to cranial nerves, leading to the loss of anti-inflammatory signaling and normal respiratory and gastrointestinal functions. Additionally, SARS-CoV-2 can infect enterocytes resulting in gut damage followed by microbial dysbiosis and translocation of bacteria and their byproducts across the damaged epithelial barrier. As a result, this exacerbates pro-inflammatory responses both locally and systemically, resulting in impaired clinical outcomes. Recent evidence has highlighted the complex interactions that mutually modulate respiratory, neurological, and gastrointestinal function. In this review, we discuss the ways SARS-CoV-2 potentially disrupts the gut-brain-lung axis. We further highlight targeting specific responses to SARS-CoV-2 for the development of novel, urgently needed therapeutic interventions. Finally, we propose a prospective related to the individuals from Low- and Middle-Income countries. Here, the underlying propensity for heightened gut damage/microbial translocation is likely to result in worse clinical outcomes during this COVID-19 pandemic.

Core Tip: Severe acute respiratory syndrome coronavirus 2 has spread rapidly, infecting and killing millions worldwide. In addition to respiratory symptoms, coronavirus disease 19 (COVID-19) is associated with enterocyte infection leading to intestinal inflammation, gut barrier damage, and microbial dysbiosis exacerbating the systemic inflammatory response. Viral infiltration to the central nervous system from cranial nerve innervation of the lungs and gut can also cause neuroinflammation and degeneration, which further dysregulates gut and lungs. This review summarizes recent findings on COVID-19 pathogenesis in the gut-brain-lung axis and offers therapeutic interventions to improve clinical outcomes.

INTRODUCTION

Starting from late 2019 and through 2020, a novel coronavirus, the causative agent of coronavirus disease 19 (COVID-19), initiated one of the deadliest global pandemics warranting extensive panic for the underprepared global health system[1-4]. The pandemic has claimed countless lives (approximately 4 million deaths worldwide of 188 million confirmed cases as of July 15, 2021) and presented unprecedented socio-economic losses[5-8]. The primary mode of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) transmission is airborne, with infectious droplets gaining access into the host respiratory tract. Subsequently, standard clinical indicators comprise fever, cough, fatigue, chills, nausea, headache, dyspnea. Additionally, the loss of taste or smell often ensues[9,10]. Coronavirus infections primarily target the upper respiratory tract, but they also manifest in other regions such as the gastrointestinal tract (GIT). Within the GIT, additional symptoms such as lack of appetite, vomiting, abdominal pain, and diarrhea have been observed in some individuals[11,12].

SARS-CoV-2 has been shown to infect GIT cells such as human gut enterocytes[13]. SARS-CoV-2 RNA has also been detected in gastrointestinal glandular epithelial cells [14-17]. During infection, compromised gastrointestinal symptom involvement has worse clinical outcomes and takes longer to recover than those with only respiratory

symptoms[18-20]. Subsequently, patients who test positive for viral RNA in feces have poor viral clearance and prolonged delays for infection resolution[21]. SARS-CoV-2 tropism in the lungs and GIT is supported by abundant cellular viral entry receptors such as the angiotensin-converting enzyme-2 (ACE2). ACE2 exists in abundance on the epithelia of the lungs and small intestine (ileum)[22,23]. ACE2 catalyzes the conversion of angiotensin II into angiotensin 1-7; it is crucial for maintaining gut balance through regulation of amino acid homeostasis, innate immunity, the balance of the intestinal microbiome, and by limiting diarrhea[24,25].

The gut is the largest immune organ and is a crucial interconnecting hub, which synchronously orchestrates multiple physiological, cellular, and organ functions[26]. The gut maintains an anti-inflammatory state that supports the growth of trillions of commensal bacteria, which modulate the function of other organs like the brain, heart, kidney, lungs, and liver while favoring its core functions like digestion, absorption of nutrients, and excretion of waste matter[27-30]. This inter-compartmentalized crosstalk infers the need to develop effective gut-specific therapeutics that could limit systemic pathology during diverse viral infections such as human immunodeficiency virus (HIV), SARS-CoV-2, and other related respiratory viruses.

IMMUNE ARCHITECTURE OF A HEALTHY GUT

The gut is one of the most complex immune organs containing a wide variety of immune cells, including myeloid cells, conventional T cells, innate lymphoid cells (*e.g.*, natural killer cells and specialized intraepithelial lymphocyte populations), and epithelial cells[31]. Homeostasis in a healthy gut is mainly fostered through the sustenance of an anti-inflammatory environment crucial for maintaining tolerance to oral antigens, commensal microflora, and bridging an intact mucosal barrier[32,33]. Commensal microflora competes with pathobionts (potentially pathogenic bacteria which are benign during homeostasis) for nutrients within the gut microenvironment, secrete toxins that favor their predominance, and release metabolites that shape gut immunity by providing appropriate anti-inflammatory signals to other immune cells such as macrophages[31,34].

Critical genera of the microbiome also ferment dietary fiber into short-chain fatty acids that support gut immune responses by sustaining the balance of T regulatory (T reg) cells and activated T cells[35]. The released short-chain fatty acids such as butyrate facilitate CD103+ dendritic cell production of retinoic acid, which in turn aid in the generation of FoxP3+ T reg cells and sampling of an antigen across the gut lumen. Increased frequencies of CD4+ regulatory T cells maintain a basal anti-inflammatory state of the gut. Released acetate also improves the integrity of gut epithelial cells[36,37]. Additionally, lamina propria macrophages are highly phagocytic and engulf any foreign microorganisms that may have breached the intact gut mucosal barrier[38]. The gut epithelial cells secrete anti-inflammatory cytokines such as interleukin 10 (IL-10) and transforming growth factor-β (TGF-β), which promote increased frequencies of T regs that are crucial for immunological suppression and induction of mucosal tolerance[39-41].

SARS-COV-2 INFECTION IN THE GUT

During gut infection, SARS-CoV-2 uses its spike (S) proteins on the virus's surface to directly bind to the ACE2 receptor that is highly expressed on target intestinal epithelial cells (enterocytes and goblet cells). A transmembrane serine protease (TMPRSS2) acts synergistically and cleaves the S protein into S1 and S2 subunits, facilitating the host cell's viral entry[15]. Like other viruses such as rotavirus, norovirus, and enteroviruses, the interferon-stimulated genes are activated, resulting in the reinstatement of an antiviral state and restricted SARS-CoV-2 replication[42-44]. Simultaneously, pro-inflammatory cytokines like IL-6, IL-1, and tumor necrosis factor-α (TNF-α) are also released[44]. Severe enterocyte apoptosis follows as soon as the virus overcomes the interferon-mediated antiviral state[16]. The tremendous loss of intestinal epithelial cells diminishes the gut barrier's integrity and gravely impacts the absorption of nutrients, secretion of mucus, and production of antimicrobial peptides [45]. The elevated secretion of pro-inflammatory cytokines also simultaneously activates macrophages towards pro-inflammatory states, which involves the increased surface expression and later shedding of markers such as CD14 and CD163 that are critical for detecting microorganisms and limiting inflammation[16].

A recent unpublished study that comprehensively investigated changes in gut dynamics during SARS-CoV-2 infection shows that there were increases in permeability of gut tight junctions as estimated using zonulin, microbial translocation, lipid-binding protein, and myeloid activation using soluble CD14[46]. Gut barrier damage, microbial translocation, and myeloid cell activation worsened as the disease transitioned into more severe states. All this was heralded when a two-fold increment in tight junction permeability was observed in individuals who died *vs* COVID-19 survivors. Unsurprisingly, alterations in gut homeostasis positively correlated with elevated IL-6, thus confirming increased inflammation as a conduit for loss of gut barrier integrity[46]. Lastly, progressive increments of disrupted citrulline metabolism accompanying the severity of SARS-CoV-2 indicate ongoing microbial dysbiosis and impaired intestinal function[47].

GUT INFLAMMATION AND SARS-COV-2

An optimal balance between T regs and inflammatory T helper 17 (Th17) cells is maintained within a healthy gut. As inflammation occurs, this balance is tipped as pro-inflammatory bacteria are favored over commensals[37]. These pro-inflammatory bacteria induce the secretion of cytokines like IL-6 and IL-17 that select for increased frequencies of Th17 pro-inflammatory CD4+ T cells and susceptibility to inflammatory conditions such as inflammatory bowel disease (IBD)[37].

An increased expression of SARS-CoV-2 receptors during other inflammatory conditions has been suggested to affect disease pathogenesis. During IBD and Crohn's disease (CD), epithelial ACE2 expression is elevated in the colon and rectum while diminished in the ileum[48]. As anticipated, gut dysbiosis occurs as pathobionts outcompete commensal bacteria, and macrophage populations transition towards inflammatory states where they secrete increased amounts of pro-inflammatory cytokines such as TNF-α, IL-6, and IL-12[49,50]. The resultant inflammatory damage leads to the destruction of tight junctions within the gut barrier. This later leads to leakage of microbial contents into the systemic circulation. Microbial translocation then ensues and later fuels chronic immune activation[49].

Several studies have investigated the co-occurrence of IBD and COVID-19-related illnesses[51-53]. Here, we discuss the possibility of leveraging IBD therapeutics for treating COVID-19-related symptoms. Current IBD treatments can be divided into two broad categories: (1) Non-biologic; and (2) Biologic therapeutics. Examples of non-biologic therapeutics include small molecules corticosteroids, thiopurines, and 5-aminosalicylates. Each of these therapeutics non-specifically targets multiple inflammatory processes.

On the other hand, biologic therapies target specific inflammatory mediators in the gut to modulate their ability to induce signal transduction[41]. Current biologics used to treat IBD include the monoclonal antibodies infliximab, ustekinumab, and vedolizumab. Infliximab and ustekinumab target pro-inflammatory cytokines TNF-α and IL-12/IL-23, respectively. Since these cytokines are not specific to intestinal inflammation, antibodies that inhibit their action can act throughout the periphery. More specific therapies target IBD like vedolizumab function by blocking the gut homing receptor α4β7 integrin, thereby blocking inflammatory lymphocyte trafficking resulting in reduced inflammation[41,54,55]. Similarly, the biologic natalizumab, an anti-α4 integrin antibody, is also used to treat Crohn's disease, albeit less frequently due to an increased risk of progressive multifocal leukoencephalopathy (Table 1)[56].

Several studies have suggested that IBD non-biologic therapies may worsen clinical outcomes during COVID-19[57-59]. For example, 5-aminosalicylate and its prodrug form sulfasalazine have increased the risk of SARS-CoV-2 infection and increased the risk of hospitalization and mortality[57-59]. Other immunomodulators include thiopurines, calcineurin inhibitors, and methotrexate. When grouped in meta-analyses, these immunomodulators were also associated with an increased risk of infection, hospitalization, and mortality during SARS-CoV-2 infection[57-59]. The data for corticosteroids is more complicated[57-59]. Owing to their nature as non-selective hormone analogs, corticosteroids target gut inflammation non-specifically, resulting in a dampening of the inflammatory response beyond the intestines. This dampened immune response can therefore inhibit the clearance of replicating virus and prolong the duration of infection. Corticosteroids may further negatively impact clinical outcomes by increasing the pro-thrombotic response to SARS-CoV-2, exacerbating already frequent clotting in intrinsically vascular disease. Several case studies have linked this hypercoagulable state in COVID-19 to worsening in the gut, including

Table 1 Comprehensive list of available gut-based and vagus nerve therapies that could be leveraged to limit the severity of coronavirus disease 19 infection

Therapy	Target	Impact	Clinical outcome
Infliximab[57,58]	TNF-α	Reduced pro-inflammatory response induction and leukocyte migration	Reduced infection rate, symptoms, hospital rate, and mortality
Ustekinumab[57]	IL-12/IL-23	Blocks T cell activation	Possible improved outcome (pooled with other biologics)
Vedolizumab[54,57]	α4β7 integrin	Reduced leukocyte trafficking to gut and associated inflammation	Possible improved outcome (pooled with other biologics)
Corticosteroids[57,58,63]	Glucocorticoid and mineralocorticoid receptors	Reduced inflammatory response	Better or worse clinical outcomes, depending on the timing
Microbiome[176]	Butyrate production	Improved gut barrier integrity and decreased microbial translocation	Reduced inflammatory response
Vitamin D[70,72,74]	Th17 cells	Reduced gut and systemic inflammation	Reduced infection risk and enhanced clinical outcomes
Nicotine and related agonists [142,152,153]	α7nAChR	Reduced Inflammatory Response	Reduced infection rate
Vagus nerve stimulation[151]	α7nAChR	Increased acetylcholine release	Reduced inflammation

TNF-α: Tumor necrosis factor-α; IL: Interleukin; Th17: T helper; nAChR: Nicotinic acetylcholine receptor.

ischemic colitis, potentially aggravating an already disrupted gut homeostasis[60,61]. Therefore, it is unsurprising that studies to determine the impact of IBD therapy on COVID-19 have not been pursued. Nonetheless, corticosteroids for IBD are typically administered long-term and precede SARS-CoV-2 infection. Corticosteroids, particularly dexamethasone, reduce mortality in hospitalized SARS-CoV-2 patients receiving oxygen and reduce intensive care unit hospitalization length when given at moderate doses over a short period (6 mg for up to 10 d)[20,62]. In this context, dexamethasone is typically given after the body has begun clearing the virus but before the worst symptoms of COVID-19 due to cytokine storm arise[63]. The difference in infection rate and clinical outcomes for patients receiving treatment before infection suggests that timing is critical for optimizing corticosteroid use.

In addition to modulating immune responses directly, non-biologic medications may influence COVID-19 pathogenesis in other ways. For instance, people receiving non-biologic medications such as corticosteroids, thiopurines, and 5-aminosalicylates have reduced ACE2 and TMPRRS2 expression on enterocytes in the inflamed colon rectum, but not the ileum[48]. This suggests that despite the adverse clinical outcomes with these medications, they may reduce productive gut epithelial infections in people living with IBD. However, these drugs did not cause changes to receptor expression in the uninflamed gut[48]. In contrast, some biologics used to treat IBD have been mostly, though not exclusively, linked to improved clinical outcomes during SARS-CoV-2 infection, offering novel therapeutic interventions. Early studies have shown that the patients administered biologics did not have an increased risk of COVID-19, despite being considered immunocompromised[64,65]. Individual case studies demonstrate that targeting TNF-α with infliximab promises to improve pulmonary symptoms related to COVID-19[66]. Further, an early study grouping multiple biologic therapies showed that clinical outcomes for individuals taking these biologics were five times less likely to be diagnosed with a SARS-CoV-2 infection[67]. However, this analysis was limited due to the small sample size and inability to separate the specific therapies.

A more recent meta-analysis, again grouping different biologics (anti-TNF-α, ustekinumab, and vedolizumab), demonstrated that their use was associated with a risk ratio of hospitalization 0.34 [95% confidence interval (CI) 0.19-0.61], need for intensive care unit 0.49 (95%CI 0.33-0.72), and mortality 0.22 (95%CI 0.13-0.38), suggesting a substantial improvement in clinical outcome[57]. However, one concern is that because people treated with biologics have such muted symptomology, they may serve as silent carriers of SARS-CoV-2[68]. In addition to reducing symptoms, infliximab has also been shown to reduce the expression of ACE2 in the colon, potentially limiting the productive infection of the gut[48]. Because of these findings, a continued study of these monoclonal antibodies is warranted. Luckily, several clinical trials are currently underway, including anti-TNF- α therapies infliximab and

adalimumab.

In addition to prescription therapeutics, other recommendations for IBD can also be applied to SARS-CoV-2 infection. COVID-19 pathogenesis has been characterized primarily by dysregulation of the systemic pro-inflammatory response of Th17 cells, particularly during the cytokine storm. This includes decreases in CD4+ T cells expressing Th17 markers CCR6 and CD161, increasing senescence and exhaustion markers CD57 and PD-1[69]. The total number of IL-17A-producing CD4+ and CD8+ T cells was significantly increased despite these findings. These studies suggest that targeting IL-17 may improve clinical outcomes for COVID-19 patients[69].

Further, early during the pandemic, low circulating vitamin D became a known risk factor for SARS-CoV-2 infection, and severe pathogenesis, including associations with significantly higher pro-inflammatory cytokines, including IL-6[70,71] was noted. For this reason, vitamin D supplementation has been recommended for high-risk individuals[70]. Oral vitamin D supplements are absorbed by the small intestine, where they may modulate local Th17 cells, including reduced production of IL-17[72]. In clinical practice, vitamin D is frequently recommended for patients prescribed corticosteroids to manage their IBD symptoms to prevent bone density loss[73]. It is also recommended to reduce or protect against IBD onset of symptoms, in part by suppressing IL-17 production[72]. Further, vitamin D has been linked to increased expression of tight epithelial junctions and blocking apoptosis in the intestine, strengthening gut integrity and preventing bacterial translocation[74,75]. However, whether dampened COVID-19 pathogenesis is linked to inhibition of pro-inflammatory Th17 cells or by a different mechanism remains unknown.

One final concern regarding SARS-CoV-2 during IBD has been the safety and efficacy of vaccination with current therapeutics, many of which are immunosuppressive because so far, phase III clinical trials have excluded patients with IBD[76,77]. Previous studies have found IBD patients treated with anti-TNF-α therapies have a muted response when administered other vaccines (pneumococcal, influenza), leading to further questioning of efficacy[76,78,79]. Despite these concerns, the benefits of vaccination outweigh many of the risks of SARS-CoV-2 infection, and vaccination is likely beneficial for most patients with IBD, even if receiving immunosuppressive therapies[76,80,81]. However, future studies are needed to determine efficacy for this population.

SARS-COV-2 INFECTION RESULTS IN MICROBIAL DYSBIOSIS IN THE GUT

SARS-CoV-2-related microbial dysbiosis manifests the enrichment of pathobionts such as *Ruminococcus gnavus*, *Ruminococcus torques*, and *Bacteroides dorei* (*B. dorei*) *Bacteroides vulgatus*. These bacteria have also been implicated in IBD and ulcerative colitis pathogenesis, further strengthening their role in gut dysfunction[82,83]. SARS-CoV-2 dysbiosis was also accompanied by loss of crucial bacteria that have been previously implicated in the lowering of inflammation, such as *Bifidobacterium adolescentis, Faecalibacterium prausnitzii* (*F. prausnitzii*), *Collinsella aerofaciens,* and *Eubacterium rectale* (*E. rectale*)[84] (Figure 1). Another study highlighted that *Clostridium hathewayi* (*C. hathewayi*), *Clostridium ramosum* (*C. ramosum*), and *Coprobacillus* were linked to COVID-19 severity[85]. Unsurprisingly, these microbial signatures (*C. hathewayi, C. ramosum, and Coprobacillus*) have also been associated with pathogenic/inflammatory gut conditions such as diarrhea, colitis, IBD, and overall inflammation[86-88]. This situation's gravitas is further supported by observations made in a separate study that showed that the inflammatory species, *Proteobacteria,* was reported in the guts of COVID-19 patients[89].

Alternatively, several anti-inflammatory bacteria, including *F. prausnitzii, B. dorei, Bacteroides thetaiotaomicron*, *Bacteroides massiliensis*, and *Bacteroides ovatus* were linked to improved clinical outcomes in SARS-CoV-2 patients. Remarkably, *Bacteroides* were reported to down-regulate ACE2 expression in the gut[85]. The fecal microbiome has also been determined to be dysbiotic for periods as long as 30 d after clearance of SAR-CoV-2 infection, further contributing to the extensive list of health complications reported in COVID long haulers who never wholly recover and recuperate to a healthy state[84,90]. To this effect, it was noted that microbiomes of recovered patients were enriched in *Bifidobacterium dentium* and *Lactobacillus ruminis* species and reduced *E. rectale*, *Ruminococcuss bromii*, *F. prausnitzii*, and *Bifidobacterium longum*[84]. Therapeutics involving antibiotics to stabilize the gut microbiome by eliminating SARS-CoV-2 associated pathobionts revealed that these regimens did not affect the

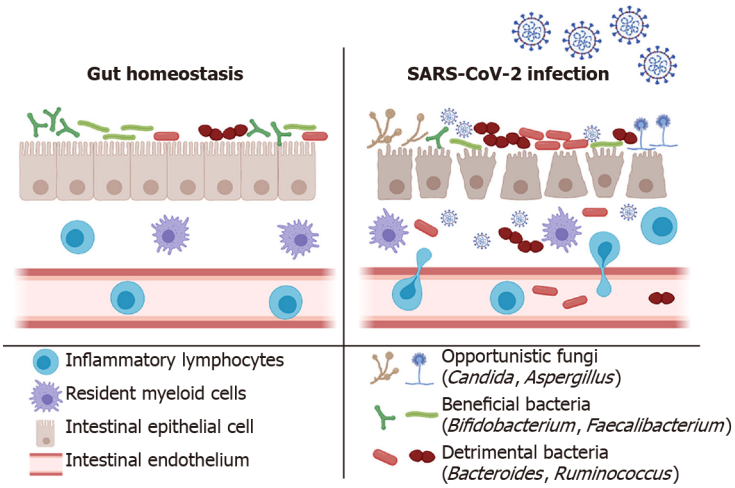

Figure 1 Severe acute respiratory syndrome coronavirus 2 infection induces microbial dysbiosis and intestinal inflammation. Severe acute respiratory syndrome coronavirus 2 infections of intestinal epithelial cells result in a pro-inflammatory immune response leading to infiltration of inflammatory lymphocytes and disrupting the gut barrier. This disruption to homeostasis allows overgrowth of detrimental bacteria resulting in dysbiosis, and the impaired gut barrier facilitates the translocation of bacteria exacerbating the inflammatory response. Additionally, opportunistic fungal infections have been found in some patients, further contributing to the dysfunction. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

recovery of the microbiome. Therefore, these findings negate this approach as a possible future gut microbial rejuvenation strategy[84]. In contrast, previous studies have shown that probiotics improve immune responses to other respiratory tract viral infections such as Influenza and Rhinoviruses[91,92]. Also, in patients with severe COVID-19 disease who cannot ingest probiotics, the use of butyrate enemas could act as adjunctive therapy for repairing intestinal epithelial cell wall damage, lowering chronic immune activation promoting gut-brain axis function[93].

Analysis of the fungal mycobiome using deep shotgun metagenomic sequencing revealed significant proportions of opportunistic fungal pathogens such as *Candida albicans, Candida auris,* and *Aspergillus flavus* were enriched in the gut microbiota of COVID-19 hospitalized patients[94]. Similarly, separate studies have detected *Aspergillus* in respiratory tract secretions and tracheal aspirates of patients with COVID-19[95,96]. Unsurprisingly, in patients with *Aspergillus* in their fecal microbiomes, the cough was noted as one of the significant symptoms that emphasized intricate systemic distortion of the gut-lung axis[97]. In such cases, antifungal medications should be considered.

THE SARS-COV-2 INFECTION AFFECTS THE HOMEOSTASIS OF THE GUT-LUNG AXIS

The gut-lung axis has been proposed to be a bi-directional conduit by which each organ can modulate the function and inflammatory state. This includes the production of metabolites such as short-chain fatty acids (SCFAs) by the gut microbiome, lymphocyte trafficking from the lungs or the gut into the periphery where they redirect systemic immune responses, and indirect neuronal innervation *via* the central nervous system (CNS) and cranial nerves bridging each organ[98,99]. The bi-directionality of the gut-lung axis, while capable of promoting beneficial communication, as noted, also represents an avenue for disruption in immune regulation. Changes in the composition and function of the gastrointestinal flora operate to effect change in the respiratory tract through the mucosal immune system, while reciprocally, disturbances to the respiratory tract flora consequently affect the digestive tract through immune regulation[100]. Infection from SARS-CoV-2 causes effector CD4+ T cells to reach the small intestine by accessing the C-C chemokine receptor type 9 (CCR9) *via* the gut-lung axis resulting in intestinal immune damage and diarrhea[101]. A study related to the influenza virus demonstrated that lung-derived CCR9+CD4+ T cell levels were increased following viral infection[102]. Ye *et al* [101] summarized that the small intestinal epithelium can express CCL25, which actively recruits CCR9+CD4+ T cells to the small intestine, resulting in intestinal immune damage and polarization of Th17 cells in conjunction with overproduction of

IL-17A. This, in turn, leads to neutrophil recruitment, thus establishing diarrhea onset and other gastrointestinal symptoms during SARS-CoV-2 infection. Generally, COVID-19 patients presenting with gastrointestinal symptoms (> 20% of cases) are more likely to be complicated by acute respiratory distress syndrome (ARDS) and are more prone to fatigue, headache, and cough[101]. Another pathway that may be involved in the severity of ARDS during SARS-CoV-2 infection is the C5a-C5aR1 axis. Proportionate to the severity of ARDS, soluble levels of C5a were found to be increased, and C5aR1 receptors were reported with high expression levels in the blood and pulmonary myeloid cells; furthermore, in C5aR1 knock-in mice, acute lung injury was prevented by the introduction of anti-C5aR1 therapeutic monoclonal antibodies suggesting that this axis could be used to limit lung inflammation[89]. Given that ACE2 is highly expressed in the gastrointestinal tract, specifically intestinal epithelial cells, the esophagus, and the lungs, this may make it a target organ for SARS-CoV-2 infection[103]. Therefore, probiotics offer a favorable potential treatment addressing the gastrointestinal symptoms in COVID-19 by operating to sustain the healthy balance of the gut microecology and protect the respiratory tract from bacterial infections[100]. ACE2, while present across different tissue types, is most prominent in the lungs, which highlights the importance of understanding the network involved to combat the hypersensitivity of the receptor in this tissue, which may lead to worse respiratory illness.

Another branch that extends from the lung-gut axis includes the lung-brain conduit, which proposes to connect severe neurological dysfunction and injury with associated lung injury. In general, CoV-induced inflammation and oxidative stress may represent a crucial mechanism for the onset of neurological symptoms. SARS-CoV-2, in particular, has been shown to have the neuroinvasive potential[104]. The vagus nerve innervates the lung's distal airway, and upon stimulation, nerve endings release acetylcholine (ACh), which functions to regulate lung infection[105] (Figure 2). ACh secreted from neuronal and non-neuronal sources acts to decrease inflammation, and using an Influenza A model, a previous study showed that viral infection caused an influx of cholinergic lymphocytes while inhibiting ACh synthesis resulted in extended pulmonary inflammation, increased inflammatory macrophage activation, and delayed tissue repair (Reviewed in[106]).

Similarly, it was demonstrated that a deficiency to the α7 nicotinic ACh receptor (nAChR) acts to worsen lung infection, inflammation, and injury while increasing circulatory levels of pro-inflammatory cytokines. Additionally, α7 nAChR activation by GTS-21, which enhances the phagocytic ability of hyperoxic macrophages, is a prominent method for improving bacterial clearance and reducing lung injury[107], suggesting an involvement of lung-gut-brain connection. During infection, viruses may breach the CNS by various routes, including the vasculature, olfactory and trigeminal nerves, or the lymphatic system. However, the direct mechanism that SARS-CoV-2 utilizes is unknown[108]. One hypothesis is that SARS-CoV-2 enters the CNS by breaching the olfactory route, thereby circumventing the blood-brain barrier (BBB). More than 80% of COVID-19 patients presented with gustatory and olfactory impairments lending support to this access point[104].

Furthermore, in a cohort of 214 COVID-19 patients, 36.4% developed neurologic symptoms ranging from acute cerebrovascular diseases, consciousness impairment, and skeletal muscle symptoms[109]. As reviewed by Nuzzo and Picone, another study used a cellular model to demonstrate that respiratory syncytial virus infection propagates reactive oxygen species (ROS) production transitively, creating oxidative stress that supports the idea that lung inflammation may be a determinant of systemic oxidative stress[104]. The brain, a primary tissue for metabolizing oxygen, is particularly vulnerable to ROS, and SARS-CoV-2 could generate enough ROS to cause brain injury.

In addition to the host immune system's direct mutual interaction in the gut-brain-lung axis, commensal and pathogenic bacteria in the gut microbiome can also influence COVID-19 pathogenesis. SCFAs such as acetate, butyrate, and propionate, being the most prominent immunomodulatory metabolites, maintain and reinforce intestinal epithelial integrity to decrease inflammation in the gastrointestinal tract and respiratory tract by increasing differentiation and fortifying against tight junction permeability[110]. During SARS-CoV-2 infection, increased permeability was associated with clinical worsening, including multiorgan failure[111]. SCFAs produced by the microbiota influence the inflammatory state of the host's epithelial cells, innate and adaptive immune cells directly or indirectly, and utilize the mesenteric lymphatic system for translocation of intact bacteria, their fragments or metabolites through the intestinal barrier, thereby modulating the lung immune response upon entry to the systemic circulation[112,113]. Additionally, SFCA butyrate suppresses intestinal

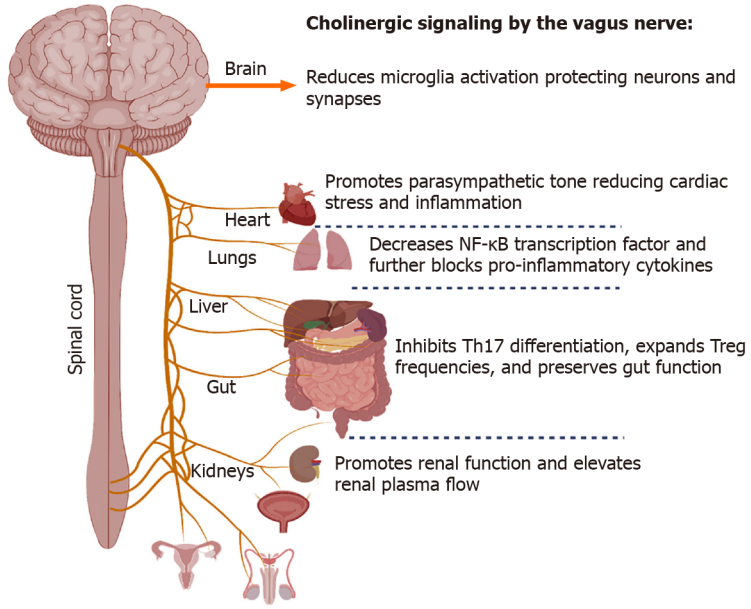

Figure 2 Role of acetylcholine on immune micro-environments in diverse tissues including the brain, heart, lungs, and gut. Cholinergic signaling can be exploited to reduce microglia activation in the central nervous system, lower systemic inflammation, and promote optimal organ function in diseased states such as severe coronavirus disease 19 infection where systemic dysfunction occurs.

inflammation by inhibiting histone deacetylase (HDAC) activity. Inhibition of HDAC enhances the mTOR-S6K pathway required for T cell differentiation and cytokine expression and enhances histone 3 acetylation at Foxp3 Locus to allow transcription to occur and Treg cell differentiation[114,115] Further, GPR43 activation by butyrate can inhibit NF-κB activity and stimulate anti-inflammatory signaling, including IL-8 and IL-10[116].

Previous work on other respiratory viruses also documents disruptions to the gut microbiota. Interestingly, SARS-CoV-2 has been reported to deplete the levels of short-chain fatty acid-producing bacteria such as *Parabacteriodes merdae, Bacteriodes stercoris,* and *Lachnospiraceae bacterium*[117]. Thus, respiratory influenza can indirectly induce intestinal immune injury and alter gut microbiota, resulting in the outgrowth of *Enterobacteriaceae* and reduction of *Lactobacilli* and *Lactococci*[113]. In the influenza-related lung response in mice, intestinal TLR activation is required for NF-κB-dependent pathways for the innate immune response. In this case, disruptions of the microbiota were unrelated to the influenza virus and mediated by Th17 cells[118].

Similarly, other respiratory infections, such as a respiratory syncytial virus (RSV), distort the gut microbiome's balance by depleting *Lachnospiraceae* and *Lactobacillaceae* families while enriching *Bacteroidaceae*[119]. Experimental studies designed to administer high fiber diets favor the enrichment of short-chain fatty acid butyrate-producing bacteria, thus promoting the interferon antiviral state within the lungs of RSV-infected individuals[120]. In turn, depletion of the gut microbiome has been shown to hinder optimal alveolar macrophages' optimal functionality by reducing oxidative respiratory burst capacity and later diminishing their bactericidal effects [121].

IMPACT OF SARS-COV-2 INFECTION ON THE BRAIN-GUT AXIS

The gut microbiome has been shown to directly modulate multiple brain functions such as immune modalities like inflammation and neuroendocrine states like mood, stress, anxiety, and memory functions[122-125]. Within the gut, two plexuses comprise the enteric nervous system (ENS): one at the submucosa and the other associated with the muscularis propria. Together, these two plexuses sense the inflammatory and local microbial milieu. The ENS can regulate many aspects of CNS health and behavior through the production of inflammatory mediators, hormones, and direct neuronal innervation of the vagus nerve from the medulla oblongata[126,127]. The release of short-chain fatty acids by gut commensal bacteria improves the BBB's integrity, reduces inflammation signaling in microglia/astrocytes, and enhances neurogenesis within neurons. Collectively, this promotes reduced aging, better memory, and

improved cognitive development[128].

During gut inflammation, as exemplified with IBD, distorted microbiota populations drive mucosal myeloid cells' activation and subsequent release of pro-inflammatory cytokines that sustain epithelial gut damage. In turn, this activates a cascade of gut pain sensory pathways, dysregulates the enteric nervous system, and simultaneous gut-brain dysfunctions[129-132]. Besides distortion of the lung-gut axis, SARS-CoV-2 dysbiosis of the microbiome could also negatively impact other organs such as the brain. SARS-CoV-2 diminishes crosstalk with the brain by depleting crucial short-chain fatty acid-producing bacteria within the gut microbiome[117] (Figure 3). Furthermore, SARS-CoV-2 has been shown to gain access to the brain by crossing the neural–mucosal interface in olfactory mucosa, where the olfactory mucosal, endothelial, and nervous tissue are closely intertwined[133]. After this, SARS-CoV-2 localizes within the medulla, where respiratory and cardiovascular activities are controlled[133-135]. Thus, this could account for the neurological symptoms such as loss of smell and taste, persistent headaches, confusion, cerebrovascular disease, muscle pain, ataxia, seizures, and dizziness observed in COVID-19 patients[136]. The CNS also supports gut function making the gut-brain axis bi-directional[137,138]. However, the impact of SARS-CoV-2 pathology within the CNS on the direction of gut functions such as peristalsis, modulation of gut immune responses, and directing digestion is yet to be fully comprehended[139].

NICOTINE RECEPTORS, POSSIBLE THERAPEUTIC TARGETS FOR LIMITING SARS-COV-2 DAMAGE IN THE GUT AND BRAIN

Several epidemiological studies from the United States, Europe, and south and east Asia have concluded that tobacco smokers have a lower risk of SARS-CoV-2 infection [140-144]. Additionally, smokers may also have a reduced risk of significant symptoms once infected with SARS-CoV-2, despite typically experiencing increased morbidity and mortality during other respiratory infections[142]. Nicotine is the receptor agonist for nAChRs that contribute to tobacco smoke's addictive and psychoactive properties. In contrast to exogenous nicotine, the endogenous agonist for nAChRs, ACh is produced by neurons and lymphocytes, an essential neuro-immune modulator. The α 7nAChR, in particular, regulates the cholinergic anti-inflammatory response (CAIP) [145]. During acute inflammation, efferent signals from the CNS induce the release of ACh at the enteric nervous system, where they modulate T-cell dynamics, including the induction of Tregs and inhibition of Th17 cells and suppression of local inflammation, including the releases of TNF-α, IL-1β, and HMGB1[146,147]. One hypothesis for nicotine's inhibitory effects is that exogenous α7nAChR agonists recapitulate the effects of ACh release by the vagus nerve, thereby reducing cytokine storm risk both locally at the inhalation site (the lungs) and systemically, including in the gut. This mechanism may be a likely reason nicotine improves ulcerative colitis symptoms[146, 148]. The argument for cholinergic modulation is made even more compelling when considering that neither smoking nor nicotine consumption decreases ACE2 or TMPRSS2 and may increase their expression in the lower airways[149,150]. COVID-19 patients should not be encouraged to smoke or consume nicotine. However, alternative methods of modulating the CAIP have been suggested. Vagus nerve stimulation (VNS) delivers electrical impulses to the left vagus nerve *via* a small device implanted below the collar bone currently used to treat treatment-resistant epilepsy and major depressive disorder. However, less-invasive transcutaneous auricular VNS is being developed. Although more extensive clinical studies are ongoing, case studies have indicated possible benefits in reducing plasma IL-6 levels when using these devices[151]. Alternatively, α7nAChR agonists or acetylcholinesterase inhibitors have been proposed to reduce systemic inflammation[152,153].

A recent report describing ACE2 and TMPRSS2 expression during chronic vagus nerve stimulation showed no changes in either protein or enterocytes[154], although each gene was strongly correlated with CHRNA7 gene expression RNA-seq[154]. Another report separately described how the spike glycoprotein's receptor-binding domain on SARS-CoV-2 possesses significant structural homology with α-bungarotoxin, a neurotoxin produced by kraits that target α7nAChR, the product of CHRNA7 translation[155]. In their discussion, the authors suggest this homology blocks normal cholinergic signaling by competitive inhibition leading to an excessive pro-inflammatory response that cannot be alleviated by vagal signaling. If that is the case, the co-expression of CHRNA7 and ACE2 with TMPRSS2 would mean that infected gut epithelial cells are producing viral particles that inhibit cholinergic

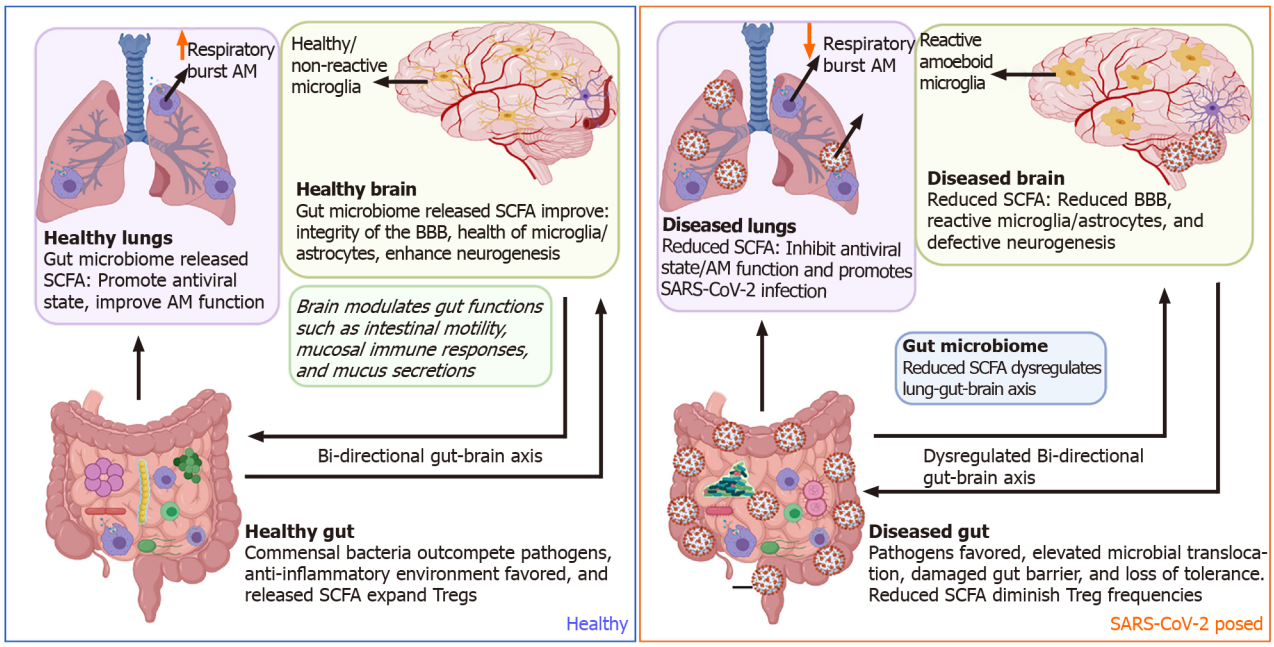

Figure 3 Potential mechanisms by which severe acute respiratory syndrome coronavirus 2 dysregulates the gut-brain axis. Side by side comparisons of the gut-brain-lung axis in a healthy state *vs* a severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) exposed state. In a healthy state, commensal bacteria outcompete pathogens within the gut micro-environment leading to a predominantly anti-inflammatory state. Peptides released by commensal gut bacteria support optimal brain and lung function. During SARS-CoV-2 infection, gut microbial dysbiosis dysregulates gut, lung, and brain function. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; BBB: Blood-brain barrier; AM: Alveolar macrophages; SCFA: Short-chain fatty acids; T-regs: T regulatory cells.

signaling on themselves. A loss of cholinergic signaling fails to block HMGB1, allowing increased microbial translocation at the gut barrier exacerbating inflammatory responses[156]. Targeting this interaction on colonocytes may offer considerable protection from pathogenesis, including the cytokine storm. A similar correlation between ACE2 and CHRNA7 expression has been found on airway epithelial cells, suggesting these cells specifically may be the mechanism by which nicotine modulates infection rates and pathogenesis when endogenous ACh fails[157].

It should be noted that in addition to a disruption to its anti-inflammatory functions, the vagus nerve may also contribute to the COVID-19 pathology in other ways. During Parkinson's disease, α-synuclein aggregates travel from the gut to the CNS in the vagus nerve *via* retrograde axonal transport[158]. The innervation of both the lungs and gut, where significant viral replication occurs, may allow a similar direct transport to the CNS[159]. This hypothesis is corroborated by the recent reports, which showed that the brain stem has an increased inflammatory response during COVID-19 compared with other brain regions. Where cranial nerves IX and X (glossopharyngeal and vagus nerves) meet, the medulla oblongata, in particular, has a higher viral load than the rest of the CNS[160]. The axonal and synaptic loss at the dorsal motor nucleus and nucleus solitarius near this region may be contributing to the loss of autonomic control of respiratory function, cardiac arrhythmias, and gastrointestinal symptoms like diarrhea and vomiting[161,162]. Complicating the role of nicotine in COVID-19 pathogenesis, its administration can inhibit Th17-driven neuroinflammation, thereby possibly protecting these regions in smokers[163]. A better understanding of this process, if it exists, could contribute significantly to minimizing neuropathogenesis during SARS-CoV-2 infection.

CONCLUSION

SARS-CoV-2 infection in the gut leads to alterations in gut microbiota with depletion of bacterial genera that produce crucial metabolites such as short-chain fatty acids that sustain optimal brain function. Future studies focusing on using probiotics to replenish commensals' dwindling populations as a strategy to reverse gut dysbiosis while maintaining the gut-brain axis during COVID-19 are needed[164]. Furthermore, additional efforts should be applied to the testing strategies currently used to manage inflammatory conditions affecting the gut for their potential in the direction of

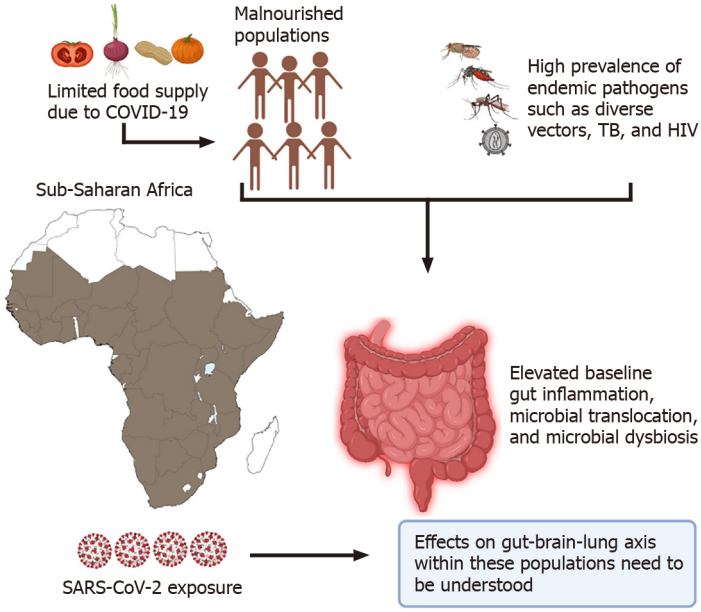

Figure 4 Elevated baseline gut inflammation observed in Sub-Saharan African individuals could lead to severe coronavirus disease 19 associated dysregulation of the gut-brain-lung axis. Continuous exposure to various endemic pathogens such as human immunodeficiency virus, tuberculosis, multiple vectors like tsetse flies, and several mosquitoes, in addition to low diets, set the ground for high levels of gut dysbiosis within the entire community populations. Additional studies focused on evaluating the effects of baseline gut dysbiosis on coronavirus disease 19 infection are highly warranted. SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; COVID-19: Coronavirus disease 19, HIV: Human immunodeficiency virus; TB: Tuberculosis.

COVID-19 associated dysbiosis, gut damage, and microbial translocation. Targeting vagal stimulation and diverse nicotinic receptors could offer lower organ inflammation and confer systemic protection across the gut-brain and lung organs.

Lastly, special consideration should be given to populations worldwide where there is a high incidence of coinfections such as HIV and tuberculosis (TB) that target the gut early on in infection, cause dysbiosis and lead to microbial translocation[165-167]. In the world's poorest regions like Sub-Saharan Africa, most individuals are continuously exposed to endemic pathogens like helminths and TB that could lead to elevated baseline levels of gut damage, immune activation, and possible microbial translocation [168-171]. Recently, Bhaskaran *et al*[172] analyzed data from 27480 individuals co-infected with HIV within the United Kingdom. Their data revealed that people living with HIV had a higher risk of COVID-19 death than those without HIV, after adjusting for the age and sex with a hazard ratio (HR) of 290 (95%CI 0.196-0.430; $P < 0.0001$). However, the absence of testing, limited case reporting, and poor health care limits our understanding of the SARS-CoV-2 pandemic on this continent[172].

The sudden lifestyle changes imparted by the pandemic within these populations have tremendously strained their chances of survival. In countries where restrictions or lockdowns are enforced, most individuals from these regions rely on the government to supply free food rations[173]. However, the low quality of this freely distributed food fuels the already highly prevalent risk of malnutrition within these populations[174]. As we have illustrated, limited dietary access within these communities could further aggravate gut dysbiosis leading to severe systemic disorientation during SARS-CoV-2 infection. The complexity of these variables, in addition to limited health service delivery and governmental support[175] could exacerbate gut-brain disruptions within diverse populations in Sub-Saharan Africa (Figure 4).

In these trying times of the COVID-19 pandemic, the connotation of a healthy gut-healthy mind could translate into one's ability to orchestrate a meaningful immune response that could limit SARS-CoV-2 infection and maintain systemic homeostasis and diminish side effects from virus exposure. Leveraging therapies currently being used to improve gut health could be exploited for better disease outcomes during severe disease. Additional studies on the gut-brain axis, particularly from diverse populations across the world, are warranted.

Abstract

Chronic infection with hepatitis B virus (HBV) remains a global health concern despite the availability of vaccines. To date, the development of effective treatments has been severely hampered by the lack of reliable, reproducible, and scalable *in vitro* modeling systems that precisely recapitulate the virus life cycle and represent virus-host interactions. With the progressive understanding of liver organogenesis mechanisms, the development of human induced pluripotent stem cell (iPSC)-derived hepatic sources and stromal cellular compositions provides novel strategies for personalized modeling and treatment of liver disease. Further, advancements in three-dimensional culture of self-organized liver-like organoids considerably promote *in vitro* modeling of intact human liver tissue, in terms of both hepatic function and other physiological characteristics. Combined with our experiences in the investigation of HBV infections using liver organoids, we have summarized the advances in modeling reported thus far and discussed the limitations and ongoing challenges in the application of liver organoids, particularly those with multi-cellular components derived from human iPSCs. This review provides general guidelines for establishing clinical-grade iPSC-derived multi-cellular organoids in modeling personalized hepatitis virus infection and other liver diseases, as well as drug testing and transplantation therapy.

Core Tip: The development of an effective treatment for hepatitis B virus relies on reliable and reproducible *in vitro* modeling systems. Recently, three-dimensional multicellular organoid systems have attracted considerable attention owing to their superior susceptibility and capability to precisely recapitulate the virus life cycle. Recent advances in organoid-generating strategies, particularly those derived from human induced pluripotent stem cells, together with future improvements in genetic modification and scalability, will undoubtedly promote personalized disease modeling and drug development.

INTRODUCTION

Hepatitis B virus (HBV), a highly prevalent global health concern, is among the most common causes of advanced chronic liver disease development. Globally, 292 million people (approximately one-third patients in China) reportedly present with chronic HBV infection[1], which is associated with a wide range of clinical manifestations, including liver cirrhosis, liver failure, and hepatocellular carcinoma[2]. Despite the availability of approved vaccines, currently, HBV treatment is mainly restricted to interferon (IFN) and nucleoside analogs, which rarely achieve absolute hepatitis elimination[3]. Notably, clinical treatment usually results in different responses and outcomes due to viral genotype diversity and patient genetic susceptibility, which further increases treatment difficulties[4]. To date, *in vitro* culture systems have been utilized to determine the characteristics and life cycle of hepatitis C virus. Furthermore, these systems have been proven to substantially contribute to our understanding of the genomic replication subsystems that ultimately led to productive viral infection, as well as successful identification of small molecules having effective activity against various hepatitis C viral enzymes[5]. Therefore, to better understand the HBV life cycle and to promote drug development, a robust personalized *in vitro* HBV modeling platform is urgently needed to recapitulate the entire HBV replication cycle, especially that of covalently closed circular DNA (cccDNA) infection and formation. Several *in vitro* modeling systems have been developed, mostly based on *in vitro* culture systems using primary hepatocytes or hepatic cells from other sources[6-9]. Besides, sodium taurocholate cotransporting polypeptide (NTCP)-transformed hepatocellular carcinoma cell lines are also available. No one system fits all studies, but findings from different systems may be complementary. Maintenance of hepatic function and increase of susceptibility to HBV infection *in vitro* are the principal focus for most established systems. In this regard, numerous culture systems have also been developed to better fit the in *vivo* microenvironment.

Considering the demand for clinical applications, the reproducibility and scalability of modeling systems have generated interest in recent years. Accordingly, as a theoretically unlimited source of stem cells without ethical implications, pluripotent stem cells [induced pluripotent stem cell (iPSC)] represent the most promising source that can be used to yield substantial quantities of homogeneous and reproducible cellular components of the liver. Moreover, with a patient-specific genetic background, iPSC-derived hepatocyte-like cells (HLCs) are optimal for individualized disease modeling, which may remarkably benefit mechanistic studies and drug development for hereditary diseases and diseases closely related to the host genetic background, such as HBV infection[10-12]. With considerable expression of major mature hepatocyte markers, as well as host factors required for HBV infection, including the NTCP, iPSC-

HLCs could support robust production of HBV particles and viral RNAs[7,13]. More importantly, significant inhibition of HBV infection was detected upon anti-HBV agent treatment, suggesting that iPSC-HLCs could be utilized as a novel HBV infection model for drug testing[14].

However, the drawbacks in maturation and difficulty in maintenance of iPSC-HLCs have raised considerable concerns. Liver organoids (LOs) can be maintained for a longer time, are more susceptible to HBV infection, and exhibit enhanced liver function[3]. Multi-cellular three-dimensional (3D) organoid culture systems have recently become an effective strategy to compensate the deficiencies and also extend the potential modeling duration. With supportive mesenchymal and endothelial cells in the 3D microenvironment, HBV susceptibility was greatly enhanced compared to monolayer culture system, while the duration for HBV propagation and virus production was also prolonged[15]. HBV-infected LOs could serve as a reliable and viable *ex vivo* infection model for hepatitis research to investigate the role of host genetic background in HBV infection and individual prognosis of infection, enabling personalized hepatitis treatment[15]. To further enhance the reproducibility and scalability, an all-iPSC-based strategy has been adopted most recently in generating multi-cellular LOs with improved hepatic functions almost equivalent to those of adult hepatocytes, although their advantages in HBV modeling remains to be confirmed in future studies[16]. With the development of 3D expansion strategies, together with advances in direct programming or induction of liver fate, novel engineered LOs are expected to be established on a large scale for broad applications in disease modeling, drug screening, and transplantation.

Here, we summarized the recent advances in *in vitro* modeling systems for HBV infection, especially using multi-cellular LOs. Additionally, we discussed the current and future challenges in the application of advanced organoid generation platforms in terms of efficiency, reproducibility, and scalability. Finally, we explored the future applications of multi-cellular LOs in personalized and precise treatments.

ADVANCES AND LIMITATIONS IN MODELING HEPATITIS B INFECTION

Cell sources

HBV only efficiently infects fully differentiated hepatic cells. Until now, primary human hepatocytes (PHHs) were the only permissive agents used for the study of HBV infection *in vitro*[17]. This system remains the gold standard and is utilized to model HBV infections *in vitro*[18]. However, fresh PHHs have markedly limited availability and unpredictable variability among donors. Furthermore, PHHs have extremely limited replication ability in conventional culture systems and cannot be easily subjected to genetic manipulation, which hinders scaled-up manufacturing and targeted gene therapy. Moreover, PHHs show rapid loss of their mature hepatic functions and infection susceptibility after plating. Thus, these cells are unsuitable for utilization as a stable source for long-term modeling and testing[19]. For a reliable and practical platform for long-term disease modeling and drug development, a new gold standard should be established.

To overcome restrictions in the use of PHHs, especially source availability and cost, researchers have shifted their attention to immortalized tumor-derived or transformed hepatocytes and hepatocellular carcinoma cell lines, such as Huh7, HepG2, HepG-2.2.15, HepAD38, HepaRG, HepDE19, HepBHAe82, and HepG2-NTCP cells[3,20,21]. HepG2.2.15 cells can stably express HBV viral gene products. However, HBV viral particles are derived from chromosomally integrated DNA rather than cccDNA during *in vivo* processing. Later, a highly HBV-permissive cell clone of HepAD38 cells was created, which could produce more robust viruses. However, this cell line failed to recapitulate the complete viral replication process[20,21]. In this regard, the liver progenitor cell line HepaRG is a more attractive source for modeling, since these cells show morphological and functional features similar to those of primary hepatocytes. More importantly, HepaRG cells are susceptible to HBV infection upon supplementation with corticoids and DMSO, which maintains the cellular maturation state [6]. However, this infection system has a relatively low infection efficiency, even under the strict culture conditions necessary to prevent dedifferentiation. Additionally, cccDNA amplification did not occur in this system[7]. Subsequently, to meet the requirements for high-throughput screening of cccDNA-targeting drugs, a HepDE19 cell line was developed in which the expression of HBV e antigen (HBeAg) was derived from cccDNA. However, the ELISA antigen shows cross-reactivity with viral HBeAg homologues, which dramatically diminishes the assay specificity[22,23]. To

address this problem, the HepBHAe82 cccDNA reporter cell line was developed based on similar principles. Importantly, this line produced high levels of cccDNA-dependent HBeAg with high, specific readout signals and did not disrupt any cis-elements that were essential for HBV replication and HBeAg secretion[21]. As a potential tool for cccDNA-targeted drug screening and testing, it remains to be determined whether cccDNA formation, stability, and transcription are recapitulated in this system. To further achieve high susceptibility to HBV infection, NTCP, an essential receptor for HBV infection[24] was introduced into liver cancer cell lines. Establishment of susceptible cell lines, such as HepG2-NTCP, permitted highly efficient HBV infection and enabled the identification of key events or processes in the viral life cycle, although this system could not be used to elucidate the entire HBV life cycle[25]. Furthermore, the physiological and functional characteristics of tumor-derived or transformed hepatoma cell lines are distinct from those of normal hepatocytes. Comparing the HepG2 transcriptome to cells obtained from liver tissue biopsies showed that most genes with upregulated expression in HepG2 cells were associated with carcinogenesis, while those with upregulated expression in the liver were enriched in heterologous biometabolism[26], thereby implying a fundamental deficiency of hepatocellular carcinoma cell lines for reliable and precise modeling. Besides, a non-hepatic cell line was recently developed for HBV modeling. Constructed by exogenous expression of human NTCP, HNF4α, RXRα, and PPARα, the 293T cell line (293T-NE-3NR) was able to support HBV entry, transcription, and replication, although the HBV production (HBV DNA, cccDNA, and pgRNA) in 293T-NE-3NR remained lower than that in the HepG2 cell line. To date, the use of a non-hepatic model is quite a new concept; however, it may serve as a beneficial complement to the current hepatocellular carcinoma cell models. Without intrinsic liver-related host factors, an exogenous construction strategy may help discover the key factors involved in HBV infection[27].

To achieve functional hepatocytes that closely resemble primary hepatocytes, HLCs differentiated from pluripotent stem cells have attracted considerable attention as a novel cell source. Since the use of embryonic stem cells is markedly hindered due to ethical issues, iPSCs induced by the ectopic expression of defined transcription factors (*e.g.*, *Oct4*, *Sox2*, *Klf4*, and *c-Myc*) in patient fibroblasts or other somatic cells have emerged as the most promising source for generating HLCs[28-30]. After conduction of stepwise hepatic differentiation[31-33], iPSC-derived HLCs could support effective HBV infection and last for a long time[14,34]. Together with their infinite expansion capability, iPSCs have enabled the provision of numerous hepatic cell sources necessary for stable and scalable modeling with less variability than PHHs[25]. Meanwhile, the epigenetic effects in human iPSCs are minimal and the genetic differences between individual donors contribute to the major heterogeneity between different iPSC lines[35]. In this regard, iPSCs may serve as stable, reliable, and powerful platforms for the precise analysis of the hepatitis virus in specific genotypes and for modeling infection in individuals with different genetic backgrounds[29,36,37]. Additionally, induced hepatocytes (iHeps) generated by direct reprogramming from somatic cells share similar hepatic features and may be potentially used to support productive HBV infection[34].

Despite the progressive improvements reported thus far, *in vitro* hepatocyte induction with transcription factors, growth factors, or chemicals cannot fully represent the complete phenotypic spectrum of PHHs. Further, inhibition of the innate immune response remains an obstacle to achieve efficient infection[38]. Thus, improvements including optimized induction strategies and niche signaling are warranted to generate transcriptional/functional and hepatitis virus-friendly hepatic sources to recapitulate *in vivo* virus-host recognition.

In vitro microenvironment

The biological characteristics and functions of primary hepatocytes depend considerably on the *in situ* liver microenvironment[39,40]. Simply covering hepatocytes with multiple layers of collagen gel can markedly extend the culture time and help retain cellular functions[41]. Nevertheless, utilization of the conventional *in vitro* culture systems results in a rapid loss of hepatocyte polarity and associated liver function[42], innate immune responses, and susceptibility to HBV infection due to the unsatisfied intrinsic requirements of the liver microenvironment. Consequently, most of these HBV infection systems require the addition of DMSO, PEG[43], or immunomodulatory agents to achieve essential susceptibility, which is not feasible for practical considerations[34]. *In vivo*, however, HBV can infect more efficiently[44], which highlights that the native hepatic microenvironment, including the physiological liver architecture and niche signaling, markedly impacts productive HBV infection.

As the most abundant non-parenchymal hepatic cell population, liver sinusoidal endothelial cells (LSECs) can efficiently enhance HBV infection by secreting epidermal growth factor (EGF)[45] and can lead to the development of liver fibrosis by constitutively expressing the major histocompatibility complex I-restricted antigens and co-stimulatory molecules, which shifts the immune balance of the liver toward tolerance[46]. Additionally, hepatic stellate cells (HSCs) maintain hepatocyte function *via* cell signaling and secretion of the necessary factors[47]. Furthermore, HSCs are actively involved in the development of hepatitis virus-induced hepatic fibrosis[48]. Kupffer cells (KCs) and Ly6C+ monocytes are closely associated with host defense in the liver and play crucial roles in the development of anti-HBV immunity. Particularly, KCs are involved in hepatitis virus recognition, suppression of infection, immune cell recruitment and activation, and are correlated with HBV progression and outcomes [49,50]. The integration of multi-cellular interactions as a whole requires precise imitation of the native liver niche. Conventionally, monolayer co-culture systems are used as a simple tool to recapitulate cell-cell interactions and signaling. However, these systems provide non-natural physiological conditions, in which only parts of the hepatocyte surface establish communication with the adjacent cells or the extracellular matrix (ECM), leaving the rest of the cell exposed to the culture medium. Although certain aspects of hepatitis or other viral infections may be elucidated using this system, there remain major concerns regarding a physiologically intact host for virus recognition and replication. Cells assembled in 3D aggregates are more similar to cells *in vivo*[15]. PHHs cultured in 3D systems preserve certain metabolic functions and permit more accurate hepatotoxicity prediction during *in vitro* modeling[42]. However, the liver microenvironment includes the 3D mass of hepatocytes and an organized architecture consisting of numerous cell types, which synergistically regulate liver-specific physiology. Therefore, reconstruction of these interactions will theoretically help in the development of a more reliable system for the initiation and long-term maintenance of the hepatitis infection cycle. Recent achievements in generating multi-cellular organoids have paved the way for the establishment of an accurate model for obtaining fundamental knowledge on disease progression, including HBV infection [15], particularly when single patient-derived iPSCs contribute to the cellular composition of desired organoids[51]. iPSC-derived multi-cellular LOs maintain mature hepatic phenotypes and functions to levels comparable to those of PHHs. More importantly, LOs are more susceptible to HBV infection than iPSC-HLCs and maintain long-term HBV propagation while producing infectious viruses. Together with the genetic characteristics inherited from the donor iPSCs, LOs help in the achievement of a promising individualized infection model[15].

In static culture systems, gas exchange, nutrient supply, and waste removal remain significant challenges. The emergence of microfluidic technology has enabled the control of the culture system with optimized temperature, pH, nutrients, and gas exchange, while providing microscale structures and parameters that may help to obtain an approximate simulation of the *in vivo* microenvironment[52,53]. Thus, the application of these systems permits organoid maintenance in *in vivo*-like physiological states or even in disease-like conditions in a controlled manner. Notably, improved drug sensitivity can be obtained using microfluidic 3D systems compared to static culture systems. With the utilization of further engineering approaches to control the initial cellular composition, shape, and size of cell aggregates; cell-cell and cell-ECM[54] interactions; and biochemical gradients similar to *in vivo* microenvironment, the incoming generation of organoids-on-a-chip has considerable potential for large-scale applications in high-throughput drug testing and screening.

Micropatterning

Highly structured organs and tissues provide a fundamental *in vivo* microenvironment for cells, in which cell polarity and functions are consistently influenced by the specific boundaries imposed by the neighboring cells and the ECM. The mechanical and spatial properties of the microenvironment are tightly correlated with intracellular signaling pathways and affect cell transcriptome status and function. In the past decade, numerous studies have been conducted and have provided insights into the geometrical modeling of the *in vitro* culture microenvironment by developing engineered substrates that precisely mimic the composition, structure, and mechanical properties of a specific organ or tissue.

To date, accumulative *in vitro* studies show that cell differentiation can be directed by using micropatterned substrates. The micropattern features on the spreading area and the aspect ratio determine the differentiation status of human mesenchymal stem cells (MSCs)[55]. Moreover, hydroxyapatite bioceramic-based hybrid structures stimulate osteogenic differentiation of MSCs by activating integrins, the BMP2

signaling pathway, and cell-cell communication. The width of micropattern stripes regulates vascular smooth muscle cell orientation by regulating cell elongation[56]. Similarly, mechanical and spatial control was observed during pluripotent stem cell differentiation. When these cells are differentiated within geometrically uniform and circular micropatterns, the patterning of regionalized cell fate can be reproducibly recapitulated[57,58]. Moreover, recent evidence shows that a decreased patterning width promotes iPSC differentiation efficiency, suggesting that stricter topographies direct cell fate specification[59]. Interestingly, the micropattern stiffness, degradability, and biochemical composition can even promote pluripotency reprogramming, thus emphasizing the critical role of micropatterns in morphogenetic and functional remodeling[60].

Although micropatterning strategies are increasingly applied in cell-based modeling and testing, they pose challenges in ensuring compatibility with rapidly advancing organoid technology that requires the use of non-adhesive substrates and extensive cell-cell interactions for self-organization. To this end, scaffold-dependent micropatterning strategies were adopted in recent studies conducted on distinct epithelial organoid generation. Meanwhile, structural and functional improvements have been increasingly reported. For example, a microfilament-based floating scaffold was developed to perform micropatterning and to guide brain organoid self-organization with increased reproducibility and improved tissue architecture[61]. Additionally, a spatially confined hydrogel scaffold was developed to guide self-organization of tube-shaped functional intestinal organoids with an accessible lumen and a physiologically relevant spatial arrangement of crypt- and villus-like domains[62]. Similarly, in terms of LOs, both colloidal crystal and hydrogel-based scaffolds were found to support advanced liver functions[63,64]. However, to date, the mechanism of spatial microenvironmental control of organ/tissue-specific cell fate specification remains undetermined. Once identified, scaffold-based micropatterning systems are expected to offer a potential platform for generating liver-specific and regionalized cell types simultaneously from a single iPSC. These platforms will be of remarkable importance for constructing multi-cellular organoids with native spatial composition, and will help to elucidate the mechanisms by which intra- or intercellular signals regulate distinct cellular identities and maturation patterns, and will fundamentally mimic the *in vivo* physiological features and hepatic functions for precise hepatitis modeling.

CURRENT CHALLENGES IN GENERATING MULTI-CELLULAR LIVER ORGANOIDS

Liver-like cellular organoid composition and reconstitution

To better mimic an *in vivo* niche resembling liver-specific function and physiology for disease modeling, vascularized functional multi-cellular LOs were first developed in 2013[65]. However, in this study, human MSCs and umbilical vein endothelial cells (HUVECs) were used to substitute the liver intrinsic stromal cellular components, including HSCs and LSECs, which remain major obstacles for future clinical applications. To address this problem, a complete all-iPSC-based strategy was established, in which hepatic functions were promoted by using iPSC-septum transversum mesenchymal and iPSC-endothelial progenitor cells. In both global transcriptome and function, the new system was more advanced than the HUVEC/MSC-based strategy and was comparable to primary adult hepatocytes[16]. However, this system remains deficient in recapitulating the immune response and inflammation due to the lack of an essential liver component, KCs. Recently, KCs, hepatocytes, stellate cells, and biliary cells were successfully induced synchronously in a multi-cellular system by facilitating co-differentiation from iPSCs, which represents a real and more complex liver-like tissue system that may be used for modeling inflammatory and fibrotic responses[51]. With advanced integration and optimization of cellular composition (Table 1), multi-cellular LOs are expected to support precise and more complex disease modeling.

With the progressive understanding of liver organogenesis and technical advancements in iPSC differentiation methods toward tissue-specific cellular compositions, the following aspects remain as future challenges: (1) The procedures that can be used to remodel the intrinsic cellular composition proportion and distribution in LOs; (2) Their specific roles in liver development and disease processes; (3) Clarification of biochemical signatures of liver-specific ECM; and (4) The use of clinically compatible ECM hydrogels or microparticles. Overcoming these challenges will be beneficial for maintaining LO physiological characteristics during modeling.

Novel strategies for synchronous induction

Before the all-iPSC-based strategy was adopted, the development of multi-cellular organoids included the collection and separate preparation of each cell type and subsequent self-organization into a 3D structure. Although the emergence of all-iPSC-based strategies facilitated the establishment of a reproducible and stable source for clinical and pharmaceutical applications, the procedure for diverse cell co-culture remains time-consuming, labor-intensive, inefficient, and cannot meet the requirements for large-scale production and practical applications. Moreover, selection of the specific culture medium and ECM to simultaneously maintain multiple cell lineages remains challenging.

To address these limitations, a stepwise organoid induction and maintenance platform was developed, which involved sequential stimulation with the addition of growth factor cocktails into the culture medium. Following the induction of foregut spheroids by retinoic acid (RA) treatment and subsequent hepatic maturation, iPSCs were simultaneously differentiated into multi-cellular LOs. However, this approach lacks precise control over multi-lineage specification and physiological functions. Furthermore, the optimization of medium and growth factors that are used to direct and maintain distinct cell specificity remains an obstacle. In this regard, systematic probing of the molecular pathways and transcriptional networks has emerged as a more precise method for direct organogenesis *in vitro*. *PROX1* and *ATF5* overexpression combined with *CYP3A4* activation enables gene regulatory network (GRN)-based engineering and facilitates direct programming or induction and the development of iPSC-derived multi-cellular LOs. Importantly, compared to primary mature hepatocytes, the established GRNs not only showed major similarities in natural liver functions, but were also responsive to perturbation and feedback regulation, and thus were superior to immature HLCs and fetal LOs[66]. Although this new method enabled the development of multi-cellular systems *via* synthetic genetic control, it is difficult to reflect every facet of human liver physiology and function, such as relatively low levels of urea production and CYP2C19 activity. Further global assessment of GRNs may be necessary to identify critical regulatory signatures for advanced liver fate. Additionally, it is important to carefully determine and avoid potential tumorigenesis by transcription factor-based genetic programming and delocalization processes using guide RNAs (gRNAs) to achieve clinical safety standards.

Taken together, synchronous induction or programming systems may substantially improve the efficiency of traditional multi-lineage differentiation, which is a promising strategy for practical applications (Figure 1). However, the lack of maturation, purity, and batch-to-batch variability remains a major challenge. Further optimization of stepwise induction or programming strategies, including medium, supplements, timing, and application of tissue scaffolding and microfluidic devices, is warranted to precisely recapitulate the intrinsic multi-cellular organ system *in vivo*.

Scaling up

The possibility of scaled-up applications is a major advantage of using *in vitro* organoid systems over animal models. The increasing biomedical and preclinical demands for high-throughput disease modeling, drug testing, and screening, have led to the identification of critical bottleneck of scaling up, which prevents their application to provide more reliable, rapid, and cost-effective modeling.

Using chemical induction, a limited expansion capability of human hepatocytes was successfully induced in 2D monolayer culture systems[67,68]. However, expansion in a 3D system is subjected to complicated factors, such as nutrient/gas exchange, contact inhibition, and complex cell-cell signaling. Although long-term expansion of organoids from human adult biliary epithelial-derived progenitor cells, fetal/adult hepatocytes, and pluripotent stem cell-derived hepatocytes has been successfully established, the expansion efficiency remains markedly lower than that observed with the application of 2D systems[69-73] (Table 2). Recently, a rotating flask-based method was developed for the large-scale expansion of human LGR5-positive liver stem cell organoids. In this system, organoids were subjected to continuous passage and stable maintenance for at least 6 wk, which was mostly achieved with improved oxygenation[74].

Scaling up multi-cellular systems is another major challenge. By developing an omni-well array culture platform, Takebe *et al*[16] adopted an all-iPSC strategy for the large-scale production of homogenized and vascularized LOs in a clinical setting and achieved a 10^8-cell grade, which seemed to be feasible for human therapeutic applications. However, this platform involved the performance of labor-intensive work, including separate preparation of diverse cell sources for co-culture, thus limiting the efficacy of scaling. Later, the same group established a synchronous co-differentiation

Table 1 Current modeling strategies and applications of human multi-cellular liver organoids

Model/application	Multiple cells (ratio)	Culture system	Advances/significance	Limitations	Ref.
ALF	iPSC-HEs, HUVECs, BM-MSCs (10:8:2)	3D, Matrigel	Multi-cellular LOs with vascularization	Low reproducibility; Time-consuming	2013[65]
ALF	HEs, MCs, ECs (all from iPSCs) (10:8:2)	3D, ULA	All-iPSC-based strategy	Time-consuming; High cost	2017[16]
ALF	iPSC endoderm cells, HUVECs, UC-MSCs (10:7:1)	3D, ULA	LOs generated from single donor-derived cells	Low reproducibility; Time-consuming	2018[75]
ALF	iPSCs, HAMECs (3:1)	EB, Agarose	HAMECs improved hepatic functions	Unable to reflect the nature cellular composition of liver	2019[102]
Liver fibrosis	HepaRG, THP-1, hTERT-HSC	3D, Hanging drop	LOs derived from cell lines	Functional deficiency	2017[103]
Liver fibrosis and steatohepatitis	PHHs, KCs, HSCs, SECs (16:2:1:1)	3D, ULA	LOs derived from primary cell sources	Low reproducibility; High cost	2018[104]
Steatohepatitis	Hepatocytes, HSCs, BCs, KCs (all from iPSC)	3D, ULA	Co-differentiation of multiple cell lineages for iPSC- LOs	Functions undetermined; Potential inter/intra-batch variability	2019[51]
HBV infection *ex vivo*	iPSC endoderm cells, HUVECs, BM- MSCs (10:7:1)	3D, ULA	Validation of advantages of iPSC-LOs in HBV modeling	Low reproducibility; Time-consuming	2018[15]
Hepatic differentiation	iPSC-HEs, MSCs, HUVECs (10:2:7)	3D, Matrigel	Platform to identify developmental paracrine signals involved in hepatocyte differentiation	Low reproducibility; Time-consuming	2017[105]
Hepatic differentiation	iHEPs, ECs, HSCs, cholangiocytes (10:7:2:1)	3D, ULA	Cholangiocytes impaired the hepatic functions in LOs and were associated with the liver disease relevant phenotype	Cholangiocyte activation in LOs was unclear	2019[106]
Liver development and angiogenesis	Hepatocytes, BCs, ECs, HSCs (all from iPSC)	3D, Matrigel	Engineered iPSC-LOs by programming of the gene regulatory network	Not completed for liver functions	2021[66]

ALF: Acute liver failure; BCs: Biliary cells; BM: Bone marrow; EB: Embryoid body; ECs: Endothelial cells; HAMECs: Human adipose microvascular endothelial cells; HBV: Hepatitis B virus; HEs: Hepatic endoderm cells; HSCs: Hepatic stellate cells; HUVECs: Human umbilical vein endothelial cells; iHEPs: Induced hepatocytes; KCs: Kupffer cells; Los: Liver organoids; MCs: Mesenchymal cells; MSCs: Mesenchymal stem cells; NPCs: Non-parenchymal cells; PHHs: Primary human hepatocytes; SECs: Sinusoidal endothelial cells; UC: Umbilical cord; ULA: Ultralow adhesion microwell plate.

method that facilitated the generation of multi-lineage organoids in a preset growth factor administration strategy, thereby saving substantial time and costs for co-culture procedures[51]. Most recently, organoid programing has emerged as a promising strategy for establishing both functionality and scalability. A tissue-specific set of factors were identified using computational analyses. These factors were then genetically introduced into LOs, and after manipulation of GRNs, multi-lineage tissue fate could be directed to develop multi-cellular systems. Notably, these LOs can be passaged and cryopreserved while retaining their vascular networks[66]. This scalable organoid production system may pave the way for personalized disease modeling, drug testing, and even transplantation. However, there remain challenges in the identification of liver-specific GRNs to directly re-establish the entire profile of human liver physiology and function. Other tissue engineering techniques, such as pinning bioreactors, microfluidics, and bioprinting may be developed before high-throughput and highly efficient platforms can be established to meet the practical demands of pharmaceutical and clinical applications.

Transplantation and gene editing

In addition to demonstrating utility as an *in vitro* tool in the modeling of a structural and functional organ unit, organoids are also potential transplantation substitutes for organ donors. Indeed, organoids exhibit various advantages over conventional cell-based strategies, as mentioned elsewhere[69,75]. By mimicking liver regeneration after injury, an advanced *in vitro* system was recently developed for the long-term expansion of functional LOs. Particularly, LOs generated from primary liver sources have demonstrated genetic stability after long-term culture[69,70], suggesting that these

Table 2 Up-to-date methods for obtaining expandable human liver organoids

Initial cells	Expansion systems (substrate for embedding)	Medium	Expansion capability (Split ratio/passage days/expansion duration)	Ref.
Fetal and adult hepatocytes	3D, Matrigel	AdDMEM/F12, B27, N-Acetylcysteine, gastrin, RSPO1, Noggin, Wnt, EGF, FGF7, FGF10, HGF, TGFa, Nicotinamide, A83-01, CHIR99021 and Y27632	1:3/7-8 d/> 16 passages	2018[70]

organoids are a safe transplantation source for clinical applications. Alternatively, autologous transplantation of iPSC-derived LOs is expected to be promising for the realization of reproducible and personalized liver disease treatment. As a highly prevalent disease, HBV infection remains a strong risk factor for developing liver cirrhosis, hepatocellular carcinoma, or other end-stage liver diseases, thus posing a major threat to health worldwide[76]. To this end, there exists a necessity of developing effective treatments for chronic HBV infection. Currently, the standard therapy for chronic hepatitis B infection includes two major agents. First, nucleotide or nucleoside analogs such as tenofovir and entecavir interfere with viral replication by suppressing the synthesis of reverse transcriptase; second, IFNs such as IFNα induce long-lasting immunological control[76]. However, available drugs show side effects or high response variability, and drug resistance leads to reduced long-term effectiveness. Currently, HBV infection cannot be absolutely cured[77]. Combined with the CRISPR/Cas9 genome editing technology, patient iPSC-derived organoid transplantation may provide a new therapeutic strategy for realizing a highly specific HBV treatment. As the functional regions in key HBV receptors (*e.g.*, NTCP) for HBV binding and post-binding entry have been identified, specific genetic knock-out or modification may markedly change HBV infection susceptibility, thereby permitting the development of transplanted organoids that are resistant to HBV infection. More importantly, the risk of HBV recurrence may be permanently avoided, which remains a major concern after liver donor transplantation and is associated with graft dysfunction or failure and cirrhosis progression[78].

Nevertheless, current research on organoids is in the preclinical stages, and clinical safety and efficacy remain to be established for adult or iPSC-derived LO transplantation. Moreover, the potential risks associated with genetic modification, tumorigenesis, and transplantation techniques should be emphasized in light of individual and societal values. In the context of continuing investigation regarding clinical concerns[79,80], quality-controlled and personalized LOs from authorized patient-derived cell banks are expected to be used routinely in the future.

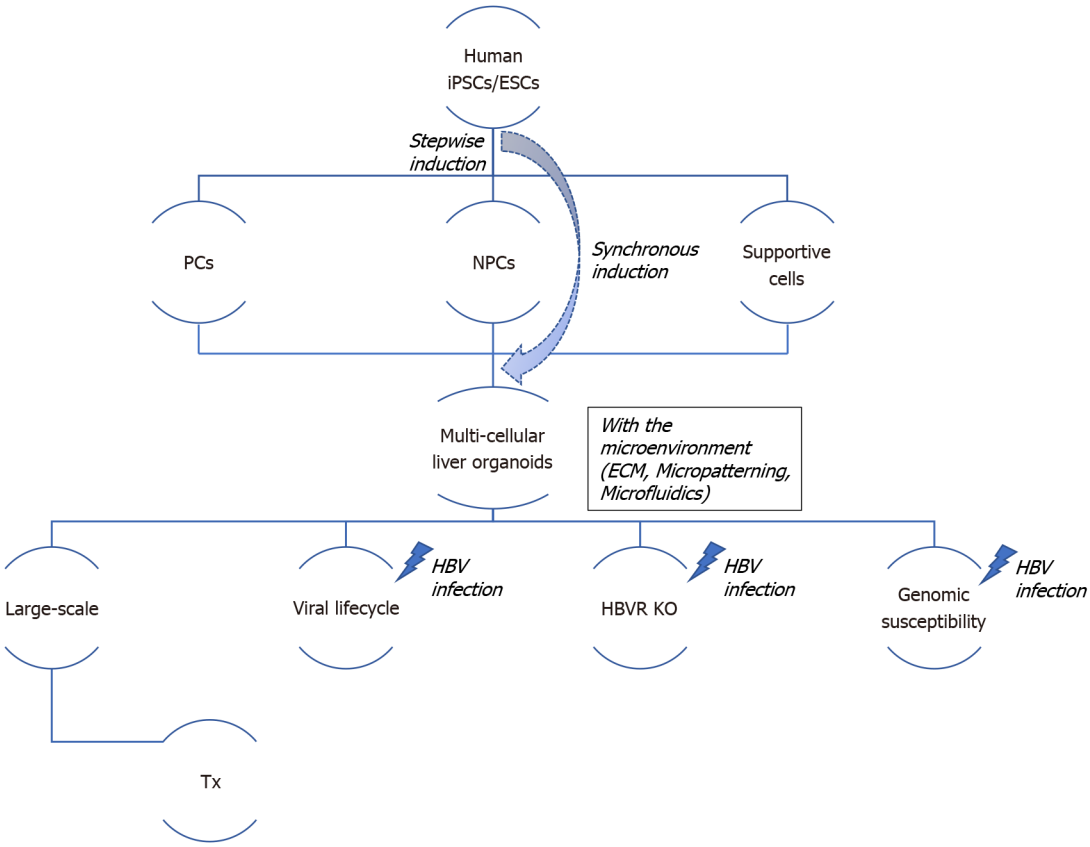

Figure 1 Schema to generate human liver organoids and strategy regarding their application potential and hepatocyte B virus modeling. Multi-cellular liver organoids are generated and self-organized with parenchyma cells, non-parenchyma cells, and other hematopoietic or/and neuronal supportive cells after stepwise induction from human induced pluripotent stem cells/embryonic stem cells; in contrast, synchronous induction using a CRISPR-based strategy markedly enhances their hepatic functions and improves their reproducibility and scalability. The personalized and population organoid system may provide a reliable platform for high-throughput hepatocyte B virus (HBV) drug screening, allowing to understand novel key points of the HBV lifecycle, gene editing to knock-out the HBV receptor, and distinguish genomic susceptibility in a large population. Transplantable multi-cellular organoids without the HBV receptor have much potential for future applications. ECM: Extracellular matrix; ESCs: Embryonic stem cells; HBV: Hepatocyte B virus; HBVR: Hepatocyte B virus receptor; iPSCs: Induced pluripotent stem cells; KO: Knock-out; NPCs: Non-parenchyma cells, including Kupffer cells, hepatic stellate cells, and liver sinusoidal endothelial cells; Supportive cells: Such as neuronal cells, hematopoietic cells, and vascular endothelial cells; PCs: Parenchyma cells such as hepatocytes; Tx: Transplantation.

PERSPECTIVES

Automated and large-scale cultural systems

Robust, consistent, and cost-effective manufacturing is extremely important for facilitating the practical applications of LOs for high-throughput disease modeling, drug testing, and therapeutic purposes. Similarly, automatic LO generation and culture systems may provide promising opportunities to meet critical requirements, especially in reproducibility and scalability.

In recent years, automated culture systems have garnered considerable attention, particularly in the maintenance and differentiation of iPSCs. Since the quality of iPSCs is dependent on the technical skills applied during culture and manipulation[81], automated culture systems can decrease technical variability. With the development of fully automated cell culture systems that have revolutionized cell seeding, medium changing, imaging, harvesting, and analysis, human iPSCs can be maintained in an undifferentiated state for a long period[82]. Additionally, reprogramming and differentiation of cardiomyocytes, hepatocytes, mesenchymal cells, neural stem cells, and retinal pigment epithelial cells have also been successfully performed using automated systems, with high quality and consistency[83-86]. Recently, an automated system was first used to produce LOs. Although the differentiation process was not fully automated, automatic LO self-assembly and maintenance substantially permitted the obtainment of reliable and reproducible results, suggesting potential applications in applied research and industry[87]. With the development of differentiation strategies and medium optimization for iPSC-derived parenchymal and non-parenchymal liver cells, the integration of automated cell production and maintenance systems is expected to further promote a completely standardized high-throughput workflow for

LO production. These workflows will enable downstream applications such as HBV and liver cancer modeling, drug screening, and regenerative medicine.

Genetic manipulation

Genetic manipulation seems extremely promising in the revelation of the biological functions of specific genes, their regulation networks, and their relevance to disease progression[88]. Moreover, genetic manipulation facilitates drug testing in various disease states with different genetic backgrounds. In recent years, the CRISPR/Cas9 technology has markedly simplified genetic engineering because of its versatility and broad application potential. Combined with the development of organoid generation and culture technology, CRISPR has enabled the establishment of multiple disease models using genetically engineered tissue-specific organoids. For example, colorectal cancer models were derived from intestinal organoids with mutations in *APC*, *SMAD4*, *TP53*, and *KRAS*[89]; injury models were derived from kidney organoids *via* podocalyxin knock-out[90]; brain tumor models were derived from cerebral organoids with mutations in *MYC* and mutations commonly found in glioblastoma[91]; and liver cancer models including hepatocellular carcinomas and intrahepatic cholangiocarcinomas were derived from LOs with mutations in *c-Myc* or *RAS*[92]. Notably, genetically modified iPSC-derived organoids may permit broader practical applications in modeling genetic diseases once consistent patient-derived organoids are developed, such as those with A1AT deficiency or Allagile syndrome. Although not reported, iPSC-derived LOs are expected to acquire altered susceptibility to HBV infection with mutated NTCP expression, which is critical in studying viral replication.

In addition to demonstrating versatility as an *in vitro* tool used for the elucidation of substantial clues to diseases, gene correction in organoid models provides a potential strategy for future gene therapy. Using the CRISPR/Cas9 genome editing system, the mutation of cystic fibrosis transmembrane conductor receptor was corrected in intestinal organoids derived from cystic fibrosis patients, which restored normal function[93]. Subsequently, mutation correction was achieved in retinal organoids derived from retinitis pigmentosa patients using a similar strategy[94]. With increasing interest in the genetic manipulation of various tissue-specific organoids, the development of a robust genome editing strategy is necessary to further enhance organoid-based disease modeling and related gene correction. Recently, CRISPR–Cas9-mediated homology-independent organoid transgenesis (CRISPR-HOT) was developed to efficiently generate knock-in human organoids[95], thus providing a powerful platform for obtaining reliable and scalable applications in this field.

However, to date, no gene editing has been performed on multi-cellular organoids, partially because of the technical difficulties in targeting specific cell types within the system. Additionally, there are several issues that are encountered with gene therapy, including off-target mutations, delivery difficulties, and the lack of standardized tests to assess anti-HBV gene therapy[96,97]. Undoubtedly, new innovations in the rapidly evolving field of the CRISPR technology may provide exciting possibilities for organoid-based clinical applications.

Susceptibility to HBV infection

The identification of NTCP, the specific receptor for HBV[98], paved the way to construct NTCP-expressing hepatoma cell lines that were originally not susceptible to HBV. Exogenous NTCP expression may render these cell lines vulnerable to HBV infection, providing a more reliable system for studying the HBV life cycle. However, this system does not help elucidate the entire HBV life cycle and permits limited viral spread, with only moderate amounts of detectable cccDNA, partially due to intrinsic deficiencies of these cell lines. As a result, an extremely high multiplicity of infection is necessary to achieve substantial infection, and the addition of polyethylene glycol is needed to enhance infection in most reported cases[99]. Meanwhile, hepatoma cells are physiologically impaired in several intracellular signaling pathways and functions after forced NTBC expression, which limits their use for studying virus-host interactions[38].

In addition to NTCP, HBV infection may also depend on other receptors, such as the sialic acid glycoprotein receptor (ASGPR)[100,101]. A comparison of iPSC-derived hepatic progenitors and HLCs revealed a significant increase in ASGPR expression in iPSC-HLCs, suggesting that ASGPR might be considered a candidate receptor for hepatitis virus infection in mature hepatic cells and might mediate HBV entry into cells. To date, NTCP expression is considered the most important factor for HBV infection in host cells[13]. However, it remains necessary to identify other unknown receptors or media that contribute to hepatitis virus infection susceptibility. The emergence of 3D multi-cellular LOs, which mimic the native liver microenvironment,

has attracted substantial attention owing to its superior HBV susceptibility compared to 2D culture[15]. Although the underlying mechanism remains unclear, these organoids may provide an opportunity for the investigation of potential receptors and related pathways involved in viral infection. Computational analyses, followed by sequential knock-out of the candidate targets in engineered multi-cellular LOs, may enable the complete understanding of the key genes contributing to HBV susceptibility. Furthermore, the role of ethnic genotypes in viral susceptibility may be studied using this system. Individuals of different races present with different susceptibilities to hepatitis virus. For example, Chinese populations have a high susceptibility to hepatitis B, while European and American populations are prone to hepatitis C infection. It would be beneficial to use iPSC-derived LOs from different genomic backgrounds to compare HBV infection in different populations with the same risk factors, or to compare susceptibility in the same population with different risk factors. In this regard, drugs, which may account for disparities in different populations and individuals, may also be developed.

CONCLUSION

With the progressive understanding of liver organogenesis, the development of 3D organoid culture systems has helped in the establishment of a novel platform for precise and personalized liver disease modeling. However, it remains particularly challenging to promote the efficiency, reproducibility, and scalability of organoid reconstitution and maintenance. It is expected that future advances in genetical engineering and automated culture system will put 3D multi-cellular organoids into a variety of practical uses, including hepatitis infection modeling and related drug development. Furthermore, the proof of concept for clinical-grade patient iPSC-derived multi-cellular LOs is expected and will contribute much to modeling and treatment of hepatitis virus infection and other liver diseases.

ACKNOWLEDGEMENTS

We thank Dr. Chen SL for helpful discussion, and Drs. Li YM and Liu LP for kind support in Institute of Regenerative Medicine of Jiangsu University.

Abstract

Colorectal cancer remains a leading cause of morbidity and mortality in the United States. Advances in artificial intelligence (AI), specifically computer aided detection and computer-aided diagnosis offer promising methods of increasing adenoma detection rates with the goal of removing more pre-cancerous polyps. Conversely, these methods also may allow for smaller non-cancerous lesions to be diagnosed *in vivo* and left in place, decreasing the risks that come with unnecessary polypectomies. This review will provide an overview of current advances in the use of AI in colonoscopy to aid in polyp detection and characterization as well as areas of developing research.

Key Words: Colonoscopy; Artificial intelligence; Computer-aided detection; Detection; Characterization; Computer-aided diagnosis

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The rapidly evolving field of artificial intelligence (AI) has found many applications in the field of colonoscopy. Specifically, we describe the technologies that have been developed to detect and characterize colonic polyps with the goal of real-time analysis as well as minimizing the risks of avoidable polypectomies. Additionally, we discuss some of the future directions of AI in this area including advancements in robotic technology.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer and the second leading cause of cancer related death in men and women in the United States. The incidence of CRC has been declining for over 30 years due in part to screening colonoscopies that detect and remove pre-cancerous polyps[1].

The adenoma detection rate (ADR) is a metric used by endoscopists representing the percentage of time at least one adenoma is detected on screening colonoscopies[2]. Adenoma detection rates differ widely among endoscopists, between 7% to 52%, with higher ADRs associated with a decreased risk of CRC. It is now recommended that endoscopists target an ADR target ≥ 25%[3]. Artificial intelligence (AI), specifically computer-aided detection (CADe) software is being studied to detect polyps during colonoscopy with the goal of increasing adenoma detection rates[2,4,5].

Broadly, artificial intelligence (AI) relates to the ability of a computer program to obtain outside data (*e.g.*, images) and to subsequently take independent actions towards a particular goal (*e.g.*, pattern identification). Machine learning is a form of AI that relies on the analysis of large datasets in order to make predictions that can be used for decision making. Deep learning, a subtype of machine learning, uses an artificial neural network comprised of layers of interconnected "computing units" that mimic biological neural connections and allow for complex "understanding" of input data. This neural network allows the computer program to learn independently from unstructured input data. Many times a deep learning program can process a large number of photos, independently identify patterns among them, and then use that information to make predictions about new images. This powerful technology that has been used to train machines in image and sound recognition is now being applied in the medical field in the form of computer-aided diagnosis and detection, which applies AI and computer vision technologies to the diagnosis of various pathologies. The technology is rapidly expanding in areas like colonoscopy where there is significant room to mitigate human error in visual diagnosis.

Many polyps detected and resected during colonoscopies are diminutive polyps (≤ 5 mm), and a significant number of these are non-neoplastic. Polypectomy increases the risk of complications during colonoscopy, including the risk for bleeding and perforation[6]. Computer-aided diagnosis (CAD) technology has been studied to characterize the histology of polyps *in vivo*.

The American Society for Gastrointestinal Endoscopy's Preservation and Incorporation of Valuable Endoscopic Innovations (PIVI) initiative has provided guidelines that aim to reduce the cost and need for pathological assessments in addition to reducing the risks associated with polypectomy. The PIVI's first guideline is known as "resect and discard", which entails resecting the diminutive polyp and discarding if the CAD technology used to characterize the polyp has a similar surveillance interval compared to the traditional pathology assessment (≥ 90%). The PIVI's second guideline allows the endoscopist to leave hyperplastic diminutive polyps in place in the rectosigmoid area if the CAD technology has a NPV ≥ 90% for characterizing adenoma histology[7].

COLORECTAL POLYP DETECTION

The first study to use CADe to detect colorectal polyps was published in 2003[8-11]. Karkanis *et al*[8] used wavelet transformation technology to detect polyps with a sensitivity of 93.6% and specificity of 99.3%. Years later, deep learning networks were applied to CADe, which has paved the way for *in vivo* and real-time analysis studies.

Urban *et al*[2] was the first to use CADe for polyp detection in real-time. The study assessed 9 standard colonoscopy videos. At the time of the colonoscopies, 28 polyps were identified and removed. Using CADe, an additional 17 polyps were detected, compared to only an additional 8 that were identified by an expert endoscopist[2,9]. Klare *et al*[12] then applied CADe in real time and *in vivo* to 55 colonoscopies. The ADR of the CADe was similar to the endoscopists' (29.1% and 30.9%, respectively). However, the CADe was inferior in detecting flat and small polyps.

More recently, there have been randomized control trials (RCTs) performed in real-time using colorectal polyp detection technology. Wang *et al*[4] included 1058 patients in a non-blinded study, 536 were randomized to colonoscopy and 522 were randomized to colonoscopy with CADe. The ADR was statistically superior in the colonoscopy with the CADe group compared to the control group (29.1% *vs* 20.3%). Moreover, CADe was better at detecting diminutive adenomas, but there was no difference in detection rate for polyps larger than 5 mm. Notably, the CADe did not miss any polyps, but had 39 false positives alarms for polyps[5]. Wang *et al*[4] then performed a double blinded RCT in which patients were randomized to a colonoscopy with sham system (n = 478) or a colonoscopy with CADe (n = 484) group. Results showed the ADR was 34% in the CADe group, which was superior to the control group, 28%. Gong *et al*[13] randomized 704 patients in a partially blinded RCT to CADe assisted colonoscopy or control standard colonoscopy. Similarly, the ADR was significantly better in the CADe group than the control group (16% compared to 8%, respectively). Repici *et al*[14] performed a similar nonblinded RCT and found an ADR of 54.8% in the colonoscopy with CADe group, which was significantly better than the ADR for the control group (40.4%). The CADe was also able to detect more adenomas that were < 10 mm in size compared to the control group. The authors also found that there was no significant difference in withdrawal time (excluding biopsy time) of the endoscope between the two groups. Liu *et al*[15] randomized 1026 patients to CADe or control groups. The ADR was significantly better in the CADe group (39%) than the control group (23%). The CADe did not miss any polyps and there were only 36 false positive alarms. It was also noted that the withdrawal times between groups were similar (CADe 6.16 minutes compared to control 6.11 min).

Su *et al*[16] created an automatic quality control system (AQCS) to improve aspects of colonoscopy using a deep learning model. They randomized 659 patients and found that the AQCS group had a superior ADR than the control group (28.9% *vs* 16.5%). However, they found the AQCS had a longer withdrawal time (excluding biopsy time) compared to the control group (7.03 ± 1.01 min *vs* 5.68 ± 1.26 min).

Recent meta-analyses have concluded that CADe was accurate at detecting adenomas[17,18]. Barua *et al*[17] included 5 RCTs (with a total of 4311 patients) and concluded the ADR was significantly better using CADe with colonoscopy (29.6%) than colonoscopy alone (19.3%), with a false positive alarm mean of 11.2%. Lui *et al*[18] analyzed 6 studies that used CADe and found the accuracy of CADe was 90% with sensitivity and specificity of 95% and 88% respectively. In both studies, colonoscopy with CADe improved detection of diminutive adenomas[17,18].

A significant limitation of CADe technology is the potential to have high false positive alarm rates. Even though Wang *et al*[5] and Liu *et al*[15] had low rates, Hassan *et al*[19] reported a total of 1092 false positive alarms, which averaged 27.3 per colonoscopy. Also, many of the studies assessing CADe had control groups with low ADRs between 8%-23%[5,13,15,16], which is below the recommended target ADR of ≥ 25%[3].

Table 1 summarizes the key recent studies in colorectal polyp detection.

POLYP CHARACTERIZATION

Going beyond merely identifying polyps, AI has been applied to provide real-time *in vivo* diagnoses of neoplastic *vs* non-neoplastic lesions. A number of different modalities for this have been described over the years.

White light endoscopy

Traditional white light (WL) endoscopy is the most familiar modality used by endoscopists today. High-definition white light (HDWL) endoscopy is the most recent improvement in this area. Recent randomized controlled trials have demonstrated that HDWL is non-inferior to other modalities, specifically narrow band imaging (NBI) and chromoendoscopy[20-22]. In 2016, Rex *et al*[20] found that there was no statistically significant difference in the number of serrated lesions detected in 804 patients randomized to undergo either WL or NBI endoscopy. The same year, Klare *et al*[21] published the results of a trial that randomized 380 patients to either HDWL or NBI. They also found no statistically significant advantage of one modality over the other in distinguishing between neoplastic and non-neoplastic polyps. Yang *et al*[22] randomized 210 patients with ulcerative colitis to undergo colon cancer screening with HDWL or chromoendoscopy and found no significant difference in dysplasia detection rates between the two modalities (5.6% for HDWL *vs* 3.9% for chromoen-

doscopy).

In 2017, Komeda *et al*[23] designed and tested a CAD system based on a convolutional neural network to augment WL endoscopy. It functioned as an AI system that trained with previously collected colonoscopy images to assist endoscopists in detecting and diagnosing colon polyps during WL endoscopy. After training on 1200 images, their CAD-neural network system correctly differentiated between adenomatous and non-adenomatous polyps in 70% of newly presented cases[23].

This strategy of applying AI to the detection and classification of colorectal lesions using WL endoscopy has continued to be an area of active study. Researchers have shown that CAD, using both convolutional neural networks and deep learning models, promises to identify suspicious lesions and accurately classify them[24-26]. Zheng *et al*[24] developed a convoluted neural network (CNN) to be used with WL endoscopy. They trained their AI system with over 600 polyp-containing images from independent public databases and found that their diagnostic model had a sensitivity of 68.3% and a precision of 79.3% when applied to 196 new polyp-containing images [24]. However, they found significant variation in model performance depending on which image database was used to train the CNN, and they also only trained and tested their CNN on still images[24]. Going beyond polyp identification, Yang *et al*[26] developed a deep learning (DL) model to assist in classification of colorectal lesions during WL endoscopy. They trained their model on 3828 images and validated it on a set of 240 new images. When classifying lesions as neoplastic *vs* non-neoplastic, their model had a sensitivity of 95.4% and specificity of 30.1%[26]. Their model was also able to classify advanced lesions (high grade dysplasia and stages T1-T4 CRC *vs* non-advanced (tubular adenomas and non-neoplastic lesions) with a sensitivity of 80.0% and specificity of 91.3%[26].

A recent prospective crossover study conducted by Wang *et al*[25] compared traditional WL colonoscopy to CAD-assisted colonoscopy in 369 patients. Patients requiring colonoscopy underwent either traditional WL colonoscopy or CAD-assisted colonoscopy immediately followed by the other, such that each study participant underwent both methods. They found that the adenoma miss rate was 40% for those undergoing traditional colonoscopy first *vs* 14% in those undergoing CAD-assisted colonoscopy first[25]. Polyp detection followed a similar trend with a miss rate of 46% in those undergoing traditional colonoscopy first *vs* 13% in those undergoing CAD-assisted colonoscopy first[25]. Interestingly, of the adenomas missed, participants undergoing CAD-assisted colonoscopy were less likely to have polyps under 5mm and under 10 mm missed, suggesting that CAD is particularly helpful in identifying

smaller lesions[25].

The key studies for polyp characterization using white light endoscopy are summarized in Table 2.

Narrow band imaging

Narrow band imaging (NBI) is used to enhance visualization of vascular patterns in the epithelium of lesions to aid in the classification of polyps[27-29]. However, training and experience is needed to operate NBI; therefore, studies have applied computer-aided diagnosis to NBI[27,29-34].

Tischendorf *et al*[29] was the first to apply CAD to magnified NBI. The CAD evaluated 209 polyps and assessed for three vessel features on each NBI image, then a support vector machine was used to classify the polyp as neoplastic or non-neoplastic. It had an accuracy of 85.3%, sensitivity of 90% and specificity of 70.2%. When compared to the consensus of the investigators (accuracy 91.9%, sensitivity 93.8%, and specificity 85.7%), the CAD was inferior. Gross *et al*[27] performed a similar study with 434 polyps, but assessed for nine vessel features. The CAD had an accuracy of 93.1%, sensitivity of 95%, specificity of 90.3%, and NPV of 92.4%, which was comparable to the results of the expert endoscopists and superior to the novice endoscopists.

Years later, Byrne *et al*[30] and Chen *et al*[31] improved CAD by creating deep learning models to analyze NBI images and categorize polyp histology. Both studies only included diminutive polyps (≤ 5 mm). Chen *et al*[31]'s deep learning model assessed still NBI images of 284 polyps and classified polyps with an accuracy of 90.1%, sensitivity of 96.3%, specificity of 78.1%, PPV of 89.6%, and NPV of 91.5%. The authors also studied the diagnosis time, which was statistically faster for the deep learning model than both expert and novice investigators[31]. Byrne *et al*[30]'s deep learning model assessed 125 endoscopy NBI video segments of polyps. Of the classified polyps, the accuracy was 94% with sensitivity 98%, specificity 83%, PPV 90%, and NPV 97%. However, the model was not able to classify 15% of polyps due to a lack of confidence. All of the CAD with NBI studies named above with the exception of Tischendorf's initial study met the PIVI criteria for resect and discard or diagnose and leave in situ[7,27,30,31].

Few prospective studies have been performed with CAD using NBI imaging to classify polyp histology. Kominami *et al*[32] evaluated 118 polyps with NBI. The CAD had an accuracy of 94.9%, sensitivity of 95.9%, specificity of 93.3%, PPV of 95.9%, and NPV 93.3%. The authors used this data to investigate colonoscopy surveillance interval which did not change in 38 of the 41 patients when using the CAD results to classify polyps. Mori *et al*[33] also performed a study assessing CAD when used with NBI on 466 diminutive polyps. The NPV for rectosigmoid neoplastic polyps ranged from 95.2% to 96.5% depending on the worst or best case scenario respectively.

Most recently, Song *et al*[35] created a CAD using a deep learning model and tested it *in vivo* by sending still NBI images during the colonoscopy to a computer. The CAD then categorized the histology in real time. The polyps were classified as serrated, benign adenoma, or deep submucosal cancer with an accuracy of 82.4%, which was superior to trainees (63.8%), but inferior to expert endoscopists (87.3%). The accuracy of trainee endoscopists improved with the addition of CAD to 82.7% showing that CAD can increase the accuracy in this group.

Table 3 provides a summary of the key recent studies of polyp characterization using narrow band imaging.

Laser-induced fluorescence spectroscopy

Another strategy currently under investigation to optically diagnose lesions during endoscopy is laser-induced fluorescence spectroscopy. This diagnostic method relies on low-power laser radiation to induce fluorescence in tissues that can differentiate normal from neoplastic lesions[36]. In recent years, CAD systems have been developed to analyze the fluorescent spectra produced when tissues are exposed to a laser. These CAD systems take advantage of the differences between the fluorescence of normal and pathological tissue to predict the likelihood that a lesion is abnormal.

Kuiper *et al*[37] and Rath *et al*[38] studied a laser-induced fluorescence spectroscopy system designed to be used in real-time to help clinicians make decisions regarding biopsy and resection of concerning lesions. However, it is important to note that the accuracy of the algorithm used by Kuiper *et al*[37] was 73.4% and the NPV only 74.4%, falling short of the performance thresholds of the American Society for Gastrointestinal Endoscopy's PIVI initiative for diminutive lesions. The pilot study conducted by Rath *et al*[38] was more promising, with an overall accuracy of 84.7%, sensitivity of 81.8%, specificity of 85.2%, and NPV of 96.1%. A 2017 randomized controlled trial by Min *et al*[39] was further able to demonstrate that use of linked color

imaging technology (which enhances the colors produced by laser endoscopic modalities) improved overall polyp detection rate when compared to traditional white light endoscopy (polyp detection rate 73% for WL and 91% with linked color imaging).

The recent key studies of laser-induced fluorescence spectroscopy are summarized in Table 4.

Autofluorescence endoscopy

Autofluorescence imaging (AFI) is a form of image enhanced endoscopy that differentiates tissues based on their various abilities to capture and reflect fluorescent light [40]. Similar to laser-induced fluorescence spectroscopy, this method takes advantage of endogenous reflective properties of various tissues (fluorophores), but instead of using a laser emitting an exact wavelength of light, AFI uses incoherent light sources. This technology aims to visually highlight tumors, which have more heterogeneous fluorescence on their surface compared to normal colonic mucosa. This image-enhancement displays normally fluorescing mucosa as green and abnormally fluorescing mucosa as red/purple.

In a 2019 study of 802 patients randomized to undergo either AFI endoscopy or white light endoscopy, Takeuchi *et al*[41] found that using AFI during endoscopy increased the number of flat neoplasms detected overall compared to WL, especially in the ascending colon. However, the overall detection rate of advanced neoplasms was not significantly improved with AF compared to WL[41]. In a meta-analysis of 11 studies, Wanders *et al*[42] calculated that the sensitivity and specificity of autofluorescence imaging for the optical diagnosis of colonic lesions were 86.7% and 65.9% respectively. This led the authors to conclude that AFI is not as reliable as other methods for visual diagnosis of colonic neoplasms. This was further confirmed in a 2018 meta-analysis by Imperatore *et al*[43] which found no significant difference between the dysplasia detection rates between AFI and WL (OR = 1.42, 95%CI: 0.74-4.11) when combining the results of two randomized controlled trials representing 92 patients undergoing surveillance colonoscopy.

More recently, researchers have developed CAD systems that can further characterize the images obtained during AFI endoscopy using software that can calculate the green to red light ratios of various tissues encountered during colonoscopy[44-47]. Such developments may help differentiate lesions from normal mucosa in cases where the green to red variation is less obvious, improving on the results of the studies looking at the use of AFI without the use of CAD.

Arita *et al*[44] created a color-contrast index (CCI) for AFI. Their CCI was developed from 54 colorectal lesions found in 43 patients who underwent either WL or AFI endoscopy. They found that as the CCI increased (*i.e.*, greater contrast between the lesion and the adjacent normal tissue), so did the malignant potential of the assessed lesion (*i.e.*, carcinomas had higher CCIs on average compared to adenomas)[44]. Aihara *et al*[45] expanded on this idea by using color-analysis software to calculate red/green ratios (RGR) for 102 Lesions in 32 patients undergoing AFI endoscopy. In their study, they were able to differentiate neoplastic from non-neoplastic lesions with sensitivity of 94.2%, specificity of 88.9%, PPV of 95.6%, and NPV of 85.2%[45]. In a similar study, Inomata *et al*[46] also calculated RGRs to distinguish between non-

Table 3 Narrow band imaging

neoplastic lesions, adenomas plus superficial cancers, and deep cancers. They were able to characterize hyperplastic polyps and neoplastic lesions, with sensitivity of 83.9%, specificity of 82.6%, PPV of 53.1%, and NPV of 95.6%[46]. Additionally, they were able to differentiate between adenomas plus superficial cancers and deep submucosal cancers with a sensitivity of 80.0%, specificity of 84.4%, PPV of 29.6%, and NPV of 98.1%[46].

In 2019, Horiuchi *et al*[47] developed software to calculate real-time RGR ratios with the specific goal of identifying diminutive neoplastic rectosigmoid polyps (≤ 5 mm). Using their CAD-assisted AFI endoscopy, they identified 429 diminutive polyps (258 rectosigmoid) in 95 patients. The endoscopists then confirmed whether the lesions identified with the CAD-assisted AFI were actually diminutive neoplastic polyps with trimodal imaging endoscopy (TME) combining findings of WL, AFI, and NBI. The CAD-assisted AFI software was able to identify diminutive neoplastic polyps with a sensitivity of 80.0%, specificity of 95.3%, PPV of 85.2%, and NPV of 93.4%[47].

Table 5 contains a summary of the key recent studies involving autofluorescence endoscopy.

Magnifying chromoendoscopy

In the technique of magnifying chromoendoscopy, suspected colonic lesions are washed with proteinases and colored with an indigo carmine or crystal violet solution in order to allow better visualization of the surface under magnification up to 150 times[48]. In a systematic review, Brown *et al*[49] showed that chromoendoscopy

significantly increased both the number of patients with polyps (OR = 1.87, 95%CI: 1.51-2.3) and neoplasms detected (OR = 1.53, 95%CI: 1.31-1.79). Kudo *et al*[48] demonstrated that certain pit patterns on magnifying chromoendoscopy are associated with malignancy, showing sensitivity of 97.8%, specificity of 91.4%, and accuracy of 97.1%. Kanao *et al*[50] demonstrated that magnifying chromoendoscopy can be used to differentiate severely irregular lesions from those with only mild irregularities, a key distinction as 56.1% of the former are associated with deep submucosal invasive

adenomas *vs* only 6.7% of the latter.

Several automated computer-based systems have been developed for analysis of pit patterns. The system developed by Takemura *et al*[51] was able to accurately diagnose 132 out of 134 (98.5%) of images captured with magnifying chromoendoscopy demonstrating that artificial intelligence aided systems can reliably predict histological changes compared to endoscopists. Häfner *et al*[52] used texture analysis of magnified chromoendoscopic images to achieve accuracy as high as 99.59%. Recent work by Qi *et al*[53] further showed that artificial intelligence can be used to quantify colonic crypts and provide objective measures of area, density, eccentricity, solidity, straightness, and parallelism which in turn can be used to reduce variability compared to human observation.

Recent studies on the use of magnifying chromoendoscopy in polyp characterization are summarized in Table 6.

Endocytoscopy

The technique of endocytoscopy uses a contact light microscope attached to a colonoscope to provide endoscopic images with ultra-magnification up to 520 times. The addition of staining allows for real-time histological diagnoses to be made. Studies have shown that the accuracy of this technique is comparable to traditional biopsy [54]. However, a major limitation is the need for expert experience in order to make real-time diagnoses. CAD has been developed in response to this shortcoming.

In 2015, Mori *et al*[54] described the use of an endocytoscopic imaging computer-aided diagnostic system. In this study, 39 non-neoplastic and 176 neoplastic small colorectal polyps less than 10 mm in size were analyzed by artificial intelligence software and compared to the results of both expert and trainee endoscopists. They showed comparable sensitivity (92% *vs* 92.7%) and accuracy (89.2% *vs* 92.3%) of the computer-aided diagnostic system compared to experts[54]. Moreover, the artificial intelligence program performed significantly better than trainee endoscopists who only had sensitivity of 81.8% and accuracy of 80.4%[54]. Takeda *et al*[55] described the development of a CAD system that used 5543 endocytoscopic images for machine learning. Following this, 188 images of a mix of adenomas and invasive cancers were analyzed by the CAD system and compared to pathological diagnoses with 89.4% sensitivity, 98.9% specificity, 98.8% accuracy, 98.8% PPV, and 90.1% NPV[55]. Moreover, the system used a support vector machine to calculate the probability of results being classified accurately. The study specifically looked at high-confidence diagnoses described as those having a ≥ 90 % probability of being correct. Out of 188 images analyzed, 134 fell into this category with 98.1% sensitivity, 100% specificity, 99.3% accuracy, 100% PPV, and 98.8% NPV[55].

In 2018, Mori *et al*[33] showed the efficacy of real-time endocytoscopy with CAD in detecting diminutive polyps ≤ 5 mm in size. 466 polyps were assessed with 98.1% pathologic prediction rate, 93.8% sensitivity, 90.3% specificity, and 94.1% PPV. Moreover, they were able to demonstrate overall negative predictive value of 96.4% which is significantly above the threshold for a "diagnose-and-leave" treatment strategy. However, the study only demonstrated 65.8% NPV for lesions proximal to the recto-sigmoid area[33].

In 2020, Kudo *et al*[56] performed a study to evaluate the efficacy of an AI system that uses endocytoscopic images to look at cell nuclei, crypt structure, and microvessels. It was able to identify malignant lesions with 96.9% sensitivity, 100% specificity, 98% accuracy, 100% PPV, and 94.6% NPV. Compared to expert endoscopists with 92.8% sensitivity, 94.3% specificity, and 93.9% accuracy as well as trainee endoscopists with 70.8% sensitivity, 65.7% specificity, and 69% accuracy, this CAD system significantly outperformed both groups[56].

Table 7 summarizes the key recent studies in endocytoscopy.

Confocal endomicroscopy

Anatomic variation can hinder accurate traditional endoscopic biopsy. Confocal endomicroscopy produces high resolution magnification of the mucosal layer of the gastrointestinal tract using laser illumination with simultaneous detection of light reflected from the tissue through a narrow pinhole. By filtering out light that is scattered from angles outside of layers corresponding to mucosa in question, this technique allows for high spatial resolution and real-time endoscopic evaluation of targeted areas of tissue. Compared to normal colonic mucosa with well-organized crypt structures, malignancy causes irregularities and interruptions[57].

André *et al*[58] designed software that used probe-based confocal laser endomicroscopy to automatically classify colonic polyps. 135 images with both neoplastic and nonneoplastic polyps were analyzed by the automated software with 92.5% sensitivity,

Table 6 Magnifying chromoendoscopy

Ref.	Study design	Algorithm type	Dataset	Results
Takemura *et al*[51]	Partially blinded retrospective study	CAD using HuPAS	134 pit pattern images	Accuracy: 98.5%
Häfner *et al*[52]	Partially blinded retrospective study	CAD using Dual-Tree Complex Wavelet Transform	484 RGB pit pattern images	Accuracy: 99.59%
Qi *et al*[53]	Diagnostic model development	CAD using automated imaged analysis	79 colon samples (14 normal, 44 normal tissue adjacent to cancer, 21 malignant)	Automated segmentation achieved precision ratio of 0.69 and match ratio of 0.73

CAD: Computer-aided diagnosis.

83.3% specificity, and 89.6% accuracy which was not significantly different compared to diagnosis by two expert endoscopists with 91.4% sensitivity, 85.7% specificity, and 89.6% accuracy. Ştefănescu *et al*[59] retrospectively analyzed 1035 endomicroscopic images processing them through a CAD system that allowed for feature identification *via* fractal analysis of glandular structures showing that homogeneity and feature number were significantly different in malignancy. In turn, this was used to design an artificial intelligence program with a diagnosis error rate of 15.5%[59].

One problem with early probe-based confocal endomicroscopic images is the need for high-level magnification which leads to a long learning-time for automated image interpretation. Taunk *et al*[60] showed the efficacy of a CAD algorithm that utilized a lower magnification method with a wider field-of-view necessitating less images. The algorithm demonstrated similar sensitivity, specificity, and accuracy compared to expert endoscopists (95% *vs* 98%, 94% *vs* 95%, and 94% *vs* 96% respectively) and significantly better performance than less experienced endoscopists who only had sensitivity of 60%, specificity of 85%, and accuracy of 73%[60].

The recent key studies on confocal endomicroscopy are summarized in Table 8.

FUTURE DIRECTIONS

Automated polyp detection and characterization

Many studies have been performed using AI to detect or classify the histology of colorectal polyps; however, little research has been done on simultaneous detection and classification of colorectal polyps using AI. Mori *et al*[33] combined previously studied CADe and CAD systems to develop AI technology that is able to detect then characterize the colorectal polyps[61,62]. White-light imaging was used to detect polyps with an accuracy of 94%[61,62]. Then, classification of the polyps was then performed using magnified NBI with a NPV of 95.2%[33,61]. Ozawa *et al*[34] created a deep convolutional neural network (DCNN) that detected polyps using white light or NBI with a sensitivity of 92% and a PPV of 86%. The DCNN then classified the polyps using either white light with an accuracy of 83% and NPV of 90% or NBI with an accuracy of 81% and NPV of 91%. Further research is needed in concurrent automated detection and characterization of colorectal polyps.

Robotics

Much of the work in robotics has centered around the use of self-propelling colonoscopes and less on polyp detection. Recent studies on the use of robotics in colonoscopy are summarized in Table 9.

Eickhoff *et al*[63] demonstrated the first use of a novel computer-assisted colonoscope in 2007 that would change shape at 16 different segments depending on insertion depth in an effort to decrease discomfort from colonoscope looping. While it required an endoscopist to steer the scope, the device used CAD to change shape as it was advanced. The device was able to intubate the cecum in 100% of patients with no complications at discharge, 48 h, and 30 d[63].

In 2016, Pullens *et al*[64] demonstrated the utility of colonoscopy with robotic steering and automated lumen centralization (RS-ALC). In a study of 18 endoscopists including 8 experts and 10 novices, the addition of RS-ALC significantly improved the time to intubate the cecum in novices (8 min 56 s compared to baseline 11 min 47 s without RS-ALC) as well as polyp detection rate (88.1% *vs* 78.6%)[64]. However,

Table 7 Endocytoscopy

Ref.	Study design	Algorithm type	Dataset	Results
Mori *et al* [54]	Pilot study	CAD using EC-CAD	176 colorectal polyps from 152 patients	Accuracy: 89.2% Sensitivity: 92% Specificity 79.5%
Takeda *et al* [55]	Retrospective study	CAD using EC-CAD	5543 endocytoscopy images for machine learning. 200 test images	Overall Accuracy: 94% Sensitivity: 89.4% Specificity: 98.9% PPV: 98.8% NPV: 90.1% High-confidence diagnosis Accuracy: 99.3% Sensitivity: 98.1% Specificity: 100% PPV: 100% NPV: 98.8%
Mori *et al* [33]	Single-group, open-label, prospective study	Real-time CAD during colonoscopy	466 diminutive polyps from 325 patients	Accuracy: 98.1% Sensitivity 93.8% Specificity 90.3% PPV 94.1% NPV 89.8%
Kudo *et al* [56]	Retrospective study	CAD using EndoBRAIN	100 polyps from 89 patients	Accuracy: 98% Sensitivity 96.9% Specificity 100% PPV 100% NPV 94.6%

CAD: Computer-aided diagnosis.

similar results were not seen with expert endoscopists whose time to intubate the cecum actually increased (13 min 1 s compared to baseline 2 min 9 s without RS-ALC) and polyp detection rate decreased (69% *vs* 80.9%)[64]. Slawinski *et al*[65] demonstrated the use of an *in vivo* autonomously controlled highly compliant magnetic flexible endoscope with diagnostic and therapeutic capability using an actuating permanent magnet in animal studies. They were able to conduct autonomous endoscopic retroflexion with 100% success in 30 attempts without perforation or trauma in pigs. However, diagnostic capability was worse than traditional endoscopy with an average detection miss rate of 21.7% and completion time of 575 s (compared to 5% and 257 s). When looking at lesion targeting alone, the robotic program took on average 251 s to identify lesions compared to only 32 s with traditional endoscopy[65].

In 2020, Formosa *et al*[66] showed the use of a sensor-enabled treaded robotic colonoscope with multiple degrees of freedom which was notable for containing all the functions of a traditional endoscope including direct visualization, channels for insufflation and irrigation as well as a tool port for endoscopy. It also had inertial measurement technology in addition to a magnetometer, motor encoders, and motor current sensors for future autonomous use. *Ex-vivo* porcine results showed locomotion ability up to 40 mm/s[66].

Table 8 Confocal endomicroscopy

Ref.	Study design	Algorithm type	Dataset	Results
André*et al* [58]	Diagnostic model development	CAD using content based image retrieval (CBIR) approach	135 polyps from 71 patients	Accuracy: 89.6% Sensitivity 92.5% Specificity 83.3%
Ştefănescu *et al*[59]	Diagnostic model development	CAD using NAVICAD and a two layer CNN	1035 endomicroscopy images including 725 for training, 155 for validation, and 155 for testing.	Testing decision accuracy error rate of 15.48% (24 out of 155 images)
Taunk *et al* [60]	Feasibility study	CAD using expectation-maximization algorithm	189 endomicroscopy images from 26 patient	Accuracy: 94.2% Sensitivity 94.8% Specificity 93.5%

CAD: Computer-aided diagnosis; CNN: Convoluted neural network.

Table 9 Robotics

Ref.	Study design	Algorithm type	Dataset	Results
Eickhoff *et al*[63]	Prospective, nonrandomized, unblinded feasibility study	CAD using NeoGuide Endoscopy System	10 patients	100% cecal intubation rate. Median time to cecum 20.5 min. 0 complications or adverse effects reported at discharge, 48 h, and 30 d
Pullens *et al*[64]	Randomized control trial with crossover design	CAD using automated lumen centralization	8 expert endoscopists and 10 endoscopy-naïve novices performing endoscopy on a validated colon model with 21 polyps	Novice Accuracy: 88.1% Time to cecum: 8 min 56 s Experts Accuracy: 69% Time to cecum: 13 min 1 s

CAD: Computer-aided diagnosis.

CONCLUSION

Traditional colonoscopy has been shown to reduce colon cancer incidence by more than 80%[67]. The application of artificial intelligence, computer-aided detection, and computer-aided diagnosis to this field provides possibilities for improving an already powerful tool. Namely, the possibility of combining these technologies for real-time endoscopic detection and analysis of lesions overall makes the procedure less operator dependent. With the ability to identify smaller diminutive lesions as non-cancerous, these techniques also offer time and resource savings. Given the widespread use of colonoscopy as a screening test and an aging world population, this potentially translates to billions of dollars in cost reductions and even the possibility of extending screening intervals. Multiple modalities have shown to increase adenoma detection rates and have negative predictive values > 90%, meeting the goals of the ASGE's PIVI initiatives.

However, multiple challenges remain including a lack of large multicenter clinical trials and comparison of computer-aided detection and diagnosis modalities. Additionally, more widespread regulatory approval on government and payer levels is needed. There is still much room for clinical research following software development and more prospective studies evaluating the real-life application of these technologies in the endoscopy suite. Nonetheless, continued development of CADe, CAD and AI in colonoscopy offers patients the possibility of living longer and healthier lives.

Abstract

Hepatitis C virus (HCV) is a global health concern associated with significant morbidity and mortality. Before the approval of second-generation direct-acting antiviral agents (DAAs), interferon therapy and liver transplantation constituted the mainstay of treatment. The introduction of well-tolerated oral DAAs in late 2013 has revolutionized HCV management with over 95% cure rates. The predominance of HCV-related liver transplantations has declined following the widespread approval of DAAs. Despite the unparallel efficacy observed among these novel therapies, pharmaceutical costs continue to limit equitable access to healthcare and likely contribute to the differential HCV infection rates observed globally. To reduce the burden of disease worldwide, essential agenda items for all countries must include the prioritization of integrated care models and access to DAAs therapies. Through transparent negotiations with the pharmaceutical industry, the consideration for compassionate release of medications to promote equitable division of care is paramount. Here we provide a literature review of HCV, changes in epidemiologic trends, access issues for current therapies, and global inequities in disease burden.

Core Tip: Hepatitis C virus (HCV) is a global health concern associated with significant morbidity and mortality. The introduction of well-tolerated oral direct-acting antiviral agents in late 2013 has revolutionized HCV management with over 90% cure rates. Equitable access to these agents remains an important issue, given that countries with the greatest burden of disease have the least access to curative therapies. Here we provide a literature review of HCV, changes in epidemiologic trends, current therapies, and highlight inequities in the burden of disease and access to treatment.

INTRODUCTION

Hepatitis C virus (HCV) is a blood-borne RNA virus first described in the 1980s. During the acute phase of the infection, a large proportion of individuals are asymptomatic, contributing to increased spread and transmission. Thirty percent of individuals clear the infection spontaneously within the acute phase or the first six months[1]. According to 2017 World Health Organization (WHO) estimates, less than 20% of individuals infected with HCV are aware of their diagnosis[1].

HCV infection is a global health concern leading to significant morbidity and mortality worldwide[1]. According to the most recent global statistics, approximately 71 million persons are chronically infected with HCV, comprising 1% of the population[1]. Chronic HCV infection is associated with significant downstream complications, including liver cirrhosis, hepatocellular carcinoma (HCC), and end-stage liver disease[2]. In 2016, the WHO developed a global strategy with the aim of reducing the incidence of HCV by 90% and associated deaths by 65% by 2030[3]. This strategy entails raising awareness, preventing transmission, increasing detection, as well as optimizing access to pharmacotherapies to ultimately ensure equitable division of resources globally[3]. Here we provide a literature review of HCV, changes in epidemiologic trends, access issues for current therapies, and global inequities in disease burden.

GLOBAL EPIDEMIOLOGICAL TRENDS

Globally, the seroprevalence of HCV is highly variable and likely underestimated in low- to middle-income countries due to inadequate infrastructure for population-wide testing. The Global Burden of Diseases, Injuries, and Risk Factors 2010 (GBD 2010) Study estimated > 184 million have been infected with HCV[4]. This study identified Central Asia, East Asia, and North Africa–Middle East as the most endemic regions, with > 3.5% of their populations affected by HCV[4]. Of these regions, Asia carries the highest burden of disease, with more than 100 million HCV-affected individuals across South and East Asia[4]. Evaluation of global epidemiologic trends with a focus on regional prevalence identifies Asian and African countries to have some of the highest reported cases, with Egypt (18%-22%) and Pakistan (4.9%) exhibiting the highest rate of chronic infections. Among high-income countries, Italy (2.5%-10%) remains the most impacted, with as high as 10% of its population reporting chronic HCV infection.

Contaminated needles are considered to be the primary cause of spread in low-to middle-income countries[5]. The population-level spread is seen in countries where infection control practices were historically insufficient. For example, treatment of schistosomiasis, an endemic parasitic infection in Egypt, between the late 1950s to 1980s with intravenous tartar emetic unintentionally contributed to HCV transmission [6,7]. Contaminated needles also account for the majority of new HCV cases in high-income countries. In fact, the highest rates of HCV transmission in the United States are currently seen among people who inject drugs, comprising 23% of new infections (1.75 million new infections in 2015) and 33% of deaths from HCV[8]. Approximately

67% of individuals who endorse a history of intravenous drug use test positive for anti-HCV, indicating current or past infection[8].

In the United States, the estimated prevalence of HCV infection in the non-institutionalized civilian population is 1.0%, corresponding to 2.7 million in 2010[9]. HCV increases the risk of HCC by up to 20-folds, making it the leading cause of HCC worldwide and accounting for approximately 34% of cases in the United States[10]. Globally, HCV-related cirrhosis and HCC together contributed to 399000 deaths in 2016[11]. For decades, HCC had been the fastest-rising cause of cancer-related death in the United States, likely attributed to the HCV epidemic, obesity, and increased prevalence of non-alcoholic steatohepatitis[12]. In 2016 we observed the first decline in the rates of HCC (Relative Rate 0.96; $P = 0.007$), resulting from improved treatments for HCC and increased availability of direct-acting antiviral agents (DAAs)[12]. In terms of HCV-related mortality, since the introduction of DAAs in late 2013, there has been a significant decrease in United States nationwide HCV-related mortality rates compared with the pre-DAAs era. Although cirrhosis and HCC-related mortality continues to increase in recent decades, HCV cirrhosis-related mortality rates markedly declined from 2014 to 2016[13].

In the advent of DAAs, global declines in HCV viremia are anticipated, and over the past decade epidemiologic surveys have demonstrated such a trend[6]. Unfortunately, few direct data exist to establish global trends of HCV burden in the post DAA era [14]. Employing previously validated simulation models, HCV is projected to become a rare disease by 2036 in the United States[15]. Population-based modeling studies employing European data predict that the number of cured HCV patients will exceed the number of viraemic patients[16]. Irrespective of cure, the same researchers foresee a large number of patients remaining untreated, undiagnosed, and developing advanced sequelae of liver disease[16]. Ultimately, it is expected the burden of the disease will shift from patients with viremia to those with virologically cured HCV and expected to reach older age[17].

HCV VIROLOGY AND GENOMIC SEQUENCING

HCV is a single-stranded RNA virus which is easily transmissible *via* microscopic amounts of as little as 0.6 microlitres of blood[18]. It is primarily transmitted through contaminated needles, inadequate sterilization of medical equipment, transfusion of unscreened blood, as well as high-risk sexual practices. We see higher rates of infection among people from low and middle-income countries, in populations who inject drugs, and in men who have sex with men[5,19].

Following exposure, the virus incubates for 2 wk to 24 wk, though only 20% of patients actually develop symptoms[11]. While a minority of patients spontaneously clear the infection within six months, 70% develop chronic HCV. These individuals are at an elevated risk for significant morbidity and mortality, whereby approximately 20-30% will subsequently develop cirrhosis at 20-30 years[5].

This virus was first described in 1989 as a non-A non-B hepatitis. This was discovered after a significant number of post-transfusion hepatitis cases were identified despite what was felt to be adequate testing for the previously identified hepatitis A and B viruses[20]. It was not until Dr. Michael Houghton's team isolated complementary DNA from a "non-A non-B" infected patient, cultivating the isolation of viral RNA, which was ultimately termed 'HCV'[21]. Following the isolation of this strain, Houghton's team were able to develop accurate serological diagnostic tests, including Elisa immunoassays[21]. Unfortunately, the establishment of HCV through antibody testing alone would under detect a quarter of chronically infected patients. These misclassifications resulted from the seroconversion processes, which occur 4-10 wk after transmission, can be circumvented by HCV RNA reverse transcription-polymerase chain reaction testing[22]. Identification of active infection is the primary utility of the HCV RNA testing modality, which is now universally employed. Genomic sequencing of the HCV was completed by Choo *et al*[23] in 1991. This remarkable achievement led to the distinct categorization of HCV by varying genotypes, now numbered from 1-7, with further subcategorizations of related HCV genotypic strains known as subtypes (labelled alphabetically)[22,24]. Despite the description of seven known genotypes, the first six remain the most commonly studied and reported[25]. Genomic isolates of HCV have been well characterized by their geographic variation, which is partly explained by human migration, environmental epidemiologic changes (attempts at eradication of schistosomiasis), and viral evolutions observed across continents[25]. A summary of the HCV genotypes, subtypes, and

geographic variation can be found in Figure 1. Understanding the genotypes, in addition to their geographic variation, is crucial, as interventions are organized for distinct genotype targets. This significant discovery and contribution to science ultimately garnered international recognition, winning Dr. Houghton's team the 2020 Nobel Prize in Physiology or Medicine[26].

OUT WITH THE OLD, IN WITH NEW–NOVEL THERAPEUTICS IN THE TREATMENT OF HCV

The goal of HCV treatment is to cure patients through the eradication of HCV RNA as measured by the sustained virologic response (SVR) at 12 wk after treatment completion[5]. Evaluation of SVR at 12 wk is still considered controversial, where historically, assessment of SVR at 24 wk following treatment completion was considered the gold standard. While high concordance between SVR measured at 12 and 24 wk has been previously demonstrated in trials of pegylated interferon and ribavirin[27], there is less evidence demonstrating the appropriateness of a 12-wk SVR target in the literature for DAAs. A recent systematic review from 2016 did evaluate the concordance of SVR at 12 and 24 wk across two studies of DAAs, demonstrating a reliable correlation of SVR at 12 and 24 wk among multiple populations infected with HCV, including treatment naïve, varying viral genotype, and prior null responders [27]. This evidence was ultimately used to inform future clinical trial design and current recommendations.

Approximately 99% of patients who attain SVR will remain infection-free 5 years later, in the absence of re-infection[28]. Treatment is associated with reduced rates of HCC, liver-related morbidity, as well as liver- and all-cause mortality[5,29,30]. Unless contraindicated, all patients with chronic HCV should be offered treatment. Between 1991 and 2011, combination treatment with pegylated interferon and ribavirin was the mainstay of therapy, achieving SVR rates of up to 40%-50%[5].

DAAs function by targeting proteins involved in HCV replication[29]. The first-generation DAAs for HCV treatments (boceprevir and telaprevir) were approved for use in combination with pegylated interferon and ribavirin in 2011, but have been largely replaced by second-generation DAAs since[29]. The introduction of second-generation DAAs from late 2013 has revolutionized HCV care, achieving cure rates of over 95% among treatment-naïve patients. These interferon-free oral regimens have allowed for major advancements in HCV management, given their ease of administration, much more tolerable side effects profile, and superior efficacy[5,29]. The choice of regimen is guided by HCV genotype, as well as other factors, including previous treatments received and liver cirrhosis[5,29]. Genotypic viral variations add to the complexity of DAA selection. The most desirable therapy would be a pangenotypic option that can be utilized across viral genotypes and subtypes[31]. This was the motive behind the novel NS5A inhibitor, velpatasvir, demonstrated to have 90% SVR at 12 wk across patients with genotypes 1 through 6[32]. Other combination therapies, including glecaprevir/pibrentasvir have also been demonstrated to show pangenoytpic effectiveness[33-35].

Drug-drug interactions (DDIs) are concerning for patients with HCV, especially in the era of DAAs where complex treatment regimens require multiple medications, in conjunction with the other therapies utilized for optimal control of comorbid disease and the side effects of hepatitis treatment itself[31]. The majority of DDIs involve interaction between drugs using the cytochrome P450 enzymes[36]. Careful observation must be given prior to any drug treatment initiation within this population. Often managing teams will include specialist pharmacists responsible for determining the risk for DDIs, approving patients already existing medications, or adding new ones.

Among pregnant women, HCV prevalence estimates range between 0.1% to 8%, depending on the setting and country[37]. However, despite the prevalence of HCV in this population, until recently, the mainstay treatment of HCV, including ribavirin, was considered contraindicated due to the teratogenic and embryotoxic properties of this therapy[37-39]. The introduction of DAAs has opened up questions around the role of DAAs in pregnancy. While there are investigations underway, overall safety data in this population is lacking, and, therefore, treatment with DAAS in pregnancy is currently not recommended in most guidelines[37-39]. For similar reasons, treatment of HCV is also not recommended in breastfeeding women or during lactation[37-39]. Where possible, women of reproductive age should be screened for HCV infection, and if found to have HCV infection, recommendations suggest offering treatment

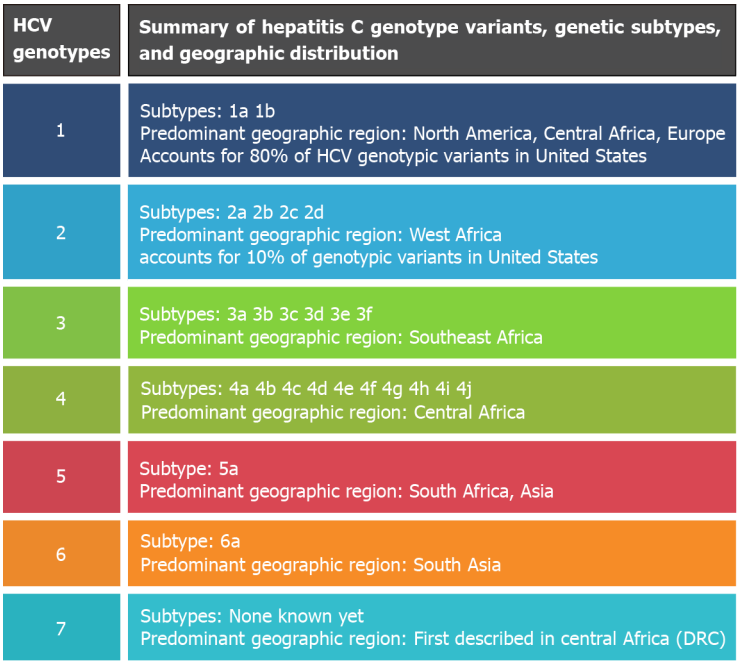

Figure 1 Summary of hepatitis C virus genotypes. HCV: Hepatitis C virus.

prior to conception and pregnancy, or following the completion of pregnancy and lactation in the postpartum period, and screening[38,39].

Compared to existing guidelines for the treatment of HCV or HBV mono-infection are well delineated in both national and international settings, treatment guidelines for HCV/HBV co-infection are less established and remain an area requiring further data [40]. Early reports on the use of DAAs and interferon-based intervention have suggested an increased risk for HBV reactivation with treatment of HCV without concomitant suppression of HBV[41]. However, the clinical significance of this is inconclusive.

While there has been evidence for lower response rates to DAA treatment in HCV populations with parallel injectable recreational drug use, a 2020 study led by Koustenis *et al*[42] offers real-world data that sustained virological response to DAAs is possible in high-risk patients who inject drugs[42]. This is in keeping with established trends revealing similar treatment responses in these higher-risk populations to that of the general population[42]. However, adherence and loss to follow-up remain ongoing concerns among high-risk populations, and during the study, over 10% of patients who inject drugs were lost to follow-up during or after treatment[42]. The risk of being lost to follow-up was correlated with several factors, including younger age and parallel recreational drug use[42].

There have been some controversies as to the safety and efficacy of DAAs for reducing HCC[43,44]. Recent studies have reported that DAAs-based SVR resulted in approximately 50%-80% risk reduction of HCC in patients with cirrhosis[45,46]. Based on the recent expert review, successfully eradicating HCV infection by DAAs confers a protective benefit with reduced incidence of HCC[47]. In terms of HCC recurrence, DAAs therapy was not associated with an overall or early increase in HCC recurrence after complete response to HCC treatment[48].

The availability and access to DAAs worldwide differ by national income and setting[49]. For example, Gilead Sciences has issued licenses that would enable over 100 countries to access generic DAA regimens, and some countries, such as Pakistan and Egypt, have enabled other companies to manufacture unlicensed DAAs in generic format. However, there are disparities among low-income countries, and several countries have not been registered for access to DAAs[49]. Lack of global funding and license provision may present potential barriers[49]. Among higher-income countries, such as countries in Europe, Japan, and the United States, overall generic drug competition among manufacturers has significantly lowered drugs prices, which has improved accessibility[49].

In the table below, we summarize drugs within each category based on their target site of action, and the HCV genotype for which they are employed[29] (Table 1).

Table 1 Classification of direct-acting antiviral agents[29]

Class	Drug name	HCV genotype
NS3/4A inhibitor	Boceprevir[1]	Genotypes 1a and 1b
	Telaprevir[1]	
	Simeprevir	
	Asunaprevir	
	Paritaprevir	
	Grazoprevir	
	Glecaprevir	
	Voxilaprevir	
NS5A inhibitor	Daclatasvir	All HCV genotypes
	Ledipasvir	
	Ombitasvir	
	Elbasvir	
	Velpatasvir	
	Pibrentasvir	
NS5B polymerase inhibitor: Nucleoside analogs	Sofosbuvir	All HCV genotypes
NS5B polymerase inhibitor: Non-nucleoside analogs	Dasabuvir	Genotypes 1a and 1b

[1]First generation direct-acting antiviral agents.
HCV: Hepatitis C virus.

Considerable efforts have focused on the design and development of a HCV vaccine. Challenges resulting from differential rates of transmission among distinct subgroups, in conjunction with the notable variability in treatment access, acceptance, and compliance, could be prevented the development of an effective vaccine. Unfortunately, many barriers have prevented its development. Challenges to the generation of live-attenuated inactivated whole virus for HCV stems largely from our inability to culture the virus effectively[50]. In the rare instances this has been accomplished, the cultured strains exhibited adaptive mutations, which increased replication in vitro [50]. These processes become further complicated by the enormous genetic diversity observed with HCV, with 7 known genotypes and more than 80 subtypes. Ultimately, major barriers to vaccine development include the significant genetic variability between HCV strains, challenges in vaccine production and testing models, as well as our incomplete understanding of the innate protective immune responses to HCV[50].

LIVER TRANSPLANTATION IN THE CONTEXT OF HCV

Prior to the approval of second-generation DAAs, interferon treatment and liver transplantation constituted the mainstay treatment options for liver disease attributed to HCV infection. HCV was previously identified as the leading cause of liver transplantation waitlist additions and surgeries over the last two decades in the United States[51-53]. However, newer data suggest that the predominance of HCV-related liver disease-related transplantations has declined following the widespread use and approval of second-generation DAAs[54]. More recently, HCV-related liver disease has been replaced by alcoholic liver disease as the leading cause of liver transplantation in the United States[51]. Between 2012 and 2015, HCV accounted for 28% of liver transplantations on average[51], by 2016, following the use of DAAs, 18% of liver transplantations were attributed to HCV-related liver disease[51].

Without curative therapies including liver transplantation, re-infection with HCV occurs in high frequency and commonly results in significant liver graft destruction, resulting in poor patient survival[55]. Approximately 80% of patients will develop allograft hepatitis within two years of liver transplantation without eradication, and 20% of those patients progress to advanced fibrosis or cirrhosis within five years of

transplantation[56]. Of note, cholestatic hepatitis C, which can occur in up to 5% to 10% of patients within one year of liver transplantation, can be rapidly progressive and life-threatening[55]. For this reason, many eligible patients will undergo treatment with DAAs prior to or following liver transplantation, ideally before recurrence[55].

Although the optimal timing of DAAs in the context of liver transplantation is still to be clarified, many eligible patients receive treatment prior to transplantation. The overall low burden of DDIs with widely used immunosuppressants poses no contraindication for use in the post-transplantation period[55]. The advantages of early or pre-transplantation viral eradication can include improved overall liver function, quality of life and liver-related complications, potential avoidance of the need for liver transplantation, and lower rate of post-transplantation infection recurrence[56]. However, pre-transplantation eradication can increase wait times for transplantation by limiting access to HCV-positive donor livers and through the improvement of liver function to the degree that de-prioritizes patients on organ transplantation wait lists [56]. This concept has been referred to as 'Model for End-stage Liver Disease (MELD) purgatory' or 'MELD limbo'[55].

The financial burden of liver transplantation remains considerable and is almost exclusive to high-income countries. In Canada, the average cost of liver transplantation in Ontario is $121732 CAN, and in the United States, the average cost is estimated to be around $163438 USD, including follow-up care and medication-related costs. This is compared to other Organization for Economic Cooperation and Development countries, where costs have been estimated at a mean of $103548 USD[57,58]. On average, the out-of-pocket expense for liver transplantation in the United States was noted to be $476.60 USD[59]. Approximately half (53.9%) patients required personal savings and credit (25%) to offset the costs. When compared to patients undergoing kidney transplantation, liver recipients were more likely to rely on alternative sources of funds, including personal loans from friends or family members, retirement funds, and community-based fundraising campaigns[59]. It is anticipated that the burden of financial costs will proportionally reduce with the lower rates of required transplantation with novel therapeutics such as DAAs.

GLOBAL INEQUITIES IN ACCESS TO CARE: THE PHARMACEUTICAL DILEMMA

The global burden of HCV is disproportionately higher among low and middle-income countries[60]. Previous epidemiologic studies from 2013 estimated 12% of globally prevalent cases lived in countries with reliable access to HCV-targeted therapies[4]. Estimates of global disease burden are directly impacted by disease screening practices. Limitations in public health funding among low- and middle-income countries is a barrier to screening and ultimately prevent widescale testing. This leads to the underestimation of HCV prevalence. It is currently estimated that 41% of the world's population lives in countries with no public health funding for the screening and management for viral hepatitis B and C[60]. Overall, limitations in public health funding and infrastructure, organization and costs of screening, expensive of therapeutics, shortages of highly specialized clinicians, and political prioritization of other infectious diseases such as HIV and tuberculosis, all contribute to the barriers inequitable access to care[61].

When distinguishing the Millennium Development Goals, prioritization of infectious diseases excluded viral hepatitis as a 'top 10' contributor to global morbidity and mortality[60,62]. The prioritization of other infectious diseases above HCV leads to considerable diversion of resources away from targeting the important health outcomes resulting from hepatitis infection, including cirrhosis and HCC[60,62]. Provided the global estimates of morbidity and mortality of both cirrhosis and HCC resulting from viral hepatitis were combined, viral hepatitis would securely rank among the top 10 infectious diseases, redefining its importance on the global arena and focus of resources[63].

The prohibitive costs of treatment for HCV infection have been well reported. Many countries will prioritize curative treatment for HCV with DAAs to mitigate downstream costs associated with end-stage liver disease[64,65]. Irrespective of savings, the total cost of DAAs are substantial. Current estimates place DAAs in the highest cost category, with wholesale acquisition prices listed between $417 USD (glecaprevir-pibrentasvir) to as high as $1125 USD (ledpasvir-sofosbuvir)[66]. Discrepancies between production and wholesale acquisition exist and contribute to substantial grievances with the pharmaceutical industry. For instance, Daclatasvir production cost

for a 12-wk course is estimated to be between $10-30 USD, yet wholesale acquisition cost is marked up to $ 63000 USD for one 12-wk treatment course[66].

DAA drug costs continue to fluctuate as a result of generic drug competition, local manufacturing, and geography[49]. In Iran, reducing pricing on generic DAAs, such as sofosbuvir/daclatasvir, has been made possible by local production and manufacturing of generic formulations, together with resultant market competition[67]. This described process has been documented in other countries, such as India, Pakistan, Bangladesh, China, Brazil, and Morocco[67]. These market factors have allowed for generic DAAs to be priced at approximately $60 USD, compared to a previously quoted price of approximately $10000 USD a decade prior[67]. Concerns, however, have been highlighted regarding the degree of oversight over generic manufacturing in these settings, which may be balanced against quality assurances based mainly on clinical observations of the safety and effectiveness of these drugs in the community [67].

Globally, the United States pays disproportionately higher costs for DAAs, even when compared to other high-income countries. For instance, the cost of sofosbuvir for 12-wk of treatment is $84000 USD, which is disproportionately higher than European countries such as Spain where the cost is estimated to be $25000 USD for the same treatment course[68]. Such discrepancies reflect the purchasing power single-payer healthcare systems hold when negotiating with the pharmaceutical industry[68].

Despite the recent United States Food and Drug Administration approval of the more affordable pan-genotypic glecaprevir-pibrentasvir through federally funded programs[66], there remains considerable inequity in access to DAAs and treatment with curative intent. This is partially driven by the lack of standardized policies within federally funded insurance such as Medicare or Medicaid to define eligibility for treatment[66]. Some insurers have gone so far as prioritizing patients with advanced liver fibrosis or those with clinical features of severe disease[66]. Variability in access to treatment is a serious problem within the United States, driven largely by limitations within the health infrastructure. Disproportionate allocation of resources has led insurers to enact restrictions on the delivery of HCV medications[68]. Regardless of the power publicly funded healthcare systems may hold, such costs are prohibitive to equitable treatment distribution worldwide.

INNOVATIVE EXAMPLES OF HCV ELIMINATION EFFORTS IN RESOURCE-LIMITED SETTINGS

Despite the advent of safely targeted pharmacotherapies, treatment access, as well as the rates of infection and re-infection, continue to soar in specific subgroups, particularly those with substance use disorders[69]. Novel approaches to reducing HCV transmission and improving access to therapeutics include integrative HCV care models, whereby delivery of care through addiction services can serve as an effective approach to HCV prevention. In fact, the scale-up of both opioid substitution therapy as well as needle exchange programs can contribute to substantial reductions in HCV transmission and prevalence[70].

Within addiction services, a variety of integrated models for improving HCV treatment have been proposed and evaluated. These models include referrals to primary care or harm reduction settings, developing specialty clinics with inter-disciplinary teams, organization of hepatology and addiction providers within primary care settings, utilizing technology to improve access with telemedicine, as well as onsite delivery of DAAs within opioid substitution clinics[71]. Prison-based HCV programs have also been proposed as a method to improve the delivery of HCV treatment among specific vulnerable subgroups. Targeting penitentiary populations provides an opportunity for micro-elimination, given the controlled setting and ease at which delivery of care can be executed, as well as organized upon transfer or release[72]. In the largest study of European inmates with hepatitis, HCV care was arranged for more than 80% of inmates exhibiting antibody positivity, with similar rates of treatment acceptance and compliance regardless of high-risk practices (*e.g.*, injecting drug)[73]. Ultimately this model of care proved effective for treatment delivery and completion [73].

Comprehensive community-based HCV care models ("educate, test, and treat" schemas) have been trialed with success in Egypt, a country that experiences one of the highest global burdens of HCV infection[74]. A study by Shiha *et al*[74] tested the real-world applicability of such models[74]. First, eligible villagers who met inclusion criteria for age were identified and screened for HCV infection using rapid diagnostic

tests[74]. Patients who screened possessive would provide an immediate sample to be tested for HCV RNA, and those who had a positive result would be scheduled for a clinic visit for education and initiation of baseline testing and, later, treatment using DAAs[74]. Patients with cirrhosis were followed up clinically at ELRIAH or satellite facilities during treatment, and among these patients, 5.2% (166 patients) were diagnosed with HCC[9]. As a result, treatment cure was established for 84.6% of the 17137 persons identified across 70 villages, and established this community-based care model as feasible and effective in this setting[74]. The data may suggest that community-based HCV care models can be a feasible model to consider in treating HCV patients with similar characteristics as those in the study. Despite their novelty and demonstrated impact within specific settings, few of these models have been tested in a clinical trial, and none have been directly compared.

FUTURE DIRECTIONS

Despite the unparallel efficacy observed among second-generation DAAs, with SVR of over 95%[75-78], the cost of such treatments continues to limit equitable access to care and likely contributes to differential rates of HCV infection globally. To reduce the burden of disease worldwide, essential agenda items for low-, middle-, and high-income countries must prioritize access to DAAs therapies. We must acknowledge the complexity of the proposed task beyond negotiations for lower prices from the pharmaceutical industry.

Ancillary costs contributing to the safe and effective delivery of HCV care are undoubtedly expensive. These expenses are largely driven by the costs associated with healthcare personnel, as well as diagnostic and laboratory testing. Provider experience (specialized training in hepatology, infectious disease, general internal medicine), technology for fibrotic staging, as well as baseline laboratory measures including transaminase levels, HCV RNA level, HCV genotype, measures of synthetic liver function (glucose, platelets, albumin), and current renal function account for the bulk of health delivery expenses. Within the United States alone, accomplishing this task may require federal level funding to negotiate in a single-payer fashion for the United States population in one pool. Given the United States is a multi-payer system, there no incentive for pharmaceutical companies to provide the bulk prices single-payer systems negotiate such as the United Kingdom.

CONCLUSION

On a global scale, continued commitment to the prioritization of HCV is required to increase its importance on the international agenda, specifically the WHO. Additionally, pharmaceutical companies need to consider providing compassionate release of medications to promote equitable healthcare worldwide, especially given that the highest burden of disease rests within low- and middle-income countries.

Abstract

Chronic infections with the hepatitis B and C viruses have significant worldwide health and economic impacts. Previous treatments for hepatitis C such as interferon and ribavirin therapy were ineffective and poorly tolerated by patients. The introduction of directly acting curative antiviral therapy for hepatitis C and the wider use of nucleos(t)ide analogues for suppression of chronic Hepatitis B infection have resulted in many positive developments. Decreasing the prevalence of hepatitis B and C have concurrently reduced transmission rates and hence, the number of new infections. Antiviral treatments have decreased the rates of liver decompensation and as a result, lowered hospitalisation and mortality rates for both chronic hepatitis B and C infection. The quality of life of chronically infected patients has also been improved significantly by modern treatment. Antiviral therapy has stopped the progression of liver disease to cirrhosis in certain patient cohorts and prevented ongoing hepatocellular damage in patients with existing cirrhosis. Longer term benefits of antiviral therapy include a reduced risk of developing hepatocellular carcinoma and decreased number of patients requiring liver transplantation. This review article assesses the literature and summarises the impact of modern antiviral therapy of chronic hepatitis B and C on clinical outcomes from liver disease.

Core Tip: Hepatitis B and C infection contribute significantly to the global burden of liver disease. With the introduction of modern antiviral therapy, there is now an effective curative treatment for hepatitis C and potent suppressive antiviral therapy for hepatitis B. Antiviral therapy has had a positive impact on liver disease by reducing hospitalisation rates and hence, cost to global health systems. Rates of decompensation, hepatocellular carcinoma and need for transplantation have all been lowered. This review article assesses the literature and summarises the impact of modern antiviral therapy of chronic hepatitis B and C on clinical outcomes from liver disease.

INTRODUCTION

Chronic viral hepatitis B and C infections remain a significant burden on global health. Modern directly acting antivirals (DAAs) have changed the landscape of hepatitis C virus (HCV) treatment with their high rates of sustained virological response and superior tolerability. HCV has a significant global impact with the World Health Organisation estimating that 71 million people worldwide are chronically infected[1]. Between 15%-30% of patients with chronic HCV infection will develop cirrhosis and its related complications within 20 years. On the other hand, despite the development and wide availability of the hepatitis B vaccine, WHO estimated that the global incidence of chronic hepatitis B virus (HBV) infection was 257 million people in 2015 [2].

Both of these chronic diseases result in substantial economic burden. The mean annual all-cause medical cost for healthcare in an American cohort with HCV was $43891 as compared to $17989 in patients without HCV[3]. A retrospective study which conducted an analysis on the United States Veteran population with chronic HBV, calculated the total cost per patient per year to be $39240 for those treated with nucleoside analogues[4]. Treatment of HCV, particularly in the early stages of fibrosis, significantly mitigates the economic burden from HCV and its resultant hepatic complications[3]. The cost of treatment of HBV has decreased significantly over the decades as Entecavir and Tenofovir disproxil fumurate are now both off-patent. On the international market, the median price of WHO-prequalified generic Tenofovir has been reduced from US$208 per year to US$32 per year in 2016[2]. Cost of HCV treatment with DAAs is significant, ranging from $40000 to $90000 depending on the drug and treatment duration. Thankfully, many countries such as Australia and Canada have heavily subsidised treatment, allowing the widespread use of DAAs.

The advent of modern DAA therapies has revolutionised the treatment of HCV. More patients are willing to start treatment with the promise of high cure rates, shorter durations of treatment and limited adverse effects. Early access to effective curative treatment will have significant long-term impact on the outcomes of HCV related liver disease. Advances in HCV therapy have led to a commitment by the member states of WHO to try to eliminate viral hepatitis by 2030. For HBV therapy, nucleos(t)ide analogues (NA) are potent antiviral agents which are becoming more widely available in low to middle economic countries. NAs suppress viral replication and therefore result in improved long-term clinical outcomes in chronic liver disease by reducing the progression of liver injury to advanced fibrosis, cirrhosis, liver failure and hepatocellular carcinoma (HCC). As a direct consequence, the requirements for liver transplantation are also reduced[5,6].

The aim of this review article is to summarise the current literature regarding modern antiviral treatment of chronic HBV and HCV infection and the effects of therapy on clinical outcomes of chronic liver disease.

EFFECTS OF CHRONIC HEPATITIS B TREATMENT ON CLINICAL OUTCOMES

Prevalence

Globally, chronic HBV is one of the most common infectious diseases[7]. In 2015, the World Health Organisation (WHO) estimated that 257 million people, equivalent to approximately 3.5% of the world's population, were living with chronic HBV[7]. In addition, 2.7 million people were coinfected with HBV and HIV[7]. Chronic HBV is associated with development of complications including cirrhosis, liver failure and hepatocellular carcinoma. HBV is a leading cause of liver cancer worldwide[8] and up to one in four people with chronic HBV will die from liver cancer or liver failure if their HBV is not monitored or treated appropriately[7]. The prevalence of HBV varies widely depending on country and is predominantly determined by age of exposure; approximately 90% of infected infants progress to develop chronic HBV, as opposed to a rate of 5% following exposure of immunocompetent adults to HBV[9]. In 2015, 65% of all infected persons with HBV were located in African and Western Pacific regions [7].

Chronic HBV infection is preventable using a readily accessible vaccine. In 2017 there were 4762 confirmed HBV cases reported in the United Kingdom and of these, 324 were acute cases of HBV[10]. The prevalence of HBV has been reduced through the incorporation of routine vaccination in the immunisation schedule in Australia and United Kingdom. In 2017, there was a 73% self-reported uptake of at least one dose of the HBV vaccine in England[11]. In Australia, there were an estimated 226566 people (0.9% of the population) living with chronic HBV[12]. Additionally, it is estimated that of those living with chronic HBV, only 68% have been diagnosed[12]. In 2020, only 22% people with chronic HBV were engaged with regular care and receiving regular monitoring or antiviral therapy[12]. Furthermore, only 9.3% were receiving antiviral therapy[13]. The national target in Australia is to have 50% of chronic HBV patients engaged with care and 20% receiving antiviral therapy by 2022[12].

Decompensation and mortality

Currently, chronic infection with HBV remains incurable. The goals of modern antiviral therapy for chronic HBV are to (1) improve survival and quality of life by preventing disease progression to cirrhosis, decompensation and HCC; (2) induce virological seroconversion of e-antigen and surface antigen; (3) induce long-term suppression of HBV DNA levels; and (4) induce normalisation of serum alanine aminotransferase (ALT) levels which reflect a biochemical response to therapy[14].

Chronic HBV infection can progress to advanced hepatic fibrosis and eventually, cirrhosis. Hepatic decompensation can occur in the context of cirrhosis or acute flare as a result of HBV reactivation. Decompensation presents clinically with the development of ascites, jaundice, encephalopathy or variceal bleeding. In HBV infection, hepatic decompensation occurs with a high HBV-DNA viral load and is more common in patients who are e-Ag positive[15].

Hui *et al*[16] conducted a study of 96 chronic HBV patients over three years and reported 29% of patients developed decompensation. The most common clinical manifestation of decompensation was ascites (70%) followed by variceal bleeding (34%), jaundice (26%) and hepatic encephalopathy (5%). Almost a third of subjects had more than one feature of decompensation. Das *et al*[17] performed a retrospective cohort study involving 253 HBV-related decompensated cirrhotic patients. They reported a mean 5-year survival rate of 19%; the commonest causes of death included hepatorenal syndrome (32%), HCC (28%), variceal bleeding (23%), liver failure (9%) and hepatic encephalopathy (9%).

Acute-on-chronic liver failure is associated with a high mortality rate and occurs in patients with chronic HBV who have experienced an acute liver decompensation event which results in jaundice, ascites, coagulopathy and/or encephalopathy[15]. Acute liver insults may result from recrudescence of HBV replication, viral superinfection (with hepatitis D, HCV, or hepatitis E virus), acute variceal bleeding, infection and/or alcoholic hepatitis[15]. Studies assessing acute-on-chronic liver failure in patients with chronic HBV infection report that antiviral therapy (including Entecavir and Tenofovir) reduces all-cause mortality[15,18,19].

Antiviral therapy suppresses viral replication and reduces the likelihood of loss of hepatic function. The literature shows that antiviral therapy reduces the probability of decompensation and progression of liver cirrhosis[15] (Figure 1). The use of antiviral therapy in HBV-related liver decompensation results in improvement of liver function, as illustrated by improved MELD scores and patients being delisted for liver

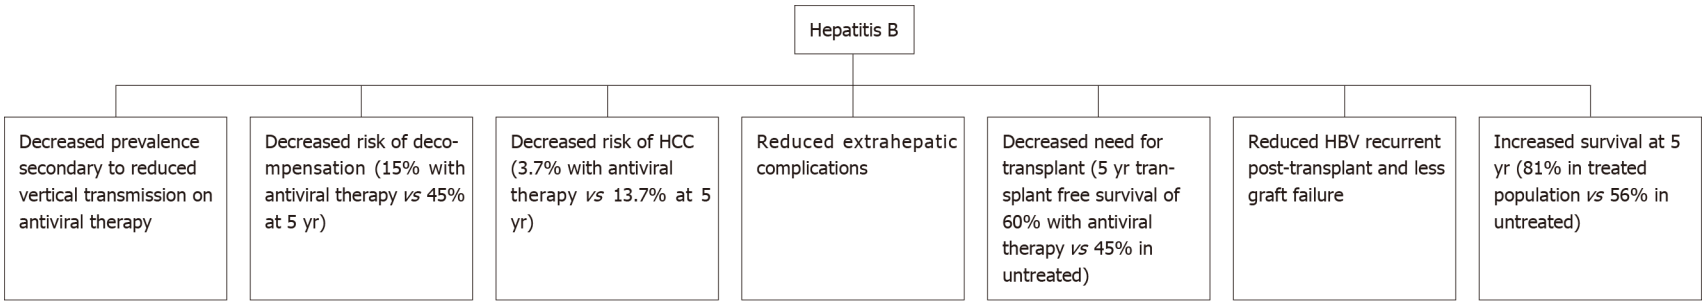

Figure 1 Outcomes of hepatitis B after introduction of antiviral therapy. HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus.

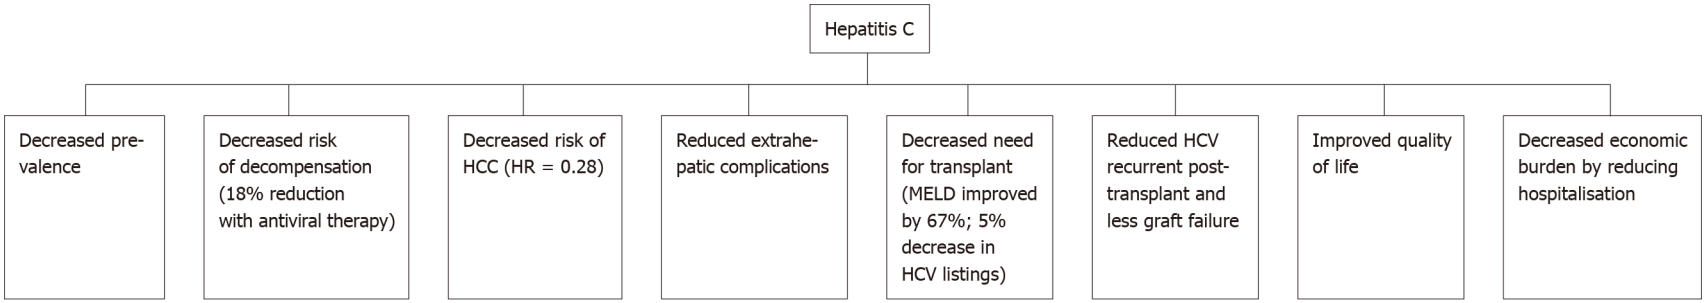

Figure 2 Outcomes of hepatitis C after introduction of antiviral therapy. HCC: Hepatocellular carcinoma; MELD: Model of End stage Liver Disease; HCV: Hepatitis C virus.

transplantation[15]. Therefore, guidelines recommend commencement of antiviral therapy in all cirrhotic patients with HBV, irrespective of viral load level. A Korean study by Kim *et al*[20] demonstrated a 15% probability of developing hepatic decompensation 5-years after commencement of antiviral therapy which was less compared to those who remained untreated and had a 45% probability of decompensation after 5 years. Overall, treatment with antivirals results in significantly improved prognosis in HBV-related cirrhosis as evidenced by 5 year survival rates of 81% in those treated with NAs compared to 56% in the untreated individuals[20].

Nucleos(t)ide analogues such as Entecavir and Tenofovir disoproxil fumurate (TDF) are considered first line agents due to their excellent safety profile, high efficacy and minimal to no risk of resistance developing in treatment-naïve patients[15]. Entecavir induces undetectable viral load in up to 89% of patients with decompensated liver disease after 12 mo[21,22]. Additionally, commencement of antiviral therapy is associated with improvement in prognosis, with a substantial reduction in Model of End stage Liver Disease (MELD) and Child-Pugh (CP) scores after twelve months of

therapy[15]. Several studies have reported a mean improvement of both MELD and CP scores by up to 2 points (compared to baseline) at twelve months in patients who respond to treatment with Entecavir or TDF[21,23-26].

Pegylated-interferon alpha could be considered as an initial treatment option for patients with compensated cirrhosis, with a treatment duration of 48 wk. It is contraindicated in patients with hepatic decompensation. Observational studies which followed up patients for a mean of 84 months and compared treatment with pegylated-interferon alpha *vs* no treatment reported a significant decrease in the risk of HCC, with a cumulative incidence rate of 14% at 5 years in those treated *vs* 23% in untreated patients. There was no difference in all-cause mortality or decompensated liver disease[17,20,27-29].

Several studies have shown that antiviral therapy improves mortality in liver cirrhosis. Suppression of viral replication prevents progression of liver disease and therefore reduces the risk of liver decompensation and HCC, resulting in improved overall survival. The 5-year survival rate in untreated patients with HBV with compensated cirrhosis is 80%-85% *vs* 14%-35% in decompensated cirrhosis[15]. Additionally, a Korean cohort study of 204 patients demonstrated the positive prognostic effect of antiviral therapy in cirrhotic patients with HBV[20]. This study reported the 5-year survival rate in untreated cirrhotic patients was 56%; the survival breakdown based on CP score was 74% for CP-A, 34% for CP-B and 10% for CP-C[20]. For those who were treated with antiviral therapy, the overall 5-year survival rates were 81%; 91% for CP-A, 63% for CP-B and 62% for CP-C[20].

A large study by Jang *et al*[26] which followed 707 patients with HBV-related decompensation for seven years illustrated the long-term benefits of viral suppression in decompensated cirrhotic patients and a trend to benefit in regard to transplant-free survival with antiviral therapy. This study reported a 5-year transplant-free survival of nearly 60% with antiviral therapy compared with 46% in the untreated group. Usually, patients with chronic HBV-related decompensated cirrhosis who are listed for transplantation have a much lower 5-year survival compared with those who undergo transplantation with fulminant HBV infection[26]. In addition, up to 60% of those patients listed for transplantation were able to either delay or negate the need for liver transplantation[26]. However, of the patients with severe hepatic dysfunction in this study, 13% of patients died within first six months of initiating antiviral treatment[26]. Hence, patients with severe decompensation should be considered for liver transplantation because it may take several months of antiviral therapy for liver function to recover.

HCC

Recent studies have reported that the incidence of annual HCC in patients with chronic HBV ranges from 0.9%–1.4% in non-cirrhotic patients and up to 5.4% in those with cirrhosis[30]. The majority of the published literature demonstrates that antiviral therapy with nucleos(t)ide analogues (NAs) reduces the risk of HCC in patients with chronic HBV, after adjusting for known background risk factors including older age, male gender, cirrhosis, family history, HBeAg positive status, elevated HBV DNA and serum ALT levels[13,31,32]. Asian studies that compared data with or without NA treatment reported significant treatment-related reductions in risk of HCC risk by up to 30% in cirrhotic patients and 80% in non-cirrhotic patients[30].

Hosaka *et al*[29] compared 472 Entecavir-treated patients with 1143 untreated patients and found that the incidence rate of HCC at 5 years was 3.7% in the Entecavir group and 13.7% in the control group, after elimination of baseline differences by propensity score matching. Additionally, after adjustment for a number of known HCC risk factors, Entecavir treatment was independently associated with reduced HCC risk[29]. A European multicentre study reported that the HCC risk began to decrease after 5 years of antiviral therapy[33]. The reduction in HCC incidence with treatment was further supported by a Taiwanese nationwide study which assessed propensity score-matched patients on antiviral therapy; those receiving NA therapy had a significantly lower 7 year HCC incidence of 7% compared to 23% in the untreated cohort[13]. The benefit of antiviral treatment was observed in both non-cirrhotic and cirrhotic patients[13].

A large study conducted by Lee *et al*[5] which consisted of a post-hoc analysis of two prospective cohorts from Hong Kong and Korea (n = 818 patients), reported the risk of HCC did not decrease after 5 years of antiviral therapy. This study finding suggests that cirrhotic patients may require longer therapy before a decline in HCC risk eventuates[5]. The higher rates of HCC may also reflect improved mortality rates related to current clinical practice, which translates to more time for HCC to develop [34].

The mechanisms by which antiviral therapy decrease HCC risk may include reductions in the hepatic inflammation and nuclear signaling pathways that lead to neoplastic transformation on a cellular level[35,36]. NAs also reverse fibrosis and the wound-healing response known to be associated with the pathogenesis of HCC[37]. Antiviral therapy may reduce the expression of hepatitis B x-protein to levels that are insufficient for HCC development, or act at a genomic level by preventing integration of HBV DNA into host chromosomes and thus affect its malignant potential[38].

Thus, HCC risk is not completely eliminated with modern antiviral therapy, and there remains a risk of developing HCC even in the context of negative hepatitis B e antigen (HBeAg) and/or negative hepatitis B surface antigen (HBsAg) status[39-42]. Seroconversion of HBsAg is associated with better clinical outcomes and lower rates of HCC incidence[32]. Even so, several studies have illustrated that the risk of HCC remains elevated in treated HBeAg-negative patients for at least 5 years after initiation of NA treatment. Therefore, HCC surveillance should be continued long term, even after seroconversion of HBsAg[31,40,43].

The association between virological suppression and HCC development remains controversial due to conflicting results. In Asian studies, virological suppression is associated with lower rates of HCC – especially in cirrhotics[30,32]. On the other hand, European studies have not consistently reported this association. This difference may be related to variation in patient characteristics such as genotype distribution[6].

A Greek cohort with 321 HBeAg-negative chronic HBV patients treated with Entecavir, reported an HCC incidence of 1.2% at a median follow-up of 1.5 years[40]. The 5-year cumulative HCC incidence rate in Entecavir-treated patients was 9% in cirrhotic patients and less than 1% in non-cirrhotic patients[40]. This result was similar to two other Asian studies[29,44]. Old age was identified to be an independent risk factor associated with increased risk of HCC[40]. A Korean retrospective analysis of 829 patients who had achieved seroconversion of HBsAg and followed up over 3464 patient-years found that the annual rate of HCC was 0.6%; the estimated annual incidence of HCC was 3% in cirrhotic patients and 0.3% in non-cirrhotic patients[39]. Independent risk factors associated with the development of HCC included liver cirrhosis, male gender and age[3] 50 years at time of HBsAg seroconversion[39]. Therefore, HCC surveillance should be recommended to continue in patients who have undergone HBsAg seroconversion if they are cirrhotic or over the age of 50 years, regardless of cirrhotic status[39].

In patients who have undergone resection of HCC, an elevated viral load and absence of antiviral therapy are independent risk factors for recurrence of HCC[45]. Choi *et al*[34] conducted a historical cohort study of 1695 patients treated with Entecavir (n = 813) or TDF (n = 882) after curative intent hepatectomy for early-stage HCC (BCLC Stage 0/A) between 2010 and 2018. During a median follow-up duration of 38 months with continuous antiviral therapy, 33% of patients developed HCC recurrence. A comparison between Entecavir and TDF therapy revealed that TDF was associated with a significantly higher recurrence-free survival, higher overall survival rates and lower rates of HCC recurrence. The 3-year recurrence free survival rates were 73% and 64% in the TDF and Entecavir groups, respectively. TDF was also significantly associated with a lower risk of both early (*i.e.*, within 2-years of resection) (adjusted hazard ratio 0.79, 95%CI, 0.64-0.97, P = 0.03) and late HCC recurrence (adjusted hazard ratio, 0.68; 95%CI, 0.47-0.97; P = 0.03) compared to Entecavir. Whilst the results of this study imply better clinical outcomes associated with TDF in regard to rates of recurrence of HCC, this was an observational study which may be subject to bias and confounding. Additionally, other limitations of the study include missing data, heterogeneity in duration of antiviral therapy treatment (*i.e.*, before or after surgery), and TDF being approved as standard-of-care therapy in Korea in December 2020 which falls within the study period.

Liver transplantation

NAs have been associated with reduced rates of liver transplantation for patients with chronic hepatitis B. A retrospective study included 5374 patients with chronic HBV, 2000 patients were treated with NA (Entecavir) and 3374 patients were treated with Lamivudine in a tertiary centre in South Korea[46]. The study demonstrated that Entecavir was associated with a significantly lower risk of death or transplantation (hazard ratio 0.49, 95%CI 0.38-0.64)[46]. A further analysis of 860 paired cirrhotic patients replicated the finding (hazard ratio 0.42, 95%CI 0.31– 0.57)[46].

Recurrence of HBV post-liver transplantation occurs when circulating HBV virions from extrahepatic reservoirs engraft the new liver. HBV re-infection has been associated with early acute cellular rejection within the first year of liver transplantation[47]. Risk factors associated with HBV recurrence include high level of

viraemia at time of transplantation, HBeAg-positive status, or history of drug resistance to oral HBV antiviral therapy[47,48]. Post-transplant immunosuppression can also induce viral replication and subsequent HBV infection in patients who have received donor liver graft with hepatitis B core antibody positivity[49]. Administration of hepatitis B immunoglobulin (HBIG) to transplant recipients has been associated with lower HBV recurrence and improved survival of 80%, compared to 80% HBV recurrence and 50% survival if no HBIG was given[47,48]. The addition of NA therapy to HBIG in liver transplant recipients has resulted in a further reduction in HBV recurrence and improved prognosis[47]. A study conducted by Cholongitas *et al*[50] which had a median follow up period of 30 mo, reported HBV recurrence was much lower in patients who received HBIG plus NA (Entecavir/Tenofovir) – 1%, compared to those who received HBIG plus Lamivudine – 6% (P = 0.0004).

Extrahepatic manifestations

Extrahepatic manifestations may be observed with acute or chronic HBV infection. It is postulated that circulating immune complexes and viral antigens activate the complement cascade resulting in organ injury, most commonly to the kidneys, vessel wall, skin and joints[51]. A multicentre retrospective cross-sectional study of HBV patients and found that 16% exhibited clinical extrahepatic manifestations - sensory-motor deficiency, sicca syndrome, myalgia, glomerulonephritis and arthralgia arthritis [52]. Other associations reported in the literature include a serum sickness-like syndrome, polyarteritis nodosa, cryoglobulinaemia, lichen planus, Gianotti-Crosti syndrome and Guillain-Barre syndrome. Awareness and recognition of these clinical manifestations are important to facilitate early diagnosis, monitoring and treatment of HBV infection and the associated organ injury.

Infection with HBV is associated with a variety of renal diseases including membranous nephropathy, membranoproliferative glomerulonephritis and rarely IgA nephropathy. A prospective French study by Mallet *et al*[53] monitored the renal function of patients with compensated chronic HBV following treatment with NAs. Treatment with TDF or Entecavir, especially in patients with an initial HBV DNA titre of 100 000IU/mL or greater, resulted in an increased estimated Glomerular filtration rate (eGFR) throughout the follow up period (median of 2.7 years)[53]. Similarly, a recent meta-analysis by Fu *et al*[54] assessed the efficacy and safety of NA monotherapy for HBV-related glomerulonephritis in 7 trials involving 182 participants. They found that antiviral therapy induced remission of proteinuria and increased HBeAg clearance.

Polyarteritis nodosa (PAN) is a multisystem necrotizing vasculitis typically affecting muscular medium-sized and small arteries. Hepatitis B has been observed in 17%-35% of patients diagnosed with PAN, although the frequency is likely decreasing due to HBV vaccination[55]. The American College of Rheumatology (ACR) has established ten criteria for the classification of PAN in patients with a vasculitis and recognises the evidence of HBV infection as one of the diagnostic criteria[56]. Other systemic features of PAN may include cutaneous livedo reticularis, testicular pain, mononeuropathy or polyneuropathy, renal artery aneurysm and unexpected weight loss. In patients in whom PAN is associated with HBV (HBV-PAN), the major focus of therapy is the use of antiviral agents for the treatment of the underlying viral disorder. Immunosuppressive therapy in the form of glucocorticoids may also be used in the short term for control of the systemic inflammation[55]. In several studies, clinical remission of PAN was observed in patients who were treated with antiviral agents and in very few patients who instead received only immunosuppressive treatment[55,57].

Mixed cryoglobulinaemia (types II and III) is caused by immunocomplexes composed of polyclonal IgG in association with either monoclonal or polyclonal IgM. These immunoglobulins precipitate with cold temperature, resulting in purpura, renal disease, arthralgia or arthritis. Cryoglobulinaemic vasculitis can develop in 1-4% of HBV patients. Treatment with NAs has been found to provide significant clinical response, preventing extrahepatic organ complications[58].

EFFECTS OF CHRONIC HEPATITIS C TREATMENT ON CLINICAL OUTCOMES

Prevalence

The WHO estimates that there are up to 71 million people worldwide who are chronically infected with HCV[1]. In Australia, mandatory reporting of HCV diagnosis

has been required since the 1990s. This allows for more accurate assessment of HCV numbers. As of 2017, it was estimated that up to 182,144 people in Australia had HCV. The incidence of new HCV infections has steadily declined since 2000. Government subsidised DAA treatment was made generally available in 2016. At the end of 2018, an estimated 130089 Australians had HCV, a decrease of approximately 50000 patients with the use of antiviral therapy (Figure 2).

In the United Kingdom, the prevalence is estimated to have decreased in recent years by one-third due to DAA treatment. Approximately 118000 people had HCV in 2019 as compared to 174000 in 2015[59]. It is expected that the prevalence will continue to steadily decrease with a corresponding increase in the number of patients who have been successfully treated.

Decompensation and mortality

It is well recognised that chronic HCV places considerable financial burden on the healthcare system, primarily related to presentations with decompensated liver disease. These individuals have prolonged stays in hospital and frequent re-admissions. A United Kingdom study demonstrated that 21.1 d was the mean length of stay in decompensated HCV patients without HCC. This translates to a mean cost of 9120 pounds per year. Within Europe, annual hospitalisation costs are estimated at 8000-20000 euros for decompensated patients in France and up to 28000 euros in the Netherlands. The inpatient hospital burden appears to be greatest within the first year after the first decompensation event[60]. With the aging population, there are increasing numbers of patients presenting to Emergency Departments with HCV-related issues which result in hospitalisation[61]. In the Scottish population, between 1996 and 2013, the total number of HCV-related inpatient admissions with decompensation increased 16-fold[60].

In the United Kingdom-based Extended Access Program cohort, achieving a sustained viral response (SVR) in HCV cirrhotics was associated with a reduction in decompensation rates of 18% within the first 6 mo[62]. Lower decompensation rates result in decreased hospitalisation rates, reduced length of stay and most importantly, mortality reduction[63]. In the Veterans Affairs cohort, achieving SVR in patients with advanced liver disease (pre-treatment FIB-4 scores of > 3.25) resulted in a 74% reduction in mortality risk, after adjusting for baseline variables[64].

A rise in the hepatic venous pressure gradient (HVPG) is the main driver behind cirrhosis-related complications such as variceal bleeding and ascites. HCV eradication is associated with a reduction in HVPG which translates to decreased complications. This was demonstrated in a prospective study by Mandorfer *et al*[65] who measured HVPG pre- and post-treatment of HCV. In patients with subclinical portal hypertension (HVPG 6-9 mmHg), portal hypertension resolved in 63% of patients. In the group of patients with HVPG 10-15 mmHg, portal hypertension resolved in 43% of the cohort. The highest risk group with HVPG > 16 mmHg showed a reduction in HVPG in 35% of patients but portal hypertension did not resolve in any of the patients[65]. This indicates the importance of treating HCV early to achieve SVR and reversibility of portal hypertension prior to development of end-stage irreversible portal hypertension and its related complications.

Quality of life

Chronic HCV infection has clearly defined effects on hepatic fibrosis, cirrhosis and subsequently, increased risk of HCC. There have been many studies looking into the clinical effects of hepatitis C-related liver disease. Patient related outcomes (PROs) or impact on quality of life are equally important measures but harder to quantify. Previous studies have demonstrated that health-related quality of life (HRQOL) is impacted by HCV and HCV causes a more severe reduction in HRQOL than certain chronic diseases such as diabetes[66,67].

Cacoub *et al*[68] investigated the impact of HCV treatment on patient-related outcomes in a large study. Data were derived from 11 multicentre phase 3 clinical trials across a range of countries. These included trials based on interferon therapy, ribavirin-based and DAA therapies. PROs were measured using a combination of four different validated questionnaires to encompass different domains including physical, emotional and social impact as well as work productivity, fatigue and functional well-being. Patients were asked to fill in the questionnaires at baseline, during treatment and post-treatment while being blinded to their HCV RNA levels.

This study demonstrated that modern antiviral therapy was associated with improvement in PROs as early as four weeks after initiation of treatment[68]. By week 4, average PRO scores had improved by 6%, with the greatest improvements in the domain of emotional wellbeing and worry. This pattern continued throughout

treatment course (increased by 8%) and was sustained up to SVR-24 (increased by 10%), becoming more pronounced with time. PROs were significantly better in the non-interferon, non-ribavirin group[68]. This provides additional support for the superiority of modern DAAs over older treatment regimes.

A systematic review by Younossi *et al*[69] also demonstrated that HCV infection negatively impacted patients' HRQOL. In particular, scores were lower in the mental health domains as compared to physical health. The prevalence of depression in HCV patients was estimated to be 24% compared to 17% in the non-HCV control group. Based on this data, the risk of developing depression in patients with HCV is substantially increased (RR = 2.30)[69]. In addition to the physical benefits derived by HCV clearance, the significant mental health improvements are also an important reason to treat HCV patients as early as possible.

HCC

HCC is the second leading cause of cancer-related death worldwide. Early on in the post-DAA treatment era, there was initial concern about an unexpected increase in the incidence of HCC after achieving viral clearance. These results were later disputed by other studies which had longer follow-up periods and larger cohorts with control groups. A cohort study by Kanwal *et al*[70] demonstrated that SVR was associated with a significantly lower risk of HCC as compared to patients who remained infected (0.90 *vs* 3.45 HCC per 100-person years; adjusted HR = 0.28). Two large cohort studies by Ioannou *et al*[71] and Singer *et al*[72] also showed a significantly reduced risk of HCC following SVR with adjusted HR = 0.84 and 0.29, respectively. Cheung *et al*[62] carried out a prospective study involving 406 patients with decompensated cirrhosis and demonstrated that the incidence of HCC was 4% within the first 6 months of DAA treatment. This was equivalent to the matched control group with untreated patients. The evidence now overwhelmingly favours the absence of any increased risk of HCC following SVR[73,74].

Post-treatment studies from the interferon era have shown that regression of fibrosis is a gradual process that can take years. As fibrosis assessment is mostly performed using non-invasive markers now, there is limited data assessing fibrosis regression post SVR with DAAs using the gold standard of liver biopsy. One small study showed that cirrhosis resolved in 7 out of 14 patients following DAA treatment[75]. A large retrospective Brazilian study of 400 patients reported that liver stiffness measurement (measured with Fibroscan) decreased significantly post-SVR (13.6 kPa *vs* 10.2 kPa, $P < 0.001$) with 42% of the treated cohort experiencing a reduction of LSM by at least 30% [76]. Thus, early viral clearance offers advantages of prevention and regression of hepatic fibrosis.

Although treatment with DAAs does not confer additional risk of HCC development, it is still important to note that patients remain at risk of HCC even following SVR. Multivariate analyses from several studies have identified risk factors for HCC occurrence post DAA treatment. These include advanced liver fibrosis (F3 or F4), older age and male sex[77,78]. Therefore, it is imperative that patients with these risk factors should continue to undergo HCC surveillance even after successfully achieving viral clearance.

Liver transplantation

HCV is one of the leading reasons for liver transplantation in the Western world. Twenty-four percent of liver transplants performed in Europe between 1999 and 2009 were HCV-related[79]. The recurrence of HCV post-transplant was also an issue leading to accelerated graft dysfunction and eventual failure. DAA treatment can reduce the need for transplantation by reducing decompensation rates. A pooled analysis of 800 decompensated cirrhotic patients demonstrated that up to 60% of patients had an improvement of their MELD score after treatment[62]. In the United Kingdom, the introduction of treatment with DAAs has resulted in a decreased number of HCV-related cirrhosis patients being listed for transplant. The rate in 2013 of new registrations with HCV-related cirrhosis was 10% and this reduced to 5% in 2016 ($P < 0.001$) In this cohort, the median UKELD for HCV remained stable at 55 in the pre and post-DAA era[62,80,81]. There has been concern that treatment of HCV patients on the transplant waitlist will decrease their MELD score, reducing their chances of receiving a transplant. Despite the reduction in their MELD score, some of these patients still require a transplant as they are experiencing symptoms of decompensation. Ironically, the lower MELD score makes it less likely for them to receive a transplant, thus leaving this group of patients in "purgatory". This data indicates that the threshold which physicians were using for listing patients had not changed over time and that the concept of entering "MELD purgatory" was not

occurring in the United Kingdom[81].

Other centres in Europe have reported an improvement in liver function of HCV patients on the transplant waitlist following DAA treatment to the point where up to 1 in 4 patients can be removed from the waitlist or delisted. This decline in listing numbers is similar to that noted a decade ago after the introduction of antiviral therapy for hepatitis B. In an era where there is a chronic shortage of donor organs and an increasing need, early treatment with DAAs is beneficial in reducing the number of patients needing to progress to transplant[82,83].

HCV recurrence in the graft was a common problem post-transplant in patients with HCV. This contributed to accelerated fibrosis progression due to an immune incompetent state, resulting in graft dysfunction and eventual failure. With the introduction of DAAs, treatment of HCV recurrence in the post-transplant setting now prevents graft loss and the need for re-transplantation in this cohort[82,83].

Extrahepatic manifestations

HCV infection has an impact not only on the liver, but also systemically. A meta-analysis of 22 studies demonstrated that HCV infection increases the risk of cardiovascular mortality, with a two-fold higher risk of subclinical carotid plaques amongst HCV patients. HCV patients also have a higher risk of peripheral artery disease, cardiovascular events and cardiovascular mortality[84]. These changes are theorized to be due to systemic inflammation and release of inflammatory cytokines within the body caused by the virus. Based on this theory, treatment of HCV should result in a reduction in risk of extrahepatic manifestations.

A prospective Italian study by Nevola *et al*[85] evaluated HCV patients before and 24 wk after treatment with DAAs. After achieving SVR, patients demonstrated an improvement in fasting blood glucose levels and reduced insulin resistance, regardless of the fibrosis state. In patients with impaired fasting glucose pre-treatment, 32% had normal blood glucose levels following SVR. Forty-five percent of diabetic patients experienced an improvement in glycaemic control, with some patients managing to reduce or cease their diabetic medications[85]. This indicates that HCV clearance is associated with a significant change in glucose metabolism, independent of baseline BMI. This has also been confirmed by other studies[86-90].

Changes in lipid profiles also occur following SVR, commonly manifest with an increase in LDL levels. The effect on HDL and triglycerides is less consistent across studies[91-95]. Lipid disturbances require closer monitoring in patients who have achieved viral clearance. Although lipid profiles may deteriorate following SVR, renal function improves. Patients in the Nevola cohort experienced an improvement in eGFR by 10% compared to baseline, regardless of the fibrosis status[85].

Depression is co-morbid with HCV infection in up to one-third of cases. Patients are often marginalized and experience psychosocial stigma due to their positive HCV status. From a physiological standpoint, it is thought that the systemic inflammation caused by the virus and the invasion of HCV into the nervous system results in disruptions of neurotransmission pathways. Moez *et al*[96] used the Beck Depression inventory scale to prospectively assess change post HCV treatment in their cohort of Egyptian patients and found a significant decrease in scores 1 month and 3 months post-SVR which correlated with an improvement in mood symptoms.

CONCLUSION

The use of NAs in HBV and DAAs in HCV has resulted in substantial benefits to patients who suffer with these chronic diseases. The therapeutic benefits gained from treatment encompass not only manifest as improvements in physical and mental health but also quality of life and economic health burden. It is hoped that there will be effective curative treatment for HBV in the coming years. Although there has been a decrease in the incidence of chronic HCV with the introduction of DAAs, there is still much work to be done before achieving the WHO's target of HCV eradication by 2030. Reaching this target will require further screening, especially in at-risk groups, and more widespread subsidised use of DAAs worldwide.

Abstract

Hepatitis C virus (HCV) infection is widespread and affects 71 million people worldwide. Although hepatic manifestations are the most frequent, ranging from chronic hepatitis to cirrhosis and hepatocellular carcinoma, it is also associated with several extrahepatic manifestations. Infected patients may present non-specific neurological symptoms, regardless of the presence of liver cirrhosis. Several pathogenetic mechanisms underlying neurological symptoms have been hypothesized: neuroinvasion, immune-mediated damage, neurotransmitter alterations and cryoglobulinemia. Alterations of the central nervous system include cerebral vasculopathy, acute or subacute encephalopathy and inflammatory disorders. HCV infection may be responsible for neuropathies, of which the most frequent form is symmetrical axonal sensory or sensory-motor polyneuropathy which causes loss of leg sensitivity and weakness. Up to 50% of patients with HCV infection may experience cognitive decline and psychological disorders, such as depression and fatigue. HCV associated neurocognitive disorder is independent of the presence of liver cirrhosis and affects different domains than in patients with hepatic encephalopathy. It can be studied using specific tests that mainly explore executive functions, verbal learning and verbal recall. These disorders significantly reduce the quality of life. The new antiviral therapies improve the extrahepatic symptoms of HCV infection and their success depends on the achievement of sustained virological response. However, the effect of therapy may differ depending on the type of organ involved; neurological symptoms can be irreversible if there is organic liver damage. The aim of this review is to provide a critical overview of physiopathological mechanisms, diagnostic and therapeutic strategies of the neurological and psychiatric effects of HCV infection.

Core Tip: The aim of this review is to provide a critical overview of neurological and psychiatric disorders in patients with hepatitis C virus infection, the underlying pathogenetic mechanisms and the effect of new direct-acting antivirals on extrahepatic symptoms. The main clinical and pathogenetic differences to hepatic encephalopathy and the different diagnostic strategies used in these two conditions are reported.

INTRODUCTION

Hepatitis C is caused by hepatitis C virus (HCV), an RNA virus belonging to the family Hepadnaviridae. It has been estimated that there are 71 million patients with HCV infection worldwide[1] and it is an important cause of liver-related morbidity and mortality[2].

Despite the prevalent hepatic involvement, HCV infection is now considered a systemic infection due to increasing evidence of the ability of the virus to enter and replicate in major cellular systems[3].

HCV infection has been associated with more than 30 extrahepatic manifestations [4], some of which are a consequence of the proliferation of B lymphocytes with consequent monoclonal and polyclonal production of antibodies showing the activity of the rheumatoid factor or cryoglobulins[5].

Extrahepatic symptoms can prevail over hepatic symptoms or aggravate them[3] and can involve cardiovascular, joint, dermatological, renal and neurological systems.

Hepatic encephalopathy is the most typical manifestation of central nervous system involvement in patients with liver cirrhosis. The hypothesis that chronic HCV infection can itself cause brain dysfunction derives from evidence from patients without cirrhosis or cryoglobulinemia who frequently have a wide range of non-specific neurological symptoms[2].

Up to 50% of non-cirrhotic patients with HCV develop neurological and psychiatric symptoms whose manifestations do not correlate with the severity of liver disease or with viral replication rate[3].

Thus, in the diagnostic work-up of a patient with neurological and psychiatric symptoms, physicians should also consider HCV infection as a possible etiological factor[3].

Finally, it should be considered that the presence of HCV in an extrahepatic and immune-privileged site could be a potential source of late relapse after antiviral therapy[2].

PATHOGENESIS

The ways in which HCV causes the occurrence of neurological and psychiatric symptoms are different and several mechanisms have been hypothesized: Neuroinvasion and direct damage: Several studies have shown that the nervous system is a permissive site for viral replication, as confirmed by the presence of intermediate replicative forms of HCV-RNA and viral proteins at this level[3].

Furthermore, the presence of HCV in the cerebrospinal fluid of patients with cognitive decline has been demonstrated through gene sequencing techniques[2], but HCV-RNA levels are 1000-10000 times lower than those found in the liver[6].

However, the viral sequences of E1 and 5′ untranslated regions found in the central nervous system are different to the hepatic sequences, suggesting an independent life of the virus in the central nervous system[3,6].

In line with this hypothesis, cerebral viral quasispecies share genomic sequences with those found in lymphoid tissues and peripheral blood mononuclear cells, but not with hepatic cells[3].

These data suggest the hypothesis that peripheral blood mononuclear cells can mediate the entry of virus into the central nervous system through a mechanism called "trojan horse"[7].

Therefore, the virus first infects peripheral monocytes and then crosses the blood-brain barrier after infection of brain microvascular endothelial cells[6]. In this way, virus, immune cells, cytokines and chemokines can enter the central nervous system causing immune brain activation[8,9].

It should be noted that microvascular endothelium cells are the only cells in the central nervous system that express HCV receptors; so, they play a critical role in allowing virus entry in this site[10].

CD-81, SR-BI and claudin 1 are expressed on epithelial and endothelial cells of different tissues and it has been shown that antibodies against these antigens inhibit virus entry into cell lines derived from cerebral endothelium *in vitro*. Therefore, they can represent the target for HCV entry in brain endothelial cells[10,11].

Other studies have shown that Apolipoprotein E (ApoE) also plays an important role in this process. In fact, anti-ApoE antibodies can neutralize infection in cell lines derived from cerebral endothelium[6].

Therefore, although normally microglia do not express the molecules necessary for HCV entry, the virus evades this obstacle by directly infecting peripheral precursors and altering the selective filter of the blood-brain barrier. This mechanism is similar to that described for HIV[12,13].

Confirming this hypothesis, immunohistochemical and molecular techniques have shown that astrocytes and microglia are target cells for HCV infection[12,14].

Cells with positivity for HCV NS3, also express CD-68 which is a marker of glial cells. When RNA of these cells is amplified, the result is expression of both microglia markers and pro-inflammatory genes such as IL-12, IL-8 and TNF alpha[14]. Moreover, the activation of infected microglia cells results in an increased production of excitatory amino acids that can induce neuronal death through excitotoxicity[15].

Metabolic and neurotransmission alteration: Magnetic resonance spectroscopy allows measurement of the concentration of certain metabolites in specific brain regions. Choline is a metabolite expressed by glial and proliferating cells and is used as a marker of inflammation and of the synthesis and turnover of cell membranes; N-acetyl aspartate is a neuronal metabolite and a marker of neuronal integrity, so its decrease is indicative of neuronal loss or dysfunction; myoinositol is produced only by glial cells and increases with glial proliferation, called gliosis, or with interruption of myelin[2,16].

Several studies have shown an increased level of choline and myoinositol, both in cerebral white matter and basal ganglia, and a reduction of N-acetyl aspartate level in basal ganglia. These findings are suggestive of glial activation and macrophage infiltration and support the hypothesis of neuroinflammation.

Neurotransmission studies using single photon emission computed tomography (SPECT) demonstrated an alteration of serotonergic and dopaminergic neurotransmitter systems in the midbrain and basal ganglia of up to 60% in HCV patients[17,18]. This can be related to high peripheral cytokine levels, particularly IL-1 and IL-6, which can negatively interfere with neurotransmitter systems and impair memory and executive functions[2,19].

Finally, perfusion studies have shown increased perfusion in the basal ganglia compared to cerebral cortex; this report suggests a vascular response secondary to immune activation due to neuronal invasion, confirming the hypothesis of neuroinflammation[20].

This picture is typical of other inflammatory conditions such as multiple sclerosis [21].

Overall, these studies have shown abnormalities in dopamine and serotonin signaling, neuronal hypometabolism and neuro-inflammation in some patients with chronic HCV infection.

Cryoglobulinemia: cryoglobulins are immunoglobulins able to bind to each other at temperatures below 37°C, causing organ damage through two main mechanisms. The first mechanism, associated with type I cryoglobulinemia, consists of "vascular sludging" which is a hyperviscosity syndrome; the second mechanism, typical of type II and III cryoglobulinemia, is a mechanism of immune-mediated vasculitis[22].

One of the consequences of HCV infection is mixed cryoglobulinemia (type II and III) which is characterized by the precipitation of immune complexes. Type II and III cryoglobulinemia are due to an increase in cryoglobulin production by B lymphocytes clones.

HCV lymph-tropism is the first step in inducing cryoglobulinemia; in fact, the E2 protein of the viral envelope interacts with the surface protein CD-81 of B lympho-

cytes, inducing proliferation and production of IgM monoclonal antibodies[23,24].

The characteristic pathological sign of cryoglobulinemia is leukocytoclastic vasculitis which affects medium and small blood vessels with transmural fibrinoid necrosis, thrombotic lumen occlusion and infiltration of polymorphonuclear cells. The consequence of vasculitis is ischemic tissue damage[4]. This condition is now referred to as HCV-associated cryoglobulinemic vasculitis (HCV-associated CV).

CENTRAL NERVOUS SYSTEM DISORDERS

Cerebrovascular disease

Acute and chronic cerebral vasculopathy is more frequent in patients with HCV than in the general population and HCV-RNA level correlates positively with the risk of cerebrovascular death[25].

Acute events such as stroke, transient ischemic attack, lacunar syndrome and, rarely, bleeding, have been reported in patients with HCV infection, in some cases representing the initial clinical manifestation of infection itself[26].

Several retrospective and prospective studies have shown an association between HCV infection and risk of stroke, which can occur at a lower age and without the classic cardiovascular risk factors[25].

Several responsible mechanisms have been hypothesized.

Chronic systemic inflammatory state can be responsible for arterial remodeling that precedes the development of carotid plaque[27], while the locally active presence of virus can cause plaque instability with erosion, rupture and thromboembolic event [28].

Furthermore, chronic HCV infection predisposes to metabolic imbalances; in particular, the virus can alter glucose homeostasis and lipid metabolism in a pro-atherogenic sense[29]. The association between infection and development of type II diabetes mellitus is well documented in the literature[6].

Mixed cryoglobulinemia in the brain can affect vasa nervorum and cerebral arterioles causing occlusive cerebral vasculopathy[2] and they constitute an independent risk factor for carotid plaque formation[4].

Finally, in some patients the ischemic event may be secondary to ANCA or antiphospholipid antibodies which can cause a non-cryobobulinemic vasculitis[4,30].

Acute or subacute encephalopathy

Chronic HCV infection can be responsible for acute and subacute involvement of white matter when associated with cryoglobulinemia or systemic vasculitis[4].

This encephalopathy is clinically characterized by cognitive decline, confusion, altered state of consciousness, dysarthria, dysphagia and incontinence as a result of widespread involvement of cerebral white matter in patients with cryoglobulins or circulating anticardiolipin antibodies[4].

This condition could be due to ischemic damage and this hypothesis is confirmed by the presence of small subcortical and peri-ventricular white matter lesions found on magnetic resonance imaging[4]. In addition, diffuse and severe changes in supratentorial and infratentorial white matter highly suggestive of cerebral vasculitis, have been observed in patients with systemic vasculitis[31].

Inflammatory disorders

HCV infection has been associated with the onset of central nervous system inflammatory diseases which can occur in different clinical scenarios.

In the literature, cases of rapidly developing leukoencephalitis clinically characterized by cognitive decline, tetraparesis and aphasia, and histologically by perivascular infiltrates of T lymphocytes and microglia nodules have been reported.

Fatally progressive encephalomyelitis presenting with epilepsy, motor, sensory and autonomic deficits and characterized by loss of neurons and perivascular infiltration of lymphocytes in the brainstem and cervical spinal cord may occur[32,33].

The hypothesized pathogenetic mechanism is that of immune-mediated damage rather than direct damage induced by virus[4]. Confirming this hypothesis is the response to steroid therapy in cases of acute disseminated encephalomyelitis, a post-infectious autoimmune disease characterized by immune-mediated damage of cerebral and cerebellar white matter and clinically characterized by alterations of consciousness, psychomotor agitation, focal neurological symptoms and urinary retention[3,34].

Chronic HCV infection can also induce myelitis due to antibody-mediated autoimmune demyelination. Transverse myelitis is a common manifestation of this group of disorders in which the immune-mediated mechanism of damage is confirmed by anti-HCV antibodies but not the presence of viral genome in cerebrospinal fluid. The prevalent symptoms are autonomic, sensory and motor dysfunction, sensory ataxia and spastic paraplegia[4].

PERIPHERAL NERVOUS SYSTEM DISORDERS

During HCV infection, a high prevalence of peripheral neuropathy has been reported, which involves 40% to 75% of patients[6].

This finding is more evident in patients with mixed cryoglobulinemia, in whom fascicular ischemia and axonal degeneration are observed as a result of vasculitis of the vasa nervorum or necrotizing arteritis of medium-sized vessels[35]. In fact, up to 60% of patients with cryoglobulinemia present peripheral neuropathy, while a smaller percentage presents involvement of the central nervous system (6%) due to direct involvement of cerebral arterioles[4].

However, peripheral neuropathy has been demonstrated in subjects who do not have mixed cryoglobulinemia. In these cases, immune complexes or autoimmune mechanisms induced by virus and dependent on T lymphocytes, may play a role in inducing vascular and perivascular inflammation[2,36].

In any case, the pathogenesis is indirect and predominantly inflammatory as the virus does not invade peripheral nerves or muscle tissue[6].

Sensory or motor axon degeneration disrupts communication between the central and peripheral nervous systems. Motor damage can be responsible for weakness, while sensory damage can cause paresthesia, hyperalgesia, allodynia, pain and numbness. Autonomic damage can result in organ damage[6].

The most frequent form of peripheral neuropathy is symmetrical axonal sensory or sensorimotor polyneuropathy which is typically characterized by loss of sensation and weakness in the lower leg region[37].

Asymmetrical forms include small fiber sensory polyneuropathy which is the most common clinical manifestation and is characterized by tingling, burning feet and restless legs syndrome. In more advanced cases, neuropathy can affect larger caliber fibers (sensory polyneuropathy of the large fibers) which presents with loss of sensation, paresthesia, cramps and numbness[38,39].

Other clinical presentations are mononeuropathy and multiple mononeuropathy, which involves non-contiguous nerves. Cranial nerves are usually spared from this phenomenon, although there have been reports of abductor, facial and trigeminal nerve involvement[4].

Rare forms of neuropathy are pure motor polyneuropathy and autonomic neuropathy[40,41].

NEUROPSYCHOLOGICAL DISORDERS

Up to 50% of patients with chronic HCV infection has neuropsychiatric symptoms, "brain fog", fatigue and impaired quality of life, regardless of the severity of liver disease[6,13]. These alterations can interfere with daily activities and with the ability to maintain independence[15].

While it is possible that psychiatric symptoms can contribute to cognitive decline in these patients, it appears unlikely that psychiatric symptoms alone can fully explain the cognitive deficits.

A more likely scenario is that both psychiatric symptoms and cognitive impairments are part of the neuropsychiatric syndrome found in patients with chronic HCV infection[15].

Fatigue

Chronic fatigue is the most common symptom of chronic HCV infection, with a prevalence ranging from 20% to 80% in different cohorts[2].

It is perceived as a feeling of physical and mental exhaustion that is often accompanied by muscle and joint pain, sleep disturbances and restless legs syndrome[4]. This "central" fatigue differs from the "peripheral" fatigue linked to muscle weakness.

Fatigue is influenced by psychological, social and physical factors, so a direct virus effect on this symptom remains unclear[2]. In fact, it is the hallmark of depression and consequent apathy, demotivation, unrefreshing sleep, disinterest and loss of energy [42].

Moreover, a positive association between fatigue and hepatic fibrosis has been demonstrated by Teuber *et al*[43] In fact, the degree of fatigue assessed with the Fatigue impact scale was higher in patients with severe fibrosis or cirrhosis than in patients with mild fibrosis, mostly in the physical domain.

However, central fatigue and depression may share possible biological changes in the brain.

It has been hypothesized that alterations in cerebral metabolism and neurotransmission in the limbic system, ascending reticular system, globus pallidus and putamen are associated with chronic fatigue[4].

Dopamine reduction in the limbic system and ascending reticular system could be secondary to cytokine-induced reduction of tetrahydrobiopterin, an enzyme involved in dopamine synthesis[44,45]. In fact, a study showed an association between fatigue and peripheral inflammation, suggesting that activity of the peripheral immune system may contribute to this symptom[46].

Impairment of serotonin transmission, implicated in depression, has also been correlated with fatigue. This finding is confirmed by the fact that treatment with ondansetron, a competitive antagonist of the serotonin receptor, is effective in improving fatigue. Therefore, this evidence supports the role of serotonin pattern dysfunction in causing fatigue and is in line with data showing a decrease in serum tryptophan levels and a reduction in serotonin synthesis in patients with chronic HCV infection[17,47].

Depression

A high frequency of anxiety and depression has been reported in patients with HCV infection and these psychiatric pathologies negatively impact the quality of life[2].

The prevalence of HCV infection in patients with psychiatric disorders is significantly higher than in the general population and can affect 20% to 50% of infected patients compared to 10% of healthy subjects[2,6]. This association would be greater in genotype 3a[48,49].

An important aspect is that depression can affect patient prognosis as it is associated with poor adherence to antiviral therapy[50]. Therefore, multidisciplinary involvement is essential both to ensure adherence to treatment and for management of depressive symptoms[45].

Depression can be reactive to physical and psychosocial sequelae of HCV infection. Being aware of infection itself constitutes a risk factor for depression due to the impairment of family and intimate relationships, stigmatization and social marginalization[2,45]. Frequent coexistence of intravenous substance abuse[51] or symptoms such as fatigue and cognitive decline may also explain the onset of depression[52]. Depression can also be secondary to comorbidities associated with HCV infection such as diabetes mellitus and insulin resistance, metabolic syndrome, cardiovascular disease and inflammatory conditions such as cryoglobulinemia and arthritis which cause skin manifestations, motor and sensory neuropathies, joint pain and reduced joint mobility[45].

A higher burden of physical symptoms from HCV is associated with increased depression, and this burden increases with complications of cirrhosis such as ascites, sarcopenia and encephalopathy, causing limitations in physical and social function [44].

However, depression is not entirely attributable to these factors.

Endotoxins and peripheral cytokines, in particular IL-2, IL-6 and IL-10, act on the blood-brain barrier stimulating prostaglandin E2 release in the central nervous system. This in turn stimulates the release of additional cytokines by microglia cells, such as IL-1, IL-4, IL-6, IL-12, IL-18 and TNF-α. These mediators can inhibit neurotransmission in areas involved in affective responses and emotional processes[53], and induce the activity of enzymes that metabolize tryptophan into neurotoxic metabolites rather than serotonin[54]. In turn, serotonin deficiency can cause an excessive release of inhibitory neurotransmitters leading to depressive symptoms. In fact, serotonergic projections from midbrain nuclei modulate the activities of cortical and subcortical structures involved in behavior, mood and attention regulation[16].

The cytokines can excessively stimulate the hypothalamus-pituitary-adrenal system leading to excessive endogenous cortisol production which can alter hippocampus neurotransmission. In addition, corticotropin-releasing hormone can directly cause neurotoxicity[45].

Confirming the direct role of virus in causing depression, in a cross-sectional study of patients with liver disease of different etiology [hepatitis B virus (HBV), HCV, alcohol abuse and metabolic syndrome], only the presence of HCV was found to be independently associated with depression. This suggests an additional and causal mechanism due to virus presence that contributes to depression.

Quality of life

The World Health Organization defines the quality of life as the individual's perception of their state of physical, mental and social well-being[2].

Several studies have highlighted the impact of chronic HCV infection on quality of life, even without significant liver disease and regardless of modality of virus acquisition, for example previous substance abuse[2].

Even in the absence of debilitating symptoms, HCV compromises quality of life by negatively impacting the physical and mental well-being of patients. Nonspecific symptoms such as asthenia, irritability, general malaise and musculoskeletal pain can occur in patients with chronic HCV infection and in many cases reduce the sense of physical well-being causing emotional problems[1]. Indeed, in quality of life studies in which the SF-36 questionnaire was used, depression and fatigue were found to be independent predictors of reduced quality of life[45].

Other factors involved in the deterioration of quality of life are the psychological impact of prognosis, comorbidities associated with infection and social stigmatization, the shame of being infected and the fear of infecting other people, unemployment and financial problems.

Furthermore, until a few years ago, patients were concerned about the limited eradication capacity of interferon-based regimens and about the disabling adverse effects associated with this therapy[1].

Quality of life is more compromised in patients with HCV than HBV infection and this may suggest a direct role of HCV virus on this aspect[55]. In fact, several prospective studies have shown that infected patients compared to non-infected, have lower scores related to quality of life even before knowing their serological status[56] and that antiviral therapy and viral suppression induce an important clinical improvement[1].

Therefore, HCV infection has a direct effect on quality of life that can be aggravated by psychological factors related to diagnosis and clinical complications of infection itself[2].

Several studies have identified which factors are independently associated with reduced quality of life as they can potentially aggravate the burden of infection.

A study by Jang *et al*[57] showed that the SF-36 physical and mental component summary scores of HCV patients, were below the normal limits. However, those with decompensated cirrhosis had the lowest health-related quality of life (HRQoL), while HCC and chronic hepatitis patients had similar HRQoL results.

Confirming this hypothesis, Golabi and colleagues demonstrated that severity of liver disease may effects patients' HRQoL; in fact worsening hepatic dysfunction in patients with cirrhosis (higher MELD score) and development of complications, such as ascites and hepatic encephalopathy, can cause severe impairment of HRQoL[58].

Thus, there may be a stage-dependent relationship between the degree of fibrosis and the impairment of QoL in patients with severe fibrosis or cirrhosis, compared to those with moderate fibrosis.

HCV-ASSOCIATED NEUROCOGNITIVE DISORDER AND MINIMAL HEPATIC ENCEPHALOPATHY

There is increasing evidence to support that cognitive impairments in patients with chronic HCV infection occur before the development of cirrhosis and are independent of liver function, viral load and genotype[15].

Many factors that may coexist in infected patients can aggravate cognitive decline such as the presence of liver cirrhosis and minimal hepatic encephalopathy (MHE), drug abuse and psychiatric disorders such as anxiety and depression[2]. On the other hand, pre-infectious intellectual functions and educational level can be protective against cognitive decline[59,60].

Genetic factors have also been seen to play a role in the development of cognitive disorders; in particular, some allelic variants of *ApoE* gene result in a lower impairment of attention and executive functions[61].

The term HCV-associated neurocognitive disorder (HCV-AND) is used to refer to this spectrum of alterations unrelated to advanced liver disease and therefore distinct from potentially reversible complications seen in patients with MHE[16].

Patients with chronic HCV infection may present symptoms related to cognitive decline. In particular, the areas mainly involved are: Executive functions: involved in problem solving, monitoring one's own behavior, self-control, cognitive flexibility, working memory, volition, sustained attention and logical reasoning; verbal learning and verbal recall. Therefore, in HCV patients there is a prevalent involvement of the frontal lobe, which is responsible for alterations of executive functions.

Cognitive domains related to posterior brain regions, primarily involved in visuospatial and visual perceptual abilities and constructive practice, are rarely involved; conversely these regions are mainly altered in patients with MHE[16]. Thus, there are some differences from both a pathogenic and a clinical-diagnostic point of view between HCV infected patients and those with hepatic encephalopathy.

Type C hepatic encephalopathy is one of the complications seen in patients with liver cirrhosis of different etiology and is a consequence of severe hepatocellular damage or porto-systemic shunts. This condition can manifest itself with a wide spectrum of neurological and psychiatric symptoms whose spectrum varies from subclinical forms to more severe forms characterized by a complete alteration of the state of consciousness.

To date, hepatic encephalopathy is divided into two types: covert which includes minimal hepatic encephalopathy and grade I hepatic encephalopathy, and overt (OHE), which includes grade II, III and IV hepatic encephalopathy[62-64].

OHE is characterized by personality alterations such as apathy, disinhibition and irritability, alterations in the sleep-wake cycle with excessive daytime rest, disorientation in time and space, altered state of consciousness, asterixis, acute confusion, stupor and finally coma.

The pathogenesis shown by hematoxylin and eosin staining is complex and sees a central role of ammonia which determines the activation of oxidative stress in astrocytes and swelling due to intracellular accumulation of osmotically active substances such as lactates and glutamine; a contribution is also linked to metal accumulation and neurosteroids that are able to activate inhibitory GABA-A receptors [65]. However, HE pathogenesis could be considered multifactorial. In fact, systemic inflammation and metabolites other than ammonia are involved.

MHE is the mildest form of hepatic encephalopathy, characterized by poor performance on psychometric tests that assess attention, working memory, psychomotor speed and visuospatial skills. Despite being subclinical, minimal HE has a heavy burden both on patients and caregivers. In fact, the relationship between MHE and QoL, driving capacity and sleeping is well known. Therefore, it is important to detect MHE, which can be recognized in asymptomatic patients using appropriate psychometric tests and neurophysiological methods.

MHE is a frequent complication of liver cirrhosis, affecting up to 80% of patients and, despite its minimal clinical expression, constitutes a significant problem as it is associated with burden on the caregiver, inability to drive, sleep disturbances, falls, worsening quality of life and risk of developing OHE[60].

Cognitive decline in patients with MHE mainly affects the following domains: Selective attention and vigilance; Psychomotor speed, with lengthening of reaction times; Inhibitory responses, with loss of inhibitory control; Visuospatial skills; Verbal skills are relatively preserved[66].

DIAGNOSTIC STRATEGIES IN HCV-AND

To distinguish between HCV-AND and MHE in terms of cognitive decline, a multimodal approach is required that includes assessment of liver function, brain imaging and extensive neuropsychological tests that assess broad aspects of cognition and not just those related to frontal executive functions[16].

In patients with suspected HCV-AND, tests that can be used to analyze the various cognitive domains are: Verbal learning and episodic memory: Rey auditory verbal learning test, Hopkins verbal learning test total recall, brief visual memory test revised total recall, digit forward span, verbal learning and memory test; Working memory: digit backward span, letter number sequencing, paced auditory serial addition task; Visuospatial skills and planning: Rey-Osterrieth complex figure test (ROCF) in the immediate trial; Lexical skills and executive functions: phonemic and the semantic verbal fluency tests, color-word-interference test (Stroop), trail making test part B,

Wisconsin card sorting test, ROCF in the 10-min delayed recall trial; Logical thinking: verbal judgment test; Non-verbal intelligence: Horn's performance test system[67-69].

Table 1 summarizes the main tests and their relative characteristics that can be used to investigate the altered cognitive domains in patients with HCV-AND.

Neuropsychological tests, such as potential P300 related to the event, have shown an increase in latency and a reduction in peak amplitude in patients with cognitive decline, regardless of confounding factors such as fatigue and depression[4].

Diagnostic strategies in MHE

The optimal measure for diagnosing MHE is still debated. In fact, none of the methods proposed cover the complexity and the heterogeneity characteristic of this syndrome. Diagnosis of MHE can be made with psychometric tests and electrophysiological tests. Tests used to investigate domains known to be affected in patients with MHE are: Selective attention and vigilance: critical flicker frequency, continuous reaction time test, SCAN test; Psychomotor speed and visuospatial skills: psychometric hepatic encephalopathy score, Stroop test, repeatable battery for the assessment of neuropsychological status; inhibitory responses: inhibitory control test; animal naming test.

Similar to non-cirrhotic patients with chronic hepatitis C, patients with MHE present emotional alterations such as depression, anxiety and alexithymia[70], especially in the final stages of their pathology which is characterized by medical complications, hospitalizations, functional limitations and changes in body image[1].

They also have a reduced quality of life which can be linked to various mechanisms such as physical problems and complications related to liver cirrhosis and psychiatric symptoms. In fact, depression, anxiety and alexithymia are among the major determinants of the quality of life of cirrhotic patients, regardless of the severity of the liver disease.

The presence of these disorders can be explored using tests such as: Depression: Zung-self depression rating scale; Anxiety: Spielberger state-trait anxiety inventory Y1 and Y2; Alexithymia: Toronto alexithymia scale[70].

Imaging in HCV-AND

Over time, several imaging studies have been conducted with the aim of finding a biological relationship between HCV infection and cognitive decline[2].

On magnetic resonance imaging, patients with cognitive decline show an increase in signal intensity in T2-weighted sequences in peri-ventricular white matter[71]. Furthermore, atrophy and cytoarchitectural alterations are observed in the lobe of insula which is involved in attention[16].

SPECT studies have demonstrated an alteration in mesencephalic/hypothalamic and striatal dopaminergic transporters in up to 60% of patients and this finding is associated with executive-attentional function decline[18].

On the other hand, a positron emission tomography (PET) with 18-fludeoxyglucose (18-FDG) study, demonstrated hypometabolism in the anterior cingulate gyrus and in the upper and middle frontal gyrus, responsible for fatigue and impaired attention, and in the parahippocampal gyrus and caudate nucleus bilaterally, causing anxiety, depression and lengthening of reaction times[16]. These data confirm the role of impaired dopaminergic transmission in the cognitive decline of patients with chronic HCV infection[2,72].

Spectroscopy studies have instead highlighted an increase in the choline/creatine ratio in the basal ganglia and frontal white matter[73], which is associated with executive functions decline[6]; another study showed a reduction in the N-acetyl aspartate/creatine ratio in frontal grey matter, which proves a reduction in the neuronal population in this area. These findings suggest an increase in cell membrane turnover and a decrease in neuronal functions, respectively[74].

The increase in myo-inositol levels agrees with chronic cellular inflammation induced by virus[75] and has been associated with fatigue and cognitive decline[76].

Overall, neurophysiological and imaging tests are important tools for characterizing cognitive impairments as they can anticipate dysfunction before it manifests clinically. They are also not subject to bias due to test batteries, self-reported measurements, different socio-cultural levels and different degrees of school education[15].

Imaging in HE

Imaging findings in patients with liver cirrhosis are different to those previously described for patients with HCV-AND.

In fact, spectroscopy studies confirm that the pathogenetic mechanism for these symptoms is different to that observed in patients with chronic hepatitis C. In

Table 1 Tests exploring cognitive domains[67-69]

Test	Tested domains	Description
Rey auditory verbal learning test (RAVLT)	Immediate memory and learning	After hearing a list of 15 unrelated words, the patient has to recite as many words as he can recall for a total of five trials.
Hopkins verbal learning test total recall (HVLT)	Verbal memory	This test consists of three parts: total recall, delayed recall and recognition. The test consists firstly of three free recall learning trials with 12 words from three different categories such as professions, food and sports (HVLT total recall). 20-min later, the patient has to name the words from the free recall learning list (HVLT delayed recall). Finally, the yes/no recognition trial is completed (HVLT recognition).
Brief visual memory test revised total recall (BVMT)	Visuospatial memory	In three learning trials, the patient views the stimulus page for 10 s and then has to draw as many figures as possible in their correct location. A delayed recall trial is administered after a 25-min delay. Lastly, a recognition trial, in which the patient has to identify which of the 12 figures were included among the original geometric figures, is administered.
Digit forward span and digit backward	Verbal learning and episodic memory	The Digit Span consists of two different tests: digits forward (repeating digits forward) and digits backward (repeating digits in reverse). This test consists of pairs of sequences of numbers read by the examiner. When the patient repeats correctly the first sequence, the examiner reads the next one, which is longer by one number than the previous one, and continues until the patient fails a pair of sequences or correctly repeats the last sequence consisting of nine numbers.
Letter number sequencing (LNS)	Working memory	During administration, the patient listens to a series of numbers and letters read by the examiner. Then he has to repeat the numbers in ascending order and letters in alphabetic order.
Paced auditory serial addition task (PASAT)	Auditory-verbal divided attention; selective and sustained attention	Numbers are presented orally at a rate of about 1-2 s. The patient has to add pairs of numbers, adding each number to the previous one. In this way, the first number will be added with the second, the second with the third, the third with the fourth and so on.
Rey-Osterrieth complex figure test in the immediate trial (ROCF)	Visoconstructive ability, problem solving, perceptual organization and visual memory	There are 18 elements overall. In the first part, the patient has to copy a figure (ROCF copy). Three minutes later, he has to perform the figure again without the stimulus (ROCF immediate recall). Two points are given when the elements are correctly reproduced; one point when the production is distorted, incomplete but placed properly, or completed but placed poorly; half point when the elements are distorted or incomplete and placed poorly; zero point when the elements are absent or not recognizable.
Phonemic and semantic verbal fluency test	Lexical skills and executive functions; verbal functioning	For the phonemic part, the patient has to list as many words as possible starting with an F, A or S during 60-s intervals. For the semantic part, he has to list as many animals as he can during a 60-s interval.
Color word interference test (Stroop)	Lexical skills, cognitive flexibility, selective attention and response inhibition (or disinhibition)	Patient has to read three different tables as fast as possible. Two of them represent the "congruous condition" in which he has to read names of colors printed in black. Conversely, in the third table, color-words are printed in an inconsistent colour ink. In this incongruent condition, the patient has to name the ink colour instead of reading the word.
Trial making test part B (TMT-B)	Lexical skills, executive functions, cognitive flexibility	In the TMT-B, the patient has to draw lines sequentially connecting numbers and words alternately. The score represents the amount of time required to complete the task.
Wisconsin card sorting test (WCST)	Lexical skills and executive functions; cognitive reasoning	Patient has to classify cards according to different criteria. There are different ways to classify each card and the only feedback is whether the classification is correct or not. Classification possibilities are the color of symbols, the shape of symbols and the number of shapes on each card. The classification rule changes every 10 cards; so, once the patient has figured out the rule, he will start making mistakes when the rule changes. This test measures how well the patient is able to adapt to changing rules.
Verbal judgment test (VJT)	Logical thinking	This test consists of an oral interview. The examiner asks the patient how he would solve a hypothetical situation.
Horn's performance test system (LPS)	Non-verbal intelligence	This test comprises 40 rows, each with 9 numbers and/or letters. Every row has a logical order with one letter or number that does not fit and the goal is to identify the mismatched character. The outcome parameter is the sum of correct rows.

RAVLT: Rey auditory verbal learning test; HVLT: Hopkins verbal learning test total recall; BVMT: Brief visual memory test revised total recall; LNS: Letter number sequencing; PASAT: Paced auditory serial addition task; ROCF: Rey-Osterrieth complex figure test in the immediate trial; TMT-B: Trial making test part B; WCST: Wisconsin card sorting test; VJT: Verbal judgment test; LPS: Horn's performance test system.

particular, the prevailing pattern is characterized by a reduction of the choline/creatine and myo-inositol/creatine ratio and an increase in the glutamine/creatine ratio.

The exact mechanism underlying the reduction in choline levels has not been fully defined.

This is partly explained by a decrease in choline transport, malnutrition and cerebral metabolism alteration secondary to liver dysfunction.

Glutamine increase could be a consequence of hyperammonemia. In this condition, astrocytes detoxify ammonium converting it into glutamine which causes low-grade cerebral edema and symptoms of HE due to its osmotic effect[77].

In addition, brain MRI reveals basal ganglia hyperintensity in T1-weighted sequences, most likely related to manganese deposits[77].

EFFECTS OF ANTIVIRAL THERAPY

Until recently, INF and pegylated INF have been the only effective treatments for HCV infection as modulators of the immune response, showing a sustained virological response (SVR) of up to 50%-80% when combined with ribavirin.

This therapy is associated with a high prevalence of neuropsychiatric disorders, which affect up to 70% of subjects. Predominant symptoms are mood disorders such as anxiety and depression, psychosis and manic agitation, suicidal ideation and cognitive decline. These disorders disappear at the end of therapy[16] and can be attributed to numerous pathophysiological complications associated with treatment such as alteration of monoamine metabolism, increase in apoptosis, reduction in cerebral neurotrophic factor, alteration of hypothalamic-pituitary-adrenal axis[78] and alteration of frontal-subcortical circuits[15]. Co-factors for the development of this disorder during antiviral therapy are low education, a known history of psychiatric disease and high serum concentrations of IL-6[79]. In subjects infected with HCV and treated with INF, PET studies with 18-FDG have shown a reduction of metabolic activity in the prefrontal cortex which agrees with a depressive state[80].

HCV infection treatment has been radically changed since the introduction of direct-acting antivirals (DAAs). INF-free regimens are better tolerated and are highly effective, reaching an SVR greater than 95%; furthermore, the simplicity of dosage and their safety profile guarantee good compliance.

These antiviral agents considerably improve extrahepatic symptoms underlining the direct and indirect pathogenetic role of virus in precipitating these disorders. Obviously, the success of this strategy depends on achievement of the SVR[6]. This has been confirmed in several clinical studies.

A recent study by Nardelli *et al*[1] showed an improvement in all domains investigated using the SF-36 questionnaire after therapy with DAAs, but also in psychiatric symptoms such as anxiety, depression and alexithymia, which were found to be among the major determinants of altered quality of life.

Some trials have shown that the improvement in quality of life is evident during the first 4 wk of therapy, coinciding with the suppression of viral replication, then continuing until the end of the therapy and beyond during the follow-up[81].

Patients who achieve SVR 12 wk after sofosbuvir therapy, including those with cirrhosis, have reported significant improvements in quality of life, general well-being, fatigue, sleep disturbances, emotional state and physical functioning[16,81].

When INF-based regimens are used, quality of life worsens during treatment due to poor tolerability of these regimens and then improves in those that reach SVR at the end of treatment. Similarly, ribavirin-based regimens are associated with greater impairment of quality of life during treatment than ribavirin-free regimens[81].

However, therapy with new antivirals improves not only psychiatric symptoms, but also cognitive changes.

The study by Kleefeld *et al*[68] demonstrated that after DAA therapy, fatigue and mental health, as well as executive functions, processing speed, learning, verbal fluency and motor skills improved in both monoinfected and those with HIV infection. However, no differences were found in working memory and verbal memory before and after therapy. The hypothesis that has been advanced to explain this phenomenon is that the compartmentalization of virus in the central nervous system may represent a potential source of reactivation of virus, thus explaining the persistence of some cognitive symptoms at the end of therapy with DAAs[45,66]. Therefore, it is unclear to what extent the new antiviral regimens can guarantee a return to normal[81].

To confirm this fact, neurocognitive tests and spectroscopy images were compared in several studies before and after antiviral therapy; patients who reached SVR had a significant reduction in the choline/creatine and myo-inositol/creatine ratio as well as an increase in cognitive functions compared to untreated patients or patients who did not achieve SVR[82].

Mixed cryoglobulinemia is strongly associated with HCV infection and its clinical expression varies from completely asymptomatic to severe vasculitis that manifests with dermatological, renal, neurological and musculoskeletal complications. Many authors report that up to 30% of HCV-infected patients have mixed cryoglobulinemia, but of these less than 10% develop symptoms. Symptomatic patients usually have higher immunoglobulin values.

Mortality and morbidity associated with mixed cryoglobulinemia are significant and treatments are focused on either eradicating the viral trigger with antiviral therapy or inhibiting B cell proliferation with immunosuppressive therapy, usually with steroids and rituximab in severe forms.

INF and ribavirin therapy has been associated with clinical and immunological improvement in patients with mixed cryoglobulinemia, in terms of cryoglobulin, IgM, rheumatoid factor and complement levels. Therefore, in patients who reach SVR, INF-based therapies exert a beneficial effect in those with HCV-CV (62%-78%). However, patients with HCV-CV have a lower rate of achievement of SVR than patients who do not (48.6% *vs* 61.4%). In fact, these patients tend to have comorbidities that can affect the achievement of SVR.

Almost all studies have also shown a complete or partial clinical response in patients with mixed cryoglobulinemia who reach SVR after DAAs therapy (61%-100%). The highest clinical response was seen in the study by Saadoun *et al*[83] in which all patients achieved a clinical response (90% complete and 10% partial) after 12 wk or 24 wk of sofosbuvir/daclatasvir therapy. A similar result was obtained by Gragnani *et al*[84] with complete or partial clinical response achieved in 93% of patients.

However, therapeutic effect may differ depending on the type of organ involved. The study by Gragnani *et al*[84] showed that the effect on dermatological symptoms is greater than that on nephrological and neurological symptoms. Furthermore, palpable purpura, renal pathology and skin ulcers resolve more rapidly than sicca syndrome, fatigue and peripheral neuropathy. In fact, neurological symptoms and sicca syndrome can be irreversible if there is permanent organ damage.

Among patients who have been cured of the infection and who continue to present symptoms of cryoglobulinemic vasculitis, an alternative explanation should be considered such as B-cell non-Hodgkin lymphoma. In fact, B lymphocyte proliferation can reach an autonomous and virus-independent replication phase demonstrated by the persistence of B lymphocyte clones t (14; 18) and small quantities of HCV-RNA in the lymphatic system after eradication therapy[85].

CONCLUSION

HCV can strongly impair the neuropsychological panorama of cirrhotic patients. In this review, we summarized the most innovative aspects of central nervous system impairment in HCV positive patients. Particular attention was paid to patients with advanced liver disease and minimal HE. DAAs therapy completely revolutionized the standard of care for HCV infected patients. In fact, these drugs, characterized by great efficacy and tolerability, have made it possible to reach levels of SVR unthinkable in the twentieth century. Further studies are needed to evaluate in depth the effects of HCV eradication, even in the long-term, on the neuropsychological alterations of these patients, and to determine if there is a residual deficit, which cannot be resolved with viral eradication.

Abstract

Sarcopenia is becoming a well-established player in evaluating patients with chronic liver disease. Data regarding its clinical significance and consequences in the course of liver disease have been growing; many of the data support the idea that it impacts decompensation event frequency, prolonged hospitalization, and mortality, as well as providing the possibility to better prioritize patients on lists awaiting liver transplantation. When assessing the whole clinical scope of the field, which includes malnutrition and frailty, as well as the complete spectrum of muscle mass, strength, and function, it becomes clear that a well-founded approach in everyday clinical practice is essential. In this respect, this article attempts to unveil the most recently published data regarding possible methods and modalities that could be used to diagnose sarcopenia as early as possible, along with the required accuracy and reliability. From the most important field discoveries to data that need further clarification, the merits and weaknesses of the very diverse existing evaluation methods are presented. Finally, a critical overview is given, in an attempt to discern study lines of importance from those that could pose further ambiguity for the theme. The author also poses relevant questions that remain unanswered but are of clinical importance in the field.

INTRODUCTION

Sarcopenia is an important part of the medical evaluation and treatment for chronic liver disease, especially in the advanced stage of the disease (*i.e.*, cirrhosis), not only due to the very frequent coexistence of both medical entities but also because of its impact on the related clinical outcomes. This article focuses on the clinical aspects and consequences of sarcopenia in liver cirrhosis, common diagnostic procedures, and suggestions for clinical therapy. A review of the presented field in the scientific literature is provided, with the intentional omission of pathophysiology, for better transparency, clinical applicability, and an attempt to critically evaluate the most recent study findings.

To facilitate the understanding of common medical terms, a short paragraph summarizing their definitions is presented (see also Figure 1), followed by a brief description of the pathophysiological processes involved. For a more detailed review of the pathophysiology of sarcopenia in liver cirrhosis-especially regarding the possible influence of the gastrointestinal microbiota on the occurrence and course of muscle dysfunction-the author recommends some excellent reviews in this field[1-4].

DEFINITIONS

Malnutrition is defined as a measurable change in physical and mental functions secondary to altered body composition and cell mass, resulting in an impaired quality of life and poor clinical outcomes. It is the consequence of insufficient protein and energy supplies.

It is well admitted that malnutrition participates in the onset of sarcopenia but the link between these two nutritional concepts remains confusing[5].

Sarcopenia is defined as the loss of muscle mass, muscle strength, and reduced physical function.

Frailty is a condition of increased vulnerability to endogenous and/or exogenous stressors associated with physiological decline.

Myosteatosis is pathological fat accumulation in muscles.

PATHOPHYSIOLOGY

Sarcopenia is often equated as a state of advanced malnutrition. The condition is associated with complications such as poor mobility and quality of life and increased mortality. Muscle loss in sarcopenia is not solely at the expense of muscle atrophy, it also involves replacing muscle cells with fat and connective tissue. Protein supply in a sarcopenic patient is low due to chronic muscle degradation which is most clearly manifested during metabolic stress when muscle proteins should be mobilized very quickly to provide the body with amino acids for the liver, gut and immune system function. Sarcopenia in patients with liver cirrhosis is connected to age-related decline in muscle mass and to malnutrition. Studies show that malnutrition develops due to negative energy balance, loss of appetite, rapid satiety and poor food absorption. Concurrent illnesses or addictions (bacterial growth in the gut, pancreatic exocrine insufficiency, alcoholism) exacerbate the condition. Iatrogenic losses include ascites paracentesis and use of laxatives and diuretics. Frequent endoscopic imaging and laboratory examinations also affect diet and weight loss as well as sarcopenia. Therefore, liver cirrhosis is a state of accelerated starvation. In liver cirrhosis, cytokines

Malnutrition - measurable change in physical and mental funcons secondary to altered body composion and cell mass, resulng in an impaired quality of life and poor clinical outcomes

Sarcopenia - loss of muscle mass, muscle strength and reduced physical funcon

Frailty - condion of increased vulnerability to endogenous and/or exogenous stressors associated with physiological decline

Figure 1 Main definitions of the presented topic.

that stimulate catabolic processes in the body are released. Due to the low glycogen stores, energy production is directed towards the breakdown of fatty acids. Gluconeogenesis is mainly pursued through amino acids breakdown, which worsens protein loss. Advancement of the state is also exacerbated by growth hormone and testosterone deficiency, decreased physical activity, and more frequent occurrence of hepatocellular carcinoma (HCC). Patients with liver cirrhosis are prone to replacing muscle fibers with fat cells (myosteatosis), which may further accelerate loss of muscle function and decline in muscle strength. Connection between hepatic encephalopathy (HE) and sarcopenia is in a form of a vicious cycle where ammonia is likely to be directly responsible for mitochondrial oxidative damage and autophagy of skeletal muscle cells; it also inhibits protein synthesis in skeletal muscle through stimulation of myostatin[1-4].

CLINICAL SIGNIFICANCE AND CONSEQUENCES OF SARCOPENIA

To facilitate the clinical application and evaluation of sarcopenia tests, The European Working Group on Sarcopenia and Older People provided consensus criteria for the diagnosis of sarcopenia using muscle mass, muscle strength, and muscle function as a practical clinical definition. In 2019, a revised definition was published. Pre-sarcopenia is defined as the presence of low muscle strength without its impact on muscle mass/quality or muscle function. Sarcopenia is defined as a low muscle strength with additional low muscle mass or quality. For severe sarcopenia, muscle mass, muscle strength, and muscle function needed to be impaired. As can be seen from the definition, muscle mass does not condition muscle function or strength. The end result of the sarcopenia process is a decline in muscle functional abilities assessed by frailty [6].

To assess frailty, the 5 Fried's phenotypes of frailty as cited by Sinclair[7] are used. While patients with 3 or more phenotypes are defined as frail, patients with 1 or 2 phenotypes are defined as prefrail, and those with no phenotype as robust[7]. The concomitant presence of sarcopenia and obesity is significantly associated with prefrailty and frailty, especially in women with cirrhosis[8]. According to a well-defined description by Buchard *et al*[5], "sarcopenia [is] not identical to frailty but there is a major overlap between definitions and diagnosis criteria of the two phenotypes. Frailty is a more multidimensional concept encompassing not only muscle conditions but also exhaustion, well-being, disability, dependency, and cognitive state. Loss of skeletal muscle mass and function remains a strong substratum of frailty, as in malnutrition. The absence of sarcopenia certainly does not rule out frailty but clues of frailty must lead to a complete body composition evaluation".

In a well-designed study, a group of authors led by Traub *et al*[8] evaluated the applicability of the latest definition of sarcopenia in patients with cirrhosis. Computed tomography (CT) examination was used to assess muscle mass, hand grip test to assess muscle strength, and 4 m gait speed test to assess muscle function. Compared to the 2019 definition, they observed that the 2010 definition identified more sarcopenia cases in male patients. In patients with cirrhosis, muscle strength seems to be preserved longer, while muscle mass is already reduced, leading to a significant difference in sarcopenia diagnosis rates when using the 2019 definition. However, the gender imbalance seen in the 2010 definition seemed to be less pronounced with the 2019 definition. They objected to the lack of data whether the 2010 or 2019 criteria is better to predict clinical complications, poorer prognoses, and the effect of specific interventions[8].

Sarcopenia is present in 30% to 70% of patients with cirrhosis, probably less frequently in the population of patients with metabolic liver disease. The prevalence increases with the disease stage and increases sharply before liver transplantation[7,

9]. Based on the Child–Pugh score, the annual rate of decrease in skeletal muscle mass is 1.3% in Child–Pugh A patients, 3.5% in Child–Pugh B patients, and 6.1% in Child–Pugh C patients[10]. The risk of developing sarcopenia is associated with male gender, ascites, and the degree of renal and hepatic dysfunction[9]. Overweight and obesity are as frequent as in general population, ranging from 20% to 40% and aggravating prognosis both in compensated and in decompensated cirrhosis[11]. Sarcopenic obesity (coexistence of sarcopenia and obesity) is present in one-fifth to one-third of patients with cirrhosis. It is determined by using an assessment of sarcopenia to which an assessment of obesity using a body mass index (BMI ≥ 25 or ≥30 kg/m^2) is added. BMI corrected for ascites is probably the most practical to use (see below under the Anthropometry section), although it may shift patients to a lower BMI grade[12]. Myosteatosis occurs in up to 50% of patients with cirrhosis and can be identified in both sarcopenic and non-sarcopenic patients with or without obesity. It meditates inflammatory responses and has been associated with lower muscle function and strength, muscle atrophy, and physical disabilities[12]. It affects mortality, more through loss of muscle function than through liver cirrhosis determinants. It probably plays an important role in the occurrence of HE[13]. Microscopic analysis of skeletal muscle fibers references special attention to atrophy of fast-twitch fibers and reduction in muscle fiber size. Reduced skeletal muscle fiber size and shift toward wider fast-twitch fibers (increased proportion of type IIA/IIX fibers concurrent with lower proportions of type IIA fibers) were visible in the muscle of a sarcopenic patient [3].

The main clinical consequences of sarcopenia are increased mortality *per se*, increased mortality from systemic bacterial infection, the occurrence of HE after transjugular intrahepatic portosystemic shunt (TIPSS) insertion, and the more frequent occurrence of acute on chronic liver failure. Regardless of the underlying disease, it has a significant effect on mortality in patients with HCC[9]. Ebadi *et al*[3] point out that it would be important to define strategies maintaining muscle mass in candidates prior to the TIPSS insertion. A study by Al-Azzawi *et al*[14] confirmed that the existence of sarcopenia in alcoholic hepatitis prolongs hospital treatment. In the case of sarcopenia, patients had a more severe course of the disease. To date, there is no solid evidence linking portal hypertension to known sarcopenia indices. In a well-defined study, hepatic venous pressure gradient (HVPG) was shown to inversely correlate with adipose tissue indices, while CT sarcopenia markers were unrelated to the degree of portal hypertension[15]. On the other hand, the Austrian study group demonstrated poorer survival and an increased risk of further cirrhosis decompensation in the group of patients with HVPG > 20 mmHg by comparing CT sarcopenia indices and invasively assessed clinically significant portal hypertension (CSPH)[16].

In the group of patients awaiting liver transplantation, sarcopenia can affect relegation from the waiting list due to excessive perioperative risk, increased need for hospitalization, and prolonged hospitalization with multiple complications after organ transplantation[9]. Decline of muscle function has a significant impact on mortality and the occurrence of complications requiring hospital treatment[17]. The presence of sarcopenic obesity in this group of patients is relatively common and is associated with higher mortality than if the entities were present separately[11]. After organ transplantation, there is a lack of clinical data regarding the impact of sarcopenia on long-term clinical outcomes[13].

Given the above-mentioned situation, it is not surprising that there are calls for the inclusion of sarcopenia among the factors of transplantation priority [Model for End-Stage Liver Disease (MELD) – score *vs* sarcopenia-MELD score]. A thorough study in this area evaluated patients on a transplant waiting list. To define sarcopenia, CT measurements with proposed cut-off values were used (see below). In this cohort of European patients, they demonstrated the sarcopenia impact on the increased mortality. When comparing MELD to sarcopenia-MELD score, the authors also confirmed a much lower priority of patients with MELD < 15. It has been observed that a better scoring option would include one encompassing the patient's age and previous occurrence of HE[18]. In the literature, other authors support the idea for better transplant priority of patients with sarcopenia and low MELD score to reduce the risk of waiting list mortality and to improve the overall outcome[19]. They also point to the strong impact of sarcopenia reflected in the mere fact that it is equivalent to adding 10 points to the MELD score if presented[20].

From a clinical point of view, it is important whether sarcopenia is worth assessing in the group of patients with cirrhosis and HCC. Sarcopenia probably affects the recurrence or progression of HCC in patients who are candidates for liver transplantation. Presumably, sarcopenia in this group of patients affects long-term mortality after surgical treatment of a single lesion with partial hepatectomy. While sarcopenic

patients have a smaller volume of preserved liver tissue, there is no data connecting sarcopenia and postoperative decompensation in this group. There is also almost no data relating the effect of sarcopenia in HCC treatment with radiofrequency ablation. In the group of patients receiving transarterial chemoembolization, sarcopenia affected survival and response to treatment. In the group of patients receiving chemotherapy with sorafenib, sarcopenia affected disease progression. Numerous data suggest that sorafenib itself has a significant effect on reducing muscle mass. The condition is codependent in both directions as sarcopenia has an impact on the systemic treatment side effects severity (*e.g.*, enteritis), and thus on the sorafenib dosage reduction[21].

In recent years, it has been pointed out that sarcopenia is a systemic disease. Cardiac sarcopenia likely manifests as a heart failure with preserved ejection fraction[1]. Relationships between heart failure and depleted lean muscle mass are indisputable and go both ways. Increased mortality in sarcopenic patients could be partly explained by this bilateral effect, especially in the posttransplant period. Cardiac ultrasound (US) is suggested to assess cardiac function in a sarcopenic patient with cirrhosis[22]. Involvement of the diaphragm leads to reduced peak cough flow in the elderly, increased rate of respiratory infections through impaired airway clearance and difficulties when weaning sarcopenic patients with cirrhosis from mechanical ventilation [5]. Impaired function of the cardiac and respiratory muscles likely contributes to clinical manifestations of dyspnea, weakness, fatigue, reduced exercise tolerance, and loss of appetite, all of which can further contribute to the propagation of sarcopenia and frailty[1].

DIAGNOSTIC METHODS IN THE FIELD OF SARCOPENIA

Questionnaires

Questionnaires take precedence over other tests because of their relatively short evaluation time and their possibility to monitor the condition in a dynamic timely manner[7]. Across the investigative options to assess malnutrition, Subjective Global Assessment (SGA) is the most frequently mentioned. Features of the SGA include a physical exam component that evaluates the loss of subcutaneous fat, peripheral or sacral edema, and muscle wasting. The quantity of muscle and subcutaneous tissue is graded subjectively by the examiner who then categorizes it as normal, mildly, moderately, or severely decreased. Multiple components on patient history are also evaluated. The first component is the amount of weight loss in the previous 6 mo. Supplementary historical features of the SGA include patient's dietary intake and the presence of gastrointestinal symptoms experienced daily for at least 2 wk. Once the history and physical examination sections are completed, patients are classified as well nourished (SGA grade A), moderately malnourished or suspected of being malnourished (SGA grade B), or severely malnourished (SGA grade C). SGA is a partially subjective method constituted by quantitative and qualitative variables, subject to varied interpretations, and reported as having low sensitivity in cirrhotic patients, as it can underestimate the nutritional state in their population[22].

Nutritional Risk Screening 2002 (NRS-2002), Liver Disease Undernutrition Screening Tool (LDUST), Royal Free Hospital-Nutritional Prioritizing Tool (RFH-NPT), and Malnutrition Universal Screening Tool (MUST) can be also used to assess malnutrition in hospitalized patients.

The NRS-2002 is a nutrition screening tool recommended by the ESPEN guidelines [17]. It includes three components—the nutritional score (BMI, weight loss, and dietary intake included), the disease severity score, and the age score (age > 70 years)[17,23]. Patients are classified as having no or low risk.

The LDUST assesses 6 factors that were identified as having the strongest associations with malnutrition in patients with chronic liver disease (nutrient intake, weight loss, loss of subcutaneous fat, loss of muscle mass, fluid accumulation, and a decline in functional status). The three potential patient responses are labeled and indicated as no signs of malnutrition, "mild to moderate" malnutrition, and "moderate to severe" malnutrition[24].

The RFH-NPT is a nutrition screening tool developed in the United Kingdom. It includes three major steps: (1) Patients who have alcoholic hepatitis or are undergoing tube feeding are immediately evaluated as high risk without proceeding to the next step; (2) Patients who do not have alcoholic hepatitis and are not undergoing tube feeding are assessed for fluid overload and its impact on food intake and weight loss; and (3) Patients who do not have fluid overload are assessed for nutritional status (BMI, unplanned weight loss, and daily dietary intake). Patients are stratified as being

at low, moderate, or high risk[2,25].

The MUST includes three categories: Current BMI, unintentional weight loss, and the presence of any acute disease that could compromise nutritional intake for more than 5 d[25].

A large study assessed the importance of RFH-NPT in the Asian population with predominantly viral liver cirrhosis. The questionnaire proved to be useful in the group of patients with a low MELD score and for assessing the prognosis of the disease. The disadvantage of the study is that different questionnaires are only compared with each other, and with only basic laboratory and anthropometric parameters[25]. In a recent publication, Buchard *et al*[5] noted that RFH-NPT and LDUST, despite recommendations for their use in patients with liver cirrhosis, have not yet been associated with clinical issues such as survival and complications appearance. Moreover, LDUST is based on the patient's statement and lacks objective data.

Laboratory tests

Myostatin is a natural muscle growth inhibitor. As a marker, it depends on gender and inflammatory processes in the body. In men with liver cirrhosis, it can be used to assess muscle mass, prognosis of decompensation events, and fit for surgery status. In contrast to Oshida *et al*[27] who came to different conclusions in the group of patients with compensated disease, the cited study used CT sarcopenia indices in a large group of patients with decompensated advanced chronic liver disease (dACLD). The limitation of the test is the decrease in the level of serum myostatin at a very low muscle mass stage which presents a major problem when defining possible cut-off values[26].

Another potential biomarker is irisin, a myokine, mainly expressed and secreted by skeletal muscles as well as functioning as an adipokine. A significant lower irisin level is proved to be a marker for muscle weakness and atrophy. In the group of patients with dACLD, the cited study demonstrated higher irisin levels in women without evidence of an association with irisin levels and the degree of hepatic impairment according to CHILD/MELD score, or the presence of ascites. Sarcopenia was assessed using a hand grip test and CT assessment of muscle mass[2]. In a related publication, a group led by Zhao *et al*[10] studied irisin levels in a group of patients with liver cirrhosis where a hand grip test and CT-assessed muscle mass were also used for the evaluation of sarcopenia. The difference between the studies was in the CT index used, as the latter used the proposed gold standard (see below). Lower irisin levels were demonstrated in the group of patients with a higher CHILD score. They also defined that it is not entirely clear whether this is the cause or the consequence of sarcopenia. Deficiency of the article are poorly defined criteria for the diagnosis of liver cirrhosis [10].

If muscles are damaged by diseases or vigorous exercise, titin is decomposed by proteolytic enzymes, and various titin fragments are detected in serum and urine. One of the isolated fragments is titin-N. The cited study defined its urinary excretion in a group of patients with metabolic-induced fatty liver disease. The study had a well-defined control group, but poorly defined comparative indices (CT indices? muscle and liver elastography? US parameters of skeletal muscle assessment?) in the article itself. According to their observations, titin-N was negatively associated with the amount of muscle mass (higher level in urine correlated with lower skeletal muscle mass) and positively associated with the occurrence of muscle myosteatosis (higher level in urine correlated with higher levels of US-assessed skeletal muscle fat). They also identified an association of the biomarker with the degree of muscle fibrosis progression which may be associated with functional muscle decline. For the latter, a knee extension test and a hand grip test were used as a comparative test[27].

Anthropometry

According to EASL guidelines, two simple criteria can be used in everyday clinical practice to stratify patients at high risk of malnutrition: being underweight (BMI < 18.5 kg/m^2) and having advanced decompensated cirrhosis (Child C patients)[28]. In patients with ascites and peripheral edema, dry weight assessment is proposed, either estimated by the post paracentesis body weight, the weight recorded before fluid retention if available, or by subtracting a percentage of weight based upon the severity of ascites (mild 5%; moderate 10%; severe 15%), with an additional 5% subtracted if bilateral peripheral edema is present[25,28].

Of the measurements that can be performed with an ordinary tape measure, the most common are mid-arm muscle circumference (MAMC), mid-arm muscle area, and triceps skinfold (TSF), all of which are simple and rapid to perform low-cost tests that are not affected by the presence of fluid retention[7,28]. Some Asian studies mention

calf circumference which showed a good association to the frailty[29] in their study population and for the assessment of sarcopenia in the group of patients with compensated ACLD (cACLD), or in patients without ascites[30]. The disadvantage of both studies is the assessment of muscle mass with tests that are less useful in the overweight or hypervolemic patients' population.

Simple tests of muscle function

This group of tests can be performed at the bedside or during outpatient consultations.

The Short Physical Performance Battery consisting of three methods - balance test, gait speed test, and five chair stand test - can be used to assess the patient's functional ability[2,7].

Handgrip strength test (HS) is the most commonly studied test in this group using a calibrated dynamometer. The test depends on the patient's age and BMI. An interesting study has shown that HS in combination with the MELD score in men awaiting liver transplantation can be superior to CT modality if mortality was observed as a clinical outcome. Study results could be explained due to the early decline in muscle function even before the decline in muscle composition and mass occurs[31].

To assess muscle function, a test cited by Buchard *et al*[5] is commonly mentioned - the Liver Frailty Index (LFI). Its role is to evaluate frailty by combining HS, chair stands, and balance tests. Using a provided cut-off, LFI was associated with mortality independently of the presence of HE and ascites[5,7].

The next frequently used test is a six-minute walk test which has a sensitivity of 90% for identifying patients with increased risk for pre-LT mortality when performed at less than 250 m[1,7].

A walking speed/gait test is offered as a third option[2,32]. In a study by Nishikawa *et al*[32], a 6 m walking test was performed to measure muscle function in a group of patients with liver cirrhosis, with walking speed (WS) and gait speed (GS) defined, respectively. As a reference to define sarcopenia, bioelectrical impedance analysis (BIA) was used and therefore only patients without ascites were included. They observed that improvement in WS requires quick movement, whereas the improvement in the GS does not. WS requires maintained cognitive function, and muscle strength may be necessary for its improvement, while the GS value will not decrease as long as muscle strength is maintained even if cognitive function is reduced. They confirmed that hypervolemia or tissue edema and the presence of various orthopedic diseases have a significant effect on both tests. It is likely that WS could have a greater impact on the assessment of frailty than on the assessment of sarcopenia[32].

Body composition measurements

These diagnostic methods represent the foundation of modern clinical body composition analysis but with several important limitations when evaluating patients with liver cirrhosis.

BIA: A fixed, low-voltage, high-frequency alternating current is introduced into the human body to assess body electrical conductivity together with resistance (impedance). Subsequently, capacitance is the parameter that makes the current lag behind the voltage, which results in a phase shift. This shift is measured geometrically as the angular transformation of the capacitance to resistance ratio, or the phase angle (PA). BIA measures belong to safe, rapid, easy-to-perform, and quite accurate methods of estimating fat mass and fat-free mass. The main limitation of its use in the group of patients with liver cirrhosis is the influence of hypervolemia, physical activity, use of diuretic therapy, BMI, and liquid or food intake before the test[13,24,33].

There are several parameters that can be measured by means of BIA: Body cell mass, total body water, extracellular water, extracellular mass, and body fat. Multifrequency BIA analysis has been proposed lately because it is less influenced by overhydration. It measures the above-mentioned parameters by passing a series of different electrical currents and electrical frequencies through the body. Segmental BIA can also be used to overcome the fluid retention bias[33].

PA was observed to be less affected by overhydration while being a reliable indicator of clinical outcome. As such, a PA result less or equal to 5.4 degrees was a predictor of reduced survival in one of the conducted surveys. The data obtained from another investigation indicated PA cut-off less than or equal to 4.9 as a predictor of disease progression and mortality in cirrhotic patients[17,33]. A Japanese study comparing the applicability of BIA to equivalent anthropometries (MAMC, TSF) found that BIA measures comparably 6%-16% higher values of muscle mass estimates. Nevertheless, the results coincided with the prognosis of mortality in the cohort where

cirrhosis was proven histologically in all patients. The disadvantage of the study is the inclusion of mostly compensated patients, and that no comparison with other tests was performed[18].

Dual energy x-ray absorptiometry: Dual energy x-ray absorptiometry (DEXA) uses low-dose x-rays to provide a comprehensive 3-dimensional analysis of the entire body, thus automatically breaking down each body compartment into bone mass, fat mass, and fat-free (or lean) mass. It is safe, inexpensive, readily available, and reproducible. In comparison to the CT scan, it uses less radiation. As with BIA, the problem of analysis may be water accumulation in muscle and fibrous tissue, especially in the elderly. Also, it is difficult to access in some medical centers[13,31,33].

In the group of patients with liver cirrhosis, it shows an association between muscle mass assessment and mortality[35]. Appendicular lean mass (APLM) has been proposed as the most appropriate method in cirrhosis to minimize confounding by ascites [31]. A well-designed Greek study that excluded the population of patients with active alcohol consumption compared the proposed APLM index (ALMI - APMI balanced to the patient's height; unit kg/m^2) to CT indices of muscle mass, together with multivariate analyses of patient's age and gender. They compared the success of detecting sarcopenia by DEXA and by the CT cut-off values proposed by several study groups (Carey, Montano-Loza, Mourtzakis, ESPEN, and indices proposed from oncological populations - Martin, Prado). They found that the proposed cut-off values in the DEXA-assisted analysis matched the detection of sarcopenia very well when comparing the CT cut-off values proposed by the various research groups[36]. An important finding of the study was also that the prevalence of low muscle mass did not reveal any statistically significant difference in relation to disease etiology in general. However, it should be noted that a significantly higher percentage of patients with an alcoholic etiology was found in the low muscle mass subgroup compared to the normal muscle mass group. As a weak point of the DEXA analysis, they mention the accessibility of the investigation in smaller hospital centers[36].

On the other hand, some studies report only a weak concordance between DEXA and CT when identifying sarcopenia in cirrhosis[24]. The rest state that DEXA indices show a sex-related distribution of body compartments. In cirrhotic women, more reduction in fat stores is observed with the maintenance of lean tissue. In men, the loss of lean tissue is the most featured early phenomenon. A described pattern is reflected by a weak association between muscle strength and muscle mass in cirrhotic women [33].

The following study in this area states the possibility of using proposed DEXA limb muscle mass indices which showed a good correlation compared to CT indices. The study was conducted in a small cohort of patients awaiting liver transplantation. They observed that fewer women were identified sarcopenic with DEXA than expected. They also cite the well-known DEXA deficiency as not being able to offer muscle structure quality determination compared to the CT examination[37].

US: US can be used to evaluate echogenicity, diameter, cross-sectional area, and muscle volume. Performing three consecutive measurements and using their mean value as a final result is proposed. The patient should rest for at least 5 min before the measurement and not exercise less than 30 min before the examination. To assess the muscle contraction potential, muscle thickness can be measured before and after the movement, especially in muscles that have a significant change in diameter during contraction. The possibility of assessing microvascularization with contrast enhanced US and the assessment of pennation angle are mentioned. A special expert group for this field lists 39 muscle groups that can be evaluated using US examination. They propose standardizations of the measurement site and explore main problems of the investigative methodology that should be solved. The inability of assessing some muscle components with US is the most common problem. Other problems mentioned are visibility, dependency of the operator's experience as well as the patient's general condition impact on the measurement value, and its dependency on the equipment quality[38].

In this area, the quadriceps muscle evaluation, especially its thickness and quality, is most often cited in the literature. Pita *et al*[39] estimated a daily decline in muscle mass in patients with cirrhosis who were waiting for a liver transplant in the intensive care unit. In a relatively small cohort, CT-estimated muscle mass was used for comparison demonstrating the ability of the US to monitor muscle mass decline with daily measurements of rectus femoris muscle diameter, as well as the association between this result and mortality in the studied patients. Another frequently cited study from this area performed quadriceps diameter measurement and proposed a model that included BMI. It states that the US of quadriceps muscle is a low-cost, reliable,

reproducible, and accurate estimate of muscle mass that can be completed at the bedside or in an outpatient clinical setting as well as repeated without concern of radiation exposure. Gender-specific nomograms that correlated well with CT control were suggested. The cohort of patients was small, but the comparability between the two operators was good[40].

Measurements of the tongue muscle thickness in the group of patients with liver cirrhosis showed an association with the CHILD and MELD score, and a distinctive difference between the group of healthy control group, but with no proven CT control correlation. The definition of liver cirrhosis in the article was relatively loose[41].

In a population of Japanese cirrhosis patients, Kobayashi *et al*[42] measured the area of the psoas muscle in the right groin area and balanced it by the square of body height. The examination was quick and performed at bedside in a large cohort of patients. The study showed a significant correlation between US and CT measurements, suggesting the reliability of the US measurement. In addition, the proposed US index was significantly associated with CT obtained measurements. There was also a good comparison between the two investigators and 100% applicability of the method in the investigated cohort. A small number of patients with dACLD, especially patients with ascites, can be mentioned as a study deficit[42]. Our group also used the psoas muscle measurement in a small group of patients with dACLD. The inferolateral area in respect to the right kidney was used as the measurement site and the estimated psoas muscle diameter was balanced to the patient's height. The proposed index showed clinical significance when predicting any subsequent decompensation and patient mortality. The measurement showed an important limitation in terms of practical use, as it was not feasible in about a quarter of patients due to technical limitations (ascites, obesity, visibility). Also, no comparison with any of the standard investigatory methods was made[43].

In recent years, the use of elastography has been suggested to assess muscle stiffness which could indirectly point to the loss of muscle function. A well-structured study in a small cohort of patients showed an association between femoral muscle elastography results and frailty[44].

The US imaging of some of the above mentioned methods is showed in Figure 2.

Cross-sectional imaging: CT: CT allows an accurate cross section assessment of muscle mass area and an estimate of tissue density using Hounsfield units (HU)[13]. It is recommended to use tissue that shows HU estimated density from -29 to +150 on two consecutive CT slices at L3 level. To make it more clinically applicable, it is suggested to use various computer programs which automatically and very reliably evaluate the muscle area (*e.g.*, SliceOmatic, ImageJ, FatSeg, OsiriX)[7]. All these programs require manual image analysis by a radiologist. In this regard, some studies have tested the concept of a methodology to measure psoas muscle features on incidental CT scans using an automated, deep convolutional neural network model, a technology routinely used for facial recognition software. Automated measurement in the cirrhosis patient population proved to be comparable to that where the measurement was performed with standardized programs. It was significantly faster and independent of human error[45]. An alternative option is open-source software for image processing which requires manual tracing of various abdominal regions to obtain body composition information. Using these results and a preprogrammed template, the operator can easily generate various muscle indices. Alternatively, the use of the method first published by Durand *et al*[35] (see below) is suggested[45].

The most common shortcomings of CT sarcopenia analysis are unclear possibility of recurrent/dynamic evaluation due to radiation exposure and the impact of the result on clinical decisions; unclear protocol of the examination method; radiation impact; examination costs; and the need for additional software to analyze images. In addition to the ability to differentiate three main body compartments, *i.e.*, muscle, visceral, and subcutaneous adipose tissue, the ability to identify muscle radiodensity to determine ectopic fat accumulation in muscles, and the fact that it is probably not affected by the presence of ascites or edema, the pros are the relative ease, speed, accuracy, and accessibility of the examination in a hospital setting. There is a strong possibility of price and radiation exposure reduction to only 2.6 mSv by a single slice CT, and CT shows a very good reproducibility between different performers[7,19,31].

The test of choice is the L3 skeletal muscle index (SMI), a muscle area on a CT scan at the level of the L3 vertebrae corrected for height (Figure 3)[7]. Carey *et al*[24] recently defined sarcopenia as SMI < 50 cm^2/m^2 in males and 39 cm^2/m^2 in females in a cohort of cirrhotic patients in the North American region awaiting liver transplantation[1,13,24]. In this cohort, a CT measured SMI was a strong surrogate of whole-body muscle mass and can be applied as a reliable marker of the whole-body mus-

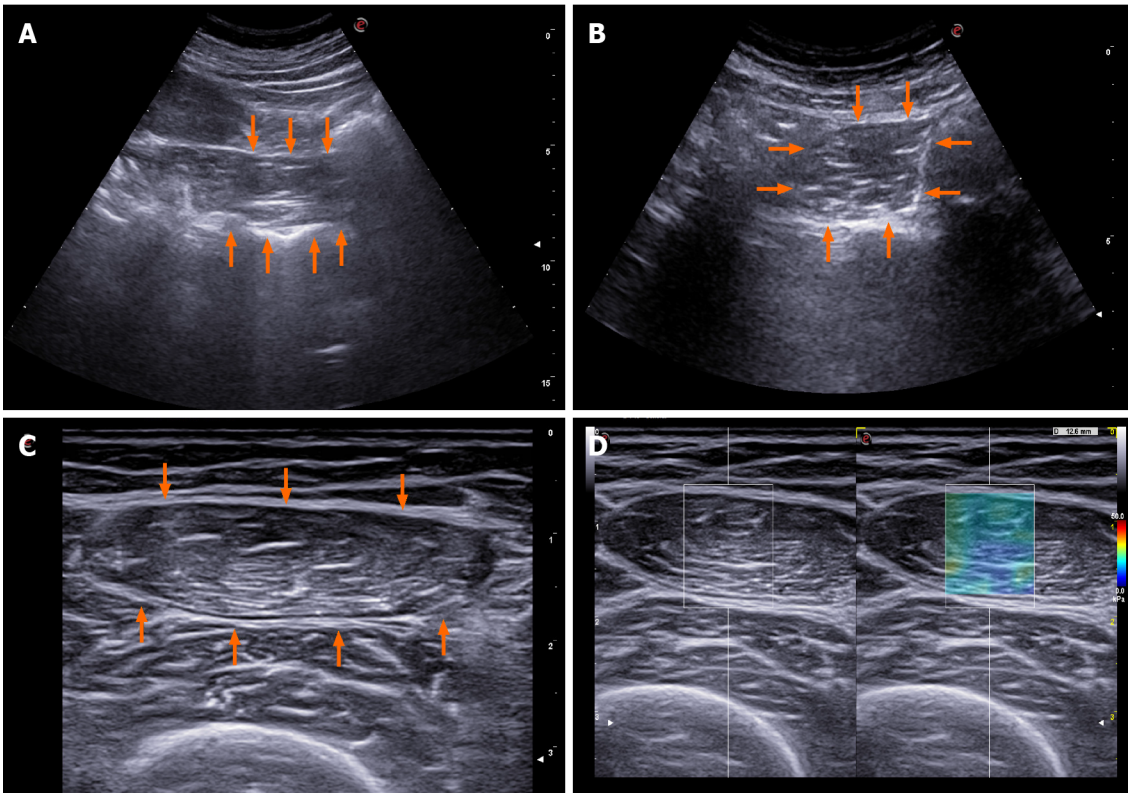

Figure 2 Reported options for ultrasound muscle mass assessment in cirrhosis. A: Psoas muscle evaluation as proposed by Hari *et al*[43]; B: Psoas muscle evaluation as proposed by Kobayashi *et al*[42]; C: Femoral muscle evaluation as proposed by Tandon *et al*[40]; D: 2D-shearwave elastography of the femoral muscle.

cularity. Defined in this way, sarcopenia was mainly delineated as sex-specific SMI values associated with mortality that were independent of age and MELD score[13,24]. When assessing sarcopenia by SMI on an abdominal CT scan, there does not appear to be a large difference between measurements at L3 *vs* L4 vertebrae[10]. There is also an excellent agreement between various software programs with respect to measurements of abdominal skeletal muscle area[46].

SMI seems to be a more complete and robust measurement than individual measurement of the psoas muscle or the psoas muscle index (PMI), especially in men with cirrhosis. In addition, low PMI identifies an incomplete subset of patients at increased risk of mortality indicated by low SMI[13,47,48]. The degree of sarcopenia can also be defined by SMI as severe sarcopenia [SMI two SD below the sex-specific mean value of a young donor (18-40 years old), sarcopenia (SMI between -1 and -2 SD of sex-specific young) donor mean values] and as a non-sarcopenic group (SMI higher than one SD below the sex-specific mean for young donors)[49]. SMI study validations include numerous publications. Important study of this area published by Ebadi *et al*[49] defined cut-off values compared to healthy controls. In their cohort, cut-off values for SMI were < 42 cm^2/m^2 in men and < 30 cm^2/m^2 in women (for severe sarcopenia) and < 50 cm^2/m^2 and < 37 cm^2/m^2 for sarcopenia. Mortality was considered as a clinical outcome. The cohort showed the presence of severe sarcopenia in 8% of patients, the majority of which had alcohol-related cirrhosis[49].

The second common cited choice is the index first proposed by Durand *et al*[35]. They demonstrated that the ratio between the transverse diameter of the psoas muscle measured at the L3 level (umbilicus is suggested as a reference point) and balanced for the patient's height [psoas to height ratio (PTHR); unit mm/m] is an objective indicator of muscle loss and a predictor of mortality in patients with cirrhosis, independent of MELD or Na-MELD score. In their retrospective study, they also demonstrated the effect of the PTHR on mortality in patients with refractory ascites [35]. A study by Paternostro *et al*[47] tested the value of a similar index. They demonstrated the clinical applicability and calculative ease of PTHR to define sarcopenia with similar cut-off values as proposed by Durand *et al*[35]. A weak point of this methodology is a variable landmark (the umbilicus) to measure muscle thickness; thus, CT-derived index from single muscle measurement can still not be recommended[46].

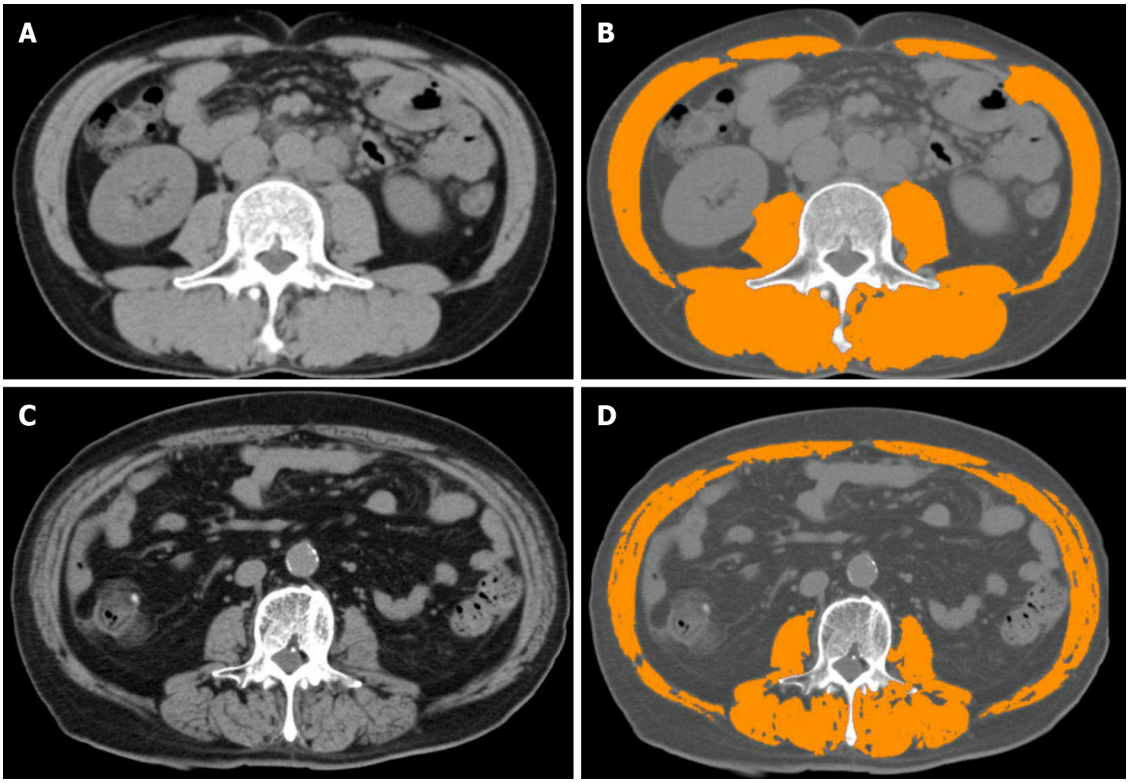

Figure 3 Computed tomography modality and skeletal muscle index. A and C: Analysing computed tomography slices obtained at the third lumbar vertebra level; B: Patient with normal skeletal muscle index (SMI) values; D: Patient with reduced SMI values. After using medical imaging software and analysing areas of predefined Hounsfield units, SMI values are calculated.

To determine myosteatosis, CT should be performed without the use of a contrast agent. Muscle density is assessed by HU values[13]. To define myosteatosis, the proposed cut-off values are > 41 HU in patients with BMI < 24.9, and > 33 HU in those with a BMI > 25. In a group of patients with liver cirrhosis, Bhanji *et al*[50] demonstrated the effect of CT-assessed myosteatosis on the occurrence of HE within one year of the measurement. It is probably a risk independent of sarcopenia.

An interesting option offered by CT is the already mentioned possibility to assess the concomitant presence of sarcopenia and myosteatosis. In a small cohort of patients with cirrhosis, Nardelli *et al*[51] assessed the presence of sarcopenia and myosteatosis with suggested CT SMI and HU values. Minimal HE defined by psychomotor tests was more common in the group of patients with both factors, as was elevated blood ammonia.

Magnetic resonance imaging: Magnetic resonance imaging (MRI) is considered as an appealing test for the diagnosis of muscle wasting due to the lack of radiation exposure and high-quality images, including information on muscle quality as evident by fat infiltration[7]. When comparing results from CT and MRI images in Traub *et al*[8] study cohort, there was no difference in the detection rate of reduced muscle mass. However, the study did not compare CT and MRI images in the same patients since they used only imaging studies that were routinely performed. The study by Beer *et al*[52] included patients with cirrhosis who had clinical or imaging cirrhosis parameters. Additionally, the FIB-4 score was used to assess the degree of liver fibrosis. Portal hypertension was defined invasively, or its signs were evaluated by gastroscopy. MRI-assessed sarcopenia using PTHR index demonstrated an association between sarcopenia rates and mortality in patients with cACLD and the influence of sarcopenia on infection or mortality due to infections. Mortality was particularly high in the PTHR < 8 mm/m (female) and < 12 mm/m (male) group. They also pointed out the advantage of the MRI for its possibility to provide sarcopenia data without the use of a contrast agent and without radiation exposure and reported good comparability with CT-PTHR measurements as well as good agreement between the two readers[52].

MRI offers another imaging technique, namely diffusion weighted imaging (DWI). DWI offers additional information regarding the composition and architecture of investigated tissue. DWI quantified by apparent diffusion coefficient (ADC) can reflect different pathological changes, such as cell density, extracellular matrix, nucleic areas,

and membrane permeability, and may have a role in the diagnosis of different muscle disorders. In the cited study, ADC maps were thus created by the implemented software and manually drawn regions of interest on the ADC maps along the contours of the iliopsoas and paravertebral muscles to avoid fat areas and vessels. They confirmed that ADC can reflect pathological muscle changes since myositis and myopathy had statistically significantly higher ADC values in comparison to unaffected muscles. The study does not offer a direct proposal for the clinical use of the proposed indices in the assessment of sarcopenia. In the multivariate analysis, the authors also used only the MELD score[53].

CLINICAL TREATMENT OPTIONS

The treatment of sarcopenia is focused on drug treatment possibilities, exercise and dietary measures, and the treatment of decompensated liver cirrhosis. There are currently no studies that prove the benefit of one or the other in terms of reducing mortality. There is a general benefit of the interventions in terms of reducing the feeling of fatigue; increasing vital capacity; improving muscle mass and ability to exercise; and last but not least, improving quality of life[7].

The general objectives of drug treatment are to focus on lowering blood ammonia and improving the action of growth hormone and testosterone in certain parts of the population with liver cirrhosis. Special emphasis should be placed on the elimination of poor appetite and complete absence of physical activity[1,2,7]. Studies suggest a possible beneficial effect of testosterone on improving muscle mass and function without significant side effects of treatment, but the evidence is yet not enough to recommend replacement therapy[2,7]. Extensive study data on the use of growth hormone in this area are not available. The importance of regulating thyroid hormone and blood sugar levels is also mentioned[24].

General nutrition advice concerns sufficient energy and adequate protein intake while avoiding prolonged fasting periods (> 6 h). The patient should eat three to five meals a day while the target caloric intake varies according to the patient's BMI. As per EASL guidelines, at least 35 kcal/kg of actual body weight per day is recommended in non-obese individuals (BMI < 30). Second, all patients should be provided with a target protein intake - guidelines have been consistent in the recommendation of 1.2 g/kg to 1.5 g/kg per day. This can be achieved by using multiple sources including meat, dairy, and vegetable proteins, with some support from the literature stating that the latter two sources may have additional benefits against HE. In obese patients with cirrhosis, a moderate decrease in caloric intake (500 kcal to 800 kcal daily and not less than 70% of previous caloric intake) with a tailored, individualized dietary plan is recommended. Best results on liver histology and on the HVPG were observed in patients achieving a weight loss of 10%, and this should probably be considered the target of lifestyle interventions. A late evening snack before night sleep with 50 g of complex carbohydrates and approximately 15 g of protein content is acceptable and significantly increases muscle mass and may also have beneficial effects on HE reccurence. Patients should be counseled on the need to eat breakfast[11,13]. Evidence is mounting regarding the benefit of Mediterranean diet -rich in vegetables, fruit, and olive oil - in the cirrhotic population. In this fashion, patients are advised to avoid processed foods and use fresh ingredients[11,17]. Among the dietary supplements, the daily use of branched chain amino acids and aromatic amino acids which are probably associated with event-free life and a quality of life is much mentioned. Special attention is also paid to the effect of L-carnitine, vitamin D, omega-3 fatty acids, and leucine[1,7,13]. Vitamin and microelement deficiency should be excluded, and in case of a deficit, vitamin D and zinc should be supplemented. Branched chain amino acid supplements and leucine-enriched amino acid supplements (6-8 g per day) should be considered, particularly in decompensated patients[11]. Ghrelin, a peptide produced in the stomach, has anabolic and anti-inflammatory properties that make it a promising agent[10]. A small study assessing ghrelin infusion in patients with heart failure showed improvement in LV function, muscle strength, lean body mass, and exercise capacity[1].

In the field of exercise, moderate intensity exercise is recommended for at least 30 min per day, 3-5 times per week. Physical exercise should start with a short-term warm-up and end with a stretching/cool-down phase. Although a combination of resistance and aerobic exercise is recommended, resistance exercise is more effective in reversing sarcopenia[9,13]. Avoidance of sedentary behavior should be recommended even in patients not willing to undergo a formal exercising program to increase daily

physical activity within the context of NEAT (nonexercise activity thermogenesis). As opposed to scheduled exercise, NEAT encourages patients to take opportunities to increase their activity within their day-to-day activities[11]. Exercise brings improvement in insulin sensitivity, an increase in muscle protein synthesis, and the use of muscle as an alternative route for ammonia detoxification. According to EASL guidelines, the target for moderate aerobic activity is to eventually reach up to 150 min per week, incorporating resistance activities on two or more days per week, except for abdominal workouts which are not recommended as they might abruptly increase abdominal pressure[11].

In the general complications of liver cirrhosis treatment area, there is evidence of the beneficial effect of TIPSS insertion on sarcopenia[1,7]. Thus, an uncontrolled study found that the insertion led to an increase in muscle mass and an improvement in overall prognosis. It also showed an improvement in psoas muscle area in 70% of patients with an increase in the mean muscle area after TIPSS insertion[2]. As previously stated, an already present sarcopenia could be considered a risk factor for mortality in patients who undergo TIPS placement[3], data, confirmed with another retrospective study in patients with cirrhosis who undergo TIPS placement for refractory ascites[54]. The therapeutic consequences of this findings are yet to be provided. The final treatment option for many patients with advanced liver cirrhosis is, of course, liver transplantation, which has been shown to have a beneficial effect on reversibility of muscle function after liver transplantation[9].

Dilemmas remain regarding the timeline of the proposed measures. It is hypothesized that an earlier intervention at a time when anabolic potential exists may be more effective than an intervention at a refractory stage of muscle wasting. Studies in this area are rare and have mostly been performed in very small populations in the field of cirrhosis[3]. To date, there is no evidence that exercise or dietary supplements affect sarcopenia through dysbiosis[4]. There is also no clear guidance on the group of patients with HCC and liver cirrhosis where interventions regarding exercise and dietary substitutions before and after treatment would probably be beneficial[21].

CONCLUSION

From their repeatability, comparability, accessibility, and realistic range for the correct clinical assessment of an individual patient, the main qualitative problem of sarcopenia assessment in the population of patients with liver cirrhosis is the great heterogeneity of the proposed clinical tests (Figure 4). Control tests in clinical trials that are not generally proposed to assess sarcopenia in patients with liver cirrhosis are also common. From the patient's point of view, correct assessment of the sarcopenia degree in the female population as well as in the population of overweight patients further exists. The unanswered question is the possibility of transferring study-confirmed findings between different races. When analysing different published studies, it is common that they address study issues within a small cohort that is occasionally incoherent or too isolative. Many studies are retrospective and represent an analysis of a difficult to verify or an incomplete mass of data stored in hospital computer systems rather than in study-specific storage programs. A common problem is the definition of the liver cirrhosis diagnosis which should in modern cACLD treatment be mostly elastographic, but certainly not a result of the ICD coding nomenclature. All with the aim to cover enough patients in the early disease stages and to discern patients who have sarcopenia at the expense of actual chronically impaired liver function. On the other side of the spectrum, many studies with sarcopenia do not pay enough attention to the population of patients with permanent decompensated disease, especially to those with refractory ascites. Many authors also point out that sarcopenia studies rarely include tests to define muscle function and focus solely on static information regarding total muscle mass which is easier to perform from the study complexity point of view. In this area, the question remains unanswered as to what is the long-term relationship between muscle mass and function, which is probably not linear throughout, and whether this relationship has a significant impact on the risks associated with the presence of sarcopenia. There is considerable incoherence in the studies regarding the use and comparison of different (especially CT-defined) indices of muscle mass or function as well as the inclusion of own study-defined claims in sequential studies (possibility of continuing primary study error).

The definition of CT-SMI as the gold standard for muscle mass assessment and the efforts of several study groups to define valid cirrhosis related sarcopenia thresholds are an important foundation for the future study and clinical applicability of this field.

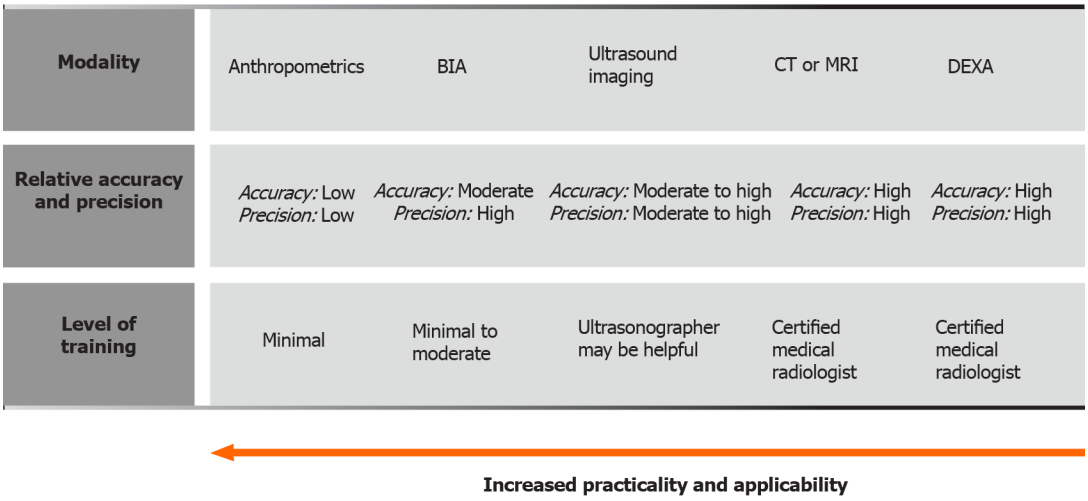

Figure 4 Sarcopenia evaluating methods. Distinctions regarding required training, applicability, practicality, accuracy and precision are presented. Adapted from Tandon *et al*[55]. Indeed, some data suggest that even small changes in the cut-off values could mean very relevant shifts in the detection and study evaluation of sarcopenia in this population[8].

Study-malnourished areas in the field of sarcopenia and liver cirrhosis are the area of sarcopenia-CSPH interdependence, the area of vulnerable groups (HCC patients, alcoholism, morbid obesity), and the influence of sarcopenia on clinical outcomes in addition to mortality, especially on various forms of disease decompensation. A small number of studies pays attention to the field of sarcopenia treatment through the therapeutic interventions. Such studies are, of course, necessary for the long-term clinical applicability of the field but difficult to perform in larger cohorts.

According to certain clues, sarcopenia could have an important decision regarding the clinical choice for liver transplantation, both in terms of the patient's higher priority and in terms of the patient's ability to be fit for a major surgery. In countries that allow such graft allocation, this could lead to the selection of poorer transplants or living donor transplants, or to the rejection of the transplant process in the event of an estimated poor yield.

At the very end, an issue remains that we as clinical professionals find difficult to face. Does the current definition of sarcopenia by the above-mentioned tests have any relevant clinical implications regarding patients' survival? Although most of the answers point to the affirmative, we are still quite a long way from the objective long-term goals of successful treatment in this area.

Nevertheless, we can certainly be justifiably pleased and proud to look at the huge leap of the last decade in terms of the knowledge gained in this clinically most relevant field. New possibilities for the use of existing and more modern indices of declining muscle mass and function in a patient with cirrhosis are coming to the fore. The tests mentioned in the article are increasingly striving for repeatability and simplicity, both in enabling dynamic sarcopenia monitoring and in reducing investigator dependent errors. A realistic desire for a study breakthrough in the upcoming years remains to define sarcopenia tests and indices that would ensure further ease of affordability and mass clinical applicability for a patient with liver cirrhosis.

Abstract

BACKGROUND

Gut microbial dysbiosis contributes to the development and progression of colorectal cancer (CRC). Natural killer (NK) cells are involved in early defense mechanisms to kill infective pathogens and tumor cells by releasing chemokines and cytokines. To better understand the relationship between the gut microbiome and CRC, it was hypothesized here that a high abundance of *Fusobacterium nucleatum* (*F. nucleatum*) in the gastrointestinal tract could cause reduced NK cell activity.

AIM

To identify associations between gastrointestinal tract *F. nucleatum* levels and NK cell activity.

METHODS

In vitro experiments were performed on NK cells treated with *F. nucleatum, Peptostreptococcus anaerobius,* and *Parvimonas micra* to identify the effects of gut microbiome species on NK cells. Following 24 and 48 h of treatment, NK cell counts were measured. In parallel studies, C57BL/6 mice were given broad-spectrum antibiotics in their drinking water to reduce resident gut flora. After 3 wk, the mice received the various bacterial species or phosphate-buffered saline (PBS) *via* oral gavage every 2 d for 6 wk. At the study end, blood samples were acquired to perform NK cell activity assessment and cytokine analysis. Intestinal tissues were collected and analyzed *via* immunohistochemistry (IHC).

RESULTS

The data show that after 3 wk of broad-spectrum antibiotic treatment, levels of total bacteria and *F. nucleatum* were markedly decreased in mice. Gavage of *F.*

manuscript.

nucleatum significantly decreased NK cell activity relative to the activities of cells from mice treated with antibiotics only and PBS. The administration of *F. nucleatum* decreased the proportion of NK46$^+$ cells based on IHC staining and increased the production of interleukin-1β and tumor necrosis factor-α.

CONCLUSION

High levels of *F. nucleatum* in the gastrointestinal tract reduced NK cell activity in mice, and the decrease in NK cell activity might be affected by increased pro-inflammatory cytokines after *F. nucleatum* treatment.

Key Words: *Fusobacterium nucleatum*; Natural killer cells; Colorectal cancer

Core Tip: Gut microbial dysbiosis contributes to the development and progression of colorectal cancer (CRC). Natural killer (NK) cells are involved in early defense mechanisms to kill infective pathogens and tumor cells by releasing chemokines and cytokines. To better understand the relationship between the gut microbiome and CRC, it was hypothesized here that a high abundance of *Fusobacterium nucleatum* (*F. nucleatum*) in the gastrointestinal tract could cause reduced NK cell activity. Accordingly, this association would impact the development of CRC in a host. To test this hypothesis, associations between the abundance of *F. nucleatum* in the murine gastrointestinal tract and NK cell activity were evaluated. In this study, we showed that a high abundance of *F. nucleatum* in the gastrointestinal tract reduced the activity of NK cells and that such outcomes might be associated with a concurrent increase in circulating levels of some pro-inflammatory cytokines, including interleukin-1β and tumor necrosis factor-α in these hosts. These findings suggest that increases in *F. nucleatum* in the gastrointestinal tract could be a factor in disrupting how the immune system prevents the development of CRC.

INTRODUCTION

Increasing evidence indicates that gut microbial dysbiosis contributes to the development and progression of colorectal cancer (CRC)[1-3]. Studies have suggested that the presence of several bacteria, including *Fusobacterium nucleatum* (*F. nucleatum*), *Peptostreptococcus anaerobius* (*P. anaerobius*), *Parvimonas micra* (*P. micra*), and *Solobacterium moorei* are significantly associated with CRC[4,5]. Other studies have described a strong correlation between the presence of *F. nucleatum* (a common oral anaerobic Gram-negative rod that is a typical cause of periodontal disease) with CRC development and pathogenicity[6-8]. The presence of *F. nucleatum* increases the proliferation of CRC cells and tumor development in mice by activating Toll-like receptor 4 signaling to nuclear factor-kappa B, and up-regulating the expression of miRNA-21. Other studies have shown that *F. nucleatum* can suppresses the tumor-immune microenvironment in a manner that could inhibit T-cell responses to antigens and arrest human T-cells in the G_1 phase or induce apoptotic cell death[9-11]. In one report, the Fap2 protein of *F. nucleatum* was shown to play a crucial role in mediating fusobacterial CRC enrichment by Gal-GalNAc that is over-expressed in CRC[6]. In addition, this protein directly interacts with the inhibitory receptor TIGIT on natural killer (NK) cells, leading to an inhibition of NK cell cytotoxicity in humans[8].

NK cells are large granular lymphocytes (unique type of cytotoxic lymphocyte) that play a role in innate immunity[12]. NK cells are involved in early defense mechanisms to kill infective pathogens and tumor cells by releasing chemokines and cytokines, as well as by helping other immune cells in targeted cell elimination[13]. Imai *et al*[14] in a follow-up study of 154 patients with cancer for 11 years found that patients with

P-Editor: Yuan YY

high cytotoxic activity among their peripheral blood lymphocytes had decreased cancer risk and, conversely, those with low cytotoxic activity had increased cancer risk [14]. In a study that evaluated 140 patients with Stage III CRC who underwent surgery, it was seen that lower pre-operative NK cell activity resulted in significant effects on the development of metachronous distant metastases[15]. A cross-sectional study performed in Canada that evaluated NK cell activity in a high-risk population of subjects screened for CRC (*via* colonoscopy) showed that subjects with CRC had lower NK cell activity compared to those without CRC[16]. In addition, NK cells have been shown to be deficient when analyzing their localization and densities within CRC tissues[17].

To better understand any relationship between the gut microbiome and CRC, it was hypothesized here that a high abundance of *F. nucleatum* in the gastrointestinal tract could cause reduced NK cell activity. Accordingly, this association would impact upon the development of CRC in a host. To test this hypothesis, associations between the abundance of *F. nucleatum* in the murine gastrointestinal tract and NK cell activity were evaluated.

MATERIALS AND METHODS

Bacterial culture

F. nucleatum (*ATCC 25586*), *P. anaerobius* (*ATCC 27337*), and *P. micra* (*ATCC 33270*) were purchased from American Type Culture Collection (ATCC, Manassas, VA, USA). All bacteria were cultured at 37°C in Anaerobe basal broth (CM0957, OXOID, Thermo Fisher Scientific, West Palm Beach, FL, USA) in an anaerobic jar (Hardy Diagnostics, Santa Maria, CA, USA). Anaerobic conditions were maintained using AnaeroGen packets (Thermo Fisher Scientific).

Culture of NK cells

For *in vitro* studies, NK92 cells (CRL-2407, human NK line) were obtained from ATCC. The cells were cultured in a minimum essential medium (MEM, Sigma, St. Louis, MO, USA) containing 12.5% fetal bovine serum (HyClone, Logan, UT, USA), 12.5% horse serum (HyClone), 200 U recombinant IL-2/mL (Invitrogen, Carlsbad, CA, USA), 2 mmol/L L-glutamine, 0.2 mmol/L myoinositol, 0.1 mmol/L 2-mercaptoethanol, and 0.02 mmol/L folic acid (all Sigma, St. Louis, MO, USA) at 37°C in a 5% CO_2 incubator. Fresh medium was replaced every 2 d; cells reached confluence at 5 d of culture.

Cell proliferation assay

Cell viability was determined by trypsin blue exclusion. Here, NK92 cells were plated at 10^5 cells/well in 6-well plates. The cells were infected with bacteria at 100:1, 250:1, and 500:1 multiplicity of infection (MOI); control cells received phosphate-buffered saline (PBS, pH 7.4). After 24 and 48 h of culture, cell viabilities were assessed.

Animal experiments

C57BL/6 mice (male, 6-wk-of-age) were purchased from Orient Bio (Gyeonggi, Korea) and housed in pathogen-free facilities maintained at 20°C with 50% relative humidity and a 12-h light:dark cycle. All mice had *ad libitum* access to standard rodent chow and filtered water. The mice were acclimated for 1 wk and randomly divided into four groups (5 mice *per* group): Control, anti-control (antibiotics only), PBS (PBS after antibiotics), and FN (*F. nucleatum* after antibiotics). All mice (except control) were treated with a cocktail of broad-spectrum antibiotics (0.2 g/L ampicillin, 0.1 g/L vancomycin, 0.2 g/L neomycin, and 0.2 g/L metronidazole) in their drinking water for 3 wk to establish flora-deficient status. After 3 wk, the mice were administered 10^9 CFU *F. nucleatum* or the same dose of PBS by oral gavage every 2 d for 6 wk. At the end of the experiments, mice were anaesthetized with chloroform and euthanized by CO_2 gas to permit collection of biomaterials. All experimental procedures were performed with the approval of the Animal Experimentation Ethics Committee of Kosin University.

F. nucleatum quantification

Stool samples were collected from all mice once a week to assess the flora-deficient status and to compare the levels of total bacteria and *F. nucleatum*. For this, total DNA was isolated using the GeneAll Exgene Stool DNA mini kit (GeneAll Biotechnology Co. Seoul, Korea) according to the manufacturer's instructions. After quantification

and confirmation of purity using the Exgene Stool DNA mini kit (GeneAll, Seoul, Korea), an aliquot of total DNA (1 mg) was used as a template to be mixed with TB Green Premix Ex Taq II (Takara Bio, Shiga, Japan). The primers used for amplification were: *F. nucleatum* 5′-CGAGGAACCTTACCAGCGTT-3′ (F) and 5′-CCCAACATCT-CACGACACGA-3′ (R); total bacteria 5′-GTGSTGCAYGGYTGTCGTCA-3′ (F) and 5′-ACGTCRTCCMCACCTTCCTC-3′ (R); and GAPDH 5′-TGGCCTTCCGTGTTCCTAC-3′ (F) and 5′-GAG-TTGCTGTTGAAGTCGCA-3′ (R). All reactions were performed in triplicate in a 7300 Real-time polymerase chain reaction (PCR) system (Applied Biosystems, Waltham, MA, USA).

Assay of ex vivo NK cell activity

At necropsy, whole blood was collected from the heart and placed in sodium heparin-coated tubes for subsequent isolation of plasma. NK cell activity was then assessed (in triplicate) using a Murine NK activity kit (ATGen Co. Ltd., Seoul, Korea) according to the manufacturer's instructions. The absorbance generated for each sample reflected the relative amount of NK cell activity in the sample.

Immunohistochemical analyses of intestinal CD3 and NKp46 cells

Murine colon tissues were collected and placed in 10% buffered formalin overnight for fixing. Sections 4-μm thick were then prepared for immunohistochemical (IHC) staining using an automated immunostainer (Bond-MAX, Leica, Buffalo Grove, IL, USA). Antibodies against mouse CD3 (rabbit polyclonal, Dako, Agilent Technologies, city, state) and NKp46 (rabbit polyclonal, R&D Systems, Minneapolis, MN, USA) were used. Stained samples were then evaluated by light microscopy and immuno-activity was assessed. The $CD3^+$ or $NKp46^+$ cells were counted in five different fields (total = 500 counted cells) under 400 × magnification; cell counts were then converted to percentages for data presentation.

Biochemical assays

Plasma levels of pro-inflammatory interleukin (IL)-6, -1β, -18, and -12p70, and tumor necrosis factor (TNF)-α were measured (in duplicate) using commercial ELISA kits (Mouse IL-6 Uncoated ELISA, Mouse IL-18 Platinum ELISA, Mouse IL-1β Uncoated ELISA, Mouse IL-12p70 Platinum ELISA and Mouse TNF-α Uncoated ELISA; all Invitrogen). All experimental steps were performed at room temperature and in duplicate. Samples were quantified by spectrophotometry at 450 nm. The sensitivity levels of the kits were 4-500 pg/mL for IL-6, 8-1000 pg/mL for IL-1β, 31.2-2000 pg/mL for IL-18, 15.6-1000 pg/mL for IL-12p70, and 8-1000 pg/mL for TNF-α.

Statistical analysis

Each experiment was repeated at least three times. Data are expressed as means ± SD from each independent experiment. A Student's *t*-test was performed for continuous variables; outcomes with $P \leq 0.05$ were considered statistically significant. Statistical analyses were performed using SPSS Statistics software (v. 23.0, IBM, Armonk, NY, USA).

RESULTS

Cytotoxic effect of F. nucleatum, P. anaerobius, and P. micra on NK cells in vitro

The effects of various gut microbiota species on NK cell survival were first assessed. Here, *F. nucleatum*, *P. anaerobius,* and *P. micra* -all known to be associated with CRC- were cultured with NK cells for 24 or 48 h. To identify optimal amounts of gut microbiome species affecting NK cells, experiments with each were carried out at 100:1, 250:1, or 500:1 MOI. As shown in Figure 1, NK cell counts were decreased in co-cultures with *F. nucleatum*, *P. anaerobius,* and *P. micra.* The results were remarkable in co-cultures at both 24 and 48 h; however, *F. nucleatum* most markedly decreased NK cell counts after 48 h. Therefore, *F. nucleatum* was selected for further study here as the representative microbiome species for use in subsequent *in vivo* studies.

NK cell activity decreased in mice treated with F. nucleatum

To test whether *F. nucleatum* could reduce the activity of NK cells in mice, the animals were divided into four groups (5 mice *per* group): Control, anti-control, PBS and FN (Figure 2A). To establish flora-deficient status, mice were treated with a cocktail of broad-spectrum antibiotics for 3 wk. Confirmation of flora-deficiency was then

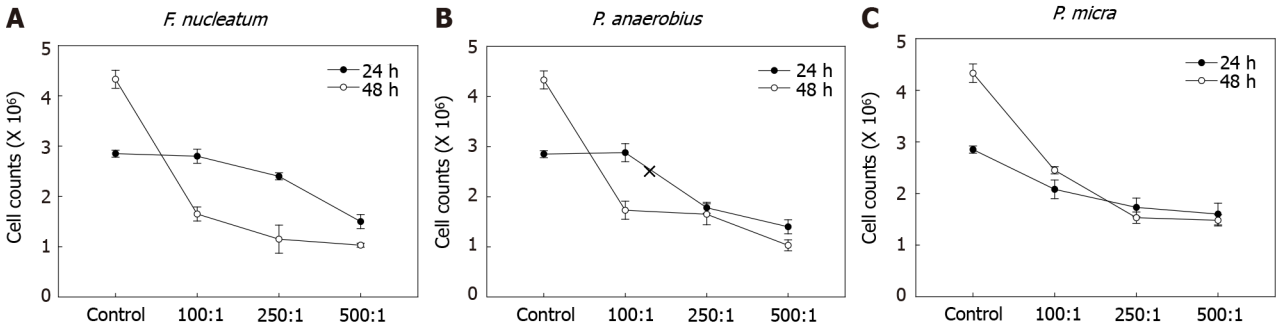

Figure 1 Effects of *Fusobacterium nucleatum*, *Peptostreptococcus anaerobius*, and *Parvimonas micra* on natural killer cells *in vitro*. Natural killer 92 cells were cultured for 24 or 48 h with each organism at a multiplicity of infection of 100:1, 250:1 or 500:1. Post-incubation, viability in the cultures was assessed using trypan blue staining. A: *Fusobacterium nucleatum*; B: *Peptostreptococcus anaerobius*; C: *Parvimonas micra*. *F. nucleatum*: *Fusobacterium nucleatum*; *P. anaerobius*: *Peptostreptococcus anaerobius*; *P. micra*: *Parvimonas micra*.

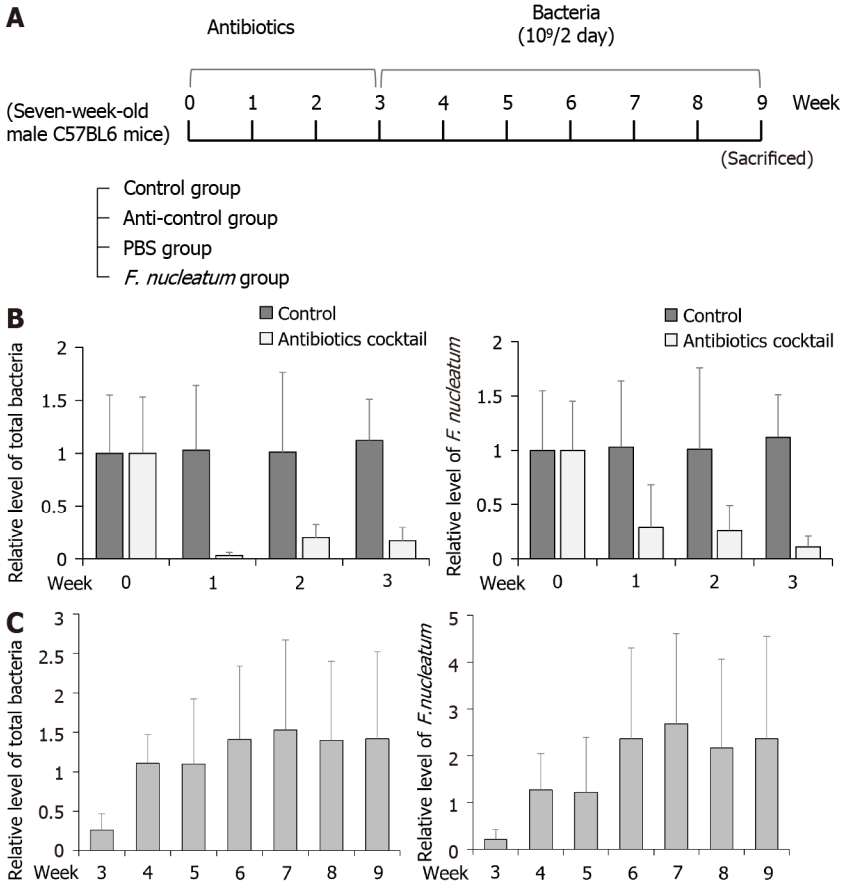

Figure 2 Experimental design. A: Mice were divided into four goups: Control, anti-control (antibiotics only), phosphate-buffered saline (PBS) (PBS after antibiotics), and *Fusobacterium nucleatum* (*F. nucleatum*) (*F. nucleatum* after antibiotics). The mice were treated with broad-spectrum antibiotics for 3 wk (except control), *F. nucleatum* was introduced to mice every 2 d for 6 wk by oral gavage; B: After treatments, the levels of total gut bacteria (left) and *F. nucleatum* (right) were evaluated; C: After administration of *F. nucleatum*, levels of total bacteria (left) and *F. nucleatum* (right) in mice were again evaluated. Data are expressed as means ± SD of three independent experiments. PBS: Phosphate-buffered saline.

assessed by quantitative PCR analyses of stool samples; the data confirmed that the levels of total bacteria and *F. nucleatum* were decreased (Figure 2B). At that point, *F. nucleatum* was re-introduced by oral gavage to the flora-deficient mice every 2 d for 6 wk. Analyses of their stools showed that levels of total bacteria and *F. nucleatum* gradually increased and then attained a plateau (Figure 2C).

The body weights of the mice were checked every week and compared. The weights of PBS and FN mice were lower compared to those of the control and anti-control groups after oral gavage; however, the differences were not significant (Figure 3A). At sacrifice (*i.e.*, after 6 wk of gavage treatments), the mice were euthanized and the entire colon of each was isolated, longitudinally-opened, and examined. No significant

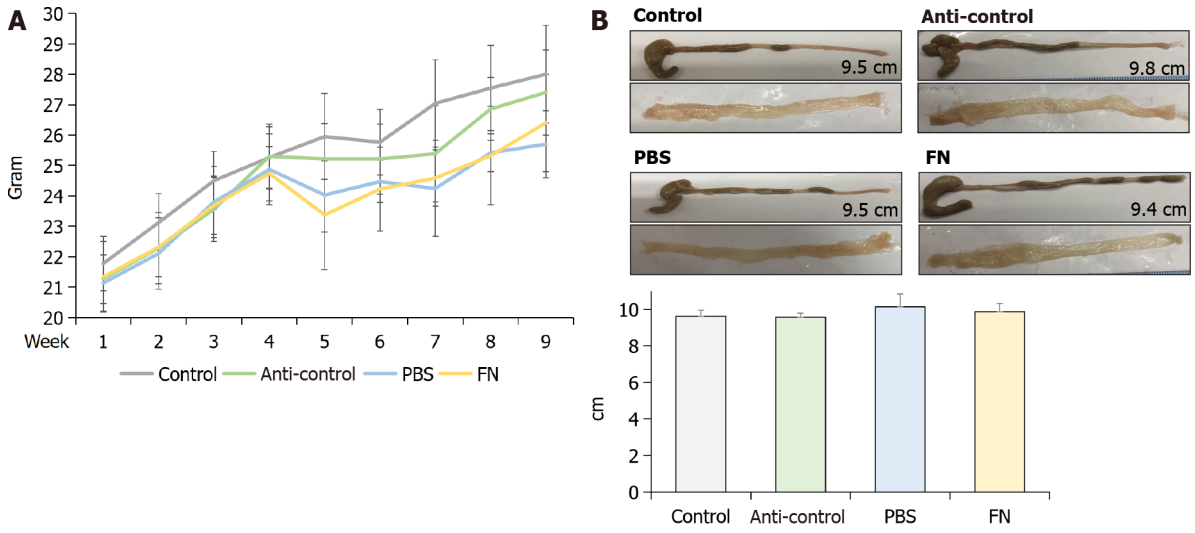

Figure 3 Body weight, colon length, and mucosal surface among the experimental groups. A: Weights of mice; B: Colon length and mucosal surface. PBS: Phosphate-buffered saline; FN: *F. nucleatum*.

differences in colonic length or colonic mucosal surface were found between the groups (Figure 3B).

To evaluate the activity of NK cells *in situ*, levels of interferon-gamma (IFN-γ) in the blood of each mouse was evaluated. The data indicated that the activity of NK cells in the FN group was significantly lower than in the control, anti-control, and PBS mice (Figure 4).

Local NK cell numbers in the gut decreased in mice treated with F. nucleatum

Using IHC staining, the intestinal tract of the mice was evaluated for the presence of NK cells. The data indicate that the levels of $CD3^+$ cells were significantly lower in the anti-control, PBS, and FN mice than in the control mice (Figure 5). The levels of $NKp46^+$ cells were lower in the FN group than in the control group, although the difference was not significant.

F. nucleatum treatments resulted in increased plasma pro-inflammatory cytokine levels

As shown in Figure 6, plasma levels of select pro-inflammatory cytokines were also evaluated at the end of the treatment regimens. The data indicated that circulating levels of IL-1β and TNF-α in the FN mice were significantly higher than in the control mice; values in the anti-control and PBS groups were not significantly higher than in the controls. Plasma levels of IL-6, IL-18, and IL-12p70 in the FN mice were not significantly higher than in the control. In addition, the values in the anti-control and PBS groups were not significantly changed compared to the control group.

DISCUSSION

Emerging evidence has shown a role for the gut microbiome, especially *F. nucleatum,* in cancer biology. Although *F. nucleatum,* a common bacterial resident in the oral cavity, has been shown to be involved in the proliferation of CRC cells and tumor development, data on how the Fusobacteria engage in the development of CRC are lacking. This study showed that a high abundance of *F. nucleatum* in the gastrointestinal tract reduced the activity of NK cells and that such outcomes might be associated with a concurrent increase in circulating levels of some pro-inflammatory cytokines, including IL-1β and TNF-α in these hosts. These findings suggest that increases in *F. nucleatum* in the gastrointestinal tract could be a factor in disrupting how the immune system prevents development of CRC.

The importance of the gut microbiome in immunity/inflammation has been more clearly elucidated in the past two decades. In a healthy state, the host immune system responds to intestinal microbiome strictly confined to the mucosal surface[18]. The mucus layer, epithelial cells, immunoglobulin A, dendritic cells, and T-cells comprise the mucosal barrier; these prevent the exposure and passage of gut microbiome to the

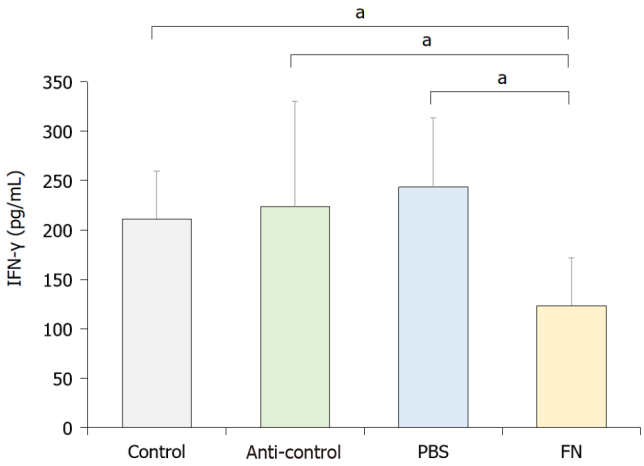

Figure 4 Blood levels of interferon-gamma. To indirectly evaluate the activity of natural killer cells, whole blood from each mouse was collected at necropsy and levels of interferon-gamma evaluated by ELISA. Data are expressed as means ± SD of three independent experiments. Value significantly different at $^{a}P < 0.05$. IFN-γ: Interferon-gamma; PBS: Phosphate-buffered saline; FN: *F. nucleatum*.

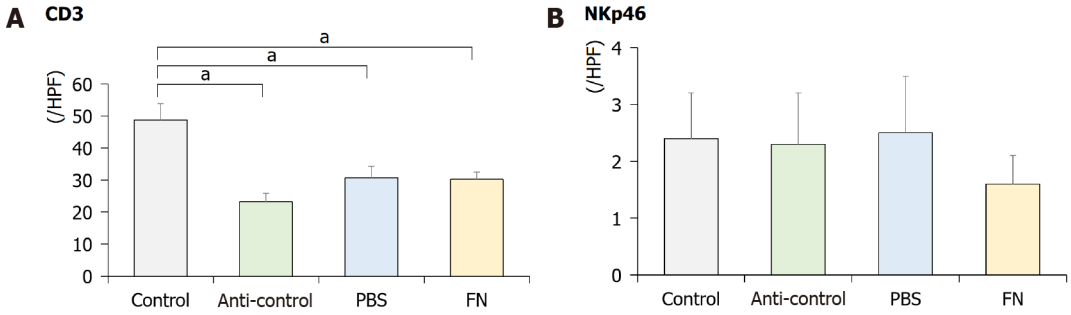

Figure 5 Intestinal levels of CD3 and NKp46 cells. A: $CD3^{+}$ cells; B: $NKp46^{+}$ cells. Data are expressed as means ± SD of three independent experiments. Value significantly different at $^{a}P < 0.05$. NK: Natural killer; PBS: Phosphate-buffered saline; FN: *F. nucleatum*.

gut-associated lymphoid tissue[19]. When the maintenance of tissue homeostasis is destroyed, translocating bacteria into the mucosal tissue causes a local (and systemic) effect on inflammatory cells, *i.e.*, tissue inflammatory monocytes can respond to microbial-derived ligands by producing prostaglandin E_2 which limits neutrophil activation and tissue damage[20].

F. nucleatum, whose presence has been proposed to correlate with CRC, can induce inflammation and suppress host immunity. There is increased evidence that *F. nucleatum* modulates immune cells in the CRC microenvironment and promotes intestinal tumorigenesis[21]. *F. nucleatum* can also stimulate autophagic pathways and alter chemotherapeutic responses of patients[22]. The current study focused on the impact of *F. nucleatum* upon gastrointestinal tract immune cells, especially NK cells. This study found that *F. nucleatum* could reduce local NK cell counts and decrease the activity of NK cells in the gut. Normally, NK cell activity is controlled by a balance of various signals that are delivered to the cells *via* inhibitory and activating NK cell receptors[23]. One study revealed that the ability of NK cells to kill tumors was inhibited by hemagglutinating *F. nucleatum* strains and that *F. nucleatum* inhibited immune cell activity by specifically targeting the inhibitory receptor TIGIT *via* the Fap2 protein[8]. Although the present study did not investigate the detailed mechanism for the observed inhibitory effects of *F. nucleatum* on the activity of NK cells in mice, the findings suggest that the gut microbiome could play an inhibitory role.

NK cells usually present as $CD56^{+}CD3^{-}$ cells and can be categorized into $CD3^{-}CD56^{dim}CD16^{+}$ and $CD3^{-}CD56^{bright}CD16^{-}$ cell classes. $CD56^{dim}$ cells appear to have more cytotoxic activity, while $CD56^{bright}$ cells produce high levels of cytokines including IFN-γ and TNF-α[24]. The activation and inhibition of NK cells are induced by an interplay among the cells' activating and inhibitory receptors[25]. NKp46 is expressed on NK cells in the tumor bed and is a major determinant of NK cell function[26]. In the current study, levels of $CD3^{+}$ cells significantly decreased after antibiotic treatment and $NKp46^{+}$ cells decreased after administration of *F. nucleatum*, although the difference

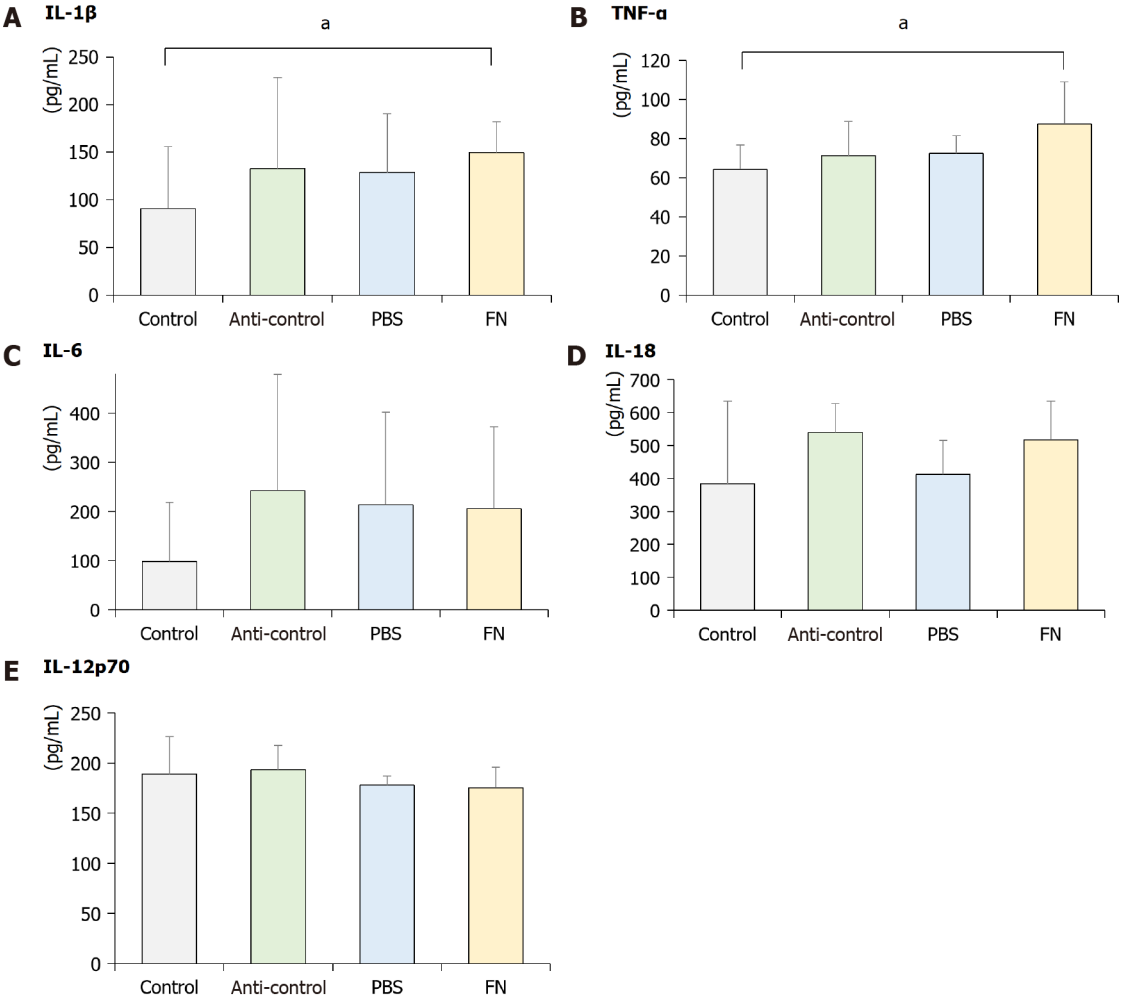

Figure 6 Plasma pro-inflammatory cytokine levels. A: Interleukin (IL)-1β; B: Tumor necrosis factor-α; C: IL-6; D: IL-18; E: IL-12p70. Data are expressed as means ± SD of three independent experiments. Value significantly different at $^{a}P < 0.05$. PBS: Phosphate-buffered saline; FN: *F. nucleatum*; IL: Interleukin; TNF-α: Tumor necrosis factor-α.

was not significant. Based on these results, it is thought that the microenvironment change after antibiotic treatment could affect these alterations, and the administration of *F. nucleatum* might decrease NK cell number.

Several inflammatory cytokines (including TNF-α, IL-6, IL-18, and IL-1β) are known to be involved in the initiation and progression of cancers[27], and could modulate the activation of NK cells. TNF-α can induce DNA damage through reactive oxygen and nitrogen species, IL-18 can induce the production of angiogenic and tumor growth stimulating factors, IL-6 can induce oxidative stress and promote early tumorigenesis, and IL-1β can promote neo-angiogenesis and evoke antiapoptotic signaling in tumor cells[28-30]. It is plausible that any changes in the expression in one or more of these could modulate tumor growth/survival *in situ* by also modulating the activation of NK cells[31]. For example, IL-12 can enhance the activity of NK cells and $CD8^{+}$ T-lymphocytes, and so is expected to impart anti-tumor activity[32,33]. In this study, it was seen that circulating levels of IL-1β and TNF-α (but not IL-6, IL-18, or IL-12p70) were significantly increased after administration of *F. nucleatum* to mice. Further studies are needed to determine if these changes directly/indirectly impact the activity of NK cells themselves in hosts.

This study has some limitations. First, whether decreased NK cell activity induces the development of CRC was not assessed. Further studies including the association between NK cell activity and CRC could strengthen the results. Second, the pro-inflammatory cytokine levels were not evaluated in NK92 cells and in colonic tissues treated with *F. nucleatum*. Therefore, changes in plasma pro-inflammatory cytokine levels in NK92 cells and in colonic tissues treated with *F. nucleatum* were not confirmed.

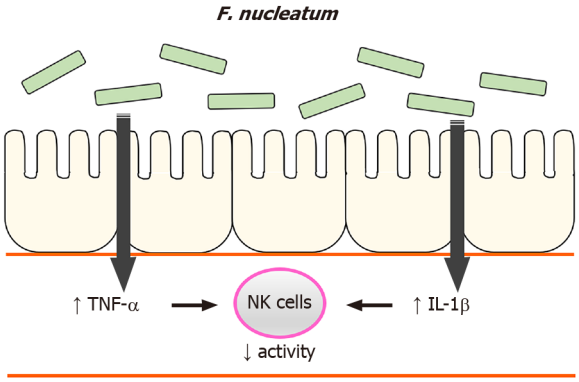

Figure 7 A possible mechanism. High levels of *F. nucleatum* in the gastrointestinal tract induce an increase in plasma pro-inflammatory cytokines, which reduces natural killer cell activity. IL: Interleukin; TNF-α: Tumor necrosis factor-α; NK: Natural killer.

CONCLUSION

In summary, the current study identified that high levels of *F. nucleatum* in the gastrointestinal tract reduced NK cell activity in mice and suggests insights on how NK cell activity was affected, *i.e.*, *F. nucleatum* induced systemic pro-inflammatory responses in the hosts. Based on these findings, we suggest a possible mechanism by which high levels of *F. nucleatum* in the gastrointestinal tract induce an increase in plasma pro-inflammatory cytokines, which reduces NK cell activity (Figure 7). Our findings illustrate another potential means by which gut microbiome can influence NK cells which, in turn could impact the development of CRC.

ARTICLE HIGHLIGHTS

Research background

Gut microbial dysbiosis contributes to the development and progression of colorectal cancer (CRC). Natural killer (NK) cells are involved in early defense mechanisms to kill infective pathogens and tumor cells by releasing chemokines and cytokines.

Research motivation

This study was designed to better understand the relationship between the gut microbiome and CRC.

Research objectives

The objective of this study was to identify associations between gastrointestinal tract *Fusobacterium nucleatum* (*F. nucleatum*) levels and NK cell activity.

Research methods

In vitro experiments were performed on NK cells treated with *F. nucleatum, Peptostreptococcus anaerobius,* and *Parvimonas micra* to identify the effects of gut microbiome species on NK cells. After 24 and 48 h of treatment, NK cell counts were measured. In parallel studies, C57BL/6 mice were given broad-spectrum antibiotics in their drinking water to reduce resident gut flora. After 3 wk, the mice received the various bacterial species or phosphate-buffered saline *via* oral gavage every 2 d for 6 wk. At the study end, blood samples were acquired to perform NK cell activity assessment and cytokine analysis. Intestinal tissues were collected and analyzed *via* immunohistochemistry (IHC).

Research results

After 3 wk of broad-spectrum antibiotic treatment, levels of total bacteria and *F. nucleatum* were markedly decreased in mice. *F. nucleatum* by gavage significantly decreased NK cell activity relative to the activities of cells from mice treated with antibiotics only and phosphate-buffered saline. The administration of *F. nucleatum* decreased the proportion of $NK46^+$ cells based on IHC staining and increased the production of interleukin-1β and tumor necrosis factor-α.

Research conclusions

High levels of *F. nucleatum* in the gastrointestinal tract reduced NK cell activity in mice, and the decrease in NK cell activity might be affected by increased pro-inflammatory cytokines after *F. nucleatum* treatment.

Research perspectives

Based on these findings, we suggest that increases in *F. nucleatum* in the gastrointestinal tract could be a factor in disrupting how the immune system prevents development of CRC.

Abstract

BACKGROUND

Primary biliary cholangitis (PBC) is a serious disease that causes significant morbidity. PBC is confirmed with liver biopsy but autoantibodies are frequently used as proxies for diagnosis. The performance of autoantibodies for the diagnosis of PBC seems to vary widely across populations.

AIM

To assess the diagnostic performance of several autoantibodies for the diagnosis of PBC in Latin American individuals.

METHODS

We studied 85 female adult Colombians, 43 cases with biopsy-confirmed PBC and 42 controls in whom a liver biopsy ruled out PBC. Plasma anti-mitochondrial antibodies (AMAs), anti-smooth muscle antibodies (ASMAs) and anti-nuclear antibodies (ANAs), as well as total immunoglobulin (Ig) M and IgG were determined using immunofluorescence or enzyme-linked immunosorbent assay in all study participants within 1 year of the biopsy. For all variables, values analyzed were those closest to the date of the biopsy. Patients with viral or alcoholic hepatitis were excluded.

RESULTS

Mean age at diagnosis was 58.7 years for cases and 56.9 years for controls, and the body mass index was lower among cases. Most cases received ursodeoxycholic acid, while most controls received vitamin E. Sjögren syndrome and Hashimoto's thyroiditis were the most frequent autoimmune comorbidities of PBC. The prevalence of AMA positivity among PBC cases was unexpectedly low. The sensitivity and specificity values were respectively 44.2% and 76.2% for AMA, 74.4% and 38.1% for ANA, 14.0% and 73.8% for ASMA, 26.7% and 80.0% for IgG, and 57.1% and 85.7% for IgM. The combination of positive AMA plus positive IgM had 91% positive predictive value for PBC. Among AMA-negative cases, the most prevalent antibodies were ANA (87.5%). In all, 62% of AMA-positive and 84.6% of IgM-positive individuals had fibrosis in their biopsy.

CONCLUSION

AMA positivity was very low among female Latin American patients with PBC. The performance of all antibodies was quite limited. These results highlight the urgent need for better PBC biomarkers.

Core Tip: Primary biliary cholangitis (PBC) is confirmed by liver biopsy, but autoantibodies are frequently employed as an indirect diagnostic method. We studied 85 female adult Latin American patients, 43 with biopsy-confirmed PBC and 42 in whom liver biopsy ruled out PBC. The prevalence of anti-mitochondrial antibodies among PBC cases was only 44.2%. Anti-nuclear antibodies and anti-smooth muscle antibodies had similarly low diagnostic performance. Eighty-two percent of immunoglobulin M-positive individuals had fibrosis in their biopsy. Among female Latin American patients with PBC, the performance of any individual antibody for PBC diagnosis was quite limited.

INTRODUCTION

Primary biliary cholangitis (PBC) is a chronic autoimmune liver disease characterized by cholestasis, autoantibodies, and chronic small bile duct injury[1]. In PBC, immune-mediated portal inflammation leads to a group of histological hallmarks: biliary epithelial damage, ductopenia, and fibrosis[2]. The disease was previously known as "primary biliary cirrhosis," a term coined in 1950 but no longer in use because in fact most individuals are not cirrhotic at the time of diagnosis[3]. The population incidence of PBC is approximately 1 case per 100000 individuals per year, but there is significant geographic variation[4]. PBC is 10 times more common among women than men, and is frequently diagnosed between 40 and 50 years of age[5]. Patients with PBC may be asymptomatic, or may present with jaundice, fatigue, or pruritus[6].

The gold standard for PBC diagnosis is liver biopsy, but measurement of plasma autoantibodies is considered a key step of the initial approach[1]. There is a large repertoire of serologic tests with diagnostic potential for PBC including anti-mitochondrial antibodies (AMAs), anti-nuclear antibodies (ANAs), antibodies against smooth muscle (ASMA), titers of immunoglobulin (Ig) G and IgM, and more than 60 other immunoassays[7,8].

However, the performance of these tests varies widely across populations[4], and there is a critical lack of information about their diagnostic value in Hispanic patients. Within this context, the primary aim of our study was to evaluate various antibodies and antibody combinations for the diagnosis of PBC in Latin American individuals from Colombia.

MATERIALS AND METHODS

Participants

We retrospectively collected information from 86 participants, 44 patients with a biopsy confirmed diagnosis of PBC and 42 controls in whom the results of liver biopsy ruled out PBC. Inclusion criteria were age over 18 years, having a liver biopsy performed between 2009 and 2019 and availability of a measurement of circulating AMA, ASMA and ANA by immunofluorescence or enzyme-linked immunosorbent assay (ELISA), within 1 year of the index liver biopsy. Exclusion criteria were alcohol consumption equal to or greater than two drinks a day on average, or viral hepatitis (serology for hepatitis B and hepatitis C viruses were available at the time of biopsy for all participants). All PBC diagnoses were confirmed or ruled out by a qualified pathologist with experience in liver diseases. Controls had to have biopsies reported as normal, non-alcoholic fatty liver disease or other, non-cholestatic liver diseases.

The definitive sample consisted of 85 participants, after we excluded the only male PBC case in order to have a more homogeneous study group. We extracted from their medical history data on demographics, blood chemistry, liver function tests, clinical presentation, concomitant medications, and autoimmune comorbidities. The laboratory values considered were those closest to the date of the biopsy. All clinical records were anonymized prior to data extraction and analysis. The study database was secured and only two researchers had access to it (Gaete PV and Puerto-Baracaldo DK).

Sample size

We calculated sample size using the expression for diagnostic tests studies in which the expected prevalence of the condition of interest is known[9]. Concerning the results of AMA for diagnosis of PBC, if *FP* is the number of false positives, *TN* is the number of true negatives, *Z* is the value of the *Z* statistic for the 95th quantile of the standard normal distribution, *SP* is the minimum tolerable specificity (90%), *W* is the confidence interval width for the estimation of specificity obtained from the study (10%) and *P* is the expected prevalence of PBC among the included individuals (50%), the sample size for specificity (N_{sp}) is given by the following expression:

$$FP + TN = Z^2 \times SP \times (1 - SP)/W^2$$

$$N_{sp} = (FP + TN)/(1 - P)$$

This gave us a minimum sample size of 69 participants. Estimating an additional 20%, 86 participants were included.

Statistical analyses

Baseline characteristics were compared between cases and controls using *t*-tests for continuous variables and chi-squared tests for categorical variables. The sensitivity, specificity, and predictive values for PBC diagnosis were calculated for each antibody and their relevant combinations, considering liver biopsy as the gold standard. Additionally, we plotted receiver-operating characteristic (ROC) curves for titers of AMA, ASMA, and ANA. The association between antibody positivity and the presence of fibrosis was assessed using odds ratio (OR) calculated with univariate logistic regression. All statistical analyses were two-tailed and performed at a 5% significance level (alpha = 0.05) using IBM SPSS, version 20.0.

RESULTS

We studied 85 female adults, 43 with PBC and 42 controls. Mean age at diagnosis was 58.7 years for cases and 56.9 years for controls. Mean body mass index was lower among cases ($P = 0.001$), perhaps because a suspicion of nonalcoholic steatohepatitis was the indication for liver biopsy in many controls (Table 1). As expected, alkaline phosphatase was significantly higher among cases, but markers of hepatocellular damage were similar in both groups. Pruritus was the most common symptom in

[1]According to the Batts Ludwig classification[33].
ALKP: Alkaline phosphatase; ALT: Alanine amino transferase; AST: Aspartate amino transferase; GGT: Gamma-glutamyl transferase; HDL: High-density lipoprotein; LDL: Low-density lipoprotein; ULN: Upper limit of normal.

participants with PBC. Fibrosis in stages II-IV of the Batts-Ludwig classification was much more common in cases (39.5% *vs* 16.7%). In both groups, the most frequent pattern of ANA was centromeric. Most cases received ursodeoxycholic acid (UDCA) while most controls received vitamin E. Sjögren syndrome and Hashimoto's thyroiditis were the most frequent autoimmune comorbidities of PBC. The most common histological findings in our PBC cases were destructive, non-suppurative cholangitis (39.5%), florid duct lesions (27.9%), interphase hepatitis in biopsy (23.3%) and granulomatous cholangitis (14.0%).

The prevalence of positivity for AMA in cases was surprisingly low, only 44.2%. Among participants with positive AMA, the most prevalent antibody was IgM, present in 91.7% of cases and 33.3% of controls. Meanwhile, among participants with negative AMA, the most prevalent antibodies were ANA, present in 87.5% of cases and 59.4% of controls. None of the AMA-negative controls had a positive IgM, while 11.1% of the AMA-negative cases did (Figure 1).

The diagnostic performance of AMA in our sample was lower than expected, with a sensitivity of 44.2% and a specificity of 76.2%. ANA showed better sensitivity (74.4%) but low specificity (38.1%). IgM had an acceptable balance between sensitivity (57.1%) and specificity (85.7%). Of note, the combination of positive AMA and positive ASMA had 100% specificity for confirmation of PBC. The combination of negative AMA and positive IgM exhibited 100% specificity and positive predictive value (Table 2).

Fibrosis was more frequent among participants with positive AMA or IgM (Figure 2): Sixty-two percent of AMA-positive and 84.6% of IgM-positive individuals had any degree of fibrosis in biopsy. There was an equal proportion of persons with and without fibrosis among AMA-negative participants, while fibrosis was unusual (33.3%) when IgM was negative. Among cases only, the proportion with fibrosis was 63% for AMA-positive and 54% for AMA-negative individuals. The OR for the association between positive AMA and any fibrosis was not significant [OR:1.63, 95% confidence interval (CI): 0.67-4.09], while the association between positive IgM and fibrosis was strongly positive (OR:11.0, 95%CI: 1.73-69.9). Fibrosis was also differently associated with the predominant pattern in liver biopsy. The proportion of individuals with fibrosis was 80% for patients with lymphocytic infiltrate, 70.6% for patients with destructive non-suppurative cholangitis, 66.6% for patients with granulomatous cholangitis or florid lesions and 65% for patients with interphase hepatitis.

In separate exploratory ROC analyses of the plain reported titers of AMA and ANA, the best cutoff for AMA titers was 1:50, showing a sensitivity of 45.2%, a specificity of 81.1% and an area under the curve (C-statistic) of 66%. Meanwhile, the best cutoff for ANA titers was 1:120, with a sensitivity of 71.8%, a specificity of 52.5% and a C-statistic of 64.1%.

We performed a sensitivity analysis in which PBC status was defined as having a pathology diagnosis of PBC plus elevation of alkaline phosphatase. The results were very similar to those obtained with PBC status defined only by biopsy results, except for a slightly better negative predictive value for AMA (63.6 *vs* 57.1%) and slightly better sensitivity for IgM (63.2% *vs* 57.1%).

Table 2 Sensitivity, specificity and predictive values of each antibody or antibody combination, for the diagnosis of primary biliary cholangitis

Antibody or antibody combination	Sensitivity	Specificity	PPV	NPV
AMA (+)	44.2	76.2	65.5	57.1
ANA (+)	74.4	38.1	55.2	59.3
ASMA (+)	14.0	73.8	35.3	45.6
IgG (+)	26.7	80.0	66.7	42.1
IgM (+)	57.1	85.7	92.3	40.0

AMA (-), IgM (+)	4.8	100	100	25.9

AMA: Anti-mitochondrial antibodies; ANAs: Anti-nuclear antibodies; ASMA: Anti-smooth muscle antibodies; NPV: Negative predictive value; IgG: Immunoglobulin G; IgM: Immunoglobulin M; PPV: Positive predictive value.

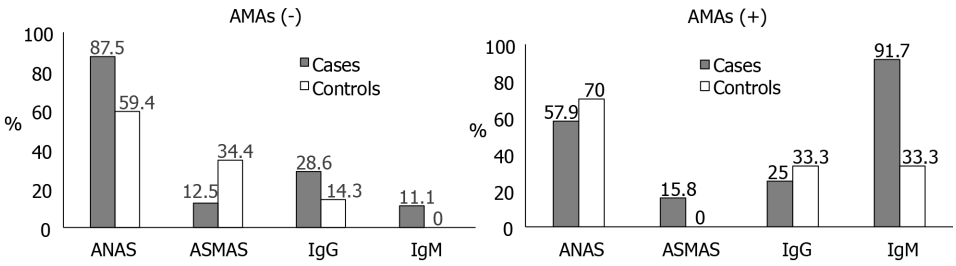

Figure 1 Prevalence of positivity for other antibodies, among participants with negative (left) or positive (right) anti-mitochondrial antibodies. Case/control status was defined by liver biopsy. AMAs: Anti-mitochondrial antibodies; ANAs: Anti-nuclear antibodies; ASMAs: Anti-smooth muscle antibodies; IgG: Positive immunoglobulin G, defined as a plasma concentration greater than the upper limit of the reference value; IgM: Positive immunoglobulin M, defined as a plasma concentration greater than the upper limit of the reference value.

DISCUSSION

In this cross-sectional study, we assessed the performance of different autoimmunity markers for the diagnosis of biopsy confirmed PBC in the context of female Latin American patients. We were surprised to find that the majority of PBC cases were AMA-negative, and that no individual antibody or antibody pair provided a distinctly superior combination of sensitivity and specificity. Our results also suggested that IgM positivity can be a tool for the diagnosis of AMA-negative PBC and that IgM may serve as a marker of liver fibrosis. The results also show that simultaneous positivity for AMA and ASMA was a relevant confirmatory finding for PBC.

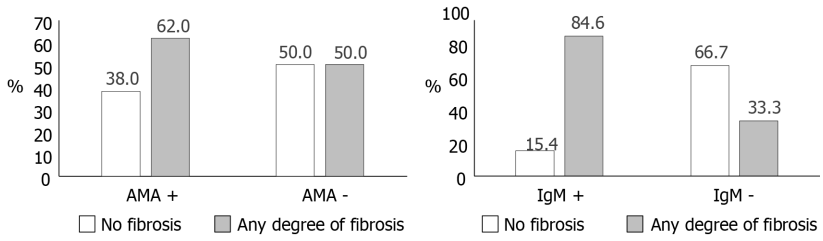

Figure 2 Distribution of the degree of fibrosis according to positivity for anti-mitochondrial antibodies (left) or immunoglobulin M (right). Odds ratio for the association between positive anti-mitochondrial antibodies and any fibrosis: 1.63 (95% confidence interval: 0.67-4.09), odds ratio for the association between positive immunoglobulin M and any fibrosis: 11.0 (95% confidence interval: 1.73-69.9). AMAs: Anti-mitochondrial antibodies; IgM: Immunoglobulin M.

The clinical characteristics of our Hispanic patients regarding age, sex, symptoms, and liver function tests were in accordance with prior reports of PBC patients worldwide and in other Latin American countries[10-15]. Sjögren syndrome and Hashimoto´s thyroiditis were the most prevalent autoimmune comorbidities in our sample, as has been reported in Mexican[13] and Italian[16] PBC cohorts. The frequent coexistence of PBC and Sjögren syndrome could be explained by the exposure of self-antigens in biliary and salivary epithelial cells, as a result of apoptosis (secondary to infections or xenobiotics), leading to autoimmune epithelitis[17]. Among PBC patients, Hashimoto's thyroiditis is the most frequently reported thyroid disorder, followed by Graves´ disease[16]. However, a study comparing two European cohorts found that thyroid disease does not influence the rate of complications nor the natural history of PBC[18]. In general, the coexistence of thyroid and liver disease is usual, as thyroid disturbances are also frequent in primary sclerosing cholangitis and non-alcoholic fatty liver disease[19]. These findings highlight the need for autoimmune disease screening in Latin American patients with PBC.

The performance of AMA, ANA, ASMA, IgM, and IgG has been evaluated before, albeit seldom in Hispanics or Latin Americans. In a Mexican cohort of 78 PBC patients, 94.8% had positive AMA, 70.5% positive ANA and 8% positive ASMA[13]. This is in stark contrast to the rate of AMA positivity of cases in our study, only 44.2%. A meta-analysis of 24 studies (none of them from Latin America), reported 84.5% sensitivity and 97.8% specificity for AMA, also quite different from our results[20]. A meta-analysis of 11 studies from Asia, Europe, and North America reported 27% sensitivity and 98% specificity for ANA in AMA-negative patients. We, in turn, found a high rate of ANA positivity among AMA-negative cases (87%)[21]. In a group of AMA-negative PBC patients from the Mayo Clinic, there was a 21% rate of ASMA positivity[22], similar to the 12.5% we found. These findings suggest the presence of factors in our population that influence the diagnostic performance of the classic autoantibodies for histologically confirmed PBC diagnosis. One of such factors may be polymorphisms in genes for proteins involved in antigen presentation at the bile ducts. It has been demonstrated that cholangiocytes express not only MHC class I molecules, but also surface markers found on antigen presenting cells including MHC class II and co-stimulatory molecules (CD80, CD86, CD40)[23]. Since the distribution of HLA alleles differs substantially across Latin America[24], it is conceivable that individuals from certain populations are better presenters of ductal self-antigens, and elicit a stronger humoral self-immunity in the context of PBC. This may constitute a potential explanation for the stark contrast between our results and those from the prior Mexican study.

The previously mentioned Mexican study also described Sjögren syndrome as the most common autoimmune comorbidity of PBC. In contrast to our results, they reported a high prevalence of AMA positivity among PBC cases, evidencing variability even within Latino populations. A cross-sectional study in the US found that Hispanic patients with PBC had a particular clinical picture, characterized by a reduced clinical response to UDCA[25].

Even though AMA are the antibodies classically related to PBC, there is evidence that most patients with positive AMA do not have PBC findings in liver biopsy[26,27]. More than half of PBC cases in our sample were AMA-negative, much higher than in prior reports (5%-18%)[28]. Evidence that clinical characteristics or response to treatment is different in AMA-negative patients has been inconsistent[29]. Nonetheless, it is clear that diagnosis of these patients tends to be delayed, treatment is usually initiated later and complications like fibrosis or liver transplantation are more frequent[22,30,31]. A study found that seven of nine patients with AMA-negative PBC

had the same immunohistochemistry findings as AMA-positive patients, supporting the idea that these subgroups have indeed the same disease[32]. One potential limitation of the use of AMAs in regular clinical practice is the availability of different techniques for their measurement, depending on the context (immunofluorescence *vs* ELISA), which may yield different diagnostic performance.

The utility of IgM in the study of PBC is being explored intensively, especially in the context of AMA-negative patients[33]. In our sample, the combination of negative AMA and positive IgM was highly specific for PBC. We also found that > 90% of AMA-positive cases had positive IgM. All things considered, IgM may be understood not only as a consequence of cholestasis, but also as a sign of alarm to look for fibrosis in PBC patients, even when AMA are negative. The mechanism underlying the high frequency of IgM positivity in AMA-positive PBC patients may involve polymorphisms in the gene for toll-like receptor 9[34].

Strengths of the study include a homogeneous sample of well-defined patients and controls of the same sex, the availability of relevant information on comorbidities and current treatments, the fact that PBC status was confirmed by biopsy and the uniqueness of the patient population ethnicity. This study is a valuable source of demographic and diagnostic information for Hispanic/Latino patients with suspected PBC.

The main limitations are the cross-sectional nature of the study, which does not allow drawing definitive conclusions about causal associations, and its relatively modest sample size, although it was appropriate for the diagnostic evaluation of the tests analyzed. Future studies are needed to describe the time-course and severity of the disease, in order to better approach PBC diagnosis and treatment in these populations.

CONCLUSION

In summary, this study showed that a large proportion of PBC cases in Latin American patients can be AMA-negative, and that IgM can be a useful marker of fibrosis, in addition to cholestasis. For all these reasons, it is urgent to find a good marker for AMA-negative PBC, especially for Hispanic/Latino populations.

ARTICLE HIGHLIGHTS

Research background

Primary biliary cholangitis (PBC) is a rare but serious and severely limiting autoimmune liver disease. Diagnosis of PBC is complicated by the different diagnostic performance of different autoantibodies in different populations.

Research motivation

There are limited data on the performance of autoantibodies for PBC diagnosis among Hispanic/Latino populations.

Research objectives

To assess the diagnostic performance of anti-mitochondrial antibodies (AMAs), anti-nuclear antibodies (ANAs), anti-smooth muscle antibodies (ASMAs), plasma immunoglobulin (Ig) M and plasma IgG for the diagnosis of histologically-confirmed PBC among female Colombian patients.

Research methods

We studied 43 PBC cases and 42 controls in whom PBC was ruled out. All antibodies were measured using immunofluorescence or enzyme-linked immunosorbent assay within 1 year of the index biopsy. A sensitivity analysis was performed using pathology + elevated alkaline phosphatase to define case-control status. Patients with viral or alcoholic hepatitis were excluded.

Research results

The sensitivity of ANA was only 44.2%, specificity was 76.2%. No individual antibody or antibody combination displayed an acceptable combination of sensitivity and specificity, but the combination of positive AMA and positive ASMA had a very high

specificity. IgM had particularly high specificity and positive predictive value.

Research conclusions

We found a remarkably high prevalence of AMA-negative PBC among female Colombian patients. IgM served not only as a marker of PBC, but also as a marker of liver fibrosis.

Research perspectives

It is urgent to find a good marker for AMA-negative PBC, especially for Hispanic/Latino populations.

ACKNOWLEDGEMENTS

We want to thank the Office of the Vice Provost for research (Vicerrectoría de Investigaciones) at Universidad de los Andes, their continued support throughout the development of this project.

Abstract

BACKGROUND

Intestinal mucosal barrier injury and gastrointestinal dysfunction are important causes of sepsis. However, few studies have investigated the effects of enteral underfeeding on gastrointestinal function in sepsis. Moreover, no consensus on goal enteral caloric intake has been reached in sepsis.

AIM

To investigate the effects of different goal caloric requirements of enteral nutrition on the gastrointestinal function and outcomes in the acute phase of sepsis.

METHODS

Patients were randomly assigned to receive 30% (defined as group A), 60% (group B), or 100% (group C) of goal caloric requirements of enteral nutrition in this prospective pilot clinical trial. The acute gastrointestinal injury (AGI) grades, incidence of feeding intolerance (FI), daily caloric intake, nutritional and inflammatory markers, and biomarkers of mucosal barrier function were collected during the first 7 d of enteral feeding. The clinical severity and outcome variables were also recorded.

RESULTS

A total of 54 septic patients were enrolled. The days to goal calorie of group C (2.55 ± 0.82) were significantly longer than those of group A (3.50 ± 1.51; $P = 0.046$) or B (4.85 ± 1.68; $P < 0.001$). The FI incidence of group C (16.5%) was higher than that of group A (5.0%) or B (8.7%) ($P = 0.009$). No difference in the incidence of FI symptoms was found between groups A and B. The serum levels of barrier

function biomarkers of group B were significantly lower than those of group A ($P < 0.05$) on the 7th day of feeding. The prealbumin and IL-6 levels of group A were lower than those of group B ($P < 0.05$) on the 7th day of feeding. No significant differences in the clinical outcome variables or 28-d mortality were found among the three groups.

CONCLUSION

Early moderate enteral underfeeding (60% of goal requirements) could improve the intestinal barrier function and nutritional and inflammatory status without increasing the incidence of FI symptoms in sepsis. However, further large-scale prospective clinical trials and animal studies are required to test our findings. Moreover, the effects of different protein intake on gastrointestinal function and outcomes should also be investigated in future work.

INTRODUCTION

Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection[1-3]. Although the latest guidelines recommend a series of treatment strategies for sepsis[1,2], the mortality of this critical illness is still approximately 20%-50% in adults[4,5]. As an essential treatment for sepsis, enteral nutrition (EN), especially early enteral nutrition (EEN), could improve immunologic imbalance and alleviate the intestinal barrier injury of patients in intensive care units (ICUs)[6-9]. Our previous clinical studies also confirmed that EEN could regulate the excessive immune response and improve the clinical severity of critically ill patients[10,11]. However, recent trials suggested that aggressive nutrition delivery may offer no benefit in the early stages of critical illness[12-17]. The TARGET trail showed that augmented energy delivery in the early phase of illness did not improve outcomes compared to standard EN[14]. The ESICM guidelines advise that EEN (within 24-48 h) should be started at a low dose and increased gradually if there are no contraindications[9]. The ESPEN guidelines also advise that the initiation of "early and progressive" EN should be only performed in sepsis without shock[18].

Until now, no consensus on goal enteral caloric intake has been reached in critically ill patients. The EDEN trial observed that initial trophic enteral feeding for up to 6 d (400 kcal/d), compared with full enteral feeding (1300 kcal/d), did not improve ventilator-free days, 60-d mortality, or infectious complications in patients with acute lung injury[19]. The PermiT Trial found that permissive enteral underfeeding was not associated with a lower mortality compared with standard feeding (46% ± 14% *vs* 71% ± 22% of goal caloric requirements) in critically ill adults[17]. Systematic reviews of clinical trials also reported that hypocaloric EN (15%-59% of caloric requirements) had

no significantly different effects on morbidity and mortality in critically ill patients when compared with full-energy nutrition[13,15]. However, most of the previous studies were based on non-sepsis patients. Furthermore, few studies have investigated the effects of enteral underfeeding on gastrointestinal function in sepsis.

Among the organ dysfunction caused by sepsis, intestinal tract is one of the most vulnerable organs[4,5]. Accompanying by sepsis, intestinal epithelial cell damaged, mucosal permeability increased, intestinal flora translocated, and then further intestinal original infection developed[3,4]. Therefore, acute intestinal barrier injury and systemic infection are a vicious cycle in critical diseases, especially in sepsis. Accordingly, it is necessary to explore an optimal goal of enteral feeding to improve the acute intestinal injury of sepsis. In this study, we investigated the effects of different goal caloric requirements (30%, 60%, and 100%) of EN on the gastrointestinal (including intestinal mucosal barrier) function in the acute phase of sepsis.

MATERIALS AND METHODS

Study design

This was a single-center, prospective, randomized clinical trial. Patients were randomly assigned to receive 30%, 60%, or 100% of goal caloric requirements of EN after enrollment. We used the complete randomization, which was based on remainder grouping method[10]. After creating random numbers with a computer, the grouping method (divided by three) was implemented to determine which group the patients would be allocated into. The intervention allocation was concealed before a patient was enrolled in this study, and patients would not be excluded from the study after intervention allocation was unblinded. The main treatment difference of the three groups was the goal calorie of enteral feeding, therefore, it was improbable to blind treating clinicians to the intervention allocations. The enrolled patients were blind to the intervention allocations. Hence, this is a single-blind randomized trial. The sample size calculation was performed with the Power Analysis and Sample Size software (2011) before the trial began. However, in view of the small sample size of our study, we defined this trial as a clinical pilot study.

The study protocol was approved by the Institutional Ethics Committee of Nanjing First Hospital (Approval Number: KY20180713-01), and informed consent was obtained from patients' first-degree relatives. The study was also registered at Clinical Trials.gov (ID: NCT03791866). Figure 1 shows the flow diagram of the participants.

Patients

From October 2018 to March 2020, all adult patients (aged 18-70 years) admitted to Department of Critical Care Medicine of Nanjing First Hospital with sepsis diagnosed were enrolled in this study. The diagnostic criteria for sepsis were in compliance with the surviving sepsis guidelines[2,3]. Patients with inflammatory bowel disease, digestive tract hemorrhage, ileus, severe abdominal hypertension (intra-abdominal pressure > 25 mmHg) or abdominal compartment syndrome, malnutrition, immunodeficiency, or chronic organ dysfunction (*e.g.*, hepatic or renal dysfunction), and patients with a history of long-term use of hormones were excluded. All patients received specialized critical care for sepsis as needed, including oxygen administration or mechanical ventilation (MV), antimicrobial therapy, vasopressor administration, fluid resuscitation, glucose control, analgesia and sedation, or renal replacement therapy[1,2,20].

Nutrition protocols

Before EN started, a nasogastric or nasojejunal feeding tube (size 10F, Flocare, Nutricia Ltd) was inserted as needed. The nasojejunal tube was intubated using our novel method of bedside post-pyloric placement[10,21]. The enteral feeding began within 24-48 h of enrollment if there were no contraindications. A peptide-based formula (Peptisorb, Nutricia Ltd) was provided in the first 24-48 h, and if the patients were tolerant, whole protein formula (Nutrison Fibre, Nutricia Ltd) was provided gradually [10]. The goal caloric requirement was determined as 20-25 kcal/kg per day, and the protein need was determined as 1.2-2.0 g/kg/d[9,10,18]. Patients were randomly assigned to receive 30%, 60%, or 100% of goal caloric requirements of nutrition. The EN feeding was started at a slow rate (10-20 mL/h) while carefully monitoring abdominal/ gastrointestinal symptoms[9]. If patients were intolerant because of high gastric residual volume (> 500 mL), diarrhea, nausea, vomiting, or abdominal distension, we slowed down the feeding rate, diluted the feeding concentration, or

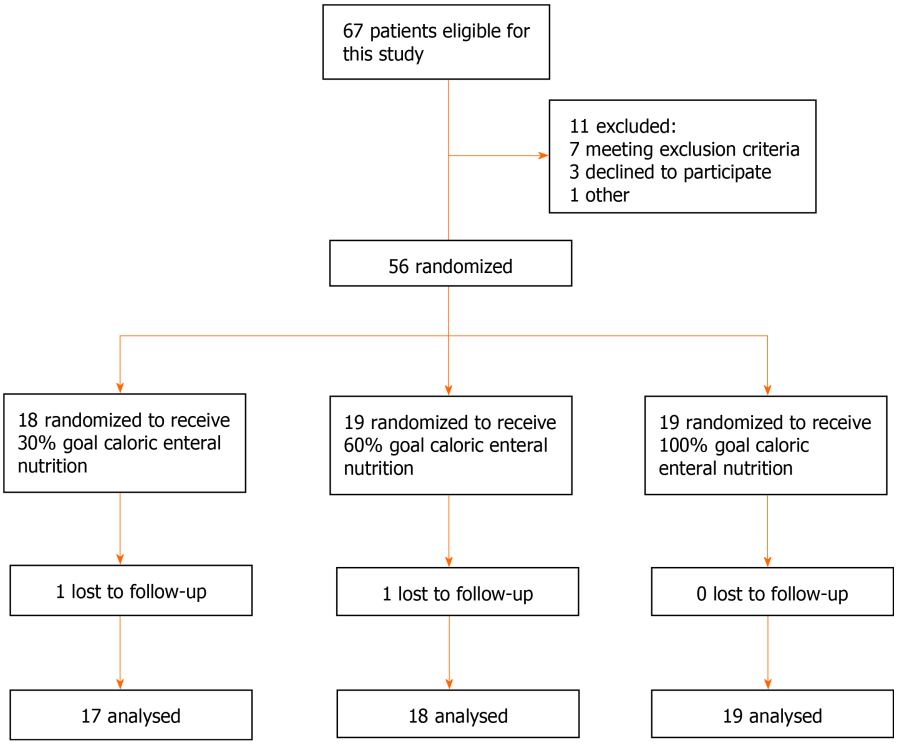

Figure 1 Flow diagram of the participants.

used prokinetic agents.

Parenteral nutrition (PN) was supplemented if the enteral nutrition could not achieve > 60% of the goal caloric requirements after 7 d[8,9,18]. The goal caloric requirement of PN was determined as 20-25 kcal/kg per day, and the calorie/nitrogen ratio was determined as 120-150:1[8,18]. Fifty to seventy percent of the total caloric requirements were supplied by glucose, whereas the provision of lipids was based on serum triglyceride levels. Moreover, sufficient electrolytes, insulin, vitamins, and trace elements were also provided.

Definitions

Sepsis was defined as life-threatening organ dysfunction caused by a dysregulated host response to infection, and septic shock was defined as a subset of sepsis with circulatory and cellular/metabolic dysfunction that was associated with a higher risk of mortality[1-3]. The definition of acute respiratory distress syndrome (ARDS) was based on the Berlin definitions[22,23]. The diagnostic criteria for acute kidney injury (AKI) were in accordance with the 2012 Kidney Disease: Improving Global Outcomes guidelines[24]. Acute gastrointestinal injury (AGI) was defined as a malfunction of the gastrointestinal tract due to acute illness and was categorized into four grades (I to IV) according to its severity[25,26]. AGI grade I was defined as an increased risk of developing gastrointestinal dysfunction or failure (a self-limiting condition); AGI grade II was defined as gastrointestinal dysfunction (a condition that requires interventions); AGI grade III was defined as gastrointestinal failure (gastrointestinal function cannot be restored with interventions); AGI grade IV was defined as marked gastrointestinal failure (a condition that is immediately life-threatening)[25,26].

Feeding intolerance (FI) syndrome was a general term indicating intolerance of enteral feeding for whatever clinical reason (vomiting, high gastric residuals, diarrhea, occurrence or worsening of bowel dilatation, gastrointestinal bleeding, presence of entero-cutaneous fistulas, *etc.*)[25,26]. Diarrhea was defined as having three or more loose or liquid stools per day with a stool weight greater than 200-250 g/d (or greater than 250 mL/d)[26]. High gastric residuals was considered if the gastric residual volume (GRV) was > 500 mL/6 h[26]. Intra-abdominal hypertension (IAH) was defined if intra-abdominal pressure (IAP) was 12 mmHg or higher, confirmed by at least two measurements, 1-6 h apart[26]. Paralysis of the lower GI tract (paralytic ileus) was defined as the inability of the bowel to pass stool due to impaired peristalsis[26]. Clinical signs of paralytic ileus included absence of stool for three or more consecutive days without mechanical obstruction. Multiple organ dysfunction syndrome (MODS)

was defined as the combined dysfunction of two or more organs.

Data collection

On admission to ICU, the baseline clinical data, including age, sex, body mass index, and the etiology of sepsis, were recorded. The acute physiology and chronic health evaluation II (APACHE II) scores and sequential organ failure assessment (SOFA) scores were collected on days 1, 3, and 7 after admission. The AGI grades, number of patients with FI symptoms, frequency of FI symptoms, days to goal calorie, and actual daily caloric intake were also registered. Since there is no "gold standard" to define the malnourished ICU patients[18,27], we used general clinical assessment markers (albumin, prealbumin, IL-6, and IL-10) to reflect nutritional and inflammatory status according to previous reports[27,28]. The levels of albumin, prealbumin, IL-6, and IL-10 in peripheral blood were tested on days 1, 3, and 7 after admission. Meanwhile, the levels of mucosal barrier function biomarkers, including diamine oxidase (DAO), D-lactate, and intestinal fatty acid binding protein (iFABP)[29-31], were also measured. Serum IL-6, IL-10, DAO, D-lactate, and iFABP levels were detected with commercially available Human Quantikine enzyme-linked immunosorbent assay (ELISA) kits (R and D Systems, Bio-Techne Corporation, United States) according to the manufacturer's instructions. The number of patients receiving MV or continuous renal replacement therapy (CRRT) was recorded. The MV-free days, CRRT-free days, and ICU-free days in 28 d of ICU admission, as well as MODS incidence and 28-d mortality, were also collected.

Statistical analysis

The Kolmogorov-Smirnov test was first performed to test the normal distribution of the data. Normally distributed data are expressed as the mean ± SD and were compared by *t* tests. Non-normally distributed data are expressed as the median (interquartile ranges) and were compared by the Mann-Whitney *U* test or the Kruskal-Wallis test. Categorical variables are presented as absolute numbers or percentages and were analyzed using the χ^2 test or Fisher's exact test. To take into account the repeated nature of the variables, analysis of variance (ANOVA) for repeated measurements of the general linear model was implemented. Survival curves for up to 28 d of enrollment were performed using the Kaplan–Meier method and were compared by the log-rank test. IBM Statistical Package for the Social Sciences (SPSS, version 22.0, NY, United States) software was used for statistical analyses, and two-sided $P < 0.05$ was considered statistically significant. The statistical methods of this study were reviewed by Qiao Liu, a biostatistician from the Center for Disease Control and Prevention of Jiangsu Province, China.

RESULTS

As shown in Figure 1, a total of 54 septic patients were enrolled in this study. Seventeen patients were randomly assigned to receive 30% of goal caloric requirements of nutrition (defined as group A), 18 received 60% (defined as group B), and 19 received 100% (defined as group C). The demographic data and clinical parameters of the patients on admission are shown in Table 1. Forty-two (42/54, 77.8%) patients had initial AGI, of whom 13 had AGI grade I, 24 had AGI grade II, and 5 had AGI grade III on admission. Sixteen (16/54, 29.6%) patients had FI symptoms during the first 7 d of enteral feeding. Forty-nine (49/54, 90.7%) patients received MV, and 20 (20/54, 27.0%) patients received CRRT. The 28-d mortality was 25.9% (14/54) in hospital stay.

Gastrointestinal function and nutritional variables

During the 7 d of enteral feeding, no significant differences in the AGI grades were found among the three groups (Figure 2A). The days to goal calorie of group C (2.55 ± 0.82) were significantly longer than those of groups A (3.50 ± 1.51; $P = 0.046$) and B (4.85 ± 1.68; $P < 0.001$) (Figure 2B). However, no difference in the days was found between groups A and B ($P = 0.077$). Figure 2C shows the differences in the actual daily caloric intake among the three groups. The daily caloric intakes of group A were all significantly lower than those of group C during the 7 d of enteral feeding ($P < 0.001$). The daily intakes of group A were significantly lower than those of group B from the 2th day of enteral feeding ($P < 0.01$). The daily intakes of group B were significantly lower than those of group C from the 3th day of enteral feeding ($P < 0.05$).

Table 1 Demographic data and clinical parameters on admission

Variable	Value
Age (yr)	67.0 (63.0-72.3)
Sex (Male:female)	29:25
BMI (kg/m^2)	24.3 (21.5-27.0)
Etiology of sepsis, *n* (%)	
Abdominal infection	27 (50.0)
Thoracic/pulmonary infection	10 (18.5)
Blood stream infection	6 (11.1)
Urinary infection	6 (11.1)
Mucocutaneous infection	3 (5.6)
Other	2 (3.7)
Initial AGI grade, *n* (%)	
I	13 (31.5)
II	24 (55.6)
III	5 (13.0)
APACHEII score	22.0 (19.5-27.8)
SOFA score	9.5 (8.0-11.8)
Feeding intolerance, *n* (%)	16 (29.6)
Need for MV, *n* (%)	49 (90.7)
Need for CRRT, *n* (%)	20 (37.0)
MV-free days	19.5 (1.8-22.8)
CRRT-free days	23.0 (13.3-27.0)
ICU-free days	17.0 (0.0-22.8)
MODS, *n* (%)	20 (37.0)
Death, *n* (%)	14 (25.9)

BMI: Body mass index; AGI: Acute gastrointestinal injury; APACHE II: Acute physiology and chronic health evaluation II; SOFA: Sequential organ failure assessment; MV: Mechanical ventilation; CRRT: Continuous renal replacement therapy; ICU: Intensive care unit; MODS: Multiple organ dysfunction syndrome.

As shown in Table 2, 16 (16/54, 29.6%) patients had FI symptoms during the first 7 d of enteral feeding. The proportion of patients with FI symptoms of group A was significantly lower than that of group C (11.8% *vs* 52.6%, $P = 0.019$). However, no difference in the proportion was found between groups B and A ($P = 0.658$) or C ($P = 0.057$). Table 3 shows the differences in the incidence of single FI symptom among the three groups. A total of 39 FI symptoms were observed during the 7 d of enteral feeding, and diarrhea was the most common manifestation. Although the total frequency of FI symptoms was different ($P = 0.009$) among the three groups, no difference in the incidence of single symptom (except for diarrhea, $P = 0.046$) was found. Moreover, there was no difference in the incidence of all symptoms between groups A and B.

Comparison of the levels of intestinal barrier biomarkers among the three groups is presented in Figure 3. The serum concentrations of DAO, D-lactate, and iFABP of group B were significantly lower than those of group A ($P < 0.05$) on the 7th day of feeding. The serum concentrations of the three biomarkers of group C were only numerically lower than those of group A on the 7th day of feeding ($P > 0.05$). Figure 4 shows the differences in the levels of nutritional and inflammatory markers among the three groups. The prealbumin level (mg/L) of group A was lower than those of groups B (71.09 ± 20.23 *vs* 103.33 ± 40.45, $P = 0.031$) and C (71.09 ± 20.23 *vs* 110.62 ± 37.05, $P = 0.008$) on the 7th day of feeding. The IL-6 level (pg/L) of group A was higher than that

Table 2 Number of patients with feeding intolerance and clinical severity and outcome variables

	Group A (*n* = 17)	Group B (*n* = 18)	Group C (*n* = 19)	*P* value
Feeding intolerance, *n* (%)	2 (11.8)	4 (22.2)	10 (52.6)	0.019

MODS, *n* (%)	6 (35.3)	8 (44.4)	6 (31.6)	0.709
Death, *n* (%)	4 (23.5)	5 (27.8)	5 (26.3)	0.856

Group A: Patients were assigned to receive 30% of goal caloric requirements of enteral nutrition; Group B: Patients were assigned to receive 60% of goal caloric requirements of enteral nutrition; Group C: Patients were assigned to receive 100% of goal caloric requirements of enteral nutrition. MV: Mechanical ventilation; CRRT: Continuous renal replacement therapy; ICU: Intensive care unit; MODS: Multiple organ dysfunction syndrome.

Table 3 Incidence of feeding intolerance symptoms, *n* (%)

	Group A (*n* = 17 × 7)	Group B (*n* = 18 × 7)	Group C (*n* = 19 × 7)	*P* value
Feeding intolerance	6 (5.0)	11 (8.7)	22 (16.5)	0.009
Nausea or vomiting	2 (1.7)	3 (2.4)	3 (2.3)	0.758
Diarrhea	2 (1.7)	2 (1.6)	8 (6.0)	0.046
Abdominal pain	0 (0.0)	0 (0.0)	1 (0.8)	0.238
Abdominal distention	1 (0.8)	2 (1.6)	6 (4.5)	0.054
High gastric residuals	1 (0.8)	2 (1.6)	2 (1.5)	0.653
IAH	0 (0.0)	1 (0.8)	1 (0.8)	0.422
Paralytic ileus	0 (0.0)	1 (0.8)	1 (0.8)	0.444

Group A: Patients were assigned to receive 30% of goal caloric requirements of enteral nutrition; Group B: Patients were assigned to receive 60% of goal caloric requirements of enteral nutrition; Group C: Patients were assigned to receive 100% of goal caloric requirements of enteral nutrition. IAH: Intra-abdominal hypertension.

of group B (115.54 ± 72.37 *vs* 62.00 ± 35.59, $P = 0.028$) on the 7th day of feeding. However, no difference in the IL-6 level was found between groups B and C ($P = 0.126$). No significant differences in the albumin and IL-10 levels were found among the three groups.

These results indicated that 60% of goal caloric requirements of enteral feeding may reduce the injury of intestinal barrier and improve the nutritional and inflammatory status without increasing the incidence of FI symptoms compared with 30% of goal caloric requirements. On the other hand, 60% of goal caloric requirements may decrease the incidence of FI symptoms without deteriorating the intestinal barrier function and nutritional status compared with 100% of goal caloric requirements.

Clinical severity and outcome variables

During the 7 d of ICU admission, no significant differences in the APACHE II scores or SOFA scores were found among the three groups ($P > 0.05$; Figure 5A and B). As shown in Table 2, no differences in the MV-free days, CRRT-free days, ICU-free days, MODS incidence, or 28-d mortality were found among the three groups ($P > 0.05$). The results of survival analysis (Figure 5C) also confirmed that the survival probability of patients was not affected by different goal caloric requirements (30%, 60%, and 100%) of enteral feeding in the acute phase of sepsis.

DISCUSSION

This clinical pilot study investigated the effects of different goal caloric requirements (30%, 60%, and 100%) of enteral feeding on gastrointestinal function and outcome of

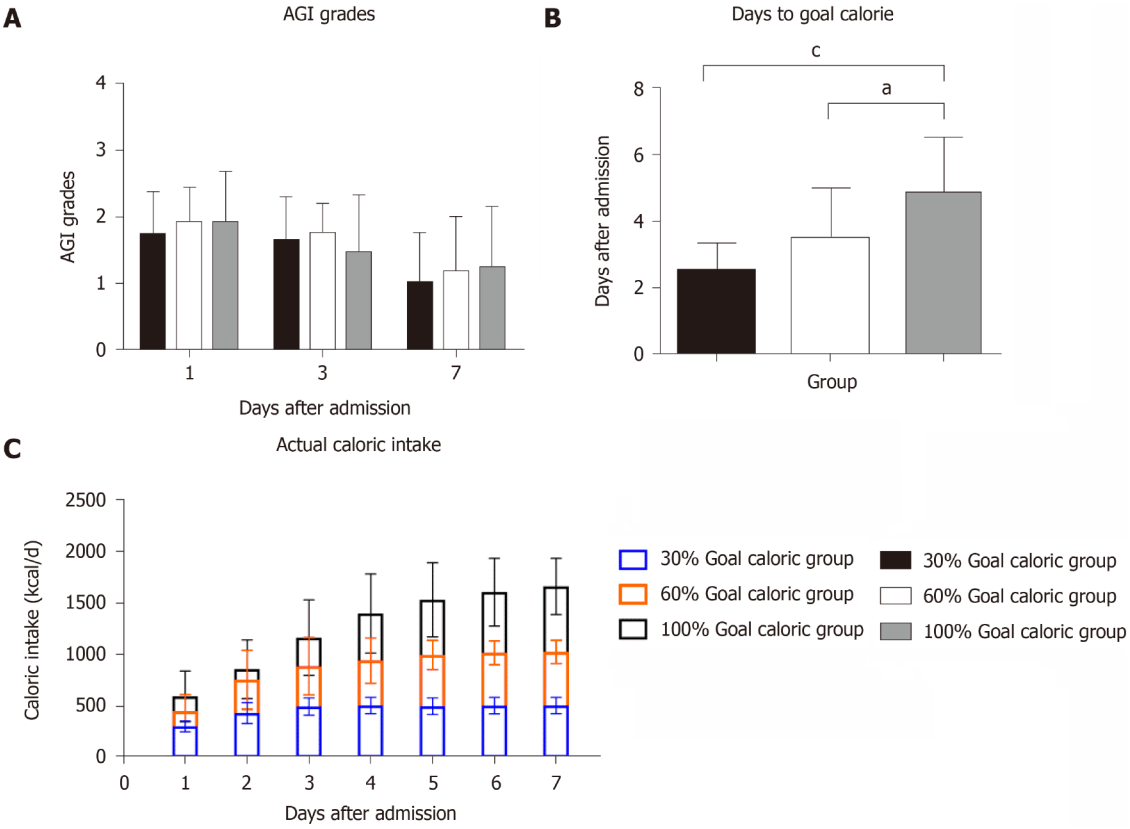

Figure 2 Comparisons of acute gastrointestinal injury grades (A), days to goal calorie (B), and actual daily caloric intake (C) among the three groups. $^{a}P < 0.05$, $^{c}P < 0.001$. AGI: Acute gastrointestinal injury.

Nutrition therapy is a crucial medical treatment during the acute phase of critical illness. Unfortunately, recent trial findings and guideline recommendations continued to be conflicting, making the translation of evidence into practice challenging[6,27]. No complete consensus has been reached on the estimation of energy expenditure, timing of feeding, choice of enteral or parenteral nutrition, protein and energy requirement, and monitoring of nutrition in sepsis. A literature review suggested that full feeding in the acute phase of critical illness did not provide an advantage over trophic feeding and may be harmful[6]. In sepsis, more or less nutrition delivery is an updated focus under exploration. Van Niekerket al[32] suggested that less nutrition supply may be beneficial during sepsis. However, the PROCASEPT study indicated that low protein intake or caloric restriction may not be of benefit in septic patients[33,34], and overfeeding during days 4-7 was related to a lower 6-mo mortality, compared with low caloric intake[34]. Due to the lack of direct or indirect calorimetric system of energy metabolism, we used the most commonly predictive equations to estimate the goal energy requirement of patients (20-25 kcal/kg per day) according to ASPEN and ESPEN guidelines[8,18]. We found that more (100%) or less (30% or 60%) enteral nutrition was not associated with the clinical outcomes, including 28-d mortality. This finding was not contradictory to the previous reports[13,17]. Nevertheless, moderate (60%) enteral nutrition may be beneficial to the gastrointestinal function and feeding tolerance during acute phase of sepsis.

Gastrointestinal dysfunction is common and closely related to adverse outcomes in critically ill patients[25]. AGI is often caused by severe trauma, infection, sepsis, shock, and other critical diseases[25]. Accompanied by that, intestinal epithelial cell damaged, mucosal permeability increased, intestinal flora translocated, and then intestinal infection and MODS developed[25,26]. Therefore, improving the intestinal barrier injury was considered to be an important measure in the treatment of sepsis. EEN was proven to regulate excessive immune response and maintain the intestinal barrier function of critically ill patients[6,9,27]. The results of our study were consistent with the previous studies. However, we found that full enteral feeding increased the incidence of FI symptoms without improving the intestinal barrier function and nutritional and inflammatory status, compared with underfeeding. This phenomenon also revealed that enteral underfeeding, especially 60% of goal caloric requirements,

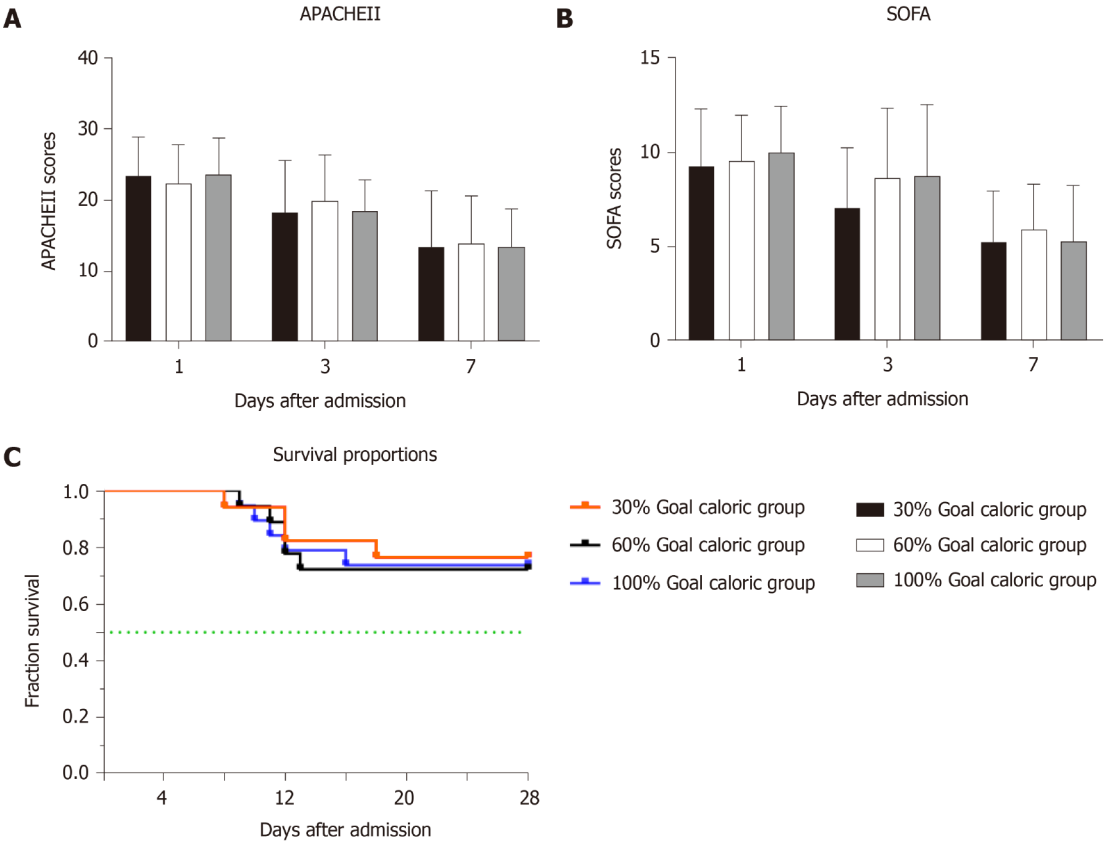

Figure 5 No significant differences in the acute physiology and chronic health evaluation II scores (A), sequential organ failure assessment scores (B), or survival probability within 28 d (C) were found among the three groups. APACHEII: Acute physiology and chronic health evaluation II; SOFA: Sequential organ failure assessment.

may be beneficial to sepsis. The underlying mechanisms of permissive underfeeding were proposed by a recent review[32]: Suppression of early feeding may result in a synergistic potentiation of catabolism and then promote cell survival and enhance immune function in sepsis. But further clinical and animal studies are required to verify this theory.

FI is the most commonly encountered challenge during enteral feeding in critically ill patients. Hu *et al*[35] reported that FI incidence was approximately 24% during the first week of ICU stay, and persistent FI was an independent risk factor for mortality in critically ill patients. A newly large-scale analysis of a multicenter, multiyear database showed that burn, gastrointestinal dysfunction, and sepsis were more likely to result in enteral feed intolerance, compared with respiratory-related illness, and enteral feed intolerance is associated with lower enteral nutrition delivery and worse clinical outcomes in mechanically ventilated critically ill patients[36]. Hence, prevention and optimal management of FI may improve nutrition delivery and clinical outcomes in important "at risk" populations. The FI incidence of this study was 29.6% during the first 7 d of enteral feeding in sepsis. Compared with full enteral feeding, 60% or 30% of total enteral feeding decreased the incidence of FI symptoms. However, 30% of total enteral feeding did not improve the nutritional and inflammatory status compared with 100% or 60% of total enteral feeding. It means that moderate underfeeding (60% of goal requirement) might be a preferable prevention and management strategy for FI and undersupply in sepsis. No difference in 28-d mortality among the three groups of different enteral intakes might be explained by our small sample size and single disease design, and large-scale prospective clinical studies are needed.

Some limitations of this study should be discussed. Due to our single-center design and small sample size, the results may not be generalizable, and the conclusions should be confirmed by large-scale clinical prospective trials. Moreover, the effects of different protein intake on gastrointestinal function and outcomes were not investigated. Finally, because our variables were only recorded for 1 wk, the later effects of enteral feeding on gastrointestinal function and outcomes should be researched in future clinical trials.

CONCLUSION

This clinical pilot study found that early moderate underfeeding (60% of goal requirements) could improve the intestinal barrier function and nutritional and inflammatory status without increasing the incidence of FI symptoms in sepsis. No difference in the clinical outcomes was found among the three groups of different enteral intakes. However, further large-scale prospective clinical trials and animal studies are required to test our findings. Moreover, the effects of different protein intake on gastrointestinal function and outcomes should also be investigated in future work.

ARTICLE HIGHLIGHTS

Research background

Few studies have investigated the effects of enteral underfeeding on gastrointestinal function in the acute phase of sepsis.

Research motivation

No consensus on goal enteral caloric intake has been reached in sepsis.

Research objectives

To investigate the effects of different goal caloric requirements of enteral nutrition on the gastrointestinal and outcomes in the acute phase of sepsis.

Research methods

Patients were randomly assigned to receive 30%, 60%, or 100% of goal caloric requirements of enteral nutrition in this prospective pilot clinical trial. The gastrointestinal function, nutritional and inflammatory markers, clinical severity, and outcome variables were recorded.

Research results

Early moderate enteral underfeeding (60% of goal requirements) could improve the intestinal barrier function and nutritional and inflammatory status without increasing the incidence of feeding intolerance symptoms in sepsis. No significant differences in the clinical outcome variables or 28-d mortality were found.

Research conclusions

Early moderate enteral underfeeding could improve the intestinal barrier function and nutritional and inflammatory status without increasing the incidence of feeding intolerance symptoms in sepsis.

Research perspectives

It is necessary to explore an optimal goal of enteral feeding to improve the acute intestinal injury in sepsis. In this study, we investigated the effects of different goal caloric requirements (30%, 60%, and 100%) of enteral nutrition on the gastrointestinal function in sepsis. Further large-scale prospective clinical trials and animal studies are required to test our findings.

ACKNOWLEDGEMENTS

The authors thank Qiu F, Shi QK, Chen WX, and Zhang WH at Nanjing First Hospital for their contributions to this study. In addition, Sun JK and his family especially thank Sun XP for her meticulous care and support during the past ten years.

Abstract

BACKGROUND

Liver diseases are associated with the excess formation of advanced glycation end products (AGEs), which induce tissue inflammation and oxidative damage. However, the trend of oxidative marker levels according to the steatosis grade in non-alcoholic fatty liver disease (NAFLD) is unclear.

AIM

To compare serum AGE levels between participants with NAFLD accordingly to steatosis severity in the baseline ELSA-Brasil population.

METHODS

In 305 individuals at baseline ELSA-Brasil, NAFLD-associated steatosis was classified by ultrasound hepatic attenuation. The participants were grouped according to the severity of steatosis: mild and moderate/severe pooled. The measurement of serum fluorescent AGE concentrations was based on spectrofluorimetric detection. Serum AGE content and clinical and laboratory characteristics of the participants were compared between groups. The correlation between

Peer-review report's scientific

serum AGE levels and the grade of steatosis was analyzed. Logistic regression analysis was used to investigate the relationship between serum AGE levels and steatosis severity. A P value < 0.05 was considered statistically significant.

RESULTS

According to the steatosis severity spectrum in NAFLD, from mild to moderate/severe, individuals with the most severe steatosis grade had a higher incidence of metabolic syndrome (63% *vs* 34%, $P \leq 0.001$), diabetes mellitus (37% *vs* 14%, $P \leq 0.001$), and high cholesterol levels (51% *vs* 33%, $P < 0.001$). Moreover, individuals with increasing severity of steatosis presented increasing waist circumference, body mass index, systolic and diastolic blood pressure, fasting blood glucose, glycated hemoglobin, insulin, triglycerides, alanine aminotransferase, gamma-glutamyl transferase, C-reactive protein, and uric acid levels and lower high-density lipoprotein. Higher serum AGE content was present in the moderate/severe group of individuals than in the mild group ($P = 0.008$). In addition, the serum AGE levels were correlated with the steatosis grade in the overall sample (rho = 0.146, $P = 0.010$). Logistic regression analysis, after adjusting for confounding variables, showed that subjects with higher serum AGE content had a 4.6-fold increased chance of having moderate or severe steatosis when compared to low levels of serum AGEs. According to the results of the receiver operator characteristic curves analyses (areas under the curve, AUC = 0.83), AGEs could be a good marker of steatosis severity in patients with NAFLD and might be a potential biomarker in predicting NAFLD progression, strengthening the involvement of AGE in NAFLD pathogenesis.

CONCLUSION

NAFLD-associated steatosis was associated with serum AGE levels; therefore, plasmatic fluorescent AGE quantification by spectroscopy could be a promising alternative method to monitor progression from mild to severe NAFLD accordingly to steatosis grade.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is characterized by abnormal liver fat accumulation in the absence of significant alcohol consumption or secondary causes of fat accumulation[1,2]. NAFLD includes a large spectrum of clinical phenotypes, from

non-alcoholic fatty liver to non-alcoholic steatohepatitis (NASH), in which inflammation and hepatocyte injury are present. Individuals with NAFLD can develop progressive fibrosis, liver cirrhosis, hepatocellular carcinoma, and end-stage liver disease[3]. In Western populations, NAFLD is rapidly becoming the top reason for liver transplants[4,5].

The prevalence of NAFLD worldwide is estimated to be 25%, with the highest prevalence in South America (30.45%). This condition is considered the leading cause of chronic liver disease in the United States and Europe[6,7]. Currently, there is a strong bidirectional association between NAFLD and metabolic syndrome (MetS) when components of MetS, such as insulin resistance and hypertriglyceridemia, increase an individual's chance of developing NAFLD[8-10]. Furthermore, metabolic disorders such as diabetes mellitus, dyslipidemia, and obesity have also been associated with NAFLD[1,11,12].

The most common imaging techniques used to diagnose NAFLD are ultrasonography, magnetic resonance, computerized tomography, and controlled attenuation parameter[13,14]. NAFLD can be histologically distinguished from alcoholic steatohepatitis based on histological markers in liver biopsy: Lobular inflammation, hepatocyte ballooning, portal granulocytic inflammation, and Mallory-Denk bodies [15]. Clinical settings and population studies with NAFLD commonly use conventional B-mode ultrasonography because it is non-invasive, easy to use, inexpensive, and widely available[16,17]. Despite the many methods available to assess NAFLD, the pathophysiology of NAFLD is extremely complex and has only been partially elucidated. Although laboratory tests, imaging techniques, and histology play a pivotal role in NAFLD diagnosis, novel alternative methods to diagnose and monitor NAFLD progression are critically needed.

According to the multiple-hit hypothesis, several factors in parallel act synergistically, causing metabolic and molecular alterations that lead to the development and progression of NAFLD[18]. Accumulation of fat in the liver is considered one of the first hits; however, the progression of the disease requires the involvement of other secondary factors, such as insulin resistance, inflammatory mediators, gut microbiome, mitochondrial dysfunction, genetics, nutritional and environmental factors, and/or ER stress[18-20]. Among the "multiple hits", advanced glycation end products (AGEs) have been observed by several studies to play a critical role in the pathogenesis of NAFLD[19,21,22].

AGEs are products of non-enzymatic reactions of reducing sugars or oxidized lipids with amino groups in proteins, lipids, and nucleic acids[23]. In addition to being produced in an endogenous manner, AGEs are also present in foods highly processed or dry heated at high temperatures[24]. Increased AGE levels can trigger loss of normal structure and protein dysfunction due to abnormal cross-linking between intracellular and extracellular proteins. Moreover, the activation of the receptor for AGE (RAGE) by binding AGEs can trigger an increase in inflammation and oxidative stress[25] and participate in insulin resistance, liver injury, and fibrosis[22,26]. AGEs are increased in several pathological conditions such as Alzheimer's disease[27], cardiovascular diseases[28-30] diabetes mellitus[31-33], and liver diseases[34]. We have previously shown that activation of the AGE-RAGE axis, oxidative stress, and inflammation could have a role in microcirculatory alterations in NAFLD[35]. The increased accumulation of AGEs in the serum or liver tissue of NASH patients could induce cell damage and necrotic-type hepatocyte death[36]. AGEs can leak outside of cells and induce inflammatory or fibrotic responses in adjacent cells[36]. To date, there is a lack of clinical studies investigating the role of AGEs in the pathogenesis of NAFLD. Given this, it is of great interest to address the specific pathophysiological mechanisms underlying NAFLD-associated steatosis association with AGEs levels in a large and mixed population cohort. Therefore, in this study, we addressed whether steatosis severity was associated with serum AGE levels in the baseline data from the Brazilian Longitudinal Study of Adult Health (ELSA-Brasil) study. We propose plasmatic fluorescent AGE quantification by spectroscopy as a promising alternative method to monitor progression of NAFLD accordingly to steatosis severity.

MATERIALS AND METHODS

Study population

This is a cross-sectional study addressing the association between NAFLD and AGEs in the baseline ELSA-Brasil population; a cohort of active or retired employees of both sexes, aged between 35 and 74 years, totaling 15105 civil servants living in six cities in

Brazil (Belo Horizonte, Porto Alegre, Rio de Janeiro, Salvador, São Paulo, and Vitoria) from predefined universities or research institutes[37]. In the present study, subjects from Rio de Janeiro were included (n = 305) (Figure 1). Exclusion criteria were as follows: no information on serum AGE content, no information on alcohol consumption, or excessive alcohol consumption (> 210 g/wk for men or 140 g/wk for women). In addition, subjects who had no NAFLD evaluation, poor ultrasound image quality, or normal hepatic deep-beam attenuation (complete viewing) were excluded. This study was approved by all the institutional review boards of the participating institutions, which conforms to the ethical guidelines of the 1975 Declaration of Helsink, and all participants provided informed consent.

Data collection

Clinical and anthropometric examination data were collected on-site by questionnaires and clinical exams between August 2008 and December 2010[38]. The questionnaire included information on age at the baseline visit (years), gender, alcohol consumption (never used, ex-user or user), and smoking habit (non-smoker or smoker). Waist circumference (cm), weight (kg), and height (cm) were measured according to standard techniques[39]. Body mass index (BMI) was calculated by dividing body weight by squared height in meters (kg/m^2). Blood pressure was measured using a validated Omron HEM 705CPINT oscillometer device (Omron Co, Kyoto, Japan) three times with a 1 min interval in the sitting position and the mean of the last two measurements defined the blood pressure value.

Participants' sera were collected after 12 h of fasting, centrifuged, and stored at -70 °C until analysis. Gamma-glutamyl transferase (GGT) was measured using a kinetic colorimetric assay; aspartate aminotransferase (AST) and alanine aminotransferase (ALT) by enzymatic assay (ADVIA Chemistry, Siemens, Deerfield, United States); uric acid by colorimetric enzyme (uricase) method; total cholesterol, high-density cholesterol, and triglycerides by the enzymatic colorimetric method. Low-density cholesterol was calculated by the Friedewald equation if triglycerides ≤ 400 mg/dL or directly measured by enzymatic colorimetric method otherwise; glucose was measured by hexokinase method (ADVIA Chemistry, Siemens, Deerfield, United States), glycated hemoglobin (HbA1c) by high-pressure liquid chromatography (Bio-Rad Laboratories, Hercules, CA, United States), fasting insulin was determined by immunoenzymatic assay (ELISA); and high sensitivity C reactive protein by immunochemistry nephelometry (BN II Siemens® nephelometer). Microalbuminuria was measured *via* an immunochemical assay (nephelometry) (Dade Behring). Creatinine levels were measured using an enzymatic colorimetric assay (ADVIA 1200, Siemens, Deerfield, United States). Diabetes was defined by previous medical history of diabetes, antidiabetic drug use, 2 h plasma glucose ≥ 200 mg/dL, fasting plasma glucose ≥ 126 mg/dL, or glycated hemoglobin ≥ 6.5%. High cholesterol was defined as the use of medication to treat dyslipidemia or low-density lipoprotein cholesterol ≥ 130 mg/dL. The presence of MetS was defined according to the NCEP ATP III definition, which requires three or more of the following five criteria: waist circumference ≥ 88 cm for women and ≥ 102 cm for men; antihypertensive drug use or systolic blood pressure ≥ 130 mmHg or diastolic ≥ 85 mmHg; triglycerides ≥ 150 mg/dL; high-density lipoprotein (HDL) cholesterol < 50 mg for women and < 40 mg for men; and fasting glucose ≥ 100 mg/dL with oral or insulin treatment using hypoglycemic agents.

Plasma AGEs

Measurement of fluorescent AGE concentrations was based on spectrofluorimetric detection[40]. Serum was diluted 200-fold with phosphate-buffered saline (KH_2PO_4 1.06 mmol/L, NaCl 155.10 mmol/L, and $Na_2HPO_4 \cdot 7H_2O$ 2.97 mmol/L, pH 7.4) and homogenized using a vortex mixer for 10 s, measured at an emission wavelength of 445 nm and at an excitation wavelength of 370 nm (SpectraMax M5 ELISA Microplate Reader, Molecular Devices, Acton, MA, United States). A solution of BSA (1 mg/mL in 0.1 N NaOH) was used as a reference and its fluorescence intensity was defined as one unit of fluorescence. The amount of fluorescence of the patient serum sample was measured at a protein concentration of 1 mg/mL and expressed in arbitrary units after normalization with the native BSA preparation[41].

Hepatic imaging and NAFLD classification

Ultrasound has been recommended as the first-line method for evaluating hepatic steatosis due to its safety, low cost, and noninvasiveness[42,43]. Among the most common ultrasonography parameters for assessing NAFLD, we have chosen hepatic attenuation of the ultrasound beam because of its better diagnostic performance as

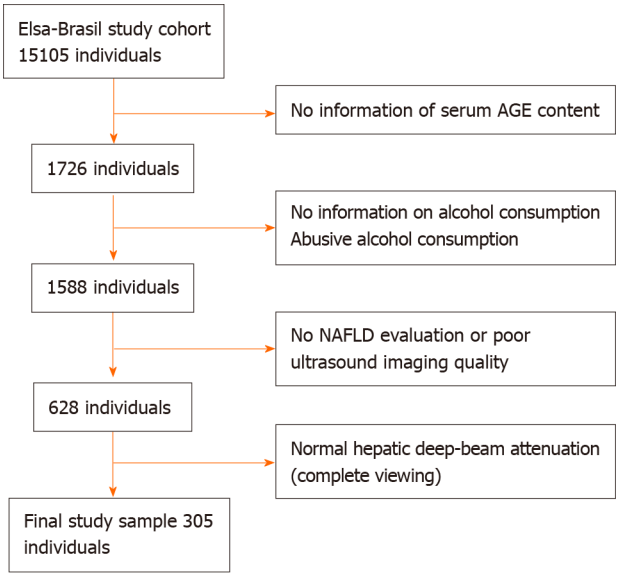

Figure 1 Flow chart of the selection of the eligible study population in the final analysis. AGE: Advanced glycation end product; NAFLD: Non-alcoholic fatty liver disease.

previously described[44]. A standard B-mode ultrasound evaluation was performed using a visual grading system based on the degree of loss of definition of the diaphragm posterior to the right hepatic lobe. Liver ultrasound examinations were performed by previously trained operators using a high-resolution B-mode scanner (SSA-790A, Aplio XG, Toshiba Medical System, Tokyo, Japan) and a convex array transducer (model PVT-375BT), with a central frequency of–3.5 MHz and a fundamental frequency of 1.9-5.0 MHz, the same models of equipment used by the participants at enrollment. After the acquisition process, the B-mode hepatic ultrasound images were read, and the quality control protocol was verified by a senior ultrasound radiologist following a standardized protocol[44]. The presence of steatosis was classified as mild (partial, *i.e.*, > 50% visualization of the diaphragm), moderate (partial, *i.e.*, < 50% visualization of the diaphragm), or severe (no visualization of the diaphragm), as previously validated[44].

Serum biomarkers

Liver steatosis predictive models previously reported in the literature were used to compare the effect of NAFLD classification method on the associations based on fatty liver index (FLI) and hepatic steatosis index (HSI), an algorithm for the prediction of fatty liver in the general population. The FLI is a prevalent biomarker panel consisting of BMI, waist circumference, triglycerides, and gamma-glutamyl transferase for identifying NAFLD, with a total score varying between 0 and 100. The presence of liver steatosis was defined as an FLI ≥ 60, and the absence was defined as FLI < 30[45]. The FLI was calculated according to the following algorithm: FLI = ey/(1 + ey) × 100, where y = 0.953 × ln (triglycerides, mg/dL) + 0.139 × BMI, kg/m^2 + 0.718 × ln (GGT, U/L) + 0.053 × waist circumference, cm – 15.745.

The HSI is a biomarker panel consisting of BMI, diabetes, and the ALT/AST ratio. Liver steatosis was defined as HSI ≥ 36[46]. HSI = 8 × ALT/AST ratio + BMI (+ 2, if diabetes mellitus; + 2, if female).

The atherogenic index (AI), a biomarker used to predict the susceptibility of individuals for developing cardiovascular diseases and atherosclerosis, is strongly associated with NAFLD, which can be used in the auxiliary diagnosis of NAFLD. AI consists of the logarithm of the molar ratio of triglyceride to HDL cholesterol. According to previous studies, AI was stratified into three groups: low (< 0.11), intermediate (0.11-0.21), and high (> 0.21) risk[47].

Statistical analysis

The participants were grouped according to the severity of NAFLD-associated steatosis: mild, and moderate/severe pooled. Clinical and laboratory characteristics were described by median (interquartile range) for continuous variables and by frequency (percentage) for categorical variables. The serum AGE content of the participants was compared across the steatosis stratification. Given the ordinal nature

of steatosis stratification groups, we ran trend analysis using Jonckheere-Terpstra for continuous variables and Cox-Mantel-Haenszel for categorical variables. The Spearman correlation coefficient was used to analyze correlations between serum AGE levels and the grade of steatosis. A P value < 0.05 was considered statistically significant. A logistic regression analysis was used to investigate the relationship between hepatic steatosis severity (moderate/severe pooled) and high levels of serum AGEs (AGEs ≥ 0.85, according to the median of AGE values in the study population). Odds ratios (ORs) were obtained from logistic regression analysis, and the results were presented as ORs with a 95% confidence interval (CI). NAFLD-associated steatosis severity was the dependent variable. In the first model, AGEs were the independent variables; in the second model, the first model plus gender; in the third model, the second model plus gamma-glutamyl transferase levels; in the fourth model, the third model plus altered fasting blood glucose (110 ≤ 125 mg/dL or ≥ 126 mg/dL); in the fifth model, the fourth model plus high cholesterol. This study achieved this model's performance by three folder cross-validations, including sensitivity, specificity, and accuracy. The receiver operator characteristic curves (ROCs) were drawn, which can assess the logistic regression model's prediction performance. Data analysis was performed using R version 3.6.2 (R Project for Statistical Computing) and run in RStudio version 1.2.5033 (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

Of the 305 individuals from the overall sample, 56% were male, and the median age was 51 (45-55) years. The median (interquartile) serum AGE content was 0.85 (0.76-0.96). Mild steatosis was present in 182 (60%), moderate in 111 (36%), and severe in 12 (4%) individuals. The AGE levels based on NAFLD-associated steatosis stratification were 0.82 (0.75-0.92), 0.86 (0.79-0.98), and 0.98 (0.82-1.10) for mild, moderate, and severe steatosis, respectively. For the subsequent analyses, due to the low frequency of severe steatosis, the moderate and severe individuals were pooled into a single group with 123 (40%) individuals.

Table 1 displays the characteristics of the participants. According to NAFLD-associated steatosis grade, from mild to moderate/severe , individuals were older, but no difference was found between genders. No difference was observed in smoking habits or use of alcohol. According to the NCEP ATP III definition, individuals with the most severe forms of steatosis had a higher prevalence of MetS (63% *vs* 34%, $P \leq 0.001$), diabetes mellitus (37% *vs* 14%, $P \leq 0.001$), and high cholesterol (51% *vs* 33%, $P \leq 0.001$). Similarly, individuals with increasing severity of steatosis presented increasing waist circumference, BMI, systolic and diastolic blood pressure, fasting blood glucose, glycated hemoglobin, insulin, triglycerides, ALT, GGT, C-reactive protein, and uric acid levels and lower HDL. There were no significant differences in total cholesterol, AST, microalbuminuria, creatinine, sodium, and potassium levels among groups (Table 1).

Table 2 shows the association between the FLI, HIS, and AI with the severity of NAFLD-associated steatosis. Notably, increased degrees of steatosis resulted in increased values of the evaluated indexes (Table 2).

Higher serum AGE content was present in the moderate/severe group of individuals than in the mild steatosis group ($P = 0.008$) (Figure 2). In addition, the serum AGE levels were correlated with the steatosis grade in the overall sample (rho = 0.146, $P = 0.010$).

Logistic regression analysis was performed to verify if subjects with higher serum AGE content were more likely to have severe forms of NAFLD accordingly to steatosis levels (Table 3). The results showed that only high AGE serum levels (OR: 2.65, 95%CI: 1.05-6.92) was an independent risk factor for severe NAFLD-associated steatosis, and all four models showed a consistent relationship with the severity of steatosis in NAFLD (Table 3). The risk of moderate or severe NAFLD-associated steatosis in the highest serum AGE content was 239% (OR: 3.39; 95%CI: 1.24-9.98) after adjustment for sex. A similar association was also observed in model 2 after additional adjustment for GGT levels. Model 3 was also associated with an increased risk of severe forms of NAFLD-associated steatosis after additional adjustment for hyperglycemia (OR: 4.53, 95%CI: 1.44-16.28). In model 4, the risk was 4.6-fold higher after adjusting for hypercholesterolemia (OR: 4.67, 95%CI: 1.46-17.17).

To further confirm the predictive power of high AGE levels for NAFLD-stratification accordingly to hepatic steatosis , ROC analysis for the diagnostic value for steatosis was done (Figure 3). The areas under the curve (AUC) for AGEs in model 4 of

Table 3 Effect of high advanced glycation end product levels on the non-alcoholic fatty liver disease-associated steatosis severity

Variable	SE	OR (95%CI)	Sensitivity	Specificity	Accuracy
Crude model	0.47	2.64 (1.04-6.92)	0.62	0.61	0.61
Model 1	0.52	3.38 (1.24-9.98)	0.60	0.73	0.64
Model 2	0.55	3.34 (1.17-10.40)	0.71	0.68	0.69
Model 3	0.61	4.52 (1.44-16.28)	0.78	0.72	0.75
Model 4	0.62	4.66 (1.45-17.16)	0.77	0.77	0.77

Model 1: Adjusted for gender; Model 2: Additionally adjusted for gamma-glutamyl transferase; Model 3: Additionally adjusted for altered blood glucose (categorical ≥ 126, 110 ≤ 125); Model 4: Additionally adjusted for high cholesterol. High cholesterol was defined as use of medication to treat dyslipidemia or low-density lipoprotein cholesterol ≥ 130. OR: Odds ratio; CI: Confidence interval.

adjustment (0.83) would have the most clinical implications for predicting the severity of NAFLD-associated steatosis, with a sensitivity of 0.77, a specificity of 0.77, and an accuracy of 0.77, followed by model 3 (AUC = 0.81), model 2 (AUC = 0.79), model 1 (AUC = 0.72), and the crude model (AUC = 0.62) (Table 3, Supplementary Table 1, and Figure 3).

DISCUSSION

Addressing the specific mechanisms by which NAFLD progresses could potentially open new frontiers for preventive and monitoring strategies for liver diseases. In this study, we investigated the relationship between plasmatic AGE levels and severity of NAFLD-associated steatosis in a racially/ethnically diverse cohort at baseline of the ELSA-Brasil study. Steatosis stratification based on serum biomarker indexes, that is, FLI, HSI, and AI, was associated with the ultrasonography grade of NAFLD previously described[45-47], with higher values for moderate/severe group. Serum AGE levels were positively correlated with the steatosis stage; that is, AGE content was significantly higher in subjects with moderate/severe forms of steatosis compared to the mild form. Logistic regression analysis after adjusting for confounding variables showed that subjects with higher serum AGE content had a 4.6-fold increased chance

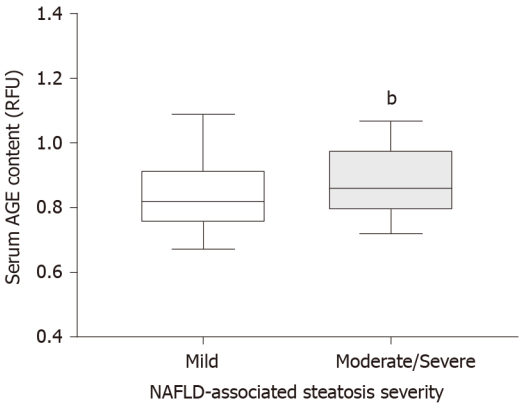

Figure 2 Boxplot showing the distribution of advanced glycation end product values in serum in the group of participants with mild steatosis and the group of participants with moderate/severe pooled steatosis. Data are shown as median ± inter-quartile range. [b]*P*< 0.001. AGE: Advanced glycation end product; RFU: Relative fluorescent units.

of having moderate or severe forms of steatosis when compared to that in those with low levels of serum AGEs. According to the results of the ROC analyses from the current study, AGEs could be a good marker of steatosis severity in patients with NAFLD and might be a potential biomarker in predicting NAFLD progression. Therefore, fluorescent AGEs could be a potential plasmatic biomarker for risk stratification of NAFLD accordingly to the severity of hepatic steatosis.

A proposed mechanism to explain why some patients with NAFLD progress to more severe forms of NAFLD is the multiple-hit hypothesis. In this hypothesis, the deposition of fat in the liver is the first hit, whereas the progression requires the involvement of other factors[48]. Emerging evidence highlighted that AGEs can act as a critical 'hit' being one factor that drives the progression from simple NAFLD to NASH and liver fibrosis[18,49]. Previously, the correlation of CML level with the clinical score of patients with liver cirrhosis showed a direct relationship with the severity of disease[50]. We and others have demonstrated increased deposition of AGEs in the liver of animals with NAFLD, MetS, and diabetes[35,41,50-57], which was associated with microcirculatory disturbances[53]. Furthermore, treatment with pyridoxamine, an AGE inhibitor, reduced the microcirculatory and metabolic alterations caused by NAFLD[53]. Using biopsies, Gaens *et al*[56] showed that Ne-(carboxymethyl) lysine (CML), as assessed by immunohistochemistry, was increased in the liver of obese individuals who underwent bariatric surgery, and AGE levels were associated with the grade of hepatic steatosis and inflammation, suggesting that AGEs could contribute to NAFLD progression. Furthermore, incubation of human hepatic stellate cells with AGEs increased the expression of fibrotic and cell proliferation markers, suggesting that these compounds can contribute to the development of NASH[58]. Mechanistically, AGE formation may result in loss of hepatocyte function, while intracellular accumulation of AGEs causes cell death[59]. Moreover, the interaction of extracellular AGEs with its receptor RAGE in hepatocytes[60] promotes inflammation, a characteristic feature of NAFLD progression to NASH[61]. In addition, fatty acids stimulate CML accumulation in hepatocytes and subsequently elicit inflammatory reactions *via* RAGE activation[56].

Although some studies have highlighted the involvement of AGEs in liver diseases, only two previous studies assessed the correlation between serum AGEs and the severity of NAFLD. The study by Hyogo *et al*[34] showed that AGE levels were elevated in NASH patients compared to individuals with simple steatosis. Świderska *et al*[62] reported that AGEs can be used as a biomarker to differentiate between patients with minimal *vs* moderate steatosis, but in a small cohort (early NAFLD n = 29 and advanced NAFLD n = 38). We addressed the AGE levels in subjects with mild and moderate/severe steatosis in a larger cohort. Presently, we assessed AGE levels by fluorescent spectroscopy, while the study by Hyogo *et al*[34] used ELISA. Fluorescence spectroscopy is an easy, rapid, and cost-effective method that has been previously proposed as a reliable tool that can be used to distinguish patients with type 1 and 2 diabetes from healthy subjects[63,64]. Recently, Heidari *et al*[65] showed that serum levels of AGEs increase progressively with increasing duration of diabetes, and proposed the monitoring of fluorescent AGEs as an estimation tool for diabetes chronicity.

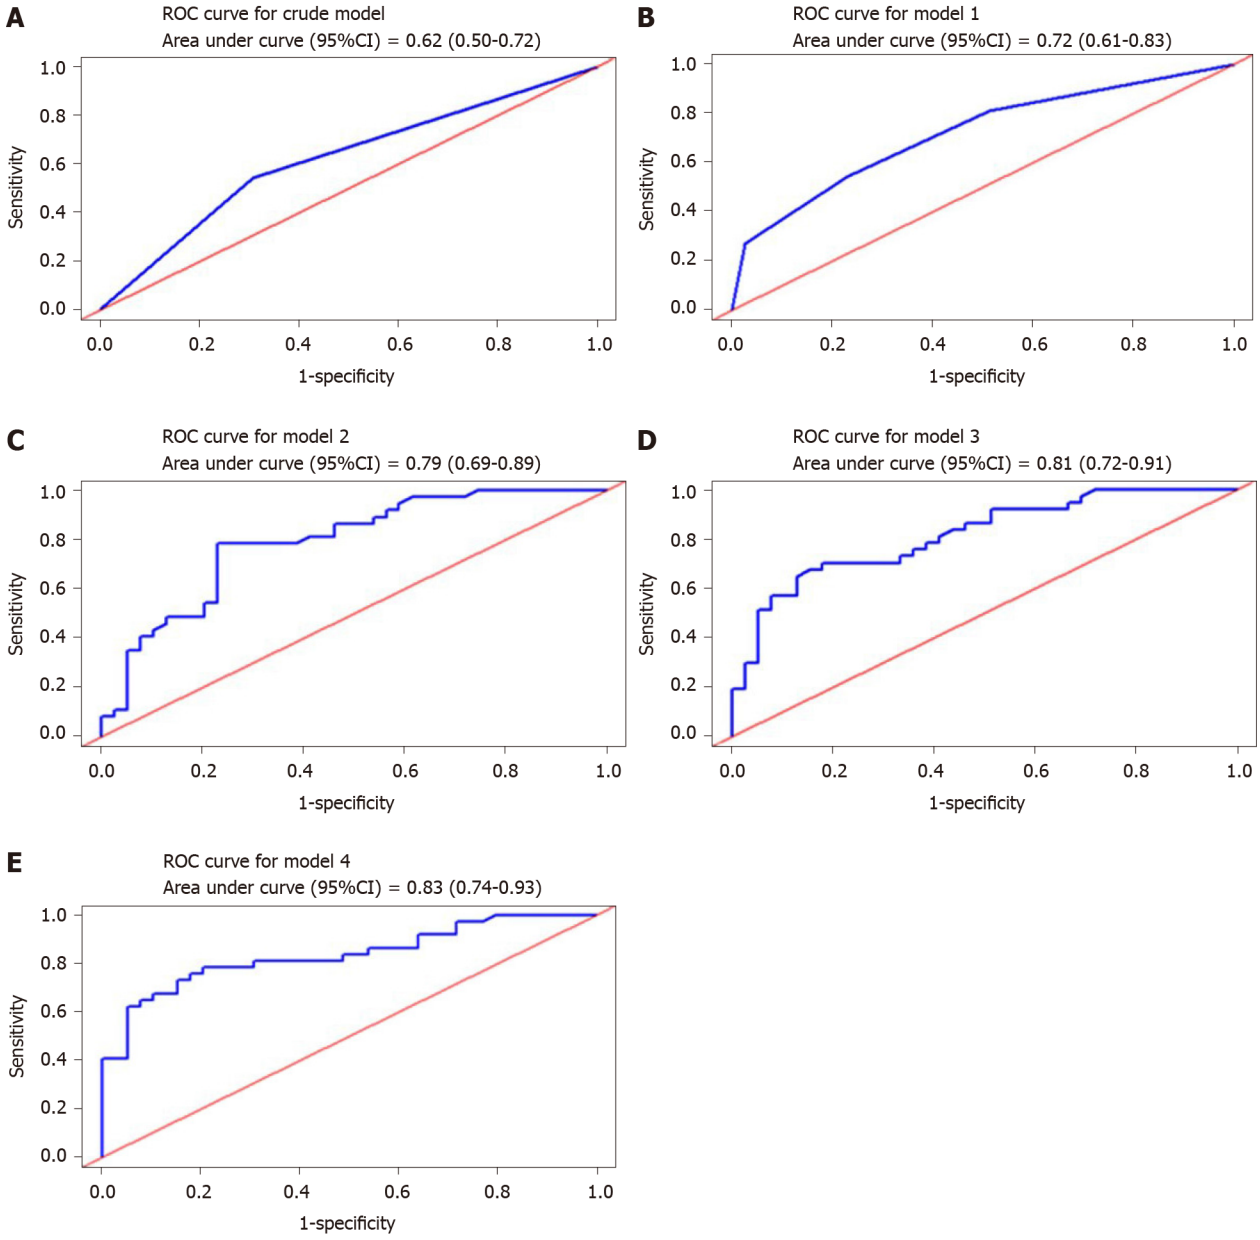

Figure 3 Receiver operating characteristic curves and corresponding areas under the curve of models to predict non-alcoholic fatty liver disease-associated steatosis. ROC: Receiver operating characteristic; CI: Confidence interval.

Along with increasing NAFLD-associated steatosis severity, increased AGE is associated with a concomitant worsening of the metabolic profile, namely MetS, diabetes mellitus, cholesterol levels, BMI, waist circumference, blood pressure, and lipid and glycemic profile[66-70]. In our study, the results of logistic multiple regression analysis showed that, as well as AGEs, altered fasting blood glucose and high cholesterol levels were associated with the severity of steatosis in NAFLD. The risk of severe steatosis in individuals with altered fasting blood glucose and high cholesterol was 6.730 and 3.490 times higher than that in subjects with a normal range of blood glucose and cholesterol, respectively. Although the precise pathological process has not been elucidated, it has been widely accepted that excess triglyceride accumulation in the liver is a prerequisite for NAFLD development. Triglyceride showed a great correlation with NAFLD in both epidemiologic studies[71] and pre-clinical research[72]. The progression of NAFLD results from an imbalance between lipid uptake and lipid disposal and eventually causes oxidative stress and hepatocyte injury. Excess lipid accumulation may result in impaired insulin signaling through cell autonomous mechanisms or through the induction of inflammation and the subsequent production of inflammatory cytokines by macrophages, which impair insulin action[73]. Increasing evidence suggests that subjects with hyperglycemia resulting from defects in insulin secretion, insulin action, or both have a particularly

high risk for NASH, with varying degrees of liver fibrosis[74,75]. Insulin resistance may cause inflammation in the adipose tissue, which triggers the acceleration of lipolysis, resulting in increased free fatty acid export to the liver, leading to the accumulation of fat in the liver and consequently NAFLD[48,76]. It has already been demonstrated that AGE formation is accelerated under a hyperglycemic state, playing an important role in the pathogenesis of NAFLD and complications of diabetes[77,78]. Lipid peroxidation is also known to be involved in the generation of AGEs, and the glycation of lipids results in the formation of AGEs, which are related to triglyceride or HDL-C levels[79].

The current study has limitations that should be mentioned. First, it was not possible to distinguish people with NAFLD from healthy controls based on serum fluorescent AGE concentrations. Moreover, given the cross-sectional design of the study, no causal relations can be established. The sample size is higher than others in the field, but the sample size of the severe form of NAFLD-associated steatosis remains small, probably due to the study population being formed by healthy employees. Thus, the associations found here may be even greater in the general population. This might have limited our results to fully explore the relationship between glycation products and disease stages. As this was a single-center study, results and glycation levels should be extrapolated to other populations carefully.

CONCLUSION

In conclusion, this cross-sectional analysis of the ELSA-Brasil cohort baseline study showed that high serum AGE content was associated with severe forms of steatosis, with high serum AGE levels being an important risk factor for NAFLD-associated steatosis severity. In addition, serum AGE content was positively correlated with the severity of steatosis. These data suggest that AGEs might be a potential plasmatic biomarker for NAFLD stratification accordingly to hepatic steatosis. Our findings strengthen the involvement of AGE in NAFLD pathogenesis. These findings highlight the importance of including the evaluation of AGE status as a part of health examinations and may help health policy-makers prevent or delay NAFLD among the population.

ARTICLE HIGHLIGHTS

Research background

Non-alcoholic fatty liver disease (NAFLD) is considered the hepatic manifestation of metabolic syndrome and it affects about 25% of the adult population, and can progress to hepatocellular carcinoma, death, and/or liver transplantation. The underlying mechanisms that account for disease progression are still not fully understood due to its complexity.

Research motivation

Liver diseases are associated with the excess formation of advanced glycation end products (AGEs), which induce tissue inflammation and oxidative damage. However, the trend of oxidative marker levels according to NAFLD severity is unclear.

Research objectives

We aim to understand whether NAFLD-associated steatosis severity was associated with serum AGE levels in the baseline data from the Brazilian Longitudinal Study of Adult Health (ELSA-Brasil) study to address the specific pathophysiological mechanisms underlying NAFLD association with AGEs in a large and mixed population cohort.

Research methods

NAFLD-associated steatosis severity was classified by ultrasound hepatic attenuation: mild and moderate/severe pooled. The measurement of serum fluorescent AGE concentrations was based on spectrofluorimetric detection. Serum AGE content and clinical and laboratory characteristics of the participants were compared between groups. The correlation between serum AGE levels and the grade of steatosis was analyzed. Logistic regression analysis was used to investigate the relationship between

serum AGE levels and NAFLD-associated steatosis severity. A P value < 0.05 was considered statistically significant.

Research results

According to hepatic steatosis grade in NAFLD, from mild to moderate/severe, individuals with the most severe forms of steatosis had a higher incidence of metabolic syndrome, diabetes mellitus, and high cholesterol levels. Moreover, individuals with increasing severity of NAFLD-associated steatosis presented increasing waist circumference, body mass index, systolic and diastolic blood pressure, fasting blood glucose, glycated hemoglobin, insulin, triglycerides, alanine aminotransferase, gamma-glutamyl transferase, C-reactive protein, and uric acid levels and lower high-density lipoprotein. Higher serum AGE content was present in the moderate/severe group of individuals than in the mild group. In addition, the serum AGE levels were correlated with the steatosis grade in the overall sample. Logistic regression analysis, after adjusting for confounding variables, showed that subjects with higher serum AGE content had a 4.6-fold increased chance of having moderate or severe forms of NAFLD-associated steatosis when compared to low levels of serum AGEs.

Research conclusions

Steatosis severity in NAFLD patients was associated with serum AGE levels, thereafter AGEs could be a good marker of NAFLD stratification accordingly to steatosis grade, strengthening the involvement of AGE in NAFLD pathogenesis.

Research perspectives

Plasmatic fluorescent AGE quantification by spectroscopy could be a promising alternative method to monitor progression from mild to severe forms of NAFLD accordingly to the severity of hepatic steatosis.

ACKNOWLEDGEMENTS

We thank all the ELSA-Brasil participants for their invaluable contribution to this study.

Abstract

BACKGROUND

Autoimmune enteropathy (AIE) and primary biliary cholangitis (PBC) are both immune-mediated diseases. AIE or PBC complicated with ulcerative colitis (UC) are rare. There are no cases of AIE and PBC diagnosed after proctocolectomy for UC reported before, and the pathogenesis of these comorbidities has not been revealed.

CASE SUMMARY

A middle-aged woman diagnosed with UC underwent subtotal colectomy and ileostomy due to the steroid-resistant refractory disease, and a restorative proctectomy with ileal pouch-anal anastomosis and proximal neoileostomy was postponed due to active residual rectal inflammation in January 2016. A few months after the neoileostomy, she began to suffer from recurrent episodes of watery diarrhea. She was diagnosed with postcolectomy enteritis and stoma closure acquired a good therapeutic effect. However, her symptoms of diarrhea relapsed in 2019, with different histological features of endoscopic biopsies compared with 2016, which showed apoptotic bodies, a lack of goblet and Paneth cells, and villous blunting. A diagnosis of AIE was established, and the patient's stool volume decreased dramatically with the treatment of methylprednisolone 60

mg/d for 1 wk and tacrolimus 3 mg/d for 4 d. Meanwhile, her constantly evaluated cholestatic enzymes and high titers of antimitochondrial antibodies indicated the diagnosis of PBC, and treatment with ursodeoxycholic acid (16 mg/kg per day) achieved satisfactory results.

CONCLUSION

Some immune-mediated diseases may be promoted by operation due to microbial alterations in UC patients. Continuous follow-up is essential for UC patients with postoperative complications.

Key Words: Autoimmune enteropathy; Primary biliary cholangitis; Ulcerative colitis; Proctocolectomy; Bacterial translocation; Case report

Core Tip: This is the first case report of autoimmune enteropathy and primary biliary cholangitis complicated with ulcerative colitis, and the female patient in this case suffered from a tortuous process of diagnosis and treatment. It is speculated that a microbial shift and subsequent immune response are involved in the pathogenesis of these comorbidities, and surgery may facilitate the progression of coexisting diseases. Understanding the progression of these diseases may help with their early recognition and treatment.

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease (IBD) affecting the colon and rectum. Dysregulated immune responses to microbial changes and epithelial barrier defects are reported to contribute to the pathogenesis of UC. Small bowel involvement in UC is usually characterized by backwash ileitis or pouchitis[1]. Diffuse and severe enteritis occurring after colectomy for UC, which is referred to as postcolectomy enteritis, has been sporadically reported in the literature[2-5]. The pathogenesis and prognosis remain obscure. A case of postcolectomy enteritis previously reported by our team[3] recently presented recurrent large-volume watery diarrhea and typical pathological features of autoimmune enteropathy (AIE) along with high titers of antimitochondrial antibodies (AMAs) and increased cholestatic enzymes. The association of UC with primary sclerosing cholangitis (PSC) has been commonly reported[6], whereas UC with primary biliary cholangitis (PBC) has been rarely reported, and the underlying pathogenesis may be different. In this report, we present a rare case of progressive AIE and PBC after colectomy for UC and propose a hypothesis to explain the potential associations of these coexisting diseases.

CASE PRESENTATION

Chief complaints

A 54-year-old woman presented to the Emergency Department complaining of large-volume watery diarrhea.

History of present illness

The patient was diagnosed with moderate to severe extensive UC at the age of 49 in December 2014. Subtotal colectomy and ileostomy were performed in February 2015 due to steroid-resistant refractory disease. The UC diagnosis was pathologically

confirmed in resected specimens without ileitis. Her general condition improved greatly after ileostomy. A restorative proctectomy with ileal pouch-anal anastomosis and proximal neoileostomy was postponed until January 2016 due to active residual rectal inflammation. Within 3 mo after the neoileostomy, the patient noticed that watery stool from the stoma gradually increased up to 3-4 L per 24 h. She was admitted to our hospital for hypovolemic shock, electrolyte and acid-base disturbances, and acute kidney injury. Laboratory tests showed numerous leucocytes in liquid stool but negative pathogenic culture and *Clostridium difficile* toxin results. Her stoma output did not respond to empiric antibiotics but decreased significantly with IV hydrocortisone (50 mg q6h). Endoscopy showed a normal gross appearance of the stomach, duodenum, and prestomal ileum (Figure 1). Pathological examinations of the endoscopic biopsy from the duodenum and prestomal ileum revealed enteritis, which manifested as moderate villous atrophy, decreased goblet cells, cryptitis, and destroyed crypts, without clear apoptotic bodies or intraepithelial lymphocytosis (Figure 2). Postcolectomy enteritis was confirmed, and the decision to close the stoma was made by our multidisciplinary team to re-establish fecal stasis. Two months after stoma closure, her stool volume gradually decreased to less than 1 L/d, and azathioprine 50 mg/d was added as maintenance treatment during prednisone tapering. Follow-up endoscopy and biopsy histology in March 2018 revealed a normal mucosal appearance and the recovery of villous atrophy, cryptitis, and inflammation in the lamina propria. She made the decision to stop azathioprine in 2018 on her own. In November 2019, she presented with recurrent hypovolemic shock secondary to large-volume watery diarrhea under no obvious predisposing causes, which had been worsened to 2-3 L liquid stool every 24 h in the last month. She also mentioned poor appetite and a body weight loss of 8 kg within a month.

History of past illness

The patient had a past medical history of poliomyelitis.

Personal and family history

Unremarkable.

Physical examination

The patient was in serious weakness with cold limbs when admitted. Her vital signs were as follows: Temperature was 36.1 °C, heart rate was 109 bpm, respiratory rate was 20 breaths/min, blood pressure was 87/66 mmHg, and oxygen saturation in room air was 99%. The clinical physical examination revealed hyperactive bowel sounds 7-8 times/min, and no abdominal tenderness during palpation.

Laboratory examinations

Blood analysis revealed hemoglobin 181 g/L, platelets 274 × 10^9/L, white blood cells 11.63 × 10^9/L, neutrophils 68.7%, and lymphocytes 20.6%. Blood biochemical values were abnormal, with alanine aminotransferase (ALT) 22 U/L, total bilirubin 22.4 μmol/L, albumin 48 g/L, creatinine 206 μmol/L, urea 10.15 mmol/L, serum potassium 5.1 mmol/L, and serum sodium 128 mmol/L. Her arterial blood gas parameters were: pH 7.55, partial pressure CO_2 23 mmHg, partial pressure O_2 113 mmHg, bicarbonate 20.1 mmol/L, base excess 0.3 mmol/L, and lactic acid 3.1 mmol/L. Serum C-reactive protein was increased at 24.55 mg/L (normal range ≤ 8 mg/L) and erythrocyte sedimentation rate at 34 mm/h. Routine stool test showed 6-8 white blood cells per high power field and occult blood was noted. Stool pathogen screening was negative except for *Candida albicans* in stool culture.

Imaging examinations

No significantly abnormal signs were found on abdominal and pelvic computed tomography (CT). Endoscopy revealed an intact mucosa with diffuse villous atrophy in the duodenum, ileum, and ileal pouch (Figure 3). Histopathological findings of biopsies showed apoptotic bodies, a lack of goblet and Paneth cells, and villous blunting, which were not prominent in 2016 (Figure 4).

FINAL DIAGNOSIS

The principal clinical manifestation of AIE was refractory diarrhea with no response to dietary modification. Characteristic histological features included villous blunting or

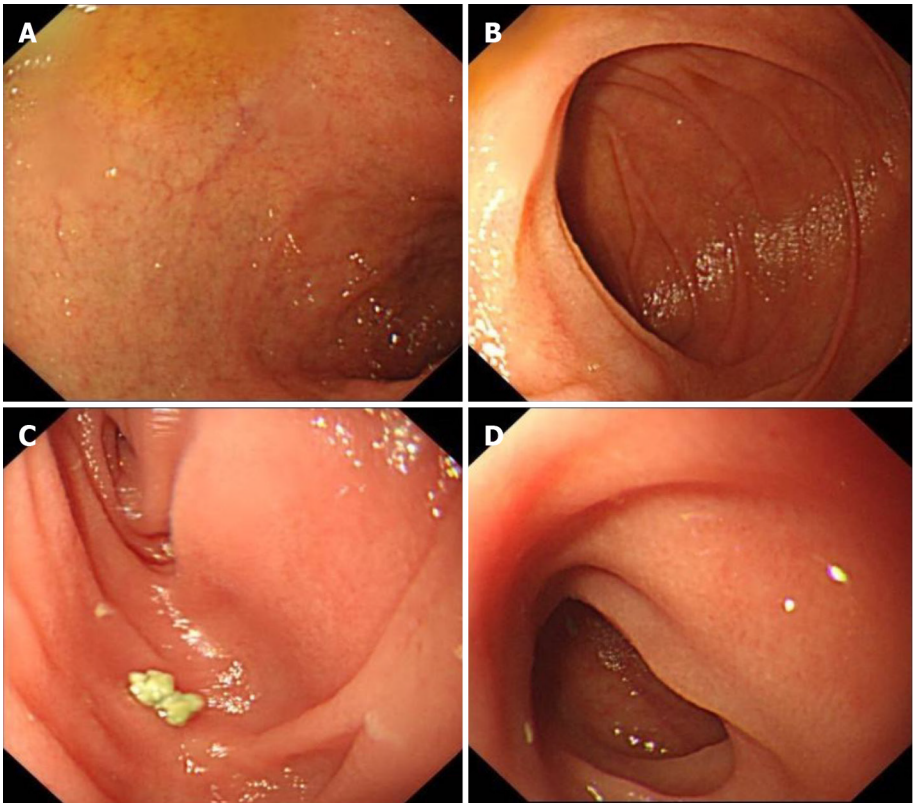

Figure 1 Endoscopic images at the onset of postcolectomy enteritis in 2016. A: Gastroscopy showing a normal duodenal bulb; B: Gastroscopy showing a normal descending duodenum; C and D: Endoscopy with loop ileostomy showing a normal appearance of the neoileum.

atrophy, apoptotic bodies, and lymphocytic infiltration in the crypt epithelium. The absence of goblet and Paneth cells also supported a diagnosis of AIE[7]. Given the typical clinical and histological features strongly supporting AIE and no evidence for other diseases causing villous atrophy and mucosal inflammation in this case, a diagnosis of AIE was established. As the sensitivity and specificity of AMA-M2 for PBC diagnosis are both 90%-95%[8], positive AMA-M2 made the diagnosis of PBC definitive. Despite having no signs of extrahepatic biliary obstruction on magnetic resonance cholangiopancreatography, small duct PSC could not be excluded completely due to a lack of histologic evidence. A previous case report showed the overlap of PBC and small duct PSC[9], indicating that typical onion-skin lesions in biliary ducts, with concentric fibrosis, can be seen in small duct PSC with MRI negativity. As a result, liver biopsy is needed to confirm the diagnosis of PBC, if possible.

TREATMENT

Supportive treatments with intravenous infusions, vasoactive drugs, and regulating electrolyte disturbances were performed timely to maintain the stable vital signs. Methylprednisolone 60 mg/d was given intravenously for 1 wk, and tacrolimus 3 mg/d (target blood concentration 3-10 ng/mL) was given to maintain the treatment response when steroids were tapered. As for PBC, ursodeoxycholic acid 16mg/kg per day was prescribed.

OUTCOME AND FOLLOW-UP

The patient's vital signs became stable under sufficient supportive treatments. After treatment with methylprednisolone 60 mg/d for 1 wk, her stool volume gradually decreased to less than 1.5 L/d. After taking tacrolimus for 4 d, the stool volume decreased to approximately 0.5 L/d and solid components could be seen in the liquid stool. The levels of ALT, aspartate aminotransferase, alkaline phosphatase, gamma-

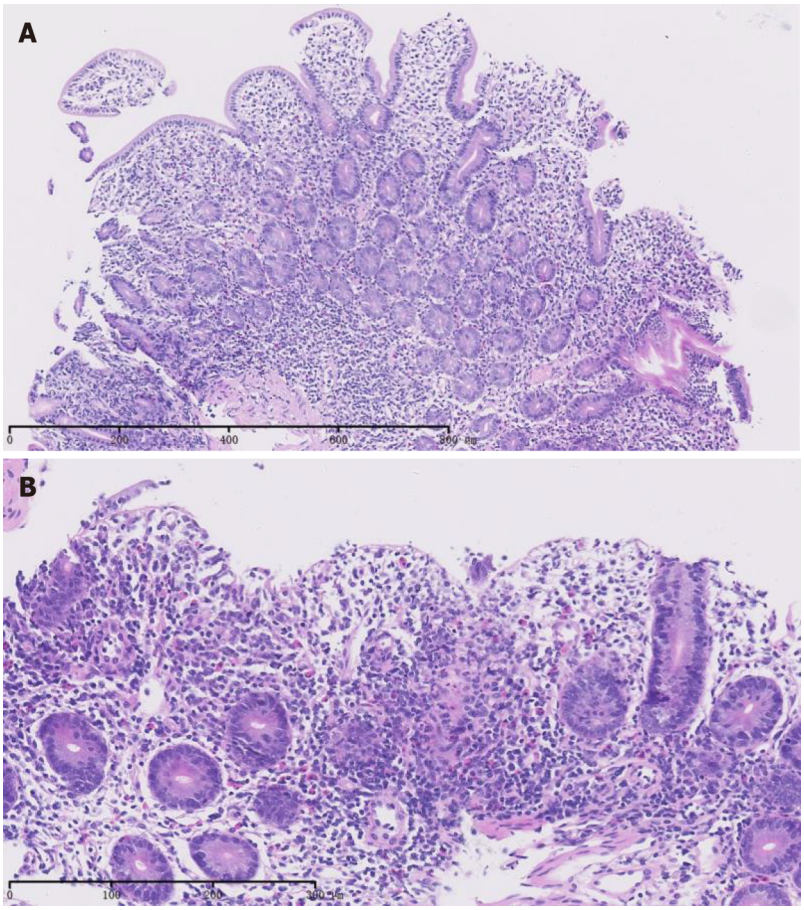

Figure 2 Pathological findings at the onset of postcolectomy enteritis in 2016. A: The biopsy from the duodenum showed chronic inflammation, moderate villous atrophy, and decreased goblet cells (× 40); B: Active inflammation, cryptitis, and destroyed crypts were observed in some areas (× 100).

glutamyl transferase, and serum total bilirubin decreased gradually compared with the peak levels (109 U/L to 67 U/L, 87 U/L to 30 U/L, 404 U/L to 87 U/L, 659 U/L to 137 U/L, and 161.8 μmol/L to 20.3 μmol/L, respectively).

DISCUSSION

We searched the PubMed and Embase databases for case reports published in English or with an English abstract before June 22, 2020, with the keywords "ulcerative colitis", "autoimmune enteropathy", and "primary biliary cholangitis" (or "primary biliary cirrhosis"). There is only one case of AIE in a UC patient[10] and 20 cases of PBC in UC patients[11-13]. Therefore, our patient is the first case of UC complicated with AIE and PBC after colectomy.

This patient presented similar watery diarrhea in 2019 as in 2016, and the pathological features of the small intestine progressed. The diagnosis of postcolectomy enteritis was based on clinical manifestations of diffuse, superficial mucosal inflammation of the small bowel after colectomy in a UC patient, and the underlying pathogenesis remains unknown. In this case, with recurrent enteritis, typical pathological features of AIE were noticed during relapse, and we speculate that this progression was mediated by the same pathogenic mechanisms. We review the 23 previous cases of postcolectomy enteritis in UC (from an English database, including two cases in Japanese with English abstracts)[2,3] and summarize the histological characteristics of small intestinal biopsies[2,4,5,14-25] (Table 1). A large proportion of these cases exhibited typical features of UC, with inflammatory infiltration of the lamina propria by lymphocytes, plasma cells, monocytes, or a few neutrophils found in 19 cases and cryptitis or crypt abscess in 9 cases. Typical features of AIE, including apoptotic bodies and decreased goblet cells (3 and 1 cases, respectively), were also reported in these patients[4,5]. Above all, we propose a hypothesis that these pathological features are present at different stages in a dysregulated immune

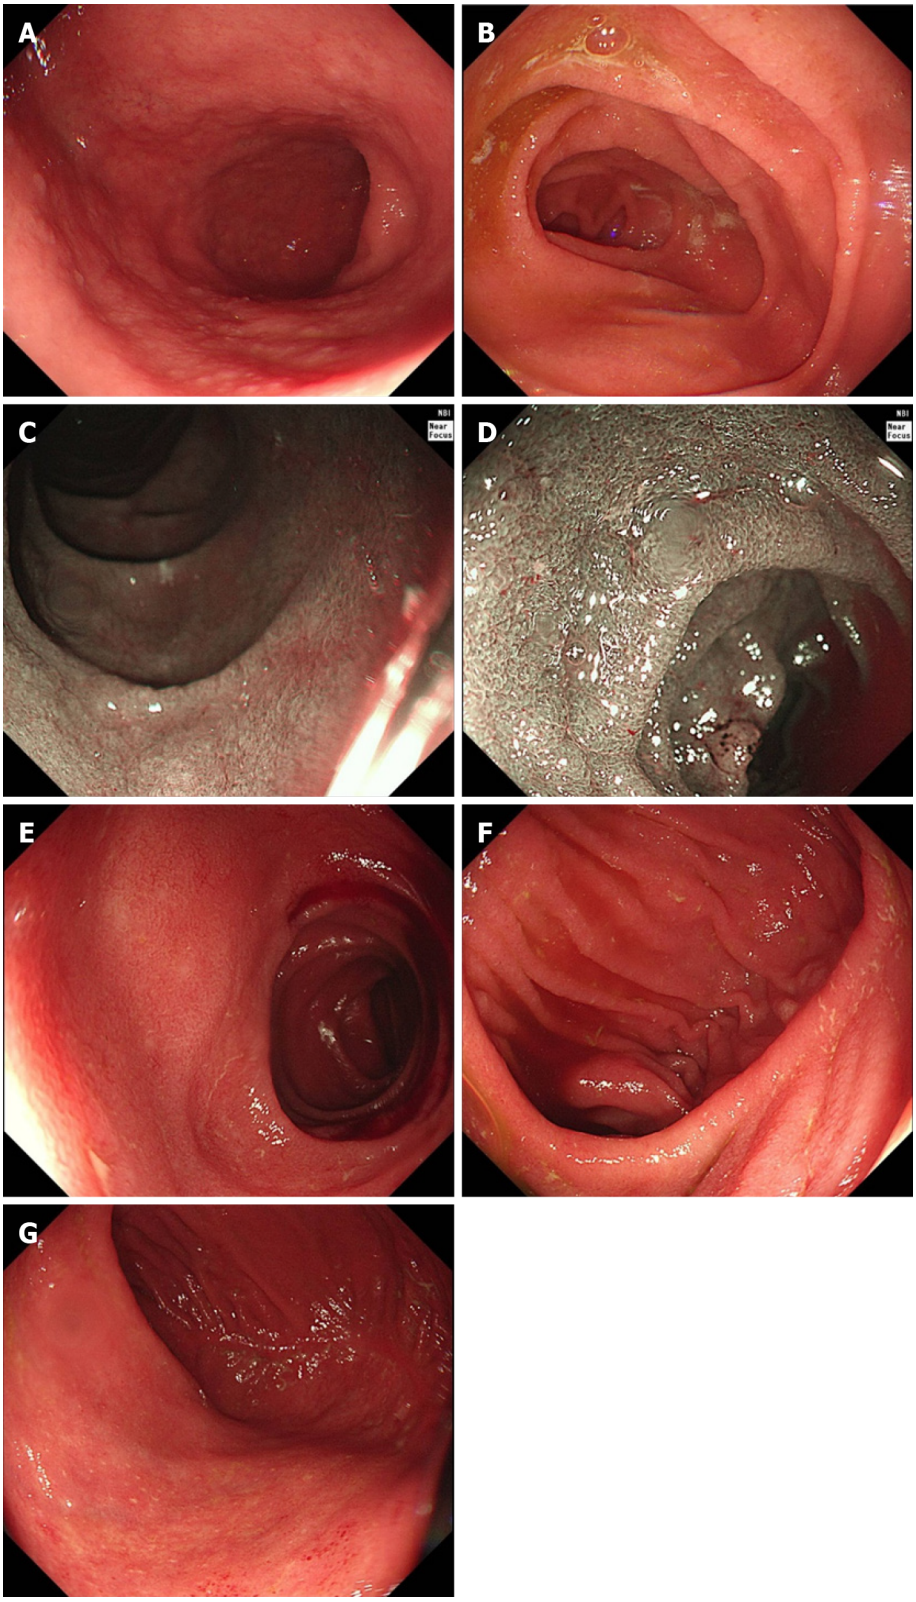

Figure 3 Endoscopic images at the onset of autoimmune enteropathy in 2019. A: Gastroscopy showing diffuse villous atrophy in the mucosa of the duodenal bulb; B and C: Gastroscopy showing diffuse villous atrophy in the mucosa of the descending duodenum; D and E: Enteroscopy showing diffuse villous atrophy in the mucosa of the ileum; F and G: Enteroscopy showing diffuse villous atrophy in the mucosa of the ileal pouch.

condition triggered by a microbial shift after colectomy. It is possible that three cases of postcolectomy enteritis with features of AIE (apoptotic bodies)[4,5] may progress to AIE during follow-up because these cases presented with severe clinical manifestations similar to our patient, with one of them even worse (dying of multiorgan failure).

Table 1 Summary of cases of postcolectomy enteritis from the English databases

Ref.	Age[1]/sex	Extent of UC	Onset of enteritis[2]	Extent of enteritis	Histological characteristics of biopsies
Corporaal *et al*[2]	23/M	Extended left sided	2 wk after colectomy	J, I	Marked apoptosis of epithelial cells, lamina propria with lymphoplasma cellular infiltrate with eosinophilic and neutrophilic granulocytes
Corporaal *et al*[2]	61/M	Pancolitis	1 mo after colectomy	S, D, J, I	Diffuse active chronic inflammatory infiltrate with (sub) total villous atrophy (D), an increase in the apoptosis of crypt epithelial cells (I), and dense active chronic inflammation (S)
Gooding *et al*[14]	52/M	Pancolitis	116 d after colectomy	D, I	Infiltration of the lamina propria by lymphocytes, plasma cells, and neutrophils; cryptitis and small numbers of neutrophils within the upper-crypt lamina and on the surface (D); shortening and irregularity of villi; mild, diffuse, chronic inflammatory cell infiltration; and mild activity with cryptitis (I)
Ikeuchi *et al* [15]	29/F	Left sided	6 yr after colectomy	S, D, I	Severe infiltration of inflammatory cells in the mucosa (I, S) and crypt abscess in the mucous glandules (S), dense, acute, and chronic inflammatory infiltrates accompanied with cryptitis (D)

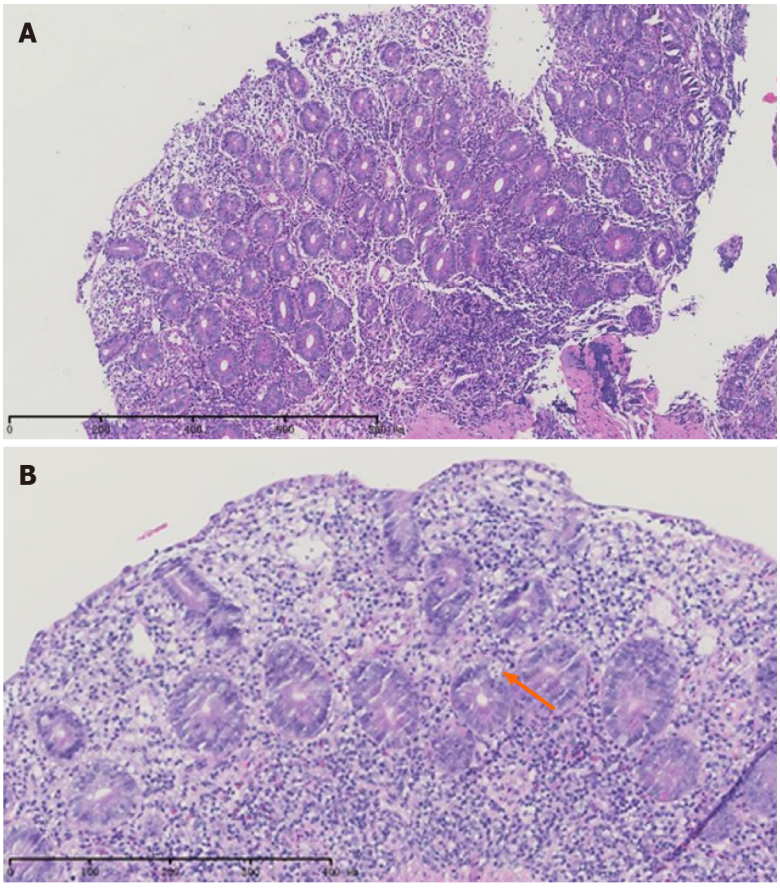

Figure 4 Pathological findings at the onset of autoimmune enteropathy in 2019. The biopsy showed prominent chronic inflammation, flat villi, and a lack of goblet and Paneth cells (A), and apoptosis bodies were found (arrow) (B).

The nature of the relationship between PBC and UC is unexplained. Immune-pathogenic mechanisms may be implicated in the pathogenesis of UC complicated with autoimmune hepatobiliary disorders[26]. Lymphocytic infiltration of portal tracts and the presence of circulating antibodies that react with bile ducts[7,27] suggest that the two diseases share common immunological pathways. Our patient initially suffered from refractory and progressive disease after colectomy in 2016, which suggests that surgery may be a potential factor that promotes disease progression. A widely accepted hypothesis regarding the pathogenesis of IBD indicates that the mucosal immune system exhibits an aberrant response towards luminal antigens, including commensal bacteria[28,29]. Meanwhile, some researchers have proposed that molecular mimicry may be a potential pathogenic mechanism underlying immune-mediated biliary damage. Antibodies that bind to the mitochondrial E2 subunit of the pyruvate dehydrogenase complex (PDC-E2) also cross-react with conserved bacterial proteins, including microbes found on mucosal surfaces and in the feces[26]. Such bacterial mimics of PDC-E2 were believed to trigger AMA-M2 formation in the early stage of PBC pathogenesis[29]. Another "leaky gut" hypothesis proposed to explain the disease process in PSC inspired us to investigate the pathogenesis of hepatobiliary disorders. The disruption of bowel permeability may lead to bacterial translocation and bile colonization and subsequently activate the inflammatory response and fibrosis in the liver by activating cholangiocytes[30]. A case report described a female patient with UC who developed PBC after proctocolectomy[31]. Whether the occurrence of AIE and PBC after proctocolectomy in this patient was accidental or predestined based on the genetic, microbial, and immune background is worthy of further investigation.

CONCLUSION

We have reported a patient with UC complicated with AIE and PBC and hypothesized the possible underlying pathogenesis. Although there is insufficient clear evidence of the mechanism, this case offers us a new explanation for the spectrum of immune-mediated diseases. Proctocolectomy may promote the progression of UC due to microbial alterations, leading to complications in other target organs. For UC patients with postoperative complications, continuous follow-up is essential for early recognition and comprehensive treatment.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Adam Cheifetz, MD, Professor of Medicine, Harvard Medical School, Director, Center for Inflammatory Bowel Disease, Medical Director, Infusion Services, Beth Israel Deaconess Medical Center, 330 Brookline Avenue, Boston, MA 022115, United States. aheifet@bidmc.harvard.edu

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. Abstract

Pancreatic cancer (PC) is often associated with a poor prognosis. Long-standing diabetes mellitus is considered as an important risk factor for its development. This risk can be modified by the use of certain antidiabetic medications. On the other hand, new-onset diabetes can signal towards an underlying PC in the elderly population. Recently, several attempts have been made to develop an effective clinical tool for PC screening using a combination of history of new-onset diabetes and several other clinical and biochemical markers. On the contrary, diabetes affects the survival after treatment for PC. We describe this intimate and complex two-way relationship of diabetes and PC in this review by exploring the underlying pathogenesis.

INTRODUCTION

Pancreatic cancer (PC) is one of the few malignancies associated with a dismal prognosis. Its incidence is on the rise and is one of the leading causes of cancer-related death worldwide[1]. Similarly, type 2 diabetes mellitus (T2DM) accounts for a significant morbidity and mortality owing to a global increase in its incidence. Its prevalence is predicted to reach up to 700 million by 2045[2]. Longstanding diabetes has been regarded as a modest risk factor for PC. On the other hand, new-onset diabetes mellitus (NOD), especially after the 5th decade of life is often observed as a harbinger of an underlying PC. There is also a simultaneous increase in obesity worldwide, which plays a key role in development of both T2DM and PC[3]. Thus, this surge in diabetes and obesity prevalence may eventually increase the risk of PC in a significant number of population in near future[4].

Diabetes and PC have a multifaceted relationship. There are different types of diabetes as per the American Diabetes Association but two types of diabetes, namely T2DM and type 3c diabetes, merit attention in relation to PC[5]. T2DM is a chronic non-communicable disease characterised by hyperglycaemia resulting from the defective insulin secretion due to progressive beta cell dysfunction in the face of ongoing insulin resistance (IR)[5]. The diabetes associated with different exocrine pancreatic disorders is known as type 3c diabetes. The duration of DM has an important relationship with development of PC. However, the time duration cut-offs to define different types of diabetes are arbitrary and are varied. The time duration taken to define NOD in the context of PC is between 2-3 years[6]. On the contrary, when the diabetes is present for more than 2-3 years before the diagnosis of PC, it is considered as a long-standing T2DM. However, differentiating between this two entities is very difficult in a given subject of PC, since many patients of T2DM have a long asymptomatic undiagnosed period[5].

T2DM can have an impact on the outcome of different treatment modalities of the PC. Moreover, different drugs used for treating T2DM can affect the risk of PC as well. Metformin has gained particular attention in this context. In the appropriate clinical context, a recent worsening glycaemic profile requiring insulin might point towards the development of PC in the elderly diabetes subjects. The main obstacle in the diagnosis of PC in DM is to identify the candidates to be screened as routine evaluation for PC is not recommended in them. Ongoing research in identifying the screening population based on clinical characteristics and biomarkers and developing different models based on the combination of such parameters continues. In this background, we aim to review the current literature for unfolding the complex but intricate relationship between diabetes and PC.

SEARCH STRATEGY

The PubMed search was carried out for relevant articles by three authors (AR, JS, PM). The references of the pertinent articles were also searched for additional appropriate studies. The keywords and combinations included in the search were: 'diabetes'; 'new onset diabetes'; 'pancreatic cancer-related diabetes'; 'pancreatic cancer' and 'diabetes'; 'new onset diabetes' and 'pancreatic cancer'; 'long term diabetes' and 'pancreatic cancer'; 'pancreatic ductal adenocarcinoma' and 'diabetes'; 'metformin' and 'pancreatic cancer' and 'diabetes'; 'Type 3c diabetes' and 'pancreatic cancer'. The

search was restricted to only English literature and predominantly focused on the recent evidence. The appropriate articles to be included in this review were selected by SK, DN and RK.

RISK OF PC IN LONG-STANDING DIABETES MELLITUS

The evidence of association between NOD and the PC is consistent (see below); however, the evidence for risk of development of pancreatic ductal adenocarcinoma (PDAC) in long-standing diabetes is mixed. PDAC is the most common form of PC. Moreover, the risk is cumulative and is in continuum with the fasting blood glucose levels and the risk consistently increases from normal glucose tolerance to prediabetes to diabetes[7].

The increased risk of PC in long-standing T2DM has been suggested across different population of the world, including Asians[8-10]. A recent report involving a large population (n = 112818 females and 46207 males respectively) over 30 years of cumulative exposure showed an increased risk of PDAC with long-standing diabetes over time (age-adjusted hazard ratio [HR] 2.16 [95%CI: 1.78-2.60])[11]. Another recently published meta-analysis also suggested an increased PC related mortality with T2DM (relative risk [RR] 1.67; [95%CI: 1.30-2.14])[12].

The summary of the evidence suggests that the reported RR for developing PDAC in long-term diabetes is modest and varies between 1.4-2.1[8,13]. The risk may persist even after adjustment for obesity and smoking, two important and independent risk factors for PDAC[14]. Additionally, PDAC risk is significantly more in NOD and although the risk reduces subsequently, it may remain significant as the duration of the diabetes gets longer as per few meta-analysis[13,15]. However, a 2015 summary review of the available meta-analysis questioned the robustness of diabetes and PDAC association[16]. Importantly, other population based studies did not find any association between long-standing diabetes and the development of PDAC[17,18]. Thus, the elevated risk of PC in long-standing T2DM is confounded by the factor that may originate from a common soil of obesity and IR. Further, the role of different anti-diabetic medications as a risk modifier cannot be ignored while assessing the risk.

The Mendelian randomization (MR) studies looking into causal association between long-standing diabetes and PC have yielded conflicting results. While some studies showed causal association, others did not[19,20]. A pooled analysis performed on MR studies including 8374 PC patients by Yuan *et al*[21], found an odds ratio (OR) of 1.08 (95%CI: 1.02-1.14; P = 0.009) for this association. Although this evidence suggests a modest increase in the risk of PDAC in long-standing T2DM, more studies are required to confirm this association in future.

RISK OF PC IN TYPE 3C DIABETES

Chronic pancreatitis is defined as the chronic progressive inflammation and fibrosis of the pancreas caused by various aetiology and finally results in both endocrine and exocrine pancreatic dysfunction[22]. Diabetes is found in 35%-50% of subjects with CP in the observational studies[23-25] and the prevalence of DM increases with the increasing duration of CP and may reach up to 90%[25]. This type of diabetes is known as type 3c diabetes. Diabetes is more common in patients with pancreatic calcifications, pancreatic exocrine insufficiency and those who underwent surgery[23,24]. In a meta-analysis including fifteen studies (8970 patients), the incidence of DM was 30% and the prevalence increased after 5 years of CP diagnosis[26]. Diabetes in CP is often difficult to manage as a significant proportion of subjects require insulin therapy[23]. Importantly, CP itself is a risk factor for the development of PC. Kirkegård *et al*[27] had shown the risk of PC in CP varies with the duration of the disease and the effect estimates were 16.16, 7.90 and 3.53 at 2, 5 and 9 years after the diagnosis of CP, respectively. Another important entity is fibro-calculous pancreatic diabetes (FCPD), also known as tropical calcific pancreatitis, a relatively common cause of type 3c diabetes in certain tropical countries. FCPD also carries a very high risk for the development of PDAC[28].

Thus, it is important to look for CP in a given patient of diabetes and a closer follow-up with appropriate imaging is needed for diagnosis of PC in suspected cases. Since CP patients are often malnourished, progressive weight loss or anorexia despite adequate glycaemic control should alert the clinician for the possibility of PDAC.

RISK OF PC IN NEW-ONSET DIABETES

NOD has been considered as an important metabolic marker for the development of PDAC within the first 2-3 years of its diagnosis. NOD serves as a harbinger of PDAC in patients more than 45-50 years of age and hence calls for a careful follow up[29-31]. An earlier study demonstrated a 0.85% chance of development of PC within 3 years of diagnosis of diabetes in persons aged 50 years or more[32]. This study also showed that the risk was almost 8 times higher in patients with NOD. In a large cohort of 2.3 million Israeli population, a very high risk for developing PC was observed both in women and men (HR of 15.24 and 13.88 respectively) during the first year after the diagnosis of diabetes[33]. Two meta-analyses[13,14] also showed a 5-7 times elevated risk of PDAC in NOD, particularly within first year of diagnosis. Such an association was confirmed in different ethnicities like African Americans, Latinos[34] and Asians [35].

Agarwal *et al*[36] reported a very high prevalence of DM (68 %) in patients with PC compared to age matched other cancers subjects or non-cancer controls. Similarly, the number of NOD within the preceding 36 mo was markedly higher in PC than the other two groups (40% *vs* 3.3% *vs* 5.7%). About 50%-74% of the PC related diabetes is of recent onset (< 2-3 years duration)[6,37]. The prevalence of dysglycaemia in PDAC was more when standard oral glucose tolerance test (OGTT) was used instead of fasting glucose levels for diagnosis (78% *vs* 45%)[36,38]. The abnormalities in glucose metabolism are frequently missed in PDAC. The importance of making a preoperative diagnosis of glucose abnormality needs to be emphasized in this setting as it is shown to influence the surgical policy in up to 15% of patients[39].

It was also observed that a significant proportion of NOD in patients with PDAC resolved after pancreatic resection[37]. This indicates that PDAC by itself is causally related to the development of NOD, which is an early and specific biomarker for PDAC rather than a mere consequence. Besides the NOD, a deterioration of the existing glycaemic control in the form of elevated glycated hemoglobin **(**HbA1c) has also been associated with the development of PDAC[38].

MECHANISM OF DEVELOPMENT OF PC IN LONG-STANDING T2DM

The potential mechanism responsible for the development of PDAC in long-standing diabetes is poorly understood (Figure 1). The proposed theories are: (1) IR and the resulting direct effect of hyperinsulinemia[40]. A very recent study performed in a large prospective cohort (> 0.5 million subjects with a median follow-up of 8.4 years) has shown that higher IR as assessed by homeostatic model assessment- IR (HOMA-IR) is an important and independent risk factor for PC related mortality even in patients without diabetes[41]; (2) Cancer promoting role of the IGFs[42]; (3) The potential role of hyperglycaemia itself to alter several biochemical pathways involved in the carcinogenesis; (4) The synergistic effect of obesity and inflammation ('the common soil hypothesis'); and finally (5) Genetic predisposition to both these conditions. Experimental evidence is emerging to explain the molecular mechanism linking T2DM and PDAC. They include the roles of cellular senescence promoted by both T2DM and obesity[43], advanced glycation end products and its receptor[44], metabolic reprogramming by hyperglycaemia[45] and the interplay between non-alcoholic fatty pancreas development in the milieu of obesity and diabetes[46].

MECHANISM OF DEVELOPMENT OF NOD IN PC

PDAC by itself induces a potential 'diabetogenic' state. PC-associated NOD is grouped under Type 3c diabetes, which also includes diabetes caused by CP[47]. The mechanisms linking PC and NOD are shown in Figure 2. The hypothesis that NOD is the result of destruction of the endocrine pancreas by PDAC is not a plausible explanation because NOD can be present even before PC becomes radiologically detectable[48] and has also been shown to improve after surgery[37]. Hence, it is essential to search for systemic mediators of NOD in PC; until now, only a few of them have been substantiated.

Role of insulin resistance

Initial pioneering studies have shown that PC-associated NOD causes marked impairment in insulin action[49-51], more profound in patients who had diabetes[50].

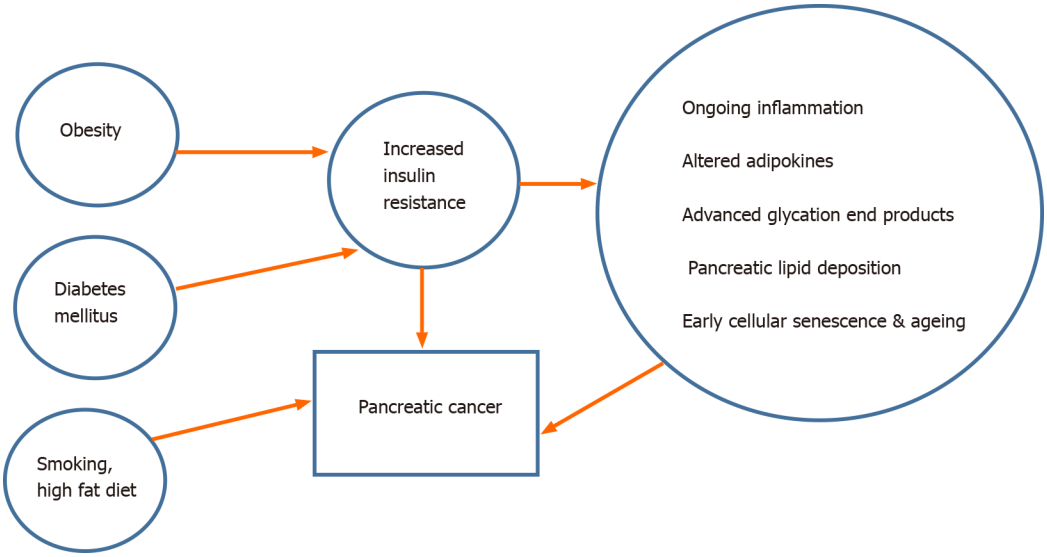

Figure 1 Schematic diagram depicting the interplay of various proposed factors leading to development of pancreatic cancer in long-standing diabetes mellitus.

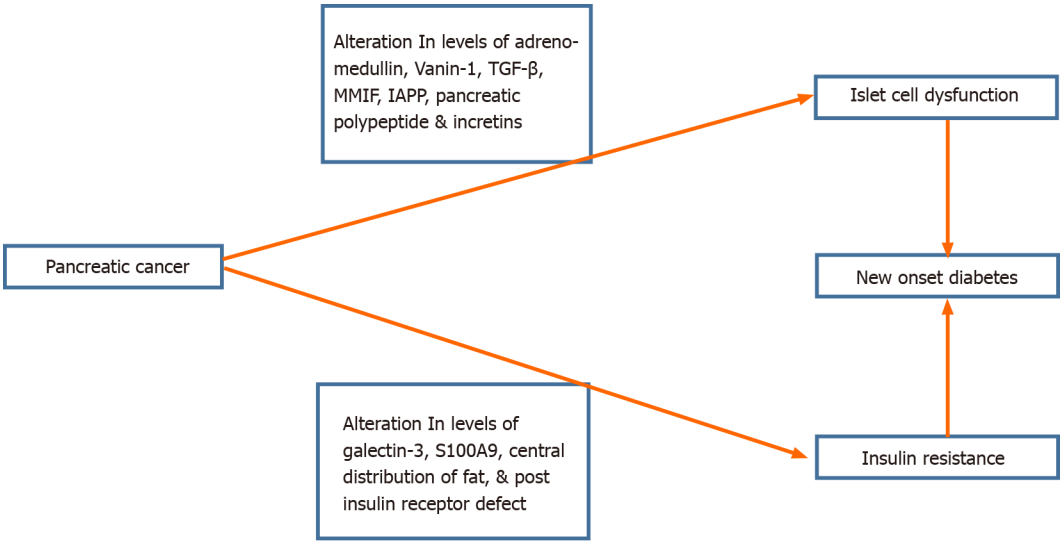

Figure 2 Schematic diagram for the possible mechanism for the pathogenesis of new-onset diabetes mellitus in pancreatic cancer. IAPP: Islet amyloid polypeptide; MMIF: Macrophage migratory inhibiting factor; TGF-β: Transforming growth factor-beta.

Insulin mediated glucose entry at the level of skeletal muscle was particularly found to be impaired significantly[52]. Interestingly, Permert *et al*[49] also demonstrated an improvement in whole body insulin sensitivity following surgery by using a hyperglycaemic clamp, which is considered to be the gold standard in evaluation of insulin sensitivity.

Thus, IR is an important determinant of the PDAC-related NOD, but the underlying mechanisms remain to be further studied. Currently available studies have suggested that IR may be related to the post-insulin receptor defect, particularly involving glycogen synthesis and storage pathways[53]. Recent experimental studies have found that PDAC-associated exosomes can inhibit the insulin receptor signalling pathway downstream of the receptor causing IR in skeletal muscle[54]. Another proteomic study revealed that galectin-3 and S100A9, which are overexpressed in PDAC-related NOD, can induce IR and can also serve as markers in distinguishing this entity from T2DM[55].

The role of islet amyloid polypeptide (IAPP) in the development of IR was initially suspected but later its clinical utility was not proven[56]. It was also suggested that PDAC-related NOD is due to the differential effect of ectopic fat as PDAC is characterized by subcutaneous fat loss and preservation of visceral fat[57]. However, a recent

study found that 30-18 mo before the diagnosis of PDAC, a significant proportion of patients had developed hyperglycaemia without any discernible change in the muscle or fat compartments[58,59].

Role of islet cell dysfunction

Pancreatic islet cell dysfunction is likely to be a crucial factor in the development of PDAC-related NOD. The morphology of the pancreatic islet in PC was recently characterized by Nagpal *et al*[60]. They demonstrated a significant reduction in islet density, beta and alpha cell area in PC compared to T2DM/control subjects. PC-related DM had lower IAPP deposition than T2DM. The lower IAPP deposit in PC related DM was also noted in an earlier study[61]. Future studies should explore the functional impact of such morphological changes.

Earlier studies have demonstrated a lower C-peptide response to glucagon stimulation suggestive of a beta cell secretory dysfunction in PDAC[62]. Beta cell function as assessed by HOMA-B was also found to be lower in PDAC patients with higher fasting glucose and diabetes[63]. In experimental studies, it was shown that beta cell in PDAC secrete increased amount of amylin preferentially while insulin secretion is diminished[64-66].

There is an experimental evidence for inhibition of insulin secretory function of the beta cell by adrenomedullin, which is released from PC-associated exosomes[67]. The role of adrenomedullin inhibiting beta cell insulin secretion in response to glucose was previously shown[68]. Moreover, adrenomedullin upregulation was noted in PC and its role in IR was also demonstrated[68]. Adrenomedullin was found to be a mediator for the increase in the exosome-induced lipolysis of the subcutaneous fat in PDAC [69]. The role of adrenomedullin as a screening biomarker is currently investigated in a prospective cohort study to identify patients with NOD and underlying PDAC[70].

Vanin-1 helps in hydrolysis of pantetheine and synthesis of vitamin B5 and cysteamine, which are required for lipid, energy and coenzyme A metabolism[71]. The role of vanin-1 is implicated in PDAC-induced paraneoplastic islet cell dysfunction, predominantly mediated by decreasing glutathione and elevating oxidative stress[72]. The same group earlier identified vanin-1 as a distinct marker of PDAC-related DM based on gene expression profile of the peripheral blood[73]. The role of transforming growth factor-beta (TGF-β) in the destruction of pancreatic beta cell had also been shown in animal studies[74,75] The macrophage migratory inhibiting factor was overexpressed in PDAC and was shown to decrease the beta cell secretory function [76].

A recent study has demonstrated that the markers of beta cell de-differentiations are consistently higher in non-diabetic PDAC patients suggesting the possible role of beta cell reprogramming in the early beta cell dysfunction even before the appearance of hyperglycaemia[77]. This dedifferentiation might be potentiated by the inflammatory milieu triggered by the PDAC.

Studies relating to alpha-cell function with PDAC-related DM are lacking. One study showed a higher glucagon/insulin ratio as a marker of NOD in PDAC[78]. Another small study revealed hyperglucagonemia in PDAC-related DM patients[79]. However, further studies are required to delineate the role of alpha cell dysfunction in PDAC-related diabetes.

Pancreatic polypeptide (PP) is released from the PP cells predominantly located in the head of the pancreas. PP cells have an important paracrine action including suppressive effect on glucagon secretion from alpha cell. Interestingly, one study had reported diminished PP response at 30 min following a mixed meal challenge in PC-related DM patients as compared to T2DM[80]. This was seen in tumours located in the ventral part of the pancreas. However, another study did not find any difference in fasting PP levels between PDAC-related DM, CP and T2DM[81]. Further studies should explore the role of PP in NOD and its use as an effective screening tool for PDAC.

Very few studies have evaluated the role of incretin hormones in the pathogenesis of PDAC-related DM. Interestingly, one study reported a lower gastric inhibitory polypeptide (GIP) and PP secretion in PDAC patients with diabetes as compared with T2DM patients, without any difference in glucagon-like peptide 1 (GLP-1) response [82]. Importantly, those with NOD or prediabetes with weight loss (> 2 kg) had significantly lower GIP. However, further studies are required to confirm this association. In-vitro studies had demonstrated that a lower GIP and GLP-1 response might be related to the inhibitory effect of the PDAC-exosomes on the proprotein convertase subtilisin/kexin type 1/3 enzyme which is responsible for cleaving the pro-glucagon molecule to generate the incretin peptides[83]. This study suggested the possibility of pancreatic exosome mediated dysfunction of the incretin hormones in

the gut.

EARLY DETECTION AND/OR SCREENING MODELS FOR PC IN DM

Clinical indicators

Till now, the recommendations regarding systemic screening of a person with diabetes to identify PDAC are not standardized. But, whom to screen and how to screen is not defined clearly by any guidelines till now to the best of our knowledge. So, it is necessary to develop a screening tool based on NOD and other risk factors. Since the yield of screening in such population is low, whether systematic screening is cost-effective and practically feasible remains an area of active debate.

The screening of patients with diabetes for PC is based on filtering of diabetes patients based on presence of associated clinical factors or level of biomarkers or a combination of such factors. NOD within 3 years of diagnosis increases the risk of PDAC 6-8 times more than the general population, but the prevalence of PDAC in such circumstances is low (0.8%-1%)[32].

It is a challenge to differentiate PC induced NOD from the more commonly encountered T2DM based on clinical and biochemical factors in clinical practice (Table 1). There are many overlaps between these two entities[84-86]. Munigala *et al* [87], identified age ≥ 65 years, heavy smoking, non-obese status at diagnosis, history of CP or gallstones as different risk factors of PC in a prospective cohort of NOD. One study reported a 40% higher risk of PC in patients with dyslipidaemia, although the association with specific lipid parameter was not mentioned[88].

Two other important factors that may provide a clinical clue for PC associated NOD are weight loss and worsening of hyperglycaemia. A continued weight loss in the presence of NOD was observed in a greater number of PC patients (59% *vs* 30%) than T2DM[89,90]. The amount of weight loss was also more in PC patients (8.3 ± 8.3 kg *vs* 0.8 ± 4.8 kg). Mueller *et al*[91] showed that weight loss of more than 10% had an adjusted OR of 3.58 (95%CI: 2.31-5.54) for development of PC. The presence of weight loss of more than 15% was not only associated with an increased odds of PC in NOD [91] but also in patients with long-standing diabetes[92]. Olson and colleagues showed that NOD and severe weight loss often occurred together before the diagnosis of PC [90]. Chen *et al*[11] observed that in a subject with NOD, when weight loss was unintentional or occurred in an individual with body mass index (BMI) less than 25 kg/m^2, then it substantially increased the risk of PC. Hence, weight change should be actively sought in elderly diabetes and warrant further investigation for PC.

Sah *et al*[58] reported worsening of hyperglycaemia, in the 18 to 6 mo before the diagnosis of PDAC. Similarly, rapid elevation of both blood glucose and HbA1c was observed by Huang *et al*[93] in the months preceding the detection of PC. The worsening of hyperglycaemia more often required the use of insulin treatment[90]. Thus, rapid deterioration of glycaemic control should alert a physician to screen for PDAC.

Another important feature is the loss of muscle mass, which is also known as sarcopenia. Sah *et al*[58] observed loss of subcutaneous adipose tissue even 6 mo before PDAC diagnosis. It was suggested that the preferential loss of subcutaneous adipose depot with relative preservation of the visceral adipose tissue might explain the IR and the worsening of glycaemic status[57]. However, a recent study did not find any difference in the prevalence of cachexia, skeletal muscle loss or weight loss between PC patients with or without DM[59]. Overall, sarcopenia suggests advanced disease and often portend poor survival, but its relationship with diabetes development need to be assessed in future studies[94].

Screening models

Interestingly, another upcoming approach is the development of a predictive model based on easily available clinical features in NOD. This model can identify NOD patients to be screened for PC and thus improve the detection rate while significantly decreasing the cost[30]. Sharma *et al*[95] came up with a model known as the Enriching New-Onset Diabetes for Pancreatic Cancer (END-PAC). This is a risk prediction model based on three different factors: change in weight, change in blood glucose, and age at the onset of DM. A score of 3 or more identified 78% of patients (n = 7/9) with 85% specificity. In the initial model, a score of more than 3 predicted a significantly increased risk of PDAC (4.4-fold) and a low END-PAC score of less than 0 had a very low risk of development of PDAC. This model was further assessed in a retrospective cohort of NOD patients (n = 13947) and 2% of high risk population (62 out of 3038)

Table 1 Factors that can help in differentiating pancreatic cancer associated new onset diabetes from type 2 diabetes mellitus

Clinical indicators	Biochemical markers
Age > 65 yr	Carbohydrate antigen 19-9
Heavy smoker	Galectin 3
Low body mass index	S100A9
History of chronic pancreatitis or gall stone disease	Insulin like growth factor-1
Recent worsening of hyperglycemia in an elderly patient	Osteoprotegerin
Weight loss associated with diabetes onset	Pancreatic polypeptide
Loss of subcutaneous fat and muscle mass in imaging studies like dual energy X-ray absorptiometry or magnetic resonance imaging	Thrombospondins- 1
	Vanin 1
	Matrix metalloproteinase-9
	MicroRNAs

were diagnosed with PDAC within 3 years yielding a sensitivity and specificity of 63% and 78% respectively at the score level of 3 or higher[96]. The positive predictive value (PPV) and negative predictive value were 2.0% and 99.7%, respectively. Another model was proposed by Boursi *et al*[97] based on The Health Improvement Network, which is a large primary care electronic research database from the United Kingdom. This prediction model included several easily available clinical parameters like age, BMI, change in BMI, presence or absence of smoking, use of proton pump inhibitors and other anti-diabetic medication including metformin. The laboratory parameters include levels of hemoglobin, creatinine, and alkaline phosphatase, HbA1c and cholesterol. The area under the curve (AUC) for the final model was 0.82 (95%CI: 0.75–0.89) and at a risk threshold of 1% for screening for PDAC, around 6% of patient with NOD would have to undergo systemic screening. The sensitivity, specificity and PPV at this level were 44.7%, 94.0% and 2.6%, respectively. Thus, though these model systems are encouraging and can narrow down on the screening population, they are limited by poor sensitivity and lower PPV[30] and further improvement is required before routine clinical use. Recently, a protocol of a multicentric, prospective observational study (NODES Trial) has been published, which intends to follow up new-onset (≤ 6 mo) diabetes patients over 60 years of age with both clinical and valid biomarkers [98]. The study also aims to evaluate for biomarkers that can distinguish patients with PDAC more precisely. Such studies will be invaluable in understanding and defining a screening protocol in NOD patients to identify PDAC as early as possible.

BIOMARKERS IN THE SCREENING OF PC IN DM

The role of different biomarkers in assisting the early diagnosis of PC among DM patients is crucial. A plethora of studies on different biomarkers have been published in the literature, though till now, none of them have reached the routine clinical use. The search for an easy-to-use clinically useful and cost-effective marker is still ongoing. Finding of suitable biomarkers is a difficult task in a relatively uncommon disease like PC and moreover, presence of diabetes can confound the measurements of different biomarkers in such setting[30]. A detailed discussion on this topic is out of the purview of this article, but a brief description on the latest biomarkers are discussed here. The proposed biomarkers are either measured in the blood or tissue fluids and they are the result of the 'multi-omics' studies involving proteomics, genomics and metabolomics.

Hormones involved in glucose homeostasis

The biomarkers, which draws our attention first is the biomarkers related to the glucose metabolism. Sharma *et al*[99] have shown that rising fasting plasma glucose itself predates the development of PDAC (36-60 mo before PDAC diagnosis) and is often related to the size of the tumour. Though fasting blood glucose levels increased concordantly with the volume of the tumour, no such relationship with the tumour gradation was reported. Another study reported a higher serum glucagon/insulin

ratio with a cut-off of 7.4 ng/mIU could differentiate PC induced NOD from T2DM with 77% sensitivity and 69% specificity[78]. A study demonstrated a higher glucose stimulated glucagon in PC patients with DM, suggesting glucagon as a potential biomarker[79].

Incretins involved in glucose homeostasis

The role of different gut polypeptides involved in the glucose homeostasis was also studied in PDAC patients. It was found that a significantly lower plasma concentrations of GIP and PP in patients with PC irrespective of the degree of glucose intolerance as compared to the T2DM and normal healthy controls[82]. A diminished PP response to a mixed meal was also observed earlier in PDAC associated diabetes in a small study[80]. However, another study could not find a difference in fasting PP levels between PDAC patients with or without diabetes and T2DM[81]. Thus the blunted PP response in PDAC can serve as an important tool for screening for PDAC, but the time-line is not well established and studies with a larger sample size may further consolidate PP as an important biomarker.

Carbohydrate antigen 19-9

A study by Choe *et al*[100] has shown that in asymptomatic NOD patients, a higher carbohydrate antigen 19-9 (CA19-9) levels above the upper normal limit had a 5.5 times risk of developing PC within 2 years of diagnosis. Another retrospective analysis showed similar results and found that the odds for development of PC in NOD patients with elevated CA19-9 was consistently higher, particularly in patients with elevated bilirubin levels[101]. Murakami *et al*[102] proposed that a cut-off of serum CA19-9 level of 75 U/mL can discriminate between patients with diabetes with or without PC. At this cut off, the sensitivity and specificity of CA19-9 for PC was 69.5% and 98.2%, respectively, while the AUC was 0.875 (95%CI: 0.826-0.924). A combination of elevated CA19-9 and carcinoembryonic antigen was also shown to detect PC among DM patients[103]. However, it is important to note that the utility of CA19-9 may be limited by the fact that it is affected by the levels of glycemia. CA19-9 levels must be interpreted in the context of ongoing glycaemic control and patients with diabetes per se may have elevated CA19-9[104].Thus there is a need to optimize the CA19-9 cut off level in DM patients for PC detection.

Thrombospondin -1

Another promising biomarker is thrombospondin-1 (TSP-1), a multimeric protein with anti-angiogenic properties. TSP-1 levels were found to be lower in PDAC patients, particularly those with diabetes as compared to non-diabetes and this lower levels were detected even 24 mo before the diagnosis of PDAC[105]. According to this study, TSP-1 levels in combination with CA19-9 yielded an AUC 0.86 in the detection of PDAC. Importantly, a lower TSP-1 levels were also noted in PDAC associated diabetes but not in the long-standing T2DM.

Vanin-1 and matrix metalloproteinase 9

Vanin-1, a protein involved in the oxidative stress pathway was found to be associated with paraneoplastic islet cell dysfunction (see earlier) and can serve as a potential biomarker in detecting PC among DM patients. Huang *et al*[73] have shown that the levels of *Vanin-1* genes were significantly upregulated in PDAC and an elevated levels of both vanin-1 and matrix metalloproteinase 9 (MMP9) in serum using quantitative real-time polymerase chain reaction could differentiate PDAC associated diabetes from T2DM. The AUC for the combination of both Vanin-1 and MMP9 was 0.950 with a sensitivity of 95% but the specificity of 76%. A combination of CA19-9 and MMP9 was also found to be helpful in discriminating PDAC-related diabetes from T2DM with an AUC of 0.886[106].

Galectin-3 and S100A9

Galectin-3 is a β-galactoside–binding lectin involved in the proliferation, migration and invasion of PC cells[107] whereas S100A9 protein is involved in the inflammation through toll-like receptor-4[108]. Liao *et al*[55] have shown that levels of both galectin-3 and S100A9 were higher in PDAC related DM than T2DM. They also found that the serum levels of both galectin-3 and S100A9 proteins can differentiate between PDAC related DM and T2DM with the AUC of 0.83 (95%CI: 0.74–0.92) and 0.77 (95%CI: 0.67–0.87) respectively.

MicroRNAs

Alteration in the profile of serum microRNAs (miRNAs) have been postulated as important biomarkers in recent times. One study reported that a panel of six miRNAs (miR-483-5p, miR-19a, miR-29a, miR-20a, miR-24, miR-25) could differentiate between PDAC related DM and T2DM[109]. The AUC for the differentiation of these two entities was 0.885 (95%CI: 0.784-0.986). However, the micro RNA profiles (miR-192, miR-196, miR-200, miR-21, miR-30 and miR-423) were found to be similar in PC patients with or without DM in a study by Skrha *et al*[110]. This list of miRNAs will be increasing in the future but the potential ones should come out from the prospective follow-up studies of the NOD patients.

Metabolomics

Studies have used extensive metabolomics approach either through liquid or gas chromatography and mass spectrometry or nuclear magnetic resonance imaging technique to identify various metabolites in order to identify specific biomarkers that can differentiate between PDAC-related DM and T2DM. One study revealed a distinct signature of 62 different serum metabolomes in PC related DM as compared to T2DM [111]. Out of them, two metabolites namely N-Succinyl-L-diaminopimelic-acid and PE (18: 2) had shown good sensitivity (93.3%) and specificity (93.1%) for PC in the logistic regression analysis. A recent nuclear magnetic resonance based study also identified a panel of eight metabolites with good accuracy (more than 80%) in the discrimination of PC and long-standing T2DM patients[112]. In future, possibly a panel of metabolites will help us to improve the precision medicine in identifying the cases requiring close follow-up for detection of PC among diabetes patients.

Other new biomarkers

There have been several other biomarkers proposed for the differentiation of the PDAC associated diabetes from T2DM. A very recent analysis of several immune related proteins including cytokines, chemokines and adhesion molecules revealed that a panel of different molecules (GM-CSF, IL-31, RANTES, RESISTIN, FASL, & ICAM1) were different between PDAC related DM and T2DM with an AUC of 0.96 (0.93–1.00)[113]. This study paved a new way in the screening of PC in diabetes patients. The other tools that can be used to screen PC are plasma free amino acid index[114], combination of either neutrophil-to-lymphocyte ratio or platelet-to-lymphocyte ratio and CA19-9[115], angiopoietin-like protein 2[116] among others with reported variable AUC.

In summary, although a great numbers of promising biomarkers have been studied to detect PC early in diabetes patients, a very few have reached routine clinical use as of now. As more translational research is emerging, the main requirement of a panel of clinically useful biomarkers for early detection of PC in DM will be fulfilled in near future.

DIABETES AND THE TREATMENT OUTCOMES OF PC

Diabetes has an important role to play as a prognostic marker in PC patients. Pancreatectomy is the initial management strategy in PDAC. Currently, the evidence that diabetes may portend an unfavourable impact on the overall outcome of PC, particularly after surgery is not concrete[117]. Whether the treatment of the diabetes modifies this risk is also not clear at present. Hank *et al*[118] showed that diabetes subjects had a poor median overall survival (18 *vs* 34 mo; $P < 0.001$). Moreover, diabetes was associated with higher 30-d mortality (3.2% *vs* 0.8%; $P = 0.019$). Importantly, a larger tumour size, a greater number of lymph node involvement and more peri-neural invasion were seen in diabetes patients with PC. A negative association of diabetes with overall survival was also noted in a meta-analysis[119]. However there are studies which do not agree on such association[120,121], and rather showed paradoxical reduction in the risk of death[122]. A 2013 review showed that diabetes patients had a higher risk of post-operative complications (45% *vs* 35%)[123]. Baseline HbA1c more that 6.5%-7.0% was also found to be associated with a shorter survival[124,125].

Long-standing DM vs new onset DM

Although studies have shown a poor outcome in all diabetes patients, the relative role of duration of diabetes on PC outcome needs further clarification. Very few studies

have shown the stratified analysis based on diabetes duration. Long-standing diabetes was found to have an association with diminished survival in prospective studies [126]. This was also confirmed in a meta-analysis[127] involving 18 studies (16181 patients). Several other studies[117,128,129] did not find any significant effect of long-standing diabetes on the survival in PC. Jeon *et al*[117] reported impact of long-term diabetes on decreased survival in those with resectable PDAC (HR, 1.42; 95%CI: 1.13–1.78) but not in advanced disease suggesting a role of staging in the outcome. It is important to note that the association of diabetes with prognosis became non-significant in most of the studies, after adjusting confounders like age, gender, BMI, smoking status and staging of the disease[128]. The evidence that diabetes patients can have a relatively larger pancreatic tumour size is well established[118,121,130,131].

On the other hand, the evidence is more consistent for a poorer outcome associated with NOD. A 2017 meta-analysis showed that only NOD was associated with shorter survival but not long-standing DM[119]. Similarly, other studies found that only NOD was a significantly independent predictor of decreased survival[129,132]. Importantly, Lee *et al*[133] have shown that NOD carries a higher risk of recurrence after pancreatic resection and may be a factor responsible for the poorer outcome. In contrast Jeon *et al* [117] did not find any impact of NOD on survival. Another point to consider is that whether post-surgery improvement of NOD has any impact on outcome. Though a study reported increased survival in patients where diabetes was resolved following surgery[134], future studies should substantiate this finding.

Impact of DM on the outcome after chemotherapy

Studies assessing the impact of diabetes in PC patients receiving chemotherapy have shown that, a prior diabetes status might be associated with a higher risk of death. Kleef *et al*[130] demonstrated a higher mortality rate in diabetes patients receiving adjuvant chemotherapy [HR 1.19 (95%CI: 1.01-1.40)]. Similarly, Hank *et al*[118] showed that median overall survival was lower in diabetes patients who received neo-adjuvant chemotherapy as compared to non-DM patients (18 mo *vs* 54 mo; $P < 0.001$). Another study showed diabetes to further add to the poorer outcome in metastatic disease treated with gemcitabine[135]. A meta-analysis looking at the impact of diabetes on the outcome following chemotherapy in PC (1034 with DM and 3207 without DM) demonstrated a lower survival and higher risk of death after chemotherapy in DM patients[136]. A high preoperative HbA1c was also found to be associated with non-completion of adjuvant chemotherapy and a higher risk of metastasis[137]. Diabetes also affects the survival in very advanced PC patients receiving palliative chemotherapy[138].

The mechanism behind the poorer outcome in PC with diabetes is not certain. Diabetes is associated with larger tumour size and hence a higher tumour stage. Hyperglycaemia has been shown to hasten the tumour development *via* sterol regulatory element binding protein 1 pathway[139]. There is also suggestion for an alteration in the tumour microenvironment in the presence of an elevated blood glucose level. Indeed, experimental studies have shown that hyperglycaemia increases the metastatic ability of the PC through aggravated hypoxia[140] or by increasing the perineural invasion[141]. The role of glycaemic variability is also suggested as a risk factor for promoting local invasion and metastasis *via* the retinoic acid receptor beta-runt related transcription factor 3-type VI collagen alpha 1 chain pathway[142].

EFFECT OF PC TREATMENT ON DIABETES

There is a complex relationship existing between patients undergoing surgery for PC and their glycaemic status. Glycaemic control is expected to worsen following pancreatectomy considering a significant loss of beta cells. However this is not often observed in clinical practice, particularly in patients with NOD after surgery. Studies[143-146] have either shown a significant improvement in their glycaemic control (75%) or resolution of NOD (20%-65%) after pancreatic surgery. It has also been reported that resolution of preoperative NOD after pancreatectomy may be a sign of a favourable outcome[134]. NOD has also been described in 15%-20% of patients[143,145,146] after surgery. One study reported deterioration of the glycaemic control in up to 40% post-operatively[147],when formal tests like OGTT and *i.v.* glucagon stimulation test were used. In the meta-analysis by Beger *et al*[148], cumulative incidence of NOD was found to be 15.5% after pancreatico-duodenectomy for malignant pancreatic tumours. Hence, it is necessary to assess the glycaemic status after pancreatico-duodenectomy even in those with pre-operative normoglycemia to achieve a better metabolic control after the

surgery.

ANTI-DIABETIC MEDICATIONS AND PC

Since diabetic patients will be receiving several medications for controlling hyperglycaemia, it is important to consider their effects in the context of PC. There are many excellent reviews[149] already available in this regard and we highlight salient points based on the recent available evidence.

Metformin

Metformin has garnered a lot of interest in recent times due to its anti-cancer effect and PC is not an exception. Metformin is the first line drug of choice for treating T2DM. A plethora of studies have looked into the three key aspects of metformin and their role in PC. They are: (1) Metformin as a risk modifier of PC development in T2DM[150-152]; (2) Effect of metformin on the overall survival following therapy[153]; and (3) Metformin as an adjuvant therapy in diagnosed PC[154].

Studies regarding metformin treatment as a risk modifier of PC have yielded mixed results. While some studies have shown risk reduction of PC in metformin users[155], other studies did not find such a beneficial impact of metformin in PC risk reduction [156,157] and even reported an increased association risk in metformin users[151]. Though earlier pooled analysis[150] had shown a decreased risk of PC, the studies included in those analysis were mostly retrospective and met with the significant lead time bias. Another complicating issue regarding the risk estimation is that the long duration of diabetes already present is itself a potential risk for PC and the NOD heralding the onset of PC often complicates the scenario further. Therefore, recent studies with better statistical designs are warranted to establish the role of metformin in PC prevention in a concrete manner.

Animal studies have shown that metformin decreases the PC cell proliferation[158, 159], its invasiveness[160] and thereby reduces the metastatic potential of PDAC[161]. Studies have also shown that metformin has a sensitization effect on chemotherapy, particularly gemcitabine[161,162]. The inhibition of TGF-β pathway is one of the several underlying mechanisms proposed to explain these effects[75,160]. Considering this finding, metformin might be expected to have beneficial result in PC. However, the clinical studies performed to assess the benefits of metformin have shown conflicting results. While few studies have suggested the survival benefit of metformin in PC patients[163-165], two phase 2 randomized controlled trials (RCTs)[166,167], observational studies[168,169] and other meta-analysis[170] refuted such finding.

The benefits of metformin observed in some earlier studies may be attributed to the immortal time bias that is inherent to meta-analysis studies[171]. Indeed, a meta-analysis taking into the account of immortal time bias did not show any additional survival benefit of metformin in DM patients with PC[170]. According to this meta-analysis, the effect size of reduction in the risk of survival was exaggerated by 18%. Again, the null effect of metformin on survival shown by the two RCTs was also flawed by the fact that metformin treatment was started late in the disease course and metastasis has already happened, leaving a small room to assess for the effect of metformin on survival outcome[166,167]. For this reason, it is important to focus on this area with well-designed RCTs in an earlier stage, including both DM and non-DM population. Further evidence is required to recommend treatment with metformin in PDAC patients with concurrent DM. Mild hyperglycaemia with obesity in early stage PC patients may be an ideal indication to start metformin. In summary, the risk reduction of PC and the overall survival following metformin therapy are not observed in recent well designed studies with improved statistical analysis taking into consideration of immortal time bias. Future phase 3 RCTs will be helpful in this context, mainly in selected PC candidates[172].

Insulin and insulin secretagogue

Insulin has a definite role in the pathogenesis of PDAC as hyperinsulinemia and IR are important risk factors for the development of PDAC (see above). Whether clinical use of insulin has any impact on PDAC development is a contentious issue. Long-term insulin use was not found to be a risk factor of PDAC development[173]. On the other hand, short-term insulin user (< 3-5 years) was found to have an elevated risk of PDAC (OR 5.60, 95%CI: 3.75-8.35)[173]. Perhaps this data reflects the other way around. It is likely that the worsening of hyperglycaemia or the severe hyperglycaemia requiring insulin injection might reflect the onset of PDAC or effect of PDAC on the

glycaemic control. Whereas few meta-analysis have suggested an elevated risk of PC in insulin users[174] the same evidence was not found in other studies[175] and also with newer insulin like glargine insulin[176]. In terms of survival benefit, insulin use had no impact on survival as shown in recent studies[120,177].

Insulin secretagogues like the sulfonylureas (SU) are also implicated as a risk modifier of PC. There are only few studies that have specifically looked into the link between SU and PC. However, studies including nation-wide cohorts[178], and meta-analyses[175] had pointed that SU use is associated an elevated risk of PC (OR varies between 1.5-1.7). However, with newer generation SU data is sparse and this association is further complicated by the effect of concurrent obesity and IR on the development of PC. Moreover, earlier analyses are met with significant methodological flaws and heterogeneity among studies[179].

Incretin based therapies: DPP-4 inhibitors and GLP-1 receptor agonist

Incretins are hormones secreted from the intestine and have a significant impact on the glycaemic control. GLP-1 analogues and inhibitors of dipeptidyl peptidase-4 (DPP-4) enzyme are established therapies for T2DM in clinical practice. Although there was a concern of acute pancreatitis and PC associated with their use from the initial preclinical[180] and adverse database review[181] studies, data regarding the risk for PC was inconsistent. Hence, both United States Food and Drug Administration and European Medicines Agency advised on continuous follow-up of patients started on these therapies for these two adverse events[182].

Earlier meta-analysis also did not find an increased risk of PC with DPP-4i treatment group[183]. Moreover, the recent meta-analysis involving 157 trials reporting PC (66897 patients in DPP-4 inhibitors and 61597 patients in control group) showed no associated risk with DPP-4 inhibitors use (OR: 0.84 [95%CI: 0.69-1.03], I^2 [for heterogeneity] = 0%). This association was found across different types of DPP-4i molecules and thus possibly reflects a class effect. Data from large population based studies also showed similar reassuring findings[184]. Due to several limitations of the trials like a shorter follow-up, reporting bias, small number of PC cases, it is important to keep a watch over this association in future. Moreover, one meta-analysis of the large cardiovascular outcome trials on DPP-4i showed an 75% increased risk of pancreatitis[185]. Such findings warrant longer duration follow-up studies and continued vigilance. A study[186] has shown that DPP-4i may be associated with increased risk of pancreatitis and PC in short-term without any relationship with exposure duration, thus implying that it might be the result of reverse causality rather than the DPP-4i exposure itself.

Similarly, more data are now available for different GLP-1 analogues. The larger cardiovascular outcome trials did not find any elevated risk of PC in GLP-1 analogue users[187,188]. Consequently, an updated pooled analyses from the cardiovascular outcome trials also did not show an excess risk of PC or pancreatitis with use of GLP-1 analogues[185]. However, it is noteworthy that such trials are not primarily meant to detect any increased malignancy risk. Thus, although the data is reassuring, a continued vigilance is warranted.

Other drugs (thiazolidinediones and sodium-glucose co-transporter type 2 inhibitors)

The other antidiabetic drugs are thiazolidinediones (TZD) and sodium-glucose co-transporter type 2 (SGLT-2) inhibitors. TZDs like pioglitazone and rosiglitazone primarily act through activation of the peroxisome proliferator-activated receptor-gamma pathway. This activation has direct and indirect implications in the PC biology. TZDs have shown to have inhibiting effect on several aspects of PC including cell proliferation and metastasis[189-191]. It also has the potential to modify the risk of PC through insulin sensitization, modification of the obesity and the inflammation [192]. However, these promising experimental findings of benefits of TZD have been replicated in clinical studies with mixed results.

While two meta-analyses did not find any association between TZD use and the risk of PC[175,193], one population based study had shown a protective role of TZDs against PC[178]. On the other hand, Lewis *et al*[194] demonstrated that TZD use might be associated with an increased risk of PC. As far as the prognostic role is considered, TZDs did not have any effect on survival[195,196].

SGLT2-inhibitors are the newest class of oral antidiabetic medication and have already made its place in the therapeutic algorithm of diabetes, owing to its cardiovascular benefits. Functional SGLT-2 are detectable in PC cells and hence, it was hypothesized that SGLT-2 inhibitors can inhibit tumour growth by blocking the entry

of the glucose within the cell[197]. An experimental study has shown canagliflozin, a SGLT-2 inhibitor to inhibit PC growth[198]. However, clinical studies are yet to confirm its effect on PDAC survival.

CONCLUSION

In this review, we have summarized the intricate relationship between DM and PC. Long-standing diabetes is considered as a risk factor for development of PC. On the other side, NOD in an elderly patient can be a manifestation of underlying PC. Though the exact mechanism remains to be eluded in future studies, the mechanism of the development of NOD in PC involves both IR and islet cell dysfunction. Diabetes has also been suggested to have an unfavourable effect on the overall survival of patients with PC.

Early detection of PC in a patient with DM is of utmost important and is a clinically challenging task. PC has a low prevalence in both general population and diabetes subjects. Thus, devising a strategy to screen diabetes population for PC is the need of the hour. There is an urgent need for a clinically useful and cost-effective screening tool to detect PC among patients with long-standing diabetes. The epiphenomenon of NOD can subserve as a potential clue along with recent onset worsening of glycaemic control and a continued weight loss. Apart from clinical pointers, many biomarkers have also been found to differentiate PC related DM from the commoner T2DM. Moreover, different clinical and biochemical parameters have been combined to develop different screening tools. Proper screening and early recognition of PC can improve the outcome of this devastating neoplasm.

Can we delay the occurrence or halt the progression of PC in a patient of DM? The strategies to improve IR like regular physical exercises, intermittent fasting, or low-fat diet can be explored in future. Moreover, other healthy behaviours like smoking cessation should be implemented in patients with long-standing DM. The role of glucose lowering medications like metformin in delaying the occurrence of PC needs to be explored further in longitudinal studies.

Abstract

Pancreatic cancer is a dismal disease with high incidence and poor survival rates. With the aim to improve overall survival of pancreatic cancer patients, new therapeutic approaches are urgently needed. Protein kinases are key regulatory players in basically all stages of development, maintaining physiologic functions but also being involved in pathogenic processes. c-Jun N-terminal kinases (JNK) and p38 kinases, representatives of the mitogen-activated protein kinases, as well as the casein kinase 1 (CK1) family of protein kinases are important mediators of adequate response to cellular stress following inflammatory and metabolic stressors, DNA damage, and others. In their physiologic roles, they are responsible for the regulation of cell cycle progression, cell proliferation and differentiation, and apoptosis. Dysregulation of the underlying pathways consequently has been identified in various cancer types, including pancreatic cancer. Pharmacological targeting of those pathways has been the field of interest for several years. While success in earlier studies was limited due to lacking specificity and off-target effects, more recent improvements in small molecule inhibitor design against stress-activated protein kinases and their use in combination therapies have shown promising *in vitro* results. Consequently, targeting of JNK, p38, and CK1 protein kinase family members may actually be of particular interest in the field of precision medicine in patients with highly deregulated kinase pathways related to these kinases. However, further studies are warranted, especially involving *in vivo* investigation and clinical trials, in order to advance inhibition of stress-activated kinases to the field of translational medicine.

Key Words: Pancreatic cancer; Stress-activated protein kinases; Mitogen-activated protein kinases; c-Jun N-terminal kinases; Casein kinase 1; Small molecule inhibitor

Core Tip: Since pancreatic cancer patients are generally confronted with poor prognosis, optimized therapeutic strategies are urgently needed. To establish new treatment options, efforts in drug development have increasingly focused on targeting protein kinases. In the cellular response to various stress signals, c-Jun N-terminal kinases (JNK) and p38 kinases as well as members of the casein kinase 1 (CK1) family are of special interest. Concentrating on pancreatic carcinoma in this review, we summarize the key roles of JNK, p38, and CK1 and provide an overview of recent achievements in the development of small molecule kinase inhibitors against these kinases.

INTRODUCTION

Pancreatic cancer is a severe disease, with overall 5-year survival rates less than 10% and only very little improvement over the last decades[1]. It is currently the fourth most common cause of cancer-related deaths, and it is expected by 2030 that pancreatic cancer will have surpassed colon and breast/prostate cancer to move up to second rank of cancer-related deaths[2]. Contributing to the immense challenge of treating pancreatic cancer, dysregulation of multiple signaling pathways can frequently be detected. With the genetic hallmark mutation of *KRAS* in over 90% of all pancreatic cancer patients, the high relevance of kinase-driven pathways is underlined[3].

So far, classic chemotherapeutic agents have only shown moderate success in prolonging overall survival of patients suffering from pancreatic ductal adenocarcinoma (PDAC). However, more and more personalized therapy concepts are becoming promising options, especially the use of small molecule inhibitors specifically targeting newly identified drug targets, such as deregulated protein kinases. Of special interest are kinases activated in cellular stress situations, like mitogen-activated protein kinases (MAPKs) and members of the casein kinase 1 (CK1) family, which phosphorylate signal integration molecules like p53 and β-catenin finally resulting in activation of processes leading to cell cycle arrest or apoptosis.

MAPKs

MAPKs are key players in transducing extracellular stimuli into intracellular signaling cascades and therefore represent interesting drug targets. Multiple isoforms have been identified, which can be clustered into six groups of MAPKs. The most prominent of those are the extracellular-regulated kinases 1 and 2 (ERK1/2), the c-Jun N-terminal kinases 1, 2, and 3 (JNK1/2/3), and the p38 kinases α, β, γ, and δ[4,5]. As a response to various stimuli such as growth factors, cytokines, and environmental stress, MAPK-triggered phosphorylation of their target transcription factors (TFs) marks the endpoint of an intracellular kinase cascade. This cascade consists of ligands binding to their cell membrane receptors, recruitment of GTPase (*e.g.*, RAS) to the plasma membrane, and activation of MAPK kinase kinases (MKKKs or MAPKKKs, *e.g.*, RAF) as well as MAPK kinases (MKKs or MAPKKs, *e.g.*, MEK1/2)[5-7]. ERK1/2 belong to the best-studied kinases among MAPKs. Their relevance for pancreatic cancer has been well documented, especially as ERKs exert their functions downstream of mutant KRAS[8,9]. JNK and p38 can be grouped together as stress-activated protein kinases (SAPKs), as their pathways are regularly activated by environmental stressors, like nutrient deprivation, inflammatory cytokines, or ultraviolet irradiation[5,10].

CK1

A remarkable association with tumorigenesis and tumor progression has also been demonstrated for the CK1 family of protein kinases. Being among the first kinases described in history, involvement of CK1 isoforms in several essential signal transduction pathways has been reported within the last decades. As a key cascade in developmental processes, the (canonical) Wnt/β-catenin signaling pathway can also be involved in promoting cell proliferation through activation of oncogenes like c-myc

and cyclin D1[11,12]. All human CK1 isoforms were identified to fulfill negative as well as positive regulatory functions in canonical Wnt signaling, thereby either acting as tumor suppressors or contributing to Wnt-induced oncogenic processes[13-15]. CK1δ and ε might furthermore promote canonical instead of non-canonical Wnt signaling, consequently resulting in reduced JNK-mediated Wnt signaling and apoptosis[16,17]. In addition, apoptosis mediated by Fas can also be down-regulated by CK1δ- and ε-mediated stabilization of Bid[18]. Apart from signaling associated with proliferation, differentiation, and apoptosis, CK1 is also involved in further mechanisms of the cellular stress response, including functions in immune response and inflammation, regulation of microtubule dynamic processes, autophagy, and DNA damage-related signal transduction[19-21]. Especially well documented is the regulatory function of CK1 isoforms in p53-mediated signal transduction with CK1δ even forming an autoregulatory feedback loop with p53[19].

Cancer itself already forms a stressful environment on the tumor cells, induced by hypoxia and nutrient deprivation as well as metabolic and replication stress. Additionally, cancer cells face genotoxic stress exerted by chemo- and radiotherapies. In this regard, pancreatic cancer is no exception since tumors of the pancreas are known for their dense stroma with impaired vasculature and the association with metabolic stressors, like diabetic conditions. This review aims to elucidate the role of the stress-activated kinases: JNK and p38 but also CK1 in the pathogenesis of pancreatic cancer and their potential as therapeutic targets.

SAPKS: JNK AND P38

The first description of JNK as a 54 kDa protein kinase activated upon peritoneal cycloheximide injection into rats dates back to 1990[22]. So far, three different JNK isoforms have been identified in the human genome, including JNK1 (MAPK8), JNK2 (MAPK9), and JNK3 (MAPK10), whereas expression of JNK3 is mainly restricted to brain, heart, and testes[23]. Alternative splicing results in generation of at least 10 different JNK isoforms with molecular weights ranging from 46 kDa to 55 kDa[24]. Activation of JNKs is dependent on phosphorylation of threonine and tyrosine residues by upstream kinases. For JNK1, phosphorylation of Thr^{180} and Tyr^{182} within its kinase subdomain VIII has been demonstrated to be essential[25]. In the activation process of JNK1, the upstream kinases MKK4 and MKK7 both fulfill non-redundant functions, with MKK4 preferably phosphorylating Tyr residues while MKK7 favors Thr residues. Phosphorylation of Thr^{180} is sufficient for JNK1 activation, however, dual phosphorylation by both kinases is required for full JNK activation[26,27]. Further upstream of the signaling cascade, a large variety of at least 14 MKKKs can activate MKK4 and MKK7[23,28].

Merging the influence of multiple upstream kinases into fewer effector kinases enables the cells to respond to a variety of stimuli, like growth factors and cytokines, reactive oxygen species, physical interactions with other cells and the extracellular matrix, as well as cellular stressors[29]. The variety of different stimuli requires multiple cell membrane receptors engaging into the JNK pathway. These include G-protein coupled receptors, Wnt-receptors, transforming growth factor-β receptors, and tumor necrosis factor-α (TNF-α) receptors[30]. Signal transfer within the SAPK pathway is generally orchestrated by docking motifs for upstream kinases and downstream substrates, as well as scaffold proteins. Those scaffold proteins express docking sites for MKKKs, MKKs, and MAPKs and play an important role in the correct stimulus response through the kinase cascade[29,31].

Even more diverse than the upstream mediators are the possible JNK substrates. As all MAPKs, JNK is a proline-targeted serine/threonine kinase, thus preferably phosphorylating Ser-Pro as well as Thr-Pro motifs[4,32]. So far, the list of JNK substrates includes more than 100 targets, among them TFs like c-Jun, p53, c-myc, and β-catenin, microtubule-associated proteins, components of focal-adhesion-complex and cell-to-cell-adhesion, as well as apoptosis-regulating proteins like Bcl-2 and Bax [30]. Figure 1 shows an overview of MAPK-related cellular functions.

The first p38 MAPK was discovered in 1994, and today four isoforms (p38α, β, γ, and δ, corresponding to MAPK14, 11, 12 and 13) are known[33,34]. While p38α is ubiquitously expressed, the other isoforms show differential tissue distribution, with p38β being mainly expressed in the brain, p38γ in skeletal muscle, and p38δ in endocrine glands[35]. Dual phosphorylation of Thr^{180} and Tyr^{182} in a Thr-Gly-Tyr motif are required for full p38 kinase activation[36]. MKK3 and MKK6 specifically activate p38, but while MKK6 can activate all isoforms, MKK3 is unable to phosphorylate p38β

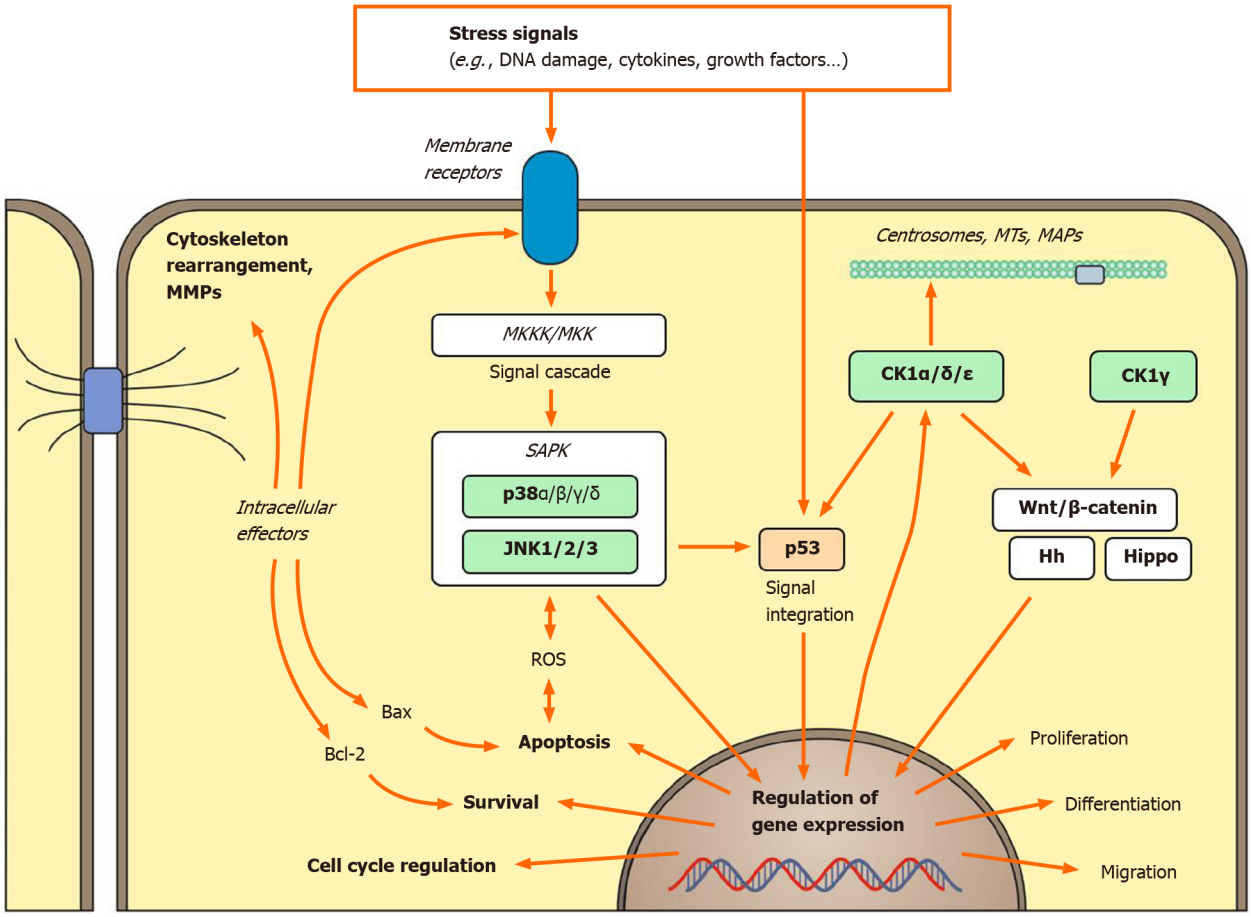

Figure 1 Signal integration mediated by stress-activated protein kinases. The stress-activated protein kinases (SAPKs) c-Jun N-terminal kinase (JNK) and p38 as well as the protein kinases of the casein kinase 1 (CK1) family are activated in response to endogenous and exogenous stress stimuli. Therefore, JNK and p38 are either activated directly or through upstream signaling cascades [mitogen-associated protein kinase kinase kinases (MKKKs), mitogen-associated protein kinase kinases (MKKs)] and subsequently exercise their functions through intracellular signal integrating effectors such as the transcription factors JNK, p53, c-myc, or β-catenin. In response to certain stress stimuli, the kinases of the CK1 family also take key functions in regulatory effects mediated *via* p53 or through various signal transduction pathways like the Wnt/β-catenin, Hedgehog (Hh), or Hippo pathway. Finally, cellular stress response including regulation of proliferation, differentiation, migration, cell cycle progression, survival, and apoptosis is initiated by modulation of gene expression. MAP: Microtubule-associated protein; MMP: matrix metalloproteinase; MT: Microtubule; ROS: Reactive oxygen species.

[37,38]. MKK4 can also contribute to p38 activation[39,40]. Multiple MKKKs contribute to the activation of MKK3 and MKK6, among which some are shared with the JNK pathway. By engaging specific MKKKs in response to defined stimuli, cells are enabled to elicit the correct stress response[35]. In T cells, a kinase cascade-independent pathway of p38α activation has also been described[41]. Similar to JNK, there are many p38-specific substrates, ranging from TFs to other protein kinases and apoptosis-regulating proteins[35].

Relevant SAPK-related pathways in cancer

The involvement of JNK and p38 in the pathogenesis of cancer has been studied extensively. Their role has been debated controversially since both can exhibit pro- as well as anti-tumorigenic functions[42,43]. For both kinases, the cellular effects provoked by JNK and p38 depend on the type, strength, and duration of the stimulus [44,45]. However, the influence of SAPKs on cancer development and progression is apparent as major cancer characteristics like cell proliferation, migration, and apoptosis are influenced by p38 and JNK. Pathways associated with these characteristics will now be discussed in general and specifically in pancreatic cancer.

A primary example of differential regulation in SAPK-related pathways is the interaction of JNKs and c-Jun. In non-stimulated cells, JNK2 activity leads to degradation of c-Jun, while after stimulation, JNK1 phosphorylates and stabilizes c-Jun. Consequently, knockdown of JNK1 decreased fibroblast proliferation through reduced activity of Activator protein-1 (AP-1), a TF of which phospho-c-Jun is a vital component[46,47]. Phosphorylation of c-Jun has also been identified as a critical step in RAS-induced tumorigenesis. Oncogenic RAS uses the same phosphorylation sites as

JNK on c-Jun and promotes transformation of rat embryonic fibroblasts, while *c-Jun*^{null} cells are resistant to RAS-induced transformation[48,49]. However, the role of JNK in this process is under dispute. In *TP53*$^{-/-}$ mouse embryonic fibroblasts, dual knockout of JNK1 and 2 reduced *KRAS*^{G12D}-induced transformation and suppressed *in vivo* growth. Furthermore, *KRAS*^{G12D}-induced lung tumor formation in mice was similarly reduced by JNK knockout[50]. This effect was in part attributed to JNK2, as only JNK2- but not JNK1-deprived mouse embryonic fibroblasts resisted RAS-induced transformation, although increased levels of AP-1 and phospho-c-Jun were observed[51]. However, not all transforming effects of RAS seem to be controlled by JNK, and in contrast to the before-mentioned studies, loss of JNK in RAS mutant cells may also contribute to enhanced tumorigenesis through apoptosis regulation[52]. A possible explanation for these findings is JNK-controlled cell cycle progression, as fibroblasts with knockdown of JNK2 show faster G1/S progression, while their JNK1-deprived counterparts show an opposing phenotype[46].

Besides proliferation, pro- and anti-apoptotic signals are also mediated by JNK in dependency of the stimulus. JNK regulates the expression of Bcl-2 family members and thereby influences apoptosis mediated *via* the mitochondrial pathway[44]. In TNF-mediated apoptosis, at early time-points, JNK activation triggers pro-survival pathways, while functioning JNK signaling is required for TNF-mediated apoptosis under persistent stimulation[53]. In murine cancer models, JNK1 was shown to promote chemically induced liver cancer, a finding that was also confirmed in human hepatocellular carcinoma[54,55]. On the other hand, knockdown of JNK1 rendered mice more susceptible to chemically induced skin tumors, while knockdown of JNK2 exerted an opposite effect[56].

The influence of p38 on oncogenesis is generally thought to be tumor suppressive, but protumorigenic functions like promotion of invasiveness has also been reported [44]. p38α controls proliferation through regulation of cell cycle progression at the G1/S and G2/M phases[57]. p38 can inhibit G1/S progression, *e.g.*, through downregulation of cyclin D1[40,58] or by phosphorylation of p53 and retinoblastoma protein [59-61]. Alternatively, p38 can also promote cell cycle progression through the induction of cyclin A or interference with the retinoblastoma protein pathway[62,63]. p38-mediated phosphorylation of p53 also activates the G2/M checkpoint in response to DNA double-strand breaks. Ironically, this also offers a survival benefit for tumor cells and increases therapy resistance, as DNA damaging drugs become less effective with functional p38 signaling[64-66]. Other tumor-promoting roles include formation of a pro-invasive phenotype through induction of matrix metalloproteinases and tumor cell dormancy, enabling metastatic relapse[42].

p38-related implication for involvement of the SAPK pathway in pancreatic cancer

The influence of the SAPK pathway on pancreatic cancer has been studied on patient samples as well as genetically engineered cell lines and mouse models, while patient cohorts are especially helpful to study population risk factors. Handra-Luca *et al*[67] offered an immunohistochemical analysis of the MAPK pathway in 99 surgically resected pancreatic cancer specimens. While high immunoreactivity for ERK1/2 was consistently associated with a worse prognosis, high expression levels of p38 could be associated with shorter recurrence-free survival in patients without adjuvant treatment. Strong staining for MKK4 was associated with increased proliferation[67]. Contrarily hereto, phosphorylated p38 with activated downstream TFs was identified as a favorable biomarker after surgical resection and associated with reduced number of lymph node metastases. Labeling of phospho-p38 showed no changes through the different cancer stages. Furthermore, pharmacologically inhibiting p38 *in vitro* and *in vivo* resulted in enhanced JNK signaling and enhanced cell growth[68]. Phospho-p38 was reported to increase during tumor progression, which is consistent with reports claiming that p38 has tumor suppressive functions during early carcinogenesis but switches towards a tumor promoting phenotype later on[69]. In our own previous work, we were able to dissect the isoform-specific functions of p38 in pancreatic cancer by genetically targeting p38 isoforms α and β. We confirmed an *in vivo* tumor suppressive phenotype of p38α but also showed a pro-invasive function. Additionally, we showed a tumor suppressive role of p38β, opposing p38α[70]. Interestingly, oncogenic KRAS induced activation of p38 and phenotypically increased invasion[71, 72].

JNK-related implication for involvement of the SAPK pathway in pancreatic cancer

Increased phospho-JNK staining was observed in pancreatic cancer tissues compared to normal controls[73] and increased phospho-JNK1 staining was determined as an independent predictor of peritoneal spread[74]. Furthermore, serum auto-antibodies

against JNK2 were identified as potential biomarker in pancreatic cancer patients[75]. By isoform-specific knockdown of JNK1 and 2 in MiaPaCa-2 and Panc-1 cells, a tumor promoting role could be attributed to JNK1, while JNK2 seems to exert suppressive functions in pancreatic cancer[76]. Upstream kinases of JNK have also been studied in pancreatic cancer, but their distinct role in tumor formation and progression remains elusive. MEKK1, as a representative of JNK-activating MKKKs, was shown to contribute to pancreatic cancer cell survival. However, unlike in other cancer cell lines, JNK signaling was not affected by knockout of MEKK1 in the PDAC cell line Panc-1 [77]. MKK4, a direct upstream kinase of JNK, was expressed in the majority of resected specimens, while expression levels were reduced in matched metastatic samples. As further hints for a potential tumor suppressive role, patients with loss of MKK4 were associated with shorter survival, and pancreatic cancer cell lines frequently showed loss-of-heterozygosity for MKK4[78,79]. However, ectopic expression of MKK4 stimulated proliferation and migration of ASPC-1 and BxPC3 cells[80].

Both kinases also act in pancreatic cancer outside neoplastic cells. *Ptf1a*$^{Cre/+}$; *Kras*$^{G12D/+}$; *JNK1*$^{-/-}$ mice showed significantly smaller tumors than their *JNK1*$^{+/-}$ counterparts. Tumors induced by transplantation of murine PDAC cells were larger in wild-type mice than in *JNK1*$^{-/-}$ mice lacking JNK signaling in stromal and immune cells. Interestingly, mice heterozygous for JNK1 showed less infiltrating $CD8^+$ T cells, possibly due to JNK-mediated downregulation of chemokine secretion of tumor-associated fibroblasts[81]. On the other hand, alternative activation of p38 through the T cell receptor in $CD4^+$ T cells resulted in more aggressive disease through secretion of pro-inflammatory cytokines like interleukin-17 and TNF-α[82].

SAPK inhibitors and their role for the treatment of pancreatic cancer

Due to the involvement of SAPKs within a variety of cellular processes and diseases, multiple researchers and the pharmaceutical industry have focused on identifying pharmacological inhibitors.

Generally, JNK small molecule inhibitors can be grouped into adenosine triphosphate (ATP)-competitive and non-ATP-competitive inhibitors. ATP-competitive inhibitors represent the majority of compounds, and most of them act as pan-JNK inhibitors, as the ATP-binding pocket is highly conserved among all three isoforms [83]. Non-ATP-competitive inhibitors target the interaction of JNK with upstream and downstream targets as well as scaffolding proteins. p38 inhibitors can also be grouped by their way of action. Similar to JNK inhibitors, many p38 inhibitors act as ATP-competitive inhibitors, either binding to the active (type 1 inhibitors) or inactive conformation of p38 (type 2 inhibitors)[84]. So far, p38 as well as JNK have been targeted in therapeutic intention for multiple pathologic conditions, like neurodegenerative diseases (*e.g.*, Alzheimer's and Parkinson's disease) and inflammatory diseases (*e.g.*, rheumatoid arthritis and inflammatory bowel disease)[85-87]. Consequently, pharmacological inhibition of both kinases has also been tested in order to explore new therapeutic strategies for the treatment of neoplastic diseases. Table 1 summarizes selective SAPK inhibitors studied in the context of cancer.

Strikingly, most studies report an antitumor effect of pharmacological SAPK inhibition. However, it needs to be noted that all inhibitors were pan-JNK inhibitors and p38α or pan-p38 inhibitors, respectively. As mentioned above, we previously reported on marked isoform-specific differences. By using genetic pathway disruption, isoform-specific tumor suppressive functions of JNK2 and p38β were detected and consequently, targeting of these isoforms might increase the risk of failure in clinical studies[76]. This effect could not be observed in our study, as pharmacological inhibition of JNK also reduced cell growth in various cell lines. Up to now, clinical studies using p38 inhibitors failed or only showed moderate success. Only one JNK inhibitor (CC-401) has been clinically evaluated for the treatment of cancer (NCT00126893), but this study has been discontinued[88,89].

In an early study, Ding *et al*[90] showed that the p38 inhibitor SB203580 [half maximal inhibitory concentration (IC_{50}) = 34 nmol/L] increases the number of Panc-1 cells in S phase as well as their proliferation. Decreased p38 activity was confirmed by detection of reduced levels of phospho-activating transcription factor. However, the same study also revealed increased phosphorylation levels of ERK1/2 and JNK[90]. Increased activation of ERK1/2, possibly as a compensation mechanism or off-target effect under SB203580 treatment, has also been shown in other reports[91,92]. Therefore, it remains unclear if the observed increased proliferation is a consequence of the loss of p38-dependent tumor suppressive actions or rather of increased ERK1/2 signaling. More recently, off-target effects of SB203580 and the closely related compound SB202190 were also described by Shanware and colleagues[93], reporting on cellular effects interestingly caused by off-target inhibition of CK1. Similar to the

Table 1 Small molecule inhibitors of stress-activated protein kinases tested for treatment effects on pancreatic carcinoma cells *in vitro* and *in vivo*

Inhibitor	IC_{50} (μmol/L)	Observed effects in cell culture and *in vivo* data	Ref.
JNK inhibitor II(SP600125)	0.040 (JNK1); 0.040 (JNK2); 0.090 (JNK3)	Antitumor effects in cancer cell lines of thyroid, stomach, lung, colon, pancreas, and brain	[104, 185-189]
JNK inhibitor XVI(JNK-IN-8)	0.005 (JNK1); 0.019 (JNK2); 0.980 (JNK3)	Covalent binding to JNK inactivates kinase function; Sensitizes pancreatic cancer cells and triple negative breast cancer cells to 5-FU/FOLFOX and triple negative breast cancer cells to lapatinib treatment	[190-192]
Bentamapimod(AS602801)	0.080 (JNK1); 0.090 (JNK2); 0.230 (JNK3)	Cytotoxic effects observed on cancer stem cells derived from pancreatic cancer, non-small cell lung cancer, ovarian cancer, and glioblastoma	[103, 193]
SB203580	0.034 (p38)	Synergistic effects observed in combination with cisplatin *in vitro* and *in vivo*; Inhibition of gemcitabine-induced apoptosis in combination therapy (tested on PK-1 and PCI-43 PDAC cell lines); $IC_{50(p38)}$ = 0.08-0.20 μmol/L *in vivo*)	[194-198]
SB202190	0.050 (p38α); 0.100 (p38β2); 0.600 (CK1)	Inhibition of gemcitabine-induced apoptosis in combination therapy (tested on PK-1 and PCI-43 PDAC cell lines); Inhibits resistance of colon cancer cell lines towards irinotecan	[93,197, 199,200]
SB239063	0.044 (p38α and β)	Dose-dependent growth inhibition observed in three pancreatic cancer cell lines	[68,201]

CK1: Casein kinase 1; EC_{50}: Half maximal effective concentration; 5-FU: 5-fluorouracil; IC_{50}: Half maximal inhibitory concentration; JNK1/2/3: c-Jun N-terminal kinases 1, 2, and 3.

above mentioned studies, Zhong *et al*[68] reported on the growth enhancing effects not only for SB203580 but also for SB202190 and SB239063 on three different pancreatic cancer cell lines. Interestingly, while environmental stressors (hypoxia and reduced serum levels) led to reduced proliferation in PDAC cell lines, p38 inhibition abolished these effects. Again, increased phospho-JNK levels after p38 inhibition were reported, and JNK inhibition through SP600125 abolished the effects of p38 inhibition *in vitro*. The pan-JNK inhibitor SP600125 ($IC_{50(JNK1)}$ = 40 nmol/L; $IC_{50(JNK2)}$ = 40 nmol/L; $IC_{50(JNK3)}$ = 90 nmol/L) also reduced the *in vivo* growth of cell lines with high phospho-p38 Levels [68]. The crosstalk of p38 and JNK has been described in various contexts previously. Although there is evidence for a synergistic role of both SAPKs in activation of downstream targets[94], an opposing function of both has also been well documented [95-97]. Possible regulation mechanisms of JNK through p38 include upstream MKKKs (MLK3, TAK1) as well as nuclear factor-κB[44]. Consequently, targeting single MAPKs is highly challenging. An alternative approach to using inhibitors could be selectively activating pathways of interest. The small molecule triptonide was shown to selectively activate the MEKK4-MKK4-p38 pathway without significantly altering phosphorylation levels of JNK and ERK1/2. This resulted in dose-dependent growth reduction of six pancreatic cancer cell lines as well as *in vivo* xenografts by inducing G2/M arrest and reduced expression of cyclin-dependent kinase 3[98].

In contrast to those studies showing an overall growth restraining effect of p38 in pancreatic cancer, Yang *et al*[99] performed a screen of p38α expression in various cancer samples of The Cancer Genome Atlas database and identified an overexpression of p38α in PDAC samples. The same study also reported enhanced phospho-p38 labeling in PDAC tissues compared to adjacent normal tissue and mostly attributed phospho-p38 labeling to cancer cells. When treating Pan02 cells with SB203580 or the p38α- and β-specific inhibitor LY2228820, Yang *et al*[99] reported growth-restricting effects. However, it needs to be noted that the used inhibitor concentrations were relatively high and potential off-target effects cannot be excluded. Finally, in order to address the issue of lacking sensitivity, possible binding pockets in p38, enabling the design of more selective inhibitor compounds in future, were identified by *in silico* modeling[99].

Previous studies indirectly suggested a growth-promoting effect of JNKs on pancreatic cancer. Takahashi *et al*[73] observed growth inhibition *in vitro* and *in vivo* after treatment with SP600125. This was associated with G1 arrest and downregulation of cyclin D1 *in vitro*. In genetically-engineered mouse models (*Ptf1a*$^{cre/+}$, *LSL-Kras*$^{G12D/+}$, and *Tgfbr2*$^{flox/flox}$) SP600125 reduced neoangiogenesis and expression levels of CD44 in PDAC cells[73]. Together with CD133, CD44 is considered as a potential marker for cancer stem cells (CSCs) or CSC-like cells (CSCLCs)[100,101]. Increased levels of phospho-JNK was also shown in CSCLCs of pancreatic cancer and other human malignancies[102]. Inhibition of JNK by the pan-JNK inhibitors SP600125 or AS602801 as well as genetic targeting of JNK1 and 2 *via* small interfering RNA-mediated knockdown reduced levels of $CD133^+$ cells in an isolated subpopulation of pancreatic

cancer-derived CSCLCs and abolished their self-renewal capacity *in vitro* and *in vivo* [102,103]. Besides growth suppression and interference with CSCs, induction of cellular differentiation can be another mechanism of JNK inhibition-mediated tumor suppression[104].

In clinical practice, SAPK inhibition will rather be used for combination therapy approaches instead of single-agent therapy. Therefore, the interference of SAPK inhibitors with standard of care chemotherapeutics is highly relevant. In addition to single treatment of CSCLCs, the group of Suzuki *et al*[105] also investigated the effects of JNK inhibition in combination with gemcitabine and 5-fluorouracil (5-FU). While CSCLCs expectedly were more resistant to these agents, pretreatment with SP600125 had a synergistic effect in combination with gemcitabine and 5-FU in a reactive oxygen species-based way of action[105]. The observed synergistic effect can furthermore be explained by JNK-mediated effects on multidrug resistance. Multidrug resistance is not only a hallmark of CSCs but of cancer cells in general, and multidrug transporters like P-glycoprotein reduce intracellular drug levels[106]. In this context, high JNK levels were shown to decrease P-glycoprotein levels in pancreatic and gastric cancer, thereby increasing intracellular drug concentrations as well as drug sensitivity[107].

The interplay of the p38 pathway and gemcitabine treatment has been well studied in pancreatic cancer cells. Apoptosis mediated through gemcitabine was consistently associated with p38 activation as well as caspase-dependent cleavage of poly (ADP-ribose) polymerase and heat shock protein 27 phosphorylation. Inhibition of p38 by SB203580 reversed these effects. Similarly, inhibition of MAPK-activated protein kinase 2, a downstream target of p38, abolished gemcitabine-mediated apoptosis in pancreatic cancer. However, combination of p38 inhibitors with mitomycin C showed synergistic effects[108].

PROTEIN KINASE CK1 FAMILY

In 1954 for the first time, an enzyme was isolated from liver tissue, which was able to phosphorylate the milk protein casein[109]. Fifteen years later, two distinct protein kinases with the ability to phosphorylate casein (at least *in vitro*) were described and termed casein kinase 1 (CK1) and casein kinase 2 (CK2), meanwhile renamed protein kinases CK1 and CK2[110]. Despite their common nomenclature and the ability to phosphorylate casein, protein kinases CK1 and CK2 are highly different with respect to their classification and cellular functions. While CK2 belongs to the CMGC [containing cyclin-dependent kinase, MAPK, glycogen synthase kinase 3 (GSK3), and cdc2-like kinase families] group of the human kinome, CK1 forms an independent family of protein kinases[111].

In the human genome, six CK1 isoforms are encoded (α, γ1, γ2, γ3, δ, and ε), and several splice variants can originate from post-transcriptional processing. While all CK1 isoforms are highly conserved within the kinase domain, the sequences of the N- and C-terminal noncatalytic domains can be quite variable[20,112]. Although the protein kinases of the CK1 family are generally considered to be constitutively active, several regulatory mechanisms have been described. Expression and/or activity levels of CK1 isoforms can be enhanced by insulin or cellular stress executed by viral transformation, topoisomerase inhibitor treatment, or γ-irradiation. Regulation of enzymatic activity is also possible on the protein level, *e.g.*, by modulation of subcellular localization, interaction with other proteins, or (auto-)phosphorylation in particular targeting the C-terminal regulatory domain but also the kinase domain[20,112].

Most CK1 isoforms are localized in the cytosol. Only the CK1αL variant possessing a second nuclear localization signal in the L-exon can be localized to the nucleus[113]. Due to C-terminal palmitoylation, CK1γ can be associated with the plasma membrane [114-116]. By modulation of subcellular localization, CK1 isoforms can be brought in proximity with different substrate pools. Substrate recognition motifs for CK1 can generally be found on most cellular proteins and, to date, more than 150 substrates being phosphorylated by CK1 isoforms at least *in vitro* have been reported[20]. Thereby, CK1 shows strong preferences for acidic or phospho-primed substrates presenting the canonical consensus sequence (phospho-Ser/phospho-Thr-X-X-(X)-Ser/Thr). In addition, several alternative noncanonical motifs targeted by CK1 have been described[117,118].

The broad range of substrates phosphorylated by CK1 gives a hint of the numerous cellular processes potentially regulated by CK1 family members. These processes involve cell proliferation and differentiation, DNA processing and repair, as well as

cytoskeleton maintenance just to name few of them. In particular, essential signal transduction pathways involving CK1-mediated regulation include Wnt and Hedgehog (Hh) signaling as well as regulation of circadian rhythm[20]. Consequently, deregulation or dysfunction of CK1 isoforms involved in regulation of these signaling pathways can result in deregulated signal transduction and subsequent development of pathological states.

Relevant CK1-related pathways in cancer

CK1 isoforms have been implicated in several signaling pathways such as the canonical and noncanonical Wnt as well as Hh and Hippo signaling pathways, which play an important role in tissue development, growth, and homeostasis[119-122]. Aberrant signaling as well as mutations of key regulator proteins of these pathways can lead to various cancer entities[123-127]. The connection between CK1 and cancer has been strengthened through the discovery of their targets such as β-catenin, p53, and mouse double minute homologue 2 and 4, which hold important roles as key regulators in signaling pathways and are generally thought to be involved in cancer development (Figure 1)[128,129]. Considering the reported CK1-mediated phosphorylation of numerous substrates essential for signal transduction, it is not surprising that CK1-specific mutations resulting in altered expression levels or enzyme activity are likely to be accompanied by dramatic changes affecting CK1-regulated signal transduction pathways.

As one of the best characterized CK1-regulated processes, the Wnt signaling pathway has an important regulatory role in cell proliferation, differentiation, and cell polarity[120,130-133]. Altered expression levels of key regulators within the pathway are associated to oncogenesis, both through increased expression of positive regulators and decreased expression of negative regulators[134-137]. Several studies showed that all CK1 isoforms are implicated in the Wnt signaling pathway and either exert positive or negative regulatory functions, respectively[14]. Acting as positive regulators of the canonical Wnt signaling pathway, CK1γ, δ, and ε were found to initiate the transcription of proto-oncogenes like cyclin D1 and c-myc resulting in increased cell proliferation and cell survival[13,138,139]. For instance, mutations within the C-terminal region of CK1δ were shown to alter its physiological role, increase the oncogenic potential, and promote colonic adenoma development[140]. Additionally, CK1 isoforms exhibit oncogenic characteristics associated to the inhibition of apoptotic processes. This assumption is supported by the findings that CK1δ and CK1ε contribute to the switching mechanism between the canonical and the non-canonical Wnt/Rac1/JNK pathway, where they may favor the canonical Wnt pathway to the detriment of JNK-mediated apoptosis[17,141]. In many Wnt-driven cancers, CK1α protein expression is suppressed, leading to an activation of proliferative processes *via* the Wnt pathway. In addition, the absence of CK1α leads to a critical involvement of p53 in controlling invasiveness, which was shown in a model for colon cancer[15].

The importance of CK1 isoforms within various signaling pathways is strengthened by reports linking CK1 to phosphorylation of components in Hh signaling pathway. Although the activity of the Hh signaling pathway is reduced in adulthood, it is critical for embryonic development, organogenesis, and maintenance of healthy adult cells[119]. In the adult organism, Hh signaling contributes to the regulation of epithelial maintenance and tissue regeneration; consequently mutations and dysregulation of components of this signaling pathway promote tumorigenesis and cancer development[142-145]. As seen in Wnt signaling, CK1 isoforms appear to have contrasting effects on Hh signaling. Acting as a negative regulator, CK1 promotes proteolysis of GLI TF and prevents target gene transcription[146-148]. In order to fulfill its positive function, CK1α and G-protein coupled receptor kinase 2 phosphorylate the positive Hh regulator Smoothened homologue precursor, thereby inducing its active conformation[149].

The major functions of the Hippo pathway have been defined to correct organ maturation through restriction of organ size by regulating cell proliferation and apoptosis[150]. As such, dysregulated Hippo signaling can trigger tumorigenesis and cancer. CK1 isoforms have been proposed to regulate Hippo signaling through phosphorylation of a phosphodegron signal in Yes-associated protein after receiving priming phosphorylation by large tumor suppressors 1 and 2. As a result, the phospho-degron signal mediates recruitment of βTrCP ubiquitin ligase causing Yes-associated protein degradation and inhibition of cell growth and differentiation[150]. Additionally, a more recent publication proposed an interaction between the Wnt and the Hippo pathways mediated through CK1ε. In this context, the Hippo upstream kinase MST1 inhibits the Wnt signaling pathway by directly binding CK1ε and thereby suppressing phosphorylation of Disheveled[151].

Implication for CK1 involvement in pancreatic cancer

In a recent study analyzing messenger RNA-based gene expression data of the International Cancer Genome Consortium Pancreatic Cancer Australia cohort, high expression levels of CK1δ detected in patients with pancreatic cancer were correlated with poor survival. Increased expression of CK1δ could be found in patients with metastatic pancreatic carcinoma, and CK1δ expression was furthermore strongly correlated with the tumor grade[152]. This observation is in line with previous studies reporting upregulation of CK1 isoforms in PDAC in general[153,154] and describing increased expression of CK1δ and CK1ε in a patient cohort with higher-graded PDAC [155]. Cell line-specific elevated expression levels of CK1δ and/or CK1ε were also detected in various tumor cell lines[152,155]. Independent of the detected protein levels, CK1δ- and CK1ε-specific kinase activities in extracts obtained from various pancreatic cancer cell lines (MiaPaCa-2, BxPC3, PancTu-1, and Colo357) significantly differed from each other by up to six orders of magnitude[156].

In general, due to the involvement of CK1 isoforms in various pathways related to tumorigenesis, altered expression and/or activity levels of CK1 isoforms can be associated with increased oncogenic potential. Using the breast cancer cell line MCF7, a regulatory function of CK1ε has been identified in the Akt pathway[157]. This is of particular interest because Akt is frequently upregulated in PDAC[158,159]. In detail, CK1ε is able to inhibit protein phosphatase 2B, consequently resulting in increased Akt phosphorylation levels and enhanced Akt kinase activity. Inhibition of CK1ε in MCF7 cells by the small molecule inhibitor IC261 has been demonstrated to reduce Akt phosphorylation as well as Akt-mediated phosphorylation of GSK3β[157]. Quite similar findings could be made using PDAC cells. Also in this case, phosphorylation of Akt was reduced in response to treatment with IC261[160]. However, these results were only based on observations made in preliminary experiments, and effects were obtained by using extremely high concentrations of the rather unspecific early-stage inhibitor IC261.

Apart from altered expression and/or activity levels, mutations in the coding sequence for CK1 isoforms can also be associated with increased oncogenic functions of the resulting CK1 mutant proteins. Several mutations in *CSNK1D*, the gene coding for human protein kinase CK1δ, identified in different types of cancer (*e.g.*, colorectal carcinoma, lung squamous cell carcinoma, bladder urothelial carcinoma, and pancreatic carcinoma) were analyzed for their enzyme kinetic parameters and their sensitivity towards the treatment with several CK1-specific small molecule inhibitors. Among the tested mutants, hyperactive (*e.g.*, R127L and R127Q) as well as nearly inactive (*e.g.*, E247K and L252P) variants could be characterized. Especially, the hyperactive CK1δ mutant R127Q showed enhanced sensitivity towards the treatment with various CK1-specific inhibitors. The two tested CK1δ mutants exclusively detected in PDAC (Q399* and H414Y) only showed slightly reduced kinase activity when compared to wild-type CK1δ[161]. The online analysis tool cBioPortal for Cancer Genomics lists even more mutations detected in PDAC and affecting CK1 isoforms, among them frameshift deletions as well as nonsense and missense mutations[162-165]. However, these mutations have so far not been investigated for their oncogenic potential.

Unfortunately, no detailed information on the role of CK1 isoforms in formation of metastasis from primary tumors located in the pancreas has been available so far. In general, the zinc-finger TF Snail is phosphorylated by CK1ε and GSK3β in a hierarchical manner. Snail can promote epithelial-mesenchymal transition by repressing expression of E-cadherin but is degraded by the proteasome upon phosphorylation by CK1ε and GSK3β. Pharmacological inhibition (using the inhibitor IC261) or RNA interference-mediated downregulation of CK1δ inhibits phosphorylation of Snail and promotes cell migration[166]. In addition, reduced proliferation and invasion could be linked with CK1ε-mediated inhibition of Wnt/β-catenin signaling and downregulation of Wnt3a, β-catenin, proliferating cell nuclear antigen, and matrix metalloproteinase 9 in colorectal cancer cells[167].

Inhibitors of CK1 and their role for the treatment of pancreatic cancer

Results obtained from numerous studies conducted within the last 10-15 years characterized the protein kinases of the CK1 family as well-established drug targets. While early-stage small molecule inhibitors (*e.g.*, IC261[168]) only demonstrated low target selectivity, several recent-stage CK1-specific inhibitors with enhanced selectivity and improved potency in the nanomolar range are available to date (Table 2)[20,112,169]. So far, none of these inhibitors advanced to the stage of clinical trials, and the use of these compounds was limited to biochemical and cell culture-based testing or animal

Table 2 Casein kinase 1-specific small molecule inhibitors tested for treatment effects on pancreatic carcinoma cells *in vitro* and *in vivo*

Inhibitor	IC_{50} CK1 (μmol/L)	Observed effects in cell culture and *in vivo* data	Ref.
IC261	1.000 ± 0.30 (CK1δ)	Reduced growth of ASPC-1, BxPC3, Capan-1, Colo357, MiaPaCa-2, Panc-1, Panc89, and PancTu-1 at 1.25 μmol/L concentration of IC261; Subcutaneous xenograft model using PancTu-2: reduced tumor size with IC261 or gemcitabine (no synergism with gemcitabine), downregulation of anti-apoptotic genes/upregulation of cell cycle- and cell death-associated regulators; Notable off target effects (affecting the cytoskeleton and ion channels)	[155, 168, 182-184, 202]
compound 11b	0.004 ± 0.001 (CK1δ); 0.025 ± 0.004 (CK1ε); 0.010 (p38α)	Cytotoxic effects observed on Colo357 (EC_{50} = 3.5 ± 0.3 μmol/L) and Panc89 (1.5 ± 0.4 μmol/L)	[174]
compound 3c	1.600 (CK1δ/ε)	In a panel of cell lines only effective against Panc-1 (EC_{50} = 9.3 ± 0.0 μmol/L); Cytotoxic effects observed on A549 (lung carcinoma) and Hek293 (normal cells) significantly higher EC_{50} values	[175]
compound 2	0.070 ± 0.01 (CK1δkd); 0.520 ± 0.05 (CK1ε)	Cytotoxic effects observed on BxPC3 (EC_{50} = 0.11 ± 0.01 μmol/L), Colo357 (0.13 ± 0.02 μmol/L), MiaPaCa (0.26 ± 0.02 μmol/L), PancTu-1 (0.70 ± 0.02 μmol/L), and Panc-1 (0.35 ± 0.08 μmol/L); Cell line-specific effects observed in screening against a panel of 82 tumor cell lines	[178]
IWP-4	1.020 ± 0.13 (CK1δ); 7.070 ± 2.01 (CK1ε)	Cytotoxic effects observed on A818-6 (EC_{50} = 0.93 ± 0.07 μmol/L), MiaPaCa-2 (0.23 ± 0.01 μmol/L), Panc-1 (0.23 ± 0.02 μmol/L), Panc89 (0.58 ± 0.12 μmol/L), and Capan (0.23 ± 0.01 μmol/L); Inhibition of Wnt signaling (Wnt3A overexpression, autocrine/paracrine) with IC_{50} = 0.71 ± 0.38 μmol/L; Inhibition of Wnt signaling (Wnt3A-conditioned medium, autocrine/paracrine) with EC_{50} = 1.47 ± 0.55 μmol/L	
SR-3029	0.044 (CK1δ); 0.260 (CK1ε)	Cytotoxic effects observed on Panc-1 (EC_{50} = 0.023 μmol/L), MiaPaCa2 (0.370 μmol/L), and BxPC3 (0.131 μmol/L); Mouse pharmacokinetic studies with promising results for animal model use of SR-3029; Orthotopic xenograft model using Panc-1, reduced tumor size using SR-3029 and/or gemcitabine (synergism with gemcitabine due to upregulation of dCK)	[152, 180]

CK1: Casein kinase 1; EC_{50}: Half maximal effective concentration; IC_{50}: Half maximal inhibitory concentration.

models.

Quite recently, we characterized optimized 4,5-diarylimidazoles as highly effective ATP-competitive inhibitors of CK1δ. Substituted isoxazoles were originally designed as inhibitors of p38α MAPK, but they share the same pharmacophore moiety that is necessary to inhibit CK1δ[93,170-172]. Substituting the isoxazole scaffold with an imidazole scaffold resulted in the generation of highly potent dual-specific inhibitors of p38α MAPK and CK1δ[173]. By further optimizing these imidazole-based compounds, CK1 isoform-specific inhibitors with IC_{50} values in the low nanomolar range like compounds 11b [$IC_{50(CK1\delta)}$ = 4 nmol/L], 12a (19 nmol/L), and 16b (8 nmol/L) could be developed, which represent the most potent CK1δ-specific inhibitors described so far. Because IC_{50} values determined for the highly related isoform CK1ε are increased by six to 12 orders of magnitude (with 25, 227, and 81 nmol/L for 11b, 12a, and 16b, respectively), these compounds can also be considered to be selective for CK1δ. Compound 11b even demonstrated superior selectivity towards CK1δ among a panel of more than 321 protein kinases. However, full selectivity with respect to side-effects on p38α MAPK could still not be achieved for this set of compounds, but IC_{50} values determined for p38α are three-fold higher compared to CK1δ. Finally, 11b demonstrated significant effects on pancreatic cancer cell lines, with half maximal effective concentration (EC_{50}) values in the low micromolar range [$EC_{50(Colo357)}$ = 3.5 μmol/L, $EC_{50(Panc89)}$ = 1.5 μmol/L)[174].

Apart from isoxazole- and imidazole-derived molecules, the quinazoline-based inhibitors (N-(1H-pyrazol-3-yl)quinazolin-4-amines) 3c and 3d have been shown to inhibit CK1δ and ε ($IC_{50(CK1\delta/\varepsilon)}$ = 1.6 and 1.4 μmol/L, respectively). In a panel of human cancer cell lines, compound 3c even demonstrated selective cytotoxicity against the PDAC cell line Panc-1, with an EC_{50} value of 9.3 μmol/L [for all others no EC_{50} value could be determined (> 100 μmol/L), except for A549 with 29.7 and HEK293 with 71.1 μmol/L]. Compound 3d also demonstrated effects on Panc-1 cells but only with an extremely high EC_{50} value of 69.4 μmol/L. However, the mechanism of selectivity of the tested quinazoline-based inhibitor remains to be determined[175].

Within the last decade, several benzimidazole-based inhibitors have demonstrated significant inhibition of CK1δ variants and superior isoform selectivity over CK1δ. The series of compounds described by Leban *et al*[176] originates from piperidinyl-thiazoles originally designed to inhibit nuclear factor-κB[176]. Following modification, these compounds also demonstrated significant inhibition of CK1 family members. Most significant inhibition of CK1δ kinase domain (CK1δkd) with superior isoform selectivity over CK1ε could be determined for compound 5 ($IC_{50(CK1\delta kd)}$ = 29 nmol/L, $IC_{50(CK1\varepsilon)}$ = 199 nmol/L). Compound 5 also induced apoptosis in various tumor cell lines

with cell line-specific effects and only moderate levels of apoptosis in Colo357 pancreatic cancer cells (tested at 4 μmol/L concentration)[177]. As reported by Richter and colleagues[178], the highly related but structurally slightly different compound 1 showed three-fold stronger inhibition of CK1δkd (IC_{50} = 10 nmol/L). By further improving the physicochemical properties of this difluoro-dioxolo-benzoimidazole derivative, inhibitor potency *in vitro* could be maintained for modified compound 2 ($IC_{50(CK1\delta kd)}$ = 0.07 μmol/L, $IC_{50(CK1\varepsilon)}$ = 0.52 μmol/L) while significantly increasing the effects observed on a panel of cancer cell lines. In comparison to compound 1, the effects on cell viability were significantly increased for cell lines treated with compound 2, among them the pancreatic cancer cell lines BxPC3, Colo357, MiaPaCa, PancTu-1, and Panc-1 (see Table 2 for EC_{50} data)[178].

Being structurally related to benzimidazole-based inhibitors, compounds derived from inhibitors of Wnt production (IWP) have recently been described as CK1-specific inhibitors. IWP-2 and IWP-4 as well as the further optimized compound 19 displayed rather potent inhibition of CK1δkd *in vitro* ($IC_{50(CK1\delta)}$ = 0.32, 1.02, and 0.09 μmol/L for IWP-2, IWP-4, and compound 19) and also demonstrated significant effects on the proliferation of pancreatic cancer cell lines as determined for IWP-4-treated A818-6 (EC_{50} = 0.93 μmol/L), MiaPaCa (0.23 μmol/L), Panc-1 (0.23 μmol/L), and Panc89 (0.58 μmol/L) cells[179].

As a benzimidazole-based inhibitor containing a purine scaffold compound SR-3029 has been described as highly potent and selective inhibitor of CK1δ ($IC_{50(CK1\delta)}$ = 44 nmol/L, $IC_{50(CK1\varepsilon)}$ = 260 nmol/L)[180]. SR-3029 shows improved cellular activity on the human melanoma cell line A375 (EC_{50} = 86 nmol/L) and the triple-negative breast cancer cell line MDA-MB-231[181]. These results suggested favorable cell penetration for SR-3029, and mouse pharmacokinetic properties indicated that SR-3029 actually was sufficient for use in xenograft studies[180].

Recently, SR-3029 has been tested for its effects on the proliferation of PDAC cell lines Panc-1, MiaPaCa-2, and BxPC3, thereby obtaining EC_{50} values in the submicromolar range (23, 370, and 131 nmol/L, respectively). Furthermore, synergistic effects have been detected for the treatment of MiaPaCa-2 and Panc-1 cells with a combination of SR-3029 and gemcitabine, the standard of care used in treatment of locally advanced and metastatic PDAC. Same effects could be observed after silencing of CK1δ by small interfering RNA. The mechanism of synergy could be explained by upregulation of deoxycytidine kinase subsequent to inhibition of CK1δ by SR-3029, resulting in enhanced metabolism and anti-proliferative effects of gemcitabine. Anti-proliferative effects of SR-3029 and synergy with gemcitabine could also be observed *in vivo* by using an orthotopic xenotransplantation mouse model. Tumors obtained from injection of Panc-1 cells into the pancreas were significantly smaller after treatment with SR-3029 or gemcitabine, and tumor size was even more reduced after combination therapy[152].

In a previous xenotransplantation study, the early-stage CK1-specific inhibitor IC261 had already demonstrated therapeutic potential. Tumor cell growth of a panel of established pancreatic cancer cell lines (ASPC-1, BxPC3, Capan-1, Colo357, MiaPaCa-2, Panc-1, Panc89, and PancTu-1) was significantly reduced by treatment with 1.25 μmol/L IC261 *in vitro*, and the size of tumors obtained after subcutaneous injection of PancTu-2 cells was significantly smaller after treatment with IC261. In the tumor tissue, downregulation of several anti-apoptotic genes (*e.g.*, Bcl-2 family members) and upregulation of cell cycle- and cell death-associated regulators (*e.g.*, p21, ataxia-telangiectasia mutated kinase, checkpoint kinase 1) could be observed following treatment with IC261 or gemcitabine[155]. However, and in contrast to the above mentioned recent study by Vena and colleagues[152], IC261 failed to sensitize gemcitabine-resistant PancTu-1 cells to treatment with gemcitabine, and no synergistic or additive action in combination with gemcitabine could be demonstrated for IC261. This failure can be due to the unspecific effects meanwhile described for IC261. Apart from its specific action on CK1 family members, IC261 is able to bind tubulin with an affinity similar to the spindle poison colchicine. IC261 can therefore be considered as a microtubule polymerization inhibitor by directly exerting its effects on microtubules independent of CK1 blockage[182,183]. Moreover, within the concentration range necessary to block CK1 kinase activity, IC261 is also able to block voltage-gated sodium channels, and consequently, well-characterized recent-stage CK1-specific inhibitor compounds like SR-3029 should be used for targeting CK1 isoforms instead of using the unspecific early-stage inhibitor IC261[184].

CONCLUSION

In recent years, there has been a lot of evidence for the involvement of stress-activated kinases like JNK and p38 but also CK1 in the pathogenesis of pancreatic cancer. Furthermore, remarkable progress has been made in designing specific small molecule inhibitors to effectively target these kinases *in vitro* and *in vivo* and to reduce off-target effects. Interestingly, due to similarities in protein structure, some inhibitor compounds even demonstrate dual inhibition of p38 and CK1 isoforms. However, further mechanisms and benefits from dual kinase inhibition have not been studied in detail. Furthermore, conclusive results from using specific inhibitors in clinical trials remain to be obtained, and knowledge on the interplay of these inhibitors with standard of care chemotherapeutics needs to be acquired in future studies.

Abstract

Malnutrition is a highly prevalent and under recognized condition in developing countries of South Asia. The presence of malnutrition causes a severe impact on patients with liver cirrhosis. The etiology of cirrhosis differs in the South Asian region compared to the West, with hepatitis B and C still being the leading causes and the prevalence of nonalcoholic fatty liver disease increasing over time. Comorbid malnutrition worsens outcomes for cirrhosis patients. Urgent attention to address malnutrition is needed to improve patient outcomes. The etiology and pathophysiology of malnutrition in liver diseases is multifactorial, as reduction in liver function affects both macronutrients and micronutrients. A need for nutritional status assessment for liver disease patients exists in all parts of the world. There are many widely studied tools in use to perform a thorough nutritional assessment, of which some tools are low cost and do not require extensive training. These tools can be studied and evaluated for use in the resource limited setting of a country like Pakistan. Treatment guidelines for proper nutrition maintenance in chronic liver disease exist for all parts of the world, but the knowledge and practice of nutritional counseling in Pakistan is poor, both amongst patients and physicians. Emphasis on assessment for nutritional status at the initial visit with recording of vital signs is needed. Simultaneously, treating physicians need to be made aware of the misconceptions surrounding nutritional restrictions in cirrhosis so that patient education is done correctly based on proper scientific evidence.

Core Tip: Malnutrition in liver cirrhosis is a serious problem in South Asia where the etiology differs from the Western population. As malnutrition is generally highly prevalent in the region, it causes an impact on patients with liver cirrhosis. Urgent attention to address malnutrition is needed to improve patient outcomes. Emphasis on assessment for nutritional status at the initial visit with recording of vital signs is also needed. Simultaneously, treating physicians need to be made aware of the misconceptions surrounding nutritional restrictions in cirrhosis so that patient education is done correctly based on proper scientific evidence.

INTRODUCTION

Malnutrition (undernutrition) is defined as an insufficient intake or assimilation of nutrients essential for development and prevention of disease[1]. Malnutrition presents as a common complication of end-stage liver failure (cirrhosis), which is characterized by mass systemic complications such as refractory ascites, spontaneous bacterial peritonitis, hepatorenal syndrome and variceal hemorrhage[2]. Due to the deterioration of health that cirrhosis causes, approximately a million people die from cirrhosis globally, making it a significant disease burden to be addressed.

Several studies have evaluated nutritional status in patients with liver cirrhosis of different etiologies and varying degrees of liver insufficiency[3,4] leading to a consensus that malnutrition is recognizable in all forms of cirrhosis[5] with the prevalence of malnutrition in cirrhosis having been estimated to range from 65%-100%[6,7]. Thus, malnutrition becomes an important prognostic indicator of clinical outcomes, which include survival rate, the length of hospital stay, post-transplantation morbidity and quality of life in patients with cirrhosis[8], particularly in patients with severe cirrhosis and alcoholic cirrhosis where malnutrition is more likely to be present[9]. While malnutrition remains potentially modifiable, it has been observed starting from the initial stages of liver disease that results in an almost direct relationship between the liver disease severity and the extent of malnutrition, with malnutrition becoming easier to detect in severe cirrhosis[10].

The causes of malnutrition in liver disease are complex and multifactorial due to the liver forming a fundamental part of the body's metabolism. It results from impaired dietary intake due to the malfunctioning liver, chronic inflammation and subsequently the altered macronutrient and micronutrient metabolism. Low patient activity is also attributed to it[7,11]. Additionally, anorexia, gastroparesis, nausea, increased leptin levels, encephalopathy and gastritis are found to be contributors of malnutrition. Ascites, frequent paracentesis, some drugs such as diuretics and lactulose, a sodium-restricted diet and alcohol consumption (decreases appetite) can also result in metabolic malfunctioning and thus contribute to a reduction in dietary intake, which leads to malnutrition in liver disease[12,13]. The deficiency of biliary salts due to liver malfunction and decreased assimilation of nutrients, abnormal motility of the digestive tract and an increased bacterial growth may subsequently lead to an impaired uptake and metabolism of nutrients, resulting in malnutrition[14]. Portal hypertension leads to an increased permeability of the intestinal mucosa, thereby causing an increased loss of proteins that may be similarly noted in cases of bleeds caused by varices or ulcers[15]. A poor nutritional status then poses significant consequences for postoperative complications among transplant candidates as well because this is an important prognosticator for mortality and morbidity among chronic liver disease (CLD) patients[9]. Subsequently, malnutrition itself becomes an independent predictor of mortality in patients with CLD.

The resultant malnutrition comprises of both macro and micronutrient deficiencies. The macronutrients (being proteins, carbohydrates and fats) have their metabolism affected[16], while protein deficiency makes patients more susceptible to hepatocellular disease, in particular. On the micronutrient level, patients with a history of cholestatic liver disease are more liable to have an insufficient calorie intake with a

higher risk of vitamin deficiencies. Detecting micro or macronutrient deficiencies at an earlier stage is crucial so that nutritional supplementation can be initiated in a timely manner, which has been proven to decrease the risk of infection and in-hospital mortality while enhancing liver function. Therefore, it has been recommended that all patients with CLD should be screened to have an early identification of those at risk of complications so that relevant interventions can be started[17].

In this article, we will be reviewing the prevalence, underlying mechanism and factors associated with malnutrition and the impact of malnutrition in cirrhosis in the setting of a developing country. This will pave the way for increased awareness regarding malnutrition in cirrhosis and its consequences to subsequently treat the patients accordingly for better outcomes.

MALNUTRITION IN SOUTH ASIA

While about 2 billion people in the world are suffering from various forms of malnutrition[18], the prevalence of malnutrition due to cirrhosis is estimated to range from 65%-100% globally[6,7]. In South Asia particularly, malnutrition is rampant with a high prevalence of low adult body mass index (BMI) (23.4% in men and 24.0% in women in 2014)[19]. In this region, Pakistan in particular has 45.3 million people (28 percent of the population) being victims of food insecurity according to the National Nutrition Survey Report 2011[20]. The global nutrition report 2020 has studied the progress of attaining 10 global nutrition targets of 2025 in 194 countries (which include anemia, low birth weight, exclusive breastfeeding, childhood stunting, childhood wasting, childhood overweight, adult obesity and adult diabetes, salt intake and raised blood pressure). Progress is not assessed at the country level for salt intake and blood pressure. Data collected for 8 of the 10 targets shows that Pakistan is on track for only 2 targets out of 8. In Pakistan, more than half of children grow up stunted or wasted. Pakistan is recognizing this issue as important, as is evident by it being 1 of the 25 countries to have revisited their nutrition budget, which has resulted in allocating increased funds towards nutrition thrice since 2015. Of this, the highest increase is towards nutrition sensitive allocation of social protection. The report highlights the importance for subnational level of financing for nutrition in areas like Balochistan in Pakistan and Rajhasthan in India. Pakistan and India comprise two of the three countries with the highest number of stunted children with 10.7 million stunted children in Pakistan and 25.5 million in India. This data reflects the severity of malnutrition in the region and can be extrapolated to the adult population of the South Asian countries[21].

LIVER DISEASES IN SOUTH ASIA

While most of the burden of liver cirrhosis in western countries is nonalcoholic fatty liver disease, most of it for South Asian countries is related to hepatitis B and C. However, increasing prevalence of nonalcoholic fatty liver disease is being seen in the South Asian population as well[22]. A survey conducted in 2015 showed the incidence of cirrhosis in South Asia to be 21.39% overall with 6.98% being hepatitis B virus related, 4.87% hepatitis C virus related, 4.84% alcohol related and 4.69% due to other etiologies[23]. The incidence of cirrhosis is estimated to be 23.6 per 100000 in Southeast Asia in 2017[24,25]. A study comparing liver resection patients between the East and the West of the world showed that patients from the East had worse Child Pugh scores and had a more advanced stage of cancer than the West[26]. A multicenter study from India revealed that at least a third of the patients presenting with CLD present at a very advanced stage of decompensated cirrhosis[27].

ETIOLOGY AND PATHOPHYSIOLOGY

The flowcharts in Figures 1 and 2 describe the pathophysiology of malnutrition as a consequence of cirrhosis and the multiple pathways that lead to it[28].

Metabolic changes occurring in CLD

Multiple changes in nutrient metabolism are observed in cirrhosis, which subsequently contributes to malnutrition. Around 14% to 40% of patients with cirrhosis

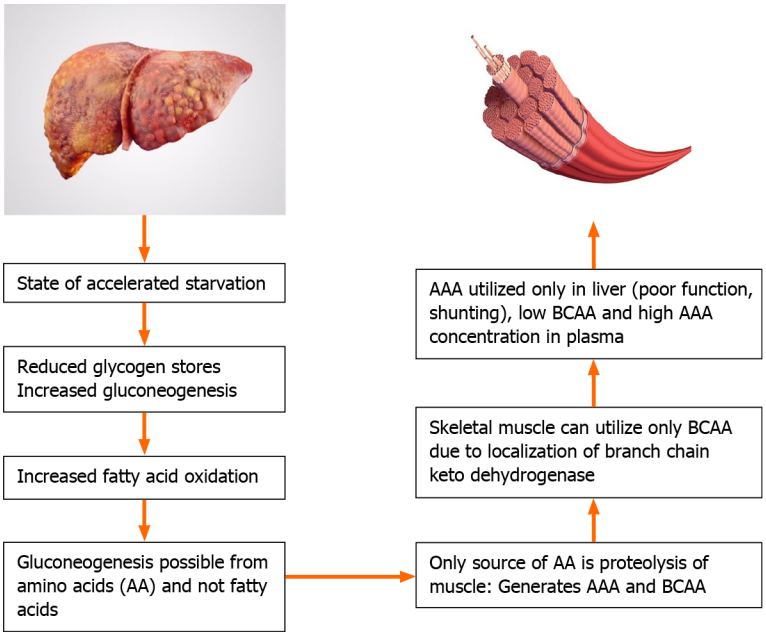

Figure 1 Pathophysiology of malnutrition as a consequence of cirrhosis and the multiple pathways that lead to it. AAA: Aromatic amino acids; BCAA: Branched chain amino acids.

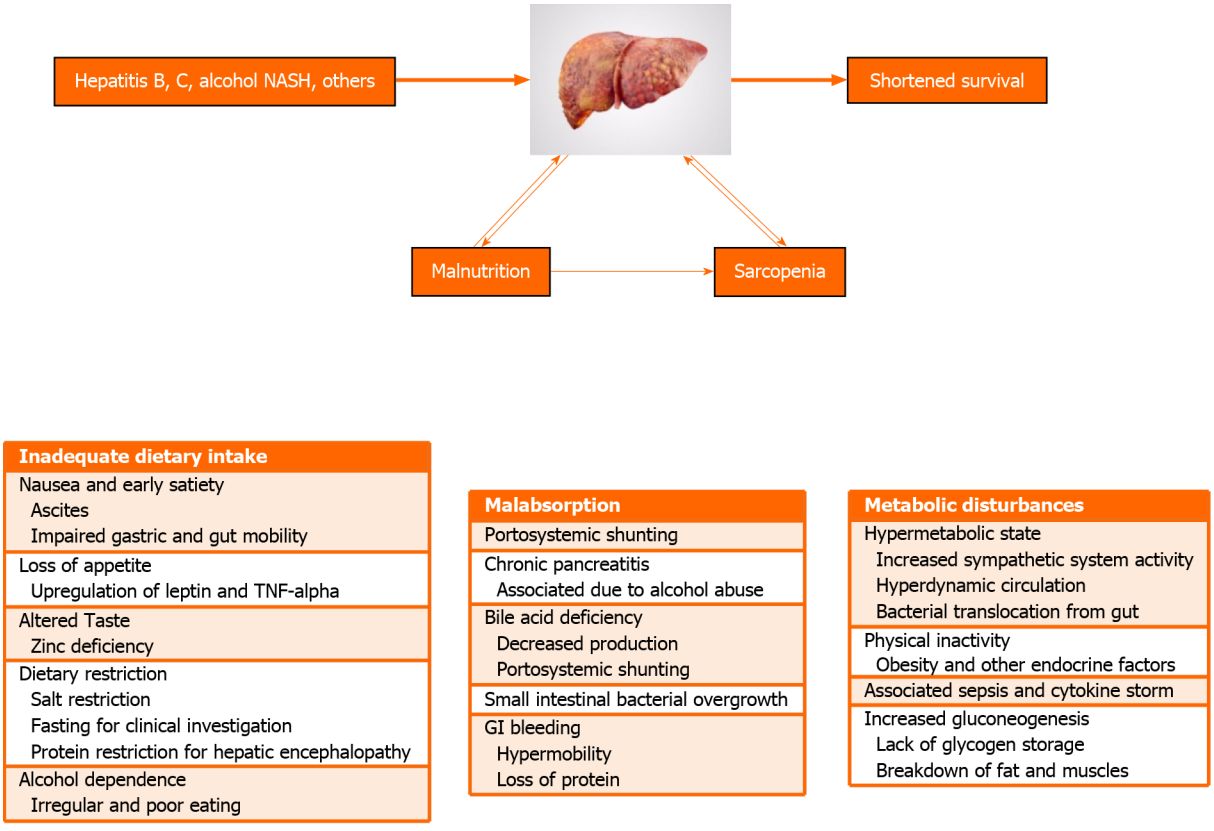

Figure 2 Pathophysiology of malnutrition as a consequence of cirrhosis and the multiple pathways that lead to it. GI: Gastrointestinal; NASH: Nonalcoholic steatohepatitis; TNF: Tumor necrosis factor.

have been diagnosed with type 2 diabetes mellitus due to glucose intolerance or end stream resistance to insulin seen in an estimated 70% of cirrhotic patients[29]. It has also been observed that the levels of hepatic and muscle glycogen are decreased, leading to a reduction in the availability of glucose as an energy substrate, with the body switching to the consumption of fats and proteins as alternative energy sources [30].

Regarding the rest energy expenditure (REE), a measure of resting metabolic rate and defined as the energy expended to sustain homeostasis at rest, conflicting results have been reported. Up to 34% of patients have been claimed to have a REE out of range by being about 120% higher, while some results show most of the patients with a REE within range[9,31,32]. Further measuring the calorie consumption, a cross-sectional study of 473 patients with cirrhosis found that 34% had hypermetabolism, measured by indirect calorimetry. The increase in REE was associated with lean body mass and an increase in beta-adrenergic activity but not with the severity or type of liver disease. Further studies have demonstrated that hypermetabolism can persist at least 1 year after liver transplant and correlates with a reduction in survival, also indicating prognosis[33]. Ascites can also contribute to an increase in REE due to which its removal results in a significant reduction in the REE when measured by indirect calorimetry. The mechanism underlying this observation is unclear[34].

The muscle plays a significant role in metabolism particularly of amino acids (AA). It also constitutes an important site for glutamine synthesis and gluconeogenesis. It should be noted that gluconeogenesis plays a direct role in the destruction of muscle tissue, with the body deriving protein substrates from the muscle for metabolism. This destruction of muscle subsequently causes a decrease in the synthesis of proteins and in its break down, also causing these patients to become protein deficient. Therefore, the most common complication of cirrhosis is a presentation of sarcopenia, observable in almost 60% of patients[35,36]. The ratio of branched chain AA (BCAA) to aromatic AA declines in CLD. A similar effect is seen in sepsis and major trauma. It is due to this change that malnourished individuals often develop hepatic encephalopathy (HE). This has established sarcopenia as an important risk factor for HE[36,37]. Further contributing to the increase in the consumption of AA by the muscles is the factor of any overnight fast that promotes an increase in ketogenesis and gluconeogenesis, even with lipids representing 75% of the calories expended during such a period. Healthy subjects after 3 d of fasting may also have a similar effect, but it occurs much slower when compared with cirrhotic patients[38].

There is an overall loss of protein from reduced synthesis of urea and hepatic proteins, reduced intestinal protein absorption and increased urinary nitrogen excretion[39]. The deficiency of AA and thus proteins gives rise to specifically a protein-calorie malnutrition (PCM). Each stage of CLD is affected by PCM with PCM being present in 65%-90% of patients with advanced disease. PCM also detrimentally causes systemic complications. There is an increased risk of HE and hepatorenal syndrome, while esophageal varices may often be seen as well. There is also a reduced regeneration capacity of the liver with a declining trend of liver function and an increased risk of surgical morbidity as well as mortality, all due to the protein and AA deficiency causing subsequent metabolic dysfunction[40,41].

Peripheral insulin resistance and β-cell dysfunction due to abnormal cell signaling pathways in cirrhotic patients leads to pancreatic dysfunction, giving rise to hepatogenous diabetes, steatorrhea and overall pancreatic disease[42,43]. The improper carbohydrate metabolism preferentially causes lipids to be oxidized instead for energy. This increases lipolysis and fatty acid oxidation, while an increase in the production of ketones may also occur. Therefore, reduced levels of plasma triglycerides, phospholipids, cholesterol, apoproteins and polyunsaturated fatty acids occurs in cirrhotic patients over time. These decreasing levels can be correlated with the severity of the liver disease, becoming an independent predictor of mortality in alcoholic cirrhosis. The respiratory quotient is also lowered when compared to non-diseased patients, also pointing towards poorer patient outcomes[44,45].

Deficiency of micronutrients

Micronutrient deficiency is common in cirrhosis, most observed in alcoholic disease. The most common deficiency seen is that of group B vitamins. Deficient levels of micronutrients are explained mainly by a decreased oral intake, malabsorption and declining hepatic reserves[46]. Fat-soluble vitamins such as Vitamin A, D, E and K have been seen to be deficient in alcoholic disease, along with steatorrhea, cholestasis and bile salt deficiency, negatively impacting patient outcomes[12,47]. Thiamine deficiency is also often found particularly in alcoholic disease as well as other forms of cirrhosis. Intake of alcohol causes a decline in the intestinal absorption and metabolization of thiamine. This increases the risk of developing Wernicke encephalopathy and Korsakoff dementia due to a decline in neurotransmitter synthesis, nucleic acid synthesis and synthesis of steroids and fatty acids[48]. Decreasing liver reserves cause a vitamin B12 and folic acid deficiency. While the levels of vitamin B12 in the serum may be increased, decreased tissue levels are observed. Anemia, glossitis and neurological symptoms may subsequently occur[12,49].

Retinol deficiency also occurs in cirrhosis and is related with decreased absorption and impaired hepatic mobilization due to hepatic stellate cell injury. This may result in dermatitis, night blindness, dyslipidemia or photophobia and increase the risk of hepatocellular carcinoma and other neoplastic disorders[50-52]. Vitamin A supplementation should be administered carefully because its excess causes hepatotoxicity [53]. Vitamin K deficiency results from declining hepatic reserves, increasing the risk of bleeding; while vitamin D deficiency can be caused from a reduced ingestion and absorption. Absorption is impaired in underexposure to ultraviolet light as well as in cholestatic disease or portal hypertension enteropathy[54]. Patients with abnormal liver functioning have deficient vitamin D levels as hydroxylation is required to synthesis calcidiol. A significant part of the liver loses function before calcidiol production is seen to be decreased. It is due to this that patient presentation with biochemical or histological evidence of osteomalacia is rare, unless a vitamin D deficiency is present concomitantly[55,56]. Therefore, decreasing vitamin D levels directly increase the risk of patient mortality where CLD is also present. It also contributes to failure of treatment of liver diseases especially in patients being treated for hepatitis C [57].

Other deficiencies present in patients with alcoholic and nonalcoholic liver disease include that of zinc and selenium. Their supplementation has improved CLD outcomes[58]. Zinc deficiency is caused by a reduction in intake and systemic assimilation. Treatment with diuretics is also a contributor. The levels of ammonia rise in the circulation, which causes dysregulation of hepatocyte functioning and an increased risk of HE. Anorexia can also be caused with this deficiency, along with the dysfunction of the immune system[38,59]. Magnesium deficiency is also noted with alcohol consumption causing not just folate deficiency but also contributing to decreasing magnesium levels. Magnesium deficiency was observed in 30% to 80% of alcoholics. Dysfunctional magnesium transport and homeostasis in vital organs such as the brain, skeletal muscle, heart and liver can result due to alcohol intake. Often magnesuria can also occur[60]. The subsequent magnesium deficiency can cause dysgeusia and contribute to minimal HE, which further decreases the patients' intakes and worsens outcomes. Clinical improvement is therefore noted with magnesium supplementation [54]. Table 1 summarizes the effects of each micronutrient deficiency caused by liver disease.

NUTRITIONAL ASSESSMENT IN CLD

A nutritional assessment determines both the macro and micronutrient state of a patient. It is necessary to identify nutritional risks that affect morbidity and mortality and helps develop a targeted therapy to benefit the patient.

Malnutrition is more evident in decompensated compared to compensated cirrhosis. The 2019 European Association for the Study of the Liver guidelines recommend a screening of all advanced CLD patients for malnutrition (undernutrition), as it is a recognized complication of liver cirrhosis. Criteria for patients at high risk of malnutrition are: (1) a BMI < 18.5 kg/m^2; and (2) advanced decompensated cirrhosis (Child-Pugh C patients)[57].

Thus, an assessment and diagnosis of malnutrition should be done thoroughly starting with a detailed history and physical examination. A thorough history can help identify poor intake, eating habits, loss of appetite, weight changes and any episodes of diarrhea and malabsorption as a potential source of malnutrition in a patient. Calculation of the patient's BMI and determination of the Child Pugh Score for severity of disease is also important with the history, as a direct correlation exists between severity of disease and malnutrition. A physical examination also provides insight about any macro and micronutrient deficiencies. Specific physical findings, such as pallor in iron deficiency anemia, are very important to observe and record[9, 61].

Skeletal muscle loss (sarcopenia) has been established as the most common complication of cirrhosis[59]. It is associated with severe outcomes in patients with liver cirrhosis and is considered useful for the global assessment of patients with CLD, therefore a physical examination for it is important[62]. A multitude of different standardized nutritional status assessment tools also exist that can be used for examination.

Subjective global assessment scale

This includes components of history and physical exam and does not rely on any lab

Table 1 Effects of each micronutrient deficiency caused by liver disease

Micronutrient	Effect caused by deficiency in liver disease
Vitamin A	Dermatitis, night blindness, dyslipidemia, photophobia, increased risk of neoplasia
Vitamin B1	Wernicke encephalopathy and Korsakoff dementia
Vitamin B9	Dementia
Vitamin B12	Anemia, glossitis and neurological symptoms (numbness, muscle weakness and ataxia)
Vitamin D	Rare osteomalacia, increased risk of mortality
Vitamin E	Reduced antioxidation
Vitamin K	Increased risk of bleeding
Zinc	Hepatocyte dysfunction, increased risk of hepatic encephalopathy
Magnesium	Dysgeusia, increased risk of hepatic encephalopathy

parameters[63]. Weight changes, dietary intake changes, presence of gastrointestinal symptoms, functional capacity and the metabolic demand associated with the disease state are the historical components, while the physical examination components include the presence of edema, ascites, muscle wasting and subcutaneous fat loss. The scale classifies patients from well-nourished to severely malnourished[64]. However, this scale underestimates the presence of sarcopenia and is not a good outcomes predictor[65].

Royal free hospital subjective global assessment

This is a modified version of the subjective global assessment and includes some objective variables as well like anthropometry and gender of the patient[66].

Assessment of sarcopenia

Computed tomography scan: Computed tomography scan can be utilized to calculate the cross-sectional area of muscles at the L3 vertebral level. The psoas, paraspinal and abdominal wall muscles are used to calculate their skeletal muscle area. The skeletal muscle index is calculated by dividing the skeletal muscle area by the patient height. A value of the skeletal muscle index less than 50 for men and less than 39 for women is considered to meet the criteria for sarcopenia. Computed tomography scan is an expensive tool and not routinely performed but if done for screening of hepatocellular carcinoma, evaluation for liver transplant or vascular shunt can be utilized for assessment of sarcopenia and calculation of the skeletal muscle index[67,68].

Anthropometry: Anthropometry as a screening tool for nutritional assessment can prove to be important in resource limited settings. The easiest and least technically challenging is the measure of the BMI using anthropometric measurements. However, the use of BMI as a nutritional assessment tool in patients with advanced liver disease is limited as patients are often in a volume overload state, which affects their body weight[9]. A corrected BMI can be calculated instead after paracentesis of ascitic fluid or by using dry body weight[65,69]. Mid arm muscle circumference is an important alternative measurement and is not reflective of the overall body volume status. Mid arm muscle circumference shows good correlation with body cell mass measurement, which is a proven marker for PCM in CLD patients. Mid arm muscle circumference is related to mortality risk in CLD patients and hence holds prognostic value as well[70]. Skin fold thickness measurement can also be used as a nutritional status assessment tool. Thickness can be measured at the triceps, biceps, subscapular and supra-iliac areas and is representative of fat reserve. It recognizes malnutrition earlier than the BMI[61].

Dual-energy X-ray absorptiometry scan: Dual-energy X-ray absorptiometry is a radiological modality that is used to measure bone mass, fat mass and fat free mass, which is representative of lean muscle mass[71]. Its use is limited in cirrhotic patients as fat free mass can also include water mass.

Bioelectrical impedance analysis

Bioelectrical impedance analysis is a low cost, easy to administer screening tool. Alternating current is applied using two electrodes, and the impedance recorded. This

can be performed at the bedside. Bioelectrical impedance analysis is used to estimate total body water, fat mass and hence fat free mass. However, bioelectrical impedance analysis was shown to underestimate malnutrition status as compared to the PCM score in a study from Pakistan. PCM score is thus calculated using anthropometric measurements and some lab parameters[40].

Liver specific tools

A few specific nutrition screening tools have been developed for liver disease patients and these include the Royal Free Hospital-Nutrition Prioritizing Tool and the Liver Disease Undernutrition Screening Tool. The Royal Free Hospital-Nutrition Prioritizing Tool score includes components involving weight loss, volume overload, BMI and reduced oral intake. Patients are then classified as being at low, moderate or high risk for malnutrition[72]. The Liver Disease Undernutrition Screening Tool includes components of oral intake, weight loss, loss of subcutaneous fat or muscle mass, volume overload and functional status[73,74]. These tools have not been studied in detail in the South Asian Population.

Dietary assessment

A dietary interview with the patient provides important insight to the patient's nutritional status. It recognizes barriers to nutritional intake and any deficiencies that need to be addressed. A thorough evaluation includes number of meals eaten, time between each meal, protein and fluid intake and total calories consumed as well as any nausea, vomiting, diarrhea or constipation. A thorough evaluation takes time and requires trained staff. Additionally, patient factors such as poor recall and lack of cooperation also play a role. A 3 d food diary is the best method for a dietary assessment, but it requires patient cooperation as well as patients being capable of writing and maintaining, which may be difficult in the mostly uneducated population of South Asia. Therefore, repeated short-term 24 h recalls are recommended and may prove to be important in this population[75,76]. Patients should at least be asked if their food intake has changed and by how much over what period of time.

In a study evaluating reasons for food aversion in a Pakistani population, it was concluded that factors such as advice from family doctor, close friends and relatives and alternative medicine practices influenced dietary restrictions in patients with advanced liver disease[77]. Lack of awareness about proper dietary intake was prevalent in both educated and uneducated populations with CLD in this population[78]. Table 2 summarizes the methods of nutritional assessment.

TREATMENT

General caloric and protein intake

A multidisciplinary approach for the treatment of malnutrition in liver cirrhosis is important for improving patient survival and long-term outcomes[79]. Nutritional counseling should be included in the patient management. According to the 2020 European Society for Clinical Nutrition and Metabolism guidelines, patients of CLD and a sedentary lifestyle should consume a daily calorie intake of 1.3 × REE (Resting Energy Expenditure)[80], where indirect calorimetry has been used to calculate the REE.

Patients with cirrhosis are recommended to consume 3 to 5 meals per day ensuring there are short starvation periods in between. A late evening carbohydrate snack has been shown to improve protein metabolism in cirrhosis by affecting nitrogen balance [81-83]. Patients should have an energy intake of 30-35 kcal/kg per day and a protein intake of 1.2-1.5 g/kg per day, whereas non-malnourished patients are recommended to intake 1.2g/kg per day of protein, and malnourished and sarcopenic patients should consume 1.5 g/kg per day of protein. However, a higher caloric intake is recommended for patients with acute decompensation or conditions with increased energy expenditure. REE should be calculated whenever possible[80]. In patients with HE, there is no recommendation for protein restriction[84-86].

Use of BCAA

In patients who are protein intolerant (develop HE with ingestion of mixed proteins), consumption of BCAA (at the rate of 0.25 g/kg per day) or vegetable derived proteins is recommended[80,87].

Table 2 Nutritional assessment methods for chronic liver disease

Nutritional assessment methods	Description
Subjective global assessment (SGA)	Uses components of history and physical exam
Royal free hospital subjective global assessment (RFH-SGA)	Modified version of SGA, includes anthropometry and gender
Sarcopenia assessment	
Computed tomography scan	Used to calculate skeletal muscle area and the skeletal muscle index at the L3 vertebral level
Anthropometry	Mid arm muscle circumference, skin fold thickness, BMI calculation
Dual-energy X-ray absorptiometry	A radiological modality that is used to measure bone mass, fat mass and fat free mass
Bioelectrical impedance analysis	Alternating current is used to estimate total body water, fat mass and fat free mass
Liver specific tools	
Royal Free Hospital-Nutrition Prioritizing Tool	Includes weight loss, volume overload, BMI, and reduced oral intake, classifies patients according to risk of malnutrition
Liver Disease Undernutrition Screening Tool (LDUST)	The LDUST includes components of oral intake, weight loss, loss of subcutaneous fat or muscle mass, volume overload, and functional status
Dietary assessment	Includes dietary review, 3 d food diary, 24 h diet recall

BMI: Body mass index; SGA: Subjective global assessment.

Prescription of long-term BCAA supplement is recommended for patients with advance cirrhosis. Use of BCAA enriched formula has been shown to improve survival in patients with alcoholic steatohepatitis and cirrhosis with an improved mental state in protein intolerant cirrhotic patients with HE[6,88-91]. However, the cost of BCAA supplements needs to be considered when prescribing them to patients.

Micronutrients

In cirrhotic patients, any micronutrient deficiency should be corrected. Micronutrient deficiencies may include both water soluble (especially thiamine) and lipid soluble deficiencies[92,93]. While there are no proven therapeutic effects directly by correcting micronutrient deficiencies, supplementation of zinc and vitamin A may improve dysgeusia and hence nutritional intake and affect the nutritional status indirectly[93,94]. While zinc deficiency has been associated with HE, supplementation has not shown any significant therapeutic effect on the encephalopathy[95-99]. Practically, a liberal supplementation is recommended in the first 2 wk of therapy, as a diagnosis of a deficiency would be costly and take time[80].

If a low sodium diet is prescribed in the scenario of ascites, the increased risk of lower intake should be considered due to the non-palatability of such a diet[100,101]. Ensuring adequate nutrition intake is important with sodium restriction.

Enteral and parenteral nutrition

If patients are unable to tolerate diet orally or if the nutritional target is unmet with oral nutrition, enteral nutrition (EN) is recommended. An adequate nutrient intake is the primary goal in cirrhotic patients. EN has been proven to be beneficial in survival and liver function[84,89]. However, with EN a risk of overfeeding exists, as the energy intake can exceed the recommended intake.

If the patient is unable to maintain oral and EN, parenteral nutrition (PN) should be used. When administering parenteral nutrition, patients are more prone to infection and sepsis through intravenous lines[25].

CONCLUSION

Malnutrition in liver cirrhosis is a serious problem in South Asia where the etiology differs from the Western population. As malnutrition is generally highly prevalent in the region, it causes an impact on patients with liver cirrhosis. Urgent attention to address malnutrition is needed to improve patient outcomes. Emphasis on assessment for nutritional status at the initial visit with recording of vital signs is needed.

Simultaneously, treating physicians need to be made aware of the misconceptions surrounding nutritional restrictions in cirrhosis so that patient education is done correctly based on proper scientific evidence.

Abstract

Metabolic associated fatty liver disease (MAFLD), formerly named "nonalcoholic fatty liver disease" occurs in about one-third of the general population of developed countries worldwide and behaves as a major morbidity and mortality risk factor for major causes of death, such as cardio-vascular, digestive, metabolic, neoplastic and neuro-degenerative diseases. However, progression of MAFLD and its associated systemic complications occur almost invariably in patients who experience the additional burden of intrahepatic and/or systemic inflammation, which acts as disease accelerator. Our review is focused on the new knowledge about the brain-gut-liver axis in the context of metabolic dysregulations associated with fatty liver, where insulin resistance has been assumed to play an important role. Special emphasis has been given to digital imaging studies and in particular to positron emission tomography, as it represents a unique opportunity for the noninvasive in vivo study of tissue metabolism. An exhaustive revision of targeted animal models is also provided in order to clarify what the available preclinical evidence suggests for the causal interactions between fatty liver, dysregulated endogenous glucose production and insulin resistance.

Key Words: Metabolic associated fatty liver disease; Nonalcoholic fatty liver disease; Endogenous glucose production; Insulin resistance; Steatohepatitis; Inflammation

Core Tip: From studies using tissue-targeted animal models, it emerges that neither insulin resistance per se induces hepatic steatosis, nor steatosis induces whole-body insulin resistance. However, it is evident that reducing inflammation has several beneficial effects both at the hepatic and whole-body level. In fact, either hepatic or systemic inflammation act as major throttle of progressive liver and systemic diseases.

INTRODUCTION

In recent years, nonalcoholic fatty liver disease (NAFLD) has become the leading cause of chronic liver disease worldwide, and the endpoint complication of nonalcoholic steatohepatitis (NASH), a major indication for liver transplantation[1]. The magnitude of the problem is highlighted by a recent model that estimated a 178% increase in deaths caused by liver disease related to NASH by 2030[2]. Among noncirrhotic NAFLD patients, the leading cause of death is cardiovascular disease[3]. Fatty liver associates with the metabolic syndrome and predisposes to all diseases (cardiovascular, digestive, metabolic, neoplastic and neurodegenerative) that are major causes of death in developed countries. As metabolic dysfunctions play a major role in the pathogenesis of fatty liver, a panel of experts has recently proposed to change the term "NAFLD," and its definition, to metabolic associated fatty liver disease (MAFLD)[4,5] in an attempt to identify clinical criteria to give a "positive" diagnosis of the disease. Furthermore, the definition of "nonalcoholic" was misleading because it is virtually impossible to exclude the endogenous production of alcohol by an intestinal autobrewery[6]. According to the new consensus, MAFLD means the evidence of hepatic steatosis accompanied either by type 2 diabetes (T2D) or overweight/obese or in normal weight/lean subjects by at least two metabolic risk abnormalities.

There are many complex physio-pathologic connections within the brain, gut, and liver (BGL) axis (Figure 1). While MAFLD per se contributes to an increased risk of neurodegeneration[7,8], one well known alteration of this axis is linked to hepatic encephalopathy (HE) a debilitating neuropsychiatric condition often associated with acute liver failure and/or cirrhosis[9]. However, the pathophysiologic mechanisms and treatment options involved in HE are much different from those involved with insulin resistance in MAFLD. Consistently, a recent study demonstrated that the nonabsorbable antibiotic rifaximin, a standard of care for HE had no effect on improving insulin resistance, adipose tissue inflammation, or plasma lipopolysaccharide (LPS) levels following an oral lipid test in obese subjects[10].

Our review is focused on the early pathophysiology of BGL in the context of insulin resistance and specifically addresses two pillars of hepatic insulin resistance, namely dysregulated endogenous glucose production and MAFLD. Of note, highly selected patients with MAFLD without any features of the metabolic syndrome, have altered endogenous glucose production[11]. Specific emphasis will be given to novel findings from imaging studies, since imaging provides noninvasive in vivo "snapshots" of the tissues of interest. We and others have highlighted that there is an imperative need of noninvasive techniques, including imaging to identify effective biomarkers and early prognostic patterns of MAFLD[12,13]. Finally, we discuss new insights that can be gained from targeted animal models in which interventions such as the knockout (KO) of the insulin receptor or the GLUT4 glucose transporter in different tissues, or the primary upregulation of lipid synthesis help to elucidate the effect of insulin resistance on hepatic steatosis and *vice versa*.

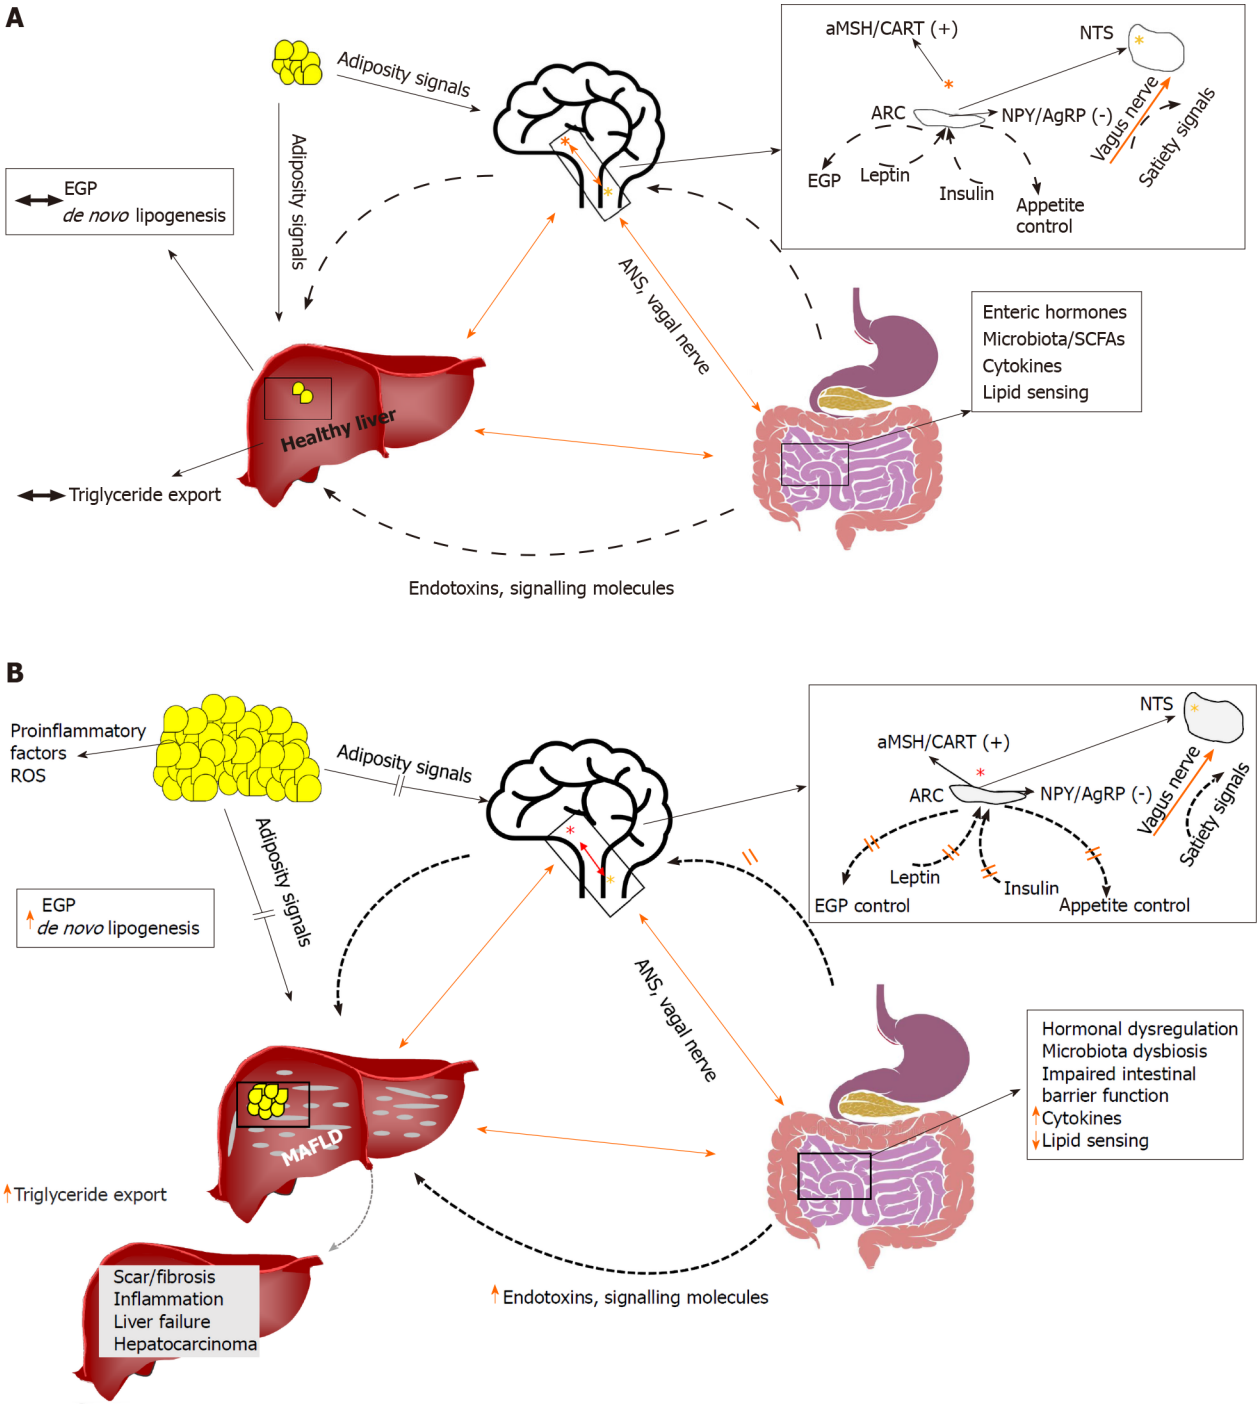

Figure 1 A summary of some interactions (A) of the brain, liver, and gut in health, and (B) in the context of insulin resistance. Several lines of research have shown that the brain may directly control endogenous glucose production. Recent evidence suggests that the brain may also control the rate of lipid turnover in the liver, thus promoting or defending from metabolic associated fatty liver disease (MAFLD). The liver is anatomically in close relationship to the gut, which represents the first line of defense against gut-derived endotoxins and signaling molecules (*e.g.*, short-chain fatty acids). Altered gut microbiota and/or a leaky gut may contribute directly to establishment of MAFLD. The gut also produces substantial amounts of hormones that, through endocrine signals, act on the brain and the liver. The autonomic nervous system and the vagus nerve constitute the basis of the brain, gut and liver axis interconnections. Orange line: liver–brain–gut neural arc; dotted line: other ways of communication (*e.g.*, hormonal, adipocytokines). Red star denotes the hypothalamic nuclei; yellow star denotes the nucleus tractus solitaries. αMSH: α-melanocyte-stimulating hormone; AgRP: Agouti-related protein; ANS: Autonomous nervous system; ARC: Arcuate nucleus; CART: Cocaine- and amphetamine-regulated transcript; EGP: Endogenous glucose production; MAFLD: Metabolic associated fatty liver disease; NPY: Neuropeptide Y; NTS: Nucleus tractus solitarius; ROS: Reactive oxygen species; SCF: Short-chain fatty acid.

MAFLD-INSULIN RESISTANCE-INFLAMMATION: A VICIOUS CIRCLE

Whereas the association between MAFLD and insulin resistance is well established, there is debate on their cause-effect relationships. Thus, it is not clear whether systemic insulin resistance induces the accumulation of lipids in the liver[11] or if hepatic

steatosis is a major determinant of systemic insulin resistance[14]. In any case, once hepatic steatosis is established, other typical characteristics are observed such as insulin resistance, insufficient suppression of endogenous glucose production (EGP), increased insulin secretion, decreased whole-body glucose disposal, increased lipolysis with consequent enhanced lipid oxidation[11], decreased insulin clearance[15], and chronic oxidative stress[16]. Both insulin resistance and MAFLD are characterized by elevated circulating inflammatory markers[17,18]. The interplay between insulin resistance, ectopic fat accumulation in the liver, and inflammation is characterized by mutual positive regulation, *i.e.* a vicious circle[19]. On one hand, ectopic fat accumulation in the liver leads to lipotoxicity, low-grade inflammation and insulin resistance in the liver[19]. On the other hand, insulin resistance enhances lipotoxicity through unsuppressed lipolysis[19]. Finally, proinflammatory markers such as tumor necrosis factor (TNF)-α and interleukin (IL)-6, which are typically increased in conditions of insulin resistance may further aggravate both insulin resistance and MAFLD[19].

In MAFLD patients, intrahepatic inflammation is the most important prognostic determinant of liver disease progression and systemic inflammatory markers correlate with hepatic inflammation[20]. A plausible hypothesis holds that in the context of MAFLD, inflammation (hepatic and/or systemic) acts as major disease accelerator[13].

BRAIN-LIVER AND BLG AXIS

Control of EGP

Preclinical studies have shown that insulin acting directly on the brain may affect EGP. More specifically, Obici *et al*[21] have shown that an intracerebroventricular (ICV) injection of insulin suppresses EGP in rats. Human evidence is slowly accumulating, and recent clinical studies have confirmed the presence of a "brain-liver axis". More specifically, intranasal insulin (INI) administration during the euglycemic hyperinsulinemic clamp was shown to suppress EGP in lean, but not in overweight, individuals[22]. Under the same euglycemic hyper-insulinemic conditions, brain imaging with ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET) has shown that brain glucose uptake (BGU) correlates positively with EGP in morbidly obese individuals, but not in healthy lean individuals[23]. On the contrary, when INI was given during fasting conditions EGP was not affected, and similarly no correlation was found between BGU and EGP in the post-absorptive state. Taken together, the data suggest that under conditions of high systemic insulin levels like those typically seen in the postprandial state, the brain may directly control (*i.e.* suppress) EGP, but the control is lost with increased adiposity.

Other lines of research also suggest that the brain may control EGP. Intracerebroventricular administration of brain-derived neurotrophic factor (BDNF) lowers blood glucose levels and suppresses hepatic glucose production (HGP) and hyperglucagonemia[24]. Of note, leptin activates BDNF-expressing hypothalamic neurons, which in turn stimulate BDNF synthesis[25]. Also, Bercik *et al*[26] have shown that the intestinal microbiota affects both the central levels of BDNF and behavior in mice.

Lipid delivery into the upper intestine has also been shown to suppress EGP through central action. More specifically, lipid delivery leads to long chain fatty acyl-CoA production that suppresses EGP, and the effect is abolished either after coadministration of the anesthetic tetracaine, by gut vagal deafferentation, or by hepatic vagotomy[27]. Wang and colleagues further demonstrated that in rats with insulin resistance induced by a high-fat diet (HFD), upper intestine lipid delivery failed to suppress EGP, suggesting a potential mechanism for dysregulated EGP in the context of insulin resistance. Along the same line, cholecystokinin (CCK) has also been reported to trigger gut-brain-liver axis control of HGP, and that HFD impaired CCK-induced afferent vagal signals to suppress HGP[28].

Enteric hormones (enteroendocrine system)

The gastrointestinal tract is a major producer of hormones, among which GLP-1, ghrelin, cholecystokinin are particularly involved in the BGL axis. GLP-1, an incretin hormone secreted from the L cells of the intestine in response to a meal, exhibits high fasting levels in subjects with insulin resistance and in whom GLP-1 does not increase sufficiently in response to a meal[29]. GLP-1-receptor mRNA has been found both in the hepatic portal region and in neurons[30]. Preclinical studies have suggested that GLP-1 may act on the liver through the nerve endings of the intestinal wall. Insulin clamp studies in GLP-1 receptor knockout mice showed a defective suppression of EGP[31], and the intraportal GLP-1 injection in rats increased the firing rate of the

hepatic afferent of the vagus nerve[32]. In healthy individuals under conditions of pancreatic clamping (*i.e.* with stable insulin and glucagon concentrations), GLP-1 inhibits EGP, and the effect is mediated either through direct GLP-1 action on the liver or through neuron-mediated inhibition[33]. GLP-1 also contributes to suppression of appetite[34]. Thus, GLP-1 may play an important role in the pathophysiology of MAFLD; and in preliminary clinical studies, exenatide, a GLP-1 receptor agonist, was shown to decrease hepatic fat content and liver enzymes[35], and to improve liver histology[36]. Similarly, liraglutide was shown to improve NASH[37].

Ghrelin is a hormone that is mainly derived from the stomach and duodenum, and its main function is to control food intake by inducing appetite. Ghrelin has recently been shown to participate in the BGL axis, as under conditions of pancreatic clamping, intraduodenal ghrelin infusion resulted in increased HGP through neural-mediated action, as administration of ghrelin, while inhibiting the vagal afferent neurotransmission, abolished the ghrelin-induced increase of HGP[38]. Similarly, vagotomy or use of N-Methyl-D-aspartate blockers abolished the ghrelin effects on HGP. Ghrelin has also been shown to block the action of cholecystokinin. The ghrelin nutrient-sensitive effects on the gut may thus be attributed to its inhibition of cholecystokinin.

CCK is released from intestinal endocrine cells during feeding, and it binds to CCK-A receptors on gut vagal fibers that project the signal to the brainstem, causing termination of the meal[39]. Insulin and CCK have complimentary actions in inducing satiety, as ICV administration of insulin enhances the satiety effect of CCK[40], whereas fasting decreases it[41]. Similar complementary effects with CCK have been proposed for leptin, as ob/ob mice and Zucker rats have been shown to be relatively insensitive to the satiety effects of CCK[42].

Adipocytokine signaling

Leptin is an adipokine, or adipocytokine with structural similarities with the cytokines of the type I cytokine family. Circulating leptin levels are directly related to expanded fat mass, but obesity is characterized by leptin resistance, and leptin resistance consists at least partially in a decreased capacity for leptin transport into the brain[43]. Even though secreted by adipose tissue, the main site of action of leptin is the central nervous system (CNS), and particularly in the hypothalamic nuclei. Leptin and insulin central actions are largely interconnected; both act on the arcuate nucleus to suppress the expression of the orexigenic peptides neuropeptide Y and agouti-related protein. Their action on other neurons is different and more complex, as leptin stimulates while insulin inhibits proopiomelanocortin neurons[44]. Apart from controlling EGP, appetite (and thus body weight), leptin is also implicated in MAFLD as it has been demonstrated that leptin deficient ob/ob mice have marked steatosis[45]. A recent preclinical study has shown that CNS-leptin signaling promotes hepatic triglyceride export and decreases de novo lipogenesis[46]; the authors propose intranasal leptin administration as potential new treatment of MAFLD.

Vagus nerve and the enteric nervous system

As already highlighted, the tenth cranial, or vagus nerve, plays a pivotal role in the BGL axis communications, which are summarized in Figure 1. The enteric nervous system, also named the "second brain" or "brain in the gut" is considered as one of the autonomic nervous system divisions and consists of approximately 500 million neurons which produce a variety of neurotransmitters including acetylcholine, adrenaline, VIP and serotonin (5-HT). It has been shown that 5-HT promotes lipid accumulation in hepatocytes in vitro[47]. In line with that, short-term treatment with tryptophan inhibitors prevented the formation of 5-HT, which is a metabolite of tryptophan, and inhibited the development of hepatic steatosis in mice fed with a high carbohydrate diet without increasing the energy expenditure in adipose tissues[48]. In addition, the same study showed that inhibition of gut-derived serotonin ameliorated hepatic steatosis. Taken together, the data suggest that gut-derived serotonin is a regulator of hepatic lipid metabolism through a gut-liver axis. On the other hand, the gut microbiota regulates both the 5-HT synthesis and its release from the enteroendocrine cells, and 5-HT plays its role on the CNS as one of the most important central neurotransmitters in the regulation of mood, sleep, and pain[49]. Consistently, modification of central 5-HT levels was shown by Pagoto *et al*[50] to affect food preferences. Following acute tryptophan depletion (transient decrease of both peripheral and central 5-HT levels), overweight individuals increased their sweet calorie intake and preferred sweet foods. Of significant note is that most tryptophan was converted to kynurenine rather than to 5-HT, and under conditions of inflammation, the rate-limiting enzyme for this transformation could be upregulated. As kynurenine and 5-HT compete to cross the blood-brain barrier through the same

transporter, it follows that inflammation-associated changes in kynurenine levels could impact on central 5-HT concentrations[51,52]. Thus, this is another pathway through which inflammation could decrease central 5-HT levels to prompt affected patients to increase their intake of sweets.

Gut microbiota

An altered gut microbiota composition is associated with obesity[53], and in obese humans specific microbiota compositions may be associated with impaired glucose control[54]. It is well established that a diet rich in fibers is healthy, with improvement of insulin sensitivity and glucose tolerance. The beneficial effects of increased fiber consumption are hypothesized to be mediated by the production of the short-chain fatty acids (SCFAs) acetate, propionate, and butyrate after fermentation of the fibers by the gut microbiota. SCFAs do not act just as substrate for colonocytes and enterocytes [55], but also as signaling molecules. For instance, SCFAs can stimulate the secretion of GLP-1 and peptide YY, and decrease the secretion of ghrelin[56-58]. Propionate and butyrate have been shown to activate intestinal gluconeogenesis (IGN), and interestingly, increased IGN was shown to have beneficial effects on glucose homeostasis even if the resulting increase in EGP is a key feature of T2D[59]. In the case of propionate, the effect occurs *via* a gut-brain neural circuit[60], as it was shown that after denervation of the periportal nervous system, propionate feeding no longer affected IGN. Even though butyrate feeding (which has a direct effect on IGN shown by gene expression *via* a cAMP-dependent mechanism) could still enhance IGN, both the beneficial effects of IGN and portal glucose sensing were lost[60].

Decreased levels of the SCFA butyrate have also been associated with tight-junction abnormalities and increased intestinal permeability[61], which have been implicated in MAFLD pathogenesis and progression. Other microbiota-derived molecules might play also an important role. Deficiency of the macronutrient choline, which is implicated in the prevention of liver steatosis by promoting the assembly and excretion of very-low-density lipoprotein[62], has been observed in NAFLD patients and was associated with abundance of specific bacteria (Erysipelotrichia taxa), which are able to metabolize choline to trimethylamine (TMA) and its oxidized form TMAO, with the net effect of reducing choline bioavailability and increasing that of steatogenic TMAO[63].

Amino acid metabolism is also important. The branched-chain amino acids (BCAAs) valine, isoleucine and leucine, contribute to insulin resistance and hepatic steatosis, and can be synthesized and metabolized by specific gut bacteria. An intervention study in rats showed that the dietary administration of BCAA reduced the accumulation of liver fat through the modification of gut microbiota[64]. The effect occurred through the gut-brain axis, accompanied by microbiota-mediated production of the SCFA acetate, which activated the parasympathetic nervous system[65]. Other amino acids, such as tryptophan, phenylalanine, and tyrosine can be metabolized by gut bacteria that produce derivates with effects on metabolism and inflammation. For example, the essential amino acid tryptophan is the precursor of serotonin and can be converted into its indole intermediate, which in turn can reduce hepatic lipogenesis and inflammation[66].

Furthermore, the bacterial-derived endotoxin lipopolysaccharide (LPS) might contribute to local and systemic inflammation by the activation of the toll-like receptor 4 pathway. Increased abundance of endotoxin-producing bacterial strains has been found in the gut of obese patients compared with controls[67], suggesting its potential implication in the development of MAFLD and its progression to NASH, with the involvement of CNS dysfunction and inflammation.

Dietary patterns are able to modulate brain lipid composition and function[68] as well as hepatic lipid content[69]. It has been shown that unhealthy diets rich in saturated or monounsaturated fatty acids have unfavorable effects on gut microbiota composition[70], promoting an increase of LPS-producing bacteria and reduction of SCFAs leading to a systemic proinflammatory state occurring through the BGL axis [71].

Finally, gut microbiota-dependent regulation of neurotransmitters interacts with vagal afferent pathways to affect liver metabolism through the gut-brain axis. Gut bacteria can modify serotonin release[72], which has a brain-dependent effect on gastrointestinal motility and secretion, and energy expenditure. It promotes liver steatosis by local endocrine mechanisms[73], and modulates the production of several other molecules, such as gamma-aminobutyric acid, acetylcholine, histamine, norepinephrine, dopamine, and endocannabinoids that affect glucose and lipid metabolism and inflammation, as deeply reviewed elsewhere[74].

A useful experimental model for studying the effects of specific microbiota on host metabolism is provided by germ-free mice, which are resistant to high-fat diet-induced obesity[75] and protected from MAFLD. In a seminal study Le Roy *et al*[76] showed that germ-free mice that received fecal transplantation from C57BL/6J mice with HFD-induced hyperglycemia and increased plasma concentrations of proinflammatory cytokines, developed hepatic steatosis. On the contrary, germ-free mice that received stool from C57BL/6J mice that were non-responders to HFD and without hyperglycemia and increased proinflammatory cytokines, did not develop hepatic steatosis. Moreover, the gut microbiota controlling the balance between proinflammatory and anti-inflammatory signals may contribute to the progression to NASH. Consistently, short-term treatment of patients with steatosis and NASH with rifaximin led to an improvement of liver enzymes levels[77]. The effect was thought to have been caused by a change of the gut microbiota composition leading to a direct reduction of leaky gut, and consequent improvement of hepatic inflammation, rather than an effect on insulin sensitivity. It was recently demonstrated by Finlin *et al*[10] that rifaximin did not improve insulin resistance.

Bile acids

Bile acids (BAs) are synthesized in the liver from cholesterol, stored in the gallbladder, and secreted after gallbladder emptying into the intestinal lumen upon food ingestion. As BAs move along the intestinal lumen, they contribute to the absorption of lipids and lipophilic vitamins. The majority of BAs (~95%) are re-absorbed by enterocytes and then transferred back to the liver where they are reused (*i.e.* enterohepatic circulation). BA are transformed to secondary BAs by the gut microbiota[78] and only in a small amount reach the systemic circulation and increases of plasma BA levels were reported after meals, suggesting that BAs could be a postprandial systemic signal [79].

In the last decades, important new insights have been gained, proposing BAs as important determinants of glucose homeostasis. Early studies showed that KO of the BA farnesoid X receptor (FXR) induced insulin resistance, whereas administration of BA agonists enhanced insulin sensitivity[80]. BA receptors are also present in the CNS, and it is now believed that the BA signal reaches the brain through three different pathways, one direct and two indirect[81]. The direct pathway consists in activating central FXR and Takeda G protein-coupled receptor (TGR5R) signaling after crossing the blood-brain barrier. Indirect activation of intestinal FXR and TGR5R results in the release of FGF19 and GLP-1, both of which can signal to the CNS. The pathways have been extensively reviewed by Mertens *et al*[81]. Even though major pathways of communication of the BGL axis through BAs were identified, their importance in pathophysiology warrants further investigation.

Nutrient intake: Role of fructose

In Western societies, increased consumption of fructose began in the 1970s after the introduction of high-fructose corn syrup as a sweetener in soft drinks. Since then, the prevalence of obesity and T2D have substantially increased and a link between high fructose consumption and MAFLD has been established[82]. Fructose is a 5-carbon carbohydrate with peculiar characteristics, as upon entry in the cell it is phosphorylated to fructose-1-phosphate by phosphofructokinase, decreasing the cell's ATP levels because of the rapid depletion of phosphate. AMP degradation increases uric acid levels, which has a proinflammatory affect in the intracellular compartment. In the liver, fructose can be transformed into free fatty acids that can either be secreted into the circulation as triglycerides or stored as intrahepatic lipids, contributing to MAFLD. How does fructose affect the liver through the BGL axis? Studies in mice have shown that fructose consumption causes a strong binge-eating response that is attributed to release of orexin from the lateral hypothalamus[83]. Chronic fructose intake leads to leptin resistance and weight gain[84]. Similar findings were confirmed in humans, who after fructose assumption, experienced increased hunger and desire for sweet foods than after glucose administration[85]. Furthermore, Spruss *et al*[86] showed that the long-term intake of fructose was associated with a marked reduction of the protein in the tight junctions of the duodenum that led to an increase in translocation of bacterial endotoxin and activation of toll-receptor-4-dependent signaling cascades in the liver. Interestingly, metformin a drug that reduces insulin resistance, was shown to protect from fructose-induced steatosis[86].

RESULTS OBTAINED FROM TISSUE-TARGETED ANIMAL MODELS

Based on the frequent coexistence of fatty liver, steatohepatitis, obesity, T2D, dysbiosis, insulin resistance, and low-grade inflammation, there is general acceptance of their possible causal interactions. However, their exact nature and implication in different subgroups of patients remains to be elucidated. In order to identify more specific causal relationships, we reviewed studies in tissue-targeted animal models in which the known primary event was either insulin resistance or hepatic steatosis or gut microbiota depletion or the induction or reduction of inflammation (Figures 2 and 3; Figure 2 is given more extensively in Supplementary Table 1). All the studies indicate that unless extreme lipodystrophy occurs (FIRKO-90%), severe insulin resistance in the whole body or skeletal muscle and/or adipose tissue does not cause hepatic steatosis and liver insulin resistance or inflammation[87-89]. GLUT4-null mice do not have hepatic steatosis or glucose intolerance and have normal EGP-related enzyme expression in their liver[90-92]. In the absence of insulin receptors or GLUT4 in both muscle and adipose tissue, glucose tolerance is normal or is less affected than expected from the degree of insulin resistance[93-95]. The key compensatory organs appeared to be adipose tissue (with upregulation in glucose uptake, increase in small adipocyte number), and the liver (with upregulated glucose uptake, balanced increase in lipid synthesis *vs* export). A chronic lack of insulin action in only the liver leads to unsuppressed EGP, resulting in severe glucose intolerance from early life onward, low insulin clearance, glycogen depletion, low expression of lipogenesis pathways, and resistance to high-fat diet-induced steatosis[96-99]. The effects of a short-term lack of insulin action are controversial[98,100]. With a normal diet in the chronic model, moderate liver steatosis occurs in older animals, with an elevation in liver enzymes, focal dysplasia, no fibrosis, and low circulating triglycerides, which may depend on blunted triglyceride export because of chronic brain exposure to hyperinsulinemia. In fact, acute *vs* chronic central insulin infusions have shown a transition from stimulation to suppression of hepatic triglyceride export[101], modulating liver fat content. Lack of insulin action in the brain also causes a moderate degree of hyperphagia in females (either with or without overweight), insulin resistance without hyperglycemia, or glucose intolerance and high or normal triglyceride levels[101-103]. Instead, the selective KO of brain GLUT4 results in normal peripheral insulin sensitivity, but unsuppressed EGP leading to glucose intolerance[104]. Although the intestine is assumed to contribute little to EGP, it was noted that the absence of insulin action in enterocytes ameliorated glucose tolerance, *via* reduced intestinal glucose absorption and downregulation of intestinal EGP enzyme expression[105,106]. From these studies, EGP (dys)regulation resulting from the action of insulin on the liver, brain, and gut seems to be the most prominent determinant of glucose (in)tolerance.

On the other hand, the primary induction of liver steatosis does not cause whole-body insulin resistance, glucose intolerance, or hepatic inflammation, but provokes an increase in hepatic ceramide and diacylglycerol content, and the enrichment of liver triglycerides with polyunsaturated fatty acids, which may increase susceptibility to inflammatory damage[107-111]. The exposure to toxins (including LPS) caused liver and lipid inflammation and reduced fasting glucose, insulin and triglyceride levels [108-111]. Consistently, older studies have shown that an injection of LPS leads to a major increase in fasting glucose consumption by the whole body, with a several-fold elevation in the liver and spleen glucose uptake lasting 48 h, possibly because of the content of macrophages[112]. More recent studies on chronic LPS infusion have revealed that, while inducing overweight and inflammation in the liver and in adipose tissue and muscle in chow and HFD fed mice, LPS caused steatosis and extra-hepatic insulin resistance only in HFD mice or hepatic insulin resistance (EGP) only in chow-fed mice, with a small impact on glucose tolerance[113]. This is in agreement with observations in germ-free mice lacking LPS showing lower liver fat, better glucose tolerance, higher insulin sensitivity, and normal circulating triglyceride and free fatty acid levels compared with colonized mice[114-116]. However, the selective inoculation of bacteria producing or not producing LPS in germ-free mice showed a direct effect only on adipose tissue inflammation and without hepatic or systemic impact[116]. All the evidence suggests that both the metabolic and hepatic effects of LPS require other microbial or dietary components and support a role for liver inflammation, but not steatosis per se, in the regulation of peripheral metabolism. In line with this, anti-inflammatory drugs have been shown to ameliorate liver function, steatosis, inflammation, and insulin resistance, with glucose and lipid lowering effects observed only in diabetic animals[117-121].

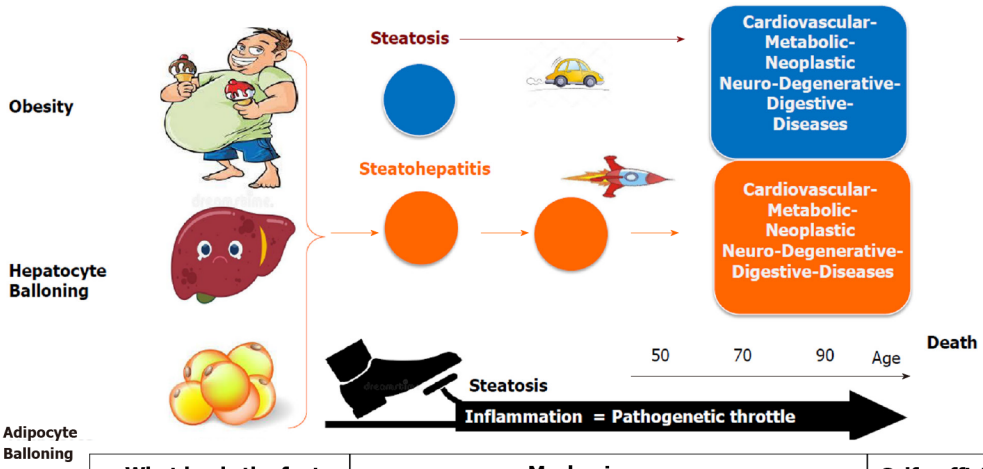
DISEASE MONITORING BY DIGITAL IMAGING: FOCUS ON PET AND MECHANISTIC UNDERSTANDING

Liver biopsy is the current gold standard in both the diagnosis and follow-up of liver disease. The presence of ballooning degeneration of hepatocytes being the hallmark of steatohepatitis, but biopsy is invasive and unsuitable for frequent monitoring[122]. Liver function tests are useful, but not diagnostic or predictive of NASH and/or fibrosis in individual patient. Imaging tools can capture and measure liver steatosis. Among them, magnetic resonance imaging (MRI)-magnetic resonance spectroscopy (MRS) has the highest sensitivity, but it is complex and not always accessible. Recently mono- and multiparametric scores obtained by the AI-processing of common ultrasound images have been proposed for repeated follow-up of liver fat and are validated against spectroscopic magnetic resonance technology[123]. Vibration-controlled transient elastography and magnetic resonance elastography provide useful measures of the combined inflammation-fibrosis index, but a reliable distinction between them remains to be achieved in the diagnostic field[12].

MRI can measure the proton density fat fraction (PDFF) and has been shown to be an objective, accurate, and reproducible quantitative indicator of hepatic fat content across the entire liver. MRI-PDFF has been validated against liver histology, and shown to be more sensitive in detecting changes in hepatic fat content and treatment response in clinical trials[124-126].



Finally, multiparametric MRI makes it possible to establish scores for assessment and quantification of liver fibrosis and inflammation, with accurate prediction of clinical outcomes in patients with chronic liver disease of mixed etiologies and/or steatosis[127]. The animal studies discussed above showed that LPS-induced liver inflammation is characterized by very high hepatic glucose uptake, possibly because of macrophages. The notion that activated macrophages and lymphocytes have high glucose-avidity has supported the use studies with PET imaging of the glucose analogue (^{18}F)-FDG in inflammatory conditions, such as osteomyelitis, sarcoidosis, vasculitis, or vulnerable atherosclerosis plaques[128,129]. Some studies, although lacking liver biopsies, have explored the relationship between computed tomography-

determined steatosis and fasting (^{18}F)-FDG-PET imaging[130-132], yielding controversial results. Two recent reports that used biopsy-proven liver diagnosis and compartmental modeling of (^{18}F)-FDG in the liver, found an inverse relationship between hepatic inflammation grades and liver blood flow, *i.e.* the K_1 rate constant representing the flow-dependent delivery of (^{18}F)-FDG to the liver[133,134]. Other rate constants (*e.g.*, fractional extraction) did not correlate with histology grades. Unfortunately, these human studies addressed relative indices and not the absolute rate of hepatic glucose uptake (HGU), which is given by the product of (^{18}F)-FDG fractional uptake × circulating glucose levels, and they did not quantify EGP.

We have previously validated a method to simultaneously estimate EGP [by (^{18}F)-FDG plasma clearance] together with HGU (by imaging) during (^{18}F)-FDG-PET, addressing their relationship with liver steatosis (by MRI-MRS) in type 2 diabetic or morbidly obese patients. The studies indicate that hepatic insulin resistance and steatosis are, to some extent, proportional and improve after weight loss by bariatric surgery in morbidly obese individuals[135]. However, very-low-calorie diets in less severe obesity had effects on glucose tolerance, EGP, and liver fat, but not on HGU [136], whereas glucose lowering by SGTL2 inhibitors in diabetic patients had a significant effect on glucose control and liver fat, but not on EGP or HGU[137]. Taken together, the studies suggest that liver fat is not a cause of hepatic dysmetabolism, but rather a consequence of glucose intolerance. It is also important to keep in mind that the euglycemic insulin clamp that was used in the studies, did not reflect the daily metabolic physiology of patients, in which glucose and insulin levels increase and decrease together after meals or under fasting conditions. HGU and EGP are dependent on the changing insulin and glucose levels, and chronic hyperglycemia and hyperinsulinemia are commonly present. For example, PET imaging studies in minipigs underscore the relevance of circulating glucose by showing that hyperglycemic- compared with euglycemic-hyperinsulinemia enhanced HGU, hepatic triglyceride content and triglyceride release in proportion to glycemia[138]. The euglycemic clamp thus provides relevant information on the sole action of insulin on tissue metabolism, being insufficient to characterize the more complex relationship between glucose and lipid metabolism occurring in the liver in real life.

By using a fatty acid PET tracer, we demonstrated that overweight was characterized by an elevation in fasting hepatic fatty acid oxidation, with normal rates of triglyceride incorporation[139]. Liver steatosis occurred in obese subjects, in whom weight loss was able to reduce hepatic fatty acid uptake and liver steatosis in a proportional manner, and EGP[140]. Notably, a chronic, *i.e.* 1-wk treatment with acipimox, suppressing fatty acid levels and liver fatty acid uptake provoked a significant improvement in systemic and liver insulin sensitivity and decreased circulating triglycerides and liver enzymes, but did not change liver fat content, as measured with MRS in healthy individuals[140]. Thus, liver and systemic insulin sensitivity were improved, together with liver function and independent of hepatic triglyceride accumulation. Again, in spite of cross-sectional correlations and consensual changes after weight loss, intervention studies disconnect liver steatosis per se from other adverse metabolic consequences, at least in healthy subjects.

In spite of the new light on pathophysiology shed by the above studies, two major needs remain unmet. Firstly, none of the above PET imaging studies included sufficient histologic information to address the progression of liver steatosis into steatohepatitis and/or fibrosis, thus the specific factors of disease progression are not yet identified. However, sufficient knowledge exists to design targeted studies for a more effective demonstration of the potential of PET-CT as diagnostic tools. Secondly, the relevance of other organs in compensating or aggravating liver disease needs a better understanding in order to address appropriate treatment strategies and targets, and intervention-time windows. We have just started to examine the brain-liver-gut axis in humans by PET imaging. Our studies during euglycemic clamp revealed a positive relationship between BGU and EGP and the predictive value of BGU of glucose homeostasis in diabetic subjects following bariatric surgery[23]. We also detected a high fasting-uptake of fatty acids in the brain in obese and morbidly obese individuals[141]. A greater elevation of BGU was also observed in reward-related but not in behavior-controlling regions in response to sensory stimulation by chocolate stimuli in overweight women with high food-addiction scores, compared with women with lower scores, independent of peripheral substrate and hormone levels, which were shown to be similar. Only in the former group was BGU reduced after a low-calorie diet, independent of similar peripheral changes[142]. Thus, high or unbalanced BGU is associated with a variety of high-risk behavioral and metabolic aspects. More important, the study underscores that the same phenotype can result from different mechanisms, and that mechanistic or intervention studies pooling patients based on a

What loads the foot	Mechanisms	Self-sufficient
Extreme deficiency in adipose tissue substrate storage	Build up of reactive oxygen species in the steatotic liver, lipid peroxidation, macrophage infiltration, later dysplasia	Yes
Hepatic triglyceride composition	Unsaturated fatty acids render the steatotic liver more susceptible to (endo/exo) toxin-mediated oxidative damage, lipid peroxidation	No
Unestablished gut microbiota factors	Germ-free (GF) conditions trigger protective responses	Yes
Lipopolysaccharide (LPS)	Hepatic proinflammatory factor, but not self-sufficient (proinflammatory effect lost in GF conditions)	No

Figure 4 Threesome ballooning hallmark of progressive fatty liver disease. Liver steatosis is associated with cardiovascular, digestive, metabolic, neoplastic, and neurodegenerative diseases; but it is the concomitant presence of inflammation that markedly accelerates the progression of these diseases. We illustrate this concept, representing steatosis as a "pedal" on which a series of aggravating factors may press as a "foot" that pushes on the "throttle", namely inflammation.

similar phenotype (*e.g.*, obesity or T2D) may be misleading both on detection of cause and on the evaluation of treatment efficacy. Evaluating the BGL axis by PET imaging with double-tracer oral glucose loading, we showed that the administration of exenatide (a GLP-1R agonist) in subjects with impaired glucose tolerance decreased EGP and HGU. A decrease in the intestinal absorption of oral glucose resulted in lower insulin levels, with an increased proportion of orally ingested glucose that was retained by the liver and increased BGU in most brain regions[143]. That underlines the importance of integrating intestinal metabolism and absorptive effects under real life circumstances in the study of the BGL axis. The quantification of intestinal glucose uptake by PET imaging has been recently validated, showing that intestinal insulin resistance in the jejunum was improved by bariatric surgery in obese subjects and in the large and small intestine by metformin and mildly improved in the small intestine of diabetic patients by rosiglitazone. Intestinal fatty acid uptake was elevated and further increased in obese subjects after bariatric surgery. Interestingly, parallel animal model observations showed that the human body could release glucose and fatty acids from the circulation into the gut lumen[144], which suggests that the gut can be a way to actively eliminate excess substrate and that the body feeds substrates to the gut microbiota, potentially modulating its composition and function. EGP was either decreased, unchanged or increased in the studies, again indicating a possible confounding effect of morbid obesity or a disconnect between insulin action in gut and liver. These studies, primarily planned to address insulin sensitivity, have set the stage for the design of gut-targeted and BGL-targeted imaging approaches under metabolic conditions that are relevant to this interaction, including the study of microbiomics.

CONCLUSION

We reviewed the most recent knowledge of the complex interplay among the organs of the BGL axis in the pathophysiology of insulin resistance and MAFLD, presenting the best established interconnections between brain, gut and liver in the context of insulin resistance and hepatic steatosis. From studies using tissue-targeted animal models it

emerges that insulin resistance per se does not induce hepatic steatosis, nor does steatosis induce whole-body insulin resistance. However, it is evident that reducing inflammation has several beneficial effects both at the hepatic and whole-body level. In fact, inflammation (either hepatic or systemic) acts as major throttle of progressive liver and systemic diseases. This paradigm is illustrated in Figure 4 together with the important diagnostic and prognostic role of the three hallmark characteristics of progressive fatty liver disease, namely visceral obesity (abdominal ballooning) and/or ballooning degeneration of hepatocytes and adipocytes (thus predominant adipocyte hypertrophy rather than hyperplasia).

There is currently no approved treatment for MAFLD, which is a multifaceted syndrome caused by pathogenetic mechanisms that, in animal studies, consistently appear to be diverse. Understanding and being able to identify and measure different factors that trigger and/or accelerate the pathogenesis of steatosis and its progression is a key issue for successful risk-stratification, prevention, and drug development.

With several drugs being potentially beneficial in the treatment of MAFLD, future clinical investigations should address carefully the most appropriate stratification of MAFLD patients to study their specific effects on liver and systemic inflammation, liver fat, and insulin resistance. On the other hand, the approach of both system biology and medicine has to be applied to address the unmet needs in the understanding of the pathophysiology of insulin resistance in different subsets of patients with MAFLD. The pooling of MAFLD patients just on the basis of their common phenotypic characteristic in clinical studies and trials can be highly misleading for both mechanistic understanding and for new drug development as the same phenotype can result from different and time/stage-evolving mechanisms, each requiring a very targeted approach (*i.e.* personalized, timely, and adequate for the disease-stage). Studies targeting the BGL axis might unveil new underlying mechanisms and fill the existing knowledge gaps in the causal links between insulin resistance and MAFLD pathophysiology, paving the way for the development of innovative diagnostic and therapeutic approaches.

Abstract

The gut microbiome is a complex microbial community, recognized for its potential role in physiology, health, and disease. The available evidence supports the role of gut dysbiosis in pancreatic disorders, including acute pancreatitis (AP). In AP, the presence of gut barrier damage resulting in increased mucosal permeability may lead to translocation of intestinal bacteria, necrosis of pancreatic and peripancreatic tissue, and infection, often accompanied by multiple organ dysfunction syndrome. Preserving gut microbial homeostasis may reduce the systemic effects of AP. A growing body of evidence suggests the possible involvement of the gut microbiome in various pancreatic diseases, including AP. This review discusses the possible role of the gut microbiome in AP. It highlights AP treatment and supplementation with prebiotics, synbiotics, and probiotics to maintain gastrointestinal microbial balance and effectively reduce hospitalization, morbidity and mortality in an early phase. It also addresses novel therapeutic areas in the gut microbiome, personalized treatment, and provides a roadmap of

Core Tip: We live in a world of microbes. There is a distinct microbiome sighted in every niche of our body. This review is based on current knowledge to define an overview of how the gut microbiota has accelerated the frontiers of understanding recently and empowered its importance in influencing human physiology through its potential role in various diseases. It further explores the possible application of microbiota-targeted therapeutics in routine clinical practice, meaning manipulating gut microbiota into the current therapeutics to minimize the potential risk of various diseases, including acute pancreatitis.

INTRODUCTION

Recent research has confirmed the importance of the human gut microbiota in maintaining health and its involvement in disease. The human gastrointestinal (GI) tract harbors a diverse microbial population of more than 10^{14} microorganisms, comprising more bacterial cells than human body cells[1] and more than 3.3 million unique genes[2]. The predominant commensal bacteria in the human GI tract are members of the phyla *Firmicutes* and *Bacteroidetes*, constituting 80%–90% of the total gut microbiota[3]. Other phyla include *Proteobacteria, Actinomyces, Actinobacteria, Fusobacteria,* and *Verrucomicrobia*[4]. The composition of the gut microbiome plays a key role in modulating human immune responses to invasive pathogens, and it also prevents the pathogens from crossing the intestinal barrier[5].

Recent improvement of advanced sequencing methods, such as next-generation sequencing and metagenomics, have added to our understanding of the involvement of gut microbiome in human health and disease[6] and the potential therapeutic value of interventions that target the composition of the gut microbiome. Such interventions would manipulate the host-microbiome community by eliminating harmful taxa or reconstituting missing beneficial taxa[6,7]. Recent evidence shows that, under ideal conditions, symbiotic relationships among the microbial species in the host GI tract can function to prevent opportunistic and nosocomial infections that have become more frequent because of the widespread use of antibiotics to treat various diseases[8-11].

Research performed over the past two decades has revealed the significance of gut dysbiosis in the pathogenesis of many diseases[12], including inflammatory bowel disease[13], irritable bowel syndrome[14], colon cancer[15], Alzheimer's disease[16], coronary heart disease[17], obesity[18], and diabetes mellitus[19]. Changes in the diversity, proportions, and dominant species of the gut microbiome are probably associated with intestinal barrier dysfunction that influences onset and clinical course of multiple diseases, including pancreatic disorders[20]. In a healthy individual, no gut microbes are present in the pancreas, but changes of the gut microbiota may be involved in the pathogenesis of pancreatic disease, including acute pancreatitis (AP)[21]. AP is a common disorder of the digestive system with high morbidity and mortality worldwide. Managing AP is challenging and has a heavy financial burden on the patient and society[22,23]. Therefore, it is important to understand the primary causes and mechanism of the pathogenesis and progression of AP to facilitate early diagnosis and treatment, avoid a course leading to severe disease, and reduce AP-associated fatality[23]. Ongoing studies of AP in humans have found that premature activation of trypsinogen, dysfunctional calcium signaling, impaired endoplasmic reticulum stress-related autophagy, unfolded protein response, and mitochondrial

dysfunction all promote AP. However, the cause of multiorgan dysfunction in AP is poorly understood[24]. The potential role of the intestine in promoting systemic inflammation and organ dysfunction is of interest.

In AP, hypovolemia, reflex splanchnic vasoconstriction, intestinal ischemia, and reperfusion injury due to fluid resuscitation may result in bacterial translocation [25, 26]. Systemic inflammatory response syndrome accompanied by intestinal bacterial translocation is associated with high AP mortality[26]. A change in gut permeability/motility that causes bacterial translocation and leads to the activation of gut-associated lymphoid tissues may result in systemic complications in AP[27]. This review summarizes relevant human and animal studies that provide insights into the potential role of the gut microbiome in AP pathogenesis. It also summarizes treatment perspectives that target the gut microbiome.

PATHOPHYSIOLOGY OF AP

Previous studies of microbiome involvement in AP described a complex cascade of events with significant involvement of pancreatic acinar cells, but the mechanisms involved in the initiation of AP are still poorly understood[28]. Development of a well-defined clinical management protocol is challenging. Most investigations of AP pathophysiology have documented injury or disruption of the pancreatic acini that triggered the activation of pancreatic enzymes (trypsin, chymotrypsin, and elastase) in pancreatic tissue. Activated proteases (trypsin and elastase) and lipase breakdown tissue and cell membranes, leading to edema, vascular damage, hemorrhage, and necrosis[28].

During the initial phase of pancreatic injury, acinar cells release proinflammatory cytokines, like tumor necrosis factor (commonly referred to as TNF)-α, interleukin (IL)-1 and IL-6, and anti-inflammatory mediators, such as IL-10 and IL-1 receptor antagonist[29]. These mediators recruit neutrophils and macrophages to enter the pancreatic parenchyma, to propagate both local and systemic responses. Reactive oxygen metabolites, prostaglandins, platelet-activating factor, and leukotriene may also be involved[29].

Recent epidemiological studies have shown that a local inflammatory response aggravates pancreatitis by increasing permeability, which damages the microcirculation and results in local hemorrhage and pancreatic necrosis in cases of severe AP. Some of the inflammatory mediators released by neutrophils aggravate pancreatic injury by activating pancreatic enzymes (see Figure 1)[26,30]. Figure 1 is a schematic description of AP pathogenesis. The acinar cells of the pancreas cause trypsin activation followed by impairment of cell membrane trafficking and activation of the zymogen cascade mediated by trypsin. Attraction and activation of leukocytes occur with the release of pro- and anti-inflammatory cytokines and chemokines. Overt, sustained activation of proinflammatory mediators leads to systemic inflammatory response syndrome (SIRS) and may progress to multiorgan failure, infection, pancreatic necrosis, and sepsis as late complications of AP.

CLASSIFICATION OF AP

Approximately 15%–25% of patients diagnosed with AP may progress to severe AP. The 2012 revised Atlanta classification and definitions by international consensus include three degrees of AP severity (*i.e.* mild, moderately severe, and severe)[31]. The three degrees primarily manifest as transient organ failure, persistent organ dysfunction, and local or systemic AP[31]. The determinant-based classification of AP is highly dependent on clinical data, and also on the available feedback from patients (to a lesser extent)[32]. Table 1 summarizes both the Atlanta and determinant-based classifications.

VARIOUS SCORING SYSTEMS USED IN THE DIAGNOSIS OF AP

The initial diagnosis of AP made on arrival at a clinic or hospital relies on known medical history, comprehensive physical examination, and increased serum amylase or lipase, with or without additional imaging evaluation. Currently, there are no specific laboratory tests with consistent accuracy and reliability for predicting AP

Table 1 Revised Atlanta classification and determinant-based classification of acute pancreatitis

Revised Atlanta classification of disease severity	
Mild AP	No organ failure
	No local or systemic complications
Moderately severe AP	Organ failure that resolved within 48 h (transient organ failure) and /or
	Local or systemic complications without persistent organ failure
Severe AP	Persistent organ failure > 48 h
	Single organ failure
	Multiple organ failure
A modified Marshal score defines a persistent organ failure	
Determinant-based classification of disease severity	
RACAP	**DBCAPS**
Mild AP	Mild AP
Absence of organ failure	Absence of organ failure
Absence of local complications	Absence of (peri-) pancreatic necrosis
Moderately severe AP	Moderate AP
Local complications and/or	Sterile (peri-) pancreatic necrosis and/or
Transient organ failure	Transient organ failure
Severe AP	Severe AP
Persistent organ failure	Persistent organ failure or
	Infected (peri-) pancreatic necrosis
	Critical AP persistent organ failure
	Infected (peri-) pancreatic necrosis

AP: Acute pancreatitis; DBCAPS: Determinant-based classification of acute pancreatitis severity; RACA: Revised Atlanta classification. Persistent organ failure is defined by a modified Marshal score or a sepsis-related organ failure assessment score.

severity. However, several scoring systems are available and are routinely used by hospital physicians to predict AP severity and prognosis (Table 2)[33-41].

BIOMARKERS AND PREDICTORS TO CONFIRM THE SEVERITY OF AP

In addition to the various clinical scoring systems, several biomarkers have also been applied as predictors of AP severity and are shown in Table 3[42-47].

microRNAs as biomarkers in AP diagnosis

Recently, circular microRNAs have been studied as potential diagnostic biomarkers in AP because of their specific properties, such as stability in biological fluids, simple identification, and sequence conservation among different species (Table 4)[48-60].

GUT MICROBIOME AND MICROBIOME IN AP

The human GI tract is home to a diverse and complex microbial community of bacteria, viruses, and fungi that help to maintain health and are involved in the pathogenesis of various diseases. The gut contains at least 1000 bacterial species and 100-fold more genes than have been identified in the human genome[4,61]. The microbiome is considered a hidden "metabolic organ", and it has a significant impact on well-being because of its influence on our metabolism, physiology, nutrition, and immune function[62]. It has been shown that the gut microbiome co-evolves with us;

Table 2 Prediction scoring systems used in acute pancreatitis diagnosis

No.	Multifactorial scoring system	Timeline	Threshold	Area under the curve	Ref.
1	Ranson score	48 h	≥ 3	0.81–0.88	[33-35]
2	Glasgow score	48 h	2	0.73–0.784	[36,37]
3	Acute Physiology and Chronic Health Evaluation-II score (APACHE-II)	24 h	7	0.80–0.895	[33,38,39]
4	Acute Physiology and Chronic Health Evaluation II score-Obesity (APACHE:-O)	24 h	7	0.893	[40]
5	Bedside Index of Severity score (BISAP)	24 h	≥ 3	0.79–0.875	[33-35,41]
6	Pancreatitis Activity Scoring System (PASS)	24 h	> 160	0.71	[36]
7	Systemic inflammatory response syndrome (SIRS)	24 h	≥ 2	0.73	[34,39]

Table 3 Blood biomarkers predicting disease severity in acute pancreatitis

No.	Blood biomarkers	Timeline	Threshold	Area under the curve	Ref.
1	Interleukin 8	Preoperative	196 pg/mL	0.778	[42]
2	Interleukin 6	24 h	50 pg/mL	0.9	[39]
3	Hepcidin	24 h	234.4 ng/mL	0.82	[43]
4	Red blood cell distribution width	24 h	13.35%	0.787	[44]
5	Procalcitonin	24 h	1.77 ng/mL	0.797	[45]
6	Blood urea nitrogen	24 h	5.945 mg/dL	0.677	[44]

hence, any changes to the microbial community can have significant consequences, both beneficial and harmful[63]. Disruption of the gut microbiota, or dysbiosis, has been associated with diverse systematic conditions, such as obesity[64,65], malnutrition[66], diabetes[67], and chronic inflammatory diseases, such as inflammatory bowel disease, ulcerative colitis, and Crohn's disease[68].

Researchers have continued to study the microbiome at an accelerated pace over the past two decades, revealing the myriad ways these microorganisms affect our day-to-day lives. The microbiome in our gut is now understood to be a significant contributor to the development of chronic disease. Gut microbiota is now known to play a critical role in human health and disease. With the advances in microbiome research over time, more and more data has become available showing the gut microbes' overall composition and functional potential. Additionally, the number of diseases associated with changes in our gut microbial community has increased simultaneously[4,6]. The human gastrointestinal tract is a habitat crowded with microorganisms contributing to the host's immunity and pathogenesis of several diseases, including acute pancreatitis [69]. Human gastrointestinal microflora is divided into three different types by the way they present themselves in the body and perform multiple functions: *e.g.*, There are three major categories of bacteria: Physiological bacteria, that hold over 90% and are nourishing and immune-modulating; opportunistic bacteria, which are pathogenic in situations of lower immune resistance or antibiotic abuse; and pathogenic bacteria, which have lower numbers and invade difficultly[70]. Progression in AP has been more complicated by gastrointestinal motility dysfunction, which is probably related to the neuroendocrine system, hypoxia-ischemia, ischemia-reperfusion injury (IRI), inflammatory mediators, and cajal cells[71].

Since many discoveries have postulated that commensal intestinal microbiomes play a crucial role in humans' health, immune system, and homeostasis recently, there has been a surge of interest in this area of study. The overall function of the intestine in the entire mechanism of AP pathogenesis (such as in acute and critical illnesses) is essential to understand, but often it is overlooked. This pathogenesis mechanism involves several factors contributing to the loss of gut barrier function, allowing bacteria and endotoxins to translocate into the bloodstream, which is critical for

generating the second inflammatory hit of AP[72]. The data of Johnson *et al*[73] suggests gut bacteria translocation (*via* hematogenous, lymphatic, and reflux) is involved in AP infection progression, which indicates the presence of a possible correlation between gut microbiota and AP infection progression. An abnormality of the gastrointestinal microbiota (dysbiosis) is associated with the systematic inflammatory response syndrome (SIRS) and a broad range of diseases[74].

When the mucosal barrier of the intestine is damaged, intestinal bacteria may migrate into the blood or to other tissues and organs, further accelerating AP[75]. In recent years, several studies have been conducted investigating changes in intestinal flora associated with AP severity. AP progression involves the abnormal release of trypsin and destruction of pancreatic tissue due to abnormal cells. Several recent studies examined the changes in intestinal flora during AP development concerning disease severity. It is observed that abnormal trypsin secretion has occurred due to AP progression and that pancreatic structure destruction leads to an abnormal pancreatic secretion, resulting in the intestinal flora and homeostasis changes[76,77].

Numerous studies have now demonstrated the function of normal gut microbes to promote healthy gut mucosa. Gut mucosal ischemia and reperfusion during AP progression can compromise the integrity of the gut barrier, causing bacterial reabsorption from the gut to other parts of the body and causing local and systemic infections[78]. Some further research findings have also revealed that intestinal mucosal barrier injury is a significant complication in many AP patients. The intestinal mucosal barrier can be destroyed by affecting intestinal inflammation and the immune response[75]. Many studies are supporting now to demonstrate that normal gut microbes play a primary role in maintaining gut mucosal integrity. However, gut mucosal ischemia and reperfusion during AP progression can damage the overall integrity of the gut barrier and lead to gut bacterial translocation to other locations, causing local and systemic infections[78]. Thus, a significant complication of an AP patient's condition involves intestinal mucosal barrier damage. This is caused by intestinal inflammation and immune response defects. Other research has also found injuries of the intestinal mucosal barrier to patients with AP[75].

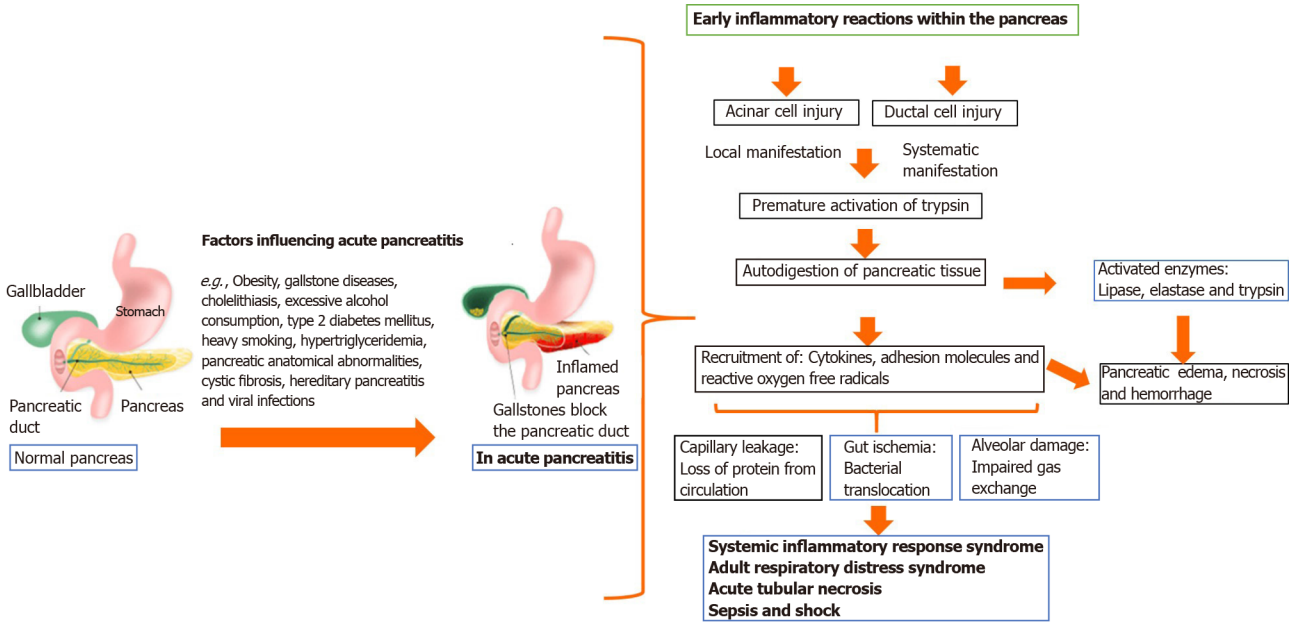

Figure 1 Pathophysiology of acute pancreatitis. Damage in the pancreas' acinar cell causes trypsin activation following cell membrane trafficking impairment, with subsequent activation of the zymogen cascade by trypsin. Attraction and activation of leukocytes occur with the release of many proinflammatory and anti-inflammatory cytokines, as well as chemokines. An overt and sustained activation of proinflammatory mediators leads to systemic inflammatory response syndrome (SIRS), which may further proceed to multiorgan failure, pancreatic necrosis and sepsis with late complications of acute pancreatitis.

In brief, the pancreas-gut communication has been described as being in AP, with bacterial translocation as a possible consequence and the homeostatic host response noted. Translocation of bacteria from the lower gastrointestinal tract occurs *via* the portal circulation - the oral course and/or the mesenteric lymph nodes. The acinar cells of the pancreas secrete pancreatic antimicrobial peptides (AMPs). AMPs have homeostatic bidirectional communication with the gastrointestinal tract[79]. The lower level of the microbiome in the gastrointestinal tract may increase pancreatic antimicrobial peptide production by short-chain fatty acid metabolites. Consequently, it induces a pancreatic immunoregulatory environment which decreases proinflammatory immune cells. Conversely, decreased antimicrobial peptide production facilitates the overgrowth of the gastrointestinal microbiota leading to the induction of proinflammatory immune cells. Thus, it subsequently alters the gut microbiome and the intestinal immune system[79].

POTENTIAL ROLE OF THE GUT MICROBIOME IN AP

Metagenomics and next-generation sequencing have facilitated the investigation of the involvement of the gut microbiome in human physiology and various diseases. The findings have allowed for consideration of the gut microbiome as a hidden organ[80]. The close interaction of the gut microbiome with host physiology can account for the harmful effects of disruptions in the former caused by various internal or external events that initiate inflammatory conditions and some types of cancer. Therefore, it is essential that specific microbial signals maintain the host immune response and other physiological functions that protect against pathogens[81].

Injury of the microcirculation and hypovolemia that occur during AP can lead to gut mucosal ischemia and reperfusion injury that result in loss of gut barrier function. Subsequent translocation of gut bacteria can result in local pancreatic and systemic infections[82]. Leading causes of AP mortality include pancreatic infection and peripancreatic necrosis[78]. The initial onset of cerulean-driven AP depends on NOD1 activation in acinar cells by commensal microbiota that have translocated from the gut. Following activation, NOD1 induces the expression of inflammatory mediators[83]. The role of the gut in neutrophil priming and release of proinflammatory cytokines is important for the initiation and propagation of inflammation and sepsis[84]. The loss of gut barrier function has been implicated in the pathogenesis of AP-related infections. Ahuja *et al*[76] reported that secretion of antimicrobials from pancreatic acinar cells regulated gut microbiota composition and innate immunity[76]. Blocking

acinar cell exocytosis in mice has been found to lead to gut dysbiosis, inflammation, systemic bacterial translocation, and ultimately, death. Additional evidence has revealed additional examples of crosstalk between pancreas acinar cells and the gut microbiome[76,77].

An ongoing investigation of the microbiota and AP has shown that microcirculatory disturbances associated with the loss of fluid into the "third space," lead to hypovolemia, ischemia, and reperfusion injury in AP patients. The gut is affected by AP, but it is not a passive victim because it plays an active role in the worsening of the illness[85]. In addition to bacterial translocation, the translocation of inflammatory compounds produced in the intestinal wall and the gut's toxic products might also be responsible for initiating SIRS and distant organ injury in AP patients[86]. The contribution of the gut microbiome for protection against pathogens in AP patients has not been clearly elucidated. An increase of such pathogenic bacteria as *Enterobacteriaceae* and *Firmicutes*, and a decrease in beneficial bacteria like *Bacteroidetes* and *Lactobacillus* has been observed in AP patients[87]. Furthermore, increased serum IL-6 has been found to be positively related to increased *Enterobacteriaceae* and *Enterococcus* and inversely related to *Bifidobacterium* and *Clostridium* cluster number. Tan *et al*[87] reported that the extent of gut microbiota modification predicted pancreatitis severity and the occurrence of systemic complications. Gerritsen *et al*[88] found that "AP-associated microbiota" replaced the normal intestinal flora in a study performed in a mouse model. In AP, changes in the populations of specific commensal bacteria have been associated with reduced levels of the inflammatory cytokines IL-1b, TNF-a, CXCL1, and IL-18, and inversely correlated with pancreatitis severity and the occurrence of systemic infectious complications. The evidence highlights the restoration of the physiological gut microbiota composition as a valuable strategy to treat AP[89].

The 16S rRNA gene is highly conserved in bacteria, and it is highly species-specific. Consequently, 16S rRNA gene sequencing is widely used to study the gut microbiota in various disease states[90]. Zhu *et al*[69] reported that the relative abundance of commensal microbiota in AP patients differed from that in a healthy individual. Members of the *Bacteroidetes* phylum decreased significantly, but *Proteobacteria* were over-represented in AP. AP patients also had a relative overabundance of *Escherichia/Shigella* compared to healthy control[69]. Increased abundance of two common opportunistic pathogens, including *Enterococcus* and an unknown genus in the *Enterobacteriaceae* family, were also observed in AP patients. Linear discrimination and effect size analysis revealed significant increases in *Acinetobacter, Stenotrophomonas,* and *Geobacillus* with decreased *Bacteroides, Alloprevotella, Blautia* and *Gemella* in patients with severe AP, as compared to those with mild and moderately severe AP[69]. Table 5[21,69,75,91] and Table 6[69,75,87,90,92] summarize the significant changes in the microbiome composition of healthy controls and in patients with mild, moderately severe, and severe AP.

Changes in the gut microbiota in AP include overexpression of opportunistic pathogens, such as *Escherichia/Shigella*, and reduced abundance of beneficial genera, such as *Bifidobacterium*[69]. It has been hypothesized that a reduction of beneficial bacteria might facilitate microbial translocation across a damaged gut barrier, thereby promoting the progression of AP. Studies performed by Li *et al*[75] and other investigators[93,94] found that dysbiosis that included the depletion of short-chain fatty acid-producing bacteria was associated with an impaired gut barrier and worsening of AP. Changes in the gut microbiome may thus serve as a diagnostic tool in AP. Restoring gut microbiota homeostasis and stabilizing the gut barrier might have therapeutic value in AP patients, as shown in Figure 2[21,30,69,75,87,93,94]. The overall literature suggests that there is an association between the gut microbiome and the severity of AP[95]. Additionally, in experimental acute pancreatitis, changes to the gut microbiome, *e.g.*, administration of *Clostridium butyricum* can suppress AP[27] pointing to the therapeutic potential of this approach is promising.

ANTIBIOTICS, PREBIOTICS, SYNBIOTICS, AND PROBIOTICS FOR THE TREATMENT OF AP

Antibiotic therapy in AP

In the past decade, substantial advancements have been made not only in understanding the pathophysiology of AP but also in treatment strategies and multidisciplinary management. Necrotizing pancreatitis occurs in about 30% of patients and has a poor prognosis and high mortality. About 80% of AP deaths are caused by infections

secondary to AP that might be attributable to gut translocation of intestinal bacteria [82,96]. Current guidelines recommend against routine antibiotic prophylaxis in AP [97]. Recent studies did not find benefits of antibiotic prophylaxis in reducing AP mortality, infections not involving the pancreas, or surgical interventions. The data on infections accompanying pancreatic necrosis in adults are conflicting[98,99].

The use of antibiotics, starting with carbapenems, quinolones, and metronidazole, has been advised in patients with AP and concomitant cholangitis symptoms, infected necrosis, or necrotizing pancreatitis accompanying a deteriorating clinical status[97]. Delaying surgical interventions decreases morbidity and mortality[100]. In some instances of AP, where infection is clinically suspected or confirmed, the use of antibiotics is recommended to avoid development of antimicrobial resistance. The predictive value of fine-needle aspiration for sampling and determination of bacterial sensitivities in diagnosing peri-pancreatic infection is comparable to that of clinical signs and imaging. The routine use of fine-needle aspiration is not recommended[101].

Early enteral nutrition is recommended in AP because it protects mucosal nutrition, the gut mucosal barrier, and gut-pancreas homeostasis[102]. In a previous randomized trial, decontamination of the gut with norfloxacin, colistin, amphotericin and standard AP therapy did not reduce mortality[103]. At present, selective gut decontamination cannot be recommended for AP patients.

Despite constant improvement in targeted therapeutics, a third of adult AP patients develop moderately severe AP and/or severe AP with SIRS, organ failure, and an increased risk of infection[104]. The gut mucosal barrier reduces the risk of infected pancreatic necrosis and thus helps to decrease mortality risk[85,105]. Microbiome-targeted therapies, such as genetic engineering of modified strains to outcompete pathogens, selective nutrient or prebiotic supplementation, or engineered bacteriophages, could steer the altered microbiome toward a healthy phenotype or change the course of critical illness[81]. Probiotics offer substantial health benefits and support the homeostasis of gut flora[81]. The most widely used probiotic bacteria in clinical trials are *Lactobacillus* and *Bifidobacterium*, which are easy to isolate from human feces or the

intestinal mucosa. Prebiotics are nondigestible foods required to propagate probiotics, and they stimulate the growth and activity of the healthy gut flora. Synbiotics are nutritional supplements that include both probiotics and prebiotics[106].

A randomized controlled trial by Pan *et al*[107] evaluated the ability of synbiotics to restore intestinal barrier damage and reduce the infection rate in early AP. A group of 45 patients were given either live or heat-inactivated *Lactobacillus plantarum* 299 with an oat fiber supplement as early enteral nutrition. Supplementation plus the symbiotic significantly reduced both pancreatic necrosis and surgical interventions[107]. A subsequent clinical trial included 62 severe AP patients treated with early enteral nutrition with four different prebiotics (inulin, beta-glucan, resistant starch, and pectin) together with four *Lactobacillus* probiotic preparations. The treatment resulted in a reduced incidence of SIRS and organ failure, supporting the use of early enteral symbiotic nutrition in severe AP[108]. Olah *et al*[109] randomized 45 AP patients to receive either a freeze-dried preparation containing 10^9 live *L. plantarum* 299 in each dose together with oat fiber or a heat-inactivated *Lactobacillus* controlled by nasojejunal tube for one week. Infected pancreatic necrosis and abscesses were significantly lower

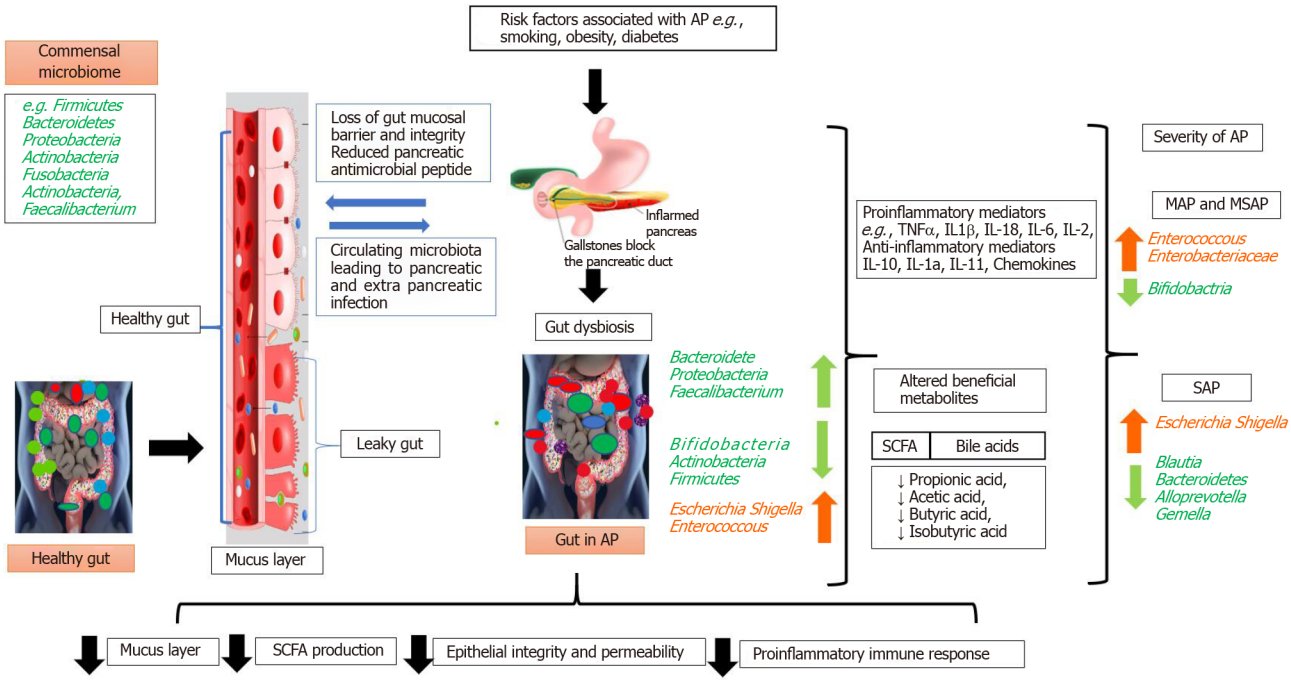

Figure 2 Role of the gut microbiota in inflammation of the pancreas and acute pancreatitis. Breakdown of the relationship between physiologic and pathogenic bacteria, the immune system, and the intestinal epithelial barrier leads to gut dysbiosis. Inflammation and gut dysbiosis causes the translocation of microbes to the pancreas. The translocation of bacteria results in pancreatic inflammation due to toxin diffusion and complications like fibrosis, digestive and absorption disorders, diabetes, and other metabolic disorders. AP: Acute pancreatitis; MAP: Mild acute pancreatitis; MSAP: Moderate severe acute pancreatitis; TNF: Tumor necrosis factor; IL: Interleukin; SAP: Severe acute pancreatitis; SCFA: Short-chain fatty acids.

in the treatment group than in the control group.

Other experimental pancreatitis studies in rat models confirmed the efficacy of *L. plantarum* spp. in reducing microbial translocation and as a possible alternative to antimicrobials[110]. Several studies have shown that probiotics containing *Faecalibacterium* and *Bifidobacterium* species had beneficial effects, including stabilizing the gut barrier, increasing anti-inflammatory responses, and attenuating bacterial translocation[111,112]. Some studies have not found any significant benefit or adverse effect of probiotics in severe AP. Still, it is essential to note the considerable patient and probiotic regimen heterogeneity in the published clinical trials of probiotics. The PROPATRIA Probiotics[113] in Pancreatitis Trial randomized 298 patients with predicted severe AP to either a multispecies probiotic mixture containing two different *Bifidobacterium*, three *Lactobacillus*, and one *Lactococcus* species or a placebo. The infectious complications in the two groups were similar, but the probiotic group had higher mortality (16% *vs* 6%) and incidence of bowel ischemia (6% *vs* 0%) compared with the placebo group. The high load of the probiotic mixture used in the study was thought to have been responsible for the increased mortality[114]. The findings highlight the challenges of supplementing the gut microbiome with beneficial microbial species in the setting of AP. Nevertheless, eight years later, the PROPATRIA trial was reevaluated by Bongaerts *et al*[115]. The team of researchers analyzed and addressed all shortcomings identified in the trial. PROPATRIA researchers contend that a lethal combination of predominantly proteolytic pancreatic enzymes and probiotic therapy was responsible for the high mortality rate, and that elevated levels of lactic acid produced by bacterial fermentation of carbohydrates significantly contributed to the high death rate. Additionally, one of them was the latency time in the first administration of probiotics; indeed, some patients were treated 24 h after onset of symptoms. Furthermore, there were errors in randomization; in fact, the onset of multi-organ failure was already present during admission in more patients in the first group than in the placebo group (41 patients *vs* 23 patients). Finally, last but not least, the team of researchers suggested that in future studies, when considering substituting probiotics in AP, it is necessary to assess the appropriate, effective doses of probiotics. However, caution should be mandatory to prevent bacterial overgrowth while conducting clinical trials in AP patients.

Previous studies have shown that *L. plantarum* decreased the occurrence of infective necrosis in AP patients[110] and that *Saccharomyces boulardi* spp. administered concomitantly with antibiotics such as ciprofloxacin decreased histopathologic scores in acute

necrotizing pancreatitis[111]. Animal studies have provided strong evidence in support of probiotic benefits in animal models of AP. A mixture of *Lactobacillus acidophilus, Streptococcus thermophilus,* and *Bifidobacterium lactis* given by oral gavage reduced pancreatitis, bacterial translocation to extra-intestinal sites, and mortality in male albino rats because of reduced duodenal bacterial overgrowth[112].

Injury of the GI barrier is a key event in the development of AP. Few studies have reported prevention of disruption of the intestinal barrier with modulation of gut microbiome balance. In one such study conducted in a mouse model of AP, *Clostridium butyricum*, a producer of small-chain fatty acids, which have immunomodulatory properties, reduced infiltration of neutrophils and dendritic cells in the pancreas and inhibited inflammatory responses mediated by NLRP3 and TLR4 signaling pathways in the pancreas and colon[27]. In summary, probiotics help to maintain gut homeostasis. Research should improve the designs of future studies, for example, by detecting a peculiar strain of microorganisms (*i.e.*, their type), standardizing the dose and duration of treatment, or standardizing the state of disease progression when considering to use in current therapy scenarios.

CONCLUSION

The gut microbiome plays a significant role in health and diseases. The resident microbiota in the human GI tract influences host metabolism, physiology, and immune system development. Disruption of this bacterial community results in GI disease. Ongoing medical and clinical research has produced a substantial body of evidence of a clear correlation between changes in the commensal microbiota and the occurrence of pancreatic disease. Application of biochemical, microbiological, and molecular biological methods have provided a description of the constituents of the gut microbiome in health and disease, their niches, and their physiological roles. Additional study is needed to explain whether microbial dysbiosis is a cause or an effect of diverse pathologies. The microbiome profile and changes in dysbiosis may influence an increase in AP severity during its clinical course.

Damage of the intestinal mucosal barrier allows migration of intestinal microbes to the blood or other tissues and organs, which enhances or aggravates AP. Changes in the resident species and abundance of the intestinal flora during AP are closely related to damage of the intestinal mucosal barrier system. Regulating the intestinal flora to repair the intestinal mucosal barrier and restore its function may be useful in AP treatment. Changes in the gut microbiota composition in AP include over-representation of opportunistic pathogens such as *Escherichia/Shigella* species and a significant decrease in the beneficial *Bifidobacterium* genus. Early dysbiosis of the gut microbiota, especially the depletion of small-chain fatty acid-producing bacteria, is probably associated with impairment of the gut barrier and increased AP severity.

The mechanisms of gut dysbiosis and the etiology of AP are not yet fully understood. The relationship of GI microbial symbiosis and AP are avenues for further research. The concomitant use of probiotics and antibiotics together with conventional treatment, such as surgery, radiotherapy, chemotherapy and targeted therapies, are further areas for research. In summary, the clinical significance of GI homeostasis during AP is emerging step by step. Thus, restoring the homeostasis of gut microbiota and stabilizing the gut barrier could be a promising therapeutic target in preventing AP progression. Challenges and specific problems that stand in the way to developing a research platform for understanding AP and its interaction with the microbiome need to be overcome. This review has explored the role of the gut microbiome in AP and the targeted use of probiotics, prebiotics, and synbiotics to maintain or restore GI microbial balance.

Abstract

Inflammatory bowel diseases (IBD) include a spectrum of chronic inflammatory disorders of the gastrointestinal tract whose pathogenesis is yet to be elucidated. The intestinal microbiome has been studied as a causal component, with certain microbiotic alterations having been observed in subtypes of IBD. Physical exercise is a modulator of the intestinal microbiome, causing shifts in its composition that are partially corrective of those observed in IBD; furthermore, physical exercise may be beneficial in patients with certain IBD subtypes. This review studies the effects of physical exercise on the human gut microbiome while investigating pathophysiologic mechanisms that could explain physical activity's clinical effects on patients with IBD.

IBD subtypes. Physical exercise is a modulator of the intestinal microbiome that has, furthermore, been associated with positive clinical outcomes in certain patients with IBD. Herein we discuss certain types of physical exercise, their effect on the intestinal microbiome, and its clinical effects on patients with IBD, as well as investigating underlying pathophysiologic mechanisms that could mediate the observed associations.

INTRODUCTION

Inflammatory bowel disease (IBD) comprises a spectrum of chronic inflammatory diseases that primarily but not exclusively affect the gastrointestinal tract, including ulcerative colitis (UC), Crohn's disease (CD), and other related conditions[1]. Their pathogenesis is classically thought to include interactions between genetic, immune-mediated, and environmental factors[2]. Studies on the molecular epidemiology of IBD have shown that the gut microbiome composition is a biomarker of prognostic importance for CD and UC[3]. Other molecular phenotypes include *NOD2*, *MHC*, and *MST1* genotypes, which are correlated to disease location and activity, microRNA miR-215 levels, and DNA methylation, which are correlated to disease activity, *FOXP3* haplotype, which is of prognostic importance, and oncostatin M and IL-1β levels, which predict response to anti-tumor necrosis factor therapy[3,4]; furthermore, serum C-reactive protein levels correlate to disease activity but are generally nonspecific[4]. Increased serum miR-595 and miR-1246 levels are associated with active IBD[4]. Serum interleukin (IL)-2 and IL-6l and positivity for anti-bacterial flagellin, anti-outer membrane porin C, anti-A4-Fla2, and anti-Fla-X antibodies predict recurrence of disease[4]. The heterogeneity of IBD phenotypes underlines the need for new markers that can subclassify, diagnose, inform prognosis, and guide IBD treatment; but owing to the low sensitivity or specificity of known molecular markers, current knowledge is far from adequate to support their use in everyday clinical practice, a limitation that includes the microbiome as biomarker[3,4].

Early studies on animal models have shown that immune cells could not cause inflammation in the absence of intestinal bacteria, therefore suggesting a putative role for the intestinal microbiome in the induction and/or maintenance of local inflammation and disease[5]. This was further supported by the observation that intestinal inflammation in IBD was greatest in parts of the bowel richer in bacteria[2]. Further studies have demonstrated that certain patterns of microbiotic alterations, including increases or reductions in the plethora of bacterial, fungal, and viral species, were likely linked to the risk for IBD[2].

Physical exercise is a possible modulator of intestinal microbiome composition, altering the functional activity of the gut ecosystem. Exercise is associated with increased biodiversity and a beneficial metabolic function, while exhaustive exercise training might be associated with dysbiosis of the gut microbiota, promoting negative metabolic effects and inflammation[6,7]. Thus, physical activity/exercise has been studied as a significant modifier of the intestinal microbiome in animal[8,9] and human[6,7,10] studies. Specifically, more active individuals' microbiomes tend to harbor a higher abundance in *Akkermansia muciniphila*, a health-promoting species, as well as decreased Bacteroidetes bacteria and increased bacterial diversity[11,12]. Specific types of physical exercise have not only been associated with microbiotic signatures, but also with a reduction in endotoxemia and serum inflammatory markers [11,13,14]. These alterations persist as statistically significant, even when normalizing for age, weight, body composition, and nutritional habits as confounding factors[15]. Nevertheless, it should be noted that researchers have also reported a lack of correlation between a certain type of exercise and changes in the microbiome[16,17]; moreover, some contradictions as to the observed patterns of microbiotic alterations associated with exercise are evident[18]. This ambiguity is, however, expected to be partly clarified when common definitions and detailed description of exercise charac-

teristics [*i.e.* frequency, intensity, type (mode), time (duration), and volume/dose (duration x intensity)] and methods of fecal sampling are utilized among the same study groups.

Given the established pathobiological role for the microbiome in IBD and taking into account the more recent data assessing patterns of microbiotic alterations associated with exercise, this review aims to summarize and clarify the important findings linking dysbiosis in IBD to physical activity, with a focus on preventative medicine and therapeutics.

METHODLOGY

Our literature search utilized the PubMed literature database. Search keywords included "inflammatory bowel disease", "IBD", "ulcerative colitis", "Crohn's disease", "indeterminate colitis", "microbiome", "microbiota", "physical activity", "exercise", as well as combinations of the aforementioned with the AND/OR operators. Articles were first filtered by title, followed by abstract screening, and the remaining were finally selected based on their full text.

EXERCISE AND ITS INFLUENCE ON THE MICROBIOME

In healthy mice, *Allobaculum* and *Clostridiales* are more abundant in exercised mice than in controls[19]. In diabetic mice, total intestinal bacteria and Enterobacteriaceae are lower in the exercise groups than in diabetic controls[9]. In high-fat diet obese mice, exercise increases Bacteroidetes as well as increases the Bacteroidetes/Firmicutes ratio in the cecum and colon[20]. In an early obesity and non-alcoholic fatty liver disease model, where male rats fed a control or a high-fat diet, a combined aerobic and resistance exercise training resulted in increased *Parabacteroides*, *Bacteroides*, and *Flavobacterium* genera, while *Blautia*, *Dysgonomonas*, and *Porphyromonas* exhibited an opposite pattern[8] (Table 1).

Several factors that modify the human gut microbiome have been identified; those include country of residence, specific genotypes (such as those affecting the ABO antigens), delivery by caesarian section, diet, cigarette smoking, breastfeeding, gastroenteritis, increased hygiene, use of antibiotics, obesity, immune response, as well as physical exercise[2,13,21,22]. Human studies have shown that sedentary individuals have a predominance of *Bacteroides* and *Parabacteroides* in their gut microbiome, while participants with a higher level of activity, as gauged by accelerometers, have a predominance of *Coprococcus*, *Blautia*, and *Eubacterium*[23]. Women with an active lifestyle have a higher proportion of *Faecalibacterium prausnitzii*, *Roseburia hominis,* and *Akkermansia muciniphila* bacteria in their gut than sedentary women[24]. Aerobic brisk walking increases *Bacteroides* species in healthy elderly women[25]. Endurance training has been observed to reduce *Streptococcus*, *Proteobacteria*, *Porphyromonadaceae*, *Odoribacter*, *Desulfovibrionaceae*, and *Enterobacteriaceae* and to increase *Verrucomicrobiaceae*, *Bifidobacteriaceae*, *Dorea*, *Anaerofilum*, and *Akkermansia* bacteria in overweight women[26]. In obese children, a strength and endurance combined training program led to an increase in *Blautia*, *Dialister,* and *Roseburia* species, accompanied by a reduction in inflammasome activation[14]. In elderly men, endurance exercise has been observed to reduce *Clostridium difficile* and increase intestinal populations[27] Male elite rugby players have been found to have a more diverse microbiome than body mass index (BMI)-matched controls, with the athletes having higher proportions of *Akkermansiaceae* and *Akkermansia* than high-BMI controls and lower proportions of *Lactobacillaceae*, *Bacteroides,* and *Lactobacillus* than low-BMI controls[10]. In swimmers, a reduction in training volume is accompanied by a significant reduction in *Coprococcus* and *Faecalibacterium* populations[28]. In marathon runners, *Lentisphaerae* and *Acidobacteria* increase in intestinal population after running[29]. Ultra-endurance exercise has been observed to increase butyrate-producing bacteria, such as *Subdoligranulum* and *Roseburia hominis*, which are thought to reduce intestinal inflammation by producing butyrate[30]. In martial arts athletes, *Parabacteroides, Phascolarctobacterium, Bilophila, and Oscillibacter* are higher in higher-level athletes than in lower-level ones, with *Allisonella*, *Citrobacter,* and *Megasphaera* found at lower levels[31]. Other researchers have reported no change in gut bacterial diversity or composition after short-term high-intensity interval training in lean and overweight men[16]. Exercise has also been found to induce microbial transformations in the context of damaging intestinal conditions, such as a high-fat diet and toxic substances[32] (Table 1). These changes

Table 1 Effect of exercise on the gut microbiome

Ref.	Study subject	Sample type	Exercise protocol	Exercise *vs* controls	Notes
Lambert *et al* [9]	Mouse, type 2 diabetic, (C57BL/KsJ-leprdb/leprdb)	Cecal matter	Treadmill, 5 d/wk, 66 min/d, 2.87 m/min	↑ Clostridium leptum ↑ Lactobacillus ↓ Total bacteria ↓ Bacteroides ↓ Bifidobacterium ↓ Methanobrevibacter ↓ Prevotella	↑ Bifidobacterium with exercise in non-diabetic mice
Campbell *et al*[19]	Mouse C57BL/6NTac, male	Fecal matter from the distal colon	Free running wheel	↑ Allobaculum ↑ Clostridiales ↑ Faecalibacterium prausnitzi	Normal-diet, not observed in a high-fat diet, except for Faecalibacterium prausnitzi
Denou *et al* [20]	Mouse, C57 BL/6, high-fat diet, obese	Feces from anal area, then full intestinal sampling	Treadmill, 6 wk total, 3 d/wk, 1 h/d, 17 m/min at 5% grade for 2 min + 2 min rest, increase by 1 m/min every week	↑ Bacteroidetes/Firmicutes ratio in the cecum ↑ Bacteroidetes/Firmicutes ratio in the rectum	-
Carbajo-Pescador *et al*[8]	Juvenile male Wistar rats on early obesity and non-alcoholic fatty liver disease onset	Fecal matter	Treadmill, 11 wk total, 60 min/d combined aerobic and resistance training (10-min running; eight 2-min progressive incline run from 10°-25° at 20-25 cm/s /1 min rest; 30 min aerobic exercise)	↑ Parabacteroides ↑ Bacteroides ↑ Flavobacterium genera ↓ Blautia ↓ Dysgonomonas ↓ Porphyromonas	
Clarke *et al* [10]	Human, rugby player, male	Fecal matter, self-collected	Rugby training, capacity determined by EPIC-Norfolk questionnaire	↑ Akkermansia (than high-BMI controls) ↓ Bacteroides (than low-BMI controls) ↓ Lactobacillus (than low-BMI controls)	-
Bressa *et al* [24]	Human, female, premenopausal, BMI 20-25 kg/m^2	Fecal matter, self-collected	No forced exercise, physical activity level gauged by accelerometers	↑ Akkermansia muciniphila ↑ Faecalibacterium prausnitzii ↑ Roseburia hominis	-
Munukka *et al*[26]	Human, female, sedentary, BMI > 27.5 kg/m^2	Fecal matter, self-collected	Ergometer, Weeks 1-2: at 60 rpm, low intensity, 3 d/wk, 40 min/d Weeks 3-4: 3 d/wk, 50 min/d, every other session 3 10-min intervals of moderate-intensity cycling, the rest low intensity Weeks 5-6: 3 d/wk, 60 min/d, four 10-min moderate intensity intervals, the rest low intensity	↑ Akkermansia ↑ Anaerofilum ↑ Bifidobacteriaceae ↑ Dorea ↑ Verrucomicrobiaceae ↓ Desulfovibrionaceae ↓ Enterobacteriaceae ↓ Odoribacter ↓ Porphyromonadaceae ↓ Proteobacteria ↓ Streptococcus	-
Taniguchi *et*	Human, male, age > 60	Fecal matter,	Cycling, Weeks 1-2: 3 d/wk, 30	↓ Clostridium difficile	-

al[27]	yr, healthy	self-collected	min/d, 60% of VO_2peak (week 1), 70% of VO_2peak (week 2) Weeks 3-5: 3 d/wk, 45 min/d, 70% of VO_2max (week 3), 75% of VO_2max (weeks 4-5)	↑ Oscillospora	
Zhao *et al*[29]	Human, marathon runners	Fecal matter, self-collected	The 2016 Chongqing half marathon, before and after the race	↑ Acidobacteria ↑ Lentisphaerae	Post- *vs* pre-running
Castellanos *et al*[23]	Human	Fecal matter, self-collected	No forced exercise, physical activity level gauged by accelerometers	↑ Blautia ↑ Coprococcus ↑ Eubacterium ↓ Bacteroides ↓ Parabacteroides	-
Keohane *et al* [30]	Human, male, athlete	Fecal matter, self-collected	Rowing race, 33 d 22 h, 151.8 km per day	↑ Roseburia hominis ↑ Subdoligranulum	Post-ultra-endurance exercise
Liang *et al* [31]	Human, martial arts athlete	Fecal matter, self-collected	Martial arts, athletes, divided into higher- and lower-level based on General Administration of Sport of China criteria	↑ Bilophila ↑ Oscillibacter ↑ Parabacteroides ↑ Phascolarctobacterium ↓ Allisonella ↓ Citrobacter ↓ Megasphaera	Higher- *vs* lower-level athletes
Morita *et al* [25]	Human, female, age > 65 yr, sedentary	Fecal matter, self-collected	Trunk strengthening training, 12 wk, 1 h/wk: 5-10 min of warm-up + 45 min of targeted resistance training of trunk muscles + 5 – 10 cool-down and at-home exercise daily	↑ Bacteroides	After 12 wk of aerobic training
Hampton-Marcell *et al* [28]	Human, age 18-24 yr, swimmers	Cotton swab sample	Self-reporting of daily swimming distance and duration during daily practice	↑ Coprococcus ↑ Faecalibacterium	Before *vs* after reduction of training volume
Quiroga *et al* [14]	Human, age 7-12 yr, obese	Fecal matter, self-collected	Strength and endurance training 12 wk, 2 d/wk: Warm-up on an ergometer for 7 min, low-medium load, 60 rpm Third minute onwards, a sprint of 30s at 3’30”, 4’30”, 5’30”, and 6’30” Strength exercises for five muscle groups, initially 3 sets of 12 repetitions at 30% 1RM, up to 3 sets of 8 repetitions at 70% 1RM Cool-down at an elliptical cardiovascular device, 7 min, 50 rpm, 4 min low-medium load + 3 min high load	↑ Blautia ↑ Dialister ↑ Roseburia	After a 12-wk strength and endurance training program
Rettedal *et al* [16]	Human, male, age 20-45 yr	Fecal matter, self-collected	9 sessions of high-intensity interval training on non-consecutive days over 3 wk: 60 s cycling at VO2peak 75 s rest 8 intervals initially, up to 12 intervals by the end of the protocol	No significant changes in composition	Before and after high-intensity interval training

BMI: Body mass index.

could in part be attributed to increased gut motility during exercise, which promotes shedding of loosely bound bacteria and the growth of health-promoting species[33].

ROLE OF THE MICROBIOME IN IBD

Patients with CD have a diminished diversity of the fecal intestinal microbiome, with Lachnospiraceae, Bacteroidetes, and the species *Clostridium leptum* being decreased, with Proteobacteria, Actinobacteria, and the genus *Prevotella* being increased[13]. Patients with inflammatory bowel disease also have increased *Fusobacterium*, *Pasturellaceae*, *Ruminococcus gnavus*, *Veillonellaceae*, *Candida albicans*, *Candida tropicalis*, *Clavispora lusitaniae*, *Cyberlindnera jadinii*, *Kluyveromyces marxianus,* and *Caudivirales* in their gut microbiota, as well as decreased *Bacteroides*, *Bifidobacterium*, *Clostridium* XIVa, *Clostridium* IV, *Faecalibacterium prausnitzii*, *Roseburia*, *Suturella*, and *Saccharomyces cerevisiae* [2]. Therefore, it can be argued that intestinal dysbiosis may be a component of IBD pathogenesis[34].

The involvement of the microbiome in the pathogenesis of IBD is further supported by the effectiveness of antibiotic therapy in the treatment of certain IBD phenotypes, such as perianal CD and pouchitis, and in the prevention of postoperative relapse in patients with CD[2].

Fecal microbiota transplantation involves the transfer of feces from a donor to the GI tract of a recipient, as an attempt to enrich the recipient's gut microbiota and correct any dysbiosis. Fecal microbiota transplantation is currently systematically used in the treatment of *Clostridium difficile* colitis[35]. Some researchers have also investigated its implementation in IBD therapeutics, with some promising findings having been reported, although no concrete conclusions can yet be drawn about its efficacy and safety, plausibly owing to the dissimilarities between the associated studies[35].

ANIMAL CLINICAL DATA

Gut microbiota transplant from exercise-trained mice leads to a reduction in inflammatory markers in the distal colons of sedentary mice, combined with an attenuated colitis histology score[36]. In mouse models of colitis, voluntary treadmill exercise has been found to reduce inflammation while forced exercise exacerbates tissue damage and leads to increased mortality[37]. The same researchers then attributed part of this effect to an increase in *Tenericutes* bacteria in the large intestine in the forced-exercise group, since the family *Mollicutes*, a member of the phylum *Tenericutes*, has been linked to UC in humans[38]. In another study, exercise was shown to ameliorate the symptoms of chemically induced colitis and to alter significantly gut microbiota, with decreased populations of *Bacteroides vulgatus* and increased numbers of *Akkermansia muciniphila*[39]. In mice born without a normal mucus layer in their intestines due to a genetic knockout of mucin-2, exercise neither significantly alters the gut microbiome nor reduces the severity of chronic colitis, in contrast to wild-type mice where both effects have been observed[40].

HUMAN CLINICAL DATA

Based on current literature, it is not clear whether dysbiosis is a cause or a result of IBD[13]; however, some conclusions could be drawn from certain scientific findings: Disease activity is mostly focused on bowel segments where the fecal stream is slower and bacterial populations are higher[2]. Mutations in genes affecting the functions of intestinal Paneth cells (*e.g.*, *NOD2*), which defend the small intestine against bacteria, are risk factors for IBD[2]; moreover, exposure to antibiotics in early life is linked to IBD later in life[13]. Antibiotics are, however, effective in certain conditions involving IBD, such as in inflammation of the ileoanal pouch after colectomy indicated by IBD-related complications[41]. Surgical fecal diversion is beneficial in the treatment of CD, as bowel segments excluded from the fecal stream tend to show remission[2]; furthermore, probiotics and fecal transfer are a therapeutic option for inducing and maintaining IBD remission[13]. These findings suggest that there exists a causal component to the microbiotic patterns associated with IBD, despite the inconsistencies between observed microbiotic changes as reported by different studies[13].

Regarding the probable protective effect of exercise in IBD, it is thought to stem from anti-inflammatory actions[6]. These include the secretion of myokines by skeletal muscles, such as myostatin, irisin, IL-15, brain-derived neurotrophic factor, myonectin, decorin, and secreted protein acidic and rich in cysteine, mediators with autocrine, paracrine, and endocrine anti-inflammatory actions[42]; moreover, in obese humans, exercise has been found to alter the gut microbiome and reduce endotoxemia, as

measured by the levels of the endogenous protein lipopolysaccharide binding protein [11], thus suggesting another probable anti-inflammatory effect for physical activity. Exercise training has also been found to reduce the levels of NLR Family Pyrin Domain Containing 3 and caspase 1, proteins that participate in the inflammasome activation pathway, in obese children[14].

Several mechanisms have been proposed by which exercise may influence gut microbiota. These include crosstalk between muscles and the gut microbiota through the 5′ adenosine monophosphate-activated protein kinase and fasting-induced adipose factor pathways as well a reduction of fecal bile acids, an increase in production of short-chain fatty acids, an increase in gut luminal immunoglobulin A, a reduction in luminal transit time, and the activation of the stress hypothalamic-pituitary-adrenal axis, effects found to be produced by exercise[43-46].

The functions of a healthy microbiome include metabolic functions, such as the production of anti-inflammatory short-chain fatty acids, vitamin K, and biotin, protective effects, such as induction of secretions that attack pathogenic bacteria, triggering of mucosal proliferation through the Toll-like receptor pathway, inhibition of adhesion of pathogenic bacteria, and trafficking of neutrophils, as well as trophic functions, *i.e.* protecting the intestinal mucosa from immune-mediated damage[46-48]. Part of the pathogenesis of IBD is thought to include a loss of these effects, probably caused by a damaging shift to the microbial composition in the gut[1]. These include reductions in Bacteroidetes, *Clostridium leptum*, *Prevotella*, *Bifidobacterium*, and *Roseburia* as well as increases in Proteobacteria, as mentioned above. All of these alterations are restored by exercise interventions in animal and human studies (Table 1), suggesting a plausible mechanism for the beneficial effect of exercise in IBD.

Current exercise guidelines from the American Heart Association for adults aged 18 years to 65 years of age recommend moderate-intensity aerobic exercise for at least 30 min, 5 d a week or vigorous-intensity exercise physical activity for 20 min, 3 d a week [49]. No specific guidelines exist for patients with IBD, however, evidence suggests that mild-to-moderate exercise harbors multiple benefits for patients with at least mild IBD, and excessive exercise could pose hazards for patients' health[41]; therefore, physicians should be cautious when prescribing exercise for patients with IBD, being on the lookout for exercise addiction[41].

Clinical data studying the association of IBD with exercise suggest that sedentary occupations confer a higher risk for IBD than more physically demanding occupations, as found in a retrospective study of German employees[50]; moreover, both CD and UC have been associated with low physical activity during childhood[51]. Exercise has been reported to decrease the risk of relapse in patients with IBD in remission[52]. Mild-to-moderate exercise is beneficial in patients with at least mild IBD[41]. A recent study reported that prolonged moderate-intensity walking did not appear to increase blood cytokine levels in patients with IBD more than it did in healthy controls, and fecal calprotectin levels were found to be comparable between patients who walked and patients who did not walk, suggesting that exercise does not cause exacerbation of IBD[53].

CONCLUSION

The findings of the present review imply that there exists a promising field of research regarding exercise-induced changes of the microbiome in IBD. What needs to be elucidated is whether the microbiome is a passive "bystander" in the systemic effects induced by physical activity, *i.e.* observing and reacting to activity-related systemic metabolic and endocrine signals by altering its composition, or whether it is a necessary physiological intermediate in the restoration of immune tolerance and normal gastrointestinal function in the context of IBD. Further research should also focus on disease determinants, such as age, sex, type, localization, histology, refractory phenotype, disease activity, molecular markers, and performance status, which could affect the disease's response to certain types of physical exercise. Besides, considering that there is not only one optimal microbiota composition for the IBD patients, more studies are also needed to reveal how microorganisms interact with each other and with their host to identify different healthy microbiota schemes and an optimal, potentially personalized, dose of exercise for these patients. Lastly, an interesting field might exist for the microbiome as an index predictive or indicative of exercise-induced amelioration of IBD clinical symptoms, as part of current research on the molecular epidemiology of IBD.

Abstract

As the gastrointestinal tract may also be a crucial entry or interaction site of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the role of the gut mucosal immune system as a first-line physical and immunological defense is critical. Furthermore, gastrointestinal involvement and symptoms in coronavirus disease 2019 (COVID-19) patients have been linked to worse clinical outcomes. This review discusses recent data on the interactions between the virus and the immune cells and molecules in the mucosa during the infection. By carrying out appropriate investigations, the mucosal immune system role in SARS-CoV-2 infection in therapy and prevention can be established. In line with this, COVID-19 vaccines that stimulate mucosal immunity against the virus may have more advantages than the others.

respiratory syndrome coronavirus 2. Given the complex interactions between the virus and the mucosal immune system after exposure, additional research is needed to elucidate the immune mechanisms and processes in the gut mucosa. The hallmark of all immune responses is the recruitment of various immune cells, such as neutrophils, dendritic cells, macrophages, and T cells in the gut mucosa. However, the mucosal inflammatory response could change intercellular space between enterocytes, leading to an increase in intestinal permeability that allows various bacterial antigens and toxins to enter the bloodstream, further complicating the disease state of coronavirus disease 2019 patients.

INTRODUCTION

It is well-established that nasopharynx-associated lymphoid tissue (NALT) and mucosa-associated lymphoid tissue (MALT) are first-line defenses. Therefore, airborne infections start by penetrating the upper airway mucosa, where a higher viral load is found, compared with the throat. NALT is involved in the induction of the immune response towards the microorganisms by promoting the differentiation and activation of immune cells such as Th1- and Th2 cells, dendritic cells, macrophages, resident microfold M cells, innate lymphoid cells, immunoglobulin (Ig)A-switched B cells, as well as immune mediators and molecules (*i.e.* beta-defensins, galectins, collectins, and cytokines)[1]. The same goes for the gut mucosal immune system.

It is thus not surprising that NALT exerts "gate control" on many infections that penetrate the mucosa, including severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[2]. SARS-CoV-2 acts cytopathically at the mucosal level by inducing injury and death of the infected cells. That can be accomplished by pyroptosis as a consequence of activation of host-cell released damage-associated (DAMPs) and viral pathogen-associated molecular patterns (PAMPs) and innate immunity along with the secretion of many cytokines [interleukin (IL)-6, interferon (IFN)-gamma, MCP1, and IP-10)][1]. On the other hand, pattern-recognition receptors and their soluble forms are mainly involved in SARS-CoV-2 infection[3,4].

Amongst the immune molecules, the collectins have a significant role in recognizing glycoside structures of the virus. For example, deficiency of mannose-binding lectin (MBL) has been associated with increased susceptibility to viral infections, including SARS-CoV[5]. Additionally, MBL can inhibit S protein by binding to it and inhibiting structural S rearrangements needed for optimal infection, thus leading to reduced virulence of SARS-CoV-2. Furthermore, as the expression of MBL declines with aging, older adults may be more prone to infection because of lack of an effective innate response[5].

Additionally, the presence of natural, pre-existing IgM and IgA antibodies produced in the absence of any antigen, provides the first-line defense[6]. Furthermore, some of the natural antibody subsets can recognize ABO blood-group antigens, which are expressed on many epithelial cells, including the lung[7]. As enveloped viruses like SARS-CoV-2 are highly glycosylated, it is thought that when virions reproduce in the alveolar epithelial cells in people with group A or B blood, those antigens may be expressed on their envelope. Thus, one may suggest that natural antibodies against A and B antigens may be protective[8]. Studies have so far revealed that anti-A antibodies can inhibit S protein binding to angiotensin-converting enzyme 2 (ACE2) receptors when the host cells express A antigen. Individuals with group O blood have a reduced risk of infection compared with those who have non-O blood groups, and those with group A blood are prone to severe coronavirus disease 2019 (COVID-19)[8].

EPIDEMIOLOGICAL SIGNIFICANCE OF MUCOSAL PENETRATION AND REPLICATION FOR THE SPREAD OF SARS-COV-2

COVID-19 is an infectious disease in which the primary mode of transmission of its causative agent, SARS-CoV-2, is by transfer of saliva microdroplets between people in close contact. The microdroplets are produced while coughing, sneezing, or talking. Infection by contact with contaminated surfaces followed by touching the face is less common. Most microdroplets fall to the ground or surfaces and are not effective over long distances. The first 3 d after the onset of symptoms is when the patient is most contagious. Transmission may occur before symptoms appear. Asymptomatic people may thus be contagious, too[9].

COVID-19 is an airborne viral disease. It was shown that SARS-CoV-2 penetration into the upper airways is the first step of the infection, as higher viral loads were found in nasal swabs than throat swabs[10,11]. The same distribution as in symptomatic patients was observed in asymptomatic patients, implicating the nasal epithelium as a portal for initial infection and transmission[12]. The nose is a critical component of mucosal immunity, providing protection in the upper airway. It is involved both in host protection and immune homeostasis between the commensal microbiota and invading pathogens. The mucosal immune system is the first line of physical and immunological defense against invading pathogens[13]. Current evidence indicates that SARS-CoV-2 enters the human body mainly through the ACE2 + transmembrane protease/serine subfamily member 2 (TMPRSS2) + nasal epithelial cells. The initial host response to this pathogen begins in the NALT system[1].

VIRAL FACTORS OF SARS-COV-2 AND IMPACT ON THE MUCOSA

Coronaviruses are enveloped, positive-sense single-stranded RNA viruses that are members of families *Coronaviridae*, order Nidovirales. There are four known genera, *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*. SARS-CoV-2 belongs to the family *Coronaviridae* and genus *Betacoronavirus*[14,15]. Diseases caused by coronaviruses comprise symptoms that range from mild respiratory illness like the common cold to severe infections causing death. These viruses can infect humans, mammals, and avian species, including farm and companion animals (pets). Hence they represent not only a challenge for public health but also are of veterinary and economic concern. From the beginning of the 21st century, the SARS epidemic in 2002-2003, the Middle East respiratory syndrome (MERS) in 2012, and the emergence of the new SARS-CoV-2, are examples of human infections caused by coronaviruses[16,17].

Coronaviruses are spherical, enveloped RNA viruses containing an impressively large (25 kb to 32 kb), nonsegmented, single-stranded, positive-sense RNA genome, which is the same sense as the messenger RNA (mRNA) found in cells. The genome codes four main structural proteins, nonstructural proteins (NSPs), and accessory proteins. The structural proteins, which include the spike (S), nucleocapsid (N), membrane (M), and envelope (E) proteins, play essential roles in the arrangement of the virus particles and other aspects of the viral life cycle[18]. Among the structural proteins, the most important is S protein, which is required for viral entry as it binds to the target cell receptors and initiates fusion with the cell membrane[19].

SARS-CoV-2 spike (S) protein is a large glycosylated transmembrane, homotrimeric protein. Each monomer has a molecular mass of about 150-200 kDa[18]. Each subunit of the protein consists of two functionally distinct domains, S1 and S2. S1 forms the bulb portion of the spike protein on the virion surface. S2 attaches the S proteins to the viral membrane. The receptor-binding domain is located on S1; S2 is necessary for membrane fusion to allow the viral cell entry[20]. Transmembrane ACE2 is the functional host receptor for SARS-CoV-2[21]. ACE2 is widely expressed in the ciliated, goblet, and surfactant-producing type-2 alveolar cells of the lungs, intestinal, cardiac, and vascular endothelia, the kidney, and the liver[22].

Other receptors, such as DC-SIGN, L-SIGN, Neuropilin-1, furin, and cathepsin B and L can serve as portals of virus entry into the cell. Taken together, the findings provide a possible explanation for the occurrence of COVID-19 complications in organs expressing those receptors. The binding of S protein to the host ACE2 receptor alone is not enough for the viral fusion. The spike protein needs to be cleaved by cell surface serine proteases at specific sites (S1/S2 boundary and S2`), releasing the S1 domain, which subsequently activates the S2 domain, leading to fusion of the viral cellular membranes[23]. Host-cell surface serine proteases shown to cleave the S proteins include, but are not limited to, TMPRSS2, furin, and trypsin. Both ACE2 and

TMPRSS2 (also furin) are highly expressed in the gastrointestinal (GI) tract, particularly intestinal epithelial cells[24]. The primary entry site of SARS-CoV-2 is host lung cells. Nevertheless, the GI may also be a crucial entry or interaction site. SARS-CoV-2 viral particles are preferentially released apically and not at the basement of the airway cells. Thus, the released SARS virus may be removed by mucociliary clearance with access to the GI *via* luminal exposure. Moreover, the early appearance of gastrointestinal symptoms such as nausea, vomiting, abdominal pain, and diarrhea in almost 30% of COVID-19 patients supports this hypothesis.

Viral factors of SARS-CoV-2 and host innate immune response

After the fusion with the cell membrane, the viral genome is released into the host-cell cytoplasm, and the highly controlled process of viral RNA replication and transcription occurs[23]. The virus interacts with cellular compartments and proteins to make its RNAs and proteins. It has been shown that some viral proteins influence critical host-cell processes such as apoptosis, necrosis, innate immunity, and others. One of the structural proteins, nucleocapsid (N) protein, despite its central role in binding to the viral RNA genome, was shown to inhibit type I IFN production and signaling. Recent studies provide evidence that NSP1 (participates in host-cell mRNA degradation and translation inhibition[25]. Hence, the translation of vital cellular proteins, including type I IFN, is shut down, allowing viral RNA to be translated effectively[26]. That may be the reason why NSP1 is cleaved and activated immediately after the production of polypeptide pp1a.

PLpro and Mpro (3CLpro) viral proteases are necessary for the proteolytic cleavage of the polyproteins (pp1a and pp1ab)[20]. Furthermore, it has been shown that the proteases play a role in inhibition of type I IFN signaling. PLpro is responsible for only a few cleavage events in pp1a, but it also can act as a deubiquitinase and deISGylating (removal of IFN-stimulated gene 15 from proteins), which are enzyme activities that lead to evasion and the initial steps of the antiviral response[27,28].

During viral RNA replication and transcription, various PAMPs are produced in the form of double-stranded RNA intermediates. It has been suggested that some of the viral proteins (*i.e.* E, N, NSPs) are involved in the formation of convoluted membranes and double-membrane vesicles to create a protective microenvironment for genomic RNA replication and transcription of subgenomic mRNAs[23]. Furthermore, the PAMPs are recognized by endosomal Toll-like receptors (TLR 3, 7, 8) or cytoplasmic RNA PRRs, such as retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein 5 (MDA5). The proper function of TLRs, RIG-I, and MDA-5 is crucial for host-cell survival, as the receptors provide a first-line defense against infections[29-31]. The viral genome attachment to the receptors, especially the TLRs, gives rise to innate immune response signaling pathways. In leukocytes (*e.g.*, dendritic cells, macrophages, natural killer cells, T cells of the adaptive immune system, and B cells), interaction with viral RNA triggers innate immune responses and development of acquired antigen-specific immunity[31]. The innate immune system senses the foreign viral materials that are possibly pathogenic, which initiates downstream signaling to the nucleus, and in turn promotes the expression of types I and III IFNs and other proinflammatory cytokines. Once activated, the IFNs induce a cascade of cellular and molecular events that lead to the suppression of viral replication and reduction in the number of infected cells. Many viral proteins influence the IFN signaling pathway, thus providing a favorable environment for virus development. PLpro, NSP1, ORF3b (a viral accessory protein), and N inhibit two proteins (IRF3 and IRF7) required for INF transcription, thus inhibiting the first steps in the innate immune response against the virus[29-31]. ORF3a and ORF3b are viral proteins that induce caspase-independent necrotic cell death and initiate an inflammatory cascade through activation of the NLRP3 inflammasome[32].

It should be noted that necroptosis and pyroptosis are highly inflammatory mechanisms of cell death that lead to increased secretion of proinflammatory cytokines and chemokines, thus contributing to further tissue damage. Several studies have found that expression of N, E, M, ORF3a, ORF3b, ORF7a, ORF8a, or ORF9b proteins in various cell lines triggered apoptosis through cytochrome C release and caspase-dependent pathways. Apoptosis is a form of noninflammatory cell death that often serves as a host response during viral infection. At the moment, it is not yet clearly elucidated what the exact role of SARS-CoV-2 induced cell death is. It may be an exit strategy to increase viral spread, a form of immune evasion, or just an indirect effect of viral replication on the host cell cycle[23].

Proteome analysis of SARS-CoV-2 has shown that viral proteins interact with more than 300 host-cell proteins, leading to cellular mRNA degradation, inhibition of translation, inhibition of IFN production and signaling, induction of apoptosis and

necrosis, and other activities. The hallmark of all these functions is an evasion of host innate immune responses that could facilitate viral spreading to nearby cells. The changes in infected enterocytes could result in the recruitment of neutrophils, dendritic cells, macrophages, and T cells in the gut mucosa. The mucosal inflammatory response could change the intercellular space between enterocytes, leading to an increase in intestinal permeability that provides an opportunity for bacterial antigens and toxins to enter the bloodstream and further complicated the disease state of COVID-19 patients.

SARS-COV-2 AND MUCOSAL IMMUNITY OF THE GI

An effective and powerful adaptive immune response follows the early antiviral innate response in the mucosa. Expansion of CD4+ T-helper cells, CD8+ cytotoxic T cells, and plasma cells simultaneously with the ongoing innate immune response is critical for virus elimination[33]. However, many factors can alter the immune response and control of the viral replication cycle. External factors such as smoking, pollutants, temperature, humidity, and internal factors such as age and genetics negatively affect the effective response to SARS-CoV-2. Additionally, defects in the immune response towards the virus, such as reduced MBL levels and natural antibodies, anti-IFN autoantibodies, and impaired cytotoxic CD8+ cells, may lead to severe infection because of a lack of effective control of viral replication and the spread of propagation from the upper to the lower airway. Simultaneously, a vast release of proinflammatory cytokines and the recruitment of neutrophils, macrophages, and other cell types contribute to uncontrolled systemic inflammation and cytokine storm [33].

We have to mention the thick layer of mucus on the respiratory, gastrointestinal, and reproductive mucosal surfaces in most mammals that contributes to the first-line defense against various infections. Many studies have reported the essential role that mucins play in infectious diseases, including COVID-19[34,35]. In addition, glycans are complex molecules glycans that play a critical role in communication between cells, including adhesion. The extracellular N-terminal domain and intracellular C-terminal domain undergo biochemical changes during bacterial, viral, and parasitic infections by directly influencing both proinflammatory and anti-inflammatory responses[36]. Mucins sense ligands of pathogenic origin and pass the information downstream by activating immunomodulatory pathways. Currently, 22 genes for membrane-bound and secretory mucins have been documented in humans. Recent data suggest that they can be an entry and/or exit for SARS-CoV-2[36]. Furthermore, mucin levels in bronchoalveolar lavage fluid were shown to correlate with cytokine levels, predicting the magnitude of inflammation (*i.e.* cytokine storm), the hallmark of severe COVID-19 and acute respiratory disease syndrome (ARDS). Prognosis and the response to therapy were also influenced by mucin levels[34].

As the virus can enter through the mouth mucosa or the conjunctival surface of the eye, an excellent immune system response would begin with primed and activated immune cells and molecules, including secretory IgA, and SIgA and then spread through the entire mucosa. Moreover, bronchus-associated lymphoid tissue might contribute to the greater resistance to COVID-19 in children, adolescents, and young people compared with older adults[37]. Particular attention should be paid to SIgA, which plays an effective role in protection against various pathogens by neutralization, inhibition of adherence, and agglutination. As SIgA does not activate the classical complement cascade pathway, it is more anti- than proinflammatory[38]. Furthermore, IgA can inhibit IgM or IgG antibody-activated complement. It has been shown that the mucosal immune response with involvement of SIgA begins around 6-10 d after SARS-CoV-2 infection, with the expression of α4β7 integrin mucosal homing receptors and terminal differentiation of B cells into pIgA-secreting plasma cells in NALT[39]. Serum and salivary IgA antibodies against the spike protein of SARS-Cov-2 have also been reported[40]. Moreover, the salivary IgA has been shown to persist for at least 3 mon. Indeed, IgA antibodies against SARS-CoV-2 were found to be higher in the nasal mucosal fluids, tears, and saliva of infected subjects[41,42], IgA-switched plasmablasts that bear the mucosal chemokine receptor CCR10 were increased in the peripheral blood of SARS-CoV-2-infected subjects[42]. Thus, now we have more data on the IgA antibody production in response to SARS-CoV-2 infection.

In addition to MALT, mucosal-associated invariant T cells were also described. They comprise innate-like T cells (*e.g.*, invariant natural killer T, innate lymphoid cells, and γδ T cells) involved in pulmonary mucosal antiviral immunity and tissue protection

and repair after resolving the infection[43]. Pearson *et al*[44] focused on local mucosal responses during viral infection, particularly with SARS-CoV-2 in both lungs and gut. They found that IL-33 and IL-8 were increased in fecal samples of COVID-19 patients due to intestinal involvement[44,45]. Simultaneously, cytokines such as IL-1b, tumor necrosis factor alpha, and IL-6 were found to decrease. IL-7, a critical cytokine for T cell development and survival was also increased during gastrointestinal infection [46]. In addition to the other T cells in the gut mucosa during COVID-19 infection, and enhanced effector function of Th17 cells has also been seen[47]. By secreting many cytokines, they contribute largely to the acute lung injury observed in severe COVID-19 cases. However, their role in mucosal SARS-CoV-2 infection needs to be elucidated.

Considering the route of infection and the relative independence of mucosal and systemic immune responses, one can suggest that appropriate investigations can establish the role of mucosal immune system in SARS-CoV-2 infection for therapy and prevention. In line with this, intranasal COVID-19 vaccines are an additional hope to promote mucosal immunity against the virus, an apparent advantage of other nasal vaccines (*i.e.* influenza)[48]. Moreover, the advantages of such vaccines including generation of both mucosal (SIgA) and circulating (IgG and IgA) antibodies and SARS-specific effector and memory T cell responses have not be seen in conventional vaccines[49].

It is speculated that anti-SIgA antibodies can neutralize and eliminate SARS-CoV-2 in the mucosa without inflammatory consequences. Furthermore, testing for IgA antibodies in nasal and saliva samples might indicate the presence of mucosal immune responses against SARS-CoV-2. Additionally, serum IgA is distinct from locally secreted IgA^+ dimers in plasma cells in the lamina propria of mucosal tissues[50]. The interaction between the virus and the mucosal immune system is shown in Figure 1.

GASTROINTESTINAL INVOLVEMENT DURING SARS-COV-2 INFECTION

Along with its other functions, ACE2 participates in the uptake of amino acids in intestinal epithelial cells, expression of antimicrobial peptides, and gut microbiome ecology[21,51]. As stated above, ACE2 is expressed in almost all human organs, but in varying degrees. Active replication of the SARS-CoV-2 virus has been detected in small-intestine enterocytes isolated from fecal specimens[52]. Other studies showed that the SARS-CoV-2 spike glycoprotein had a 10- to 20-fold higher binding affinity to ACE2 compared with SARS-CoV[53]. ACE2 is highly expressed in the GI[11], and in addition to the small intestine, ACE2 is also highly expressed in the pancreas[54]. Recent studies of single-cell mRNA expression found enriched expression of ACE2 and TMPRSS2 in enterocytes and mucus-producing cells[11,55].

The physiological activities of ACE2 include the absorption of nutrients from digested food. It also maintains osmotic and electrolyte balance across the GI lining epithelium by regulating sodium-dependent amino acid and glucose transporters in the enterocyte brush border[51]. Infectious diarrhea and malabsorption disorders that result from SARS-CoV-2 infection can be explained from a pathophysiological standpoint by the dysregulation of intestinal ion transporters[56]. Studies also suggest dysregulation of these transporters leads to inflammation and GI symptoms[57]. A similar mechanism of enhanced ACE2 expression is known to occur in irritable bowel disease patients who present symptoms similar to those of patients with SARS-CoV-2 [58]. GI cells are potential sites for virus replication of SARS-CoV-2 because of the enriched expression of ACE2 receptors in the mucosal glands and enterocytes[53]. A study using a recombinant strain of SARS-CoV-2 confirmed in situ that the virus could potentially infect and replicate in human intestinal tissue[52]. Once the virus enters the GI cells, it can replicate there, and viral toxin-mediated cell injury can cause gastroenteritis-like symptoms, including diarrhea, nausea, vomiting, and abdominal pain[59].

Infection caused by SARS-CoV-2 is often associated with typical respiratory response and prevalent gastrointestinal symptoms. ACE2 receptors in the GI play a vital role in the genesis of gastrointestinal symptoms. The mechanism underlying the gastrointestinal symptoms may involve damage to the intestinal mucosal barrier and promote the production of inflammatory factors[60]. Studies show that the incidence of gastrointestinal symptoms in SARS-CoV-2 and MERS-CoV infection is more than 20%[61]. Gastrointestinal symptoms may include vomiting, diarrhea, or abdominal pain in the disease's early phases[62]. The cause of the symptoms is an alteration of intestinal permeability and enterocyte dysfunction[63]. One of the first COVID-19 studies included 204 patients from Wuhan, China, infected with the virus with typical respiratory symptoms, many of whom also showed gastrointestinal symptoms, most
