ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Güray Can, MD, Associate Professor, Chief, Department of Gastroenterology, Bolu İzzet Baysal Education and Research Hospital, Bolu Abant İzzet Baysal University, Gölköy Campus, Bolu 14030, Turkey. guraycan@ibu.edu.tr

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Magnetic resonance imaging (MRI) is considered the gold standard for the evaluation of anal fistulas. There is sufficient literature available outlining the interpretation of fistula MRI before performing surgery. However, the interpretation of MRI becomes quite challenging in the postoperative period after the surgery of fistula has been undertaken. Incidentally, there are scarce data and no set guidelines regarding analysis of fistula MRI in the postoperative period. In this article, we discuss the challenges faced while interpreting the postoperative MRI, the timing of the postoperative MRI, the utility of MRI in the postoperative period for the management of anal fistulas, the importance of the active involvement and experience of the treating clinician in interpreting MRI scans, and the latest advancements in the field.

Core Tip: Magnetic resonance imaging (MRI) plays a pivotal role in the preoperative management of anal fistulas, but there are little data on postoperative MRI. There are no existing guidelines available to the operating surgeon and the radiologist regarding the challenges faced, utility, timing, and other aspects of MRI interpretation of anal fistulas in the postoperative period. This is the first paper on this theme and presents the first guidelines to be formulated for postoperative MRI in anal fistula management. These guidelines are based on an extensive experience of interpreting 2404 MRI scans in 1719 patients, including 685 postoperative MRIs in 411 patients.

INTRODUCTION

Anal fistulas are known and feared for their high rate of recurrence and risk to the continence mechanism if the anal sphincters are damaged during surgery[1-5]. Newer diagnostic modalities, especially magnetic resonance imaging (MRI) and transrectal ultrasound (TRUS)[6,7], have helped in better understanding the pathophysiology and management of the disease[8-11]. MRI is slightly better than TRUS and is considered the gold standard to assess anal fistulas[12]. Most colorectal surgeons prefer MRI over TRUS for managing anal fistulas[13]. A recent study showed that 97% of surgeons preferred MRI and only 12% opted for TRUS[13]. There is plenty of literature available on the role and interpretation of MRI in anal fistulas before surgery, but the same is not true about the postoperative period[12]. There are hardly any data on the role and interpretation of MRI in the postoperative period after fistula surgery[12]. This is the first paper in which the guidelines for postoperative MRI in anal fistulas are discussed, and they are presented under five headings (Table 1).

It is important to understand that fistula healing can be clinical or radiological[14,15]. The most common definition of clinical healing is cessation of pus discharge from all the external openings and the anus for at least 3 mo[14,15]. On the other hand, radiological healing is defined as complete healing of the internal opening, the intersphincteric portion of the fistula tract, and tracts in the ischiorectal fossa on MRI or TRUS[14,15].

CHALLENGES IN INTERPRETING THE MRI IN THE POSTOPERATIVE PERIOD

Interpretation of the MRI in the postoperative period is not straightforward and poses a few challenges[15]. The active (infected) fistula tracts and abscesses appear hyperintense on T2 and short tau inversion recovery (STIR) sequences. The main conundrum in the postoperative period is that inflammation of tissue due to surgical trauma also appears hyperintense (white) on T2 and STIR[15]. Another confusing feature is that the granulation tissue that leads to healing of the fistula appears hyperintense (white) on T2 and STIR[15,16] as well. Therefore, the overall picture can be quite confusing as all three (infected fistula, post-surgery inflammation and healing granulation tissue in the fistula tract) appear similar and therefore require careful assessment (Figure 1). This problem or confusion can be resolved if the check MRI is delayed for a few weeks[15,16].

After a few weeks, the postoperative inflammation of tissues subsides and the healing granulation tissue is converted to scar tissue when the fistula heals completely [16]. The scar tissue appears hypointense (black) on T2 and STIR (Figure 2). Therefore, after this time, any hyperintensity (white) on T2 and STIR would most likely indicate fistula persistence or fistula/abscess recurrence[16] (Figures 3 and 4).

(4) Active involvement and experience of clinician in interpreting MRI scans
(5) Other advancements

MRI: Magnetic resonance imaging.

Recommendation

An active fistula tract, post-surgery inflammation and healing granulation tissue in the fistula tract look similar on postoperative MRI and cause confusion. Waiting for a few weeks can resolve this confusion.

TIMING OF POSTOPERATIVE MRI

As discussed above, the timing of postoperative MRI assumes great significance if meaningful information is to be gained from it. The appropriate cut-off time period for performing MRI to confirm fistula healing should be 12 wk after the date of surgery [16]. However, MRI to check for a missed tract, inadequate drainage of an abscess or to identify a newly developed tract or abscess may be done at any time in the postoperative period as necessitated by the clinical picture.

By 12 wk after surgery, the postoperative inflammation of tissues subsides almost completely and fistula healing occurs completely in cases where fistula closure eventually occurs. In such cases with complete fistula healing, the hyperintense (white) active infected fistula tract or healing granulation tissue, both become hypointense (black) on T2 and STIR[12,16] (Figures 2 and 4-6).

Though a fistula may heal even before 12 wk (Figure 5) or the healing granulation tissue may persist beyond 12 wk after surgery, a minimum wait of 12 wk seems prudent[16]. Any wait greater than 12 wk is better; rather, the longer the delay in scheduling MRI, the clearer the picture (Figure 6). This is because, with greater delay in performing MRI (*e.g.*, 5-6 mo), all tissue inflammation and healing granulation tissue is expected to disappear, and any hyperintensity (white) on T2 and STIR would mean fistula persistence or fistula/abscess recurrence. However, most patients do not like to wait for such a long time (5-6 mo)[16].

Recommendation

The postoperative MRI to confirm fistula healing after surgery should be optimally done at least after 12 wk. However, the postoperative MRI to check for adequacy of abscess drainage or development of a new fistula tract may be scheduled as per clinical requirement.

UTILITY OF MRI IN THE POSTOPERATIVE PERIOD FOR ANAL FISTULA MANAGEMENT

MRI serves as an extremely useful tool in the armamentarium of surgeons managing complex anal fistulas. The main indications for performing MRI in the postoperative period after anal fistula surgery are as follow.

Checking for a missed tract or confirming adequate drainage of all abscesses: In complex fistulas with multiple tracts or abscesses, it is possible that a tract or an abscess may be missed during surgery or is inadequately drained[15]. This may lead to non-improvement or even deterioration of symptoms after surgery. An MRI in the postoperative period would lead to correct identification of the cause (missed fistula tract or inadequately drained abscess) (Figure 7) and timely intervention[16].

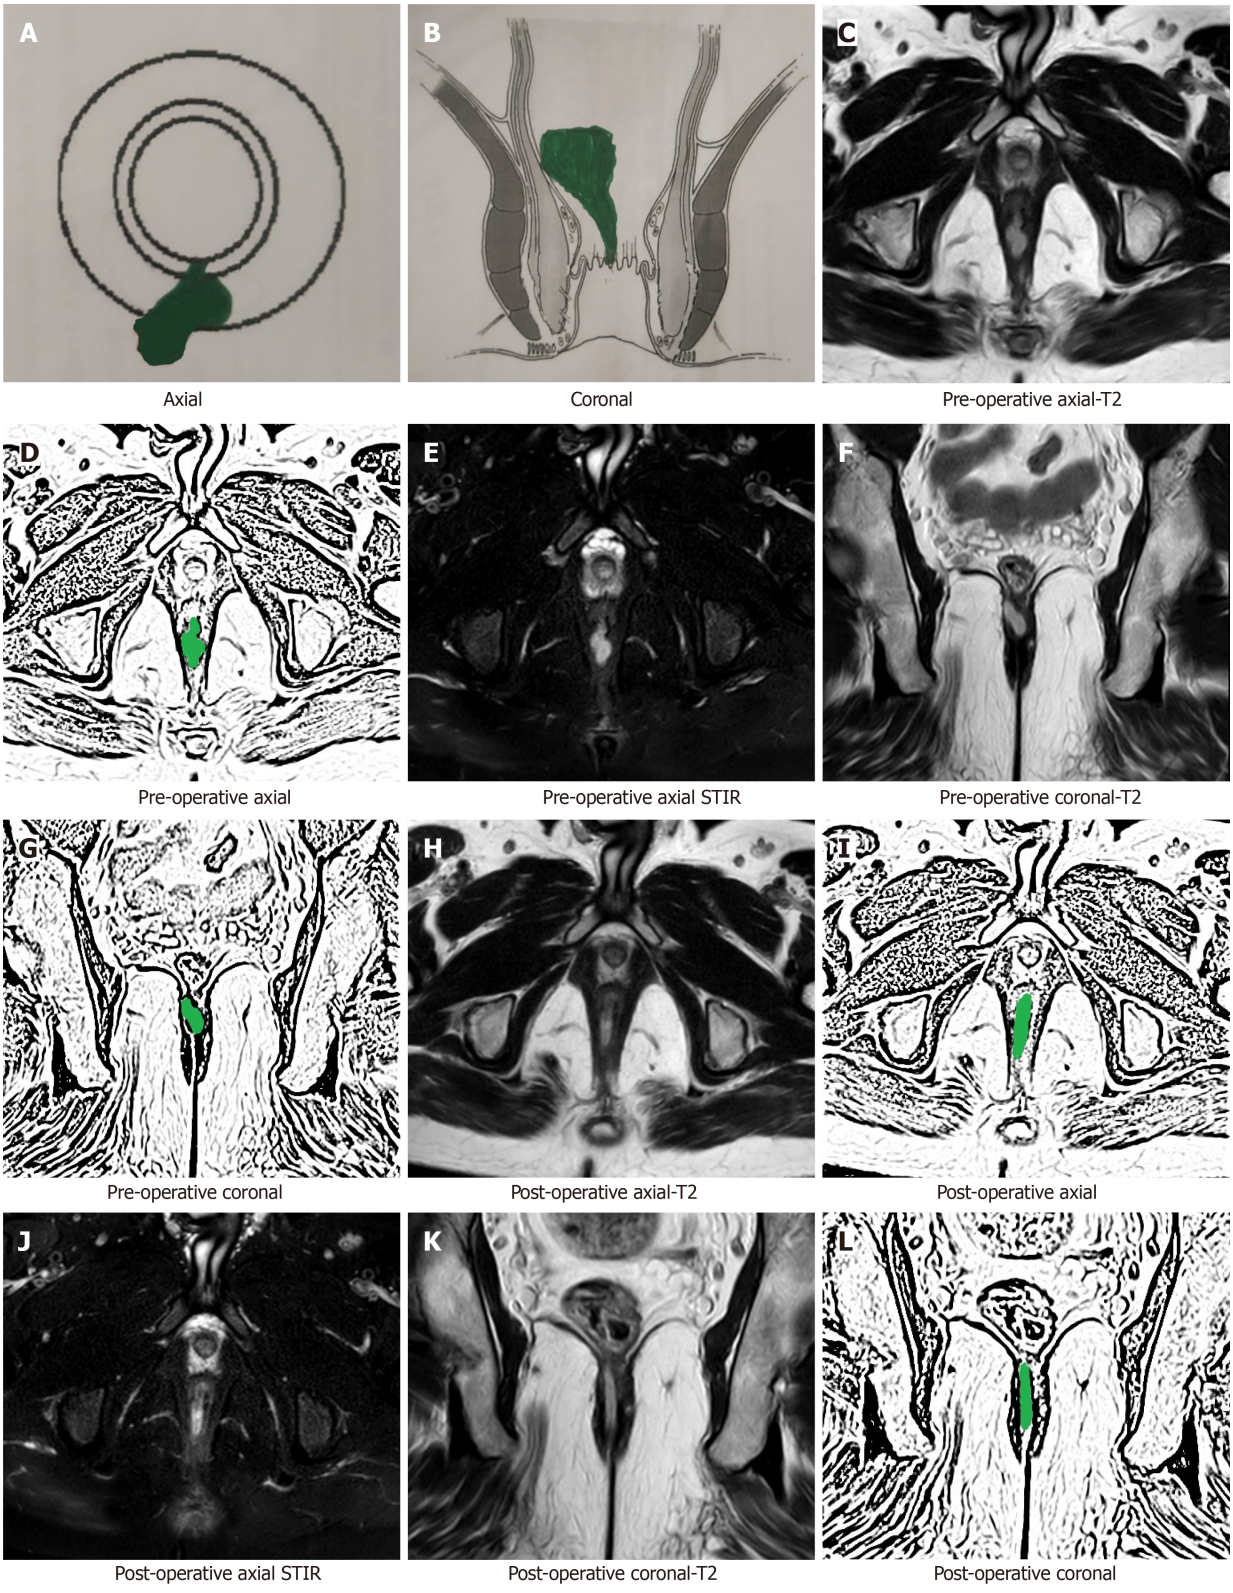

Figure 1 A 37-year-old male patient with a high posterior intersphincteric abscess was drained by transanal opening of the intersphincteric space procedure. Magnetic resonance imaging (MRI) done after 3 wk after surgery showed hyperintense signal (due to healing granulation tissue) at the same location similar to the hyperintense signal in the preoperative images (due to pus collection). A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted MRI; D: Sketch of pre-operative axial MRI image highlighting abscess (green color); E: Pre-operative short-T1 inversion recovery (STIR) axial MRI; F: Pre-operative T2-weighted coronal MRI; G: Sketch of pre-operative coronal MRI image highlighting abscess (green color); H: Postoperative T2-weighted axial MRI; I: Sketch of postoperative axial MRI image highlighting healing granulation tissue (green color); J: Postoperative STIR axial MRI; K: Postoperative T2-weighted coronal MRI; L: Sketch of postoperative coronal MRI image highlighting healing granulation tissue (green color). STIR: Short-T1 inversion recovery.

Checking for new abscess/tract development: There are instances when a patient

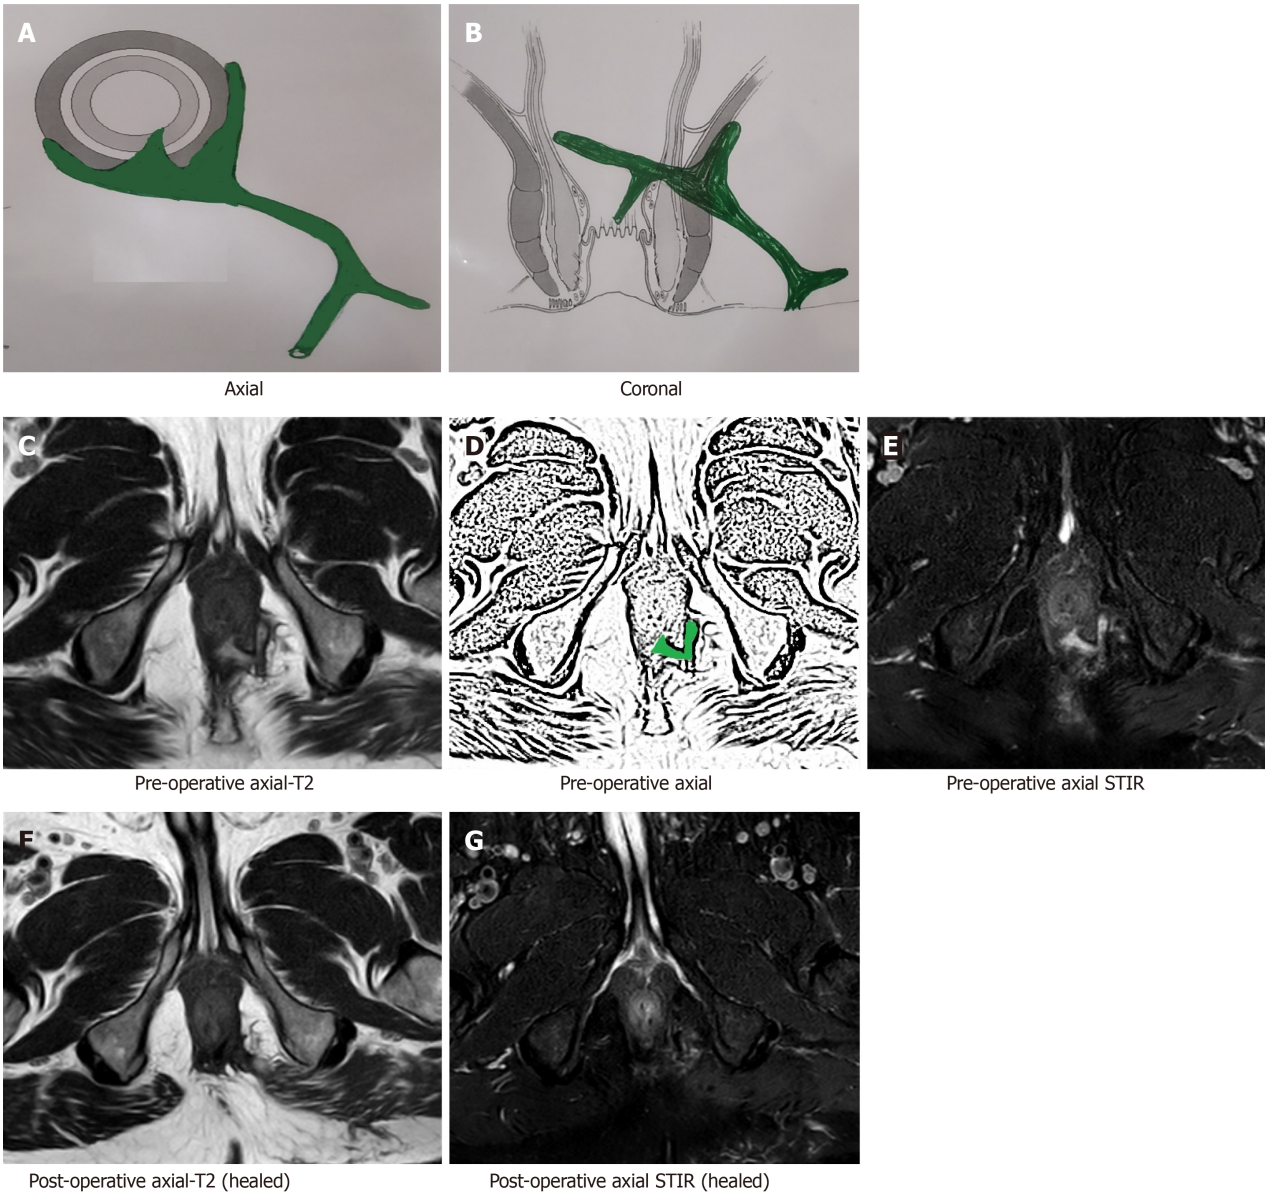

Figure 2 A 64-year-old male patient with a high transsphincteric fistula with multiple branches. Magnetic resonance imaging (MRI) done after 19 wk post-surgery showing fistula has healed completely. The hyperintense signal (white) in the preoperative images has turned hypointense (black). A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted axial MRI; D: Sketch of pre-operative axial MRI image highlighting internal opening and the intersphincteric portion of fistula tract (green color); E: Pre-operative short-T1 inversion recovery (STIR) axial MRI; F: Postoperative T2-weighted axial MRI (after 19 wk) showing completely healed fistula; G: Postoperative STIR axial MRI (after 19 wk) showing completely healed fistula. STIR: Short-T1 inversion recovery.

who was improving in the postoperative period starts to deteriorate due to development of fistula tracts or abscesses in new sites[15]. This could be due to undiagnosed tuberculosis (TB), Crohn's disease, or virulent microbes. An MRI would be of immense help in determining the presence as well as the location of the new tract or abscess and its subsequent management[16].

MRI is fairly accurate in assessing and confirming the healing of fistulas radiologically. Not uncommonly, the external opening of the fistula tract closes and the fistula appears healed clinically. However, the internal opening and intersphincteric component of the fistula tract have not healed and this leads to a recurrence weeks to months later[16] (Figures 3 and 4). This phenomenon of a fistula appearing healed followed by recurrence makes fistula management unpredictable and creates uncertainty in the minds of patients and surgeons alike. Therefore, many patients desire confirmation of whether the fistula which appears clinically healed has actually healed radiologically as well. This is especially true in patients who have suffered from multiple recurrences of the fistula[16].

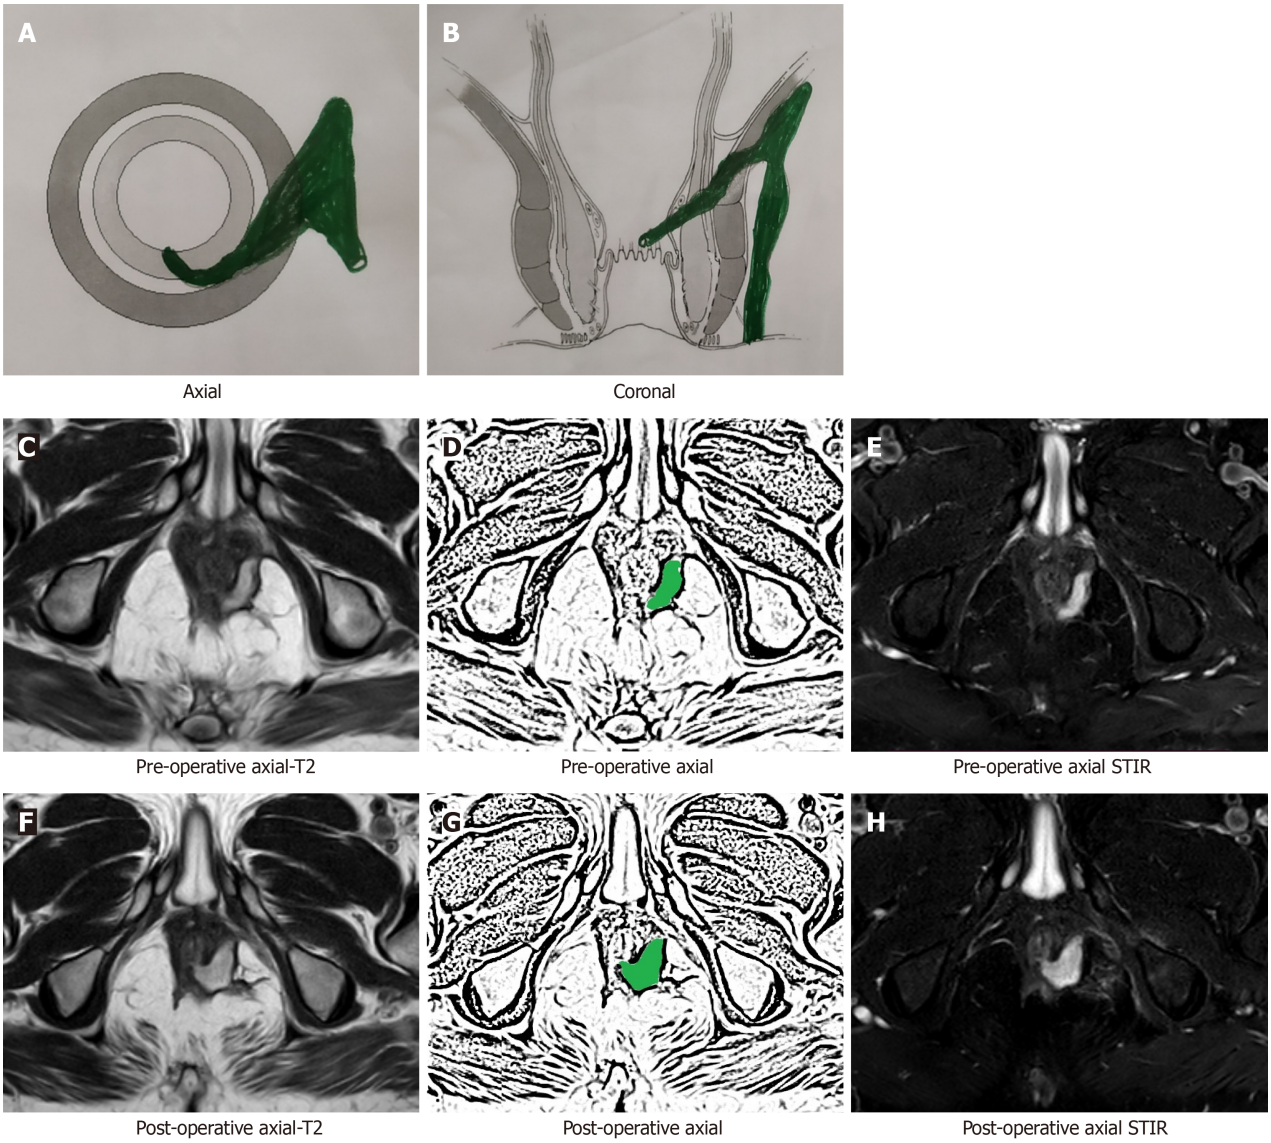

Figure 3 A 54-year-old male patient with a high transsphincteric fistula. The fistula appeared to have 'clinically' healed as the external opening had closed with cessation of all pus. However, magnetic resonance imaging (MRI) done after 28 wk post-surgery showed patent internal opening and widening of intersphincteric portion of fistula tract. A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted MRI; D: Sketch of pre-operative axial MRI image highlighting internal opening and the intersphincteric portion of fistula tract (green color); E: Pre-operative short-T1 inversion recovery (STIR) axial MRI; F: Postoperative T2-weighted axial MRI (after 28 wk) showing patent internal opening and persistent intersphincteric portion of fistula tract; G: Sketch of postoperative axial MRI image highlighting patent internal opening and persistent intersphincteric portion of fistula tract; H: Postoperative STIR axial MRI (after 28 wk) showing patent internal opening and persistent intersphincteric portion of fistula tract. STIR: Short-T1 inversion recovery.

Of all its benefits, this indication of MRI (to confirm fistula healing) is perhaps the most important of all motives for obtaining an MRI in the postoperative period[14]. It has been shown in a large study with long-term follow-up, that corroboration of clinical healing with radiological healing on MRI correlates quite well with actual long-term healing[14,15]. In a study of 125 patients of complex anal fistulas in whom the fistula had healed radiologically and who were followed-up for 38 mo, 99.2% (124/125) remained healed and only 1/125 patients had a recurrence on long-term [14]. This is important evidence that if clinical healing is corroborated by radiological healing on MRI, then the chances of long-term recurrence are minimal.

A fistula can be divided into three distinct parts for the purpose of MRI assessment: Internal opening; intersphincteric component of fistula tract; and component of fistula lateral to the external sphincter (external tracts).

The first two components, the internal opening and the intersphincteric component of the fistula tract, are deep and are difficult to assess on clinical examination, whereas the external tracts are relatively easy to assess clinically[14]. Second, any persistent infection in the external tracts leads to pus discharge from the external opening and will be clinically manifested. On the other hand, a fistula with healed external tract

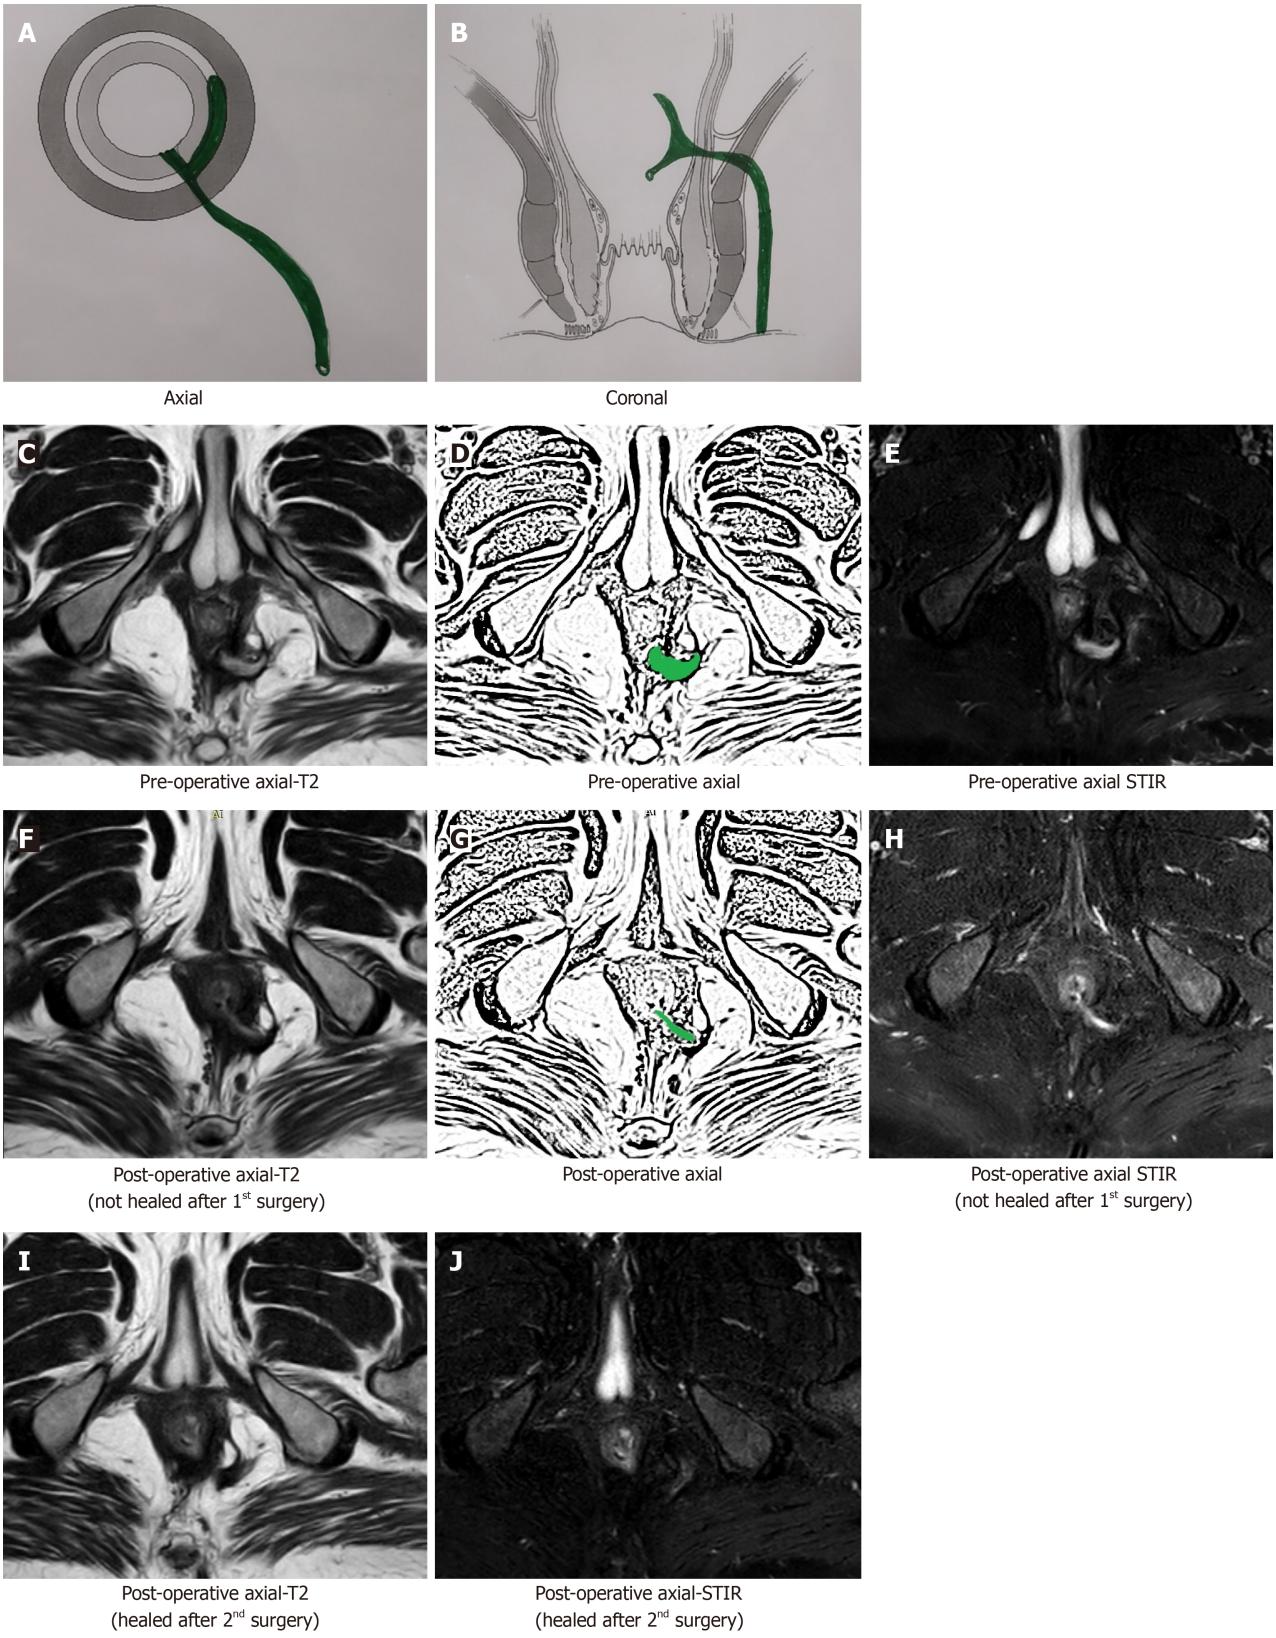

Figure 4 A 47-year-old male patient with a high transsphincteric fistula with supralevator extension. The fistula appeared to have 'clinically' healed as the external opening had closed with cessation of all pus. Magnetic resonance imaging (MRI) done after 26 wk post-surgery showed patent internal opening and active intersphincteric portion of the fistula tract [hyperintense on T2 and short-T1 inversion recovery (STIR)]. The patient was operated again. MRI done after 14 wk after 2nd surgery showed fistula has healed completely. The hyperintense signal (white) in the preoperative images has turned hypointense (black). A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted MRI; D: Sketch of pre-operative axial MRI image highlighting internal opening and the intersphincteric portion of fistula tract (green color); E: Pre-operative STIR axial MRI; F: Postoperative (26 wk after 1st surgery) T2-weighted axial MRI showing patent internal opening and persistent intersphincteric portion of fistula tract; G: Sketch highlighting patent internal opening and intersphincteric portion of fistula tract (green color); H: Postoperative (26 wk after 1st surgery) STIR axial MRI showing patent internal opening and persistent

intersphincteric portion of fistula tract; I: Postoperative (14 wk after 2nd surgery) T2-weighted axial MRI showing completely healed fistula; J: Postoperative (14 wk after 2nd surgery) STIR axial MRI showing completely healed fistula. STIR: Short-T1 inversion recovery.

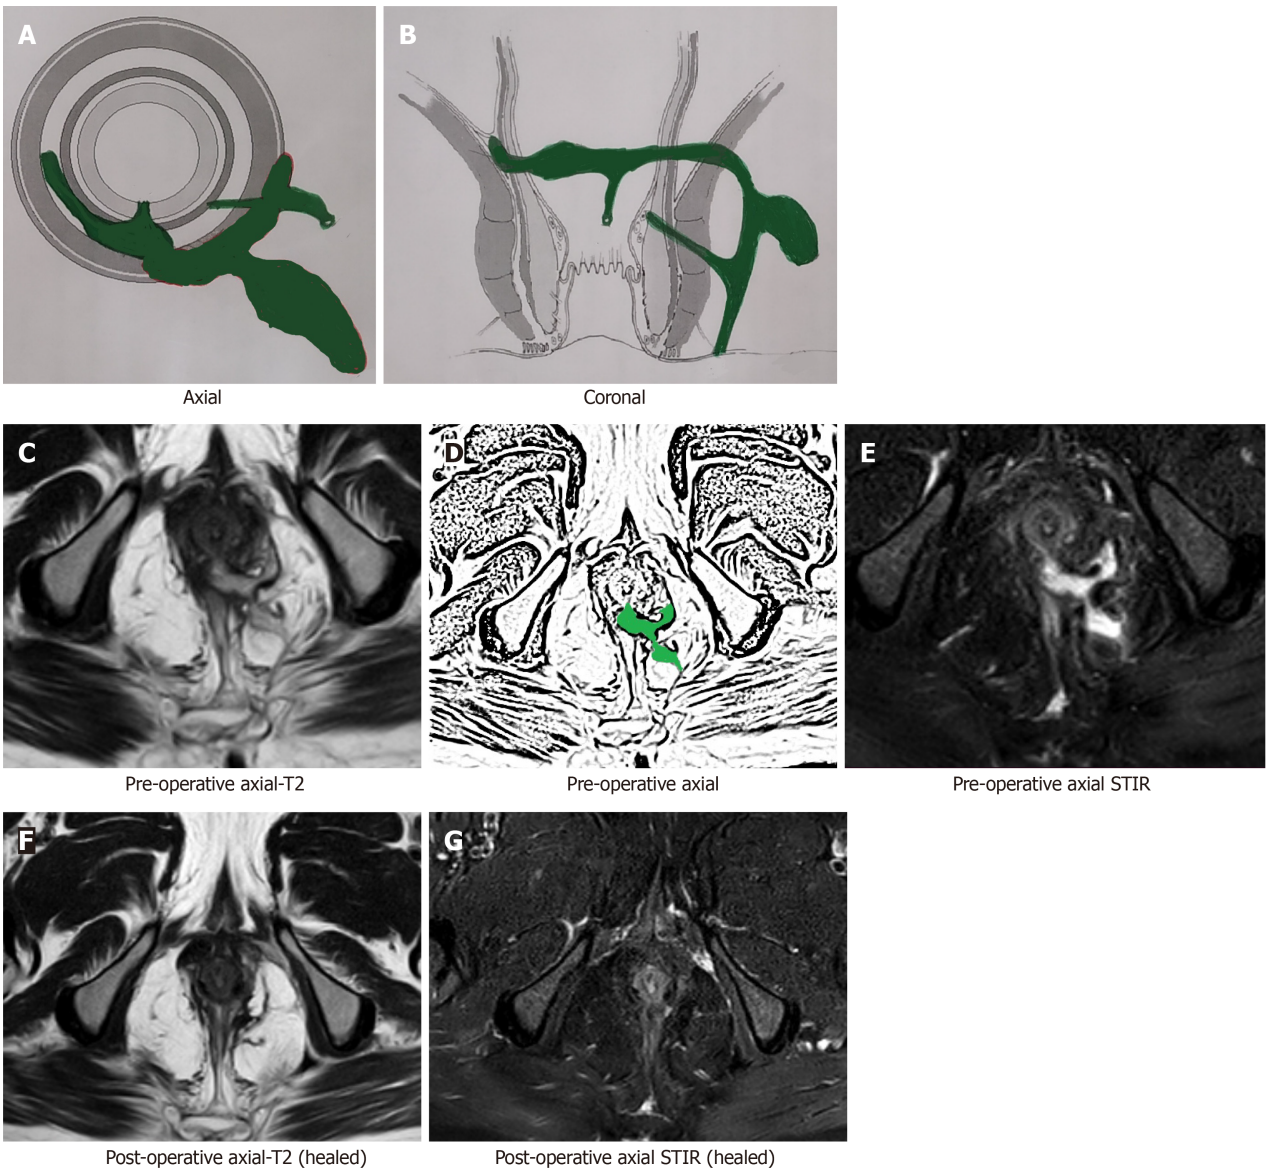

Figure 5 A 51-year-old male patient with a high transsphincteric fistula with multiple branches. Magnetic resonance imaging (MRI) done after 8 wk post-surgery showing fistula has healed completely. The hyperintense signal (white) in the preoperative images has turned hypointense (black). A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted axial MRI; D: Sketch of pre-operative axial MRI image highlighting internal opening, the intersphincteric portion of fistula tract and transsphincteric fistula tract (green color); E: Pre-operative short-T1 inversion recovery (STIR) axial MRI; F: Postoperative T2-weighted axial MRI (after 8 wk) showing completely healed fistula; G: Postoperative STIR axial MRI (after 8 wk) showing completely healed fistula. STIR: Short-T1 inversion recovery.

and closed external opening may have persistent infection/sepsis in the intersphincteric component of the fistula tract[14,15] (Figures 3 and 4). Such fistulas have no clinical manifestation for a few weeks and may appear healed even on clinical examination (Figures 3 and 4). Therefore, MRI is primarily useful in assessing the patency of the internal opening and assessing healing of the intersphincteric component of the fistula tract[14,15] (Figures 2 and 4-6). Moreover, once the internal opening and intersphincteric component of the fistula tract have healed completely, even the external tracts eventually heal in most cases. Therefore, a clinically healed fistula may be radiologically unhealed and such a fistula has a high likelihood of recurrence. On the other hand, a radiologically healed fistula with occasional serous discharge from the external opening for a few days (thus appearing clinically unhealed), has a high likelihood of healing and a low risk of recurrence.

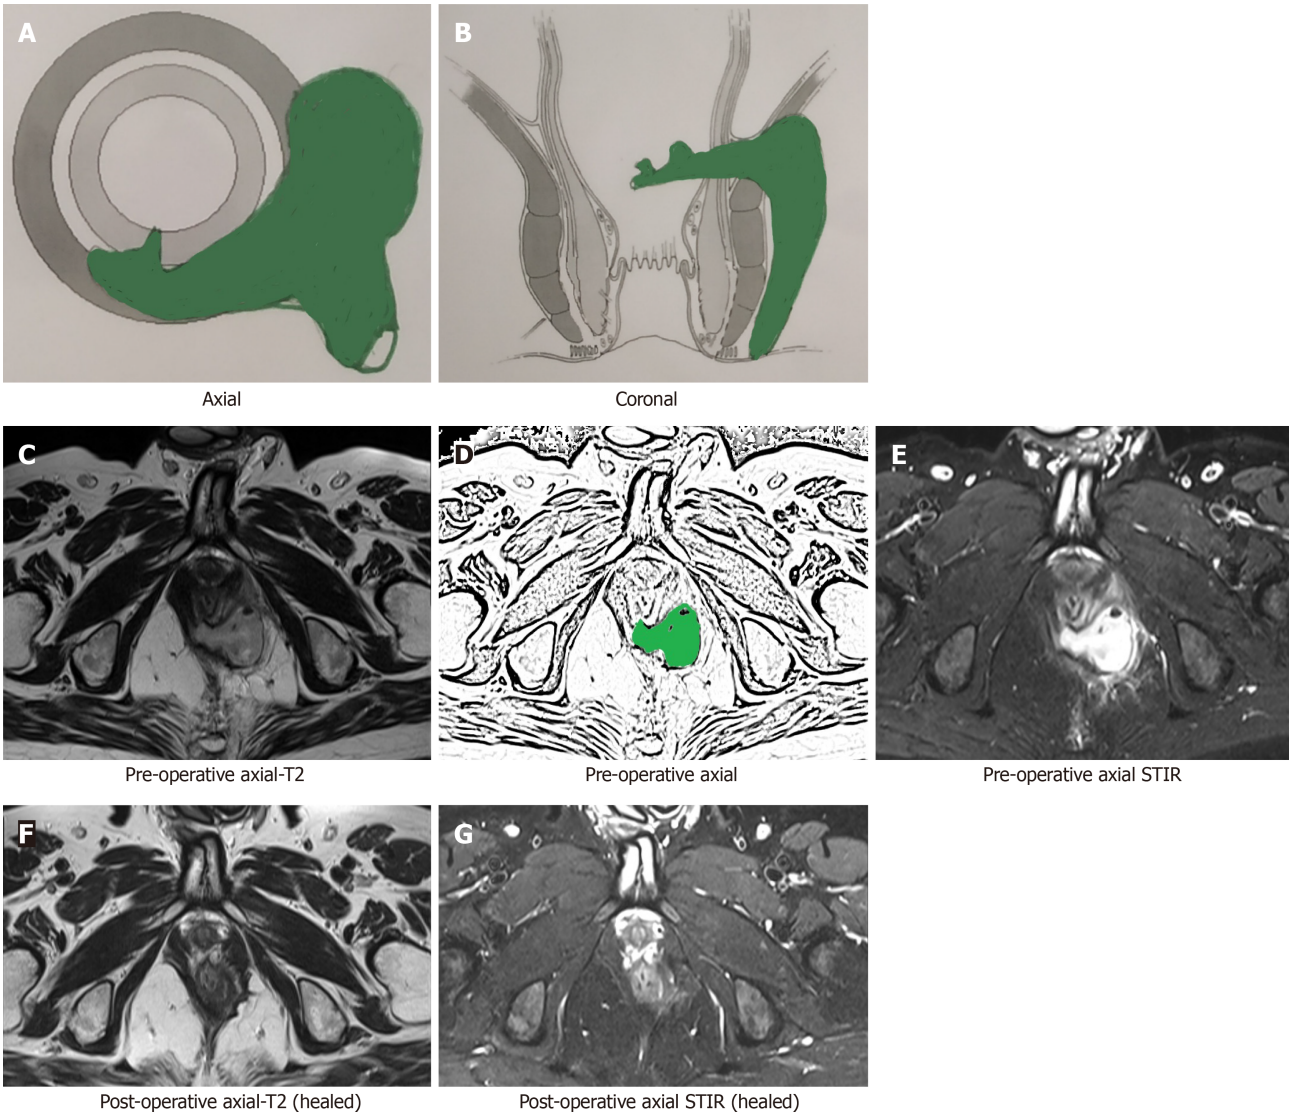

Figure 6 A 40-year-old male patient with a suprasphincteric fistula. Magnetic resonance imaging (MRI) done after 16 wk post-surgery showing fistula has healed completely. The hyperintense signal (white) in the preoperative images has turned hypointense (black). A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Pre-operative T2-weighted axial MRI; D: Sketch of pre-operative axial MRI image highlighting internal opening and the intersphincteric portion of fistula tract (green color); E: Pre-operative short-T1 inversion recovery (STIR) axial MRI; F: Postoperative T2-weighted axial MRI (after 16 wk) showing completely healed fistula; G: Postoperative STIR axial MRI (after 16 wk) showing completely healed fistula. STIR: Short-T1 inversion recovery.

As mentioned above, the patent internal opening and actively infected intersphincteric component of the fistula tract appear hyperintense (white) on T2 and STIR (Figures 3 and 4) whereas the healed internal opening and intersphincteric component of fistula tract appear hypointense (black) on T2 and STIR (Figures 2 and 4-6).

Recommendation

The healing of the internal opening and the intersphincteric component of the fistula tract correlate very well with both immediate and long-term fistula healing.

ACTIVE INVOLVEMENT AND EXPERIENCE OF THE CLINICIAN IN INTERPRETING MRI SCANS

A pivotal point in the management of complex anal fistulas is the active involvement of the operating surgeon in the interpretation of MRI scans.

Apart from being slightly more sensitive than TRUS, the main advantage of MRI over TRUS is that MRI interpretation is not operator dependent[15]. MRI films can be meaningfully interpreted by anyone independent of who conducted the procedure.

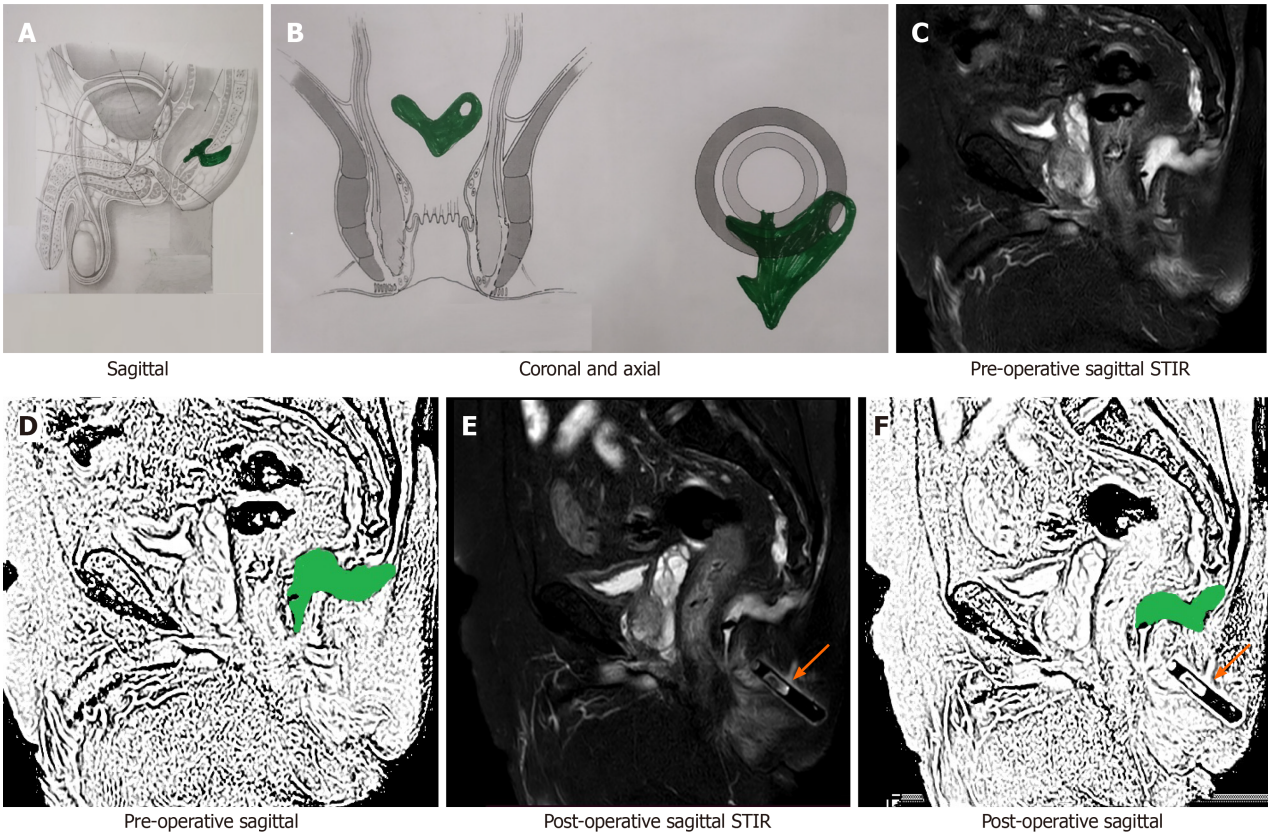

Figure 7 A 69-year-old male patient with a posterior fistula with a presacral abscess. A wide bore drainage tube was inserted into the cavity intraoperatively. However, the patient did not improve. Postoperative check magnetic resonance imaging (MRI) demonstrated that the tube was in the wrong plane and the presacral abscess was not properly drained. A: Axial section (schematic diagram); B: Coronal section (schematic diagram); C: Preoperative short-T1 inversion recovery (STIR) sagittal MRI; D: Sketch of pre-operative sagittal MRI image highlighting anal fistula and presacral abscess (green color); E: Postoperative STIR sagittal MRI showing drainage tube in the wrong plane and persistent presacral abscess; F: Sketch of postoperative sagittal MRI highlighting persisting anal fistula and presacral abscess (green color) (orange arrows show the drainage tube). STIR: Short-T1 inversion recovery.

This is a big advantage for the treating surgeon as the MRI scan can be analyzed in the office or operating room. We have realized that analyzing the MRI on computer *via* DVD/CD is more informative than interpreting it on films (hard copy). This is because each frame can be studied in high resolution on the monitor and can be enlarged as desired.

Active involvement of the surgeon in radiological analysis is important in preoperative management but holds even more significance in the postoperative management of complex anal fistulas. As the operating surgeon is well versed with the clinical picture, the operative procedure done and the postoperative course, he or she can correlate the radiological picture much better than the radiologist[5]. This holds true for other diseases as well but is far more applicable in managing complex anal fistulas. Needless to say, the full input of the radiologist needs to be considered in every case but the surgeon should be actively in the driver's seat alongside the radiologist while interpreting MRI scans. The surgeon should not passively make deductions from the radiologist's report.

Garg Fistula Research Institute is a specialized referral center for managing anal fistulas in North India. Over the last 8 years, 2404 MRI scans done in 1719 patients were analyzed at the institute[15]. Of the 1255/1719 patients who were operated for anal fistulas, 621/1255 patients had complex anal fistulas and 634/1255 had simple fistulas. Preoperative MRI (n = 1255) was done in all 1255 patients, whereas postoperative MRI (n = 685) was done in 411/1255 patients. Many patients required multiple postoperative MRI scans as their fistulas were more complex. The details are tabulated in Tables 2 and 3. The above data is mentioned in order to highlight a couple of points. First, the operating surgeon (Garg P) was actively involved in interpreting all the MRI scans along with the chief radiologist (Kaur B). The latter has the experience of reading more than 12000 anal fistula MRI scans over the last 30 years. Second, a reasonably high cure rate of 93.5% could be achieved over a long-term follow-up (median: 3 years) in this large cohort[15]. Active involvement of the operating surgeon in MRI interpretation was one of the key factors in achieving these

Garg classification is a recently proposed classification (2017), which has been shown to correlate accurately with fistula complexity[15,16]. F: Female; M: Male.

results.

Approval for analyzing the data was obtained from the Indus International Hospital-Institute Ethics Committee. The patients were informed about the purpose of the study, and the study was conducted in accordance with the Declaration of Helsinki.

It is a standard recommendation to obtain pre-operative MRI in recurrent fistulas. However, there is no consensus on performing MRI in all patients including those with seemingly primary, simple fistulas on preoperative clinical examination. A recent large study highlighted that 34% of fistulas that appeared simple on clinical

examination turned out to be complex after an MRI was performed, leading to a change in surgical decision for these patients[16]. Considering the results of this study and since our institute is a referral center for anal fistulas, we perform MRI in all patients as a standard protocol. This might appear expensive, but it works out to be economical even if it prevents recurrence in half the patients. Additionally, as MRI is not very costly in our country (USD 75), it does not financially burden the patients. Therefore, the cost-effectiveness of performing MRI for all fistulas (including simple-looking fistulas) would depend on the prevailing cost and availability of MRI in the region, experience of the operating surgeon in clinical examination as well as his/her past experience, and correlation of the results of the clinical examination with actual fistula complexity.

Recommendation

The operating surgeon should be actively involved with the radiologist in interpreting preoperative as well as postoperative MRI scans for managing anal fistulas.

OTHER ADVANCEMENTS

Newer advancements like contrast-enhanced MRI and three-dimensional modelling are being evaluated for anal fistulas[9,17-22]. These have been utilized more in Crohn's disease rather than cryptoglandular fistulas. However, the data on their utility is limited, and the exact indications and advantages have not been outlined yet. Contrast-enhanced MRI might provide additional input in preoperative MRI scans, but its role in the postoperative period has not been studied in great detail[21]. Diffusion-weighted MRI (DW-MRI) is superior to fat-suppressed T2-weighted images in detecting fistula tracts and also helps avoid the need to administer contrast (gadolinium chelate) in many cases[9,20]. However, its role in postoperative management has not yet been evaluated[9,20].

Various MRI-based scoring systems have been developed based on disease severity. The first of these was the Van Assche scoring system[23] which has been modified and subsequently used[24-26]. However, these scores have been utilized only in fistulizing Crohn's disease and have not been evaluated in cryptoglandular fistulas. The major shortcoming of these scoring systems is that they are based on both fistula complexity and MRI features. A more complex fistula is assigned higher scores as per these scoring systems. These studies evaluated the correlation between postoperative fistula healing and the assigned scores. A fistula with lower scores was expected to heal more readily and *vice versa*. However, this correlation was not seen in many patients[26]. In summary, these scores did not correlate accurately with postoperative healing in Crohn's fistulizing disease. The point, perhaps overlooked by most of these studies, is that the scoring system primarily assessed fistula complexity. A complex fistula is expected to have a lower likelihood of healing, but this correlation may not always be accurate as, apart from complexity, fistula healing depends on additional factors. These include the surgeon's competence (a simple fistula treated by an inexperienced surgeon may recur), the procedure employed (an expert surgeon performing an inappropriate procedure in a simple fistula can cause a recurrence), associated comorbidities like diabetes, undetected fistulizing disease like TB, poor patient compliance *etc*. Therefore, it is not prudent to use a single scoring system to evaluate fistula complexity as well as to predict postoperative healing. Both these parameters should be assessed by separate scoring systems.

Recommendation

In future, DW-MRI, three-dimensional modelling scans and MRI-based scoring systems will play an important role in the interpretation of postoperative MRI after fistula surgery.

CONCLUSION

To conclude, this is the first paper in which the guidelines for postoperative MRI in anal fistulas have been discussed. Postoperative MRI is an extremely useful tool available to surgeons managing complex fistulas. Though its interpretation is somewhat more challenging than analyzing preoperative MRI, with diligence and adequate experience, the treating surgeon can acquire proficiency in interpreting

postoperative MRI as an active member of the clinician-radiologist team. This will go a long way in improving management of anal fistulas, especially complex ones.

Abstract

Gastrointestinal (GI) cancer is a high-risk malignancy and is characterized by high mortality and morbidity worldwide. Neutrophil extracellular traps (NETs), a weblike structure consisting of chromatin DNA with interspersed cytoplasmic and granule proteins, are extruded by activated neutrophils to entrap and kill bacteria and fungi. However, accumulating evidence shows that NETs are related to the progression and metastasis of cancer. In clinical studies, NETs infiltrate primary GI cancer tissues and are even more abundant in metastatic lesions. The quantity of NETs in peripheral blood is revealed to be associated with ascending clinical tumour stages, indicating the role of NETs as a prognostic markers in GI cancer. Moreover, several inhibitors of NETs or NET-related proteins have been discovered and used to exert anti-tumour effects *in vitro* or *in vivo*, suggesting that NETs can be regarded as targets in the treatment of GI cancer. In this review, we will focus on the role of NETs in gastric cancer and colorectal cancer, generalizing their effects on tumour-related thrombosis, invasion and metastasis. Recent reports are also listed to show the latest evidences of how NETs affect GI cancer. Additionally, notwithstanding the scarcity of systematic studies elucidating the underlying mechanisms of the interaction between NETs and cancer cells, we highlight the potential importance of NETs as biomarkers and anti-tumour therapeutic targets.

Key Words: Neutrophil extracellular traps; Gastric cancer; Colorectal cancer; Biomarkers; Therapeutic targets

Core Tip: Neutrophil extracellular traps (NETs) have been reported to participate in progression and metastasis in gastrointestinal (GI) cancer. Recent reports demonstrate that NET formation is enhanced in GI cancer patients as well as some mouse models and that elevated levels of NETs indicate an adverse outcome in patients. Furthermore, NETs can trap disseminated cancer cells and assist the formation of metastatic lesions although the underlying mechanisms remain vague. More studies are needed before NETs can be used as reliable biomarkers and therapeutic targets in GI cancer.

INTRODUCTION

According to cancer statistics, gastric cancer (GC) ranks third globally in terms of mortality, while colorectal cancer (CRC) is the second leading cause of cancer-related death. Both constitute a major cause of cancer-related death worldwide[1,2]. Despite advances in the techniques applied for cancer treatment, surgical resection accompanied by adjuvant therapy (chemotherapy, radiotherapy and molecular targeted therapies) remains the primary approach[3]. However, the efficacy of aforementioned treatment is related to tumour heterogeneity in patients[4]. Once the tumour progresses and spreads to distant organs (*e.g.*, liver and lung), neither conventional surgery nor targeted therapies can reverse the dismal outcomes[5]. Therefore, it is of high importance in all future studies to understand the mechanisms of deterioration of GI cancer, by measuring not only the tumour itself, but also the surrounding cells that can be modified by the tumour to generate a supportive microenvironment; these cells include macrophages (tumour-associated macrophages), fibroblasts (cancer-associated fibroblasts) and neutrophils (tumour-associated neutrophils)[6,7].

Neutrophil extracellular traps (NETs) are extruded by activated neutrophils into the extracellular environment and have three-dimensional lattices, which are composed of decondensed chromatin with interspersed proteins such as neutrophil elastase (NE), cathepsin G, myeloperoxidase (MPO), histones and some other antimicrobial peptides [8,9]. NETs were originally discovered to ensnare and kill extracellular bacteria and fungi and may act as a physical barrier to impede the dissemination of microbes[10]. However, recent studies have revealed that NETs, if dysregulated, can contribute to the development or progression of some inflammatory or immune-related diseases[11,12], such as atherosclerosis[13], systemic lupus erythematosus (SLE)[14], diabetes[15], vasculitis[16], wound healing[17] and coronavirus disease 2019 (COVID-19)[18]. COVID-19 is still spreading worldwide, and clinical evidence shows that increased NET formation after the COVID-19 infection can be a potential biomarker for disease severity[19]; thus, targeting NETs may alleviate the condition of patients[20]. More work is needed before NETs can be used as reliable biomarkers in these diseases. In addition to the roles of NETs mentioned before, studies have expanded their biological scope and suggest that elevated numbers of neutrophils and levels of NETs in peripheral circulation are a hallmark of cancer[21]. Recently, NETs have been suggested to participate in the biological process of cancer[22-24]. Several studies have shown that NETs can cause hypercoagulability[25], accumulate in peripheral blood vessels and impair organ function[26], promote cancer development and metastasis[27-30], sequester circulating tumour cells[31,32], and even stimulate dormant cancer cells[33]. Therefore, more work needs to be done to elucidate the mechanism between NETs and cancer.

In this review, we will discuss the role of NETs in GC and CRC according to the latest findings and consider their potential of NETs as biomarkers and therapeutic targets.

NETS

The formation of NETs, known as NETosis, was first observed by Takei *et al*[34] *via* stimulation with phorbol-12-myristate-13-acetate (PMA) and is regarded as a novel form of neutrophil death that is different from apoptosis and necrosis. The antibacterial role of NETs was confirmed in 2004 and is dependent on the web-like structure [10]. The core scaffold of NETs is the nuclear DNA extruded from neutrophils and that forms a three-dimensional meshwork with a number of interspersed specific cytoplasmic and granular proteins[35]. Notwithstanding the lack of mechanistic or interventional studies investigating NET formation in peripheral circulation, initial studies suggest that NETs are released by dying neutrophils. This phenomenon of NET formation can be mainly described by at least two mechanisms. One mechanism requires the lytic suicide of neutrophils, while the other mechanism is independent of this process[36,37]. Neubert *et al*[38] demonstrated that entropic chromatin swelling is the major physical driving force of NETosis. In addition, other myeloid cells, such as human blood monocytes[39], mast cells[40] and eosinophils[41], have been discovered to release DNA networks. However, neutrophils seem to remain the main source of these networks because of their high efficiency of secretion.

The functions of NETs in defending against infection depend on the composition of the network, including the DNA itself, which is a chelator of divalent cations that possesses antibacterial ability. The citrullination of histones loosens their grip on DNA and provides a chance for interaction between DNA and bacteria[42]. Moreover, highly toxic modified histones, which constitute the major part of NET-associated proteins, are also mediators of bactericide[43]. Moreover, NE synergizes with MPO to assist the formation and antibacterial role of NETs[44]. More generally, NETs prevent dissemination of infection by entrapping microbes and facilitate their killing by bactericidal proteins which have been shown to be involved in both direct and indirect mechanisms. In addition, NETs are revealed to be vital factors in non-infectious diseases. Hakkim *et al*[45] suggested that the persistence of NETs exacerbates the autoimmune response and forms a vicious cycle in SLE. Similarly, studies on diabetes [15], vasculitis[16], wound healing[17] and COVID-19[18-20] have described the pathophysiological role of NETs.

Recently, an emerging role of NETs in promoting cancer progression has been described. Solid tumours are prone to generating a leukemoid reaction and pre-educate neutrophils to form extracellular DNA traps, and intratumoural NET formation is associated with thrombosis[46]. The accumulation of tumour-induced NETs in the peripheral circulation drives the systemic inflammation and vascular dysfunction in mice with cancer[26]. Leal *et al*[47] indicates that NETs serve as scaffolds and collaborate with tumour-derived procoagulant exosomes in the establishment of a prothrombotic phenotype in cancer. CXCL8 (interleukin-8, IL8) is a chemokine that can be produced by tumour cells and its role in promoting angiogenesis in cancer has been well discussed[48]. Furthermore, the presence of IL8 activates the extrusion of NETs with potential involvement in cancer progression and promotes cancer cell metastasis partially through AKT and STAT3 signalling pathways[49,50]. NETs produced by tumour-infiltrating neutrophils mediate the crosstalk between the tumour microenvironment and deterioration by regulating the HMGB1/RAGE/IL8 axis[51]. IL17 is a cytokine described as a protumourigenic factor involved in the initiation and development of cancer[52]. A recent study demonstrated that IL17 can induce NETosis through epithelial cell signalling to favour tumour growth[53]. Rocks *et al*[54] associated NETs with cancer cells and confirmed that the release of NETs favour tumour cell dissemination and colonization in organs.

Since the discovery of NETs, the role of neutrophils and NETs has attracted increasing attentions. Additional studies have reported on numerous stimuli that affect NET formation *in vitro* and *in vivo*. PMA, a potent artificial activator of the neutrophil respiratory burst, has been broadly applied to identify the mechanism of NETosis. Cytokines, such as the aforementioned IL8, IL17 and tumour necrosis factor alpha[55], have been investigated with respect to their role in expediting NET formation. Nicotine, a major addictive component of tobacco, is reported to induce NETosis in a dose-dependent manner, implying potential threats to human health[56]. Moreover, sulfasalazine, a drug used to treat inflammatory bowel disease and rheumatoid arthritis, has been found to significantly promote NETosis by accelerating lipid oxidation [57]. Most recently, Yasuda *et al*[58] established the relationship between NETosis and epigenetics and demonstrated that DNA demethylation enhances spontaneous NET formation by reinforcing PAD4 expression and histone citrullination.

NETS IN GC

GC is the fifth most common cancer and ranks third in terms of mortality worldwide. Several studies have tried to confirm the characteristics of NETs in GC and clarify the underlying mechanisms *in vitro* and *in vivo* (Table 1).

Notwithstanding advances in diagnosis and therapy, recurrence and metastasis are still common as a result of its high molecular and phenotypic heterogeneity[59], which contributes to a coagulable state that causes the proliferation and invasion of GC cells [60-63]. In GC patients, NET formation is significantly upregulated and its increased level is consistent with advanced TNM stage. Moreover, a procoagulant role of NETs in GC has been confirmed. When NETosis is inhibited by DNase I, the levels of TAT and D-dimers are downregulated. Furthermore, NETs obtained from GC patients can also stimulate control plasma to generate thrombin and fibrin[64].

A common target of metastatic gastrointestinal cancer is the peritoneal cavity[65]. The invention of heated intraperitoneal chemotherapy[66] and postoperative chemotherapy[67] has indeed reduced the rate of peritoneal recurrence and metastasis. However, limitations still exist with regard to the benefit of these treatments, and severe general toxicity has always been an unavoidable side effect. To elucidate the underlying mechanisms, Kanamaru *et al*[68,69] collected the peritoneal lavages from GC patients before and after radical surgery. Then NET formation emerged after short term culture of purified low-density neutrophils (LDNs) separated from the lavages fluids. Moreover, the majority of NET-like structures were discovered on the surface of omental tissue. In a *in vivo* study, GC cells lines such as MKN45, OCUM-1 and NUGC-4 were found attached to the NETs and remained healthy; this interaction was entirely prevented upon treatment with DNase I, which can degrade NETs.

Notwithstanding the advances of therapeutic strategies in GC, surgical resection remains the mainstay treatment. Therefore, the subsequent surgical stress, which suppresses immunity, constitutes one of the key factors that influence the prognosis of GC patients[70,71]. The percentage of LDNs in the peripheral circulation of GC patients who underwent abdominal surgery was elevated and *in vitro* studies observed the adhesion of cancer cells to NET structure, suggesting that partial adverse effects of surgical stress may be explained by the formation of NETs[72].

According to a pulmonary metastasis model of GC, accumulation of neutrophils in the adjacent vascular vessels has been found during the colonization of GC cells. Extracts from the root of *Salvia miltiorrhiza* (*Danshen*)[73], a medicinal plant used for cancer therapy, have been observed to prevent neutrophil trafficking to the metastatic sites and obstruct the formation of NETs *via* inhibitory activities on MPO and NADPH oxidase (NOX)[74]. A recent study has proposed that obstruction of NETosis by Cl-amidine or DNase I significantly suppresses the progression of GC cells by regulating the expression of apoptosis-associated genes, among which Bcl-2[75] levels were downregulated and the expression of Bax[76] and NF-κB p65[77] increased significantly[78].

NETS IN CRC

CRC is the third most frequent malignancy and second leading cause of cancer-related mortality worldwide. To date, metastasis and cancer-associated thrombosis are still the main causes of death in CRC patients. To address this issue, much work has been done or is currently in progress; recently, more attention has been drawn to the establishment of tumour microenvironment. Of note, recent accumulating evidence has shown that NETs may play a pivotal role in the progression of CRC (Table 2).

CRC patients are at high risk of venous thrombosis as a result of hypercoagulable state and the levels of NETs in the peripheral blood are positively related to cancer progression. A comparison between 60 newly diagnosed CRC patients and 20 healthy controls revealed that neutrophils in CRC patients can release more NETs, and this tendency parallels increased TAT levels and fibrin formation, which is indicative of a hypercoagulable state[79]. Thus, a vicious cycle can be established between activated platelets and neutrophils. Additionally, *in vitro* studies show that NETs can convert endothelial cells to a procoagulant phenotype[80]. Another study observed that NETs were concentrated in the centre of CRC tissues and reduced gradually towards adjacent normal tissues, and this characteristic could help surgeons determine a better surgical area through pathological examination of the tumour margins. Furthermore, tissue factor, a stimulus of coagulation and a pro-angiogenic factor, was discovered in NETs from the primary tumour and metastatic lymph nodes[81]. Altogether, the

Table 1 Role of neutrophil extracellular traps in gastric cancer

Ref.	Cell lines	Model (*in vitro*, *in vivo*, human)	Conclusion
Yang *et al*[64], 2015	-	Human	NETs contribute to the hypercoagulable state in GC patients with stage III/IV
Kanamaru *et al* [68], 2018	MKN45, NUGC-4, OCUM-1	*In vitro*, *in vivo*	NETs on peritoneal surface assist the clustering and growth of GC tumor cells disseminated in abdomen
Tao *et al*[74], 2018	BGC-823	*In vitro*, *in vivo*	NET formation is inhibited by Sal B and DHT I at the earlier stage

Table 2 Role of neutrophil extracellular traps in colorectal cancer

Ref.	Cell lines	Model (*in vitro*, *in vivo*, human)	Conclusion
Arelaki *et al* [81], 2016	Caco-2	*In vitro*, human	NETs concentration is gradually reduced from the tumor mass to the distal margin
Tohme *et al* [83], 2016	MC38	*In vitro*, human	Surgical stress and intratumoral hypoxia induce NETs formation and NETs can trigger HMGB1 release and activate TLR9-dependent pathways to promote adhesion, proliferation, migration, and invasion in CRC
Richardson *et al* [84], 2017	-	Human	NET production in the later postoperative period appears to coincide with surgical recovery
Arelaki *et al* [88], 2018		Human	PolyP is present in human colon cancer and increase NETosis
Rayes *et al*[82], 2019	MC38, H59	*In vitro*, *in vivo*, human	Circulating NET levels are elevated in advanced CRC and blocking NETosis significantly inhibits spontaneous metastasis to the lung and liver
Yazdani *et al* [89], 2019	MC38, HCT116, Hepa 1-6, Huh7	*In vitro*, *in vivo*, human	NETs facilitate the growth of stressed cancer cells by altering their bioenergetics
Zhang *et al*[80], 2019	HUVECs	*In vitro*, human	NETs are involved in the progression of CRC and act as potential agonists in CRC-related hypercoagulability
Rayes *et al* [113], 2020	HT-29, MC38, A549	*In vitro*, *in vivo*, human	NET-associated CEACAM1 acts as a putative therapeutic target to prevent the metastatic progression of colon carcinoma
Shang *et al*[92], 2020	DKs-8, DKO-1, PMN	*In vitro*, *in vivo*, human	Exosomes may transfer mutant KRAS to recipient cells and trigger increases in IL-8 production, neutrophil recruitment and formation of NETs, eventually leading to the deterioration of CRC
Xia *et al*[105], 2020	MC38, HepG2	*In vitro*, *in vivo*	AAV-mediated DNase I liver gene transfer is a safe and effective modality to inhibit metastasis and represents a novel therapeutic strategy for CRC
Yang *et al*[91], 2020	HT29, MC38	*In vitro*, *in vivo*, human	A novel positive feedback between elevated tumorous IL-8 and NETs can promote CRC liver metastasis
Yang *et al*[93], 2020	HCT116, MDA-MB-231, MCF-7, 4T1, HEK293T, HeLa, E0771	*In vitro*, *in vivo*, human	CCDC25 mediates NET-dependent metastasis and is suggested to be a therapeutic target for the prevention of cancer metastasis

NETs: Neutrophil extracellular traps; CRC: Colorectal cancer; AAV: Adeno-associated virus.

presence of NETs contributes to thrombosis in CRC.

By analysing large-scale human data, Rayes *et al*[82] demonstrated that NETs can not only bind tumour cells but also promote metastasis. In addition, established preclinical models of gastrointestinal cancer revealed that tumours induce neutrophils to extrude NETs into the extracellular environment in the absence of surgical stress. Furthermore, NET formation could promote CRC metastasis after surgical stress[83,

84]. In a cohort study, increased postoperative NET formation was associated with disease-free survival in patients undergoing hepatic surgical resection, and the mouse model of surgical stress has obtained similar results. Further studies demonstrated that the hypoxic environment in solid tumours provides a favourable condition for NETosis and that NETs could in turn promote CRC progression by releasing HMGB1 [85], a DNA-binding protein that participates in the activation of TLR9[86]. Additionally, the protumourigenic effects of NETs are abolished by DNase and PAD4 inhibition[83]. Another clinical trial suggested that increased preoperative NETosis is related to an increased hospital stay and complications of CRC patients who undergo colorectal resection, suggesting a promising therapeutic benefit of surgery focused on the relationship between CRC and NETs[84].

In malignant and premalignant colon tissues, CD68+ polyP-expressing cells and NETosis were detected, suggesting a possible interaction between them in the tumour microenvironment. Further investigation indicates that polyP[87], which is secreted by activated platelets and could induce inflammation and thrombosis in CRC, may promote the formation of NETs[88]. A PAD4-KO mouse model, which is genetically incapable of NETosis, showed that inhibition of NETs halted CRC growth through its negative regulation of mitochondrial biogenesis-associated genes. Further studies show that CRC cells subjected to hypoxia have upregulated expression of HMGB1 [85], which acts as an inducer of NETosis, and NE released from NETs could assist tumour proliferation as a result of inducing mitochondrial biogenesis by activating the TLR4-p38-PGC1α pathway in CRC[89].

In CRC, IL8 has been reported to participate in growth, angiogenesis and metastasis [90]. High expression of IL8 also implicates adverse survival in patients. A recent study explains a promotional role of IL8 in the formation of NETs. *In vitro* adhesion system, CRC cells such as HT29 and MC38 cells are more prone to be entrapped into NETs than neutrophil monolayers, giving the chance for disseminated CRC cells to form micrometastases in the liver; this process can be enhanced by overexpression of IL8[91]. Another study focuses on exosomes secreted by CRC cells. The authors showed that exosomes derived from KRAS mutant cells could transfer mutant KRAS to receptors and upregulate IL8 Levels, eventually activating neutrophils to form NETs and leading to enhanced proliferation and invasion of cancer cells[92].

The aforementioned studies have highlighted an interaction between CRC cells and NETs, suggesting that NET formation is enhanced in tumours and that the increase in NETs can promote the progression and metastasis of CRC. Although several pathways have been described, the detailed mechanisms of how NETs interact with and boost the metastasis of CRC remain elusive. Most recently, a remarkable discovery not only precisely illustrates the underlying mechanism between CRC cells and NETs but also partially explains why CRC cells have a tendency to disseminate into the liver. Yang *et al*[93] investigated several metastatic lesions in the clinic and discovered the most abundant NET infiltration in liver metastases and the formation of NETs began before the appearance of the metastases. According to a pull-down assay, CCDC25, a potential cell-surface DNA receptor, was identified on the cytoplasmic membrane of cancer cells. Furthermore, amino acids 21-25 at the extracellular N-terminus of CCDC25 were found to be the binding site of NET-DNA. Further immunoprecipitation assays indicated that the intracellular C-terminus of CCDC25 binds integrin-linked kinase and that this interaction can be stimulated by NET-DNA, eventually inducing liver metastases of CRC cells *via* initiating the β-parvin-RACI-CDC42 cascade.

NETS AS POTENTIAL BIOMARKERS AND THERAPEUTIC TARGETS

An increasing number of investigations have suggested a protumourigenic role of NETs in providing a microenvironment favouring interactions and promoting cancer proliferation, thrombosis and metastasis in GI cancers. This has led to the question of whether NETs can act as potential biomarkers and therapeutic targets.

Zhang *et al*[94] compared the levels of NETs in different patient populations, suggesting that NETs, as a diagnostic biomarker, have better value than carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 in GC. Additionally, NET formation is associated with tumour stage, poor overall survival and poor recurrence-free survival. Moreover, tumour-infiltrating NETs has been demonstrated to be an independent prognostic biomarker according to the assessment of clinical outcomes of cancer patients[95-97]. Considering the potential diagnostic significance of NETs, conventional histological staining is ineffective for their detection in tissue. To solve

this problem, a protocol has been created to detect NETs in paraffin-embedded tissue [98]. Additionally, machine learning is described as a useful tool to quantitate NETosis [99]. Citrullinated histone H3, a central marker of NETs, is elevated in blood and regarded as a potential diagnostic and prognostic serum marker to predict the risk of venous thromboembolism and mortality in patients with advanced cancer[100-102]. A CitH3DNA binding assay has also been developed to quantify NET formation[103].

Taking into account the confirmed role of NETs in promoting the progression and metastasis of GI cancer cells, disruption of NETosis can be a possible new therapeutic strategy and the identification of NETosis inhibitors is of high interest. DNase I can degrade the DNA backbone of NETs and abrogate the protumourigenic ability of NETs in several aforementioned animal models. Moreover, DNase I has been safely used in cystic fibrosis and SLE patients[104], implying that DNase I can act as a promising candidate for the treatment of GI cancer patients. In a mouse model of CRC liver metastasis, an adeno-associated virus gene therapy vector was created to specifically express DNase I in the liver, inducing an inhibition of liver metastasis[105]. However, it is worth noting that everything is a double-edged sword. Inappropriate use of DNase I may lead to a systemic inflammatory response in patients[106]. Owing to the critical role of NE and PAD4 in the process of NETosis, NE inhibitors or PAD4-inhibitors are also commonly used to prevent the release of NETs. Nanoparticle-mediated delivery of NE inhibitors has been suggested as a feasible approach to decrease NETosis[107]. In addition, NOX inhibitors[108], MPO inhibitors[109] and RAF inhibitors[110] have been reported to arrest the inception of NETosis. Recently, a group of tetrahydroisoquinolines was found to be a novel class of NET formation inhibitors, but their underlying mechanism remains to be determined[111]. A drug screening of 126 compounds shows that appropriate use of anthracyclines (drugs used for cancer treatment) together with dexrazoxane could be a promising therapeutic candidate for suppressing NETosis without cytotoxicity against healthy neutrophils [112]. NET-associated CEA cell adhesion molecule 1 (CEACAM1) was identified by Rayes *et al*[113] Knockdown of CEACAM1 on NETs abrogates the adhesion between NETs and colon cancer cells, thus indicating a potential therapeutic therapy or preventing liver metastases. A novel study revealed that PKCα, a lamin kinase that mediates the phosphorylation of lamin B, contributes to the formation of NETs; hence, blocking PKCα provides a new perspective towards treating NET-associated cancer progression[114]. Since the application of 5-fluorouracil (5FU) has been shown to trigger the formation of NETs in the blood of cancer patients, Amph-PVP self-assembled nanoparticles are proposed as an efficient delivery system for 5FU to avoid the generation of NETs, partially improving the anticancer effect and reducing the risk of long-term metastasis[115]. The previously mentioned studies mainly focus on the inhibition of NETosis or the proteins assembled in NETs. Unusually, Cao and King [116] proposed that NETs per se can be utilized as an anti-tumour drug delivery vehicle. By re-engineering neutrophils, supercharged eGFP-TRAIL, an apoptosis-inducing chimeric protein, is expressed on NETs to entrap and kill tumour cells.

CONCLUSION

NETs, initially identified as a host defense system designed to trap and kill bacteria, have now been suggested to play an important tumorigenic role in many cancers. Accumulating evidence has shown that NETs are involved in GI cancers, including GC and CRC. As mentioned above, NET infiltration in primary tumour tissues implies a poor outcome in GI cancer patients, indicating that a rapid intraoperative histopathological examination of NETs in the resected tissue margins may help determine the range of surgical resection. Moreover, several cytokines and genetic mutations trigger the formation of NETs and NETs per se can promote the progression of cancer partially by initiating downstream signalling pathways. On the other hand, the fact that NETs can entrap disseminated cancer cells, combined with the situation that an abundance of NET infiltration in the liver is formed before metastases can be detected, increases the likelihood of liver metastasis and explains the high incidence of liver metastasis in patients with GI cancer.

Further studies are needed to elucidate the detailed underlying mechanism of the interaction between NETs and GI cancer. Clarifying the roles of NETs in cancer could open a new door in the design and development of therapeutic approaches. Transforming inhibitors of NETs into drugs that can be safely used in GI cancer patients or utilizing NETosis as a drug delivery system may evolve into promising anti-tumour therapies.

Abstract

Changes in gut microbiota influence both the gut and liver, which are strictly connected by the so-called "gut–liver axis". The gut microbiota acts as a major determinant of this relationship in the onset and clinical course of liver diseases. According to the results of several studies, gut dysbiosis is linked to viral hepatitis, mainly hepatitis C virus and hepatitis B virus infection. Gut bacteria-derived metabolites and cellular components are key molecules that affect liver function and modulate the pathology of viral hepatitis. Recent studies showed that the gut microbiota produces various molecules, such as peptidoglycans, lipopolysaccharides, DNA, lipoteichoic acid, indole-derivatives, bile acids, and trimethylamine, which are translocated to the liver and interact with liver immune cells causing pathological effects. Therefore, the existence of crosstalk between the gut microbiota and the liver and its implications on host health and pathologic status are essential factors impacting the etiology and therapeutic approach. Concrete mechanisms behind the pathogenic role of gut-derived components on the pathogenesis of viral hepatitis remain unclear and not understood. In this review, we discuss the current findings of research on the bidirectional relationship of the components of gut microbiota and the progression of liver diseases and viral hepatitis and *vice versa*. Moreover, this paper highlights the current therapeutic and preventive strategies, such as fecal transplantation, used to restore the gut microbiota composition and so improve host health.

Core Tip: Changes within the gut microbiota have an impact on the mutual crosstalk between intestinal microbiota and the liver. Gut dysbiosis is linked to viral hepatitis, mainly hepatitis C virus and hepatitis B virus infection. However, concrete mechanisms behind the pathogenic role of gut-derived components on the pathogenesis of viral hepatitis remain unclear. We discuss recent studies to understand the role of gut microbiota.

INTRODUCTION

The gut contains a large, complex microbial community that has much more genetic material than the total human genome[1]. Gut microbiota (GM) acts as a major determinant of complex bidirectional communication between the gut and brain to maintain intestinal homeostasis and host health[2,3]. However, gastrointestinal tract bacteria produce several enzymes, metabolites, and cellular components that can contribute to many disorders such as liver disease[3], diabetes mellitus[4], inflammatory bowel disease[5], irritable bowel syndrome[6], obesity[7], colorectal cancer[8], and mental illness[9].

The term gut-liver axis refers to the anatomical and physiological connection between the gut and the liver[3]. The gut-liver axis is based on the very close anatomical relationship of these organs and consequently, enzymes, metabolites, and immune signals are transferred to the liver through the portal vein circulation[10-12]. These gut-derived metabolic products modulate immune functions and moderate liver disease formation, pathogenesis and treatment responses, by acting as signaling molecules[10-13].

The GM represents one of the main factors influencing the gut-liver axis and its role in the alteration of liver function has recently received considerable attention[3].

Gut dysbiosis may specifically lead to an inflammatory response due to increased production of pro-inflammatory cytokines, which are recognized by receptors in the portal circulation[10,12,14]. Production of these pro-inflammatory cytokines largely depends on the response of the innate immune system to the presence of microbial products[12]. It was documented that the GM profile in patients with chronic hepatitis differs considerably from that observed in healthy patients[15,16]. Moreover, the degree of liver insufficiency is closely related to the severity of gut dysbiosis[10]. Recent studies support the fact that GM dysbiosis helps the advancement of viral hepatitis infection[17]. During chronic viral hepatitis, the intestinal microbiota has a marked impact on viral host cell interaction as well as on viral replication[18]. *Escherichia coli* (*E. coli*), *Enterobacteriaceae*, *Enterococcus faecalis*, and *Faecalibacterium prausnitzii* represent the most harmful bacteria that can alter the good profile of GM in viral hepatitis and consequently lead to a decreased number of lactic acid species[19,20]. In addition, an increased number of *Candida sp*. in the stool is usually detected in patients with progression of hepatitis B virus (HBV), while *Neisseria, E. coli*, *Enterobacteriaceae*, *E. faecalis, F. prausnitzii*, and *Gemella* are the most common bacterial species present in the GM of patients with HBV and hepatitis C virus (HCV) infection and are correlated with the progression of liver disease[20-22].

This paper provides an overview of the state of the art of this complex matter. We discuss recent updates on the interactions of GM, liver diseases and viral hepatitis and potential therapeutic interventions that target the gut–liver axis.

GM in pathologic liver

As previously mentioned, the liver and intestine extensively interact *via* the biliary tract, the portal vein and systemic mediators. The liver is a crucial immunological organ, mainly enriched with innate immune cells and persistently exposed to numerous circulating nutrients, microbial components and metabolites in close contact with the intestinal tract. Liver compounds, on the other hand, mainly affect the GM

structure and integrity of the gut barrier, while intestinal conditions control the synthesis of bile acids, glucose and lipid metabolism in the liver. Currently, many lines of research have established a relationship between the GM and liver disease. Indeed, a concurrent surge in liver diseases and gastrointestinal and immune disorders confirms the crosstalk between the gut and the liver[23]. Among the liver diseases, the pathogenesis and progression of non-alcoholic fatty liver disease (NAFLD) and the most severe form non-alcoholic steatohepatitis (NASH), alcohol-related liver disease (ALD), primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), cirrhosis and hepatocellular carcinoma (HCC) have been associated with changes in the gut-liver axis[24]. In light of this evidence, the latest advancements in the understanding of the gut-liver axis support studies to enhance liver disease treatment in microbiome-based, diagnostic, prognostic, and therapeutic modalities.

NAFLD

A large number of preclinical and clinical studies from the last decade have investigated the role of the GM in NAFLD and NASH, showing different results. In general, NAFLD patients display a decreased GM diversity[25,26], with a decrease of Bacteroidetes and Firmicutes, along with an increase of *Lactobacillus*[27]. Moreover, steatosis was related to an abundance of *Ruminococcus gnavus* and *Coprococcus* and lower bacterial diversity in NAFLD[28], while NAFLD severity was related to shifts in both GM composition and metabolic functions[29,30]. Recently, a correlation between specific immune cells and GM fecal signatures was observed in NAFLD. In detail, *F. prausnitzii* was negatively correlated with CD163+ and CD45+ cells, while *Prevotella* was negatively correlated with CD20+ cells[31]. In addition, a GM signature was also demonstrated in fibrotic NASH[32], where advanced liver fibrosis was related to augmented *Proteobacteria* levels, whereas Firmicutes were significantly decreased[32]. Patients with NASH also showed decreased *F. prausnitzii*, *Ruminococcus*, and *Coprococcus* abundance in comparison with healthy controls[27], while pediatric patients exhibited an increased abundance of *E. coli*[25]. In NASH patients, bacterial overgrowth can inhibit intestinal tight junction function and encourage epithelial barrier dysfunction[33]. Although several reports have evaluated the GM, much less has been reported regarding the virome, defined as the total collection of viruses in and on the human body. More advanced NAFLD was associated with reduced viral (and relative bacteriophages) diversity[34]. Additionally, a recent panel including microbiota features was able to detect NAFLD-cirrhosis[35], providing evidence for a fecal-microbiome derived profile to detect NAFLD. A choline-based diet has been shown to be compatible with NAFLD by GM structure changes that benefit bacteria that break down choline[36]. However, very recent animal model research, revealed sex variations in GM abundance changes, behaviors, and hepatic steatosis in response to dietary copper-fructose interaction in rats[37]. Finally, a particular symbiotic used for therapy changed the fecal microbiota in a placebo-controlled trial, but failed to change hepatic steatosis in subjects with NAFLD[38].

ALD

Several studies have been conducted in mouse and human models based on how alcohol can induce dysbiosis associated with microbiota, which in turn can lead to ALD pathogenesis and development[39]. Regarding the GM composition, ALD patients show lower levels of *Bifidobacterium*, *Enterobacterium* and *Lactobacillus spp.*[40-43], while cirrhotic patients with ALD showed an important reduction in Firmicutes and Bacteroidetes phyla[23,44]. In fecal samples, a reduction in *Lactobacillus spp.*, has been observed in alcoholic patients, whereas cirrhotic patients showed lower amounts of *Bifidobacterium spp.*[45,46]. In addition, the GM of alcoholics with liver cirrhosis contained increased levels of *Enterobactericeae*[41]. In general, an increase in the number of microorganisms was found in the small bowel of alcoholic patients[47-49], with higher levels of microbial metabolites in the blood compared to healthy controls [19,50]. During ALD progression, a shift in the GM profile from steatohepatitis to pre-cirrhosis to cirrhosis has been reported[51]. In addition, research on chronic alcoholics has demonstrated that bacterial overgrowth is central to disease progression[52]. These findings are also supported by mouse studies[53]. Alcohol-associated dysbiosis can decrease biosynthesis of long chain fatty acids (LCFA) in mice and LCFA supplementation can restore eubiosis. In fact, a significant correlation between *Lactobacillus*

spp. and bacterial LCFA has been observed in ALD patients[54,55]. Alcohol can also reduce the development of butyrate and the administration of butyrate modulates alcohol-induced liver damage in mice[56].

PBC

Patients with PBC show a significant general decrease in bacterial diversity[57]. Indeed, *Bacteroidetes spp*. were significantly decreased and *Haemophilus*, *Fusobacteria*, *Clostridium*, *Veillonella*, *Lactobacillus*, *Pseudomonas*, *Streptococcus*, *Klebsiella*, *Proteobacteria spp*. and *Enterobacteriaceae* were over-represented in PBC patients compared to healthy controls[57]. Cross-sectional research has shown that GM, metabolism and immune alterations are associated in PBC patients[58]. In detail, beneficial intestinal microbes, including *Lachnobacterium spp*., *Acidobacteria*, *Ruminococcus bromii* and *Bacteroides eggerthii*, were found to be depleted and higher levels of opportunistic pathogens, such as *Enterobacteriaceae*, y-*Proteobacteria*, *Neisseriaceae*, *etc*., were reported[58]. In the same study, PBC-related GM modulation was associated with increased markers of liver damage and serum inflammatory cytokinesis[58]. Moreover, a recent study[59] demonstrated that the concentration of particular secondary bile acids was inversely correlated with upregulated microbes in PBC patients, but was positively correlated with upregulated bacteria in healthy controls[59]. The relationships between clinical profiles, reaction to treatment with ursodeoxycholic acid and GM composition in patients with PBC have recently been studied[60], suggesting the decrease in *Faecalibacterium* as an innovative prognostic element in PBC.

PSC

Several reports investigating the role of GM in PSC show an overall reduction in GM diversity[61]. Alterations in biliary and fecal microbiome in PSC patients are characterized by higher abundance of *Lactobacillus*, *Fusobacterium*, and *Enterococcus* and low diversity[62,63]. In addition, PSC patients showed an overrepresentation of *Enterococcus*, *Rothia*, *Clostridium*, *Streptococcus*, *Haemophilus*, *Veillonella*, *Fusobacterium* and *Lactobacillus* genera[64,65]. In particular, *Veillonella* abundance was clearly increased in PSC patients matched with healthy controls[63]. Furthermore, the GM profile of PSC intestinal biopsies was distinguished by *Barnesiellaceae* abundance and a decline in *Clostridiales*[66,67]. The pathogenesis of PSC was linked with GM dysbiosis by causing *bacterobilia*, which in turn stimulates a pro-inflammatory mechanism contributing to fibrosis and inflammation in cholangiocytes[68,69].

HBV infection

Liver failure and disease progression in patients with chronic HBV infection was found to be connected to GM dysbiosis in a large proportion[18,70]. There are differences in the composition of the intestinal flora between patients with HBV and HCV infection (Figures 1 and 2). Compared to healthy controls, patients with chronic HBV infection showed an abundant *Anaerostipes* taxon[71,72]. Liu *et al*[70] aimed to find the differences in the GM composition of HBV and non-HBV non-HCV related HCC compared with healthy controls. HCC patients with HBV were found to harbor higher species richness, more potential anti-inflammatory bacteria (such as *Prevotella*, *Faecalibacterium*, *Pseudobutyrivibrio*, *Lachnoclostridium*, *Ruminoclostridium*), and fewer pro-inflammatory bacteria (such as *Escherichia-Shigella*, *Enterococcus*) while *Proteobacteria* abundance was decreased. The role of anti-inflammatory bacteria such as *Faecalibacterium* and *Prevotella* is in their anti-inflammatory and anti-carcinogenic potential[73], but HBV infection leads to their progressive decline compared to healthy subjects[70]. In addition, Ren *et al*[74] documented that butyrate-producing bacteria declined in early HCC HBV positive patients. This further indicated that HBV indeed plays a role in GM changes. In HBV infection, a beneficial bacterium, *Lachnospiraceae*, plays a role *via* a reduction in lipopolysaccharide (LPS) secretion and bacterial translocation[74,75]. The study by Lu *et al*[16] suggested that cirrhotic patients with HBV infection exhibit a decrease in *F. prausnitzii*, *E. faecalis*, *Enterobacteriaceae*, *Bifidobacteria* and lactic acid bacteria, while *Enterococcus* and *Enterobacteriaceae* levels are significantly increased compared to healthy individuals.

On the contrary, HBV and HCV negative patients with HCC harbored fewer potential anti-inflammatory bacteria and more pro-inflammatory bacteria. Taken together, these data indicated that GM plays an important role in the progression of

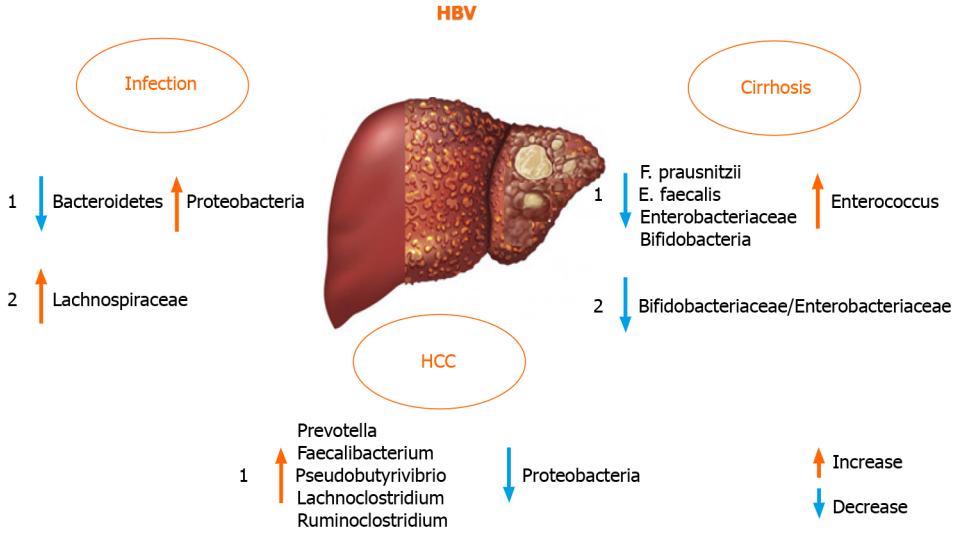

Figure 1 Differences in altered microbiota in patients with HBV during infection and cirrhosis. HBV: Hepatitis B virus; HCC: Hepatocellular carcinoma.

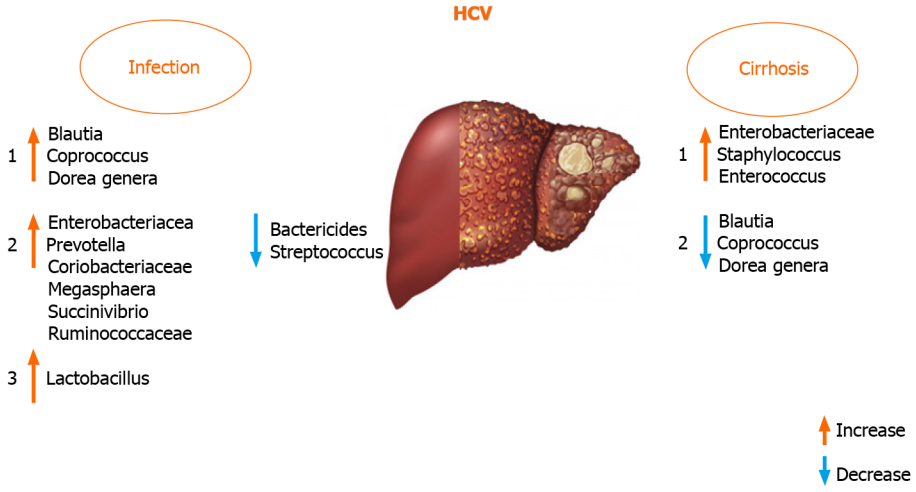

Figure 2 Differences in altered microbiota in patients with HCV during infection and cirrhosis. HCV: Hepatitis C virus.

HBV or non-HBV non-HCV related HCC. These findings were different from previous reports on HBV-induced liver diseases[16,70,76]. The discrepancy in these findings was probably due to the progression of liver diseases and the group of patients in evaluated studies. To analyze the GM role in HBV positive patients, it is appropriate to use a defined cohort of patients suffering from HBV infection[77], excluding patients with different etiologies of liver cirrhosis (including alcohol abuse) that itself may change the composition of the intestinal microbial community and the same might be true for other liver diseases[70,78]. Therefore, the discrepancy of fecal microbiota between HBV positive and HBV negative patients in the study by Liu *et al*[70] is perhaps due to the HBV infection[70,77].

Not only gut dysbiosis, but also dysbiosis of the oral microbiota was observed in HBV patients, and yellow tongue coating is suggestive of a reduction in *Bacteroidetes*, but an increase in *Proteobacteria*. Zhao *et al*[79] also suggested a positive correlation between serum HBV-DNA and the number of *Neisseriaceae* in oral microbiota.

Furthermore, the GM composition differed according to the level of alanine aminotransferase (ALT) in HBV patients[80,81]. *Desulfovibrio* had a positive correlation, while *Acidaminococcus* showed a negative correlation with high ALT level[81]. Lu *et al*[16] found a significantly decreased ratio of *Bifidobacteriaceae/Enterobacteriaceae* (B/E) in cirrhotic HBV positive patients, while Yun *et al*[72] observed no difference in the B/E ratio in non-cirrhotic HBV patients with positive HBsAg and normal or high ALT. These findings lead to the conclusion that the B/E ratio is disturbed only in the GM of patients with cirrhosis. However, another study observed that the *Megasphaera* genus

of the Firmicutes phylum was abundant in the HBsAg positive high ALT group compared to the normal ALT group. In HBsAg positive patients with normal ALT, butyrate-producing bacteria (*e.g.*, *Anaerostipes*) are more often present in GM compared to HBsAg negative patients[72]. These bacteria produce short-chain fatty acid as a by-product of lactate fermentation and butyrate. In Figure 1 we show the main microbiota alterations in HBV.

Recently, Wang *et al*[82] defined serum zonulin as an intestinal permeability marker and showed its association with AFP levels in HBV-associated liver cirrhosis and HCC, especially helpful in correlating it with advanced stages of these diseases[83]. It has been reported that the diagnostic model of one location may be not used in other locations, as the diagnostic efficiency declined when the geographic scale was increased[79]. The characteristic GM changes had the strongest relationship with the host location; thus, the diagnostic potential of microbial markers should consider these geographic differences[79].

HCV infection

The liver-gut interaction controls GM homeostasis during HCV infection, which might be an ideal model to study the interaction between the GM and liver[18,80]. A review of previous reports provides the rationale for the hypothesis that GM dysbiosis could also be employed as a biomarker and a therapeutic target to mitigate disease progression. Interestingly, HCV-RNA and HCVcoreAg were frequently found in the stool of patients with chronic HCV[84]. Therefore, direct interactions between virus particles and intestinal bacteria might facilitate or inhibit growth as in rotavirus infection[85]. Heidrich *et al*[86] found that progression of HCV infection is related to a reduced alpha diversity revealing that the relative abundance of phylotypes is associated with the stage of the disease. Additionally, Sultan *et al*[2] characterized the GM from a cohort of adult patients with HCV before starting any treatment and confirmed the presence of GM dysbiosis. Microbial taxa in HCV positive patients identified during this study were characterized by increased microbiota diversity, the enrichment of *Enterobacteriacea*, *Prevotella*, *Coriobacteriaceae*, *Megasphaera*, *Succinivibrio*, and *Ruminococcaceae*, and the depletion of *Bacteroides* and *Streptococcus*. In addition, the GM of HCV-infected subjects was characterized by the depletion of carbohydrates and lipid metabolism, specifically galactose, fructose, mannose, and sphingolipid metabolism. In the presence of HCV infection, microbiota-associated histidine metabolism was decreased, while the metabolism of cysteine and methionine and translation proteins was enriched compared to healthy controls[2]. The findings of Sultan *et al*[2] contradict previous literature that showed a decrease in GM diversity and changes within the abundance of some taxa such as *Prevotella*, *Ruminococcaceae*, *Enterobacteriacea*, and *Faecalibacterium* in patients with chronic HCV infection[2,15,86-88]. This could be due to many aspects such as different stages of the disease, treatment or other medication-related factors, different genotypes, demographics, diet, alcohol consumption or smoking. Specifically, treatment regimens were not controlled in most of these reports, which may obscure a possible key microbe, a protective role, or a diagnostic-related signal. The impact of specific treatment has also received significant attention in GM research in other health disorders[5,89,90].

It was documented that antiviral HCV treatment with ribavirin + pegylated interferon has no direct impact on gut dysbiosis, and in fact, it increases bile acids, which is very important in GM metabolism[91]. Some pathogenic bacteria such as *Enterobacteriaceae*, *Staphylococcus*, and *Enterococcus* decreased the steroid in HCV-infected cirrhotic patients, which normalized after direct-acting antivirals (DAAs). In addition, DAAs are helpful in improving GM, especially from the *Lachnospira* and *Dorea* genera, and in restoring TNF-α levels[92]. However, following DAA treatment, the expression of calprotectin, ZO1, and LPS was more intensive in HCV patients with cirrhosis[92]. Pérez-Matute *et al*[92] showed that the administration of DAAs in HCV patients was not able to improve GM bacterial richness. However, partial restoration of inflammation, alpha diversity and a few bacterial genera (except *Actinobacteria*) were observed after 3 mo in patients with a lower fibrosis degree, stressing the concept that gut dysbiosis and liver damage are gradual[92]. Liver fibrosis degree might be a key factor contributing to a definite GM profile. A lower abundance of *Akkermansia muciniphila* was also found in HCV infected patients with higher fibrosis degrees and it is proposed that these bacteria could have a major role in the evolution of HCV infection and liver damage. *Akkermansia muciniphila* is proposed as a new candidate for developing novel supplements with beneficial effects for GM recovery[93] and to intensify the action of DAAs at this level. These results confirm those previously observed with prior treatments in cirrhotic patients[94]. Thus, with severe liver damage, a greater impact on GM is observed, and, therefore, there are more difficulties to

counteract such changes with antivirals. These data highlight the need to treat patients as soon as possible in order to reverse the negative actions caused by HCV infection on GM diversity and future clinical correlated consequences.

It was found that *Blautia*, *Coprococcus*, and *Dorea* genera were increased in HCV positive patients, which is opposite to the lower presence of these bacteria observed in disease stage 4[95]. Such conflicting findings could be explained by the various fibrosis degrees of the study groups. Several studies have demonstrated an over-representation of *Veillonella* in cirrhotic patients (both, HBV and/or HCV infected) and its positive correlation with ALT or AST levels in serum[20,75,92]. In conclusion, the role of this genus in the GM of healthy people has not been completely revealed.

An increased presence of *Lactobacillus* in HCV-infected patients was found in very few studies, although the study cohorts were not uniform (treatment-naïve and patients under a treatment regimen)[86,92]. However, the impact on the progression of HCV infection of this genus and a few bacterial species belonging to that genus (such as *L. ruminis*) has to be specifically addressed, as some probiotics are supported by bacterial strains belonging to this genus[96]. The main microbiota alterations in HCV infection are reported in Figure 2.

The GM varies in patients with different HCV genotypes[86]. Statistically significant differences in GM composition between patients with and without liver cirrhosis are only found in genotype non-1. In genotype 1, differences in the microbial composition are associated with the persistent HCV infection rather than with the fibrosis stage. Therefore, studies investigating patients with liver diseases compared to healthy controls might overlook the influence of the underlying disease on the intestinal microbial communities, and so other diseases and stages of diseases need to be investigated for potential associations[15,75].

Cirrhosis

A recent study has shown that the GM has a lower abundance of *Bacteroidetes* and higher levels of *Prevotella*, *Enterococcus*, *Veillonella*, *Proteobacteria*, *Megasphaera*, *Burkholderia*, and *Fusobacteria* in patients with cirrhosis[20,43]. In the duodenal mucosa of cirrhotic patients, an overrepresentation of *Veillonella*, *Megasphaera*, *Dialister*, *Atopobium*, and *Prevotella* was reported, compared to controls. A reduction in diversity, a rise in immunostimulatory pathogens (*e.g.*, *Staphylococcaceae* and *Enterococcaceae*) and a decline in potentially beneficial *Firmicutes* (*e.g.*, *Ruminococcaceae* and *Lachnospiraceae*) have been identified with respect to the fecal microbiota in patients with cirrhosis[15]. Moreover, similar changes were detected in the colon mucosa[97], serum[98], and saliva[99] of patients with cirrhosis. Interestingly, the improvement in GM composition was correlated with the outcomes of patients with (*i.e.*, compensated *vs* uncompensated[100], inpatient *vs* outpatient, and noninfected and infected patients [19]), indicating microbiota alterations as potential new biomarkers. Intriguingly, a higher abundance of buccal-derived microflora was recorded in fecal specimens from cirrhosis patients, as well as dramatically altered salivary microbiome levels[15]. In a very recent and innovative study, an analogous microbiome profile was observed independently of the etiology of cirrhosis using a machine-learning-based methodology and matching their outcomes with other cohorts containing different etiologies of liver cirrhosis. These outcomes suggest that the etiology of liver disease tends to be less relevant regarding the GM alterations[101]. Such an approach may allow the non-invasive diagnosis of liver cirrhosis[101].

HCC

Alterations in the composition of the microbial profiles are suspected of having a role in carcinogenesis[1]. Indeed, recent studies suggested a correlation between particular bacterial profiles in HCC patients[74]. However, the contribution of GM to HCC pathogenesis is intricate: (1) A disturbed intestinal barrier brings a series of TLR ligands to the liver and activates the inflammatory response; (2) *via* downregulation of hepatocyte apoptosis and upregulation of hepatic stellar cell proliferation, the TLR signaling pathways mediate hepatocarcinogenesis[102]; and (3) Finally, impaired immunosurveillance is associated with abnormal GM in HCC. Moreover, microbiota dysbiosis can be related to HCC pathogenesis by increasing oxidative stress, steatosis, and the inflammatory response[103]. Additionally, the GM of HCC patients undergoing liver transplantation was compared to the GM of patients who did not have HCC, but had an analogous etiology of cirrhosis and MELD stage. An increased number of fecal *E. coli* was associated with HCC[104]. Moreover, the presence of *Helicobacter spp*. in HCC tissue samples indicated intestinal translocation as a possible trigger of tumorigenesis[105]. Finally, the GM structure could theoretically predict reaction rates in liver cancer patients treated with particular immune checkpoint

inhibitors[106], indicating the potential to harness the microbial flora for HCC immunotherapy[107].

Role of fecal microbiota transplantation in viral hepatitis - future directions

Different therapeutic approaches have been proposed to improve the health of patients with chronic viral hepatitis through the manipulation of GM composition, the modulation of immune signaling, and the production of metabolites[88,108]. It was found that some bacteria of the intestinal microbiota disappeared in patients who received antibiotics within 3 mo[109]. It is speculated that region and eating habits might affect the flora of HBV positive patients[109]. Fecal microbiota transplantation (FMT) is considered a promising new treatment option for HBV and HCV infection, due to its ability to restore GM dysbiosis[108].

Ren *et al*[110] reported a clinical trial of FMT for the treatment of HBeAg positive patients with chronic HBV with ongoing entecavir and tenofovir therapy. The results demonstrated that FMT induced HBeAg clearance in a significant number of patients that had persistent positive HBeAg even after long-term antiviral treatment. This result was especially encouraging for HBeAg positive patients who otherwise could not stop oral antiviral treatment[110]. In addition, this trial provided evidence that FMT could be a beneficial treatment option for modulating GM in patients with chronic HBV. HBV carriers might be suitable donors for FMT as their GM composition seems to be more appropriate compared to the healthy population. The results of Yang *et al*[108] confirmed that HBV carriers have altered GM although they are asymptomatic. The high treatment FMT potential from HBV carriers comes from the evidence that they are able to keep a long-life balance with the virus without developing clinical symptoms. These data confirm the previous allegations that the change in flora composition of HBV carriers may play an active role in the struggle between the human body and the virus[94,110]. Of course, more detailed studies are needed to verify these claims.

The use of probiotics in HBV positive patients was shown to be beneficial and suggested that probiotic VSL#3 plays an important role in the management of HBV infection[111]. In addition, the use of probiotics in HCV-infected patients with cirrhosis has been shown to be significantly beneficial[88]. It was suggested that during HCV infection, *L. acidophilus* and *Bifidobacterium spp.* can act as a supportive supplement with antiviral and antibacterial activities[112]. The results of Doskali *et al*[113] suggested that a healthy GM increases the cytotoxic effects of NK cells against viral infected cells; thus, inhibiting HCV replication. Finally, Yang *et al*[108] confirmed that some probiotics, such as lactic acid bacteria, may have a negative impact on disease progression. The results of Yang *et al*[108] indicated that the intake of *Lactobacillus* should be cautious as these bacteria are negatively associated with environmental adaptation, energy metabolism, and the immune system and may have an influence on the progression of HBV infection[70,108].

CONCLUSION

This literature review provides evidence on the association between gut dysbiosis and the clinical course of both chronic HBV and HCV infection. The evidence in humans seems to confirm the potential role of intestinal overgrowth of pathogenic bacteria and the development of chronic viral hepatitis observed in animal-based studies. In addition, current clinical trials with different therapeutic strategies have improved the present knowledge on the gut–liver axis, showing positive and encouraging results on how to overcome the battle with viral hepatitis. More studies on the liver-gut mechanistic interaction during HCV and HBV infection are still needed to unravel the cause-effect relationship between gut homeostasis and disease complications and to evaluate the efficacy of modulation of the GM as a preventive strategy against chronic viral hepatitis progression and especially the development of hepatocarcinoma.

Abstract

Metabolic diseases are highly prevalent worldwide and have been associated with adverse clinical outcomes, including mortality, in patients developing coronavirus disease (COVID-19). Because of the close relationship between metabolic diseases such as type 2 diabetes mellitus and obesity and the presence of metabolic-associated fatty liver disease (MAFLD), a high number of cases of patients affected by both MAFLD and COVID-19 would be expected, especially in high-risk populations. Some studies have shown an increased risk of adverse clinical outcomes, viral shedding, and deep vein thrombosis, especially in patients with MAFLD- related liver fibrosis. The predisposition to poor outcomes and severe acute respiratory syndrome coronavirus 2 infection in patients with MAFLD could be secondary to mechanisms common to both, including preexisting systemic chronic inflammation, endothelial dysfunction, and involvement of the renin-angiotensin system. Because of the increased risk of adverse outcomes, MAFLD should be screened in all patients admitted for COVID-19. Available computed tomography scans could be of help, assessment of liver fibrosis is also recommended, favoring noninvasive methods to limit the exposure of healthcare workers. Liver involvement in this population ranges from abnormalities in liver chemistry to hepatic steatosis in postmortem biopsies. Finally, preventive measures should be strongly advocated in patients already known to have MAFLD, including the use of telemedicine and vaccination in addition to general

Core Tip: The coronavirus disease 2019 (COVID-19) pandemic arrived amid a population increasingly affected by metabolic diseases such as type 2 diabetes mellitus and metabolic-associated fatty liver disease (MAFLD). Patients with MAFLD can have chronic inflammation, endothelial dysfunction, and increased expression of angiotensin-converting enzyme 2 receptor, which could synergize with severe acute respiratory syndrome coronavirus 2 pathophysiology, predisposing to a greater risk of adverse outcomes. Interestingly a high prevalence of liver steatosis in postmortem samples of patients who had COVID-19 has been found. Moreover, the presence of liver fibrosis has been shown to worsen prognosis in those patients. As a result, all patients with COVID-19 should be assessed for the presence of these comorbidities and closely follow-up.

INTRODUCTION

In late 2019, a new coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was first described in Wuhan, China[1], and has since spread to the rest of the world[2]. The dimension of this pandemic can be partly explained by the higher level of transmissibility of SARS-CoV-2 and a higher number of asymptomatic carriers, compared with other viruses such as Middle East Respiratory Syndrome (MERS) and SARS-CoV[3]. SARS-CoV-2 belongs to the beta-coronavirus family, and together with MERS and SARS-CoV virus, has been responsible for a high fatality rate during outbreaks[4].

The clinical manifestations of SARS-CoV-2 infection are extensive, ranging from asymptomatic disease, mild respiratory symptoms, to severe disease that may require mechanical ventilation because of severe acute respiratory syndrome, with a high risk of death. Most patients dying from COVID-19 are clustered by the presence of risk factors including older age, obesity, and chronic and metabolic diseases[5-8]. Among the risk factors, highly prevalent metabolic diseases such as type 2 diabetes mellitus (T2DM), hypertension, and obesity, are of utmost importance, being associated with a more severe clinical course that includes the need for intubation, and death[9]. Nonalcoholic fatty liver disease (NAFLD), recently renamed as metabolic-associated fatty liver disease (MAFLD), is strongly related to metabolic comorbidities and insulin resistance. It is regarded as the hepatic manifestation of metabolic syndrome[10,11]. The most important predictor of liver and non-liver-related outcomes in patients with MAFLD is the presence of liver fibrosis[12]. The association between metabolic risk factors such as obesity and diabetes, and MAFLD, means that the probability of facing patients with MAFLD and COVID-19 is high. Therefore, understanding the possible mechanisms of synergism between these entities, epidemiology, risk factors, clinical assessment, and prevention is of great clinical relevance. This review addresses these topics, focusing on proposing ways to identify and manage MAFLD in patients with COVID-19.

EPIDEMIOLOGY OF MAFLD

MAFLD is the most prevalent chronic liver disease worldwide, found in 10%-30% of the general population. The prevalence varies across countries and at the same time it varies among different regions from the same country[13]. Several factors can explain the variability in the prevalence of MAFLD, including age, sex, genetic factors such as the PNPL3 allele, environmental factors such as the typical western diet and sedentary lifestyle, access to health care, and the diagnostic methods used in epidemiological studies, especially with its recent re-classification[13-15].

EPIDEMIOLOGY OF SARS-COV-2 INFECTION

As of July 29, 2021 the World Health Organization reported more than 195 million confirmed cases of COVID-19 infection worldwide, with a death toll of more than 4 million[16]. United States is the country with the most confirmed cases, followed by India, Brazil, Russia, and France, and the United Kingdom. The countries with the highest mortality are the United States, Brazil, India, Mexico, and Italy. Interestingly the fatality rate is considerably higher in countries like Mexico, Iran, and Peru. The disparity in mortality could have several explanations including population characteristics (*e.g.*, sex, age, presence of comorbidities, and genetic factors), time since the initial outbreak, outbreak management, quality of the healthcare system, and the number of testing and treatment options, including the availability of mechanical ventilation[17].

Figure 1 shows the ten countries with the most COVID-19 cases and the prevalence of NAFLD reported by each country[13,18-21]. It its noteworthy that of the ten countries five have a prevalence of NAFLD > 30%, four between 20% and 29.9%, and only one country has a prevalence < 10%. Figure 2 shows the countries with the highest case fatality rate, which refers to the proportion of deaths in the population diagnosed with the disease. The rate is disproportionally higher in Mexico, and once more, five of the countries have a prevalence of NAFLD > 30% and three have a prevalence between 20% and 29.9%. Although this is not a causal explanation, it is certainly an interesting association. Finally, Figure 3 shows the number of deaths adjusted for every 100,000 habitants in order to standardize the comparison. Two countries have rates > 30% and four have rates between 20% and 29.9% while the rest have rates between 10% and 19.9%.

PROPOSED MECHANISMS OF LIVER INJURY IN PATIENTS WITH MAFLD AND SARS-COV-2 INFECTION

Multiple factors in MAFLD contribute to liver damage and progression of the disease, beyond insulin resistance and oxidative stress alone, as was previously thought[22]. In general, three mechanisms are associated with a higher risk of adverse outcomes in patients with MAFLD who develop COVID-19. The relationship stems from the fact that MAFLD is a part of the metabolic syndrome, and shares the following characteristics: (1) A preexisting systemic inflammatory milieu (*i.e.* systemic chronic inflammation and insulin resistance); (2) Endothelial dysfunction; and (3) Differential regulation of the renin-angiotensin-aldosterone system (RAAS)[23-29].

Long-term inflammation is a common denominator in chronic metabolic diseases, including MAFLD[30]. Obese patients express 2.5-fold more tumor necrosis factor (TNF)-α in fat tissue compared with lean controls, and weight loss is accompanied by a decrease in TNF-α mRNA expression[31]. Contrary to the belief that patients with simple steatosis do not have inflammation, some studies have shown otherwise. In murine models, it has been shown that liver steatosis leads to inflammation through NF-kB activation and downstream cytokine production[32]. Patients with both NAFLD and nonalcoholic steatohepatitis (NASH) have significantly higher serum levels of IL-6 and CRP compared with healthy controls, where inflammation levels are similar in both stages[33,34]. Also CCL2/MCP-1, which regulates migration and infiltration of monocytes/macrophages was found to be increased in both NAFLD and NASH patients[33]. The studies reported that patients with NAFLD were characterized by low-grade systemic inflammation; furthermore, compared with healthy individuals, the presence of advanced liver fibrosis was accompanied by significantly higher markers of systemic circulatory dysfunction and higher levels of proinflam-

matory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-8, monocyte chemoattractant protein (MCP)-1, interferon-γ–inducible protein (IP)-10, and macrophage inflammatory protein (MIP)-1b[35]. On the other hand, in patients with COVID-19, the presence of hyperinflammation, described as hypercytokinemia or "cytokine storm", immune hyperactivation, and even in some cases secondary hemophagocytic lymphohistiocytosis have been reported[1,36-38]. One of the cytokines reported to be elevated in patients with COVID-19 is IL-1B, which is the final effector of pyroptosis, a known mechanism of liver cell death[39,40]. Apart from IL-1B, other cytokines have been found to increase in COVID-19, including IL-6, IP-10, TNF, interferon-γ, vascular endothelial growth factor, and MIP 1α and 1β[36]. Obese patients with COVID-19 present a more prominent inflammatory profile than

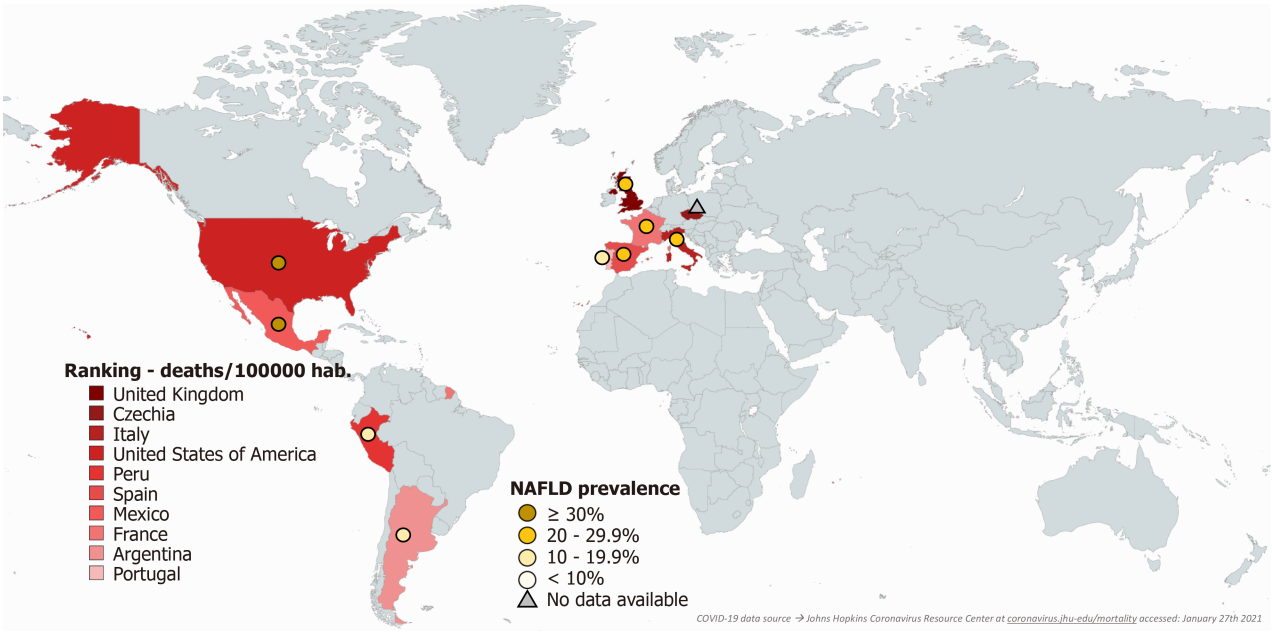

Figure 3 Number of deaths from coronavirus disease 2019 per 100000 habitants and nonalcoholic fatty liver disease prevalence. nonobese COVID patients[41]. Dexamethasone has shown a mortality benefit in patients with severe COVID-19 because of its ability to inhibit the generation of cytokines and their deleterious effects[42]. The possible effect of an "acute-on-chronic inflammation" process in patients with MAFLD, including those with or without liver fibrosis, and COVID-19, deserves further research, including the possibility of different anti-inflammatory responses to corticosteroids such as dexamethasone.

Another point of convergence between COVID-19 and metabolic diseases such as MAFLD is endothelial dysfunction. Endothelial dysfunction has been described in patients with liver steatosis. Healthy individuals have better endothelial function than biopsy-proven NAFLD patients[27], which partially explains the increased risk of cardiovascular disease in that population[43]. Endothelial dysfunction results in a prothrombotic state leading to occlusion and micro thrombi formation in patients with COVID-19[44]. Moreover, endothelial dysfunction can result in insufficient nitric oxide and consequent vessel constriction[45]. Taken together, the studies show that preexisting endothelial dysfunction could explain the high prevalence of thrombosis in patients with COVID-19 and MAFLD[46].

Finally, some of the pathways involved in liver fibrosis, which is the key event determining the outcome in patients with NAFLD[12], are specially relevant and could have an important role in patients with COVID-19. One of them, the RAAS, is involved in liver fibrosis development, where angiotensin II induces a profibrogenic phenotype in stellate cells and has an important role in the pathophysiology of cirrhosis[47,48]. Similarly, RAAS has a role in the pathogenesis of NAFLD, where the hepatic local RAAS is overactivated, and more importantly, patients with NASH have significantly higher expression of angiotensin-converting enzyme 2 (*ACE2*) gene, suggesting that those patients have a greater risk of liver affection by SARS-CoV-2[49] given the fact that SARS-CoV-2 entry into the cell is accomplished through the binding and interaction of the spike glycoprotein (S-glycoprotein) andACE2[50]. This could partially explain the relationship between adverse outcomes and liver fibrosis in patients with MAFLD and COVID-19.

In conclusion, various mechanisms explain the association observed in different studies between MAFLD and/or fibrosis and adverse outcomes in patients with COVID-19, where its directionality is important to explain what happens in the liver. One is that a previous chronic state (*e.g.*, inflammation, endothelial dysfunction, differential regulation of the RAAS, *etc.*) "primes" the body to develop a stronger response upon SARS-CoV-2 infection, thereby increasing its lethality. Another possible scenario is that acute systemic inflammation induces a prosteatotic and profibrogenic response in patients with COVID-19. These mechanisms need further study in order to shed light on the main pathways explaining the relevance of MAFLD in patients with

COVID-19.

METABOLIC RISK FACTORS ASSOCIATED WITH SEVERE COVID-19

The risk of severe COVID-19 is higher in older individuals and in those with underlying medical comorbidities. The established risk factors for severe COVID-19, according to the Centers for Disease Control and Prevention (CDC), are T2DM, serious cardiovascular disease, obesity, chronic kidney disease, cancer, chronic obstructive pulmonary disease, immunocompromised state from solid organ transplant, smoking and sickle cell disease[51]. Given the association between MAFLD, obesity, and diabetes mellitus, it could be proposed as a high-risk metabolic condition[52,53].

Obesity

Obesity is a fast-growing public health problem. In 2016, 39% of the adult population worldwide were overweight and 13% were obese. There is a direct relationship between obesity and adverse clinical outcomes[54]. The association has also been observed in patients with SARS CoV2 infection, where observational data links obesity with an increased risk of severe disease and death[55-61]. In addition to the body mass index (BMI), visceral adiposity probably favors the development of severe COVID-19. This was addressed in a single-center cohort study in Italy, where the investigators found that abdominal adipose tissue distribution positively correlated with the risk of intensive care unit (ICU) admission in patients with COVID-19[62].

Diabetes mellitus

Diabetes is among the ten leading causes of death worldwide[63]. There is a relation between diabetes mellitus and the development of severe COVID-19[64-69]. In an observational cohort study, COVID-19-related mortality in people with diabetes mellitus was associated with the preceding level of hyperglycemia (HbA1c). In T2DM patients, the risk was significantly higher in those with an HbA1c > 7.5% and the risk increased as HbA1c levels did[70]. Another study found lower mortality in hospitalized patients with COVID-19 and T2DM with better glycemic control[65]. Conversely, Agarwal *et al*[71] did not find a clear association between HbA1c level and mortality in patients with diabetes and COVID-19, but the risk of mortality was greater in patients on previous insulin therapy.

The pathophysiological mechanisms that increase the risk of mortality in people with COVID 19 and obesity/diabetes mellitus are complex and not completely clear. The two factors have immune dysfunction characterized by a state of chronic low-grade inflammation in common[72,73]. There is evidence that patients with obesity and SARS CoV2 infection have a higher expression of inflammatory markers including IL6, IL-4, erythrocyte sedimentation rate, and high-sensitivity C-reactive protein (hsCRP) than nonobese patients[74].

SPECTRUM OF LIVER DAMAGE IN PATIENTS WITH MAFLD AND COVID-19

Several studies have been conducted to elucidate whether MAFLD is a risk factor for adverse clinical outcomes in patients with COVID-19. A summary of all of the studies, published until December 7, 2020 evaluating the association between MAFLD and clinical outcomes in patients with COVID-19 is presented in Table 1. It is important to acknowledge that comparison of the studies is limited by differences such as the number of available cases, the clinical outcomes evaluated, definitions of severity, demographic characteristics and comorbidities, and the methods of assessing both MAFLD and liver fibrosis. Despite this limitation, there are consistent results among the published data. All studies compared patients with or without MAFLD and all found different risk factors for the development of various poor clinical outcomes. Most studies concluded that MAFLD patients have an increased risk of developing abnormal liver function tests, liver injury, and severe disease in the acute setting of COVID-19. In addition, some studies found no differences in disease severity, disease progression, complications, or mortality among patients with or without MAFLD. Others emphasized that MAFLD only conferred an increased risk of severe disease in younger patients < 60 years of age, in those with advanced fibrosis detected by noninvasive methods such as the FIB-4 score or NAFLD fibrosis score (NFS) or with an

Hashemi *et al*[81]	Cohort, n = 363 pts, United States	55/308 (69 w/CLD)	Imaging evidence or biopsy evidence of hepatic steatosis	N/A	Clinical outcomes	MAFLD: Increased risk of ICU admission (OR 2.30, 95%CI: 1.27-4.17, P = 0.03) and need of mechanical ventilation (OR 2.15, 95%CI: 1.18-3.91, P = 0.02). No difference in mortality rates

ALT: Alanine aminotransferase; BMI: Body mass index; CLD: Chronic liver disease; COVID-19: Coronavirus disease; 2019; CT: Computed tomography; DVT: Deep vein thrombosis; HSI: Hepatic steatosis index; MAFLD: Metabolic-associated fatty liver disease; N/A: Not available; NAFLD: Nonalcoholic fatty liver disease; NASH: Nonalcoholic steatohepatitis; NLR: Neutrophil/lymphocyte ratio; US; Ultrasound.

elevated neutrophil/lymphocyte ratio (NLR) of > 2.8. One study found that MAFLD patients had increased viral shedding time and another identified an increased risk of deep vein thrombosis[46,52,53,75-88].

HISTOLOGICAL FINDINGS

Information regarding liver histopathological findings in COVID-19 is scarce. Some case series have reported a high prevalence of liver steatosis in postmortem biopsies and autopsies, ranging between 48% and 75%. Sonzogni *et al*[89] reported liver biopsies from 48 patients who died from COVID-19 in northern Italy, none of whom had signs or symptoms of liver disease before and during hospitalization. Obesity was present in 16% of the patients, hypertension in 53%, and diabetes in 29%. Macrovesicular steatosis was observed in 48% of the samples; all patients with obesity had liver steatosis. The use of steroids was not reported in this paper. Lagana *et al*[90] reported the liver histology of 40 patients who died of COVID-19 in New York, 50% had diabetes and 75% had hypertension. The most common finding was macrovesicular steatosis, present in 75% of the patients. Interestingly, the distribution of liver steatosis was not typical of MAFLD and did not correlate with BMI or T2DM. Twenty-two patients (55%) received steroids during their hospital stay. Bradley *et al*[91] reported postmortem examinations performed on 14 patients who died of COVID-19 in Washington state. Liver steatosis was reported in 64% of the patients. Ten of the 14 patients had at least one metabolic disease (*i.e.* hypertension TD2M, dyslipidemia, or obesity), steroid use was not reported. A report of autopsy findings of 22 COVID-19 patients in Italy revealed microvacuolar and microvacuolar steatosis in 54% of the patients[92]. Table 2 further describes the studies.

Table 2 Histological findings from liver biopsies of coronavirus disease 2019 patients

Ref.	Inclusion criteria	Population characteristics *n* (%)	Histopathological results	
Sonzogni *et al*[89]	Postmortem SARS-CoV-2-positive patients. (*n* = 48)[1]; Male/Female (*n*): 35/13[1]; Age (yr): 71 (32-86)	No comorbidities: 6 (13.3); Hypertension 24 (53.3); Cardiovascular Disease (different than hypertension) 17 (37.8); Diabetes 13 (28.9); Obesity 7 (15.6); Kidney disease 10 (22.2); Pulmonary disease 5 (11.1)	Portal vein parietal fibrosis	Absent 39%; Focal 29%; Multifocal 22%; Diffuse 8%

			Congestion	10 (45.5%)
			Steatosis	12 (54.5%)

[1]Age was reported as median (interquartile range). SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; BMI: Body mass index.

Two explanations can be made of the high-frequency of macrovesicular steatosis in patients who died with severe COVID-19. The first is that the patients had liver steatosis before they acquired COVID-19, which represents a risk factor for mortality as the prevalence was higher than that reported in the general population[93]. MAFLD might contribute to the COVID-19-induced inflammatory "storm" through the hepatic release of proinflammatory cytokines, thereby contributing to the severity of the disease[79]. The second explanation is that liver steatosis developed in some patients during the course of the infection, with the etiology being multifactorial[90]. Hypoxia is associated with lipid homeostasis maintained by hypoxia-inducible factors (HIFs). HIFs regulate hepatic lipid metabolism to increase the liver lipid storage capacity[94,

95]. The corticosteroid therapy that is frequently given to patients with severe COVID-19 can cause hepatic steatosis. The effect can occur rapidly and is not usually clinically relevant[96]. Liver steatosis has been associated with viral infections, specifically hepatitis C virus infection, through impaired secretion, increased neosynthesis, and impaired degradation[97]. In summary, there is no pathophysiological evidence supporting SARS-CoV-2 as a direct cause of liver steatosis. However, as seen above, liver steatosis is a common histopathological finding in patients who died from severe COVID-19. The explanation of the findings is undoubtedly multifactorial, including a history of metabolic risk factors, use of corticosteroid therapy, and the universal presence of hypoxia in these patients.

FUTURE PERSPECTIVES IN PATIENTS WITH MAFLD AND COVID-19

MAFLD patients can be vulnerable to SARS-CoV-2 infection and COVID-19 complications because of the deleterious interaction of complex inflammatory pathways[98]. As we show in this review, based on currently available clinical evidence, patients with MAFLD have an increased risk of developing abnormal liver function tests and are more likely to progress to severe COVID-19[52,53,80-82,84,86-88]. Therefore, MAFLD should be considered a prognostic indicator for COVID-19.

We recommend taking these observations into account when assessing such patients. It is important to identify and closely monitor patients with preexisting liver diseases, including those with MAFLD. An Asia-Pacific position statement also recommends proper monitoring and management of blood pressure and glycemic control in MAFLD patients who have COVID-19, as it is associated with poor clinical outcomes[99]. As we do not yet know the long-term effects that COVID-19 can have on patients with MAFLD with respect to fibrosis, we also encourage long-term monitoring. Below, we discuss the available options for clinical assessment and prevention.

Clinical assessment

Given the high prevalence of MAFLD and the implications of liver fibrosis for the risk of adverse outcomes in patients with COVID-19[100], all patients admitted to hospital should be evaluated for the presence of MAFLD and assessed for the risk of liver fibrosis. Most patients with MAFLD are asymptomatic, and therefore, are not aware of their disease. Establishing the diagnosis of MAFLD requires the presence of metabolic risk factors such as overweight/obesity, T2DM, or evidence of metabolic dysregulation in addition to evidence of fat accumulation in the liver[101]. The first step in the evaluation of MAFLD and fibrosis in patients with COVID-19 should be to determine the presence of metabolic risk factors such as insulin resistance, T2DM, hypertension, obesity, and dyslipidemia. In those patients, the presence of liver steatosis should be determined either by imaging or by risk scores. The ideal imaging methods to assess liver fat content are ultrasound, transient elastography, or magnetic resonance imaging, however in the context of COVID-19 patients, the use of available images such as those derived from chest computed tomography (CT) scans can be useful, shorten the evaluation time, and limit the exposure of healthcare workers. Chest CT has high sensitivity and specificity for detecting lung lesions in patients with COVID-19 and is performed frequently in patients with severe disease[102]. Images of the liver and the upper pole of the spleen can be seen in chest CT scans. In those cases, the CT scan can be used to diagnose moderate and severe steatosis[101]. CT diagnostic criteria for steatosis are liver attenuation of at least ten Hounsfield Units (HU) less than that of the spleen or an absolute liver attenuation of less than 40 HU. These criteria have variable specificity (43%-95%) and high sensitivity (90%–100%)[103]. When a chest CT is not available or the image is not ideal, risk scores are a useful alternative. Several scores have been developed for that purpose, including the NAFLD liver fat score, the Framingham steatosis index (FSI), and the Dallas Steatosis Index. The NAFLD liver fat score is calculated using the presence of metabolic syndrome, T2DM, fasting serum insulin, fasting serum aspartate transaminase (AST)/alanine transaminase (ALT) ratio. A cutoff of 0.640 predicts increased liver fat content with a sensitivity of 86% and specificity of 71%[104]. The need of a serum insulin assay makes this score impractical in some hospitals. The FSI includes the patient age, sex, BMI, triglyceride level, hypertension, T2DM, and the ALT/AST ratio. At a cutoff point of 23, the FSI has a sensitivity of 79%, a specificity of 71%, a positive predictive value (PPV) of 50%, and a negative predictive value (NPV) of 90% for hepatic steatosis[105]. The disease severity index is a novel, recently developed score based on ALT level, DMI, age, sex, trigly-

ceride and glucose levels, T2DM, hypertension, and ethnicity. At a threshold of < 20% risk, MAFLD can be excluded with 86% sensitivity and 90% NPV[106]. A major drawback of these scores is that all of them require transaminase values, which may be elevated in patients with COVID-19[107], increasing the risk of overestimating the risk of liver steatosis.

For patients who meet the criteria for MAFLD, evaluation of fibrosis is essential. The gold standard for the evaluation of liver fibrosis is liver biopsy, however, as it is an invasive procedure, is not suitable for this clinical scenario. Elastography is another useful method, and it has become the noninvasive method of choice to quantify liver stiffness. However, liver inflammation caused by SARS-CoV-2 can by itself increase liver stiffness[108]. Furthermore, elastography is not widely available in all hospitals, and biosecurity measures could make it difficult to perform this evaluation of patients with COVID-19 and MAFLD. Noninvasive tools for the assessment of liver fibrosis include serologic tests, risk scores, and imaging studies[12]. None of the currently available biomarkers by itself has sufficient accuracy for diagnosing fibrosis, therefore, predictive scores have an important role in evaluating the risk of advanced fibrosis in patients with MAFLD. Among the prediction scores, FIB-4 index, NFS, the BARD score, FibroTest, HepatoScore, Hepamet fibrosis score (HFS), and AST/platelet ratio index (APRI) score, are the most widely used. Overall, predictive scores for fibrosis have high NPVs for excluding advanced fibrosis with low PPVs. Therefore, these scores may be confidently used for baseline risk stratification to exclude advanced fibrosis. A Fagan's nomogram analysis of post-test probability for detecting advanced fibrosis found that the HFS, HepatoScore and FibroMeter test to be the best noninvasive measures[12]. As mentioned before, a major disadvantage of these scores is the use of liver transaminases as a variable, and as previously known, patients with COVID-19 frequently have hypertransaminasemia, which would increase the risk of overestimating the presence of liver fibrosis. A confirmatory test should be made after the patient has been discharged and close follow-up should be continued.

Preventive measures

The general preventive recommendations for patients with MAFLD and liver fibrosis are those given for the general population, and include, wearing a mask when out in public or in areas without ventilation, practicing social distancing, and performing frequent hand hygiene. If possible, healthcare visits should be avoided in favor of telemedicine consultations[109]. It is important to mention that vaccination against SARS-CoV-2 has started worldwide and there are many doubts to be clarified regarding patients with liver diseases. We must keep in mind that several thousand people have participated in clinical trials of the different vaccines against SARS-CoV-2. However, there are few data on patients with liver diseases, and some trials have excluded such patients[110].

Three SARS-CoV-2 vaccines have been approved recently. The BNT162b2 vaccine (Pfizer-BioNTech) was evaluated in 43,448 participants of whom 0.6% (n = 214) had mild liver disease, only three had moderate or severe liver disease, 31% (n = 13218) of the participants had obesity, and 8.4% (n = 3163) had diabetes. In both conditions associated with MAFLD the vaccine safety and efficacy were high[111]. The ChAdOx1 nCoV-19 vaccine (AstraZeneca/University of Oxford), excluded individuals with chronic liver diseases, and only 135 (0.5%) patients with diabetes were included[112]. The mRNA-1273 vaccine (ModernaTX) was evaluated in 30,420 volunteers of whom 0.6% (n = 96) had unspecified liver disease, 9.5% (n = 2874) had diabetes, and 6.7% (n = 2046) had severe obesity[113]. Considering the high risk of severe COVID-19 in patients with chronic liver and metabolic diseases, the potential benefit of the newly developed vaccines outweigh the possible risks, therefore all patients should have the recommendation to get vaccinated and in those with with chronic liver diseases they should be counseled about the potential reduction in the immune response to the vaccine and the importance of continuing with the general preventive measures even after vaccination.

CONCLUSION

MAFLD is the most common liver disease worldwide and conveys an increased risk of adverse clinical outcomes in patients with COVID-19, especially in those patients with a high-risk of liver fibrosis. All patients with COVID-19, and principally those admitted to the hospital, should be screened for the presence of steatosis and fibrosis, and efforts should be made to promptly detect patients at risk for the provision of

early treatment. Close follow-up is encouraged after discharge. New studies of the pathophysiology, diagnostic approach, and the effectiveness of the available therapy and prevention are needed, aiming to improve the overall outcome in patients with MAFLD and COVID-19.

Abstract

Coronavirus disease 2019 (COVID-19) is an infectious disease caused by the novel coronavirus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2); since its first description in December 2019, it has rapidly spread to a global pandemic. Specific concerns have been raised concerning patients with inflammatory bowel diseases (IBD), which are chronic autoimmune inflammatory disorders of the gut that frequently require immunosuppressive and biological therapies to control their activity. Accumulating evidence has so far demonstrated that patients with IBD are not at increased risk of contracting severe acute respiratory syndrome coronavirus 2 infection. As for the general population, the identified risk factors for severe COVID-19 course among IBD patients have been established to be advanced age and the presence of comorbidities. Treatment with high-dose corticosteroids has also been associated with an increased risk of death in IBD patients with COVID-19. Information on COVID-19 is constantly evolving, with data growing at a rapid pace. This will guarantee better knowledge and stronger evidence to help physicians in the choice of the best therapeutic approach for each patient, concurrently controlling for the risk of IBD disease under treatment and the risk of COVID-19 adverse outcomes and balancing the two. Moreover, the impact of the enormous number of severe respiratory patients on healthcare systems and facilities has led to an unprecedented redeployment of healthcare resources, significantly impacting the care of patients with chronic diseases. this newly changed environment, the primary aim is to avoid harm whilst still providing adequate management. Telemedicine has been applied and is strongly encouraged for patients without the necessity of infusion therapy and whose conditions are stable. The severe acute respiratory syndrome coronavirus 2 pandemic has already revolutionized the management of patients with chronic immune-mediated diseases such as IBD. Direct and indirect effects of the COVID-19 pandemic will be present for some time. This is the reason why continuous research, rapid solutions and constantly updated guidelines are of utmost importance. The aim of the present review is, therefore, to point out what has been learned so far as well as to pinpoint the unanswered questions and perspectives for the future.

Key Words: Inflammatory bowel disease; Ulcerative colitis; Crohn disease; COVID-19; SARS-CoV-2; Autoimmunity

Core Tip: The Severe acute respiratory syndrome coronavirus 2 pandemic has abruptly impacted the management of patients with chronic immune-mediated diseases such as inflammatory bowel diseases. In a setting of general uncertainty, gastroenterologists have faced the need to rapidly reorganize facilities and redefine priorities in inflammatory bowel disease clinical management. With an enormous research effort, accumulating evidence is deepening our understanding of the multifaceted interaction of inflammatory bowel disease care and coronavirus disease 2019. Direct and indirect effects of the pandemic will be present for some time; it is, therefore, necessary to keep recommendations constantly updated.

INTRODUCTION

Until the beginning of this century, coronaviruses were known to cause common colds in humans. However, in 2002 and 2013, respectively, the severe acute respiratory syndrome coronavirus (SARS-CoV) and the Middle East Respiratory Syndrome-CoV emerged. Both viruses caused severe respiratory syndromes and were highly pathogenic for humans, with more than 8000 people infected and 919 death caused by SARS-CoV and 2494 cases and 858 death by Middle East Respiratory Syndrome-CoV [1,2]. The third coronavirus epidemic was first reported in December 2019 in Wuhan, China. A new coronavirus, firstly named 2019-nCov and then severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was isolated[3]. The World Health Organization then proceeded to name the disease produced by SARS-CoV-2 as coronavirus disease 2019 (COVID-19). COVID-19 has rapidly spread to become a global pandemic, affecting populations in nearly all areas of the world, with high morbidity and mortality rates especially in elderly patients and those affected by chronic illnesses[4]. So far, COVID-19 has infected more than one hundred million people worldwide, causing more than two million deaths[5].

Inflammatory bowel diseases (IBD) encompass ulcerative colitis and Crohn's disease. They are chronic, relapsing, autoimmune inflammatory disorders of the gut, frequently requiring immunosuppressive and biological therapies to control disease activity. Patients with IBD, treated with immune suppressants, are at an increased risk of opportunistic and serious infections[6], including viral infection[7,8]. Hence, particular concerns have been raised for patients suffering from IBD throughout the SARS-CoV-2 pandemic[8], leading the medical community to rapidly generate research in this field and international organizations to release timely recommendations under constant and frequent review.

The gastroenterological community has faced an unprecedented challenge, requiring not only to adapt the therapeutic management of IBD patients and redefine medical priorities but also to reorganize health care facilities.

COVID-19 IN IBD PATIENTS

Accumulating evidence has demonstrated that angiotensin-converting enzyme 2 (ACE2) can mediate SARS-CoV-2 entry into cells[9]. Briefly, the spike protein of SARS-CoV-2 binds to the extracellular portion of ACE2, resulting in the internalization of the complex receptor-virus. This internalization process is favored by the presence of another protein, *i.e.* TMPRSS2, a protease that cleaves the intracellular portion of ACE2. Conversely, another transmembrane protein, called ADAM17, can cleave ACE2 generating its soluble form that could in turn act as a decoy receptor for the virus[10].

ACE2 and TMPRSS2 are physiologically expressed by different cells within the human body, including in the gastrointestinal tract, with peaking concentrations in the terminal ileum and colon. Various single nucleotide polymorphisms have been detected in both genes, but the data so far obtained studying different populations are controversial, not demonstrating a clear genetic predisposition to SARS-CoV-2 infection[11,12]. Nonetheless, in IBD-affected patients, levels of ACE2 are higher than in the general population[13], being the latter independently and differently regulated in the large and small intestines upon inflammation[14,15]. This feature could represent a significantly increased risk of contracting SARS-CoV-2 for IBD patients, even though inflammation also triggers the expression of ADAM17[16], which could have an opposite effect.

Another protein with an increased expression in both IBD and COVID-19 is interleukin 17 (IL-17)[17,18]. It is a cytokine produced and released by T helper 17 lymphocytes, displaying complex and variegate immune functions, and involved in the immune pathogenesis of IBD. In acute respiratory distress syndrome induced both by SARS-CoV-2 infection and other betacoronaviruses, IL-17 levels have been reported to be significantly elevated, and preliminary evidence supports its contribution to immunopathology[19]. Furthermore, it seems that synergism between IL-17 and other cytokines, *i.e.* IL-6, can promote viral replication[20]. The exact role of IL-17 expression and the risk of SARS-CoV-2 infection or COVID-19 disease course is still to be determined; however, agents endowed with anti-IL-17 function, among which probiotic strains of *Bifidobacteria*, have already been proposed as an adjunct therapeutic approach[21,22].

Based on these findings, it was initially hypothesized that patients with IBD could have an increased risk to become infected with SARS-CoV-2. However, the evidence collected so far suggests that the cumulative incidence of the infection [assessed through nasopharyngeal swab (NPS) tests] in IBD patients is similar or even lower to that observed in the general background population during the same pandemic period [23-26]. In a recent Danish nationwide population-based study on IBD-affected patients, the latter displayed a significantly lower prevalence than the general population (2.55% *vs* 3.7%; $P < 0.01$). Whether this occurred secondarily to a more stringent self-isolation and shielding of IBD patients as compared to healthy subjects is yet to be understood.

Furthermore, it seems that immunosuppressive treatments do not increase the risk of contracting SARS-CoV-2[27,28]. This aspect was also confirmed by seroprevalence studies, which showed similar seroprevalence in IBD patients treated with biological agents to the one determined in the general population from the same geographical region[29,30].

Regarding the clinical presentation of COVID-19 in IBD patients, the most frequent symptoms were fever and cough[31]. Yet, diarrhea was more commonly reported in IBD patients with SARS-CoV-2 compared to non-IBD patients, with a prevalence ranging from 8% to 49% in different studies[25,31-36] and a pooled estimate of 20%, which was twice as high as the cumulative prevalence of diarrhea in the general population of COVID-19 patients[31]. This could be attributed to the inflammatory disease itself, but it could also occur as a consequence of exacerbation of intestinal inflammation through a direct viral action on the intestinal epithelium, as suggested by the higher concentration of fecal calprotectin in infected patients with diarrhea[33]. Indeed, a recent cohort study reported a higher prevalence of diarrhea among IBD patients with COVID-19 as compared to non-infected patients, independently from baseline disease activity at multiple regression analyses[32].

Moreover, gastrointestinal (GI) symptoms, including diarrhea, have been described as the sole manifestations of COVID-19 in about 10% of patients[25,37], which is of particular relevance in patients with IBD since the infection could be misinterpreted as disease reactivation. It is therefore of paramount importance to raise awareness among clinicians on these specific clinical features of COVID-19 in patients with IBD and on the need for testing patients accordingly.

GI manifestations may actually help to spot SARS-CoV-2 infection in patients with negative NPS tests, through the assessment of stool samples. PCR testing for SARS-CoV-2 infection with NPS is the currently recommended diagnostic approach, yet false-negative results have occurred[38-43]. Explanations for this have included, besides poor specimen collection, absent or intermittent viral shedding from the upper airways and viral recovery in the oropharyngeal mucosa, whilst the virus may still be present in other tissues. Solid data demonstrated that fecal viral shedding may persist for up to nearly 5 wk following the negativity of NPS[44-48], being more prevalent in patients with GI symptoms in comparison to those with respiratory symptoms alone (73.3% *vs* 14.3%; P = 0.033)[49]. This may indicate that the virus can continue to replicate in the gut after being cleared from the respiratory tract, thus implying the possibility of fecal-oral transmission[45]. Although no clear evidence on the diagnostic performances of PCR testing on stools is available to date, patients with negative NPS and PCR positive stool samples were reported[46,50], and research in this field is rapidly evolving. The current knowledge allows us to speculate that testing for fecal SARS-CoV-2 RNA may be helpful as a complementary tool to the NPS, at least in patients presenting GI alterations and particularly in patients with IBD to distinguish infection from disease reactivation.

On the other hand, it is currently unknown if SARS-CoV-2 infection can interfere with IBD natural history, possibly inducing a disease reactivation. Very preliminary data from a Danish population study demonstrated no risk of relapse in a very small number of patients at 35 d of follow-up[51]; ongoing studies will help to clarify this point.

It has been very recently reported that patients with COVID-19 exhibit significant alterations in fecal microbiota composition, including an increase in opportunistic pathogens and the depletion of commensals. These alterations correlated both with fecal levels of SARS-CoV-2 and COVID-19 severity, irrespective of the medications received, and persisted up to 30 d after disease resolution[52,53]. Whether this persistent dysbiosis could have a role in the development of de novo IBD or in the progression of a pre-existing disease remains to be investigated.

When compared to non-IBD patients, the clinical course and severity of COVID-19 might be somewhat more severe, although definitive evidence is lacking. Data from the SECURE-IBD registry demonstrated, at the earlier stages of the pandemic, a trend toward increased age and sex-standardized mortality ratios compared to the general population in China, the United States and Italy, indicating up to 50% higher mortality in patients with IBD[54]. Though the data were originally not statistically significant, a more recent analysis, based on a total of 3493 reported cases, confirmed earlier findings and reached statistical significance[55]. However, this finding must be interpreted with caution due to the voluntary nature of reporting in the registry, which is therefore affected by several biases. Indeed, a recent population-based retrospective cohort study with propensity score matching for demographic and comorbidities found no difference in hospitalization and mortality for COVID-19 in IBD patients[36].

As in the case of the general population, identified risk factors for severe SARS-CoV-2 infection among IBD patients are advanced age and the presence of comorbidities[26,36,51,54,56].

When considering the risk connected with IBD medications at the time of viral infection, in the SECURE-IBD registry data analysis, systemic corticosteroid administration was positively associated with an increased risk of death (adjusted odds ratio (OR) = 11.62, 95% confidence interval (CI): 2.1-64.7); conversely, the use of anti-tumor necrosis factor (TNF) was associated with a lower rate of hospitalization or death (adjusted OR = 0.60, 95%CI: 0.38-0.96)[57]. A recently published retrospective multicenter study has also confirmed the negative impact of corticosteroids in IBD patients with COVID-19[36]. Similar data emerged from an analysis of 600 patients with rheumatic diseases in which glucocorticoid exposure correlated with a higher odds of hospitalization (OR = 2.05, 95%CI: 1.06-3.96), while the opposite occurred for anti-TNF agents (OR = 0.40, 95%CI: 0.19-0.81)[58].

This might be explained by a selective action of targeted therapies in contrasting some key mediators of the cytokine storm, a major factor in the occurrence of acute respiratory distress syndrome[59], which could counterpart the hypothetic risk of reduced viral clearance.

Conversely, the results from the RECOVERY Trial, the largest randomized controlled trial examining corticosteroids in the treatment of COVID-19 to date, demonstrated that treatment with dexamethasone in dose equivalents similar to those used for IBD treatment are indeed protective against adverse outcomes and mortality for patients hospitalized with COVID-19[60]. These data were confirmed by a recent meta-analysis considering a large number of SARS-CoV-2 infected patients included in seven clinical trials[61].

A possible explanation for such contrasting results may be related to the differential timing of steroid treatment, perhaps leading to diverse clinical scenarios. Indeed, we can speculate that the use of systemic steroids before contraction of a viral infection hampers the immune-system response, thus fostering viral replication. Conversely, treatment at later stages may quench the cytokine storm responsible for the onset of acute respiratory distress syndrome, positively impacting overall survival.

In the most recent analysis of the SECURE-IBD registry collecting 1439 cases and specifically analyzing the effect of IBD medications on COVID-19 course, thiopurine therapy, both alone and in combination with anti-TNF, has emerged as an independent risk factor for severe COVID-19 (aOR of 4.08 and 4.01, respectively) when compared with TNFα antagonist monotherapy[62]. Thiopurines have indeed previously been associated with increased risk of viral infection compared to anti-TNF agents [6]. However, data from the SECURE-IBD, though extremely helpful, need to be interpreted with caution since they are subject to reporting bias, and considering the high proportion of patients treated with anti-TNF agents, they might have overestimated the effect of thiopurines. Recently collected data from a nationwide population-based study of IBD patients with COVID-19, for instance, revealed no impact of immune modulators or biological therapies on the risk of hospitalization or death[51].

For what concerns anti-interleukin-12/23 and anti-integrins, limited data are available on their impact on the course of COVID-19, though general safety data suggests that they are not associated with a significant increased infectious risk. To date, the SECURE-IBD analysis demonstrated no differences compared to anti-TNF drugs[54].

Some concerns have been raised for tofacitinib since it may blunt the innate immune response to viral infection, including inhibition of interferon-gamma activity. Tofacitinib has so far been associated, both in clinical trials and in post-marketing monitoring, with an increased risk of infection, particularly of herpes zoster reactivation [63]. However preliminary data from the SECURE-IBD registry, though focused on a very small number of patients, showed no significant differences between tofacitinib-treated patients and other IBD patients in the occurrence of hospitalization, intensive care unit admission and severe COVID-19[64]. Moreover, recent preclinical evidence is emerging that tofacitinib treatment might in fact reduce ACE2 upregulation and ACE2-mediated intestinal viral uptake[65], and randomized clinical trials for the treatment of COVID-19 pneumonia are ongoing.

Last but not least, it should be kept in mind that the treatment-related risk of infection should be balanced against the disease activity related risk of infection. It has been previously demonstrated that the risk for systemic viral infections (cytomegalovirus and Epstein-Barr virus primary infections and reactivations) in IBD is significantly higher in patients with a clinically active disease[7]. Moreover, active disease is a known risk factor for malnutrition and may lead to hospitalization, thus again raising the infectious risk.

As for SARS-CoV-2 infection, preliminary data coming from two Italian studies identified a correlation between IBD activity and COVID-19 negative outcome[32,56], including a higher risk for pneumonia (OR = 10.25, P = 0.003) and death (OR = 8.45, P = 0.02)[56].

CONCEPT OF FRAILTY FOR IBD PATIENTS

Intensive efforts have been made by the scientific community to identify frail patients requiring more stringent social distancing and further precautions taken to limit the risk for SARS-CoV-2 infection. Since the presence of comorbidities correlates with a higher risk of severe COVID-19, most patients with chronic disorders are considered frail. Specifically regarding IBD patients, while initial data seem reassuring, they should also be regarded as frail. This has been recently supported by the data emerging from the SECURE-IBD registry, pointing towards increased sex-standardized mortality ratios in patients with IBD infected with COVID-19[55].

With these regards, early in the pandemic, the British Society of Gastroenterology categorized IBD patients into three risk groups, each associated with different necessities of social isolation (Table 1)[66]. This risk profiling remains substantially valid, also bearing in mind the newly accumulated evidence. Yet, since the pandemic diffusion varies greatly between countries and constantly fluctuates in severity across time, it is necessary to adapt preventive measures applied to each category accordingly. This would allow tailored preventive measures, according to individual fragility, risk of viral exposure and subsequent negative outcomes upon infection, avoiding on the other hand unnecessary limitations that can negatively impact patient quality of life.

GENERAL RECOMMENDATIONS AND CLINIC REORGANIZATION

Strict social distancing, regular use of face masks and meticulous sanitization of hands and frequently used surfaces, such as phones, tablets, desks, *etc*., with alcohol-based solutions remain the most important recommendations for the general population and should therefore apply to IBD patients as well.

Patients with IBD, still require regular medical follow-up and to some degree hospital access. In this setting, among the adopted general measures to reduce the risk of viral exposure, there has been the postponing of non-urgent outpatient visits and elective endoscopic procedures. As for the latter, the reduced distance between patients and hospital workers, and the air insufflation required by the procedure may increase the risk of SARS-CoV-2 transmission. Specific recommendations on endoscopy in IBD during the COVID-19 pandemic have been released[67].

The use of noninvasive inflammatory markers, such as C-reactive protein and fecal calprotectin for monitoring disease activity, should be encouraged during the pandemic[68]. Fecal calprotectin has been proven to correlate with endoscopic disease extension, mucosal healing and histological activity[69,70]. Home-test measurements of fecal calprotectin could be a valuable alternative, as evidence has demonstrated a good correlation with laboratory determinations[71].

Virtual clinics or online consultants are encouraged for patients without the necessity of infusion therapy and with stable disease, maintaining as much as possible the same timing as the originally scheduled visit. Several accessible and widely available digital technologies have been explored with exciting results[72]. Whenever hospital visits cannot be avoided, symptoms and fever checks at hospital entry, the social distancing of at least 2 m, the use of face masks and strict handwashing policies are highly recommended, even whenever not imposed by state laws.

Patients should ideally be provided with an emergency helpline, given the paramount importance of promptly controlling a disease flare.

Infusion units are dedicated spaces, often located within hospitals, which provide high-quality care during the administration of intravenous drugs for the treatment of several chronic disorders, including IBD. The infusion unit should be regarded as an essential service. A proper organization of the infusion unit is essential to guarantee the safety of both patients and healthcare workers, again through symptoms and fever checks at hospital entry, distancing of beds/chairs of at least 2 m, the use of face masks and strict hand and surface sanitization policies. Furthermore, the turnover of healthcare workers should be limited as much as possible to reduce the risk of viral spread[73]. A telephone screening for symptoms before the scheduled appointment time and rapid SARS-CoV-2 testing can also be considered, based on local epidemiology and resource availability.

Finally, home delivery of subcutaneous drugs should be implemented.

The stress on the healthcare system, with an extremely increased number of severe respiratory patients, has turned the spotlights on the importance to vaccinate people for common influenza virus and *Streptococcus pneumoniae*[74]. It is recommended that all patients with IBD are offered both vaccinations.

It is too early to bring conclusions; however, this pandemic might have sped up the process of a technological revolution in medicine, which will likely change the landscape for the management of patients with chronic diseases, including IBD, also with long-term benefit.

Table 1 British Society of Gastroenterology stratification of inflammatory bowel disease patients according to the risk of severe acute respiratory syndrome coronavirus 2 infection

Highest risk patients"shielding indicated"	Moderate risk patients"stringent social distancing"	Lowest risk patients"social distancing"
Patients who either have a comorbidity (respiratory, cardiac, hypertension or diabetes mellitus) and/or age ≥ 70 yr old and are on any "moderate risk" therapy for IBD (per middle column) and/or have moderate to severely active disease. Patients of any age regardless of comorbidities and who meet one or more of the following: (1) intravenous or oral steroids ≥ 20 mg prednisolone or equivalent per day (only while on this dose); (2) began biologic plus immunomodulator or systemic steroids within previous 6 wk; (3) moderate-to-severe active disease not controlled by "moderate risk" treatments; (4) short bowel syndrome requiring nutritional support; and (5) requirement for parenteral nutrition	Patients with moderate to severely active disease who are not on any of the medications in this column. Patients on the following medications: (1) anti-TNF (infliximab, adalimumab, golimumab) monotherapy; (2) biologic plus immunomodulatory in stable patients; (3) ustekinumab; (4) vedolizumab; (5) Thiopurines (azathioprine, mercaptopurine, tioguanine); (6) methotrexate; (7) calcineurin inhibitors (tacrolimus or ciclosporin); (8) JAK inhibitors (tofacitinib); (9) immunosuppressive trial medication; (10) mycophenolate mofetil; (11) thalidomide; and (12) prednisolone > 20 mg or equivalent per day	Patients on the following medications: (1) 5ASA; (2) rectal therapies; (3) orally administered topically acting steroids (budesonide or beclometasone); (4) therapies for bile acid diarrhea (colestyramine, colesevelam, colestipol); (5) anti-diarrheals (*e.g.*, loperamide); and (6) antibiotics for bacterial overgrowth or perianal disease

5ASA: 5-aminosalicylic acid; IBD: Inflammatory bowel diseases; JAK: Janus kinase; TNF: Tumor necrosis factor.

THERAPEUTIC MANAGEMENT OF IBD DURING SARS-COV-2 PANDEMIC

During this turbulent historical period, the care of chronic patients, including patients with IBD, has necessarily changed and is constantly evolving, reacting and adapting to the evolution of the pandemic.

As a general principle, we must not depart from solid evidence for the therapeutic management of IBD based solely on emergent data that, though extremely valuable, are certainly subject to many biases. Therefore, the principles of IBD management should remain largely unchanged during the pandemic, yet we certainly need to tailor patient care considering whether the patient is infected with SARS-CoV-2, has symptomatic manifestations of COVID-19 and shows underlying activity of the IBD.

Stable IBD course

Published guidelines, position statements and expert opinions agree in affirming that IBD patients with stable disease course and without SARS-CoV-2 infection should maintain the ongoing immunomodulatory treatment since the risk of disease reactivation outweighs the risk of SARS-CoV-2 infection (Table 2)[55,74-78]. As the pandemic ensued, the impossibility to reach hospitals has led to treatment discontinuation in some areas. Among 386 Chinese IBD patients on maintenance therapy during the epidemic[79], 107 (27.7%) have suspended medications, mostly biologics, with resulting disease relapses and hospitalization rates of approximately 25% and 50%, respectively.

Based on the available data, patients on high-dose corticosteroids (prednisolone dose ≥ 20 mg daily) should be informed about the higher risks they are exposed to and therefore encouraged to observe extra protective measures. It is more important than ever to minimize corticosteroid exposure and consider corticosteroid-sparing therapies where appropriate[57,62].

In patients with stable disease, a de-escalation of combination therapy with thiopurine and anti-TNF should be considered[62].

If necessary, it could also be considered to extend dose intervals of intravenous drug injection to reduce hospital visits; for instance, infliximab and vedolizumab infusions can be postponed up to every 8 wk and 10 wk, respectively[80,81]. The switch from infliximab to subcutaneous adalimumab treatment is not recommended, unless intravenous infusions cannot be performed safely; in fact, this elective shift is associated with loss of tolerance and efficacy within 1 year[82].

Patients with stable IBD and positivity for SARS-CoV-2 infection should be considered individually, simultaneously balancing the risk of inflammatory disease reactivation with the risk of severe COVID-19 course (Table 3).

Treatment with non-immunosuppressive medications (5-aminosalicylates) should be continued irrespectively of viral symptoms[74,78] , despite data from the SECURE-IBD registry indicating their association with severe COVID-19 disease course[57,62]. The unexpected nature of this finding from a biological perspective and the presence

Table 2 Summary of treatment in severe acute respiratory syndrome coronavirus-2 negative patients with stable inflammatory bowel disease disease course

Drug	Suggestions	Additional comments
	Continue therapy	
Salicylates	Yes	Data from the SECURE-IBD of possible harm need to be confirmed.
Locally acting steroids	Yes	No specific data available
Systemic steroids	Yes	Limit use to strictly necessary and taper rapidly
Azathioprine	Yes	Data from the SECURE-IBD of possible harm need to be confirmed, the risk of reactivation seems to outweigh the risk of continued treatment
Methotrexate	Yes	Limited data available
Anti-TNF	Yes	Data from the SECURE-IBD indicate better outcomes compared to other treatments; there are ongoing trials for the treatment of COVID-19
Vedolizumab, anti-IL-12/23	Yes	Limited data available
Tofacitinib	Yes	Limited data available

COVID-19: Coronavirus disease 2019; IBD: Inflammatory bowel diseases; IL: Interleukin; TNF: Tumor necrosis factors.

Table 3 Summary of treatment in severe acute respiratory syndrome coronavirus-2 positive patients with stable inflammatory bowel disease disease course

Drug	Suggestions	Additional comments
	Continue therapy	
Salicylates	Yes	A pause can be considered since data suggest a possible association of their use and poor COVID-19 outcome
Locally acting steroids	Yes	No data available
Systemic steroids	Rapid tapering	Dosage below 40 mg/d is suggested along with rapid tapering, particularly in patients without pneumonia and need for oxygen supplementation
Azathioprine	No	Delay treatment for 2 wk and/or until COVID-19 symptoms resolve
Methotrexate	No	Delay treatment for 2 wk and/or until COVID-19 symptoms resolve
Anti-TNF	No	Delay treatment for 2 wk and/or until COVID-19 symptoms resolve. Continued therapy may be considered in selected patients since no data demonstrated adverse outcome to date.
Vedolizumab, anti-IL-12/23	No	Delay treatment for 2 wk and/or until COVID-19 symptoms resolve
Janus kinase inhibitors	No	Delay treatment for 2 wk and/or until COVID-19 symptoms resolve

COVID-19: Coronavirus disease 2019; IL: Interleukin; TNF: Tumor necrosis factors.

of potential unmeasured confounders linked to data collection make further investigations necessary to confirm this association.

Corticosteroids should ideally be rapidly tapered off to the lowest possible dose in patients without symptoms or with mild symptoms. IBD patients presenting COVID-19 symptoms and requiring oxygen supplementation should probably maintain the dose equivalent to prednisone 40 mg/d since data from the RECOVERY trial has demonstrated the beneficial role of 6 mg of dexamethasone (equal to 40 mg prednisone) for up to 10 d in reducing 28 d mortality in patients receiving either invasive mechanical ventilation or oxygen supplementation[60].

The major guidelines state that patients positive for SARS-CoV-2 should interrupt the treatment with azathioprine, 6-mercaptopurine, biologics and Janus kinase inhibitors irrespective of the presence of COVID-19 symptoms[74,76].

However, uncertainty remains on the possibility of continuation of maintenance therapy with biologics in asymptomatic patients, with data from the SECURE-IBD registry and recent evidence suggesting no harm[54,83]. Even if these findings are insufficient to drive any solid conclusion, we might consider maintaining biologic agents in those patients with a high risk of IBD reactivation.

IBD disease reactivation

Telemedicine visits are encouraged as a first approach to gain insights into type and severity of symptoms reported by a patient. The cause underlying the symptoms should be deeply addressed in order to exclude an alternative diagnosis. In particular, all patients with IBD reactivation should undergo SARS-CoV-2 testing through NPS irrespective of respiratory symptoms[84]. Standard stool testing for bacterial and parasitic infections, including test for *Clostridioides difficile* toxins, should always be performed in patients presenting with diarrhea. Functional symptoms should also be considered during this stressful period.

A rapid assessment of the severity of disease activity is advisable, coupling clinical evaluation with noninvasive tests, including blood tests and fecal calprotectin. The reason for a disease flare should be quickly addressed (*i.e.* coinfection, drug immunogenicity or drug resistance) in order to be able to rapidly adjust medical therapy.

The need for face-to-face evaluation should be considered on a case-by-case basis, evaluating both clinical and biochemical parameters. Endoscopic procedures should be limited to what is strictly necessary for treatment decision; whenever possible, it should be replaced with ultrasound examinations or cross-sectional imaging[68].

SARS-CoV-2 negative patients. The management of IBD reactivation in SARS-CoV-2 negative patients should follow the current local and international guidelines, as it occurred in the pre-COVID era[74].

As stated, it appears to be even more important to minimize steroid exposure and consider steroid-sparing maintenance treatments if appropriate. There is currently no conclusive evidence to prefer one agent over another.

Patients must follow general and specific recommendations to reduce the risk of being infected with SARS-CoV-2, considering that active disease may represent an additional risk factor (Table 1).

SARS-CoV-2 positive patients. In mildly active disease a course of locally acting steroids can be instituted, despite the lack of specific evidence on the course of COVID-19. Alternatively, a reasonable approach would be to postpone treatment for 2 wk in order to observe the clinical course of COVID-19 and/or allow resolution of infection[85].

In a moderate to severe flare, there remain doubts about the use of systemic steroids, especially in patients without symptoms of COVID-19 or without need for oxygen supplementation. Indeed, besides the increased risk for adverse outcomes that emerged from the analysis of the SECURE-IBD registry data[54], in the RECOVERY trial patients receiving no respiratory support did not experience any benefit, but rather a trend toward harm was observed[60]. However, the role of high-dose systemic steroids in controlling the underlying IBD disease activity remains often pivotal.

Whenever necessary, a reasonable approach might be to limit the dose of prednisone to 40 mg daily, with rapid dose tapering and switch to maintenance biologic therapy[85].

When needed, biologic agents should be preferred as the first-choice treatment for the induction and maintenance of remission in IBD patients with SARS-CoV-2 since data available indicate their higher safety profile as compared to other drugs[6,54].

A strong emphasis needs to be put on the role of thromboprophylaxis for patients with both active IBD and SARS-CoV-2 infection, given the high rate of thrombotic complications observed in COVID-19 patients[85].

PSYCHOLOGICAL IMPLICATIONS OF SARS-COV-2 IN IBD PATIENTS

Since its first description in December 2019, COVID-19 has created a worldwide sense of fear, termed "coronaphobia," steeply increasing the incidence of various psychiatric manifestations[86]. Even before the pandemic onset, IBD patients were at an increased risk for mental health impairment and psychological comorbidities[87], with a reported incidence of depression and anxiety of up to four times higher than that of the general population[88,89]. During this pandemic, self-isolation, future uncertainty and lack of regular face-to-face contact with the referred physician will likely lead to

the amplification of latent psychopathological conditions or the development of new ones.

In the early phase of the pandemic, an online survey supported by the European Federation of Crohn's and Ulcerative Colitis Associations clearly demonstrated a communication gap between patients and physicians, as only 11% of patients had found relief from their worries from medical consultations[90].

Bearing all this in mind, the role of telemedicine, and perhaps of telepsychology, seems pivotal alongside a close-knit collaboration with patients' associations.

SARS-COV-2 VACCINATION

In December 2020 two mRNA vaccines and one replication-incompetent viral vector vaccine against SARS-CoV-2 have been approved, while many other candidates are currently in phase 3 testing. Vaccination campaigns have started in most countries with prioritization criteria mainly based on the risk of SARS-CoV-2 exposure and the risk of COVID-19 adverse outcomes.

Patients with IBD and other immune-mediated diseases were not included in the registration trials. Data on the safety and efficacy of SARS-CoV-2 vaccinations in these populations are therefore lacking.

The International Organization for the Study of Inflammatory Bowel Disease has recently released recommendations[91], mainly based on the extrapolation of safety and efficacy data from other vaccines.

Non-live vaccines are considered to be safe in patients with IBD, irrespective of immune-modifying treatments, though in the latter case it is acknowledged that the response may be to some degree blunted. In particular, previous studies have shown reduced response to influenza and pneumococcal vaccinations in IBD patients treated with immunosuppressant and anti-TNF agents[92-94]. Treatment with ustekinumab and vedolizumab, on the contrary, does not seem to impair response to influenza and pneumococcal vaccines[95,96].

Therefore, it is recommended that all IBD patients should be vaccinated against SARS-CoV-2, as soon as possible based on local policies, and irrespective of medications. According to the International Organization for the Study of Inflammatory Bowel Disease expert panel, the available SARS-CoV-2 vaccines are safe for patients with IBD, but patients should be informed that vaccine efficacy could be decreased when the latter are administered during corticosteroid therapy[91].

Further studies are definitively needed to assess the safety and efficacy of SARS-CoV-2 vaccines in IBD patients. Whether IBD patients on immune-modifying treatments may benefit from intensified vaccine administration regimen should also be evaluated.

CONCLUSION

Existing evidence shows that IBD patients are not at an increased risk for SARS-CoV-2 infection. As in the case of the general population, older age and presence of comorbidities are the primary risk factors for more severe COVID-19 course. Moreover, systemic steroids exposure has been consistently associated with COVID-19 negative outcomes. For what concerns the other class of IBD medications, no definite evidence of harm has emerged. In the clinical management of patients with IBD the risk of under treatment should be balanced against that of potential adverse outcomes of COVID-19, particularly in the setting of SARS-CoV-2 positive patients. Despite the lack of data, SARS-CoV-2 vaccination is recommended in IBD patients since the risk of the disease outweighs the uncertainty of potential adverse effects.

Abstract

Surveillance with abdominal ultrasound with or without alpha-fetoprotein is recommended by clinical practice guidelines for patients who are considered to be at risk of developing hepatocellular carcinoma (HCC), including those with cirrhosis, advanced fibrosis and special subgroups of chronic hepatitis B (CHB). Application of the standard surveillance strategy to all patients with chronic liver disease (CLD) with or without cirrhosis imposes major sustainability and economic burdens on healthcare systems. Thus, a number of HCC risk scores were constructed, mainly from Asian cohorts, to stratify the HCC prediction in patients with CHB. Similarly, even if less than for CHB, a few scoring systems were developed for chronic hepatitis C patients or cirrhotic patients with CLD of different etiologies. Recently, a few newsworthy HCC-risk algorithms were developed for patients with cirrhosis using the combination of serologic HCC markers and clinical parameters. Overall, the HCC risk stratification appears at hand by several validated multiple score systems, but their optimal performance is obtained only in populations who show highly homogenous clinic-pathologic, epidemiologic, etiologic and therapeutic characteristics and this limitation poses a major drawback to their sustainable use in clinical practice. A better understanding of the dynamic process driving the progression from CLD to HCC derived from studies based on molecular approaches and genetics, epigenetics and liquid biopsy will enable the identification of new biomarkers to define the individual risk of HCC in the near future, with the possibility to achieve a real and cost/effective personalization of surveillance.

Core Tip: The risk of hepatocellular carcinoma (HCC) is not uniform and may increase due to underlying parameters in chronic viral hepatitis. Several clinical HCC risk scores and biomarker integrated algorithms have been proposed to stratify patients according to their HCC risk level. In the present review, we summarize the efforts for personalized HCC surveillance in the literature and discuss their applicability to clinical practice.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the second leading cause of cancer-related deaths globally[1]. The majority of HCC cases (> 90%), at least in the Western countries, occur in the setting of cirrhosis, as approximately one-third of patients with cirrhosis eventually develop HCC in the long term, with an annual risk of 1%-8%, varying upon several risk factors[2,3]. Globally, approximately 80% of HCC are associated with hepatitis B virus (HBV) or hepatitis C virus (HCV) infection and their geographical distribution depends on the epidemiology of the two viral infections. Most HCCs are associated with chronic hepatitis B (CHB) virus infection (> 60%) in Asian countries, whereas chronic hepatitis C (CHC) appears to be the most commonly established etiology for HCC in western countries[4]. However, in recent years, a progressive increase of HCC in patients with non-viral (mainly metabolic) liver disease has been reported[5].

CHB has carcinogenetic potential itself by several insertional mutagenetic routes, and up to 30% of CHB-related HCCs arise in non-cirrhotic liver, mainly in Asian patients[6]. Current management of CHB with long-term nucleotide analogues treatment by inhibiting HBV replication had been shown to decrease HCC incidence. Nevertheless, despite on-therapy virological remission, the annual incidence of HCC ranges from 0.01% to 5.4% in CHB[7]. In the last decade, wondrous new achievements occurred in the treatment of CHC, and sustained virological response (SVR) rates exceeded 95% with direct-acting antiviral (DAA) therapies[8]. Successful DAA treatment has resulted in a 71% reduction in HCC risk[9]. The HCC incidence fell from 3.6% to 1.8% per year with the DAA therapies[10]. However, many patients, after the clearance of HCV infection, maintain additional co-factors of liver disease (*i.e.* metabolic or alcohol-induced liver damage) that may contribute to the persistence of a significant HCC risk. Accordingly, a recent long-term study conducted in the Veterans cohort showed that HCC incidence remained stable at 1.5 to 2.3/100 person years, even up to 3.6 years, after DAA-induced SVR[11]. Cirrhosis is the primary risk factor for HCC regardless of liver disease etiology, with an annual HCC incidence greater than 1%[12]. CHC patients with cirrhosis and advanced fibrosis (F3) continue to have a significantly elevated risk of HCC despite achieving SVR and have stayed the target of surveillance programs. According to the general principles of surveillance, the definition of the target population must consider the incidence of HCC in a specific set of patients and the probability that effective therapies, particularly the curative ones, can be applied to these patients. Decision analysis and cost-effectiveness models suggest that an intervention is considered cost-effective if it provides life expectancy increases of at least 3 mo with a cost below the threshold of ultrasonography (US) of $50000 per year of lives saved[13]. Based on these premises, there is currently a general consensus on using abdominal US with or without alpha-fetoprotein (AFP) as a diagnostic tool to perform HCC surveillance.

Beyond the fact that several host-related (cirrhosis, chronic hepatic necroinflammation, older age, male sex, African origin, alcohol abuse, chronic co-infections with other hepatitis viruses or human immunodeficiency virus, diabetes or metabolic syndrome, active smoking, positive family history) and virus-related (high HBV-DNA and/or hepatitis B surface antigen [HBsAg] levels, HBV genotype C > B, specific mutations) factors influence the risk of HCC development[14], in the setting of CHB, HCC surveillance is recommended by American Association for the Study of Liver Diseases (AASLD), Asia-Pacific Association for the Study of Liver Diseases and European Association for the Study of Liver Diseases (EASL) for all patients with cirrhosis, hepatitis B carriers with a family history of HCC, Asian males older than 40 years, Asian females older than 50 years, and African males older than 20 years[15-18]. Additionally, all patients with chronic liver disease (CLD) and advanced fibrosis (F3) are also recommended to undergo HCC surveillance by EASL[18] (Table 1). In general, a cut-off for HCC incidence of 0.2%/year for hepatitis B, 1.5%/year for hepatitis C and all cirrhotics regardless of etiology is considered cost-effective for HCC surveillance, since it was first described in AASLD guidelines in 2005[19]. However, an area of uncertainty exists for CHC patients with viral clearance but F3 fibrosis. On one hand, the AASLD HCV guidance statement recommends HCC surveillance for this group, but on the other, the AASLD HCC guidance statement recommends surveillance only in presence of cirrhosis[16,20]. A recent study, using the Markov model, found out that HCC surveillance is cost-effective among CHC patients with cirrhosis but not for those with F3 fibrosis[21]. However, in clinical practice, the differentiation between advanced fibrosis (F3) and cirrhosis is not always straightforward. For this reason, EASL recommends HCC surveillance to patients with F3 fibrosis regardless of etiology, with a more clinically oriented approach. Given the limitations of the current surveillance protocols, several HCC risk scores have been developed mainly from Asian cohorts for patients with CHB. Even if in limited number, a few risk scores are also available for CHC or all-cirrhotic patients.

In this review, we summarize the characteristics and discuss the applicability of HCC-risk scores in clinical practice, with a special focus on chronic viral hepatitis. Several reviews investigated the impact of HCC risk scores on clinical practice in recent years, but newer scores and comparison studies have emerged since then[22-25]. Furthermore, new serologic biomarkers have been introduced for early detection of HCC with promising results, and some of them got involved in algorithms in combination with clinical and laboratory parameters.

HCC RISK SCORES FOR CHB PATIENTS

Risk scores for untreated CHB patients

The guide with age, gender, HBV-DNA, core promoter mutations, and cirrhosis (GAG-HCC) risk score was the first attempt to stratify HCC risk among CHB patients, which was published in 2009[26]. The study was conducted with 820 untreated CHB subjects (15% with cirrhosis) from Hong-Kong, and all patients were followed up for a median period of 77 mo. They showed that cirrhosis, age, gender, viral load, and precore mutation were independent predictors of HCC and used them all in the risk score. However, due to the unavailability of pre-core mutation assays in the routine clinical practice, they repeated the analysis without this variable and showed no loss of performance in the risk score. The area under the receiver-operating characteristics curve (AUROC) for GAG-HCC to predict HCC in 5 and 10 years was 0.87 and 0.88, respectively. The determined optimal cut-off value of 101 showed high sensitivity (88%) and specificity (78.7%) for the prediction of HCC at 10 years. Chinese University-HCC risk score (CU-HCC) was the second attempt for HCC risk stratification in CHB patients, which was published in 2010[27]. Using the same methodology, the investigators confirmed age, viral load, and cirrhosis as independent predictors of HCC during a median follow-up period of 10 years, with the addition of two markers of liver function (bilirubin and albumin). They proposed a three category risk score to distinguish low (< 5), intermediate (5-20), and high risk (> 20) CHB patients for HCC development. The model showed a good general performance in predicting 5- and 10-year HCC risk by showing AUROC values of 0.76 and 0.78, respectively. The 5-year HCC-free survival rates were 98.3%, 90.5%, and 78.9% in the low-, medium-, and high-risk groups, respectively. The determined cut-off value of 5 ruled out the risk of HCC development with high accuracy (negative predictive value [NPV] of 97.8% and 97.3 in training and validation cohorts, respectively), suggesting that HCC surveillance in low-risk group may not be cost-effective. Interestingly, the

Table 1 Patients for whom surveillance of hepatocellular carcinoma is recommended according to society guidelines

Cirrhotic patients regardless of etiology, Child-Pugh stage A-B[12-14]
Cirrhotic patients regardless of etiology, Child-Pugh stage C awaiting liver transplantation[12-14]

Hepatitis B carriers with a family history of HCC[12-14]
Non-cirrhotic F3 patients, regardless of etiology, may be considered for surveillance based on an individual risk assessment[14]

HCC: Hepatocellular carcinoma.

authors of GAG-HCC and CU-HCC, despite proposing their risk scores as tools to identify CHB patients at high risk for HCC development, never suggested their applicability in selecting candidates for HCC surveillance.

After two relatively small-sized studies, another HCC-risk score for untreated CHB patients without cirrhosis was proposed from Taiwan in 2010[28]. The risk estimation for hepatocellular carcinoma in chronic hepatitis B (REACH-B) score was developed in 3584 CHB Taiwanese patients without cirrhosis and validated in 1505 patients (18% of whom with cirrhosis) from Hong Kong and Korea[29]. The REACH-B score included male sex, age, alanine aminotransferase (ALT), hepatitis B e antigen (HBeAg), and HBV-DNA as parameters, but not cirrhosis, as the training cohort only consisted of patients without cirrhosis. Instead of using cut-off values, the score was proposed as a range from 0 to 17 points, with a progressively increasing risk of HCC development. The REACH-B score had a 5 and 10-year AUROC of 0.796 and 0.769 in the validation cohort. The 5 and 10-year AUROC values decreased to 0.698 and 0.647 in the analysis of the cirrhotic group only. This finding confirms that the presence of cirrhosis per se is a major determinant for HCC development. These findings suggest that the training cohort should reflect the overall population at HCC risk more balanced to produce a reliable score for use in clinical practice.

In the upcoming years, the score was revised (REACH-BII) with the inclusion of quantitative HBsAg, which proved to be an additional independent predictor for the development of HCC[30]. In 2014, REACH-B risk score went through a final modification in a South Korean cohort where liver stiffness measurement (LSM) by transient elastography substituted HBV-DNA level: The better performance of the modified score (AUROC values; mREACH-B: 0.814 *vs* REACH-B: 0.629) was consistent with the fact that the CHB patients included in the Korean study were under entecavir treatment[31]. Similar findings were reported by the investigators of the original REACH-B risk score study when they applied the old and modified score to CHB patients treated with nucleotide analogue[32].

Liver stiffness values, in addition to age, albumin and HBV-DNA were used by the group of investigators of the CU-HCC score in 2014, to develop a new score for untreated CHB patients, namely LSM-HCC[33]. The new scoring system ranged from 0 to 30, with an optimal cut-off value of 11 to identify patients at HCC risk. Patients with a LSM-HCC score lower than 11 had a very low 5-year risk for HCC, with 92% sensitivity, 71% specificity, and 100% NPV. In 2016, another HCC risk score was developed based on real-world data of 538 untreated CHB patients from Singapore, namely the real-world score-HCC (RWS-HCC)[34]. The RWS-HCC score included gender, age, cirrhosis, and AFP as independent predictors. Upon validation in 3353 patients from REACH-B, GAG-HCC and CU-HCC cohorts, RWS-HCC score had AUROC values of 0.767, 0.830, and 0.902 and NPV of 97.0%, 97.9%, and 93.0% respectively. In 2018, a novel score (HCC-ESC) was developed for 723 CHB patients who achieved HBeAg seroclearance; age, gender, cirrhosis, albumin, HBV-DNA, and ALT serum levels were the parameters of the risk score to identify the long-term risk. The HCC-ESC score showed an AUROC value of 0.92 in the validation cohort[35]. Finally, in 2019, another HCC risk score (AGED score) was proposed from a longer term (21-year follow-up period) cohort study[36]. The AGED score included age, gender, HBeAg status, and HBV-DNA as independent parameters. The AGED score categorized patients into three groups according to their HCC risk as low (0-4), intermediate (5-9), and high (10-12) risk using a 12-point score. A total of 1663 HBsAg-positive participants were recruited as the validation cohort, and the AGED score had AUROC values of 0.73 and 0.74.

Risk scores for treated CHB patients

At present, most CHB patients are under antiviral treatment, as it has a significant positive impact on the course of liver disease, reducing the progression to cirrhosis and its complications, including HCC[37,38]. Therefore, scores developed in cohorts of untreated CHB patients could not be adequate for treated patients because they include parameters that are not any more relevant in patients with sustained suppression of viral replication. PAGE-B is the first risk score developed in 1815 Caucasian CHB patients including those under nucleos(t)ide analogue (entecavir/tenofovir) treatment for at least 1 year[39]. This was a multicenter study where 1325 patients were set in derivation and 490 enrolled as validation cohort. The regression analysis identified age, gender, and platelet count as independent predictors of HCC. Cirrhosis was not included in the model, but the platelet count can be considered the surrogate marker for the cirrhotic (portal hypertension) stage. The c-statistic of PAGE-B score was found 0.82 in both the derivation and validation cohorts. Having a PAGE-B score < 9 (low risk), 10-17 (intermediate risk), > 18 (high risk) resulted in 5-year cumulative HCC incidences of 0%, 3%-4% and 16%-17%, respectively. The PAGE-B score shows a higher discriminatory ability in the identification of high-risk HBV patients from those with low-risk (100% NPV), contributing to define different surveillance strategies according to the individual risk. By contrast, the intermediate-risk group has to be considered as a borderline group, where the definition of individualized surveillance algorithm is more difficult. The original findings of the PAGE-B score were confirmed and validated in Spanish and South Korean cohorts[40,41]. In 2018, Kim *et al*[42] revised the PAGE-B risk score in 3001 Asian CHB patients receiving entecavir/tenofovir therapy by adding albumin to the PAGE-B risk score. They showed a significant improvement of prediction as compared to previous models, including CU-HCC, GAG-HCC, REACH-B, and PAGE-B, with an AUROC value of 0.82 at 5-year in HCC prediction and 100% NPV. Low- and intermediate-risk patients had an annual HCC development risk of approximately 0.2%-1%, which turned to be higher than 3% in the high-risk group. In an independent Asian HBV cohort, the mPAGE-B score showed similar accuracy with PAGE-B and GAG-HCC scores, but its discrimination ability was better than the REACH-B and CU-HCC scores[43]. PAGE-B and mPAGE-B risk scores showed promising results for adoption to HCC surveillance algorithm, particularly because of the very high NPV.

In 2017, the HCC-Risk Estimating Score in CHB patients under Entecavir (HCC-RESCUE) score based on age, gender, and cirrhosis was proposed for South Korean treated CHB patients[44]. The AUROC at 1, 3, and 5-year was 0.82, 0.81, and 0.81, respectively, in the validation cohort. In the same year, the age, platelet, AFP (APA)-B score was proposed from Taiwan[45]. It ranged from 0 to 15, with the optimal cut-off for low risk set at 6. The AUROCs for 2-, 3-, and 5-year HCC prediction was 0.939, 0.892, and 0.862, and the NPV for the low-risk group was 99.1% in the validation cohort.

In 2018, the cirrhosis, age, male gender, diabetes (CAMD) score, which aimed to predict HCC during antiviral treatment, was proposed by the analysis of population-wide data from the healthcare systems in Taiwan (training cohort of 23851 CHB patients) and Hong Kong (validation cohort of 19321 patients)[46]. The CAMD score was the first to integrate diabetes mellitus as a risk factor for HCC, extracted from the multivariable Cox proportional hazards model. These four parameters were weighed to develop the CAMD score ranging from 0 to 19 points, with the categorization of CHB patients in three groups as low (< 8), intermediate (9-12), and high (> 13) risk. Low-risk patients had an annual HCC incidence of 0.3%. The c-indices were higher than 0.75 within the first 5 years in the training and validation cohorts. The CAMD score can be easily computed with simple information at the baseline of treatment initiation.

In 2019, a multicenter study from Korea proposed the Age-Albumin-Sex-Liver cirrhosis (AASL-HCC) score[47]. Age, albumin, male gender, and cirrhosis were extracted as independent predictors of HCC development while under entecavir or tenofovir treatment in a cohort of 1242 consecutive treatment-naive HBV patients, who were followed from 2007 to 2017. Low (< 5), intermediate (6-19), and high (> 20) risk groups showed HCC incidence rates of 0%, 3.7%-7.4%, and 17.6%-30.9%, respectively. The AUROC value for HCC prediction in 3-year, 5-year and total follow-up period was 0.850, 0.805, and 0.797, respectively, in the validation cohort.

In 2020, a multicenter study, enrolling 8048 Asian CHB patients under antiviral treatment from 25 centers in the United States and Asian-Pacific region, developed the REAL-B score[48]. It includes seven variables (male gender, age, alcohol use, diabetes, baseline cirrhosis, platelet count, and AFP) to categorize patients into the following three groups: Those at low (0-3), moderate (7), and high (8-13) risk. All AUROCs for

HCC prediction were higher than 0.8 at 3, 5, and 10 years, with a better predictive performance than PAGE-B in the same cohort (AUROC values at same time points; 0.73-0.74). The previously described HCC-ESC score was revised in 2020 in a Korean cohort of CHB patients under antiviral treatment and called HCC-ESC$_{AVT}$[49]. The risk score targeted CHB patients with HBeAg seroclearance like the original version and used the following three parameters: Male gender, cirrhosis, and fibrosis-4 index. The AUROC values for 5-year HCC prediction were 0.770 and 0.774 in the training and validation cohorts, respectively.

Interpretation and comparison of CHB-specific HCC risk scores

CHB specific HCC risk scores are summarized in Table 2. Most of them had been developed in Asian CHB patients, resulting from the urgency to have an accurate, precise, simple-to-use HCC risk score to be used in routine clinical activity, particularly in geographical areas where the burden of HBV infection is higher. The majority were developed in Asian patients and were also validated in Caucasians with acceptable performance. Nevertheless, most validation performances were lower than in the training cohort. Accordingly, the validation studies with Caucasian CHB patients showed AUROC values ranging from 0.74 to 0.86 for GAG-HCC, 0.62 to 0.91 for CU-HCC, 0.54 to 0.77 for REACH-B, and 0.85 for RWS-HCC risk scores[41,50-54]. These findings indicate that specific features of the population significantly influence the risk of HCC development. On the other hand, it is well known that the duration of HBV infection and florid viral replication, HBV genotype, exposure to other oncogenic factors (such as aflatoxins), and co-morbidities play a relevant role in HCC development[14]. As a consequence, a universal and highly accurate HCC score is unrealistic. Conversely, a predictive model based on data reflecting the virologic and clinical features of a given geographical area will provide a reliable tool for the same specific population. Nevertheless, such a model will require continuous adjustments reflecting the dynamic variations of the population based on the changing patterns of both HBV epidemiology and cirrhosis prevalence, HBV population aging, the variable impact of antiviral treatment according to its timing during the CHB course, and the variations of all the other co-factors of liver disease. Accordingly, the GAG-HCC, CU-HCC, REACH-B, LSM-HCC, and RWS-HCC scores, all derived from untreated CHB cohorts, as they were developed from patients followed in the 1990s or early 2000s, are not any more of interest because at present most of HBsAg carriers with evidence of CHB are under antiviral therapy. Another vital issue is the prevalence of cirrhosis in the studied cohorts, which may modify and alter the power of other parameters significantly involved in the scoring systems. The best example for this issue is that the REACH-B score, derived from a cohort of purely non-cirrhotic patients, has degraded performance in validation studies involving cirrhotic patients. In general, all the validated risk scores showed high NPV (95% to 100%) in both the original and external validation cohorts, suggesting redundancy of standard surveillance strategy to low-risk groups. The high-risk groups showed a wide range of annual HCC incidence, ranging from 2.3% to 9.2%, in CHB specific risk scores. By contrast, it indicates that we require additional studies to stratify the individual risk and define new surveillance strategies with more sensitive imaging or serologic tools.

In conclusion, risk stratification is attainable by validated HCC risk scores, but the optimal performance is obtained only in populations with similar characteristics to those where the score was developed. Besides, continuous validation of the predictive models is required to adjust them according to the dynamic variation of all factors influencing the individual HCC risk.

HCC RISK SCORES FOR CHC PATIENTS

As compared to CHB, there are a few proposed modeling studies in CHC patients to predict their HCC risk (Table 3), and their major limitation is the lack of external validation cohorts for most. The latter drawback for their use in clinical practice is the heterogeneity of CHC patients. It may be due to different co-factors affecting the disease progression of HCV and different prevalence across the world. Furthermore, the availability of DAAs in clinical practice acted as a watershed in the clinical needs to optimize the management of CHC patients with advanced fibrosis or cirrhosis; the current unmet need is an algorithm to guide the clinician to personalize the surveillance according to the residual HCC risk. The antiviral treatment proved useful to improve the outcome of CHC and reduce the HCC incidence since the introduction of interferon and ribavirin[55]. However, patients with advanced liver disease had a

Table 2 Hepatocellular carcinoma prediction risk scores for chronic hepatitis B patients

Risk scores	Cohort: Patients/ratio of cirrhosis	Study population	Antiviral treatment	Variables	External validation

HCC-ESC$_{AVT}$ (Lim *et al* [49], 2020)	Training: 769/41.5%; Validation: 1061/26.1%	Asian (South Korea)	ETV/TDF	Gender; Cirrhosis; Fibrosis-4 index	- (Internal only)

GAG-HCC: The guide with age, gender, hepatitis B virus DNA, core promoter mutations, and cirrhosis risk score; CU-HCC: Chinese University-hepatocellular carcinoma risk score; REACH-B: The risk estimation for hepatocellular carcinoma in chronic hepatitis B score; RWS: Real-world score; APA-B: Age, platelet, alpha-fetoprotein-B score; CAMD: Cirrhosis, age, male gender, diabetes score; AFP: Alpha-fetoprotein, ALT: Alanine aminotransferase, HBeAg: Hepatitis B e Antigen, HBV: Hepatitis B virus, LSM: Liver stiffness measurement.

significantly lower SVR rate and reduced compliance to treatment. Thus, the availability of scoring systems to identify individuals at higher risk of HCC development among those with advanced liver disease was perceived as a major clinical interest.

The first HCC risk score attempt was derived from the Hepatitis C Antiviral Long-Term Treatment Against Cirrhosis cohort in 2009[56]. During a median follow-up of 4.6 years, 48 of 1005 (4.8%) patients developed HCC, with a 5-year HCC incidence comparable in peginterferon-treated or untreated patients (5.4% *vs* 5.0%). The presence of cirrhosis together with older age, Black race, lower platelet count, higher alkaline phosphatase, esophageal varices, and smoking status identified patients at higher risk. A few years later, another study conducted on 11721 HCV-related cirrhotic patients from the Veterans Administration Hepatitis C Virus Clinical Case Registry in the United States investigated the possibility to develop an AFP-based algorithm where biomarkers of disease activity (ALT) and disease stage (platelet count) were used to

adjust the predictive accuracy of AFP[57]. At any given AFP value, low numbers of platelets and ALT and older age were associated with increased risk of HCC, and high levels of ALT and normal/high numbers of platelets were associated with low risk for HCC. The advantage of the model was its inclusion of routine laboratory tests and easy to manage parameters.

Two studies from Asia tackled the same issue with different approaches. Masuzaki *et al*[58] investigated the possibility to use LSM determined by FibroScan as a predictor of HCC in 866 HCV-infected patients. The cohort was prospectively followed for a mean period of 3 years after initial LSM determination. The odds ratio of HCC development was correlated with increasing LSM, and a LSM cut-off value of > 15 kPa had a greater association with HCC development. The other study from Taiwan enrolled 871 biopsy-proven CHC patients who achieved sustained response after peginterferon and ribavirin. They integrated the histologic fibrosis status with other parameters (age, AFP, low platelet counts) to define a HCC risk score[59]. Accordingly, low (< 10), intermediate (11-15), and high (> 16) risk groups had 1.37%, 9.14%, and 30.7% chances of HCC development, respectively. The authors proposed their novel risk score for HCC screening in CHC patients achieving SVR.

In 2016, a multicenter French cohort (ANRS CO12 CirVir) study with 1323 CHC-related cirrhosis patients was conducted to develop an individualized score for HCC prediction[60]. An 11-point risk score was established using the five variables independently associated with HCC (age > 50 years, past excessive alcohol intake, low platelet count, gamma-glutamyltransferase (GGT) > upper limit of normal, and absence of SVR). This new risk score was able to stratify the CHC-cirrhosis population into three groups according to HCC risk as low (< 3), intermediate (4-7), and high (> 8) risk. However, this score also lacked external validation.

In 2020, a different approach was used to refine HCC risk among patients with CHC-related cirrhosis from the same French cohort, by applying predictive machine learning approaches (Fine-Gray regression model) rather than traditional multivariate linear regression analysis[61]. The study was interesting in terms of bringing a new breath to risk-stratification models and personalized HCC-surveillance efforts. As expected, the authors showed that factors influencing the HCC risk varied after SVR. Only elevated AST, low platelet count, and shorter prothrombin time was independently associated with HCC risk after SVR, whereas there were six independent predictors (past excessive alcohol intake, genotype 1, elevated AFP, GGT, low platelet count, and albumin levels) before SVR. However, the interactions between the different parameters were quite complex, and eight different groups were identified with varying cancer risks and predictors depending on SVR achievement. The findings were interesting but not yet directly applicable in clinical practice. Nevertheless, the study showed that machine learning algorithms can refine the HCC risk assessment by revealing complex interactions between cancer predictors and eventually prompting more cost-effective tailored surveillance programs development.

An absolute simplified model was derived and proposed from 1088 Japanese CHC patients who achieved SVR after DAA in the same year[62]. They revealed age and AFP as independent predictors of HCC after achieving SVR with DAAs. Using AFP and age only, they developed a scoring system (0-2 points) where the incidence of HCC at 2-years was 0.3% in the 0 points group, 6.27% in the 1-point group, and 18.37% in the 2-points group. This oversimplified approach is captivating; however, external validation in different populations is required, as specific features, such as HCV epidemiology in the geographical area, could significantly influence the findings. The General Evaluation Score (GES) was recently proposed by a study performed in Egypt on 4400 patients, with cirrhosis or advanced fibrosis who achieved a SVR[63]. Age, sex, serum albumin, AFP and, pretreatment fibrosis stage was identified as risk factors for HCC and used to construct the risk score, and categorized CHC patients into three groups. The 2-year cumulative HCC incidence was 1.2%, 3.3%, 7.1% for low-, medium-, and high-risk groups, respectively. The GES score had high predictive ability in internal and external validation cohorts from Egypt with c-statistics values of 0.80 and 0.81. Unfortunately, the findings of this interesting and promising study cannot be generalized because it included only HCV genotype 4-infected patients.

Overall, it appears that in the setting of CHC patients from one side, the proposed scoring systems are lacking adequate external validation, which is mandatory to warrant their use in clinical practice. Furthermore, the high variability of the epidemiology of HCV infection (different genotype distribution worldwide, distinct modalities of HCV spreading in the various geographical area and overtime) is even more complicated than in HBV, necessitating the implementation of a model in a different context. Nevertheless, the evidence that the risk of HCC significantly declines over time in patients who achieved SVR underlines the urgent need for new algorithms to personalize the HCC surveillance and optimize its cost/benefit.

PREDICTION OF HCC RISK FOR PATIENTS WITH CLD OR OTHER RISK FACTORS

HCC prediction risk scores, regardless of underlying liver disease etiology, are summarized in Table 4. Flemming *et al*[64] developed an HCC risk prediction model to estimate the 1-year probability of HCC to assist clinicians with patient counseling by studying a large cohort of patients (n = 34932) with cirrhosis from the United States liver transplantation waiting list database. Thus, the authors did not mean to create a score to modify the surveillance of cirrhotic patients but to provide an individualized approach to HCC counseling based on specific patient characteristics. They identified six baseline variables (age, diabetes, race, etiology of cirrhosis, sex, and severity [ADRESS] of liver dysfunction) independently associated with HCC and the c-indices of the ADRESS-HCC risk model were 0.704 and 0.691 in the derivation and internal validation cohorts, respectively. The major limitation of the study was the selection of patients with advanced liver disease, as they were cirrhotic already on the transplant waitlist. In 2017, the Toronto Hepatocellular carcinoma Risk Index (THRI) was developed to predict 10-year HCC risk, using simple clinical and laboratory parameters (age, gender, etiology, platelet)[65]. The THRI weighed etiologies, including the SVR status of HCV-related cirrhosis, and its performance had been studied in three external validation cohorts from different regions (Netherlands, China, Turkey) with similar accuracy in predicting HCC development[65-67]. All AUROC values ranged from 0.75 to 0.80, using the same cut-off value of 240 to identify the high-risk HCC group.

Diabetes is a risk factor for HCC in patients with CLD. Li *et al*[68] in 2018 approached the issue in the other way round, developing a risk score system to predict the HCC risk in patients with diabetes. They studied a cohort of 31723 Taiwanese patients with type 2 diabetes mellitus, followed-up for 8.3 years, and the final model (scores ranging from -6 to 40 points) included age, gender, smoking status, hemoglobin A1c, glutamic-pyruvic transaminase, cirrhosis, hepatitis B, hepatitis C, anti-diabetic and anti-hyperlipidemic medications, and total/high-density lipoprotein cholesterol ratio. The 3-, 5-, and 10-year AUROC values to predict HCC risk were 0.81, 0.80, and 0.77.

More recently, an ambitious study aimed to develop a global universal HCC risk score to predict the HCC development for patients with chronic hepatitis, published by an international study group. A total of 17374 patients (10578 Asian and 2510 Caucasian treated CHB patients, 3566 CHC; 2489 of whom with cirrhosis and SVR, and 720 patients with non-viral hepatitis) from 11 international prospective observational

Table 4 Hepatocellular carcinoma prediction risk scores regardless of etiology

Risk scores	Cohort: Patients	Study population	Variables	External validation
ADRESS-HCC, (Flemming *et al* [64], 2014)	Training: 17124/100%; Validation:17808/100%	North America (United States)	Age; Diabetes; Race; Etiology of liver disease; Gender; Child-Pugh Score	- (Internal only)
THRI, (Sharma *et al*[65], 2017)	Training: 2079/100%; Validation: 1144/100%	Caucasian (Canada)	Age; Gender; Etiology of liver disease; Platelet count	Asian, Caucasian

aMAP, (Fan *et al* [69], 2020)	Training: 3688/19.3%; Validation cohorts: 13686/11.4%-100%	Multicenter (Asian + Caucasian)	Age; Gender; Albumin-bilirubin score; Platelet count	Asian, Caucasian

THRI: Toronto hepatocellular carcinoma risk index; ADRESS: Age, diabetes, race, etiology of cirrhosis, sex, and severity; HbA1c: Hemoglobin A1c; HDL: High-density lipoprotein.

cohorts or randomized controlled trials were analyzed[69]. This study is unique in terms of having a large validation cohort from several ethnicities and etiologies; however, the majority were still CHB patients. The aMAP score was obtained from a training cohort of 3688 Asian patients and validated in nine cohorts with different etiologies and ethnicities. The score ranges from 0 to 100 and involves age, male, albumin-bilirubin score, and platelet count; the value of 50 was identified as the optimal cut-off to predict HCC, with a sensitivity of 85.7%-100% and 99.3%-100% NPV. The authors proposed their risk score, based on five common parameters, showing high performance regardless of etiology and ethnicity, as a potential new tool to establish a risk score-guided HCC surveillance strategy worldwide.

TUMOR MARKERS AND HCC RISK SCORES

Several serologic biomarkers, other than AFP that have already been discussed and included in some scoring systems, such as osteopontin, alpha-fetoprotein-L3 (AFP-L3), des-gamma-carboxy prothrombin (DCP), also known as the protein induced by vitamin K absence or antagonist II (PIVKAII), glypican-3, alpha-1-fucosidase, midikine, dikkopf-1, Golgi protein-73, squamose cell carcinoma antigen, and fucosylated glycoprotein, have been investigated for their potential role in HCC screening. Ideally, blood-based biomarkers with adequate sensitivity or specificity could enable early detection of HCC, avoiding cumbersome ultrasound-based surveillance. However, at present, none of the biomarkers has been validated in phase III clinical trials and are used in clinical practice, with the exclusion of AFP and PIVKAII, recommended by Japanese HCC guidelines, particularly in Japan[70]. This can be explained by the high heterogeneity of HCC biology, where several pathway alterations are involved in the tumorigenesis process[71]. Therefore, the combination of different biomarkers and the available clinical and laboratory variables has been evaluated to develop predictive scores (Table 5).

The GALAD algorithm combining three biomarkers (AFP, AFP-L3, and DCP) with sex and age showed a remarkable overall performance (AUROC values of 0.95, 92% sensitivity, and 85% specificity) that remained high (AUROC: 0.92, sensitivity 92%, specificity 79%) for early HCC detection[72]. The model was validated in independent cohorts from Japan, Germany, and Hong Kong, with overall sensitivity ranging from 80%-91%, specificity from 81%-90%, and AUROC values from 0.85 to 0.95[73]. Both in the original and validation studies, the etiologies were mixed and dominantly consisted of alcohol-related liver disease and CHC patients. The homogeneity of the studied cohorts as far as the etiology of CLD is concerned is critical as the diagnostic performance of the most widely used standardized HCC biomarkers, namely AFP and PIVKAII is significantly influenced by the etiology and activity of CLD, and their combination provides a better diagnostic accuracy[74]. Interestingly, the GALAD score showed an AUC of 0.96 in the identification of HCC in a German cohort of patients with nonalcoholic steatohepatitis (NASH), with comparable performance in patients

Table 5 Algorithmic approaches using the combination of serologic and clinical parameters for hepatocellular carcinoma risk prediction

Risk scores	Cohort: Patients/ratio of cirrhosis	Study population	Variables	External validation
GALAD score (Johnson *et al*[72], 2014)	HCC case: 670/90%; CLD control: 339/97%	Caucasian (England)	AFP; AFP-L3; DCP	Asian, Caucasian
Doylestown algorithm (Wang *et al*[76], 2016)	Training HCC case: 165/100%; CLD control: 195/100%; Validation 1 HCC case: 432/100%; CLD control: 438/100%; Validation 2 HCC case: 113/100%; CLD control: 586/100%; Validation 3 HCC case: 425/100%; CLD control: 804/100%	North America (United States)	Age; Gender; ALT; ALP; AFP; Fucosylated kininogen	North America (United States)
GALADUS score (Yang *et al*[75], 2019)	Training HCC case: 111/98%; CLD control: 180/85%; Validation HCC case: 233/100%; CLD control: 412/100%	North America (United States)	AFP; AFP-L3; DCP; Ultrasonography	North America (United States)
HES algorithm (Tayob *et al*[78, 79], 2019)	HCC case: 4804/100%; CLD control: 33627/100%	North American (United States Veterans Administration)	Age; Rate of AFP change; ALT; Platelet count; Etiology of cirrhosis	-

AFP: Alpha-fetoprotein; AFP-L3: Alpha-fetoprotein-L3; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; DCP: Des-gamma-carboxy-prothrombin, HCC: Hepatocellular carcinoma; CLD: Chronic liver disease.

with or without cirrhosis. A cut-off value of -0.63 GALAD score identified patients with HCC within Milan Criteria with an AUC of 0.91 (68% sensitivity and 93% specificity). The same threshold had been proposed to identify NASH patients who will have imaging diagnosis 200 d later. The GALAD score performance for HCC detection was also compared with liver US and showed to be superior. The combination of GALAD and US score further improved the performance score in a single-center cohort, achieving an area under the curve of 0.98[75]. Overall, these findings indicate that the GALAD score can detect patients with early-stage HCC and might facilitate surveillance of patients, particularly those with NASH, who are often obese, which limits the sensitivity of detection of liver cancer by US. However, the optimal cut-off value has to be defined to develop a shared and standardized surveillance algorithm. Another risk score, namely the Doylestown algorithm, incorporates two biomarkers (AFP and fucosylated kininogen) with two clinical (age, gender) and two laboratory (ALT and alkaline phosphatase) variables[76]. The Doylestown algorithm had an 89% detection rate for early HCCs with an AUROC value of 0.97 in low-AFP patients. The promising results of the Doylestown algorithm require adequate validation in larger and adequate cohort series.

In 2015, White *et al*[77] published an adjusted AFP-based algorithm for HCC detection in patients with HCV-related cirrhosis. It was the implementation of a previously reported score where age, platelets, ALT values, and interaction terms (AFP and ALT, and AFP and platelets) were used. In the new model, serial AFP measurements were included, showing an improvement in the overall performance. More recently, the Hospital Episode Statistics (HES) algorithm was validated in a cohort, which included 33627 patients with cirrhosis of any etiology who did not develop HCC during follow-up (controls) and 4804 patients with incident HCC (cases)[78]. At 90% specificity, the HES algorithm identified HCC cases with 52.56% sensitivity, compared to 48.13% sensitivity for the AFP assay alone, within 6 mo before diagnosis, which was an absolute improvement of 4.43% ($P < 0.0005$). Overall, the algorithm offers a modest advantage over AFP alone in HCC surveillance. The findings were substantially confirmed in a subsequent study, where the etiology of cirrhosis was added to the model[79].

POTENTIAL MOLECULAR CANDIDATES FOR INTEGRATION TO HCC RISK SCORES

Several lines of research are aiming to identify new biomarkers for detection of HCC at a very early stage. CancerSEEK is a recently proposed platform assessing eight circulating proteins (CA125, CEA, CA19-9, prolactin, hepatocyte growth factor, osteopontin, myeloperoxidase, and tissue inhibitor of metalloproteinases 1) and mutations in cell-free DNA[80]. By a machine-learning approach, an algorithm was

developed with an overall sensitivity of 70% and a specificity of 99% in detecting eight cancers, including HCC. A major limitation is that the study enrolled known cancers, whereas the aim would be to identify HCC in asymptomatic patients. Furthermore, using cancer gene panels in cell-free DNA could give rise to a high number of false-positive in healthy individuals[81]. A large number of other biomarkers, such as circulating tumor cells, microRNAs, tumor cell-free DNAs, tumor-derived/associated extracellular vesicles, metabolites, and proteins, are under investigation to obtain a liquid biopsy for HCC[82]. Another interesting approach has been proposed recently by Liu *et al*[83], who showed that a viral exposure signature (VES) obtained by a synthetic viral scan technology of viral antibodies could discriminate HCC with high confidence from at-risk individuals (area under the curve of 0.91 at baseline and 0.98 at diagnosis) or healthy volunteers. The VES was validated in at-risk patients in a prospective HCC cohort; however, larger prospective studies are needed to evaluate its utility in HCC surveillance.

Finally, germ-line single gene polymorphisms have also been analyzed in genome-wide association studies as specific host factors that determine HCC susceptibility for chronic viral hepatitis patients. *EGF, IFNL3, MICA, TLL1, MERTK, K27 of histone H3-H3K27ac* for CHC[84-90], and *KIF1B, STAT4,* and *HLA-DQB1/HLA-DBA2* for CHB patients were the most promising ones[91,92]. It is not very likely that a single germ-line genetic variant may affect HCC development in chronic viral hepatitis, but future attempts may include integrating them into HCC-risk scales. The future efforts will be incorporating molecular profiling into HCC-surveillance algorithms that could also identify targets for potential chemo-preventive interventions.

CONCLUSION

The epidemiology of CLD is rapidly changing, with a progressive reduction of viral hepatitis burden and an increase of non-alcoholic fatty liver diseases (NAFLD). Considering the significant rise in NAFLD-related HCC cases globally, the ability to stratify the risk of HCC is becoming another urgent need. HCC does also occur in patients with non-cirrhotic NAFLD but surveillance is not recommended to this group as incidence rates are lower than 1% a year[93]. The HCC risk stratification tools in patients with NAFLD is not discussed here, as the aim of the present article is to focus on HCC surveillance of patients with chronic viral hepatitis. The incidence of HCC has become highly heterogeneous within patients with chronic viral hepatitis since it differs significantly according to the period of both viral infection, the beginning of treatment, and the rate of cirrhosis. As a consequence, the incidence of HCC differs according to the geographical distribution of risk factors. Thus, the identification of appropriate tools for tailoring the HCC screening decisions according to the different subgroups of patients based on the CLD etiology, relevant clinicopathologic and epidemiologic factors is a growing need in clinical practice. The individually tailored HCC surveillance would imply a cost-effective application of personalized protocols using highly sensitive imaging techniques[94]. However, such an important medical need remains currently unmet and it appears unlikely that it will be fulfilled by a universal generalized score. The HCC-risk stratification models appear helpful to generate reliable and personalized HCC predictive scores only if the scoring system is applied to cohorts whose clinic-pathologic characteristics are highly similar to those of the original discovery cohort for the particular model.

On the other hand, the more widespread use of current HCC biomarkers to increase the specificity for identifying patients with a more significant risk is controversial. All HCC markers so far identified have a highly dis-homogeneous prevalence in patients with different etiology of CLD that imposes their use in multiple markers panels. Furthermore, the serum levels of HCC biomarkers change over time, and the detection of this velocity might improve their specificity. Their analytical cut-off needs to be better standardized in this regard. For instance, the levels of AFP are influenced by liver regeneration prompted by flares of intrahepatic necroinflammation; thus, the range of AFP normality values vary consistently from patients with chronic viral hepatitis and sustained antiviral response to those with metabolic-associated fatty liver disease and ongoing steatohepatitis. Future studies should address these issues using, for instance, algorithms of the combined dynamics of ALT and AFP levels.

In conclusion, according to existing knowledge, there is a strong recommendation to perform surveillance in patients with cirrhosis regardless of their liver disease etiology, origin, age, and sex. The question remains as to whether the time intervals of US screening can be safely reduced in lower risk cirrhotic patients who recovered from

chronic viral hepatitis and maintain normal liver function tests after sustained response to antiviral therapy. The issue of HCC surveillance is much more complicated in patients without cirrhosis. An ideal risk score system should define optimal cut-off values to discriminate high-risk HCCs with high annual HCC incidence (> 3%-5%) and high PPV and low-risk HCCs with high NPV (> 99%). Most of the existing risk scores for CHB reached or were close to this performance, but they did not target the non-cirrhotic patients specifically and were highly dis-homogeneous for the cirrhosis rate. For HCC-risk scores specific for CHC patients without cirrhosis, there is a lack of validation in independent cohorts and proposed scores are not yet representative of CHC patients with complete SVR in the current era of DAAs. Currently proposed HCC-risk scores are not yet standardized to be incorporated into sustainable HCC-surveillance decision algorithms, and more efforts should be made to personalize HCC surveillance in CHB patients without cirrhosis and CHC patients with F3 fibrosis, at least in the near future. Patients with cirrhosis have to undergo HCC-surveillance regardless of liver disease etiology and prospective, large-scale multinational study with stratification on the basis of underlying CLD etiology, fibrosis status, ethnicity (including Africans and other parts of the world) are required. The potential of such a study must include a dynamic calculation of HCC-risk scores every 6 mo. Individual molecular profiling will provide a crucial integration of HCC-surveillance decision algorithms and help identify high-risk target populations in the future, but they are currently not widely available.

Abstract

A significant breakthrough in the field of obesity research was the demonstration that an obese phenotype could be manipulated by modulating the gut microbiota. An important next step is to elucidate a human-relevant "map" of microbiota-host interactions that regulate the metabolic health of the host. An improved understanding of this crosstalk is a prerequisite for optimizing therapeutic strategies to combat obesity. Intestinal mucosal barrier dysfunction is an important contributor to metabolic diseases and has also been found to be involved in a variety of other chronic inflammatory conditions, including cancer, neurodegeneration, and aging. The mechanistic basis for intestinal barrier dysfunction accompanying metabolic disorders remains poorly understood. Understanding the molecular and cellular modulators of intestinal barrier function will help devise improved strategies to counteract the detrimental systemic consequences of gut barrier breakage. Changes in the composition and function of the gut microbiota, *i.e.*, dysbiosis, are thought to drive obesity-related pathogenesis and may be one of the most important drivers of mucosal barrier dysfunction. Many effects of the microbiota on the host are mediated by microbiota-derived metabolites. In this review, we focus on several relatively well-studied microbial metabolites that can influence intestinal mucosal homeostasis and discuss how they might affect metabolic diseases. The design and use of microbes and their metabolites that are locally active in the gut without systemic side effects are promising novel and safe therapeutic modalities for metabolic diseases.

Core Tip: The manner in which the gut microbiota influences obesity development remains incompletely understood. Recent studies have indicated that the changes in the gut barrier functions act as an important driver of metabolic disorders. There is currently an urgent need to define molecular and cellular modulators of intestinal mucosal barrier homeostasis. Here, we discuss the current understanding of microbiota-derived metabolites in regulating mucosal homeostasis and how they contribute to the metabolic health of the host.

INTRODUCTION

The gut microbiota is thought to function as an organ that can markedly influence human health and disease[1]. It plays an essential role in the progression of obesity and related metabolic syndromes[2-4]. Many effects of the microbiota on the host are mediated by microbiota-derived metabolites[5-8]. A complex interplay between the host immune system and the gut microbiota under normal physiological conditions maintains the mucosal barrier in a homeostatic state. This symbiotic relationship is often broken during the progression of obesity. Increased levels of circulating bacterial flagellin, lipopolysaccharides (LPS), and peptidoglycans are frequently observed in obesity and its complications due to mucosal barrier dysfunction[9-12]. The objective of this review is to provide an overview of the emerging field related to the role of gut microbiota-derived metabolites in regulating gut barrier function and metabolic health.

MUCOSAL HOMEOSTASIS IN OBESITY

Intestinal barrier dysfunction leads to the translocation of microbial molecules into the systemic circulation, resulting in a state of so-called "metabolic endotoxemia" that is considered to be one of the most important initiators of metabolic disease in obesity [13-16]. However, the mechanisms underlying barrier dysfunction accompanying metabolic syndrome remain poorly understood. Thus, there is an urgent need to elucidate the molecular and cellular modulators of intestinal mucosal barrier homeostasis to devise improved strategies to counteract metabolic disease progression. Hyperglycemia has been suggested as a contributor to obesity-associated dysfunctions of the intestinal barrier[17]; however, this condition may not be the initial trigger for barrier dysfunction, as hyperglycemia often occurs after metabolic syndrome manifestation. The gut microbiota is involved in the regulation of multiple host metabolic pathways *via* interactive host–microbiota interactions. Early phase alteration of the composition and function of the gut microbiota may induce intestinal barrier dysfunction and lead to the development of metabolic disorders. Here, we briefly review several microbial metabolites that regulate mucosal homeostasis.

Microbiota-derived short-chain fatty acids as regulators of mucosal homeostasis

Short-chain fatty acids (SCFAs) are derived predominantly from gut microbial fermentation of otherwise indigestible dietary fiber[18]. According to a clinical study, the major SCFA-producing bacteria promoted by dietary fibers in humans were found to be *Faecalibacterium prausnitzii* and *Eubacterium*, *Lactobacillus*, and *Bifidobacterium* species[19]. The roles of SCFAs in mucosal homeostasis and metabolic health are summarized in Figure 1.

SCFAs regulate gut epithelial cell metabolic programming: Gut epithelial cells express peroxisome proliferator-activated receptor gamma (PPAR-γ)[20], which can sense microbial-derived SCFAs (*e.g.*, butyrate). The activation of PPAR-γ by butyrate drives the energy metabolism of colonic epithelial cells toward beta-oxidation and limits the luminal bioavailability of oxygen[21-24]. This is important for maintaining

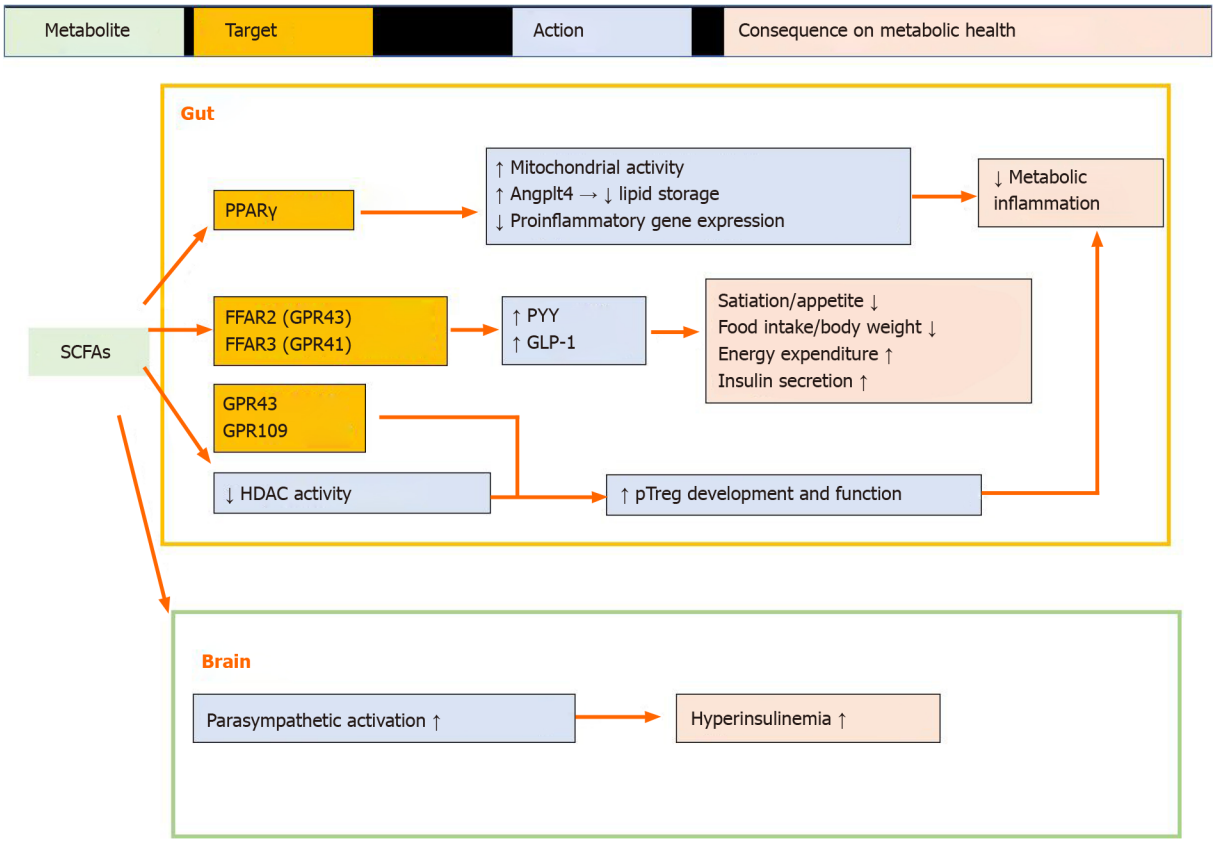

Figure 1 The roles of short-chain fatty acids in mucosal homeostasis and metabolic health. Short-chain fatty acids (SCFAs) can engage various molecular targets in the gut, and play positive roles in maintaining mucosal barrier integrity and systemic metabolic health *via* regulating gut epithelial cell metabolic programming by activating peroxisome proliferator-activated receptor gamma signals, maintaining immune homeostasis by promoting peripheral regulatory T helper cell development and functions, and stimulating energy expenditure and insulin secretion by releasing the gut hormones peptide tyrosine and glucagon-like peptide-1. SCFAs also exert some negative influences on host metabolic health *via* the gut–brain axis. Angplt4: Angiopoietin-like protein 4; FFAR: Free fatty acid receptor; GLP-1: Glucagon-like peptide-1; GPR: G-coupled receptor; HDAC: Histone deacetylase; PPAR: Peroxisome proliferator-activated receptor; pTreg: Peripheral regulatory T helper cell; PYY: Peptide tyrosine.

the colonic surface in a physiological hypoxic state, thereby limiting the aerobic outgrowth of facultative anaerobic bacteria[25]. Short-term high-fat diet (HFD) consumption can perturb epithelial PPAR-γ signals and disrupt the microbial and physiological ecosystems within the gut[26].

PPAR-γ activation by SCFAs can also increase angiopoietin-like protein 4 (ANGPTL4/FIAF) secretion from the gut epithelium[27]. ANGPTL4 is a circulating lipoprotein lipase inhibitor, and its expression levels can affect the process of dietary energy harvesting and storage in the host[28]. Additionally, PPAR-γ activation inhibits the transcription of proinflammatory genes induced by interferon (IFN) gamma and/or LPS[29].

Effects of SCFAs on gut hormones: The gut is the largest endocrine organ within the body and can release more than 20 different peptide hormones that are sensitive to gut nutrient content stimulation and function to regulate a variety of physiological processes[30]. As a gut nutrient, free fatty acids (FFAs) can serve as not only cellular energy sources but also natural ligands for a group of orphan G protein-coupled receptors (GPCRs), which are known as FFA receptors (FFARs) and are expressed in the gut epithelial cells to regulate gut peptide hormone production[31-34]. In particular, FFAR3 (GPR41) and FFAR2 (GPR43) are activated by SCFAs, primarily acetate, butyrate, and propionate[32]. SCFAs can stimulate the release of the anorexigenic hormone peptide tyrosine (PYY) and glucagon-like peptide-1 (GLP-1) from colonic L cells[30] *via* their cognate FFARs. The release of PYY into circulation after food intake can reduce energy intake[35]. GLP-1 can act directly on pancreatic beta cells to activate insulin secretion in a glucose-dependent manner[36]. Thus, SCFA-induced release of PYY and GLP-1 from colonic L-cells may play a role in preventing the development of obesity and its related complications[37].

Role of SCFAs in maintaining mucosal immune homeostasis: The gut microbiota has co-evolved with the intestinal immune system to facilitate the maintenance of mucosal homeostasis[38]. Regulatory T cells (Tregs) are critical for limiting intestinal inflammation[39]. SCFAs play an important role in the generation of peripheral Tregs and control Treg homeostasis and function within the gut[40,41]. Butyrate, acetate, and propionate are the major bacteria-derived SCFAs that control mucosal Treg differentiation and function[40]. Several mechanisms are involved in the promotion of mucosal Treg differentiation and function by SCFAs. First, SCFAs can regulate the size and function of the colonic Treg pool through the activation of GPCRs (GPR43 and/or GPR109)[40,42]. Second, SCFAs can regulate Treg differentiation by inhibiting histone deacetylase (HDAC)[43]. HDAC activity in T cells can be suppressed by acetate, propionate, and butyrate[43]. Butyrate enhances the acetylation of histone H3 Lysine 27 at the promoter and conserved non-coding sequence regions of the Foxp3 locus, which is critical for peripheral Treg generation to promote Foxp3 gene expression[41,44]. Furthermore, the HDAC inhibitory activity of butyrate and propionate promotes the ability of dendritic cells to support Treg differentiation by repressing the expression of LPS-responsive genes and by rendering lamina propria macrophages hyporesponsive[41,45]. Additionally, the binding of SCFAs with GPR43 expressed on neutrophils and eosinophils has been reported to dampen gut inflammatory responses [46]. Collectively, these data indicate that SCFAs can maintain mucosal immune homeostasis, particularly by inducing Treg generation and function, which may be beneficial for alleviating obesity and its related metabolic syndrome[37]. Consistent with this idea, fat-resident Tregs have been reported to be significantly reduced in obese hosts and Tregs protect against obesity-associated inflammation, insulin resistance, and other related metabolic disorders[47-49].

It should be noted that although SCFAs are generally thought to play positive roles in maintaining mucosal homeostasis, they exert negative impacts on host metabolism. In experimental studies involving mice, treatment with acetate promoted metabolic syndrome through the action of the gut–nervous system axis[50]. In a clinical trial, consumption of a propionate-containing meal resulted in the activation of catecholamine-related insulin counter-regulatory signals, thus leading to insulin resistance[51]. Approaches to avoid such negative impacts of SCFAs on host metabolism are warranted.

Role of microbiota-derived amino acid metabolites in mucosal homeostasis

Microbiota-derived tryptophan metabolites protect the gut barrier: Recent discoveries indicate that the gut microbiota modulates immune homeostasis and mucosal barrier physiology by modulating amino acid metabolism. Among the amino acids, the effects of aromatic amino acid tryptophan (Trp) derivatives produced by bacterial fermentation are relatively well studied. Gut microbiota can directly utilize Trp as a biosynthetic precursor for a large number of microbial metabolites, and approximately 4%–6% of Trp can also be further metabolized to indole, indican, tryptamine, skatole, and indole acid derivatives[52,53]. Trp can be converted into indole by tryptophanase, which is expressed in *Escherichia coli* and *Lactobacilli*[54], or into tryptamine by a Trp decarboxylase found in *Clostridium sporogenes*[55]. It can also be transformed into indoleacetic acid *via* an uncharacterized oxidative pathway or into indolepropionic acid (IPA) *via* a reductive pathway that requires a phenyllactate dehydratase that is found in *C. sporogenes*, *Peptostreptococcus anaerobius* CC14N, and three strains of *Clostridium cadaveris*[56].

Many indole derivatives, including IPA and indoleacrylic acid (IA) are ligands for the aryl hydrocarbon receptor (AhR)[54,57,58]. AhR signaling is crucial for intestinal homeostasis because it influences epithelial renewal, barrier integrity, and immune cell activity[59]. AhR mediates the activation of type 3 innate lymphoid cells to produce IL-22[60]. IL-22 plays an important role in maintaining the mucosal barrier and regulating host metabolic functions[61,62]. IPA induces IL-10R1 by activating AhR, thus exerting anti-inflammatory effects in the intestinal mucosa[58]. IA-AhR signaling promotes barrier function and mitigates LPS-stimulated inflammatory responses[63]. Indole-3-aldehyde (IAld) promotes AhR-dependent IL22 production to provide mucosal protection against inflammation induced by the fungus *Candida albicans*[57]. Trp-derived AhR ligands are reduced in both HFD-induced metabolic impairments in animals and in individuals with metabolic syndrome, and supplementation with an AhR agonist or an AhR ligand-producing *Lactobacillus* strain leads to the improvement of metabolic disorders[64,65].

Additionally, IPA has been reported to act as a ligand for the pregnane X receptor (PXR), and *in vivo*, PXR signals regulate mucosal integrity through toll-like receptor 4

[66]. Indole and IAld can also activate enteroendocrine cells through transient receptor potential ankyrin A1 to increase gut motility[67]. Gut microbiota-produced tryptamine activates intestinal epithelial GPCR serotonin receptor-4 (5-HT4R) to increase cAMP levels and drive colonic fluid secretion[68]. Collectively, Trp metabolites produced by the microbiota can protect gut barrier functions.

Microbiota-derived tyrosine metabolites regulate mucosal homeostasis: The aromatic amino acids phenylalanine, tyrosine (Tyr), and Trp share a decarboxylation pathway to generate trace amines, including phenylethylamine, tyramine, and tryptamine, respectively. Tyramine and tryptamine are high-affinity ligands for trace amine-associated receptor 1, which is expressed in the stomach, intestinal neuroendocrine cells, and pancreatic β cells, and regulates energy metabolism and modulates immune homeostasis[69,70].

Another common pathway involves aminotransaminase-mediated transamination, which subsequently undergoes oxidation and reduction, ultimately leading to the production of the corresponding acetic acid or propionic acid derivatives[56]. Desaminotyrosine (DAT, also known as 4-hydroxyphenylpropionic acid or p-hydroxyhydrocinnamic acid) is a degradation product derived from microbial Tyr metabolism. DAT can also be produced from microbial degradation of dietary flavonoids[71,72]. A recent study revealed that DAT protects the host from influenza virus infection by enhancing type I IFN signals[73]. Our recent data demonstrated that DAT supplementation alleviated HFD-induced fat mass accumulation and body weight increment, both of which are correlated with the anti-inflammatory effect of DAT with regard to maintaining mucosal immune homeostasis[7] (Summarized in Figure 2).

Bile acid modification by gut microbiota impacts mucosal homeostasis

Primary bile acids (BAs) are cholesterol metabolites that are produced in the liver and converted to secondary BAs by the gut microbiota[74]. The two key microbiota-dependent processes are BA deconjugation and 7α-hydroxylation. The enzyme bile salt hydrolase, which is produced by many commensal genera such as *Bacteroides*, *Clostridium*, and *Enterococcus*, deconjugates primary BAs. However, only a small number of known bacteria from the *Lachnospiraceae* and *Ruminococcaceae* families perform subsequent 7α-dehydroxylation to generate secondary BAs[75]. BAs are lipid solubilizers that are crucial for dietary lipid absorption and function as signaling molecules that coordinately regulate host metabolism and inflammation by interacting with their cognate cellular receptors, including the nuclear receptors farnesoid X receptor (FXR), PXR, vitamin D receptor, membrane G protein-coupled BA receptor 1 (also known as GPCR19 or TGR5), and sphingosine-1-phosphate receptor[76,77]. Different BA profiles can produce both agonists and antagonists of their cognate receptors, thus creating a great deal of complexity regarding the beneficial or deleterious influence of BAs and their derivatives on health and disease. In the gut, BA-TGR5 signaling leads to GLP-1 expression and secretion, whereas BA-FXR signaling inhibits GLP-1 production[78]. BAs influence gut-associated inflammation by regulating gut mucosal immune cells, including T helper cells expressing IL-17a and Tregs[79-81]. The BA-TGR5–cAMP–PKA axis inhibits NLRP3 inflammasome activation in macrophages[82]. Certain BAs can exert protective effects on the gut epithelium[83] or inhibit intestinal pathogens such as *Clostridium difficile*[84]. In an experimental model, tauroursodeoxycholic acid inhibited intestinal inflammation and barrier disruption in mice with nonalcoholic fatty liver disease[85]. *Parabacteroides distasonis*, one of the core members of the gut microbiota of humans, alleviates obesity and obesity-related dysfunction in mice, at least partially, based on its ability to produce secondary BAs[86] (Summarized in Figure 3).

Other dietary-derived microbial metabolites in regulating mucosal homeostasis

Polyphenols are a class of plant-derived macromolecules[87]. Approximately 90%–95% of dietary polyphenols are poorly absorbed and are partially processed by the gut microbiota[88]. Fermentation of polyphenols by the gut microbiota results in the production of bioactive metabolites that can affect host physiology. Urolithins are gut microbial metabolites derived from the polyphenol compounds, ellagitannins that are present in some fruits, nuts, and seeds (*e.g.*, pomegranates, black raspberries, raspberries, strawberries, walnuts, and almonds)[89]. Ellagitannins are hydrolyzed to ellagic acid under physiological conditions *in vivo*, and ellagic acid is then gradually metabolized by the gut microbiota to produce different types of urolithins. Urolithins have been demonstrated to protect against obesity and related metabolic diseases in animal studies[90]. These effects are related to their protective role in mucosal epithelial integrity and anti-inflammatory functions[91,92].

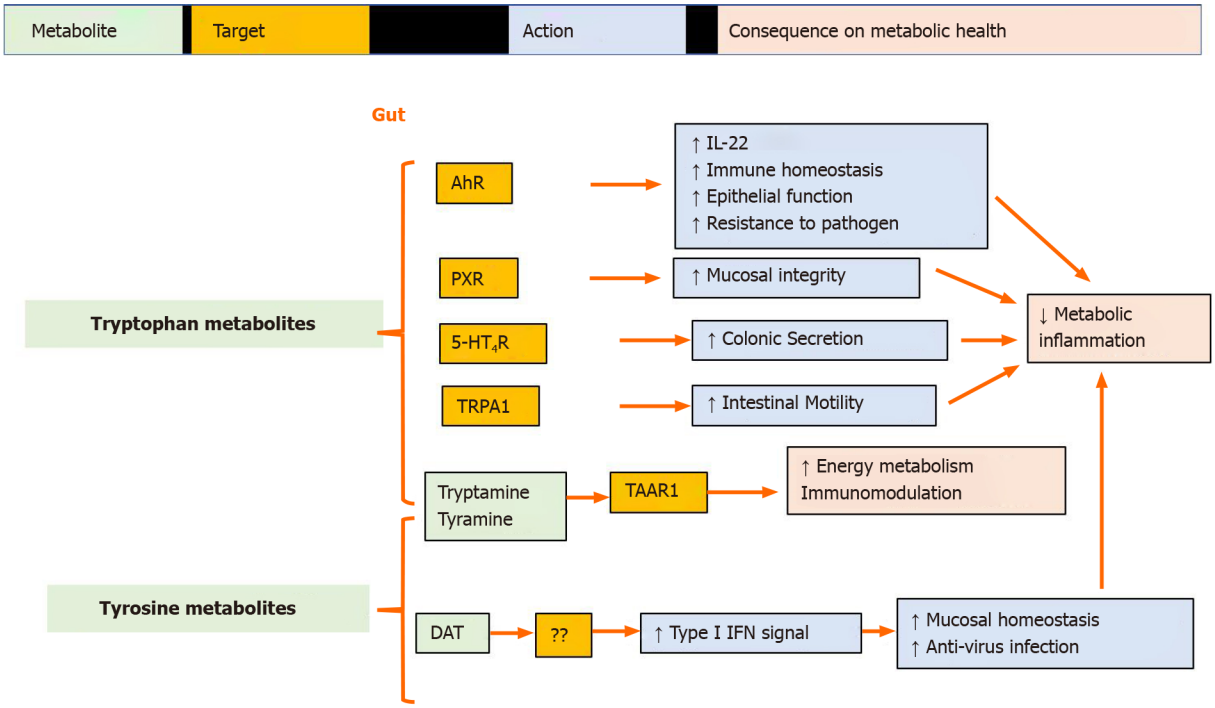

Figure 2 The roles of the indicated amino acid metabolites in mucosal homeostasis and metabolic health. Tryptophan and tyrosine metabolites can engage various molecular targets in the gut, and play positive roles in maintaining mucosal barrier integrity and regulating systemic metabolic health at least in part by modulating mucosal immune and epithelial cell functions *via* cytokine IL-22 or type I interferon, *etc.*, or by promoting host energy metabolism *via* trace amine-associated receptor 1. The question mark indicates that the molecular target of desaminotyrosine is currently unknown. 5-HT4R: Serotonin receptor-4; AhR: Aryl hydrocarbon receptor; DAT: Desaminotyrosine; PXR: Pregnane X receptor; TAAR1: Trace amine-associated receptor 1; TRPA1: Transient receptor potential ankyrin A1.

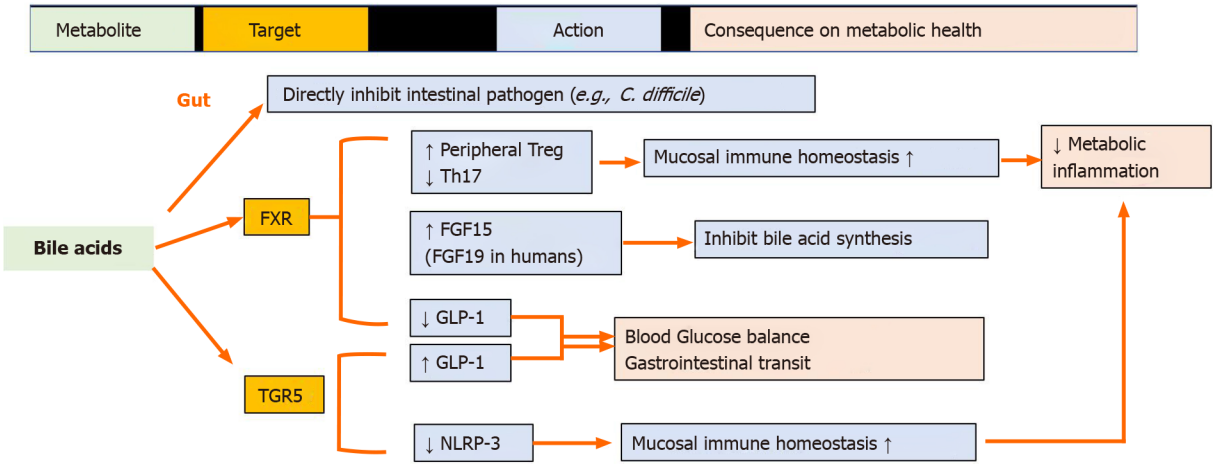

Figure 3 The roles of bile acids in mucosal homeostasis and metabolic health. Bile acids (BAs) have complicated roles in regulating mucosal immune cell activation and gut epithelial cell functions. Different BA profiles can produce both agonists and antagonists of their cognate receptors. Only the well-characterized intestinal targets of BAs and their actions are indicated here. FGF15: Fibroblast growth factor 15; FXR: Farnesoid X receptor; NLRP3: NLR family pyrin domain containing 3; TGR5: Membrane G protein-coupled bile acid receptor 1; Th17: T helper cells expressing IL-17a; Treg: Regulatory T helper cells.

Omega-6 polyunsaturated fatty acids (PUFAs) are abundant in the Western diet and can contribute to obesity and metabolic syndrome[93,94]. The increased ratio of omega-6/omega-3 fatty acids correlates with the incidence and prevalence of overweight individuals and obesity[94,95]. The gut microbiota confers host resistance to HFD-induced obesity by modulating dietary PUFA metabolism[96]. One of the metabolites is 10-hydroxy-cis-12-octadecenoic acid (HYA). HYA promotes GLP-1 secretion in colonic L cells and improves glucose homeostasis *via* the activation of GPR40 and GPR120. Additionally, HYA promotes intestinal peristalsis by acting as a low-affinity prostaglandin EP3 receptor agonist[96].

CONCLUSION

The gut microbiota plays a key role in obesity. Our current understanding of host–microbiota interactions remains in its early phase. Several challenges must be resolved before the field can be advanced. The design and use of microbes and their metabolites that are locally active in the gut without systemic side effects are promising novel and safe therapeutic modalities for metabolic diseases.

Abstract

BACKGROUND

Oral intake is dependent on the gastric ability to accommodate the food bolus. Comparatively, neonates have a smaller gastric capacity than adults and this may limit the volume of their milk intake. Yet, we previously reported that the newborn rat gastric milk volume is greatest after birth and, when normalized to body weight, decreases with postnatal age. Such age-dependent changes are not the result of intake differences, but greater gastric accommodation and reduced emptying rate.

AIM

Hypothesizing that breastmilk-derived adiponectin is the factor regulating gastric accommodation in neonates, we comparatively evaluated its effects on the rat fundic muscle tone at different postnatal ages.

METHODS

In freshly dispersed smooth muscle cells (SMC), we measured the adiponectin effect on the carbachol-induced length changes.

RESULTS

Adiponectin significantly reduced the carbachol-stimulated SMC shortening independently of age. In the presence of the inhibitor iberiotoxin, the adiponectin effect on SMC shortening was suppressed, suggesting that it is mediated *via* large-conductance Ca^{2+} sensitive K^+ channel activation. Lastly, we comparatively measured the newborn rat gastric milk curd adiponectin content in one- and two-week-old rats and found a 50% lower value in the latter.

Core Tip: Gastric accommodation regulates the stomach content volume. Lactating rats continuously breastfeed to keep a full gastric milk volume and their gastric emptying time is directly related to the gastric content volume. Little is known about the gastric fundic accommodation regulatory factors early in life. In this study, breastmilk-derived adiponectin is shown to promote gastric fundic relaxation, thus playing an important regulatory role during the lactating period.

INTRODUCTION

Among other factors, oral intake depends on the gastric muscle accommodation to its content. The estimated receptive gastric milk volume is 20 mL for a full-term infant[1]. For an average full-term infant weighing 3.5 kg, this amounts to 5.7 mL/kg receptive gastric volume. The comparative adult gastric receptive volume has not been adequately assessed, but often referred to as 600 mL, or 8.5 mL/kg for a 70 kg body weight person. The implications of a lower gastric receptive capacity in the immediate neonatal period, specially, for preterm infants, requires further evaluation.

Comparative studies addressing the nutritional benefit and risks associated with lower (150-180 mL/kg/d) and higher (> 200 mL/kg/d) total enteral feed intake for preterm infants have been conducted. A recent metanalysis of such studies reported limited data and concluded that insufficient evidence is available[2]. Yet, at least one recent review on nutritional support strategies for preterm infants advised that more gestationally mature neonates can tolerate and benefit from a daily milk intake as high as 240 mL/kg/d or 20 mL/kg/feed[3].

Since the recommended maximum daily intake of milk exceeds the estimated stomach receptive volume, adaptive mechanisms must be present to overcome the reduced gastric functional capacity early in life. In adult life, the gastric accommodation response to the food bolus increases the stomach receptive volume by relaxes the fundic muscle thus enabling the stomach to accommodate a larger volume. The factors regulating this response are incompletely understood, but involve activation of the oropharynx, stomach and duodenum[4].

Aside from increasing total enteral intake, gastric accommodation may also have an important role in maximizing its content emptying potential. We have previously reported that the rat gastric functional capacity is increased during the immediate neonatal period and this facilitates its content emptying rate[5]. Figure 1 shows our previously reported data on the rat gastric content volume and emptying rates early in life[5]. The younger the rat, the higher is the gastric milk content, such that in the one-week pup the volume after breastfeeding, is two-fold greater, when compared with measurements obtained in the second week of life[5]. The mechanism accounting for the age-related gastric accommodation changes, early in life, is poorly understood and the main goal of the present study.

Adiponectin is an adipose tissue-derived adipokine that plays a major role in appetite regulation and other important physiological mechanisms[6]. The adiponectin concentration in human and rodent breastmilk, is more than 40 folds greater, when compared with the other major adipokines present[7,8]. The available evidence

suggest that breast-derived adiponectin may play a functional role in the regulation of gastric milk volume accommodation. Adiponectin receptors are present in fetal rodents' gastrointestinal tract[9] and in the adult rat, adiponectin modulates gastric tone[10].

A study comparatively evaluating the maternal breastmilk adiponectin content and their infants' gastric emptying time showed an inverse relationship between these parameters[11]. That is to say that the higher the maternal adiponectin breastmilk content, the slower is their infant's gastric emptying time. This suggest that adiponectin plays a facilitating role in the stomach receptive potential for milk volume by increasing gastric accommodation. Such regulatory role has not been previously evaluated in the newborn.

Therefore, the main goal of this study was to evaluate the adiponectin effect on the newborn rat gastric fundic muscle response to an agonist-induced contraction. We hypothesized that adiponectin downregulates the newborn fundic muscle tone thus allowing for greater accommodation to a larger milk volume, early in life.

MATERIALS AND METHODS

Design

Studies were conducted in a laboratory setting utilizing newborn and adult rat gastric tissue.

Animals

Sprague-Dawley (Charles River, Montreal, QC, Canada) newborn (3-7 d old; n = 9; female n = 5, male n = 4), juvenile (8-14 d old; n = 4 female n = 2, male n = 2) and adult (> 60 d old; n = 7 female n = 2, male n = 5) rats were studied. The adult rats were fed a regular rodent diet composed of animal and vegetable protein (Certified Rodent Diet 5002, LabDiet, St. Louis, MO, United States) and housed under standard lighting and temperature conditions.

The animals were sacrificed with pentobarbital sodium injection (60 mg/kg i.p). Immediately after death, the gastric tissue was removed fresh for functional studies. The gastric milk curd was completely removed intact, snap-frozen in liquid nitrogen and stored at -80°C for less than one month, for later processing. The rationale for studying this stomach anatomical segment relates to the fact that accommodation of the food bolus occurs in the gastric fundus.

Freshly dispersed smooth muscle cells

To evaluate the adiponectin effect on the gastric muscle contraction independently of its innervation, and other tissue factors, as well as under the more physiologic isotonic conditions, we measured the individual smooth muscle cells (SMC) shortening response to this metabolite. In summary, the gastric tissue was digested in 1 mL/mg collagenase and 0.01% Soybean Trypsin Inhibitor (ThermoFisher, Burlington, Ontario, Canada) and the SMCs were dispersed in DMEM cell culture media (Wisent, St. Bruno, Quebec, Canada). One hour after dispersion the SMCs were exposed to carbachol-at a final media concentration of 10^{-4} for 15 min, while maintained at 37°C and 5% CO_2 in a conventional incubator in the absence or presence of adiponectin (4 μl/mL). To study the mechanism by which adiponectin downregulates smooth muscle contraction, we evaluated the iberiotoxin (10^{-7} M) pre-incubation effect on the carbachol-induced response.

Following this, the cells were immediately fixed with 1% acrolein. Cells maintained for a similar duration in Calcium-free PBS media served as control. Light microscopy images at 20 × magnification was obtained using Leica DM IRE2 microscope (Wetzlar, Germany) and the cells' length were measured using ImageJ (NIH, Bethesda, MA, United States). H_2O_2-induced cells length changes (shortening) were expressed as percentage of average control SMC length. The cells were obtained from seven newborns and five adult animals. A minimum of 50 H_2O_2-exposed and control cells from age group were evaluated.

Milk curd adiponectin content

Milk curds were obtained from newborn (3-7 d) and juvenile (8-14 d) rats. The curd proteins were extracted, and their adiponectin content quantified by utilizing a commercially available ELISA kit (RRP300, R&D systems) according to the manufacturer's recommendations. Briefly, the pup's milk curd was carefully extracted from the gastric cavity at once, after they were euthanized. The curd was weighed and sonicated in RIPA buffer for 5-10 s three times. The mixture was centrifuged at 17949 g. The separated middle layer (skim milk) was used for adiponectin measurement and protein quantification.

Statistical analysis

Data were first evaluated to determine Gaussian distribution by Skewness, Kurtosis and Omnibus testing. Normally distributed data were analyzed by parametric tests. Group differences were statistically evaluated by unpaired Student's t-test or two-way ANOVA with multiple comparisons obtained by the Tukey-Kramer test. Statistical significance was determined at $P < 0.05$. All statistical analyses were performed with the Number Cruncher Statistical System software (NCSS, Kaysville, Utah). Data are presented as mean ± SE.

The sample size utilized for each experiment is listed in the Figure legends and refers to SMC number. Given their high yield, we utilized large sample sizes for freshly dispersed SMCs, to minimize the possibility of a type I error.

RESULTS

SMCs derived from rat's gastric fundus significantly shortened in response to carbachol stimulation. One-, two-weeks and adult SMC showed a similar response. Pre-incubation with adiponectin suppressed the carbachol-induced SMC shortening at all ages (Figure 2).

To investigate the mechanism accounting for the adiponectin-dependent effect on the agonist-induced newborn fundic SMC shortening, we tested the effect of iberiotoxin on the response (Figure 3). This large-conductance Ca^{2+} sensitive K^+ channel inhibitor was shown, by others, to be involved in the adiponectin-induced vascular smooth muscle relaxation[12]. Following pre-incubation with iberiotoxin the carbachol-induced SMC shortening was not altered by the presence of adiponectin. This observation suggests that the adiponectin downregulation of agonist induced fundic SMC shortening is mediated *via* modulation of large-conductance Ca^{2+} sensitive K^+ channels.

Lastly, as a surrogate measurement of the maternal breastmilk concentration, we evaluated the newborn rat milk curd adiponectin content at one- and two-weeks of age. Adiponectin was present at both ages, but the one-week milk curd adiponectin content was two-fold higher, when compared with values obtained from two-week old rats (Figure 4).

DISCUSSION

The findings of the present study suggest that breastmilk-derived adiponectin is the key regulator of gastric milk volume and clearance rate in the neonatal rat. Activation of large-conductance Ca^{2+} sensitive K^+ channels in fundic smooth muscle cells by adiponectin mediates this response.

Whereas in humans, the newborn enteral intake is dependent on milk offer, rodent pups can independently breastfeed on demand. This leads to the well-known observation of a consistently milk-filled stomach in suckling newborn rats. Experiments conducted decades ago showed that the regulation of gastric content in the newborn rat is not based on satiety, but stomach distention[13]. In a recently published study, we took advantage of this unique neonatal behavior to evaluate *in vivo,* the developmental pattern of gastric content volume and emptying time.

We showed that the rat gastric content volume, normalized to body weight, is highest at one-week, when compared with the later breastfeeding period[5]. In addition, the newborn rat's gastric milk emptying rate is directly proportional to the stomach's curd volume[5]. We further documented that a similar positive correlation between gastric milk volume and its emptying rate is present in preterm neonates[14].

Such observations imply that, in the immediate neonatal period, an operative physiological mechanism is present and geared at maximizing enteral intake to enhance gastric accommodation to the milk volume. The present study findings suggest that breastmilk-derived adiponectin is the factor responsible for this gastric accommodation response in newborn rats.

By downregulating the fundic smooth muscle agonist-induced contraction potential, adiponectin increases gastric accommodation thus maximizing the stomach's milk volume retention. As shown in this study, the developmental pattern of this response is mediated not by age differences in the gastric SMC properties, but by the post-partum changes in breastmilk adiponectin content.

Adiponectin is an adipokine primarily secreted by adipose tissue that has important physiological modulatory roles[15]. These include anti-inflammatory, antioxidant, antiatherosclerosis, appetite regulation and insulin-sensitizing effects. Yet, its presence in breastmilk raises provocative questions about its function in neonates.

Adiponectin is secreted by the breast adipose tissue and is the most abundant adipokine in human breast milk[7]. In humans, the breastmilk adiponectin content is highest in the early postpartum period and decreases overtime[16]. Similar pattern of breastmilk adiponectin content and postpartum changes were previously reported in rats[17], and the finding confirmed in the present study. Most importantly, adiponectin is rapidly taken-up by the gastrointestinal tract resulting in peak serum concentrations two hours after enteral administration in newborn mice[8]. This suggest that breastmilk-derived adiponectin plays a functional role early in life.

AdipoR1 and AdipoR2, the two adiponectin receptors are expressed during embryogenesis in mice, with the former being the predominant one in most tissues[9]. These receptors are also present in adult rodents' gastric tissue and the electrical field

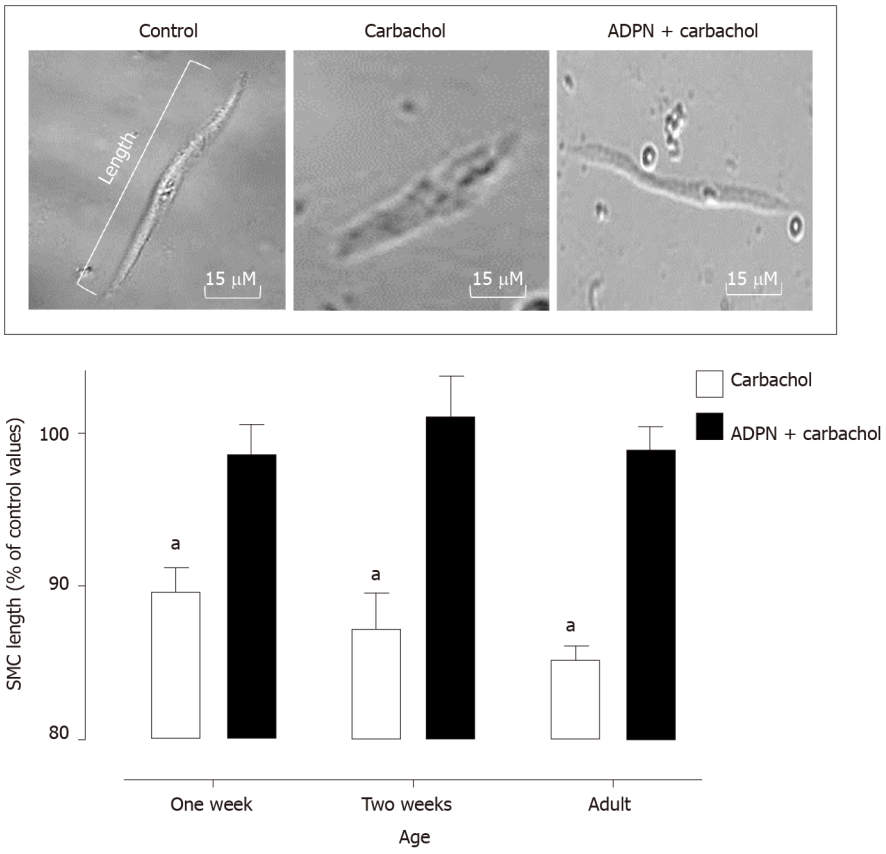

Figure 2 Smooth muscle cells shortening in response to carbachol stimulation (carbachol) in the absence and presence of adiponectin (ADPN + carbachol). Rat fundic smooth muscle cells (SMC) were freshly obtained from one- (*n* = 178: carbachol; *n* = 198: ADPN + carbachol), two-weeks (*n* = 109: carbachol; *n* = 93: ADPN + carbachol) old pups and adult rats (*n* = 924: carbachol; *n* = 564: ADPN + carbachol). Data are expressed as mean ± SE percentage of basal length measurements prior to contraction. $^{a}P < 0.01$ *vs* respective ADPN + carbachol. Insert shows representative SMC length measurements (magnification: 20 ×) under the different conditions. SMC: Smooth muscle cells.

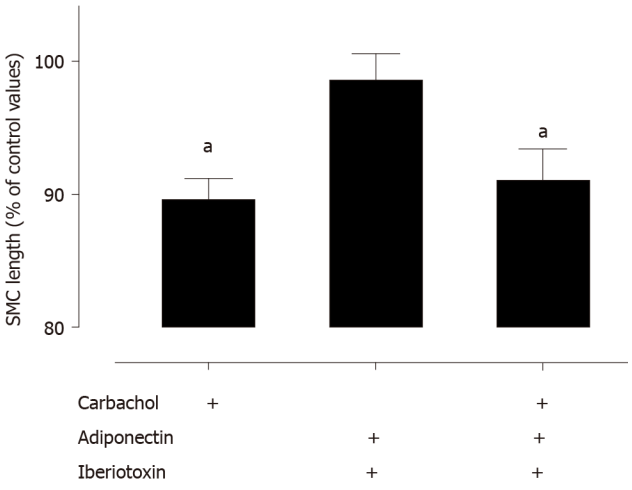

Figure 3 Newborn rat smooth muscle cell length expressed as a percentage of basal (non-stimulated; *n* = 178) length following pre-incubation with adiponectin and carbachol stimulation in the absence (*n* = 198) and pre-incubation presence of Iberiotoxin, a large-conductance Ca^{2+} sensitive K^{+} channel inhibitor (*n* = 96). Data are mean ± SE $^{a}P < 0.01$ *vs* basal smooth muscle cell length values. SMC: Smooth muscle cells.

stimulation contractile potential of its muscle is reduced in the presence of exogenous adiponectin[10,18]. Whether adiponectin modulates the nerve stimulus conduction, or the gastric smooth muscle itself if unclear since one study in adult mice showed an effect on the vagal nerve [18]. In adult mice, adiponectin downregulates gastric muscle cell excitability[19], but this report is the first to study fundic SMCs from a newborn

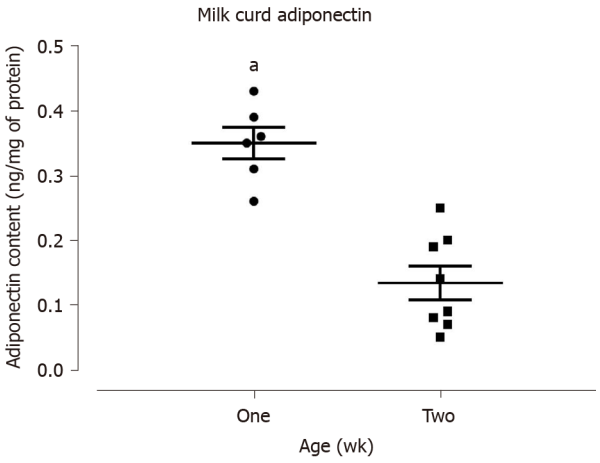

Figure 4 Freshly obtained, one-week old (*n* = 6) and two-weeks old (*n* = 8) rat milk curd adiponectin content. Data are shown as individual values and mean ± SE $^{a}P < 0.01$ *vs* two-weeks old values.

rodent.

Adiponectin not only reduces gastric muscle tone but has a similar effect on other smooth muscle dependent organs. In vascular tissue, adiponectin induces vasodilation [20] and reduces uterine contractions[21]. In the present study we evaluated the adiponectin effect on freshly dispersed rat SMCs from newborn, juvenile and adult animals. At all ages we documented a similar reduction in agonist-stimulated SMC shortening showing that adiponectin acts directly on the fundic muscle.

The signal-transduction pathway responsible for the adiponectin modulation of smooth muscle contraction remains unclear. In vascular tissue, adiponectin promotes endothelial-derived nitric oxide generation and it enhances its biological activity, both of which mediate the adiponectin vasodilatory response[22-24]. In addition, adiponectin has a direct effect on vascular smooth muscle large-conductance Ca^{2+} sensitive K^{+} channels that also result in reduced vasomotor tone[12,25].

The present data show that large-conductance Ca^{2+} sensitive K^{+} channels modulate the newborn rat gastric SMC contraction potential. Iberiotoxin, a large-conductance Ca^{2+} sensitive K^{+} channels inhibitor of rodent fundic muscle relaxation[26], suppressed the adiponectin-mediated reduction in the carbachol-induced shortening. Our findings are in keeping with the adult mice gastric fundus, where adiponectin hyperpolarized the SMC resting membrane potential resulting in reduced voltage-dependent Ca^{2+} currents[19].

In support of breastmilk being a major source of adiponectin to the newborn, we confirmed its presence in newborn and juvenile rats' milk curds. As previously shown to be the case for human breastmilk[16], we documented that the rat milk curds' adiponectin content was inversely proportional to postpartum age and two-fold lower in the second, when compared with first postnatal week.

Together our findings suggest that breastmilk-derived adiponectin plays an important role in the newborn rat milk volume intake. Human derived data support the current findings. An evaluation of mothers' breastmilk adiponectin content and their infants' gastric emptying time showed an inverse relationship between these parameters. The higher the breastmilk adiponectin the longer was the infant's gastric milk clearance[11].

This study has obvious limitations. Rat fundic SMCs agonist-induced shortening was used as a surrogate marker of gastric milk accommodation and the breastmilk adiponectin content was obtained from the newborn milk curds. Yet, it is well known that gastric accommodation to the food bolus depends on the fundic muscle relaxation [27] and thus the fundic SMC shortening response allows for the study of the adiponectin direct effect its muscle tone. Although the adiponectin content of the newborn gastric curd is probably not similar to the one from fresh breastmilk, if anything the former value is likely lower, when compared with breastmilk.

CONCLUSION

In conclusion, adiponectin reduces the gastric fundus motor tone allowing for greater

accommodation of the food bolus. This response is present in newborn-derived smooth muscle cells and mediated *via* large conductance Ca^{2+} sensitive K^+ channels. Breastmilk has a high adiponectin content and this adipokine likely enhances volume intake by increasing the gastric functional volume capacity (accommodation). These observations have translational importance since preterm infants are often fed either processed breastmilk or formula, both of which may not contain sufficient adiponectin to promote gastric fundic relaxation.

ARTICLE HIGHLIGHTS

Research background

Oral intake depends on the gastric ability to accommodate the food bolus. The preterm infant has a lower gastric capacity, normalized to body weight, when compared with adults, thus potentially limiting their milk intake. Yet, we previously shown that one-week rat pups milk intake is greater than observed, as they mature.

Research motivation

The main rationale for the study experiments was to understand the mechanism accounting for greater food accommodation early in life.

Research objectives

The main objective was to evaluate the hypothesis that the adiponectin in breast milk increases the newborn rat ability to accommodate the food bolus by reducing the fundic muscle tone.

Research methods

Rat freshly dispersed smooth muscle cells were used to measure the adiponectin effect on carbachol-induced fundic muscle shortening.

Research results

Adiponectin significantly reduced the carbachol-stimulated smooth muscle cells shortening independently of age, *via* large-conductance Ca^{2+} sensitive K^+ channel activation.

Research conclusions

Breast milk containing adiponectin regulates the newborn rat milk intake by increasing the gastric fundic accommodation potential.

Research perspectives

Maternal-neonatal interaction *via* breast milk components content provides a novel and likely important regulatory role on intake volume early in life.

Abstract

BACKGROUND

Helicobacter pylori (*H. pylori*), a bacterium that infects approximately half of the world's population, is associated with various gastrointestinal diseases, including peptic ulcers, non-ulcer dyspepsia, gastric adenocarcinoma, and gastric lymphoma. As the burden of antibiotic resistance increases, the need for new adjunct therapies designed to facilitate *H. pylori* eradication and reduce negative distal outcomes associated with infection has become more pressing. Characterization of the interactions between *H. pylori*, the fecal microbiome, and fecal fatty acid metabolism, as well as the mechanisms underlying these interactions, may offer new therapeutic approaches.

draft of the manuscript; all authors approved the final version of the article.

AIM

To characterize the gut microbiome and metabolome in *H. pylori* patients in a socioeconomically challenged and underprivileged inner-city community.

METHODS

Stool samples from 19 *H. pylori* patients and 16 control subjects were analyzed. *16S rRNA* gene sequencing was performed on normalized pooled amplicons using the Illumina MiSeq System using a MiSeq reagent kit v2. Alpha and beta diversity analyses were performed in QIIME 2. Non-targeted fatty acid analysis of the samples was carried out using gas chromatography-mass spectrometry, which measures the total content of 30 fatty acids in stool after conversion into their corresponding fatty acid methyl esters. Multi-dimensional scaling (MDS) was performed on Bray-Curtis distance matrices created from both the metabolomics and microbiome datasets and a Procrustes test was performed on the metabolomics and microbiome MDS coordinates.

RESULTS

Fecal microbiome analysis showed that alpha diversity was lowest in *H. pylori* patients over 40 years of age compared to control subjects of similar age group. Beta diversity analysis of the samples revealed significant differences in microbial community structure between *H. pylori* patients and control subjects across all ages. Thirty-eight and six taxa had lower and higher relative abundance in *H. pylori* patients, respectively. Taxa that were enriched in *H. pylori* patients included *Atopobium*, Gemellaceae, Micrococcaceae, Gemellales and *Rothia* (*R. mucilaginosa*). Notably, relative abundance of the phylum Verrucomicrobia was decreased in *H. pylori* patients compared to control subjects. Procrustes analysis showed a significant relationship between the microbiome and metabolome datasets. Stool samples from *H. pylori* patients showed increases in several fatty acids including the polyunsaturated fatty acids (PUFAs) 22:4n6, 22:5n3, 20:3n6 and 22:2n6, while decreases were noted in other fatty acids including the PUFA 18:3n6. The pattern of changes in fatty acid concentration correlated to the Bacteroidetes:Firmicutes ratio determined by *16S rRNA* gene analysis.

CONCLUSION

This exploratory study demonstrates *H. pylori*-associated changes to the fecal microbiome and fecal fatty acid metabolism. Such changes may have implications for improving eradication rates and minimizing associated negative distal outcomes.

Key Words: Gut microbiome; Metabolome; *Helicobacter pylori*; Antibiotic resistance; Dysbiosis; Eradication

Core Tip: *Helicobacter pylori* (*H. pylori*) infects half of the world's population and is associated with various diseases, including malignancy. Research of microbiome and metabolomic changes associated with *H. pylori* may hold therapeutic potential. We sought to characterize the fecal microbiome and fatty acid metabolism among *H. pylori* patients in our community. We observed differences in alpha and beta diversity among *H. pylori* patients compared to controls, particularly for those over 40 years old. Changes in several fecal fatty acids, including those associated with anti-inflammatory activity, were observed. Our findings may have implications for improving *H. pylori* eradication and minimizing associated negative distal outcomes.

INTRODUCTION

Helicobacter pylori (*H. pylori*), a bacterium found in the stomach of roughly half of the world's population, is associated with various gastrointestinal diseases, including peptic ulcers, non-ulcer dyspepsia, gastric adenocarcinoma, and gastric lymphoma. Although many infections are asymptomatic, eradication of *H. pylori* has been shown to reduce the incidence of gastric cancer and is thus universally recommended[1]. For decades, clarithromycin-based triple therapy was considered the first-line therapy for *H. pylori* eradication and associated gastric cancer prevention. Following the global trend in emerging antibiotic resistance, rates of clarithromycin, metronidazole, and levofloxacin resistance among *H. pylori* strains have increased markedly, causing an alarmingly high rate of eradication failure[2]. In the absence of universally available antibiotic susceptibility testing, current guidelines advocate for the use of empiric quadruple therapy strategies; however, the efficacy of these regimens may be limited by dual resistance, local availability, and patient adherence[3].

As the burden of antibiotic resistance increases, the need for new adjunct therapies designed to facilitate *H. pylori* eradication and reduce negative distal outcomes associated with infection has become more pressing. The relationship between *H. pylori* and the microbiome has garnered particular attention of late[4]. With the advent of high throughput *16S rRNA* gene sequencing methods and open-source software for subsequent analysis and visualization, researchers have been able to characterize changes in microbial diversity and community structure, as well as specific taxa that are differentially abundant in association with particular phenotypes[5]. Many studies have focused on *H. pylori*-mediated changes to the gastric microbiome, in which data have demonstrated variable effects on multiple metrics of microbial diversity and community structure[4]. *H. pylori*-associated gastric dysbiosis is particularly significant in the context of studies which suggest increased relative abundance of particular taxa, including *Lactobacillus* and *Lachnospiraceae*, among patients who develop premalignant lesions and gastric cancer[6,7]. *H. pylori*-associated gastric dysbiosis has also prompted researchers to evaluate the adjunct therapeutic role of probiotics, which may increase the rate of *H. pylori* eradication and limit negative side effects of antibiotic treatment[8-11].

More recently, researchers have also focused on the impact of *H. pylori* infection on distal gut, *i.e.*, fecal microbiota. Despite *H. pylori's* role as an almost exclusively gastric pathogen, animal and clinical studies have demonstrated alterations in distal gut microbiota associated with *H. pylori* infection[12-15]. The mechanisms by which gastric *H. pylori* infection may influence the distal gut microbiome are unclear, although authors have speculated that multiple factors, including alterations in hydrochloric acid secretion, gastrointestinal hormones, and immune regulation, may be involved [12-14]. As stated above, microbiome modulation with probiotics may have a role in improving eradication rates and minimizing adverse effects of antibiotics. Additionally, *H. pylori*-mediated changes to the distal gut microbiome may be significant in the context of research that implicates gut dysbiosis in the development of colorectal cancer (CRC)[16]. Indeed, authors of a large case-control study found that seropositivity for the *H. pylori* virulence factor VacA was associated with increased odds of CRC[17]. The well-documented associations between gut dysbiosis, type 2 diabetes, and metabolic syndrome has also prompted speculation about the role of *H. pylori*-associated gut dysbiosis in diabetes, which has been associated with *H. pylori* infection [18-21]. Further characterization of the interactions between *H. pylori* and the gut microbiome, as well as the mechanisms underlying these interactions, may lead to a better understanding of the role of microbiome modulation in *H. pylori* therapy, as well as the development of novel therapies and screening tools aimed at the negative distal outcomes associated with *H. pylori* infection, including CRC and metabolic diseases.

Given the association between *H. pylori* infection and gastrointestinal inflammation, attention has also been paid to compounds with anti-inflammatory activity, including fatty acids. Polyunsaturated fatty acid (PUFA) supplementation in particular may have therapeutic potential for *H. pylori* treatment *via* multiple mechanisms, including suppression of inflammatory cytokines and enzymes and direct bacteriocidal effects *via* disruption of cell membranes[22-24]. 10-hydroxy-cis-12-octadecenoic acid (10-HOE; a linoleic acid derivative) and docosahexaenoic acid (DHA) have both been shown to inhibit *in vitro* growth of *H. pylori* and gastric infection in mouse models[25,26]. Nevertheless, the effects of *H. pylori* infection on fatty acid metabolism in the gastrointestinal tract are not completely understood. Furthermore, the extent to which such metabolomic changes may relate to alterations in the gastrointestinal microbiota are unknown. Notably, short-chain fatty acids (SCFAs) produced by gut microbiota

are thought to play a role in intestinal homeostasis, regulation of immune function, and dysbiosis in the setting of inflammatory bowel disease, which is associated with decreased levels of these important molecules[27,28]. Exploration of changes in fatty acid production and metabolism associated with *H. pylori*-mediated alterations of the fecal microbiome is warranted, as it may reveal strategies to inhibit the cascade of events leading to neoplasia.

Previously, we studied the pattern of *H. pylori* prevalence and antibiotic resistance in our socioeconomically challenged and underprivileged inner-city community[29]. As a next step, we then sought to characterize the gut microbiome associated with *H. pylori* infection in our patients. We further explored interactions among *H. pylori* infection, the gut microbiota, and the gut metabolome by comparing stool fatty acid profiles between subjects with and without *H. pylori* infection. Our overarching goal is to identify potential targets for intervention that could improve *H. pylori* eradication rates and limit associated negative distal outcomes.

MATERIALS AND METHODS

Patients and sample collection

Patients presenting to the Cooper Digestive Health Institute in Camden, New Jersey were recruited for our study. *H. pylori* patients at least 18 years of age and diagnosed *via* biopsy between June 1, 2017 and December 31, 2019, were eligible for inclusion. Patients less than 18 years old, pregnant women, patients taking antibiotics at the time of recruitment or sampling, and non-English speaking patients were excluded from participation. *H. pylori*-positive patients are identified in our electronic medical record system (EPIC) by ICD-9 codes of 041.86, 531.90, 535.60, 795.79, 008.47, 531.00, V12.08. Histological examination of the biopsied samples showed positive outcome indicating *H. pylori* infection. Control participants were recruited from a healthy population, also seen at Cooper Health Institute for well visits. The control subjects were screened for lack of previous history and current documentation for *H. pylori* infection as well as lack of any GI-related symptoms before recruitment. Their stools were tested by reverse transcription-polymerase chain reaction (PCR) based biprobe assay for presence of *H. pylori* DNA[30]. None of the stool samples from the control subjects showed presence of *H. pylori* DNA. Informed consent was obtained by one of several Institutional Review Board (IRB)-approved team members. Surveys about demographic information and relevant medical history were collected. Information on diagnosis, disease features, medication, history of antibiotic use, and treatment regimen were collected from the electronic medical record. Patients were asked to provide a stool sample before initiating eradication therapy, and samples were collected and stored in Stool Nucleic Acid Collection and Preservation Tubes (Cat. No. 45630, 45660, Norgen Biotek Corp., Thorold, Ontario, Canada) prior to freezing at –80 ℃ as described previously[29].

Processing of samples and 16S rRNA gene sequencing

Total genomic bacterial DNA extraction was performed from frozen fecal samples using the Qiagen DNeasy PowerSoil HTP Kit (Cat. No. 12955-4, Qiagen, Valencia, CA, United States). Adequate DNA yield was confirmed using NanoDrop spectrophotometry. For high throughput sequencing, 515F–806R Golay barcodes were used to target the hypervariable V4 region of the *16S rRNA* gene, which is highly conserved and ideal for gut microbiome analysis. Marker genes in isolated DNA were PCR-amplified using GoTaq Master Mix (Cat. No. M5133, Promega, Madison, WI, United States) as described in Caporaso *et al*[31]. PCR products were cleaned and normalized using the SequalPrep™ Normalization Plate Kit (Cat. No. A1051001, ThermoFisher, Waltham, MA, United States) following the manufacturer's instructions. Purification of PCR product amplicons was performed with the QIAquick PCR Purification Kit (Cat. No. 28104, Qiagen). Quantification of the PCR amplified library was performed with the Invitrogen™ Quant-iT™ PicoGreen™ dsDNA Assay Kit (Cat. No. P7589, ThermoFisher). *16S rRNA* gene sequencing was performed on normalized pooled amplicons using the Illumina MiSeq System using a MiSeq reagent kit v2 (300 cycles; Cat. No. MS-102-2002, Illumina Inc.). FASTQ files for reads 1 (forward), 2 (reverse), and the index (barcode) read were generated using the BCL-to-FASTQ file converter bcl2fastq (ver. 2.17.1.14, Illumina, Inc.). Sequencing of the samples was conducted at the University of Colorado Boulder BioFrontiers Next-Gen Sequencing core facility.

Sequencing data analysis

Analysis was performed using Python-based packages (Python 3.6.12), QIIME 2 2019.4 (denoising and taxonomy assignment), Quantitative Insights Into Microbial Ecology (QIIME) 2 2020.11 (statistical testing), and Linear Discriminant Analysis (LDA) using LDA Effect Size (LEfSe)[32,33]. Sequences were de-multiplexed, then filtered and clustered into sub-operational taxonomic units (sOTUs) using QIIME 2 DADA2[34]. A masked phylogenetic tree was created using MAFFT *via* QIIME2[35,36]. Taxonomy was assigned using a naïve-Bayes classifier based on the latest Greengenes *16S rRNA* gene database available as of August 2019 *via* the QIIME 2 interface (gg_13_8). Additional Python packages (SciPy.stats, Scikit-bio) were used for statistical tests on QIIME 2-generated data. Inter-class comparisons were made based on attributes of our population including: *H. pylori* status, gender, age group, race, education, and alcohol use. Alpha and beta diversity analyses were performed in QIIME 2, rarefied to an even sampling depth of 22400[37]. Alpha diversity was assessed by Faith's phylogenetic diversity, chao1 index, and observed OTUs. Differences in alpha diversity between groups were determined by Kruskal-Wallis non-parametric rank test for categorical variables or by Fisher Z transformation on Spearman rho values for differences between alpha diversity correlations with numeric data across groups. Bacterial composition (beta diversity) was analyzed by principal coordinate analyses (PCoA) of both unweighted and weighted unique fraction metric (UniFrac) phylogenetic distance matrices[38-41]. Beta diversity was assessed for statistical significance between groups using Monte Carlo permutations [Adonis and permutational multivariate analysis of variance (PERMANOVA)], and dispersion of group samples was assessed using permutational analysis of multivariate dispersions (PERMDISP)[42,43]. Comparisons of relative abundances of microbial taxa between groups were performed using LEfSe with the Segata *et al*[44] online interface. Taxa with an LDA value of 2.0 or greater and a two-tailed P value ≤ 0.05 with Kruskal-Wallis and pairwise Wilcoxon analyses were considered significantly enriched. The code is available at https://github.com/sterrettJD/H-pylori-microbiome-analysis.

Non-targeted fatty acid analysis

Collected fecal samples were stored at –80 ℃ until analysis. Sample preparation and analysis were performed using gas chromatography-mass spectrometry (GC-MS) by Metabolon, Inc. (Durham, NC, United States). This method (Metabolon TAM112-002) measures the total content of 30 fatty acids in stool samples after conversion into their corresponding fatty acid methyl esters (FAMEs). The measured concentrations are provided in weight corrected μg/g of sample. NQ (not quantified-below the lower limit of quantification) values were treated as a concentration of 0.001 mg/mL.

Briefly, stool samples were homogenized and the suspension was weighed out in a 100 mg aliquot in a test tube. Liquid/Liquid extraction was performed to extract fatty acids and remove the nucleic acid preservative. A 250 μL aliquot of each extract was transferred to a clean analysis tube. The solvent was removed by evaporation under a stream of nitrogen. Internal standard solution was added to the dried sample extracts, quality controls (QCs), and calibration standards. The solvent was again removed by evaporation under a stream of nitrogen. The dried samples and QCs were subjected to methylation/transmethylation with methanol/sulfuric acid, resulting in the formation of the corresponding methyl esters (FAME) of free fatty acids and conjugated fatty acids. The reaction mixture was neutralized and extracted with hexanes. An aliquot of the hexanes layer was injected onto a 7890A/5975C GC-MS system (Agilent Technologies, Santa Clara, CA, United States). Mass spectrometric analysis was performed in the single ion monitoring positive mode with electron ionization. Quantitation was performed using both linear and quadratic regression analysis generated from fortified calibration standards prepared immediately prior to each run. Raw data were collected and processed using Agilent MassHunter GC-MS Acquisition B.07.04.2260 and Agilent MassHunter Workstation Software Quantitative Analysis for GC-MS B.09.00/ Build 9.0.647.0. Data reduction was performed using Microsoft Office 365 ProPlus Excel. Volcano plot data are included as Supplementary Tables 1-3 (Supplementary Table 1: Volcano plot data with all *Helicobacter* data set; Supplementary Table 2: Volcano plot data with High Bacteroidetes; Supplementary Table 3: Volcano plot data with High Firmicutes).

Procrustes analysis

Multi-dimensional scaling (MDS, using the Python package Scikit-learn) was performed on Bray-Curtis distance matrices created from both the fecal metabolome and fecal microbiome datasets (using the Python package SciPy.distance), and a Procrustes

test was performed on the metabolomics and microbiome MDS coordinates. As described by Peres-Neto and Jackson, a Procrustes randomization test (PROTEST) was performed by randomly sampling the MDS coordinates and performing a Procrustes test on the reordered coordinates 10000 times, and the *P* value was calculated based on the portion of randomized Procrustes tests with resulting m^2 (Gower's statistic) scores lower than the Procrustes m^2 score of the observed datasets[45].

Ethics approval

This study received approval by the Cooper Health System IRB (17-077EX) and all the steps were carried out as *per* the standards set by the IRB.

RESULTS

Fecal microbiome analysis

Selected demographic attributes of our participants are presented in Table 1. Fecal microbiome analysis of 35 stool samples collected from 19 *H. pylori* patients and 16 healthy control subjects was carried out. The mean number of reads *per* sample was 269462 with a minimum of 22483 reads/sample. Rarefaction was set to 22400 for even sampling based on this minimum. We analyzed the association of each of the factors included in Table 1 with alpha and beta diversity (*via* Kruskal-Wallis and PERMANOVA for nominal variables or *via* Spearman correlation and Mantel test for numerical variables, respectively). Age was the only factor that showed statically significant differences (*P* value of $\leq$ 0.05) in alpha diversity in the *H. pylori* patients compared to the control participants, with *H. pylori* patients over 40 years of age having lower richness than control participants over 40 years of age. Significant differences in community composition and group dispersion were seen between *H. pylori* patients and control participants.

Information was collected about each participant regarding (1) If they had been treated for *H. pylori* infection in the past; (2) If so, the date infection was diagnosed; (3) Treatments given; and (4) Outcomes: Eradication testing with dates. Only one patient had *H. pylori* infection 10 years ago and had successfully completed treatment at that time. History about antibiotic treatments for any infection and proton pump inhibitors (PPIs) use for both *H. pylori* patients and control subjects in the past five years was also documented and these data values were included in the statistical analyses. Our statistical analyses showed that the differences seen in *H. pylori* patients were not due to the previous treatments.

Analysis of alpha diversity

Chao1 index alpha diversity between *H. pylori* patients and control subjects and regression analysis of observed OTUs by age are shown in Figure 1. Alpha diversity, which estimates the diversity of a microbial community within a sample, incorporates the number of different OTUs and their respective abundance in each sample. Alpha diversity was lowest in *H. pylori* patients over 40 years of age, who had significantly lower Chao1 scores compared to control subjects over 40 years of age (Kruskal-Wallis $H = 6.036$, $P = 0.014$). *H. pylori* patients over 40 years old also had lower Chao1 scores approaching statistical significance when compared to *H. pylori* patients under 40 (Kruskal-Wallis $H = 2.813$, $P = 0.094$). Additionally, the correlation of age with observed OTUs (Figure 1B), Faith's phylogenetic diversity, and Chao1 was consistently different between *H. pylori* patients *vs* control subjects, as evidenced by a Fisher *Z* transformation on Spearman rank correlation *rho* values (observed OTUs: *H. pylori rho* = –0.21 *vs* control *rho* = 0.50, Fisher $P = 0.041$; Faith: *H. pylori rho* = –0.04 *vs* control *rho* = 0.57, Fisher $P = 0.067$; Chao1: *H. pylori rho* = –0.15 *vs* control *rho* = 0.44, Fisher $P = 0.097$).

Analysis of beta diversity

Next we analyzed beta diversity of our samples, which estimates how samples differ from each other. An unweighted UniFrac PCoA plot of *H. pylori* patients *vs* control subjects is shown in Figure 2. Adonis testing revealed that current *H. pylori* infection represented 7% of the variation in unweighted UniFrac beta diversity ($F = 2.523$, $R^2 = 0.071$, $P = 0.002$). Additionally, unweighted UniFrac PERMANOVAs identified significant differences between *H. pylori* patients and control subjects ($F = 2.523$, $P = 0.001$). Furthermore, unweighted UniFrac PERMDISP did not reveal differences in dispersion among *H. pylori* patients *vs* control subjects ($F = 0.0506$, $P = 0.809$), but

H. pylori: *Helicobacter pylori*.

weighted UniFrac PERMDISP did (F = 6.82955, P = 0.017). We also explored the effect of the use of PPIs *via* beta diversity analysis as PPIs are the medications commonly given to *H. pylori* patients and we had previously noted their influence on the antibiotic resistance of *H. pylori*[29]. Unweighted UniFrac PERMANOVA identified differences between PPI users and non-users across all participants (F = 1.939, P = 0.012), though the magnitude of the effect was smaller than that seen for *H. pylori* infection as described above. It should also be noted that only four *H. pylori* patients and one control subject were on PPI at the time of study and sample collection, so its contribution to the results described here may not be significant.

LDA effect size

LEfSe scores for taxa that were differentially distributed across *H. pylori* patients *vs* control subjects are shown in Figure 3. Thirty-eight taxa had lower relative abundance in *H. pylori* patients relative to healthy control subjects, and six taxa had higher relative abundance in *H. pylori* patients relative to healthy control subjects. Taxa that were enriched in *H. pylori* patients include *Atopobium,* Gemellaceae, Micrococcaceae, Gemellales and *Rothia* (*R. mucilaginosa*). Figure 4 shows the arcsin square root transformed relative abundances of each phylum, grouped by *H. pylori* status. Notably, relative abundance of the phylum Verrucomicrobia, and its main constituent, *Akkermansia muciniphila*, was decreased in *H. pylori* patients compared to control subjects.

Procrustes analysis

The Procrustes randomization test was carried out to investigate the relationship between the fecal microbiome and fecal metabolome. Procrustes analysis identified a significant relationship between the two datasets, as the resulting P value of 0.017

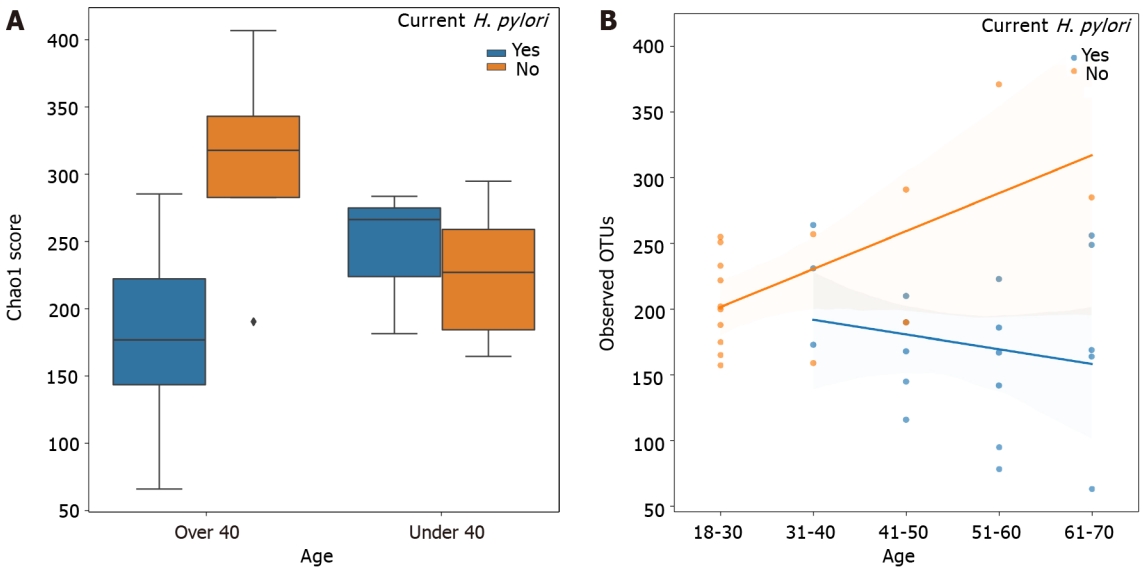

Figure 1 Chao1 index alpha diversity and observed operational taxonomic units by *Helicobacter pylori* status stratified by age. A: Chao1 index alpha diversity is compared between *Helicobacter pylori* (*H. pylori*) patients (blue) and control subjects (orange), subgrouped by age. *H. pylori* patients over 40 years old (n = 16) had significantly lower Chao1 scores compared to control subjects over 40 (n = 4) (Kruskal-Wallis H = 6.036, P = 0.014). Boxes represent 1st and 3rd quartiles, and central lines represent median values. Whiskers represent non-outlier high and low values. Points show outliers, which were determined by having a distance from the 1st or 3rd quartile greater than 1.5 times the interquartile range; B: Observed operational taxonomic units (operational taxonomic units) are compared between *H. pylori* patients (blue, n = 19) and control subjects (orange, n = 16), as a function of age. Shading around the regression lines indicates 95% confidence intervals. OTU: Operational taxonomic units; *H. pylori*: *Helicobacter pylori*.

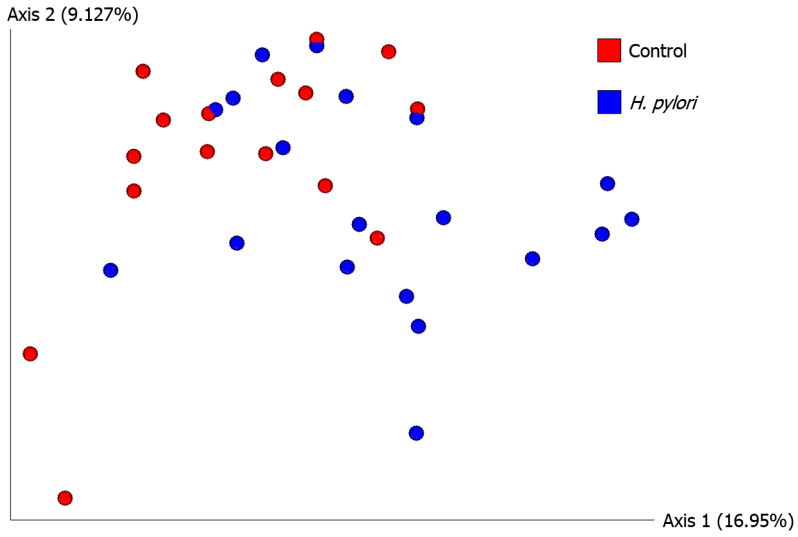

Figure 2 Beta diversity analysis by unweighted UniFrac principal coordinate analysis. Unweighted principal coordinate analysis (PCoA) plot is shown comparing *Helicobacter pylori* (*H. pylori*) patients (blue, n = 19) to control subjects (red, n = 16). Significant differences between *H. pylori* patients and control subjects were identified by unweighted UniFrac PERMANOVA (F = 2.523, P = 0.001). The proportion of variance explained by each principal coordinate axis is denoted in the corresponding axis label; PCo1 explains 16.95% of the variability and PCo2 explains 9.13% of the variability. *H. pylori*: *Helicobacter pylori*.

indicates that the correspondence of each participant's fecal microbiome to their fecal metabolome was better than 98% of randomly sampled simulations (Figure 5).

Fecal fatty acid analysis

To evaluate the impact of *H. pylori* infection on fatty acid composition, we performed non-targeted metabolomics analysis of a panel of 30 fatty acids including long chain fatty acids (LCFAs), monounsaturated fatty acids (MUFAs) and PUFAs. We prepared a volcano plot evaluating changes in fatty acid profile for the entire population of *H. pylori* patient samples relative to healthy control subjects (Figure 6A). In addition, we prepared separate volcano plots for subgroups of the *H. pylori* patients with high Bacteroidetes and high Firmicutes based on *16S rRNA* gene analysis (Figure 6B and C).

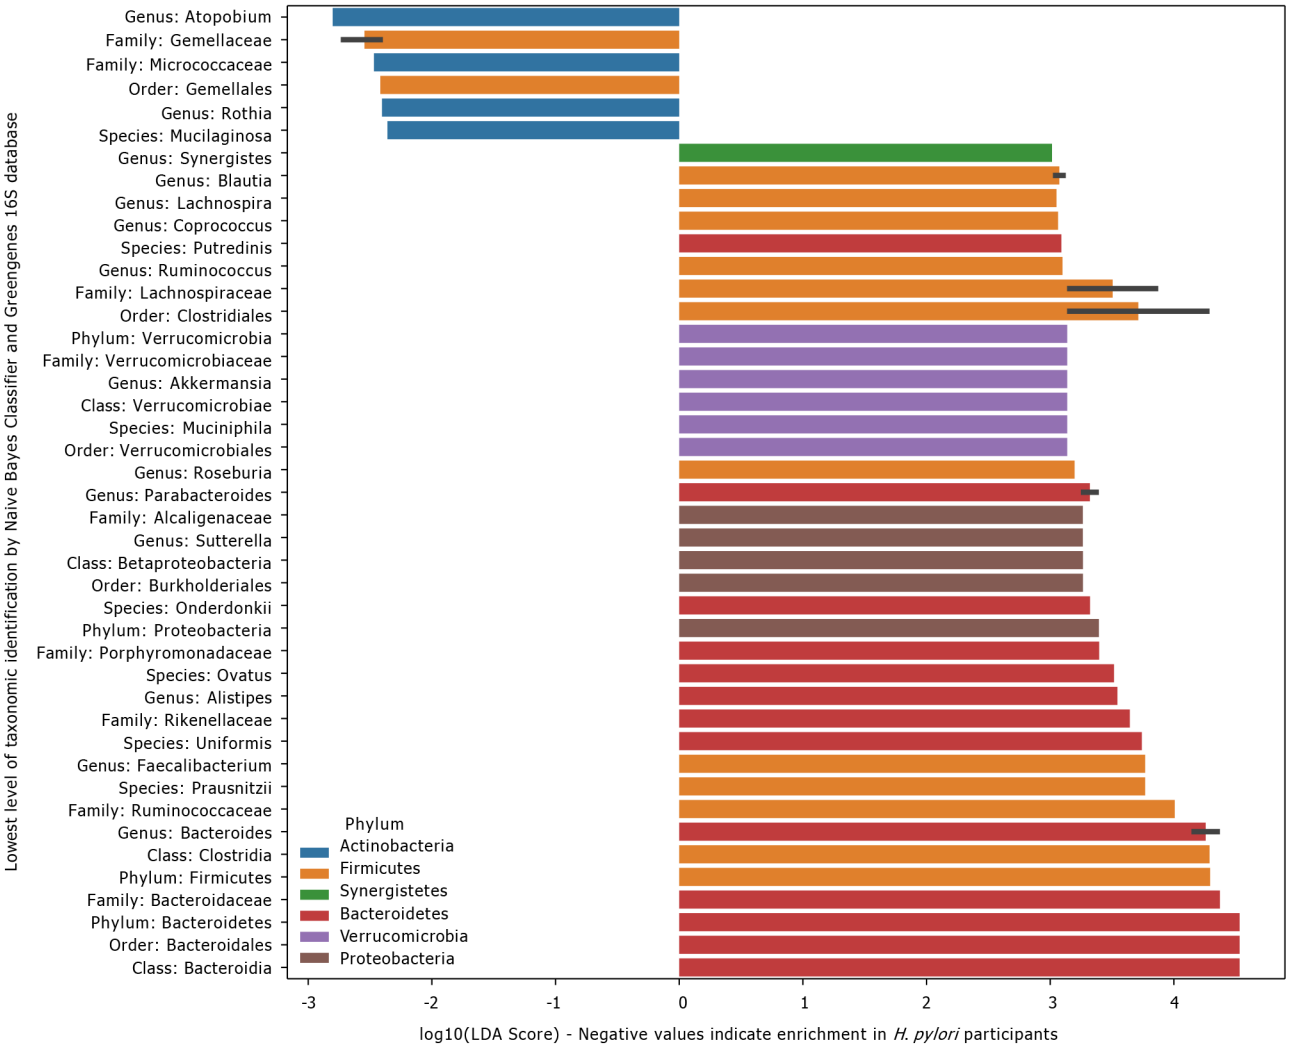

Figure 3 Linear discriminant analysis effect size scores for taxa enriched in *Helicobacter pylori* or control participants. Linear discriminant analysis effect size (LEfSe) scores for taxa that were differentially distributed across *Helicobacter pylori* (*H. pylori*) patients (n = 19) *vs* control subjects (n = 16) *via* Kruskal-Wallis and Wilcoxon tests with two-tailed α = 0.05. Negative values represent taxa that were enriched in *H. pylori* patients, whereas positive values represent taxa that were enriched in control subjects. Error bars represent a 95% confidence interval and are only present if the listed taxonomic identity was the lowest level classified for multiple operational taxonomic units highlighted by LEfSe. Color represents the phylum. *H. pylori*: *Helicobacter pylori*.

See Supplementary Tables 1-3 for the full volcano plot data. Volcano plots allow for the plotting of *P* values *vs* fatty acid fold change from control samples for all evaluated fatty acids.

Stool samples from *H. pylori* patients showed increases in several fatty acids including the PUFAs 22:4n6, 22:5n3, 20:3n6 and 22:2n6 while decreases were noted in fatty acids including the PUFA 18:3n6, relative to healthy control subjects. The pattern of changes in fatty acid concentration was correlated to the Bacteroidetes:Firmicutes ratio (determined by *16S rRNA* gene analysis). Among the sub-population of *H. pylori* patients identified to have high Bacteroidetes (Bacteroidetes:Firmicutes ratio ≥ 1 standard deviation above the ratio in control participants, n = 7) we found several fatty acids that were diminished relative to control participants including the LCFAs 24:0, 22:0 and 15:0 along with MUFAs 20:1n9 and 18:1n9. By contrast, in the sub-population of *H. pylori* patients identified to have high Firmicutes (Firmicutes:Bacteroidetes ratio ≥ 1 standard deviation above ratios in control participants; n = 4) a distinct set of fatty acids were found to be significantly increased and decreased relative to control participants. In this subpopulation of *H. pylori* patients we observed increases in the PUFA 22:2n6 and decreases in PUFAs 18:3n6 and 20:4n3 relative to control participants.

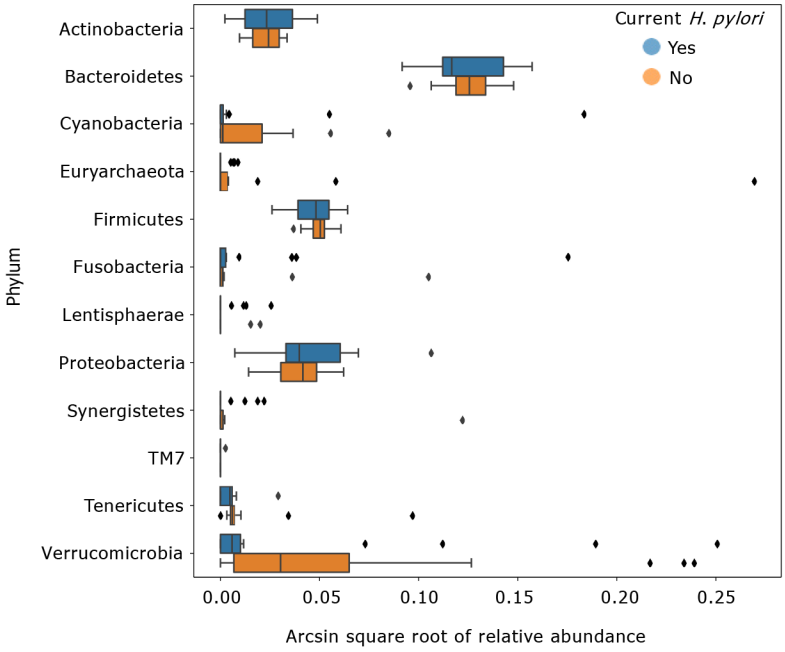

Figure 4 Transformed relative abundances of phyla grouped by *Helicobacter pylori* infection. Arcsin square root transformed relative abundances of each phylum, grouped by *Helicobacter pylori* (*H. pylori*) status. Bacterial relative abundances of *H. pylori* patients (n = 19) are shown in blue, whereas healthy controls (n = 16) are shown in orange. Boxes represent the 1st and 3rd quartiles, and vertical lines in the middle of the boxes represent median values. Whiskers represent the lowest and highest non-outlier values. Points show outliers, which were determined by having a distance from the 1st or 3rd quartile greater than 1.5 times the interquartile range. Of note, relative abundances of Verrucomicrobia were significantly lower in *H. pylori* patients compared to healthy controls (Kruskal-Wallis H = 4.455, P = 0.034). *H. pylori*: *Helicobacter pylori*.

DISCUSSION

As little is known about the microbiome of *H. pylori* patients in an underprivileged community, this study is useful due to its exploratory nature. A sample size calculation for microbiome analysis was not thus performed prior to collecting samples. Casals-Pascual *et al*[46] outline that in human microbiome studies knowledge of the baseline microbiome diversity and composition, along with knowledge of the magnitude of changes that confer clinically relevant outcomes are important for determining sample size. However, this could not easily be predicted in our sample demographic due to lack of previous research. Though the effects of *H. pylori* and low socioeconomic status (SES) on the gut microbiome have been investigated separately in previous studies, the two states (*H. pylori* infection and low SES) could potentially have conflicting relationships with diversity and composition, making it difficult to determine the baseline microbiome diversity and composition without large assumptions. Thus, much of this study provides the baseline to characterize the microbiome of *H. pylori* patients in an underserved population, which was previously understudied to a degree by which sample size calculations would have required a large number of assumptions. Though the power is likely weak in this study, especially for post-hoc analyses such as alpha diversity in *H. pylori* patients over 40 years of age *vs* control participants over 40 years of age, multiple lines of evidence, including both the Kruskal-Wallis test with age group and the Spearman correlation with actual age support the relationship in our sample. These results can provide a basis for future study design and power calculations.

Our sample size is modest in part due to the limitations posed by the socioeconomic and cultural attributes of our patient population and logistic challenges associated with sample collection. Camden County has the lowest median income and highest poverty and unemployment rates in southern New Jersey. It also has the lowest educational attainment and the greatest socioeconomic disparities among ethnic minority groups. More than one third of the population in Camden City, where our hospital is located, lives below the national poverty line, and the median household income is USD $26105[47]. Our local community is thus considered one of the poorest and most economically distressed communities in the United States. A significant fraction of adults over 25 years old (almost one quarter) have not completed high school. It is possible that this influences patients' appreciation of the relevance of the study and willingness to participate. A significant portion of potential participants

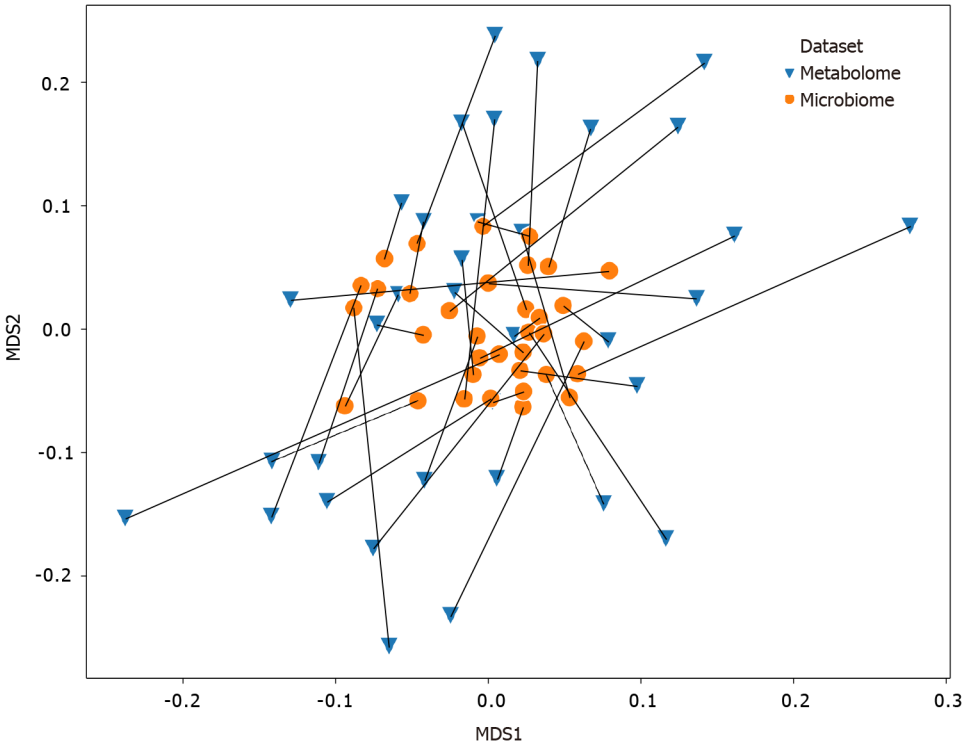

Figure 5 Procrustes-transformed Bray-Curtis multi-dimensional scaling of microbiome and metabolome. Connections between the fecal microbiome and fecal metabolome Bray-Curtis multi-dimensional scaling plots. The microbiome data shown here have been transformed by the Procrustes analysis to minimize disparity between the two datasets, and lines have been drawn to indicate microbiome and metabolome from the same participants. Orange dots represent the microbiomes, whereas blue triangles represent the metabolomes. The Procrustes randomization test showed a significant relationship between the datasets (m^2 = 0.86, P = 0.017). MDS: Multi-dimensional scaling.

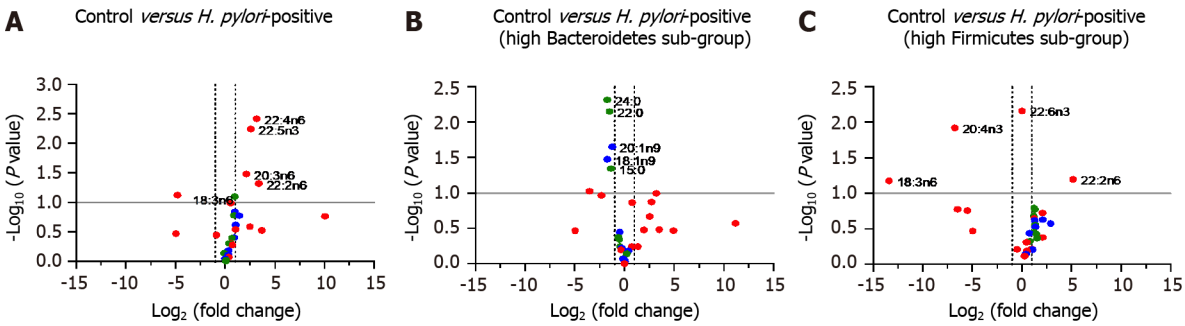

Figure 6 Volcano plots of composition of evaluated fatty acids. A: Control *vs* entire *Helicobacter pylori* (*H. pylori*) patient group; B: Control *vs* sub-group of *H. pylori* patients identified as having high ratio of Bacteroidetes to Firmicutes (n = 7 of 19 patients); C: Control *vs* sub-group of *H. pylori* patients identified as having high ratio of Firmicutes to Bacteroidetes (n = 4 of 19 patients). Selected long-chain fatty acids (green), monounsaturated fatty acids (blue) and polyunsaturated fatty acids (red) are highlighted. *H. pylori*: *Helicobacter pylori*.

were excluded due to non-English-speaking status, thus being unable to partake in the informed consent process. Logistic challenges imposed by the process of stool sample collection also limited the number of subjects. A large number of potential participants were unable to return to the clinic for stool sample delivery due to poor transportation access or inability to leave employment or domestic responsibilities during the window for sample collection (after diagnosis but prior to initiation of antibiotics). Nonetheless, the present study yielded meaningful results.

H. pylori infection was associated with significantly decreased fecal microbial diversity relative to over the age of 40 years. Among all participants, correlations between age and multiple metrics of microbial alpha diversity were consistently different between *H. pylori* patients and control subjects. *H. pylori* was also shown to account for a significant portion of the variation in beta diversity between infected patients and control subjects. Collectively, these results may suggest an *H. pylori*-mediated alteration of the fecal microbiome that progresses with age. While other

authors have attributed decreased diversity of gastric microbiota to the ability of *H. pylori* to outcompete other species, secretion of antibacterial peptides, and local pH alterations, the mechanisms by which *H. pylori* affect distal gut microbiota remain unclear[4,48-50]. Although our study was not designed to uncover these mechanisms, multiple factors hypothesized by other authors, including alterations in hydrochloric acid secretion, gastrointestinal hormones, and immune regulation, may be involved in the mediation of distal gut dysbiosis[12-14]. The impact of *H. pylori* on fecal microbial diversity observed in our study may be reversible, as a recent study showed that *H. pylori* eradication could restore gastric microbial diversity to levels seen in uninfected controls[51].

Less likely is the possibility that the data reflect a preceding decrease in gut microbial diversity that facilitates *H. pylori* infection, potentially mediated by other factors or exposures that accumulate with age. In other words, patients who experience decreased gut microbial diversity as they age, potentially mediated by diet or chronic inflammation, may be more prone to *H. pylori* infection, particularly by mid-adulthood. In our previous study of 2014 *H. pylori* patients, we observed that 80% of our patients were above the age of 40 years, consistent with studies showing increased prevalence of *H. pylori* infection with age in both developing and developed countries [29,52]. Antibiotic exposure is known to alter the gut microbiome, and increased rates of antibiotic-resistant *H. pylori* among older adults have been attributed to increased antibiotic use compared to younger patients[53,54]. Conceivably, decreased gut microbial diversity induced by cumulative antibiotic exposure could create an intragastric niche for *H. pylori*, and antibiotic-resistant *H. pylori* strains in particular, to thrive. However, *H. pylori* infection is thought to be acquired in infancy and carried through to adulthood, and this observation would not be consistent with preceding microbiome alteration facilitating *de novo H. pylori* infection in adulthood[55].

LEfSe showed that multiple taxa were differentially enriched or depleted in stool from *H. pylori* patients compared to controls. The significance of differential expression of these taxa is unknown; however, certain taxa stand out. The enrichment of *Atopobium* in *H. pylori* patients is notable in the context of a metagenomic analysis that revealed increased *Atopobium parvulum* abundance among patients with colorectal intramucosal carcinomas[56]. Although *H. pylori* is predominantly associated with gastric cancers, a recent meta-analysis suggested a significantly increased risk of CRC as well, and our data suggest that *H. pylori*-associated increases in *Atopobium* abundance may have a role in the distal gut carcinogenesis[57].

Over-representation of *Rothia mucilaginosa*, a commensal oral microbe, has previously been observed in fecal samples from patients with primary sclerosing cholangitis (PSC)[58]. Because of the sensitivity of *R. mucilaginosa* to gastric fluid, Bajer *et al*[58] hypothesized that its presence in PSC patients represented contamination of the intestine *via* previous endoscopic retrograde cholangiopancreatography. The enrichment of *Rothia* sp. in fecal samples from our *H. pylori* patients may reflect the potent gastric acid suppression by *H. pylori*, allowing translocation of swallowed oral flora to the distal gut. The clinical consequences of the colonization of the distal gut by *Rothia* sp. are unknown, although the bacteria has been implicated as a cause of myriad syndromes, including dental caries, pneumonia, and bacteremia, particularly in immunocompromised patients[59]. The increased abundance of Gemellaceae in *H. pylori* patients is consistent with the observation of increased organisms from the *Gemella* genus in patients with current *H. pylori* infection reported by Gao *et al*[60]. Increased relative abundance of Gemellaceae in the Crohn's ileum has been reported by other groups[61,62].

Interestingly, the phylum Verrucomicrobia was significantly depleted in *H. pylori* patients. Verrucomicrobia includes *Akkermansia muciniphila*, a mucus-residing commensal bacterium of the large intestine. *A. muciniphila* is an obligate chemoorganotroph, utilizing mucus as a sole carbon, nitrogen, and energy source that produces SCFAs including acetate, propionate, and, to a smaller extent, 1,2-propanediol[63,64]. Our study was not designed to study this aspect in detail, but the decreased relative abundance of Verrucomicrobia may suggest disruption of the gut mucosal environment by *H. pylori*. In a mouse stress model, exposure to chronic psychosocial stress resulted in expansion of *Helicobacter* spp., which has been demonstrated to proliferate in response to glucocorticoid administration as well as psychosocial stress exposure [65]. Specifically, stress-induced increases in *Helicobacter* spp. were associated with increases in other *Proteobacteria* spp., including unidentified genera belonging to the Enterobacteraceae and Desulfovibrionaceae families. Concurrently, relative abundance of *Mucispirillum*, an obligate mucus-residing bacterium, decreased; a decline of *Mucispirillum* in rodents is associated with early disruption of the gastrointestinal surface mucus layer and a prolonged delay to recovery after the period of pathogen clearance

[66]. Potential disruption of the gut mucosa by *H. pylori* infection is also consistent with decreased relative abundance of *Faecalibacterium prausnitzii*. *F. prausnitzii* is an important gram-positive human commensal that produces butyrate and other SCFA through the fermentation of dietary fiber. Reduced relative abundance of *F. prausnitzii* has been associated with inflammatory conditions including Crohn's disease, obesity, asthma, and stress-related psychiatric disorders in which inflammation is a risk factor, such as major depressive disorder[67-70].

Strategies to promote increased gastric microbial diversity among patients with *H. pylori* infection, particularly those over 40 years of age, may hold therapeutic potential in eradicating infection, and some clinical trials with adjunctive probiotic formulas have shown promising results in this regard[71]. Likewise, treatment of gut dysbiosis in patients with *H. pylori* infection may limit its associated pathologies. Reduced fecal microbiome diversity is associated with multiple disease markers including increased adiposity, insulin resistance, dyslipidemia, and a pro-inflammatory state[72]. *H. pylori* infection is associated with higher rates of diabetes, specifically, and addressing gut dysbiosis in such patients could conceivably aid primary dietary and pharmacologic strategies to achieve glycemic control and insulin sensitivity[20]. Rehabilitation of the gut microbiota in patients with *H. pylori* may also have a role in minimizing the risk of malignancy. Mouse studies suggest that the carcinogenic effects of *H. pylori* partly depend on interactions with the gut microbiome, and persistent infection with *H. pylori* may create a niche favorable for taxa that are found in increased abundance in gastric cancer, including *Lactobacillus* and *Lachnospiraceae*[73,74]. It has been suggested that lactic acid bacteria can influence gastric cancer by a number of mechanisms such as (1) Supply of exogenous lactate, that acts as a fuel source for cancer cells; (2) Production of reactive oxygen species and N-nitroso compounds; and (3) By allowing colonization of carcinogenic non-*H. pylori* bacteria[75]. Accordingly, reversal of abnormalities in gut microbiota associated with *H. pylori* may also limit its carcinogenic potential. Finally, consideration must be given to the effects of *H. pylori* treatment on the gut microbiome, as data suggest that current therapies may be associated with dysbiosis and subsequent adverse effects[76]. Several factors including lifestyle and diet can act as confounders in analysis of the diversity and composition of the gut microbiome. However, given the challenges associated with controlling for such variables, their presence should not prohibit drawing meaningful conclusions from significant observations of gut dysbiosis in association with *H. pylori*.

While evaluating changes in the LCFAs palmitic (16:0) and stearic (18:0) concentrations, we found that palmitic acid concentrations were increased in our test samples compared to control samples [625.23 ± 598.82 mg/g (n = 18) *vs* 334.10 ± 284.58 mg/g (n = 12)], whereas concentrations of stearic acid were comparable between populations. Interestingly, when we evaluated the high Firmicutes (> 1.4:1 Firmicutes:Bacteroidetes, n = 4) sub-group compared to the high Bacteroidetes (> 2.7:1 Bacteroidetes:Firmicutes, n = 7) sub-group of our test population, we found the concentrations of both these LCFAs to be diminished in the high Bacteroidetes population while the concentrations of both were enhanced in the high Firmicutes sub-population. This is consistent with previous studies in mice where administration of LCFA-rich diets resulted in an observed increase in Firmicutes to Bacteroidetes ratio[77]. Ktsoyan *et al*[78] implicated a characteristic profile of serum LCFA concentrations in association with *H. pylori* infection compared to healthy controls. It is plausible that diet can modulate the impact of *H. pylori* on the gut microbiome, which in turn may relate to different disease phenotypes, *i.e.*, asymptomatic infection, peptic ulcer disease, and gastric cancer.

The accumulation of the saturated LCFAs is regulated under normal physiological conditions by desaturation of 16:0 to 16:1n7, elongation of 16:0 to 18:0 and/or desaturation of 18:0 to 18:1n9 which can be further elongated to 20:1n9 (Figure 7). While only small changes in concentrations of these MUFAs were noted between our *H. pylori* patients and control subjects, the changes in MUFA concentrations in our high Firmicutes and high Bacteroidetes sub-populations showed more significant and consistent changes across the series of MUFAs. The concentration of 16:1n7, 18:1n9 and 20:1n9 were decreased in the high Bacteroidetes sub-group, whereas these MUFAs were slightly increased in the high Firmicutes sub-group. Interestingly, this contrasts published data on the benefits of high MUFA diets in animal models and humans. In previous studies, high MUFA diets have been reported to lead to increased ratios of Bacteroidetes to Firmicutes and were correlated with reductions in several disease indicators[77]. Together, these observations may suggest that either the patients in our high Bacteroidetes sub-population have severely limited MUFA production/intake, contrasting previous work on MUFA rich diets or that the endogenous biosynthetic pathways for MUFA production are dysregulated in this patient population.

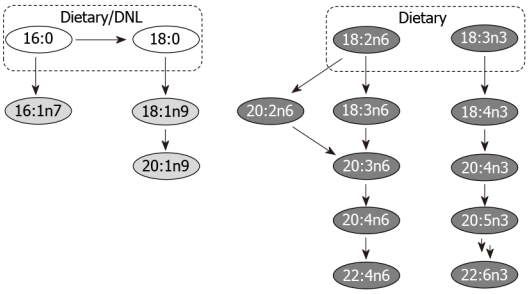

Figure 7 Major metabolic pathways. Selected long-chain fatty acids (no fill), monounsaturated fatty acids (light grey fill) and polyunsaturated fatty acids (dark grey fill) are highlighted. Although many of the fatty acids shown may be supplemented by diet, key parent members of these pathways acquired from *de novo* lipogenesis and/or diet are indicated. DNL: *De novo* lipogenesis.

The range of PUFAs observed endogenously have essential physiological roles and are produced from dietary alpha-linolenic acid (18:3n3) and linoleic acid (18:2n6). We observed that both of these dietary PUFAs were increased in our test samples compared to the control samples. In humans, C18:3n3 is converted through multiple steps to eicosapentaenoic acid (20:5n3) and DHA (22:6n3), whereas 18:2n6 proceeds to produce arachidonic acid (AA, 20:4n6) (Figure 7). As these two biosynthetic pathways share enzymes for their respective dehydration and elongation steps, they are antagonistic to each other. In general, a high 18:3n3 (n-3 fatty acid) diet is correlated with positive physiological effects whereas a high 18:2n6 (n-6 fatty acid) diet is correlated with metabolic dysbiosis and negative physiological effects[79,80]. Accordingly a balanced dietary intake of n-6/n-3 fatty acids is recommended to be 1:1-2:1, although the average ratio in a typical Western diet has been reported to be > 15:1[81]. In accordance with published ratios for n-6/n-3 fatty acid intake in Western diets, we find the ratio of 18:2n6/18:3n3 to be 22:1 in our control samples and 15:1 in our *H. pylori* patient test samples.

Endogenously, the essential dietary fatty acid 18:3n3 undergoes multiple dehydration and elongation steps to produce docosapentaenoic acid (DPA, 22:5n3) and DHA (22:6n3). For all intermediates along this biosynthetic pathway, with exception to 18:3n3 and 22:5n3, we observe concentrations at or below the limit of quantification for the majority of samples making an evaluation of the individual steps of this biosynthesis pathway difficult.

Contrasting the low concentrations observed for 18:3n3 and fatty acids produced along this biosynthetic pathway, higher overall concentrations were observed for fatty acids derived from 18:2n6, perhaps reflecting the higher concentration of dietary n-6 fatty acids as described earlier. In humans, the dietary fatty acid, 18:2n6 undergoes dehydration to produce 18:3n6. This intermediate undergoes a subsequent elongation to produce 20:3n6, which is dehydrated to 20:4n6 (AA). Alternatively, 18:2n6 can undergo elongation first to produce 20:2n6, which is dehydrated to produce 20:3n6 (Figure 7).

We found that the early steps in the metabolism of 18:2n6 were significantly impacted in all of our *H. pylori* samples by comparison of downstream fatty acid metabolites to controls. Most notably, in all *H. pylori* test samples the concentration of 18:3n6 was significantly diminished. Concentration of 18:3n6 was 10.7 ± 18.2 mg/g (n = 12) in the control samples and 0.36 ± 1.50 mg/g (n = 18) in the test samples. While we would anticipate that this deficiency in dehydration of 18:2n6 would lead to lower levels of fatty acid metabolites downstream of 18:3n6, this is not the case. In fact, by the following biosynthetic step, *i.e.*, elongation to produce 20:3n6, the fatty acid concentration of 20:3n6 in test samples was found to be higher than in controls. These higher concentrations were also reflected in arachidonic acid (20:4n6) and adrenic acid (22:4n6). It is plausible that the alternative *d-8-desaturase* mediated route *via* 20:2n6 may be prominent in these *H. pylori* patient samples, which are marked by a deficiency in *d-6-desaturase* mediated pathway *via* 18:3n6[82]. We observed a striking decrease in the concentration of the PUFA C18:3n6 in *H. pylori* infected patients. Interestingly, among the multiple liposomal fatty acids evaluated by Thamphiwatana *et al*[83], only the linolenic acid formulation (C18:3) showed bactericidal activity by impacting the *H. pylori* membrane structure and stability.

As the burden of antibiotic resistance grows, populations like ours are impacted greatly by the high prevalence of *H. pylori* colonization. As eradication by a one-size-fits-all approach becomes more and more difficult, it becomes even more important to look towards strategies that can provide insight into community attributes that can

help guide targeted therapies, predict likelihood of treatment outcomes, and possibly create strategies towards mitigating the impact of increased antibiotic usage. A greater, more individualized understanding of gut microbiome features among patients experiencing *H. pylori* colonization, especially in our underserved population, will pave the way for better community impact and reduce healthcare burdens of repeated treatment and mounting antibiotic resistance. As gut dysbiosis is inextricably tied not only to *H. pylori* infection but also to the use of antibiotics itself, the cycle of treatment and re-treatment may very well only further exacerbate vulnerability to enteric pathogens. Our results add to the growing evidence suggesting that *H. pylori* is associated with alterations in distal gut microbiota, particularly in those over 40 years of age. Strategies to better understand gut dysbiosis features among affected groups may create opportunities for improving eradication rates and reducing negative associated distal outcomes.

CONCLUSION

This exploratory study demonstrates *H. pylori*-associated changes to the fecal microbiome and fecal fatty acid metabolism. Such changes may have implications for improving eradication rates and minimizing associated negative distal outcomes.

ARTICLE HIGHLIGHTS

Research background

Helicobacter pylori (*H. pylori*), a bacterium that infects approximately half of the world's population, is associated with various gastrointestinal diseases, including peptic ulcers, non-ulcer dyspepsia, gastric adenocarcinoma, and gastric lymphoma. Following the global trend in emerging antibiotic resistance, rates of clarithromycin, metronidazole, and levofloxacin resistance among *H. pylori* strains have increased markedly, causing high rates of eradication failure.

Research motivation

As the burden of antibiotic resistance increases, the need for new adjunct therapies designed to facilitate *H. pylori* eradication and reduce negative distal outcomes associated with infection has become more pressing. Characterization of the interactions between *H. pylori*, the fecal microbiome, and fecal fatty acid metabolism, as well as the mechanisms underlying these interactions, may offer new therapeutic approaches.

Research objectives

The aim of this study is to characterize the fecal microbiome and metabolome in *H. pylori* patients in a socioeconomically challenged and underprivileged inner-city community.

Research methods

Stool samples from 19 *H. pylori* patients and 16 control subjects were analyzed. *16S rRNA* gene sequencing was performed on normalized pooled amplicons using the Illumina MiSeq System using a MiSeq reagent kit v2. Alpha and beta diversity analyses were performed in QIIME 2. Non-targeted fatty acid analysis of the samples was carried out using gas chromatography-mass spectrometry, which measures the total content of 30 fatty acids in stool after conversion into their corresponding fatty acid methyl esters. Multi-dimensional scaling (MDS) was performed on Bray-Curtis distance matrices created from both the metabolomics and microbiome datasets and a Procrustes test was performed on the metabolomics and microbiome MDS coordinates.

Research results

Fecal microbiome analysis showed that alpha diversity was lowest in *H. pylori* patients over 40 years of age compared to control subjects of similar age group. Beta diversity analysis of the samples revealed significant differences in microbial community structure between *H. pylori* patients and control subjects across all ages. Thirty-eight and six taxa were identified by Linear Discriminant Analysis (LDA) using LDA Effect Size to be enriched in *H. pylori* patients *vs* control individuals, respectively. Taxa that

were enriched in *H. pylori* patients included *Atopobium,* Gemellaceae, Micrococcaceae, Gemellales and *Rothia* (*R. mucilaginosa)*. Notably, relative abundance of the phylum Verrucomicrobia was decreased in *H. pylori* patients compared to control subjects. Procrustes analysis showed a significant relationship between the microbiome and metabolome datasets. Stool samples from *H. pylori* patients showed increases in several fatty acids including the polyunsaturated fatty acids (PUFAs) 22:4n6, 22:5n3, 20:3n6 and 22:2n6, while decreases were noted in other fatty acids including the PUFA 18:3n6. The pattern of changes in fatty acid concentration correlated to the Bacteroidetes:Firmicutes ratio determined by *16S rRNA* gene analysis.

Research conclusions

The study suggests *H. pylori*-associated changes to the fecal microbiome and fecal fatty acid metabolism. Such changes may have implications for improving eradication rates and minimizing associated negative distal outcomes.

Research perspectives

Future study with greater power should be directed to confirming the distal gut dysbiosis and changes to fecal fatty acid metabolism seen in our exploratory analysis of patients with *H. pylori* infection, as well as towards exploring the relationships between such phenomena and eradication success, colorectal cancer, and metabolic disease.

ACKNOWLEDGEMENTS

We thank Drs. Robert Cooper, Anjali Mone and Sanket Patel for their help in the collection of some of the samples for the study; these were also approved in the IRB protocol.

Abstract

BACKGROUND

Despite its decreased incidence in Japan, gastric cancer continues among the leading causes of cancer-related deaths in both men and women. Accordingly, efforts are still required to lower the mortality rate of gastric cancer in Japan. Maebashi City introduced endoscopic gastric cancer screening in 2004, and participants are able to choose between direct radiography and endoscopy. Hence, we expected to see a decrease in mortality rate from gastric cancer after introducing endoscopic screening and a difference in mortality rate reduction between screening methods.

AIM

To evaluate the impact on gastric cancer mortality rate of two types of gastric cancer screening in Maebashi City, Japan.

Participants aged 40 to 79 years of the Maebashi City gastric cancer screening program in 2006 who were screened by direct radiography (n = 11155) or endoscopy (n = 10747) were included. Participants were followed until March 31, 2012, by cross-referencing their data against the Gunma Prefecture cancer registry data. We compared the detection rate of gastric cancers. Then, we compared the mortality rate between the two groups. The Cox proportional hazards model was used to estimate the hazard ratio (HR) of gastric cancer death. Finally, the reduction in gastric cancer mortality rate associated with each screening method was evaluated.

RESULTS

Gastric cancer was detected in 22 participants undergoing direct radiography (detection rate, 0.20%) and in 52 participants undergoing endoscopy (detection rate, 0.48%). However, most gastric cancers detected by endoscopic screening were early cancers that may not have resulted in death. We found no significant difference in gastric cancer mortality rate between participants receiving annual screening and those who do not. When the number of gastric cancer deaths in the direct radiography group was set as 1 in the Cox proportional hazard analysis, the HR of gastric cancer death was 1.368 (95%CI: 0.7308–2.562) in the overall group of participants. The results showed no significant difference between the two screening methods in any of the analysis groups.

CONCLUSION

Although endoscopic screening detected more gastric cancer than direct radiographic screening, no significant difference in the reduction of gastric cancer mortality rate between the two screening methods was found.

Key Words: Gastric cancer; Radiography; Endoscopy; Population-based cancer screening; Mortality reduction

Core Tip: Although the incidence rate has declined in Japan, gastric cancer is still the leading cause of cancer-related deaths in men and women. Therefore, Japan still needs to work hard to reduce the death rate of gastric cancer. Maebashi City introduced endoscopic gastric cancer screening in 2004. Endoscopic screening detects more gastric cancer than direct radiographic screening does, but both screening methods have similar effects on reducing the mortality rate from gastric cancer.

INTRODUCTION

In 2017, 24.5 million patients globally had a cancer diagnosis, and 9.6 million patients died of cancer. Of these deaths, 861000 were due to gastric cancer (men, n = 542000; women, n = 319000). Furthermore, gastric cancer was the third-highest cause of death among men dying from cancer and the fourth-highest in women dying from cancer[1].

In Japan, the prevalence of *Helicobacter pylori* (*Hp*) infection—a known cause of gastric cancer—has decreased, and the incidence of gastric cancer and the age-adjusted mortality rate from gastric cancer have also been decreasing. Nonetheless, in 2018 gastric cancer was the second-highest cause of death among Japanese men dying from any cancer and the fourth-highest among Japanese women dying from any cancer[2]. Accordingly, further efforts are still required to lower the mortality rate of gastric cancer in Japan.

In Japan, for many years, gastric cancer mass screening programs conducted by municipal governments were performed by using indirect radiography to examine large numbers of people, and direct radiography was used to examine individual patients at medical institutions. However, in 2015 the Gastric Cancer Screening Guidelines were revised to recommend endoscopy for organized gastric cancer screening[3]. Accordingly, many municipal governments subsequently started using endoscopy rather than indirect radiography for gastric cancer screening.

In Maebashi City, endoscopic gastric cancer screening was introduced in 2004, and subsequently, participants were able to choose between direct radiography and endoscopy[4]. Therefore, we examined clinical data from participants in the Maebashi City gastric cancer screening program in 2006 to assess whether the mortality rate from gastric cancer decreased after the introduction of endoscopic screening.

MATERIALS AND METHODS

Study design and participants

Citizens aged 40 years and older are eligible to participate in the Maebashi City gastric cancer screening as part of their personal health check, and participants can choose between direct radiography and endoscopy every year. Gastric cancer screening is conducted at practitioner clinics or at hospitals in Maebashi City that have elected to participate in the screening program, and institutions do not have to fulfill any eligibility criteria to participate. In 2006, 23963 citizens participated in gastric cancer screening, accounting for 20.5% of the overall eligible population. A total of 12014 participants underwent direct radiographic screening and 11949 endoscopic screening.

The present study included participants aged 40 to 79 years; 79 years was chosen as the upper age limit because, in Japan, the average lifespan is 79.00 years in men and 85.81 years in women[5]. A total of 21802 participants were included, comprising 11155 individuals who underwent direct radiography and 10747 who underwent endoscopy.

First, we investigated the number of gastric cancers detected and the cancer stage at detection. Next, we compared the detection rate between the two participant groups undergoing direct radiography or endoscopy. Then, we compared the mortality rate between the two groups. The clinical data of the present study cohort, including the name, sex, date of birth, and history of participation in gastric cancer screening, were extracted from the Maebashi Medical Association cancer screening database. The participants were followed up until March 31, 2012, using the Gunma Prefectural Cancer Registry data. The 2006 Maebashi City gastric cancer screening was conducted from May 2006 until the end of February 2007, and participants could choose to be screened by either of the two imaging methods. The follow-up period ranged from 5 years, 1 mo, to 5 years, 11 mo.

The two screening methods are offered by at least 80 institutions each year. Direct radiographic examination is performed by the standard imaging method (8-image method). For endoscopic gastric cancer screening, 30 to 40 images are taken that cover the esophagus and duodenum. Screening physicians are required to submit the images to the Maebashi Medical Association, where they are reviewed by two other physicians commissioned by the Maebashi Medical Association; these physicians check the quality and look for missed lesions (secondary review). Generally, endoscopic images are reviewed by physicians who are board-certified by the Japan Gastroenterological Endoscopy Society.

All procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national) and with the Helsinki Declaration of 1964 and later versions.

Outcomes

The primary outcome was death from gastric cancer. We compared the incidence rate of the primary outcome between the two screening methods in the whole group of participants and between those participants who had also participated in the gastric cancer screening in the previous year and those who had not.

The secondary outcome was the incidence rate of death from any cancer except gastric cancer, and the same comparisons were performed for the secondary outcome as for the primary outcome.

To obtain additional information on causes of death, we compared the data in the Gunma Prefectural Cancer Registry with the death certificates.

The accuracy of the 2006 Gunma Prefectural Cancer Registry was low with 40.5% of incidence cancer rate registered as death certified only; however, the data of death was perfectly obtained.

Statistical analysis

We compared the participants' background factors between the two groups using Fisher's exact test and Student's *t*-test. The Cox proportional hazards model was used to estimate the hazard ratio (HR) of gastric cancer death, and death from any cancer other than gastric cancer, in the overall group of participants and the subsets of participants who had or had not participated in gastric cancer screening in the previous year. HRs were adjusted for sex and age group. Finally, the average covariate method was used to estimate and plot the survival curve adjusted for sex and age groups[6,7]. All test statistics were 2-tailed, and a *P* value less than 0.05 was considered to indicate a statistically significant difference. Analyses were performed with EZR (easy-R)[8]. The use of Gunma Cancer Registry data was approved by Gunma Prefecture. The statistical review of the study was performed by Moki F from Gunma Health Foundation.

RESULTS

Participants and gastric cancer detection rates

The percentages of male participants and participants aged 60 years or older were slightly higher in the endoscopic screening group (Table 1). Similar results were found in the subsets of participants who had also participated in the screening in the previous year (Table 2) and those who had not (Table 3).

Among all screening program participants, gastric cancer was detected in 25 participants undergoing direct radiography (detection rate, 0.21%) and in 72 participants undergoing endoscopy (detection rate, 0.60%). Thus, the gastric cancer detection rate with endoscopy was triple that of direct radiography. In the participants aged from 40 to 79 years, gastric cancer was detected in 22 individuals undergoing direct radiography (detection rate, 0.20%) and in 52 individuals undergoing endoscopy (detection rate, 0.48%). Thus, endoscopic screening detected gastric cancer in participants aged 80 years or over more frequently than direct radiographic screening.

In the participants aged from 40 to 79 years, the categories of gastric cancer lesions detected by direct radiographic screening and respective numbers and percentages of participants were as follows: Stage IA, n = 6 (27.2%); stage IB, n = 2 (9.1%); stage II, n = 3 (13.6%); stage IIIA, n = 1 (4.5%); stage IIIB, n = 4 (18.2%); stage IV, n = 5 (22.7%); and unspecified stage, n = 1 (4.5%). The respective data for gastric cancer detected by endoscopic screening were as follows: Stage IA, n = 30 (57.7%); stage IB, n = 3 individuals (5.8%); stage II, n = 6 (11.5%); stage IIIA, n = 1 (1.9%); stage IIIB, n = 2 (3.8%); stage IV, n = 7 (13.5%); and unspecified stage, n = 3 (5.8%)[9]. The stage IA gastric cancer lesions detected by endoscopic screening were treated by endoscopic submucosal dissection (ESD) in 21 of the 30 individuals, and all 6 of the stage IA lesions detected by direct radiographic screening were treated by gastrectomy.

Gastric cancer mortality rates

Gastric cancer deaths were detected in 17 of the 11 155 individuals who underwent direct radiography and in 23 of the 10 747 individuals who underwent endoscopy. The five-year survival by the Kaplan-Meier method was 0.998 (95%CI: 0.998–0.999) in individuals who underwent direct radiography and 0.998 (95%CI: 0.997–0.999) in individuals who underwent endoscopy. Overall, no significant difference was observed between the two screening methods (P = 0.285) (Figure 1). Among participants who had not participated in screening in the previous year, gastric cancer deaths were detected in 10 of 4 382 individuals who underwent direct radiography and in 16 of 6 915 individuals who underwent endoscopy. The five-year survival rate was 0.998 (95%CI: 0.996–0.999) in individuals who underwent direct radiography and 0.998 (95%CI: 0.996–0.999) in individuals who underwent endoscopy. No significant difference was observed between the two screening methods (P = 0.971) (Figure 2). Among participants who had also undergone screening in the previous year, gastric cancer deaths were detected in 7 of 6 773 individuals who underwent direct radiography and 7 of 3832 individuals who underwent endoscopy. The five-year survival rate was 0.999 (95%CI: 0.998–1.000) in individuals who underwent direct radiography and 0.998 (95%CI: 0.996–0.999) in individuals who underwent endoscopy. Again, no significant difference was observed between the two methods (P = 0.280) (Figure 3).

	60–69 yr	3667 (34.1)	3986 (35.7)	
	70–79 yr	4085 (38.0)	3900 (35.0)	
Age group, *n* (%)	40–59 yr	2995 (27.9)	3269 (29.3)	0.019
	60–79 yr	7752 (72.1)	7886 (70.7)	
Age, mean (SD), yr		64.75 (9.69)	64.30 (9.57)	< 0.001

NA: No significant.

Table 2 Characteristics of individuals aged 40 to 79 years who participated in gastric cancer screening in Maebashi City, Japan, in 2006 and did not subsequently receive annual screening

		Screening method		
		Endoscopy	Radiography	*P* value
Participants, *n*		6915	4382	
Sex, *n* (%)	Male	2680 (38.8)	1570 (35.8)	0.002
	Female	4235 (61.2)	2812 (64.2)	
Age group, *n* (%)	40–49 yr	764 (11.0)	552 (12.6)	NA
	50–59 yr	1483 (21.4)	1032 (23.6)	
	60–69 yr	2372 (34.3)	1528 (34.9)	
	70–79 yr	2296 (33.2)	1270 (29.0)	
Age group, *n* (%)	40–59 yr	2247 (32.5)	1584 (36.1)	< 0.001
	60–79 yr	4668 (67.5)	2798 (63.9)	
Age, mean (SD), yr		63.54 (9.99)	62.51 (10.08)	< 0.001

NA: No significant.

A Cox hazard analysis was conducted. Because the proportional hazard was not maintained for participants who had not participated in the previous year, the HR was estimated for participants who had also participated in the screening in the previous year and those who did not. When the number of gastric cancer deaths in the direct radiography group was set as 1 in the Cox proportional hazard analysis, the adjusted HR of gastric cancer death was 1.368 (95%CI: 0.7308–2.562) in the overall group of participants and 1.600 (95%CI: 0.5604–4.569) in the subset of participants who had also participated in gastric cancer screening in the previous year. These results showed no significant difference between the two screening methods in any of the analysis groups (Table 4).

Mortality rates for any cancer

Deaths from any cancer other than gastric cancer occurred in 163 of 11 155 individuals who underwent direct radiography and 178 of 10 747 individuals who underwent endoscopy. The five-year survival rate was 0.987 (95%CI: 0.985–0.989) in individuals who underwent direct radiography and 0.986 (95%CI: 0.984–0.988) in individuals who

Table 4 Cox proportional hazards analyses of gastric cancer deaths in individuals aged 40 to 79 years who participated in gastric cancer screening in Maebashi City, Japan, in 2006

	Screening method	Participants, *n* (%)	Gastric cancer deaths, *n* (%)	Adjusted reduction rate[1]	95%CI
All participants	Radiography	11155	17	1.000	
	Endoscopy	10747	23	1.368	0.7308–2.562
Participants receiving annual screening after 2006	Radiography	6773	7	1.000	
	Endoscopy	3832	7	1.600	0.5604–4.569

[1]Adjusted for sex and age group (40–59 years and 60–79 years).

underwent endoscopy. No significant difference between the two screening methods was observed in the overall population (P = 0.249) (Figure 4A).

Among participants who had not participated in screening in the previous year, gastric cancer deaths were detected in 77 of 4 382 individuals who underwent direct radiography and 110 of 6 915 individuals who underwent endoscopy. The five-year survival rate was 0.985 (95%CI: 0.981–0.988) in individuals who underwent direct radiography and 0.986 (95%CI: 0.983–0.989) in individuals who underwent endoscopy. No significant difference was observed between the two screening methods (P = 0.509) (Figure 4B).

Among participants who had also participated in screening in the previous year, gastric cancer deaths were detected in 86 of 6 773 individuals who underwent direct radiography and 68 of 3 832 individuals who underwent endoscopy. The five-year survival rate was 0.988 (95%CI: 0.985–0.990) in individuals who underwent direct radiography and 0.985 (95%CI: 0.981–0.989) in individuals who underwent endoscopy. A significant difference was observed between the two screening methods (P = 0.038) (Figure 4C). The Cox proportional hazard test was conducted. For participants who had not participated in the previous year, the Cox hazard was not maintained. Accordingly, the HR was estimated for the overall population and participants who had also participated in the screening in the previous year.

When the number of deaths from any cancer other than gastric cancer in the participants who received direct radiographic screening was set as 1 in the Cox proportional hazard analysis, the adjusted HR of deaths from any cancer other than gastric cancer was 1.090 (95%CI: 0.8813-1.3480) in the overall group, 1.284 (95%CI: 0.9334–1.7650) in the participants who had also participated in the screening in the previous year. Again, no significant difference was found between the two screening

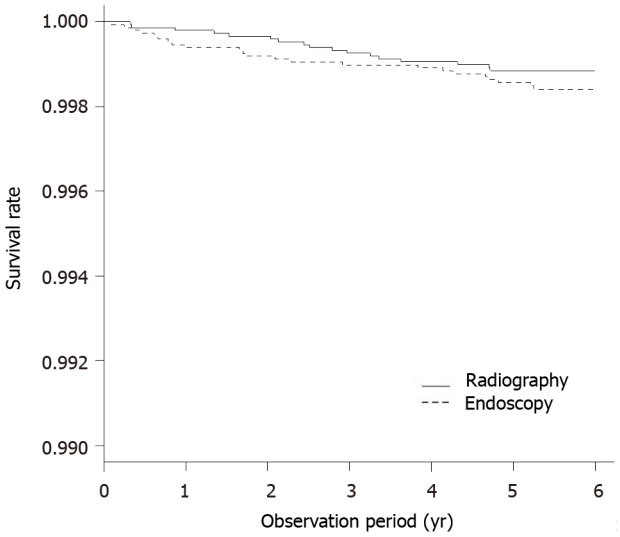

Figure 1 Survival curves of gastric cancer deaths in all individuals aged 40 to 79 years old who participated in gastric cancer screening in Maebashi City, Japan, in 2006. Survival curves are adjusted for sex and age group (40–59 years and 60–79 years). No significant difference was observed in the 5-year survival rate between the direct radiography and the endoscopy groups (P = 0.285).

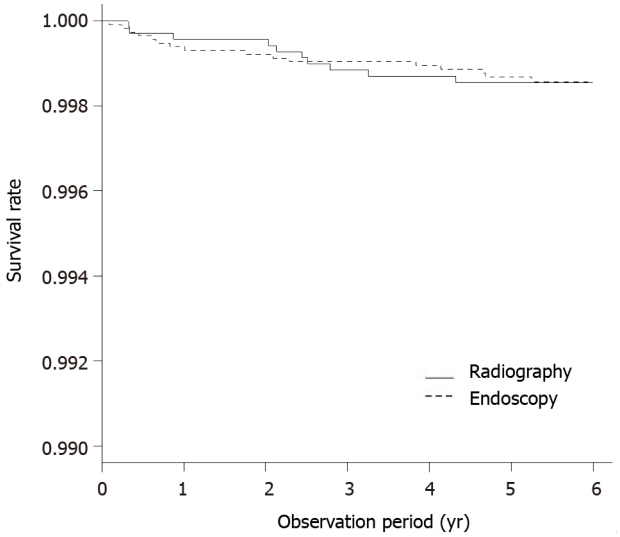

Figure 2 Survival curves of gastric cancer deaths in individuals aged 40 to 79 years old who participated in gastric cancer screening in Maebashi City, Japan, in 2006 and did not subsequently receive annual screening. Survival curves are adjusted for sex and age group (40–59 years and 60–79 years). No significant difference was observed in the 5-year survival rate between the direct radiography and the endoscopy groups (P = 0.971).

methods in terms of death from any cancer except gastric cancer (Table 5).

DISCUSSION

In this study, we examined clinical data from participants in the Maebashi City gastric cancer screening program in 2006 to assess whether the mortality rate from gastric cancer decreased after endoscopy was introduced as an additional screening method in addition to direct radiography. We found that although endoscopy detected more gastric cancers than direct radiography, the mortality rate from gastric cancer showed no difference between the two screening methods. Hence, endoscopy likely detected relatively slowly progressing gastric cancer (mainly differentiated gastric cancer common in older adults), whereas failed to detect gastric cancer that rapidly progresses in the early stage.

Hamashima *et al*[10] performed a study, the Tottori Cohort Study, on data from gastric cancer screening by radiography and endoscopy conducted in Yonago City and

Table 5 Cox proportional hazards analyses of all cancer deaths, without gastric cancer, in individuals aged 40 to 79 years who participated in gastric cancer screening in Maebashi City, Japan, in 2006

	Screening method	Participants, *n* (%)	Cancer deaths[1], *n* (%)	Adjusted reduction rate[2]	95%CI
All participants	Radiography	11155	163	1.000	
	Endoscopy	10747	178	1.090	0.8813–1.3480
Participants receiving annual screening after 2006	Radiography	6773	86	1.000	
	Endoscopy	3832	68	1.284	0.9334–1.7650

[1]Gastric cancer deaths are not included.

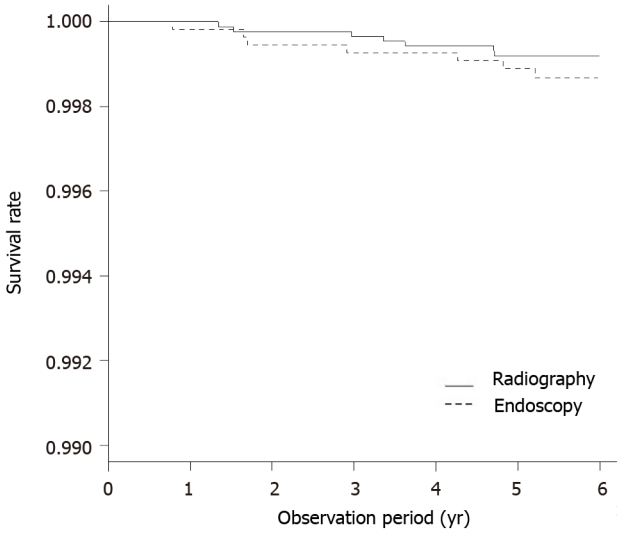

Figure 3 Survival curves of gastric cancer deaths in individuals aged 40 to 79 years old who participated in gastric cancer screening in Maebashi City, Japan, in 2006 and subsequently received annual screening. Survival curves are adjusted for sex and age group (40–59 years and 60–79 years). No significant difference was observed in the 5-year survival rate between the direct radiography and the endoscopy groups (P = 0.280).

Tottori City in 2007 and 2008[10]. This study included people aged 40 to 79 years who had not participated in gastric cancer screening in the previous year and followed them until the end of 2013 by using data from the Tottori Prefectural cancer registry. The authors reported that endoscopic screening reduced the gastric cancer mortality rate by 67% compared with radiographic screening[10]. In contrast, our study results found that the introduction of endoscopy in an organized gastric cancer screening program did not significantly reduce the gastric cancer mortality rate compared with direct radiographic screening. In Tottori Prefecture, institutions are allowed to conduct endoscopic screening if they perform at least 50 endoscopies annually, submit arbitrary endoscopic films, and attend seminars specified by the Tottori Prefecture Health Promoting Council[11]. In Maebashi City, institutions do not have to fulfill any particular eligibility criteria, and all of the institutions wishing to conduct endoscopic screening are allowed to participate in the gastric cancer screening program. Accordingly, the institutions conducting endoscopic screening in Yonago City and Tottori City may have achieved higher accuracy than those in Maebashi City, which may explain the inconsistent findings between the Tottori Cohort Study and our study.

Endoscopy of the upper gastrointestinal tract has become the more common evaluation method in routine clinical care in Japan. In 2014, endoscopies were performed in 527086 patients *per* month at hospitals and in 378195 patients *per* month at general clinics; and in 2017, in 572409 and 500447 patients *per* month, respectively. Thus, the use of endoscopy has increased markedly in recent years, especially at general clinics[12].

In Japan, endoscopies are not always performed by endoscopists with specialized training in the procedure, particularly at general clinics, and most of the general clinics in Maebashi City that routinely perform endoscopies participated in the 2006 gastric

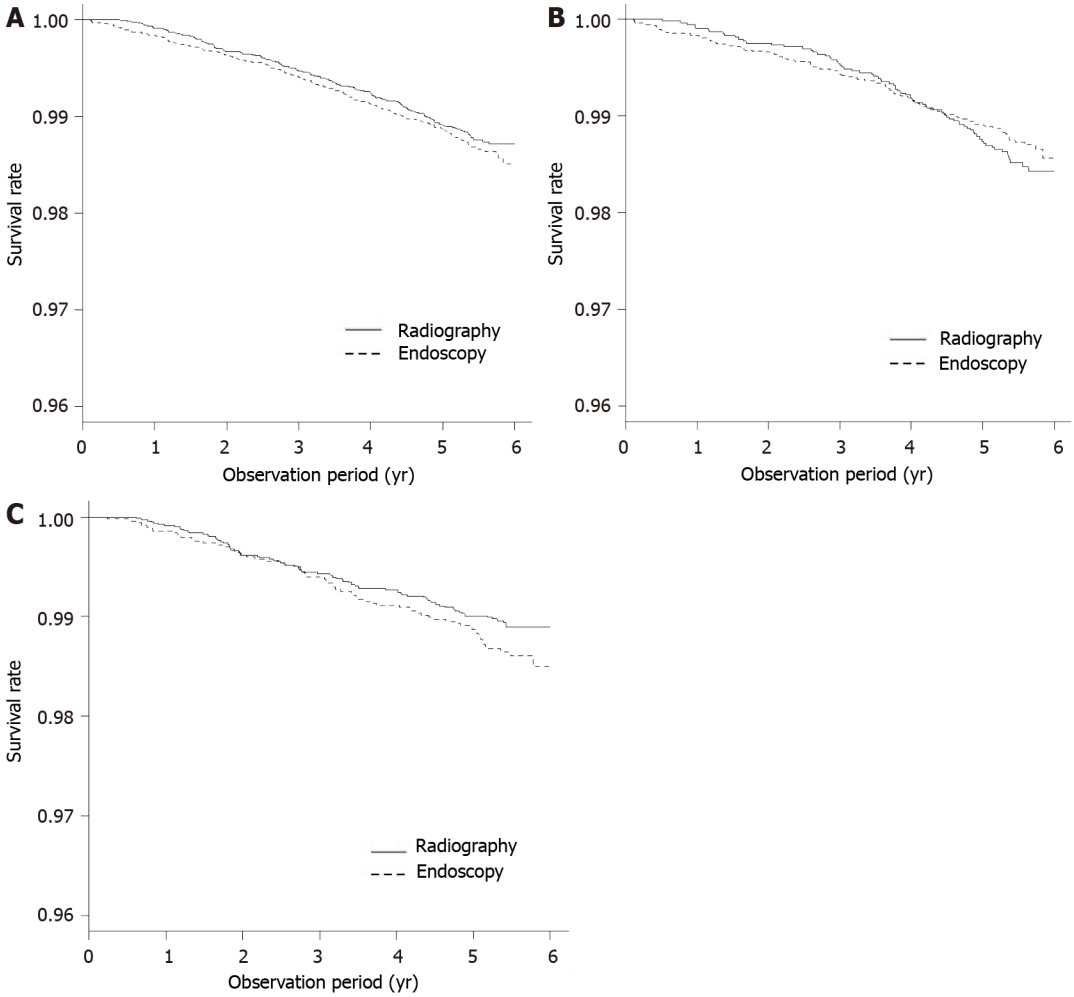

Figure 4 Survival curves of all cancer deaths, other than gastric cancer, in individuals aged 40 to 79 years old who participated in gastric cancer screening in Maebashi City, Japan, in 2006. Survival curves are adjusted for sex and age group (40–59 years and 60–79 years). A: All participants; B: Participants not receiving annual screening; C: Participants receiving annual screening. No significant differences were observed in the 5-year survival rate between the direct radiography and the endoscopy groups in both A and B (A: $P = 0.249$, B: $P = 0.509$). A significant difference was observed between the direct radiography and the endoscopy groups in C ($P = 0.038$).

cancer screening. In this study, endoscopies were performed by endoscopy experts only at 22 of the 82 participating clinics. Shimodate *et al*[13] reported that expert physicians certified by the Japan Gastroenterological Endoscopy Society detected gastric cancer in 1462 patients and that the gastric cancer lesions had been missed in the previous endoscopies in 157 of these patients; in 13 of the 157 patients, the lesion had progressed to advanced gastric cancer at the time of detection. Hosokawa *et al*[14] evaluated the precision of endoscopy for cancer detection and found a false-negative rate during the three years after endoscopy of 22.2%. They also reported that the false-negative rate was higher when the screening doctors had less experience. However, false-negative results were observed in 19.6% of patients even when the endoscopy was performed by trained doctors certified by the Japan Gastroenterological Endoscopy Society. In recent years, the quality of endoscopy devices and their images has increased substantially, but to our knowledge, no study has clarified whether the false-negative rate of diagnosing cancer has decreased.

Physicians of varying skill levels participate in endoscopic gastric cancer screening. Therefore, secondary review of endoscopic images by physicians who are board-certified by the Japan Gastroenterological Endoscopy Society is considered mandatory to compensate for any skill gaps among physicians and to standardize image interpretation[11]. Secondary review of endoscopic images was reported to decrease failures in identifying cancer and reduce the number of unnecessary biopsies[15,16]. Nevertheless, double-checking of images cannot achieve its mission if the inside of the stomach has not been thoroughly and systematically investigated and photographed and if a lesion site is missed during photography or the lesion image is unclear. A study that examined previously taken images to find reasons for false-negative cases

found that the physician had failed to take an image of the lesion site in 16.4% of the cases, even at institutions where a trained doctor certified by the Japan Gastroenterological Endoscopy Society was available[14]. An earlier study we performed also found that no endoscopic image was taken of the lesion site in 39.5% of the false-negative cases among participants in the 2006 to 2007 gastric cancer screening[17].

The "Manual for Organized Gastric Endoscopic Screening" published by the Japanese Society of Gastrointestinal Cancer Screening specifies that physicians who are qualified to perform endoscopic gastric cancer screening include expert physicians certified by Japanese endoscopy-related medical societies, physicians who have been performing endoscopies in at least 100 individuals annually, and physicians who have at least the equivalent ability to investigate the stomach and take endoscopic images [11]. This level of experience and skill in performing endoscopies is necessary to completely monitor and photograph the inside of the stomach so that the number of false-negative results of gastric cancer screening can be reduced as far as possible.

The efficacy of radiographic screening in reducing mortality has been well verified. A recent study found that the efficacy of radiographic screening in reducing gastric cancer mortality rate is equivalent to that of endoscopic screening[18]. In contrast, another study found that radiographic screening did not show efficacy in reducing the gastric cancer mortality rate[19]. The Japan Gastroenterological Endoscopy Society has recommended "a new radiography method" based on a double-contrast examination that uses high-density, low-viscosity barium sulfate[20]. Radiographic screening by this new method was reported to increase the detection rate of early cancer and reduce the requirement rate for detailed examinations when compared with the conventional screening method that uses medium-density barium sulfate[21,22].

The maximum follow-up period in our study was 5 years and 11 mo (*i.e.*, 71 mo). Early cancer was reported to become advanced cancer over 44 mo and to lead to death over 75 mo[23]. The Tottori Cohort Study showed a significant difference in gastric cancer mortality rate from 3 years after the screening. Therefore, the present study may have had a different result if the follow-up period were longer.

In the present study, we were unable to evaluate the difference between the two screening methods based on the number of times participants had previously undergone gastric cancer screening because we did not know how many participants newly received endoscopic screening after receiving direct radiographic screening in the previous year. Participants in the screening program were allowed to choose the screening method freely and could change the screening method from year to year, so we also had difficulties acquiring the history of participation in each screening method. Therefore, in the present study, we divided the participants into three analysis groups: The whole group of participants, participants who had also participated in the screening in the previous year, and participants who had not participated in the previous year. We conducted survival curve analyses for each of these three analysis sets and calculated gastric cancer mortality and the proportional HR for the mortality rate for any cancer other than gastric cancer. For the mortality rate from any cancer other than gastric cancer, among participants who had also participated in the screening in the previous year, survival analysis detected a difference between individuals undergoing direct radiography and individuals undergoing endoscopy. However, no difference was found with the Cox proportional hazard model. This may be due to slight differences in demographic characteristics between the two screening groups for participants who had also participated in screening the year prior. The reason for this may be as follows. When comparing the screening database *vs* the cancer registration, patients diagnosed with cancer prior to the study period were excluded in both groups. However, the quality of the cancer registration was low, and, therefore, cancer patients may have been included in the analysis set, resulting in a bias. Hence, for participants who had also participated in screening the previous year, differences in demographic characteristics between screening groups may exist for those with gastric cancer mortality. However, this effect is considered less significant when restricted to gastric cancer.

The analyses revealed no significant difference between the screening methods in any of the analysis sets, suggesting no noteworthy difference in the history of undergoing either of the two screening methods.

Stage IA gastric cancer detected by endoscopy was treated by ESD in 70% of the participants who were found to have a lesion. Intramucosal gastric cancer was more commonly detected by endoscopic screening. On the other hand, all cases of stage IA cancer detected by direct radiographic screening were treated by gastrectomy. Therefore, introducing direct radiographic screening and endoscopic screening has made it possible to detect gastric cancer in earlier stages. The Maebashi City gastric cancer screening detected higher percentages of stage III and IV gastric cancers than those

reported by other authors. Six of the seven participants who were found by endoscopic screening to have a stage IV lesion, and both of the participants who were found by endoscopic screening to have a stage IIIB lesion, had initially undergone endoscopic screening, and five participants who were found by direct radiography to have stage IV cancer and one of the four participants who were found by direct radiography to have stage IIIB cancer had initially undergone direct radiographic screening. We previously reported that stage III and stage IV cancers were more often detected among participants who reported the presence of stomach pain or appetite loss or both on the medical questionnaire for gastric cancer screening[24]. The Maebashi City gastric cancer screening may have included a larger number of participants with such symptoms, even though people with these symptoms are normally supposed to undergo examination at a clinical practice rather than gastric cancer screening.

Endoscopy is able to detect early gastric cancers more frequently than direct radiography, and endoscopic detection of early cancer may be related to overdiagnosis of gastric cancer. In fact, the number of gastric cancers detected by endoscopic screening has previously been reported to be twice the predicted number[25]. Moreover, endoscopic screening detected gastric cancer in a very large number of participants aged 80 years or over. Therefore, the gastric cancer screening system in Japan should be amended to provide an upper age limit.

Infection with *Hp*, current smoking, and salt and alcohol intake are known risk factors of gastric cancer. A previous study reported odds ratios of 2.56 for *Hp* infection, 1.61 for current smoking, 1.34 for salt intake, and 1.19 for alcohol intake[26]. We did not investigate the presence of *Hp* infection in participants in the 2006 Maebashi City gastric cancer screening because testing for *Hp* infection only began to be covered by health insurance in 2013. We also did not investigate smoking, salt intake, or drinking habits. Smoking and alcohol drinking are also risk factors for other cancers, but the present study found no significant difference between the two screening methods in terms of mortality rate from any cancer, which indicates that our comparison of the two screening methods had no risk factor-related bias.

The number of participants undergoing direct radiographic gastric cancer screening has decreased since its peak of 6.9 million or more in 2012[27]. Therefore, the introduction of endoscopic screening was needed to attain the government's target participation rate of 50%. In Maebashi City, in 2003, a total of 18494 citizens (equivalent to a participation rate of 15.8%) participated in gastric cancer screening by direct radiography alone. In 2015, when endoscopic screening was introduced, the number of participants increased to 33607 (participation rate, 28.8%). Nevertheless, it will be challenging to increase the participation rate further if the current screening system remains as it is now, partly because of the lack of qualified staff to perform the screening procedures. We need to establish a screening system that corresponds to the risk of developing gastric cancer and conduct gastric cancer screening efficiently, taking into account a possible reduction in the incidence rate of gastric cancer associated with a reduction in the incidence rate of *Hp* infection.

The present study had some limitations. First, because of the low reporting rate to the Gunma Prefecture cancer registry in 2006, we were unable to determine whether the gastric cancer incidence rate in screening participants was similar across the two screening methods, even though we were able to collect information on cancer deaths from death certificates. Therefore, the incidences of gastric cancer may not be completely accurate. Second, the group of participants undergoing endoscopic screening was highly likely to include a large number of people who had been instructed to undergo endoscopy because of the result of their previous direct radiographic screening; however, we were not able to collect such data. Third, compliance with the screening operation manual and precision control, including secondary review, were insufficient because the present screening was conducted at an early stage after the introduction of endoscopic screening. Because of these limitations, the usefulness of endoscopic screening should be further evaluated in a larger number of participants. In addition, we expect that future studies will examine this topic in regions where endoscopic screening has been newly introduced.

CONCLUSION

We used the data from the Maebashi City gastric cancer screening program in 2006 to compare the efficacy of direct radiography and endoscopy in reducing the gastric cancer mortality rate. In Maebashi City, a larger number of older adults participated in endoscopic gastric cancer screening than in direct radiographic screening. As a result,

endoscopic screening detected more early gastric cancers than direct radiographic screening; however, the mortality rate showed no significant difference between the two screening methods. For future gastric cancer screening, physicians' technical level gap across screening institutions should be corrected, and physicians' interpretation accuracy in secondary review should also be further supported.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer is among the leading causes of cancer mortality worldwide, including in Japan. Initiatives have been implemented to lower the mortality rate of gastric cancer in Japan, including mass screening programs. In 2015, guidelines were revised to recommend endoscopy.

Research motivation

In Maebashi City, endoscopic gastric cancer screening was introduced in 2004, allowing eligible participants to choose between direct radiography and endoscopy. Comparing outcomes is essential to reduce gastric cancer mortality and ensure an effective and efficient screening program.

Research objectives

This study aimed to assess whether the mortality rate from gastric cancer decreased after the introduction of endoscopic screening in Maebashi City and compare gastric cancer mortality rates between screening methods.

Research methods

A retrospective analysis of the Maebashi City Gastric Cancer Screening Program in 2006 was conducted. Participants aged 40 to 79 were screened by direct radiography (n = 11155) or endoscopy (n = 10747) and followed until March 31, 2012. Data was cross-referenced against the Gunma Prefecture cancer registry data. The detection rate of gastric cancer and gastric cancer mortality rate were compared between the two screening groups.

Research results

Gastric cancer detection rate for direct radiography was 0.20% and 0.48% for endoscopy; however, endoscopic screening detected a higher number of early-stage cancers that may not have resulted in death. No significant difference in gastric cancer mortality rate was found between participants who underwent annual screening and those who did not. In addition, no significant difference was found in gastric cancer mortality rate between direct radiographic screening and endoscopic screening (P = 0.285). The five-year survival by the Kaplan-Meier method was 0.998 (95%CI: 0.998–0.999) in individuals who underwent direct radiography and 0.998 (95%CI: 0.997–0.999) in individuals who underwent endoscopy.

Research conclusions

No significant difference in gastric cancer mortality rate was found between direct radiographic screening and endoscopic screening. Screening programs should address gaps in endoscopists' skill levels across screening institutions to ensure the quality of endoscopic examination. Finally, an efficient gastric cancer screening system should consider gastric cancer risk by combining endoscopic and radiographic screening.

Research perspectives

Further research with a larger number of participants and high-quality cancer incidence data is needed to better clarify the usefulness of population-based endoscopic screening.

ACKNOWLEDGEMENTS

The authors are deeply grateful to the doctors at medical institutions in Maebashi City for performing gastric cancer screening and secondary reading, as well as the staff members of the Maebashi Medical Association office for collecting data on gastric

cancer screening.

Abstract

BACKGROUND

Perineural invasion (PNI), as a key pathological feature of tumor spread, has emerged as an independent prognostic factor in patients with rectal cancer (RC). The preoperative stratification of RC patients according to PNI status is beneficial for individualized treatment and improved prognosis. However, the preoperative evaluation of PNI status is still challenging.

AIM

To establish a radiomics model for evaluating PNI status preoperatively in RC patients.

METHODS

This retrospective study enrolled 303 RC patients in a single institution from March 2018 to October 2019. These patients were classified as the training cohort (n = 242) and validation cohort (n = 61) at a ratio of 8:2. A large number of intra- and peritumoral radiomics features were extracted from portal venous phase images of computed tomography (CT). After deleting redundant features, we tested different feature selection (n = 6) and machine-learning (n = 14) methods to form 84 classifiers. The best performing classifier was then selected to establish Rad-score. Finally, the clinicoradiological model (combined model) was developed by combining Rad-score with clinical factors. These models for predicting PNI were compared using receiver operating characteristic curve (ROC) analysis and area under the ROC curve (AUC).

RESULTS

One hundred and forty-four of the 303 patients were eventually found to be PNI-

Data sharing statement: No additional data are available.

positive. Clinical factors including CT-reported T stage (cT), N stage (cN), and carcinoembryonic antigen (CEA) level were independent risk factors for predicting PNI preoperatively. We established Rad-score by logistic regression analysis after selecting features with the L1-based method. The combined model was developed by combining Rad-score with cT, cN, and CEA. The combined model showed good performance to predict PNI status, with an AUC of 0.828 [95% confidence interval (CI): 0.774-0.873] in the training cohort and 0.801 (95%CI: 0.679-0.892) in the validation cohort. For comparison of the models, the combined model achieved a higher AUC than the clinical model (cT + cN + CEA) achieved ($P < 0.001$ in the training cohort, and $P = 0.045$ in the validation cohort).

CONCLUSION
The combined model incorporating Rad-score and clinical factors can provide an individualized evaluation of PNI status and help clinicians guide individualized treatment of RC patients.

Key Words: Radiomics; Perineural invasion; Rectal cancer; Computed tomography; Preoperative prediction; Model building

Core Tip: In this study, a radiomics model integrating Rad-score and clinical factors was developed and validated for predicting perineural invasion status in patients with rectal cancer. Radiomics features were extracted from intra- and peritumoral regions. This radiomics model showed good performance and outperformed the clinical factors. Therefore, the combined model might assist in predicting perineural invasion status and improving prognosis of patients with rectal cancer.

INTRODUCTION

Rectal cancer (RC) is one of the most common cancers of the digestive tract worldwide, with a growing morbidity[1]. In the last decade, the combination of neoadjuvant chemoradiotherapy (nCRT) and surgery has improved local control of locally advanced RC, but it does not significantly affect prognosis[2]. Different biological characteristics of RC may cause different treatment responses, risks of distant metastasis, and outcomes[3].

Recently, there is an increasing interest in perineural invasion (PNI) as a potential route of tumor spread, in addition to the well-known routes of direct extension, lymphatic metastasis, and hematogenous metastasis[4]. PNI refers to the biological process characterized by cancer cells invading the nerves and spreading along the nerve sheaths[5,6]. This process can be found in the main tumor and peritumoral area [7,8]. Previous studies have demonstrated the prognostic value of PNI in RC in terms of both recurrence and survival[9-11]. Other studies have shown that PNI can be an indicator for identifying patients who can benefit from nCRT and postoperative adjuvant chemotherapy[12,13]. Therefore, understanding PNI status in advance is helpful for clinicians to make individualized treatment plans for RC patients.

However, PNI status can only be confirmed by assessing the pathology of surgical specimens. In other words, neither biopsy nor imaging examinations [computed tomography (CT)/magnetic resonance imaging (MRI)] can accurately determine PNI status of RC[6]. Recent advances in radiomics have enabled researchers to extract numerous quantitative features from medical images and provide a comprehensive overview of heterogeneity in tumors[14]. Latterly, radiomics analysis has been used to predict PNI status in colorectal cancer[14,15]. Considering the higher incidence of PNI

in RC (compared with colon cancer)[16], several researchers evaluated the performance of MRI-based radiomics for PNI prediction in RC[6,17,18]. However, the sample sizes in the previous studies were really small (PNI^+: 26-32). At present, there is still a lack of CT-based radiomics research in this field. Therefore, we aimed to evaluate the predictive value of CT-based radiomics for PNI prediction in a bigger cohort of RC patients.

MATERIALS AND METHODS

Patients

The local ethics committee approved this study (document number: 1159), and the requirement of informed consent was waived because of the retrospective nature of this study.

The RC patients were reviewed by browsing the radiological and pathological databases from March 2018 to October 2019. A total of 303 patients (170 men and 133 women, mean age 58.9 ± 11.7 years, age range 23-86 years) were enrolled, according to the following inclusion criteria: (1) Adults with histologically confirmed rectal adenocarcinoma; (2) Clinical materials such as enhanced CT images and tumor markers were complete; and (3) No prior therapy before CT examination. The exclusion criteria were as follows: (1) Quality of CT images was poor; (2) Patients treated without surgery; and (3) Patients with other malignant tumors besides RC. The patient recruitment pathway is shown in Figure 1. The workflow of the radiomics analysis is shown in Figure 2.

The clinical and pathological data of each patient were derived from medical records. The baseline data including age, sex, tumor volume, location, tumor markers [carcinoembryonic antigen (CEA), carbohydrate antigen (CA) 19-9, and CA125], pathological TNM stage, and histological grade are shown in Table 1.

Reference standard for pathology

All patients with RC were diagnosed by pathology based on resected specimens. The pathological confirmatory reports were acquired from electronic medical records. PNI status was defined as positive, if (1) At least 33% of the nerve circumference was surrounded by cancer cells (without invasion of nerve sheath); or (2) Cancer cells were within any layer of the nerve sheath[6,19].

CT examination and evaluation

In our hospital, the chest-abdomen-pelvis enhanced CT is used to detect both primary and metastatic lesions for patients with clinically suspected RC. The CT scanners were restricted to Somatom Definition AS+ and Somatom Definition Flash in this study. The parameters of CT examinations are shown in the Supplementary material.

Two experienced radiologists (10 years' and 5 years' experience in abdominal imaging) were assigned to review CT images. The identification of patients was removed from CT images, and the readers were blinded to all clinical and pathological information. The CT-reported T stage (cT) and N stage (cN) were determined by summarizing the results of the two readers (Table 1). The inter-observer variability of cT/cN was evaluated by a weighted kappa statistics test. Because CT is limited to distinguish T1 from T2 in RC, lesions of cT1 were classified as cT2 in this study. When reviewing the CT images, the radiologists solved disagreements by discussion.

Feature extraction and model building

The stability of radiomics features was tested on 20 patients. One radiologist drew volumes of interest (VOIs) twice for evaluating intra-class correlation coefficient (intra-ICC), and the other drew VOIs once for evaluating inter- ICC. The features with ICC < 0.75 were deleted according to the commonly admitted knowledge: ICC < 0.5, poor reliability; 0.5-0.75, moderate reliability; ICC > 0.75, good reliability[20]. The main tumor and peritumoral area were separately drawn slice by slice to obtain intra- and peritumoral features (Figure 2).

The CT images were resampled to a pixel spacing of 1.0 mm in three anatomical directions. Then high- and low-pass wavelet filters, Laplacian-of-Gaussian filters, and other transformation methods such as square, square root, logarithm, exponential, gradient, lbp2d, and lbp3 were used to pre-process the original images. Radiomics features were extracted by using PyRadiomics[21]. A total of 4214 features (three types: First-order statistics, shape features, and texture features) were extracted from

[1]Location: Low (0-5 cm from the anal verge), middle (5.1-10 cm from the anal verge), and high (10.1-15 cm from the anal verge). This table summarized the results of cT-stage and cN-stage for the two readers. CT: Computed tomography; PNI: Perineural invasion; CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9; CA125: Carbohydrate antigen 125; cT stage: Computed tomography-reported T stage; cN stage: Computed tomography-reported N stage; pT stage: Pathological T stage; pN stage: Pathological N stage.

intra- and peritumoral regions. Z-score was used to normalize the features for eliminating the differences in the value scales. Redundant features were randomly removed by correlation analysis with a threshold of 0.48. Then the features were selected using six different methods (analysis of variance, Pearson, mutual information, L1-based, tree-based, and recursive). Subsequently, 14 different machine-learning methods were used to build 84 classifiers. The optimal parameters were adjusted to improve the area under the receiver operating characteristic (ROC) curve (AUC) of the test set and output the best classifier (Rad-score).

Statistically significant risk variables (Rad-score and clinical factors) from the univariate logistic regression analysis were then entered into a multivariate analysis for developing the clinical and combined models. A nomogram was generated for the combined model visualization, graphical evaluation of variable importance, and the calculation of predictive accuracy. ROC curve analyses were performed to assess the diagnostic performance of the models.

Statistical analysis

All statistical analyses were performed using R software (version 3.6.1), SPSS (version 21), Stata (version 15.0), and Medcalc (version 15.2.2). Differences of the factors in Table 1 were assessed by chi-square test or Fisher's exact test, Mann-Whitney test, and *t*-test. AUCs of the models were compared by DeLong's test.

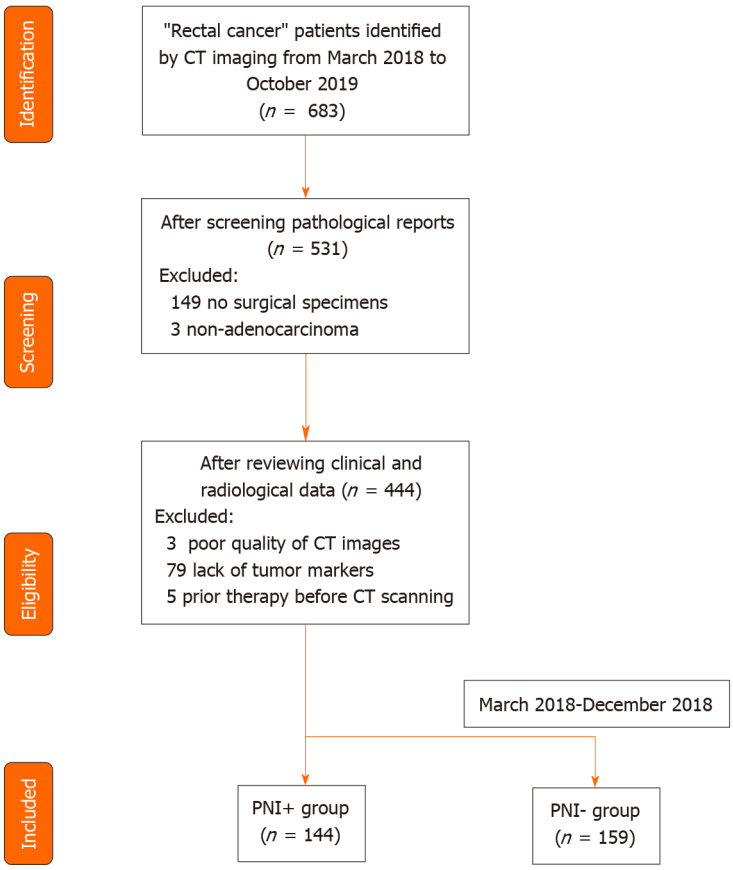

Figure 1 Flowchart of patients' recruitment pathway. CT: Computed tomography; PNI: Perineural invasion.

RESULTS

Patient characteristics

A total of 303 RC patients (144 PNI^+ and 159 PNI^-) were enrolled in this study. Clinical factors such as cT/cN stage, CEA (+/-), pathological T/N stage, and grade had significant differences between PNI^+ and PNI^- groups (Table 1). The weighted kappa coefficients of cT and cN between two readers were 0.709 [95% confidence interval (CI): 0.630-0.789] and 0.849 (95%CI: 0.801-0.897), which showed substantial consistency for cT and almost perfect consistency for cN (0.41-0.60, moderate, 0.61-0.80, substantial and 0.81-1.00, almost perfect)[22]. There were no significant differences in sex, age, volume, location, CA19-9, and CA125 between PNI^+ and PNI^- groups (Table 1). The patients were randomly divided into the training cohort (n = 242) and the validation cohort (n = 61). Except for location (P = 0.045), there were no significant differences in other factors between the training and validation groups (Table 1).

Feature selection and model building

A total of 3095 features (1490 intratumoral and 1605 peritumoral) had good reliability with ICC > 0.75. After deleting redundant features, we selected only seven intratumoral and 13 peritumoral features using the L1-based method. Rad-score was established by logistic regression, as shown in Supplementary material. Rad-score was an independent risk factor for predicting PNI [odds ratio (OR) = 3.148, P < 0.001]. As for clinical factors, CEA, cT, and cN were independent risk factors for predicting PNI preoperatively (OR = 2.528, 1.636, and 1.458; P = 0.003, 0.087, and 0.001, respectively), as shown in Table 2. The factor location had a significant difference in the univariate logistic regression analysis; however, it was excluded by multivariate analysis (Table 2). Thus, the combined model (Rad-score + CEA + cT + cN) was built by multivariate logistic regression analysis. The formula of the combined model is shown in Supplementary material.

A nomogram was generated for the visualization of the combined model (Figure 3). Higher total score obtained from the nomogram is associated with greater predicted risk of PNI. The combined model had good fit according to the Hosmer-Lemeshow test (P = 0.122). In the calibration curve of the nomogram (Figure 4), the y axis

Table 2 Risk factors selected by logistic regression analysis

represents the actual observed probability of PNI, and the x axis represents the predicted probability of PNI. A locally weighted regression line (solid line) of calibration plots is used to demonstrate the general trend of predicted risk. The model had a good agreement between the predicted and observed probability, because the solid line was close to the reference line (dotted line) in this study. This conclusion was consistent with the result of the Hosmer-Lemeshow test. However, among patients with predicted probability > 83%, the model overestimated actual risk of PNI$^+$ (about 15% at most). The decision curve was performed to assess the clinical usefulness of the combined model in predicting PNI. The net benefit is measured on the y axis. Figure 4 shows that the combined model (nomogram) obtained more benefit than "treat all", "treat none", Rad-score, and the clinical model, when the threshold probability was

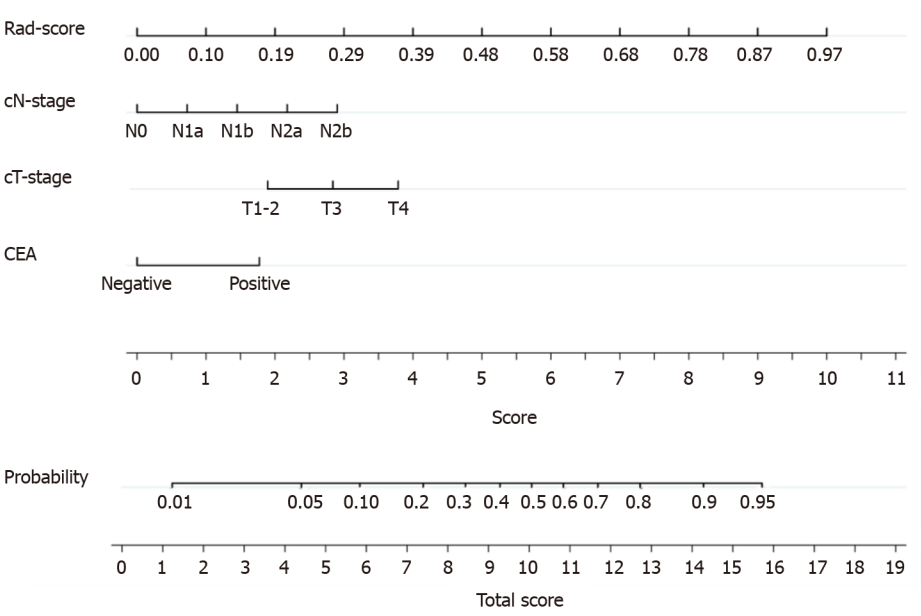

Figure 3 The nomogram was developed in the training cohort. Sum the points of variables in the "score" axis to get the total points. The risk of perineural invasion is the corresponding value on the "probability" axis. CEA: Carcinoembryonic antigen; cT: Computed tomography-reported T stage; cN: Computed tomography-reported N stage.

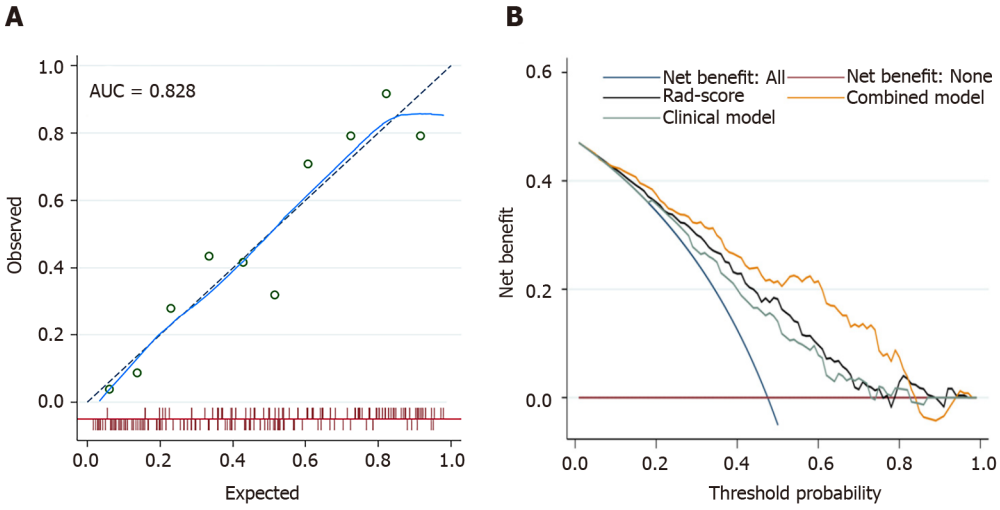

Figure 4 The fit and usefulness evaluation of the nomogram. A: The calibration curve of the nomogram shows a good agreement between the predicted and observed risks in the training cohort; B: The decision curve demonstrates that the nomogram (combined model) obtains more benefit than "treat all", "treat none", Rad-score, and the clinical model, when the threshold probability is in the range of 10% to 83%. AUC: Area under the receiver operating characteristic curve.

found to be in the range of 10% to 83%.

Classification results

In the case of the clinical model (cT + cN + CEA), the resulting AUCs were 0.718 (95%CI: 0.657-0.774) in the training cohort and 0.674 (95%CI: 0.542-0.789) in the validation cohort. Improved performance was achieved by adding Rad-score to the clinical factors. The AUCs of the combined model (0.828; 95%CI: 0.774-0.873 in the training cohort and 0.801; 95%CI: 0.679-0.892 in the validation cohort) were higher than those of the clinical model ($P < 0.001$ and $P = 0.045$, respectively), as shown in Table 3 and Figure 5. The combined model had a higher AUC than Rad-score (AUC = 0.828 *vs* 0.760, $P = 0.020$) in the training cohort. However, there was no significant difference between the combined model and Rad-score in the validation cohort (AUC = 0.801 *vs* 0.782, $P = 0.640$).

Table 3 Comparisons of variables and models in the training and validation cohorts

	The training set				The validation set			
	AUC	SEN (%)	SPE (%)	*P* value	AUC	SEN (%)	SPE (%)	*P* value
CEA	0.597 (0.533-0.660)	50.00	76.38	< 0.001	0.635 (0.502-0.754)	96.55	40.63	0.042
cT stage	0.613 (0.549-0.675)	84.35	33.86	< 0.001	0.589 (0.456-0.714)	75.86	43.75	0.004
cN stage	0.670 (0.607-0.729)	42.61	84.25	< 0.001	0.684 (0.553-0.797)	86.21	40.63	0.045
Rad-score	0.760 (0.701-0.812)	72.17	69.29	0.020	0.782 (0.658-0.878)	68.97	78.12	0.640
Clinical model	0.718 (0.657-0.774)	63.48	70.08	< 0.001	0.674 (0.542-0.789)	65.52	71.87	0.045
Combined model	0.828 (0.774-0.873)	66.09	88.19		0.801 (0.679-0.892)	62.07	93.75	

P value: Compared with the combined model by DeLong's test. AUC: Area under the receiver operating characteristic curve; SEN: Sensitivity; SPE: Specificity; CEA: Carcinoembryonic antigen.

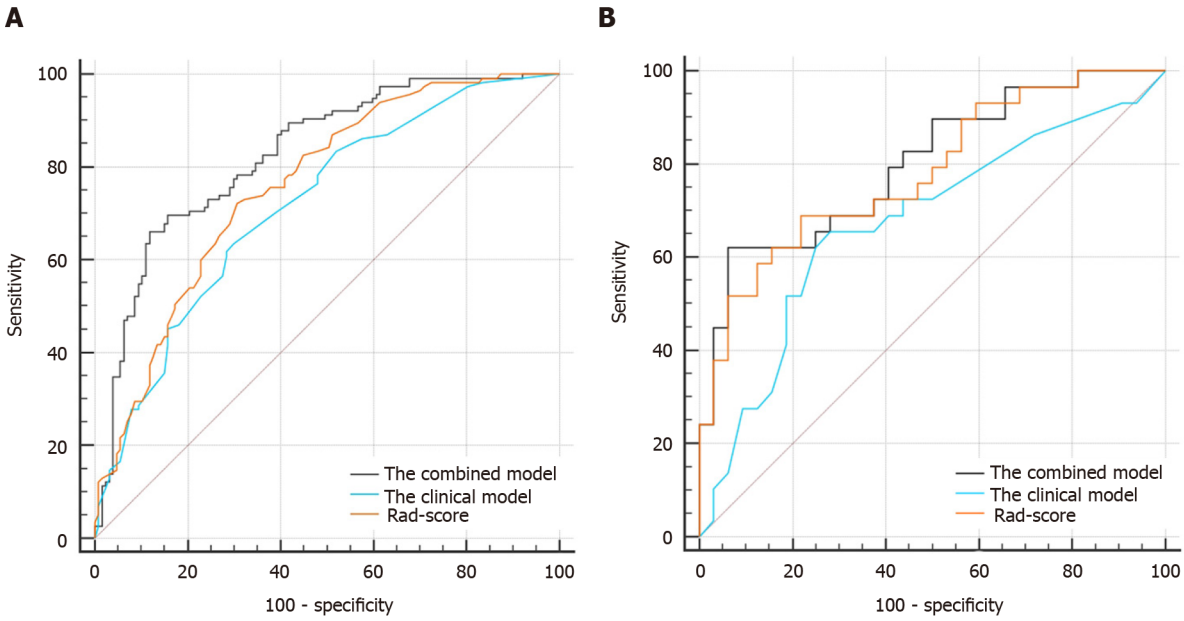

Figure 5 The comparisons of receiver operating characteristic curves in this study. A: In the training cohort: Area under the receiver operating characteristic curve (AUC) = 0.828 for the combined model, 0.718 for the clinical model, and 0.760 for Rad-score; B: In the validation cohort: AUC = 0.801 for the combined model, 0.674 for the clinical model, and 0.782 for Rad-score.

Subgroup analysis

In the cohort of patients treated with nCRT, the AUC of the combined model was higher than that of the clinical model (AUC = 0.853 *vs* 0.710, *P* = 0.011) (Table 4). Among stage III patients, the combined model still had a higher AUC than the clinical model (AUC = 0.796 *vs* 0.630, *P* < 0.001). As for the performance among stage II patients, the combined model failed to outperform the clinical model (AUC = 0.670 *vs* 0.553, *P* = 0.098). Considering the difference between the upper third RC and middle-lower RC in prognosis[23], we performed a subgroup analysis showing that the AUC of the combined model in upper RC group (0.817; 95%CI: 0.730-0.885) was similar with that of the middle-lower RC group (0.824; 95%CI: 0.764-0.875).

DISCUSSION

In this study, a combined model showing potential for predicting PNI of RC outperformed the clinical model (AUC = 0.828 *vs* 0.718, *P* < 0.001 in the training cohort; 0.801 *vs* 0.674, *P* = 0.045 in the validation cohort), indicating that adding Rad-score to the clinical factors improved the predictive value. However, model calibration was not perfect due to the modest overestimation of PNI risk for high-risk patients.

Table 4 Subgroup analyses of the models in the whole cohort

	The clinical model			The combined model			*P* value
Subgroups	**AUC**	**SEN (%)**	**SPE (%)**	**AUC**	**SEN (%)**	**SPE (%)**	
nCRT							
With (*n* = 62)	0.710 (0.581-0.818)	68.00	75.68	0.853 (0.740-0.930)	68.00	89.19	0.011
Without (*n* = 241)	0.712 (0.650-0.768)	48.74	83.61	0.814 (0.759-0.861)	65.55	87.70	< 0.001

III (*n* = 193)	0.630 (0.558-0.698)	56.52	69.23	0.796 (0.732-0.851)	73.04	79.49	< 0.001

P value: Comparisons between the clinical model and combined model. AUC: Area under the receiver operating characteristic curve; SEN: Sensitivity; SPE: Specificity; nCRT: Neoadjuvant chemoradiotherapy.

It has been shown in recent studies that PNI is not only the simple diffusion of cancer cells along connective tissues covering the nerve sheath, but also the interaction of a variety of neurotrophic factors and chemokines between cancer cells and the surrounding microenvironment[5,6]. This process may induce cancer invasion, local recurrence, and metastasis, resulting in poor prognosis. Accurate prediction of PNI helps to evaluate prognosis of RC patients. Currently, the sole approach to determine PNI status is the pathological examination of surgical specimens. Preoperative prediction of PNI helps the formulation of individualized treatment[16,24]. For example, PNI$^+$ patients should accept more aggressive treatment; for instance, nCRT.

In contrast to CT and MRI, radiomics may achieve desirable outcomes for predicting PNI by extracting high-throughput features that can quantify differences between tissues invisible to the naked eyes. Different MRI-based radiomics models have been reported in RC[6,17,18]. However, the sample sizes in the previous studies were small (PNI$^+$: 26-32). In our study, a total of 144 PNI$^+$ patients were enrolled, which increased the reliability of the conclusion.

As for the methodology of radiomics, the machine-learning methods used in our study and previous studies were similar. However, the previous studies only included the intratumoral region, ignoring the peritumoral region in which PNI can also appear [7]. There is evidence that radiomics features of peritumoral regions can offer information about biological characteristics of other tumors, such as gastric[25], breast [26], and lung[27] cancer. Different from the previous studies[6,17,18], we built the model by using both peri- and intratumoral regions, and the model had comparable AUCs with the previous MRI-based models[6,18]. The specificities of our model were 88.19% in the training cohort and 93.75% in the validation cohort, as shown in Table 3, indicating low false-positive rate (misdiagnosis rate) for detecting PNI. However, the sensitivities were low (66.09% in the training cohort and 62.07% in the validation cohort).

In terms of clinical factors, cT and cN included in our model revealed a higher risk of PNI in patients with more advanced RC, which was consistent with the conclusion of a meta-analysis[28]. As for Rad-score, it was more important than clinical factors in the prediction of PNI, due to its longer axis in the nomogram. For example, a PNI$^+$ lesion in Figure 2 was incorrectly identified as PNI$^-$ by the clinical model (CEA = negative, cT = T3, cN = N1a) and correctly determined after adding Rad-score (0.805) to the clinical model with a total score of 12 points in the nomogram, showing a probability of 73% to be PNI$^+$.

Referring to the 62 patients receiving nCRT, we found that AUC of the combined model was improved (0.853; 95%CI: 0.740-0.930), suggesting that this model was also suitable for patients treated with nCRT. With the consideration of individualized evaluation of RC patients with different stages, the combined model obtained a higher AUC than the clinical model for stage III patients (AUC = 0.796 *vs* 0.630, $P < 0.001$). However, the combined model failed to outperform the clinical model among stage II patients (AUC = 0.670 *vs* 0.553, $P = 0.098$), which might be caused by the small sample size of stage II patients. As for the subgroup analysis of location, the combined model had similar predictive values in upper RC group (AUC = 0.817) and in middle-lower RC group (AUC = 0.824), indicating good applicability of the model for both upper and middle-lower RC patients.

There were several limitations to this study. Firstly, bias may have existed due to the retrospective design of this study. Secondly, PNI^- patients from January 2019 to October 2019 were not included, because the current PNI^- patients were sufficient to complete this radiomics analysis. Thirdly, all patients were enrolled from a single institution. In the future, it is necessary to conduct a multicenter validation to extend the versatility of the radiomics model.

CONCLUSION

A combined model incorporating a radiomics signature and clinical factors was described in this study. This model can provide assistance in the individualized prediction of PNI status in patients with RC.

ARTICLE HIGHLIGHTS

Research background

Perineural invasion (PNI) has emerged as an independent prognostic factor in patients with rectal cancer (RC). The preoperative prediction of PNI status is beneficial for individualized treatment and improved prognosis.

Research motivation

Nowadays, preoperative assessment of PNI status is still challenging.

Research objectives

To build a radiomics prediction model for evaluating PNI status preoperatively in RC patients.

Research methods

We enrolled 303 RC patients in a single institution from March 2018 to October 2019. These patients were classified as the training cohort (n = 242) and validation cohort (n = 61). A large number of intra- and peritumoral radiomics features were extracted to build the Rad-score and combined model.

Research results

Our study enrolled more patients (144 PNI^+ and 159 PNI^-) than previous studies[6,17,18]. Rad-score was built by logistic regression analysis. The combined model was developed by combining Rad-score with computed tomography (CT)-reported T stage and N stage, and carcinoembryonic antigen. The combined model showed good performance to predict PNI status, with an area under the receiver operating characteristic curve of 0.828 [95% confidence interval (CI): 0.774-0.873] in the training cohort and 0.801 (95%CI: 0.679-0.892) in the validation cohort.

Research conclusions

The combined model incorporating Rad-score and clinical factors helps to provide an individualized PNI status evaluation.

Research perspectives

Other biological characteristics besides PNI are also related to the prognosis of RC patients; for instance, intramural lymphovascular invasion (LVI). Intramural LVI cannot be determined by magnetic resonance imaging and CT. Therefore, using radiomics or deep learning to predict intramural LVI of RC is valuable in the future.

Abstract

We recently read with interest the article "Diagnostic approach to faecal incontinence: What test and when to perform?". This is a comprehensive and practical review, which has particular significance for guiding clinicians to improve the examination strategy. Although we appreciate their work very much, based on the in-depth analysis of this research, we found some detailed problems in the article and will give our comments in this letter. If the author can further improve the relevant research, it will be valuable.

Key Words: Faecal; Incontinence; Manometry; Diagnostic; Pathophysiology; Tools

Core Tip: Faecal incontinence (FI) has caused social, psychological, and economic pressure on an increasing number of people. It is essential to explore the diagnostic strategies and treatment techniques for FI. We read with great interest the article "Diagnostic approach to faecal incontinence: What test and when to perform?". This article had substantial clinical reference value and minor problems. We want to share our views and opinions on this valuable work.

TO THE EDITOR

We read with pleasure the article "Diagnostic approach to faecal incontinence: What test and when to perform?"[1]. Within this article, the authors analyzed and summarized systematically the assessment and examination of patients with faecal incontinence (FI), thereby providing a valuable reference for clinicians. The salient highlight of this review was that it not only systematically expounded the etiology and pathogenesis of FI but also combined clinical evaluation and inspection strategies and provided unique insights into the structured and step-by-step method of evaluating and diagnosing FI. This research has a strong reference and practical value for sorting out the management strategies for FI and overcoming limitations. We found some details through further research and analysis and anticipate a discussion with the authors.

First, the authors analyzed the etiology and clinicopathologic features of patients with FI and described the diagnostic strategies including high-resolution anorectal manometry, perineal ultrasound, transrectal ultrasound, endopelvic magnetic resonance imaging, and electromyography of the anal sphincter. The use of a standardized quality-of-life assessment tool to define the extent and impact of FI is the first step in assessing patients with FI[2,3]. For instance, the PERFECT system in the modified OXFORD scale is available for evaluating vaginal and rectal resections. However, the most critical step was not detailed in this review.

From this paper, the authors concluded that the incidence of FI had no differences in both males and females, but the pathogenesis is different. To this end, we have reviewed a great deal of relevant literature and obtained different conclusions. For example, a study from the United States reported that the prevalence of FI is 2.2%, with 63% in females and 37% in males, and approximately 30% of patients are over 65 years of age[4]. Consequently, we conclude that females are more likely to develop FI owing to their physiology and childbearing experiences[5]. In addition, the factors that cause FI are different in women and men, with women being more susceptible to anal sphincter disorders due to obstetric trauma and reduced pelvic floor muscle training (PFMT), whereas men are more likely to suffer from anorectal sensory disturbances [6]. Based on a careful analysis of the authors' list of etiologies and risk factors for FI, we found that some factors overlooked are becoming increasingly important with the increasing incidence of rectal tumors and gynecology in women. For example, undergoing rectal surgery, pelvic radiotherapy, or the presence of the tumor or inflammatory stricture (IBM) is usually accompanied by impaired rectal storage function and decreased compliance[3]. Therefore, we consider that the abovementioned factors should be supplemented.

Finally, the authors provided a review of common tools and strategies for diagnosing FI, which in turn provides guidance and reference for clinical application. Unfortunately, after extensive reading of the associated papers, we found that such strategies were insufficiently comprehensive. For example, an increasing number of studies recommend the usage of NS neurostimulation electrodes for diagnosis and treatment as a preliminary step in the absence of contraindications[7,8]. In 2012, Cochrane *et al*. conducted a meta-analysis of 21 studies and found that there is a lack of sufficient trials to support the effectiveness of pure anal sphincter exercise and biologic therapy. Consequently, a combination of biofeedback and PFMT with other methods is recommended (*e.g.*, neuroelectrical stimulation combined with techniques) may improve the overall outcome[9].

In summary, this review can be a valuable basis and reference for the diagnosis of patients with FI and is of particular practical value for guiding clinicians in the development of screening strategies. Of course, we only offer our comments based on the existing literature or data on the shortcomings of this review, and more comprehensive and clinically verified examination strategies and treatments are expected to be served for patients with FI.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Konstantinos Triantafyllou, MD, PhD, FEBGH, Professor, Hepatogastroenterology Unit, 2nd Department of Propaedeutic Internal Medicine, Medical School, National and Kapodistian University of Athens, Attikon University General Hospital, 1, Rimini Street, Athens 12462, Greece. ktriant@med.uoa.gr

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

The serrated pathway accounts for 30%-35% of colorectal cancer (CRC). Unlike hyperplastic polyps, both sessile serrated lesions (SSLs) and traditional serrated adenomas are premalignant lesions, yet SSLs are considered to be the principal serrated precursor of CRCs. Serrated lesions represent a challenge in detection, classification, and removal–contributing to post-colonoscopy cancer. Therefore, it is of the utmost importance to characterize these lesions properly to ensure complete removal. A retrospective cohort study developed a diagnostic scoring system for SSLs to facilitate their detection endoscopically and subsequent removal. From the study, it can be ascertained that both indistinct border and mucus cap are essential in both recognizing and diagnosing serrated lesions. The proximal colon poses technical challenges for some endoscopists, which is why high-quality colonoscopy plays such an important role. The indistinct border of some SSLs poses another challenge due to difficult complete resection. Overall, it is imperative that gastroenterologists use the key features of mucus cap, indistinct borders, and size of at least five millimeters along with a high-quality colonoscopy and a good bowel preparation to improve the SSL detection rate.

INTRODUCTION

The serrated pathway accounts for 30%-35% of colorectal cancer (CRC)[1]. Serrated lesions are characterized histologically by a saw-tooth or serrated glandular pattern, likely secondary to a lack of apoptosis of dividing cells in the colonic crypts, resulting in the cells folding onto each other and giving it a serrated appearance. While a variety of molecular mechanisms contribute to neoplastic progression, hypermethylation of DNA promoter regions resulting in a CpG island methylator phenotype is believed to be the major mechanism driving the serrated pathway to CRC[2] . According to the 2019 World Health Organization 5th edition classification, serrated colorectal lesions can be further defined into four main categories: Hyperplastic polyps (HPs), with microvesicular (MVHP) and goblet cell-rich subtypes; sessile serrated lesion (SSL) and SSL with dysplasia, both previously known as SSA/Ps with or without cytological dysplasia; traditional serrated adenoma (TSA); and serrated adenoma, unclassified[3]. HPs are the most common non-neoplastic polyps in the colon, typically located in the rectosigmoid region and are often less than five millimeters in size. These polyps are polypoid in appearance and do not exhibit dysplasia and therefore do not increase the risk of CRC[4]. SSLs are usually more prevalent in the proximal colon and have a smooth surface with a "cloud-like" appearance[2]. They can be flat or sessile, and may be covered in mucus. TSAs can be pedunculated or sessile in appearance and are typically found in the rectosigmoid colon. Unlike HPs, both SSLs and TSAs are premalignant lesions, yet SSLs are considered to be the principal serrated precursor of CRCs[5]. Therefore, SSLs must be distinguished from HPs to ensure an accurate diagnosis.

THE CHALLENGES OF SERRATED LESIONS

Serrated lesions represent a challenge in detection, classification, and removal. As portrayed in Figure 1, the mucus cap, flat nature, and indistinct borders makes these lesions difficult to localize endoscopically, resulting in them being incompletely removed or easily missed[6]. In terms of classification, SSLs may initially be misclassified as HPs due to similarities in histological appearance. Serrated lesions may exhibit MVHP pathology in some areas, but display SSL morphology, blurring the lines between SSLs and HPs and resulting in a misclassification and misdiagnosis[5]. In fact, certain factors such as location in the proximal colon as well as size greater than five millimeters have been shown to change the pathological diagnosis of HP to SSL[7]. For all of these reasons combined with the fact that they tend to exhibit a more rapid progression to cancer, SSLs play a role in post-colonoscopy cancer[6]. Therefore, it is of utmost importance to characterize these lesions properly to ensure complete removal and a reduction in post-colonoscopy cancer. Nishizawa *et al*[8] 2021 performed a retrospective cohort study to develop a diagnostic scoring system for SSLs to facilitate their detection endoscopically and subsequent removal.

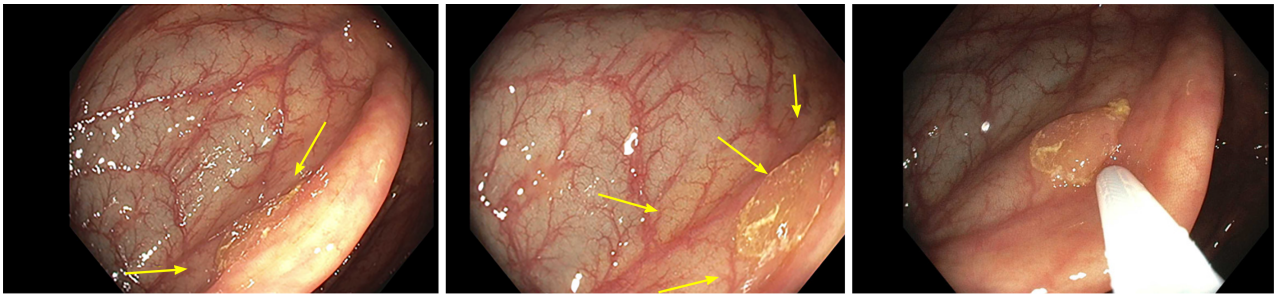

Figure 1 Flat polyp with visible mucus cap and indistinct border identified on colonoscopy at hepatic flexure. This polyp was only able to be visualized with an excellent bowel prep.

DIAGNOSTIC SCORING SYSTEM FOR SERRATED LESIONS

Nishizawa *et al*[8] 2021 collected data on serrated lesions diagnosed either by endoscopic or pathologic means. They analyzed 232 polyps that were diagnosed as serrated polyps, and univariate analysis determined that the proximal colon location ($P = 0.003$), size greater than five millimeters ($P < 0.001$), presence of mucus cap ($P < 0.001$), presence of cloud-like surface ($P < 0.001$), and presence of microvascular vessels ($P = 0.024$) were significantly associated with the presence of SSLs. Through multivariate analysis, mucus cap ($P = 0.005$), size greater than five millimeters ($P = 0.033$), and indistinct borders ($P = 0.033$) were deemed as characteristics independently associated with the diagnosis of SSLs. Each of these characteristics were assigned one point, the sum of them defining the endoscopic SSL diagnosis score. Through receiver-operating characteristic curve analysis, a cut-off score of three was determined to be most optimal, resulting in prediction of pathological SSLs with a 75% sensitivity, 80% specificity, and 78.4% accuracy. Overall, the authors determined that serrated polyps with a size greater than five millimeters, presence of a mucus cap, and indistinct borders should be removed during colonoscopy[8].

THE IMPORTANCE OF AN EXCELLENT BOWEL PREP AND HIGH-QUALITY COLONOSCOPY

From the study, it can be ascertained that both indistinct border and mucus cap are essential in recognizing and diagnosing serrated lesions. The mucus cap can mimic the appearance of a benign mucus collection and thus be missed by the untrained eye easily on colonoscopy. A practical word of advice would be to wash the mucus gently starting at the edge to observe if there is polyp tissue hiding underneath. This further emphasizes the importance of a good colon preparation and a high-quality colonoscopy. Bowel preparation should be adequate to consistently allow for detection of polyps greater than five millimeters after leftover stool suctioning[9]. It is important to note that chyme from the small intestine can coat the proximal colon when bowel preparation agents are given the day prior to the procedure, resulting in impaired detection of flat lesions[10]. Furthermore, as the time interval between the end of bowel preparation and the start of colonoscopy increases by the hour, the likelihood of having a good or excellent bowel preparation of the cecum is decreased by ten percent [11]. Splitting of bowel cleansing to half of the preparation given on the day of the procedure has shown to have overwhelmingly superior efficacy when compared to traditional regimen[12]. Split dose leads to higher adenoma detection rate and several guidelines have endorsed its use[13,14].

The proximal colon poses technical challenges for some endoscopists, which is why high-quality colonoscopy plays such an important role. Both retroflexion and second-look techniques have been shown to improve adenoma detection rate in the right colon[15,16]. Retroflexion in the right colon is a maneuver in which the colonoscope makes a U-turn, allowing better visualization of the proximal sides of the haustral folds[17]. A 2017 meta-analysis found that retroflexion detected 17% of adenomas of the right colon that would have otherwise been missed on conventional colonoscopy [15]. Superiority of retroflexion to the second examination has not been confirmed. Second examination of the right colon has been shown to improve adenoma detection rate by a very similar amount and may be preferred over retroflexion as it is an easier

maneuver to perform[16].

The indistinct border of some SSLs poses another challenge due to difficulty of complete resection. For instance, studies have suggested that residual tissue determined to be complete after polypectomy ranges from 6.5%-22.7%[18]. A pooled analysis from eight surveillance studies that followed patients with adenoma post-colonoscopy suggested that roughly 20% of malignancies were due to incomplete resection while nearly 50% of post-colonoscopy malignancies were acquired from missed lesions[19]. It is recommended that the type of resection method (*e.g.*, cold snare, hot snare, EMR) is thoroughly documented. It is also recommended that, if resected en block, non-pedunculated lesions are to be pinned to a flat surface prior to being submitted to pathology and be measured for the depth of the submucosal invasion[10].

CONCLUSION

The key constituents of the diagnostic score proposed by Nishizawa *et al*[8] 2021 provide essential information about the nature of the serrated lesions. It is imperative that gastroenterologists use those key features along with a high-quality colonoscopy and a good bowel preparation to improve the SSL detection rate. The article also stresses the importance of complete resection of the SSL and training of endoscopists to recognize and fully resect such challenging lesions.

Abstract

Coronavirus disease 2019 (COVID-19), which is caused by severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2), has affected millions of people globally. It was declared a pandemic by the World Health Organization in March 2020. The hyperinflammatory response to the entry of SARS-CoV-2 into the host through angiotensin-converting enzyme 2 is the result of a "cytokine storm" and the high oxidative stress responsible for the associated symptomatology. Not only respiratory symptoms are reported, but gastrointestinal symptoms (diarrhea, vomiting, and nausea) and liver abnormalities (high levels of aspartate aminotransferase, alanine aminotransferase transaminases, and bilirubin) are observed in at least 30% of patients. Reduced food intake and a delay in medical services may lead to malnutrition, which increases mortality and poor outcomes. This review provides some strategies to identify malnutrition and establishes nutritional approaches for the management of COVID-19 and liver injury, taking

Core Tip: The Coronavirus disease 2019 (COVID-19) outbreak caused by severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2), was declared a pandemic by the World Health Organization in 2020. It has since affected millions of persons worldwide. In some cases, entry of the virus into the cell leads to a hyperinflammatory response, giving rise to all of the associated symptomatology. Liver abnormalities have been detected frequently during the course of COVID-19, with or without related symptoms. Herein we discuss the infectious process, the response to the immune system and to the oxidative stress induced, and provide a brief guideline for nutritional therapy in patients affected by SARS-CoV-2 and liver injury.

INTRODUCTION

Severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2) belongs to the family of coronaviruses; the genome is +ssRNA, which is nonsegmented and has a size of 30 kb[1,2]. In the cytoplasm of the host cell, it can be translated immediately into protein, as occurs with messenger (m)RNA. The genome encodes 16 nonstructural proteins (nsps) that are not part of the virion and have various functions in genome replication, protein processing, viral assembly, the exit of viral progeny, and others[3]. It also codes for four structural proteins, including spike (S), nucleocapsid (N), membrane (M), and envelope (E) that are required to constitute the complete virus particle (Figure 1)[2,4]. The origin of the disease may be from BatCov RaTG13 (GenBank: MN996532), a relatively close virus and one that was isolated from horseshoe bats[5]. SARS-CoV-2 causes the disease known as coronavirus disease 2019 (COVID-19). Since March 2020, a pandemic has been declared, and up to December 31, 2020, 81475053 cases were confirmed and 1798050 deaths had been reported. The global lethality rate is 2.22%[6].

SARS-CoV-2 can affect various organs that express the entry receptor. The main receptor described is angiotensin-converting enzyme 2 (ACE2)[1]. Distribution of the ACE2 protein was investigated by immunohistochemistry, and the protein was found present in endothelial cells from small and large arteries and veins, arterial smooth muscle cells, myofibroblasts, the membrane of fat cells in various organs, and in the basal layer of nonkeratinizing squamous epithelium. Importantly, ACE2 is expressed in nasal and oral mucosae and the nasopharynx in type I and type II alveolar epithelial cells in normal lungs, which explains the respiratory tract infection. Gastrointestinal manifestations can be explained by the presence of the receptor in smooth muscle cells and in the endothelium of vessels in the stomach, small intestine, and colon. In addition, the receptor can be found in the brush border of enterocytes in the small intestine, including the duodenum, jejunum, and ileum, but not in enterocytes of the colon. In the kidney, weak glomerular visceral ACE2 staining was observed, whereas parietal epithelial cells were moderately positive. In the skin, ACE2 was present in the basal cell layer of the epidermis extending to the basal cell layer of hair follicles. Smooth muscle cells surrounding the sebaceous glands were also positive for ACE2. In the brain, ACE2 receptors were found in only endothelial and smooth muscle cells[7]. Some of the extra respiratory manifestations can be explained by the previous fin-

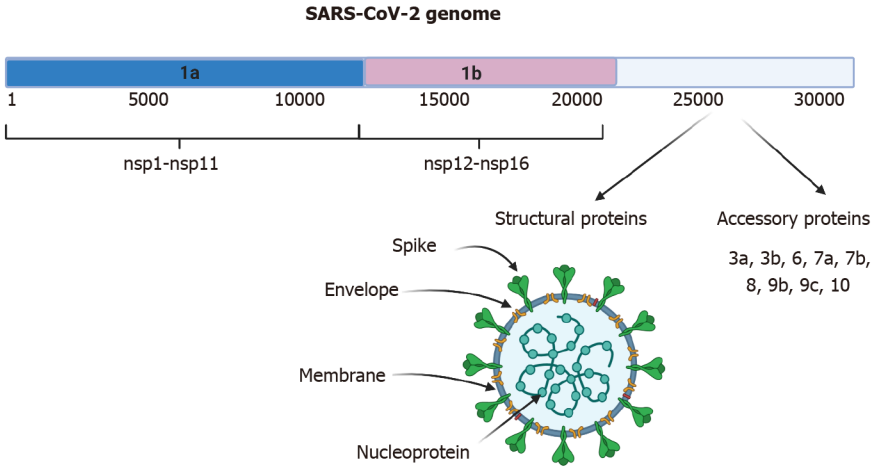

Figure 1 Genome and structure of severe acute respiratory syndrome-coronavirus-2. The 30-kb severe acute respiratory syndrome-coronavirus-2 virus genome is shown. It possesses different open reading frames (ORFs). ORF 1a generates the nonstructural proteins (nsp) from nsp1-nsp11, ORF 1b generates proteins nsp12-nsp16. The spike, envelope, membrane, and nucleoprotein structural proteins and accessory proteins are generated from the 3' region. Created with BioRender.com. SARS-CoV-2: Severe acute respiratory syndrome-coronavirus-2.

dings. However, several alterations, such as those related to the liver, require explanation. The underlying mechanisms of acute liver injury associated with COVID-19 have yet to be determined. The possible mechanisms of damage are described below.

PATHOPHISIOLOGY IN COVID-19 INFECTION

Viral receptor

The ACE2 receptor has been described as the main entry receptor for the SARS-CoV and SARS-CoV-2 viruses, and it is abundantly expressed in the cells of the biliary system (*i.e.* cholangiocytes)[7]. Thus, it has been implicated in elevated levels of alkaline phosphatase and gamma-glutamyl transferase (GGT). However, those changes have been found in a small number of patients[8], compared with elevated levels of aminotransferases directly related to functions of hepatocytes that do not express the ACE2 receptor (Figure 2)[9].

Direct damage of liver cells by SARS-CoV-2 has been reported, based on ultrastructural changes and SARS-CoV-2 viral particles observed in the cytoplasm of hepatocytes by transmission electron microscopy of liver biopsies of two COVID-19 who subsequently died, one of acute respiratory distress syndrome (ARDS) and the other of septic shock distress syndrome[10]. In a subsequent letter to the editor[11], multiple observations were made indicating that the elevation of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were not sufficient for the condition to be called acute liver injury, the number of biopsies performed were those of two patients, the characteristics of liver cell renewal could be mistaken for hepatic injury, "corona-like" particles could have been intrahepatic cholesterol crystals, and lamellations, or "crown-like" structures are observed in patients with nonalcoholic fatty liver disease.

In addition to the above observations, we would ask how the virus enters cells that do not have the receptor? In the case of cells with high phagocytic capacity that could swallow the virus, viral replication capacity would have to be investigated by the detection of nonstructural proteins. In the case of suspected viral reservoir cells, detecting at least some of the viral structural proteins would require staining, as has been reported for other viruses[12].

On the other hand, SARS-CoV-2 can use transmembrane protease serine 2 (TMPRSS2), which has not been detected in the liver, to enter cells. However, other transmembrane serine proteases have been detected, in particular furin and hepsin (in Huh7-25-CD81 cells)[13]. In three-dimensional (3D) culture systems, liver bile duct-derived progenitor cells form "liver ductal organoids" that retain their tissue-of-origin commitment and genetic stability. In a SARS-CoV-2 infection model with human liver ductal organoids, cholangiocytes expressing ACE2 and TMPRSS2 were preserved *ex vivo* in long-term culture. In addition, the expression of TMPRSS2 mRNA was found in

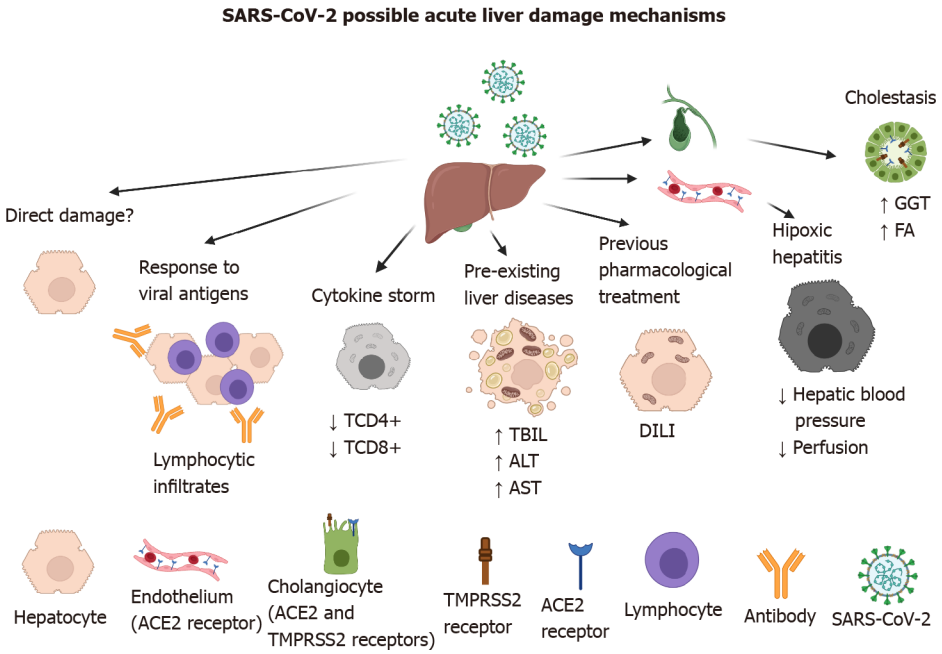

Figure 2 Possible mechanisms of acute liver damage by severe acute respiratory syndrome-coronavirus-2 infection. Direct damage to the hepatocyte is does not occur because it does not possess the viral entry receptor. However, indirect damage-associated with the immune response against viral antigens, cytokine storm, pre-existing liver diseases such as hepatitis A, B, and C viruses infection, and treatment with hepatotoxic drugs like acetaminophen, remdesivir, lopinavir, *etc.* has been characterized. In severely affected patients, oxygen deficiency can give rise to hypoxic hepatitis. Severe acute respiratory syndrome-coronavirus-2 damage to cholangiocytes has been documented, because they both possess the angiotensin-converting enzyme 2 and transmembrane protease serine 2 receptors. Created with BioRender.com. ACE2: Angiotensin-converting enzyme 2; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; DILI: Drug-induced liver injury; FA: Alkaline phosphatase; GGT: Gamma-glutamyl transferase;SARS-CoV-2: Severe acute respiratory syndrome-coronavirus-2; TBIL: Total bilirubin; TMPRSS2: Transmembrane protease serine 2.

a subset of hepatocytes and cholangiocytes[14]. In other experiments, human liver ductal organoids showed increased expression of viral mRNA 24 h after being infected with SARS-CoV-2[15]. The experimental evidence suggests that viral receptors are not static and that they can be regulated by mechanisms that involve the presence of the virus and have not yet been described.

Response against viral antigens

Damage to the liver is known to be caused by hepatotropic viruses that replicate in the liver (*e.g.*, hepatitis A, B, C, and E viruses). However, some viruses that attack the respiratory tract can cause liver damage, from small alterations in transaminases to fulminant liver failure, for example, the influenza virus[16,17], parvovirus[18], and respiratory syncytial virus bronchiolitis[19]. In general, hepatitis is thought to be a consequence of an immune response to viral antigens and to the loss of regulation of the inflammatory response. SARS-CoV-2 infection has been associated with hepatitis characterized by focal lobular lymphocytic infiltrates[20]. SARS-CoV-2 viral antigens were recently detected in liver as nucleocapsids and spike proteins[21].

Cytokine storm

The first line of antiviral defense is the innate immune response, initiated by the production of interferon (IFN) type 1 or IFN-α/β[22,23]. IFN-α/β binds to its cellular receptor and initiates autocrine and paracrine signaling to stimulate the expression of genes involved in the antiviral response (interferon-stimulated genes, *ISG*), in order to build resistance to infection and limit the spread of the virus. However, poor interferon response and high viral replication have been characterized in severe cases of COVID-19[24]. High viral replication stimulates an exaggerated systemic inflammatory response that is related to a sustained elevation of interleukin (IL)-1β, IL-2, IL-7, IL-8, IL-9, IL-10, IL-17, granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM)-CSF, IFN-γ, TNF-α, interferon γ-induced protein 10 kDa (IP-10), monocyte chemoattractant protein (MCP)-1, macrophage inflammatory protein (MIP)1α, and MIP-1β, and decreases in CD4+ T cell (TCD4+) and TCD8+ cell counts[25-27]. The latter could contribute to altered liver function[28] and to activation of the coagulation cascade[29,30], and an alteration of iron homeostasis

with elevated ferritin levels[31].

Pre-existing liver diseases

Correlations between the severity of COVID-19 and chronic diseases such as diabetes mellitus, arterial hypertension, obesity, renal alterations, and cardiovascular disease have been clearly described[32-34]. Regarding the impact of liver diseases on the progression of COVID-19, ALT and AST activity, and the concentration of C-reactive protein (CRP) have been related to the prediction of disease severity. The prediction of mortality was correlated with liver failure, total bilirubin, platelet count, and serum albumin concentration. Chronic hepatitis B and chronic liver disease were not related to disease severity, the requirement for treatment in the intensive care unit (ICU), or mortality[35]. In another study, 17 inactive hepatitis B virus carriers with SARS-CoV-2 co-infection were found to have abnormal liver function tests (total bilirubin, ALT, and AST)[36]. Thus, it is not clear whether pre-existing liver diseases, such as viral hepatitis, are associated with the severity of COVID-19 infection[37].

Previous pharmacological treatment

The liver contributes mainly to the elimination of lipophilic drugs by increasing their solubility, therefore facilitating their elimination through the cytochrome P450 isoenzyme complex. Therefore, it is important to inquire whether patients diagnosed with COVID-19 are using medications for the treatment of chronic diseases or even anti-influenza or antipyretic drugs[38]. Drugs that are especially potentially hepatotoxic, such as acetaminophen, lopinavir/ritonavir, remdesivir, corticosteroids, and immune modulators, should be taken into account[39] because they can predispose to drug-induced liver injury.

Hypoxic hepatitis

Ischemic hepatitis, also known as hypoxic hepatitis or liver shock, is defined as extensive and potentially severe predominantly centrilobular hepatocellular necrosis resulting from a significant decrease in hepatic perfusion. In patients with severe COVID-19, mechanical ventilation, or hemodynamic disturbance and the occurrence of a sudden drop in systemic blood pressure, can lead to a reduction in hepatic blood pressure, decreased perfusion, and hepatocellular hypoxia. The pathogenesis involves hepatic ischemia and hepatic venous congestion because of elevated central venous pressure, which can predispose the hepatocytes to irreversible hypoxic injury[39,40]. Additionally, the hypoxia can directly affect the tissue–oxygen demand[41].

LIVER MANIFESTATIONS IN COVID-19

Various hepatic manifestations associated with COVID-19 have been documented, ranging from mild enzyme disruption to acute hepatic injury (Figure 3). The manifestations can be grouped into enzymatic (ALT and AST), metabolic (hypoglycemia and hyperammonemia), secretory (hyperbilirubinemia), synthetic (hypoalbuminemia and prothrombin time), and degradation (D-dimer) dysfunctions. Cholestasis with impaired GGT and alkaline phosphatase (FA) is rare, but it is suggested that it may be caused by the dysfunction of the bile duct cells rather than by liver cell damage[8].

Enzymatic liver dysfunction

Liver enzyme abnormalities in patients with COVID-19 are usually transient and are associated with disease severity. Alanine and aspartate aminotransferases (ALT and AST) are generally found to be elevated in the serum and are more often observed in hospitalized patients[33,42-44] than in patients with subclinical disease. Acute hepatic injury can be diagnosed by an ALT at 10 times the upper reference limit and by AST at three times the appropriate upper reference limit[45].

Metabolic liver dysfunction

Hypoglycemia and hyperammonemia suggest liver failure and have not been found in COVID-19 patients, but there is a hypothesis that coronaviruses can cause a transient dysfunction of pancreatic beta cells[46], leading to acute hyperglycemia and relative insulin deficiency. The hypothesis is supported by a previous study including 39 patients with SARS and without a history of diabetes. Twenty of the patients developed diabetes, all but two temporarily. In addition, ACE2 has been identified in the pancreas of patients with SARS[47].

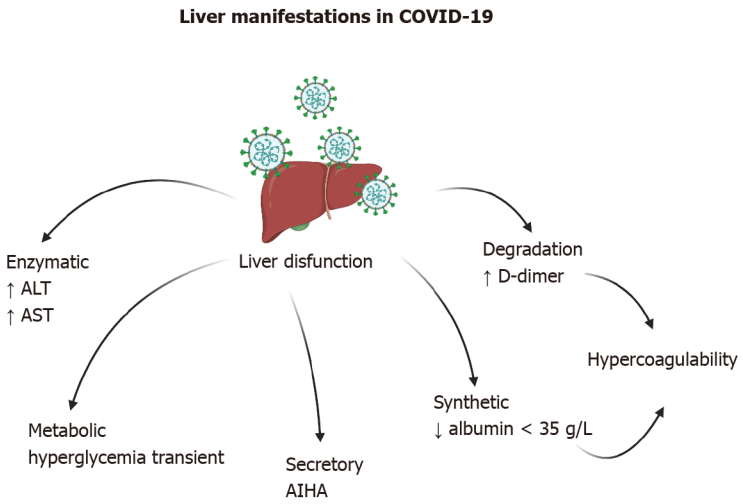

Figure 3 Liver manifestations in coronavirus disease 2019 are quite varied. Increased transaminases and hypercoagulability have been observed in the majority of patients. In rare cases, autoimmune hemolytic anemia has been observed. Created with BioRender.com. AIHA: autoimmune hemolytic anemia; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; COVID-19: Coronavirus disease 2019.

Secretory liver dysfunction (hyperbilirubinemia)

Regarding bilirubin, no relationship has been directly associated with SARS-CoV-2. However, there are reports of autoimmune hemolytic anemia (AIHA) in patients with symptomatic COVID-19[48,49]. Additionally, there is a report of a patient without clear evidence of SARS-CoV-2 infection for 2 wk and a subsequent positive PCR test. The final diagnosis was AIHA secondary to COVID-19)[50].

Synthetic liver dysfunction (hypoalbuminemia) elevated prothrombin time

Albumin is a protein synthesized in the liver and has a serum half-life of approximately 21 d[51]. In the majority of cases, a decrease in serum albumin can be explained by two factors, either a decrease in its synthesis in the liver) or an increase in renal permeability. However, the prevalence of hypoalbuminemia (< 35 g/L) in COVID-19 patients was increased in critically ill patients in an ICU, but liver damage or albuminuria were not detected. hypoalbuminemia was associated with high-sensitivity C-Reactive protein (hs-CRP) and elevated D-dimer, which is considered to be a marker of thrombin. Therefore, an attempt was made to establish a cause–effect relationship between hypoalbuminemia and hypercoagulability, in that albumin possesses anticoagulant and antiplatelet activity[52]. In a separate study, it was determined that hypoalbuminemia (< 35 g/L) on hospital admission increased the risk of death in COVID-19 patients by at least six-fold. Lower albumin levels on hospital admission can predict the outcome of COVID-19 independently of other known indicators, such as lymphocyte count or comorbidities[32,53].

D-dimer levels

D-dimer is the end-product of fibrin degradation, and it serves as a serological indicator of the activation of coagulation and of the fibrinolytic system. D-dimer levels have been reported as elevated in patients with COVID-19 and have been used as a tool for the prediction of disease severity in 178 studies[54]. In one study, it was determined that elevated D-dimer levels predicted in-hospital mortality in patients with COVID-19[55]. However, the usefulness of D-dimer is diminished by poor reporting of the values. The majority of publications did not identify either the assay manufacturer or the D-dimer product used for the determination. The majority of the authors did not identify whether D-dimer values were reported as D-dimer units or fibrinogen equivalent units (FEU), which differ by approximately ×2. The studies did not report normal cutoff values, and the units of comparison were not the same[56].

IMMUNE SYSTEM AND OXIDATIVE STRESS

Response of the immune system in infection by SARS-CoV-2

The innate immunological system functions as the first line of defense of the host

against infection by SARS-CoV-2; it is crucial for identifying and eliminating the infected cells, and at the same time, for coordinating an adaptive immunity response [57]. The immune response of the host in cases of COVID-19 can be described as an early local immune response (antiviral defense) and a later local/systemic response phase, followed by uncontrolled inflammatory responses and cytokine storm syndromes (Figure 4)[58]. Because SARS-CoV-2 initially affects the upper respiratory tract, its first interactions with the immunological system during the inductive and effector phases, should take place predominantly on the surfaces of the respiratory and oral mucosae[57,59]. Exposure to the virus antigens causes immunoglobulin (Ig)A-mediated responses in the mucosa[60,61] that can be accompanied by the systemic production of IgA, but the systemic production can be absent, transitory, or delayed [61]. The response involving IgA antibodies of the mucosa that maintains an essentially noninflammatory medium[59] and can be particularly prevalent in young people with a mild infection by SARS-CoV-2 without evidence of pneumonia[61].

If the immunological system of the individual does not counteract the virus during the initial phase of exposure through a rapid early response, the virus advances to the lower respiratory tract (LRT)[62,63]. Once the virus reaches terminal respiratory pathways and the alveoli, B and T cells are activated, which results in the production of specific anti-SARS-CoV-2 antibodies[61], with the predominance of an inflammatory environment dominated by IgG[59]. The S and N proteins are the two principal antigens of the coronavirus that induce the production of Ig[64,65]. The IgA, IgM, and IgG antibodies against the N and S proteins, and the IgM and IgG antibodies against the protein receptor-binding domain, as well as the presence of neutralizing antibodies (nAbs) against SARS-CoV-2 are positive from day 1 after the appearance of symptoms [64]. The antibody levels, especially IgG, increase during the disease course, while a limited increase of IgA and IgM is observed[64]. The antibodies against the S1 and N antigens persist for at least 3 mo after the infection[60,65]. In addition, higher levels of nAbs as well as IgG and IgM antibodies and anti-S1 and -N antibodies have been observed in patients with very severe symptoms[9]. In addition, depletion of memory B cells of IgM was associated with worse outcomes, including a higher mortality rate and a greater risk of developing superimposed infections[66].

In response to viral invasion, the innate immunological system recognizes viral nucleic acids by host recognition-pattern (HRP) receptors, which are expressed in innate immune cells (*e.g.*, neutrophils, dendritic cells, epithelial cells, and macrophages)[67], and by toll-like receptors (TLRs) and retinoic acid-inducible gene I-like (NOD-like) receptors (NLRs) (Figure 4C). For the production of cytokines and the induction of an antiviral state[57,58], as a response to specific pathogen-associated molecular patterns and damage-associated molecular patterns (DAMPs)[57,68]. HRP receptors can activate antiviral responses in neighboring cells and recruit innate and adaptive immune cells and the participation of phagocytes such as macrophages and neutrophils, as well as natural killer (NK) cells[59,68].

Once the virus was detected by an HRP receptor, intracellular signaling pathways are triggered that activate interferon regulatory factor 3 (IRF3) and the nuclear factor kappa beta (NF-κB) signaling cascade[58]. The initial phase of the production of interferon (IFN) mediated by IRF3 performs the initial phase of the innate immune response to detect and brake viral replication[69]. Viral detection stimulates the production of type-1 and type-3 IFN, which results in the expression of interferon-simulated genes ISG (*IRF1*, *IFI44L*, and *IFIT3*) and antiviral genes (*OAS3* and *ADAR*) [70], and the release of large amounts of inflammatory procytokines like interferon gamma (IFN-γ), interleukin (IL)-1RA, IL-6, IL-8, IL-10, and IL-19, monocyte chemoattractant protein 1 (MCP-1), MCP-2, and MCP-3, bonding with C-X-C motif chemokines, including CXCL9, CXCL10, and CXCL5, and tumor necrosis factor alpha (TNF-α)[71]. Stimulation of TLRs activates NF-κB, giving rise to the production of inflammatory markers deriving from monocytes (IL-1, TNF-α, and IL-6) to control the infection by means of direct antiviral pathways and the recruitment of other leukocytes[67]. Signaling is elevated 24 h after infection by SARS-CoV-2, leading to the progressive loss of the pulmonary alveolar epithelial function[62]. The activation of complement, and especially of the C5a/C5aR1 axis, was also implicated in the pulmonary pathology of COVID-19[71].

HRP receptors, particularly the nucleotide-binding oligomerization domain-like (NOD)-like receptor (NLR) family, subsequent to the SARS-CoV-2 infection, assemble a multiprotein complex called inflammasome NLRP3, which results in the activation of caspase-1. Activated caspase-1 splits from the pro-interleukin IL-1β, pro-IL-18, and gasdermin D (GSDMD) and releases the GSDMD N-terminal fragment that can be oligomerized within membranes to form membrane pores and "pyroptosis"[57]. The excision of caspase-1-dependent GSDMD leads to the release of IL-1β and IL-18[72],

which are key mediators of the inflammatory response, and their increase in the plasma have been correlated with COVID-19 mortality or severity[73]. Apoptosis, another type of cell death, also occurs during SARS-CoV-2 infection and is driven by the excision of the caspase-8, -9, -10 initiators of the executioner caspase-3 and -7. Apoptotic caspase-3 activates gasdermin E (GSDME) to induce the lytic form of cell death; the protein ORF3a of the SARS-CoV-2 virus also induces the excision of caspase-8 and -9 and causes apoptosis[57]. The activation associated with the death pathways of the inflammatory cells can give rise to critical tissue damage, severe inflammation, and lactate dehydrogenase (LDH), which is a marker of cell death that has high concentrations in COVID-19 patients. The LDH concentration is considered a predictive factor for the early recognition of pulmonary lesions in severe cases[74].

Macrophages are a key respiratory system. They produce chemokines and IFN-β. Infected dendritic cells (DCs) produce antiviral cytokines, like IFN-α and IFN-β; the proinflammatory cytokine TNF, IL-6, and high levels of the inflammatory chemokines CCL3, CCL5, CCL2, and CXCL10. The cytokines/chemokines are key factors for the chemotaxis of neutrophils, monocytes, and activated T cells[75]. Activated neutrophils, whose main function is the elimination of pathogens and dendrites by means of phagocytosis[67], release leukotrienes and reactive oxygen species (ROS) that induce local damage to pneumocytes and the endothelium, which in turn leads directly to acute lung lesions[68].

Neutrophils can also develop DNA networks called neutrophilic extracellular traps (NETs)[68] through the process of NETosis, or the release of nucleic acids enveloped in histones, which retain viral particles and promote the inactivation of the viral infection and cytokine production to restrict replication of the virus[67]. NETosis is conditioned to the production of ROS by means of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. In addition to the physical containment promoted by NETosis, NETs contain proteases and cytotoxic enzymes that permit the neutrophils to centralize lethal proteins at the sites of infection. A variety of stimuli, including toxic factors, viruses, and proinflammatory cytokines such as TNF-α and IL-8, can drive neutrophils to release NETs (Figure 4D)[67]. The uncontrolled production of NETs is correlated with the severity of the disease and the extension of the pulmonary lesion, with acute respiratory insufficiency and multiple organic dysfunction syndromes[76]. NETs also contribute to the formation of thrombi, or immunothrombosis, which can amplify the production of cytokines[68]. The inflammatory process comprises a triggering of thrombotic complications that are usually observed in patients with COVID-19, and immunothrombotic dysregulation appears to be an important marker of the severity of the disease[77,78]. In SARS-CoV-2, elevation of the neutrophil/lymphocyte ratio (NLR), a marker of infection and systemic inflammation, suggests a poor disease prognosis. In addition, patients with COVID-19 have the lowest lymphocyte count and the highest neutrophil count and NLR during severe disease[67,79,80].

The inflammatory responses in the respiratory system intended to eliminate SARS-CoV-2 result in the generation of metabolic-acid waste material that, together with an increase in respiratory muscular work, lead to the development of metabolic acidosis. Metabolic acidosis compromises adaptive cellular immunity and the efficient eradication of SARS-CoV-2[81]. Activated neutrophils and the T lymphocytes depend mainly on glycolytic metabolism for their proliferation, differentiation, and function, which results in the accumulation of lactic acid[81]. A low pH induces anergy in CD8+ T cells, suppresses NK cells, and inhibits the function of CD4+ T cells. Acidosis also increases the levels of circulating glucocorticoids; thus, their anti-inflammatory and immunosuppressor properties compromise immunity against viruses to an even greater degree[81].

Infection by SARS-CoV-2 promotes mechanisms that antagonize proinflammatory signals, particularly the signaling of IFN-I and IFN-III, but increases the expression of chemokines and proinflammatory cytokines in order to counteract the host's innate immune response[57,58,63]. Thus, the expansion and early differentiation of T cells depend on the direct action of IFN-I[82]. The descending production of interferons promotes intracellular antiviral defenses in neighboring epithelial cells that can limit viral dissemination, while the release of IL-6 and IL-1β from other immune cells promotes neutrophil recruitment and immune cell activation[68].

The three most critical components of the adaptive immune responses are viral protein-specific CD4+ T cells, CD8+ T cells, and nAbs. The nAbs produced by B cells can bind to and neutralize the extracellular SARS-CoV-2 proteins. If the Abs cannot prevent the virus from entering cells, cytotoxic CD8+ T cells are called upon to destroy the cells directly infected with their granules[83,84]. Pulmonary cytotoxic CD8+ T cells recognize and induce apoptosis in cells infected through direct mechanisms (*i.e.*

cell–cell contact) and indirect mechanisms with the participation of the perforin and granzyme-secreted cytolytic enzymes, as well as with the cytokines IFN-γ and TNF-α [85]. However, cytotoxic cells by nature do not prevent the infection, they destroy already infected cells, thus reducing propagation of the infection (Figure 4B)[59]. Transitory increases of the CD8 effector T and memory T cells constitute an effective and efficient response during early viral infection[81]. High counts of CD8+ T cells in the lungs are correlated with better control of SARS-CoV-2[80,85].

CD4+ T cells, the third arm, are auxiliaries and coordinators of the production of Abs and of the activation of the cytotoxic CD8+ T cells[83,84]. After being infected with SARS-CoV-2, CD4+ T cells are activated and differentiate to Th1 cells or circulating T follicular helper T cells (Tfh)[68,80] that secrete proinflammatory cytokines, such as IL-2, IL-6, IFN-γ, and granulocyte-macrophage colony-stimulating factor (GM-CSF)[68] that participate in the activation, proliferation, and differentiation of cytotoxic T lymphocytes. In addition, elevated levels of cytokines secreted by Th2 cells, such as IL-4 and IL-10), which inhibit Th1 inflammatory responses have been reported[86]. The severity of SARS-CoV-2 infection has been related to diminished adaptive immunity responses, mainly because of depletion of T cells and lymphopenia[80], alteration of the differentiation of T follicular helper (Tfh) cells[63,87], low levels of CD8+ NK cells[83], CD4+ auxiliary T cells[87], and memory T cells[84]. However, Abs by themselves do not correlate with the severity of the disease[64,83]. It is probable that the level of inflammation and the amount of proinflammatory cytokines are associated with the activation and depletion of T cells, but it has not yet been determined whether the early response reaches a state of depletion in individuals with severe hyperinflammation[63,70].

Lymphocytes gradually decrease as the disease advances, which results in immunosuppression manifested as atrophy of the organs of the immune system, secondary infection, and multiple organ dysfunction syndrome[75]. Lymphopenia is consistent with overrepresentation of nonfunctional T lymphocytes, with increased percentages of virgin Th lymphocytes (*i.e.* CD45RA+, CXCR3−, CCR4−, CCR6−, and CCR10−) and a persistent low frequency of markers associated with effector memory T cells, TFH cells, and regulatory T cells (Tregs)[80]. Lymphocytopenia is negatively correlated with inflammatory biochemical parameters (ferritin, fibrinogen, PCR, D-dimer, LDH) and the percentage of lymphocytes and positively correlated with the neutrophil count [80]. From an immunological point of view, lymphopenia could depend on the possibly dysfunctional deactivation of dendritic cells and on the increased concentration of cytokines such as TNF-α, IL-6, and IL-10, which act as negative regulators of the proliferation and survival of the T lymphocytes[88]. The production of acute-phase proteins such as ferritin and CRP, in addition to affecting the equilibrium of pro- and anticoagulant pathways (*i.e.* increasing D-dimer), can induce lymphocyte apoptosis [82].

The host capacity to generate efficient T cell responses after infection by SARS-CoV-2 probably depends on the directed epitopes, the presence or absence of pre-existing cross-reactive T cells, and genetic factors such as the human lymphocyte antigen (HLA) type, and the repertory of T cell receptors (TCRs)[85]. Given that activated T cells in elderly persons and in those with chronic disease present reduced responses to IFN-I, a longer time is needed to generate effective adaptive immune responses because of the deterioration of the immune functions such as the production of virgin T cells and memory T cells, which diminish with aging[84], and present asynchronous immune responses with high Ab levels and weak T cell responses[83]. Delayed activation of SARS-CoV-2-specific T cells and a reduction of the clarification of the virus increase the risk of cytokine storm, the earlier appearance of severe disease, and increased mortality[68].

In contrast with innate immune responses, which are produced before the infection and participate fully in the elimination of the virus, the adaptive immune responses begin 4-7 d after infection. If the body does not generate effective adaptive antiviral responses in time to eliminate the virus, the innate immune responses will be maintained, but without eliminating the virus in an effective manner and even leading to systemic inflammatory responses and the uncontrolled release of inflammatory cytokines[68].

The inflammatory cytokine storm, also known as the cytokine release syndrome, is a severe excessive immune response caused by positive biofeedback circuit damage of immune cells by the cytokines[67,75,87]. The formation of a cytokine storm leads to a "suicide attack" that not only limits additional propagation of the virus, but also induces secondary tissue damage[68]. The marked release of proinflammatory cytokines causes lymphopenia, lymphocyte dysfunction, granulocyte and monocyte anomalies[58], coagulation disorders such as capillary extravasation syndrome, formation

of thrombi, and even the combined immunodeficiency syndrome[76,81]. A series of destructive effects on tissues, including destabilization of the interactions among endothelial cells, damage to the vascular barrier, diffuse alveolar damage characterized by the formation of hyaline membranes[13], ARDS[57,68], tissue toxicities that affect the respiratory, hematological, gastrointestinal, cardiovascular, renal, hepatic, and neurological systems[89], multiorgan failure[80] and, ultimately death may occur [58,68,75,76]. Despite the large number of studies much of the physiology of the immune response in COVID-19 has yet to be described.

Oxidative stress and infection by SARS-CoV-2

Oxidative stress is the result of disequilibrium between the oxidant system, which consists principally of free radicals, ROS), and reactive nitrogen species (RNS), and the antioxidant systems that neutralize the free radicals[90]. Reactive oxygen and nitrogen species (RONS) are characterized by unpaired valance electrons, obliging them to react with diverse biological molecules[90,91]. ROS comprise the hydroxyl (OH) radicals, superoxide anion (O_2^-), singlet oxygen ($^1O_2$), hydrogen peroxide (H_2O_2), and ozone (O_3). RNS include nitric oxide (NO), peroxynitrite ($ONOO^-$), nitrosyl cation (NO^+), the nitrosyl anion (NO^-), and nitrose acid (NH_2O_2)[90]. Under physiological conditions, the reactive species play an important role in cellular signaling (redox signaling) and the regulation of cytokines, and growth factors such as immunomodulators, cellular differentiation, and others. However, when the equilibrium of oxidant agents and antioxidant systems is disturbed, harmful effects are generated[90,91]. The damage caused by free radicals affects cellular membranes by lipid peroxidation, oxidation, protein denaturalization, DNA damage that can induce inflammatory immune responses and increase the risk of mutations and tumorigenesis, and apoptosis[90]. In general, hydroxyl radicals are highly reactive and are responsible for the greatest cellular damage modification of biomolecules induced by ROS. H_2O_2 is considered the least harmful and can travel to and penetrate cell membranes, and the superoxide is intermediately harmful[92].

In the pathology of COVID-19, the cytokine storm is an important source of endogenous oxidative stress, and excessive production of ROS that in turn stimulates the increased release of cytokines, causing an exaggeration of the already initiated inflammatory responses (Figure 4A)[93-97]. The interaction of ROS and cytokines generates a self-sustaining cycle involving the cytokine storm and the production of oxidative stress that eventually leads to a high pulmonary protein exudate with a low hemoglobin carrier, the generation of free radicals and proteases, and an increase in the permeability and entry of edematous fluid into the alveoli. The results in deficient gas exchange in the lungs, pulmonary hypoxia, cytopathic hypoxia, damage to the epithelium, acute pulmonary lesions, disseminated coagulation, multiorgan failure and death in patients with COVID-19[95-98].

The cytokine storm with hyperinflammation accompanied by cytopenia and hyperferritinemia is known to generate ROS, by means of the Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^- + HO^-$). Additionally, the cytokines and endotoxins stimulate an isoform of nitric oxide synthase (iNOS), the inducible isoform NO, which stimulates the production of NO that in turn reacts with the superoxide to yield peroxynitrite ($ONOO^-$)[90,96]. Both peroxynitrite and NO are toxic to mitochondria, producing dysfunctional mitochondria that, in turn, result in cytopathic hypoxia[96,99]. In addition, they cause a possible oxidative storm with all of the harmful effects of RONS, in particular the peroxidation of lipids and oxidation of membrane proteins that contribute to the transformation and hyalinization of the pulmonary alveolar membranes, with lethal respiratory difficulty[90].

SARS-CoV-2 activates oxidant-sensitive pathways through inflammatory responses following activation of the NF-κB pathway[93]. The reduction of oxygen saturation leads to the generation of superoxide radicals and H_2O_2 by the mitochondria. Hydrogen peroxide triggers the expression of genes that positively regulate proinflammatory cytokines, such as IL-1, IL-6, and TNF-α, and inducible nitric oxide synthase (iNOS) by means of the activation of the (iNOS) NF-κB pathway[94,96,98,100]. That, together with the ROS, activates NLRP3 inflammasomes[101]. IFN-γ, IL-1β, IL-2, IL-6, and TNF-α stimulate the generation of NO[96]. IL-6 and TNF-α give rise to superoxide generation in neutrophils, and hydrogen peroxide stimulates the generation of IL-6[98, 102]. In cyclical fashion, the proinflammatory cytokines activate macrophages, neutrophils, and endothelial cells through NADPH oxidase (NOx) to produce more superoxide and H_2O_2. Patients with COVID-19 exhibit an overactivation of NOx2, a mechanism that favors ischemic events related to thrombotic events and associated with severe disease[103].

At the same time, the IFN-γ pathways are activated by oxidative stress induced by the inflammation intended to combat the infection by the virus[33]. Circulation of the inflammatory cytokines and ROS damage erythrocytes, leading to the generation of heme and free iron and diminish the circulating nitric oxide (NO), which worsens the existing ischemia of the organs. Deterioration of the mitochondria leads to cytopathic hypoxia, which results in a partial reduction of oxygen with the generation of ROS and the reduced energy production[98]. In addition, macrophages and activated neutrophils produce respiratory bursts that generate superoxide radicals and H_2O_2[94,98] that maintain the oxidative stress[98].

Poorly coordinated iron, especially in the presence of high concentrations of oxygen and reducers have the potential to generate hydrogen peroxide, superoxide, and hydroxyl radicals in the lung[92]. The radical superoxide anion reduces Fe (III) to Fe (II) that, in the presence of H_2O_2, produces hydroxyl radicals ($^{\bullet}OH$), which are extremely toxic and promote the formation of lipid peroxidases in the cell membrane and the oxidation of proteins, causing cell death by apoptosis[94]. Hydroxyl radicals plus free iron convert soluble plasma fibrinogen into abnormal fibrin clots in the form of enzymatic degradation-resistant dense and entangled deposits, leading to microthrombosis in the vascular system and in the microcirculation[95,96].

Oxidative damage resulting from SARS-CoV-2 infection can produce viral mutations that affect the immunological response. In addition, overproduction of ROS suppresses T-lymphocyte responses and results in weakened adaptive immunity[94], altering the structure and function of the circulating lymphocytes, principally $TCD4^{+}$, with selective depletion reduced antiviral activity of CD8+[94] T cells. In general, the host response to stress and to combat an inflammatory condition is marked by a strong increase of the cortisol level. Cortisol supports the mechanisms of the host immunological defense in a permissive manner, and high levels of cortisol suppress inflammation and prevent tissue damage[93]. However, in the case of severe COVID-19, patients can develop a corticosteroid insufficiency related to a critical disease[93]. It is known that overproduction of ROS and the weakening of antioxidants are needed for viral replication and the subsequent disease associated with the virus[97]. Viral infections alter antioxidant mechanisms leading to an unbalanced oxidative-antioxidant state and consequent oxidative cellular damage. Exposure to various pro-oxidants generally leads to activation of nuclear factor erythroid 2-related factor 2 (Nrf2) and to an increase of the expression of components of the antioxidant response. However, respiratory virus infections have also been associated with inhibition of the Nrf2 pathways that leads to inflammation and oxidative damage[97]. Nrf2 is a transcription factor responsible for the adaptation of cells and tissues including alveolar epithelium, endothelium, and macrophages to electrophilic or oxidative stress. Under normal conditions, Nrf2 is found in the cytoplasm bound to its inhibitor Keap1, which is directed to Nrf2 for ubiquination and later degradation. In the presence of electrophiles or ROS, the Keap1–Nrf2 complex dissociates and Nrf2 migrates to the nucleus where it stimulates the transcription of target genes with sequences of antioxidant response elements in their promoters[104]. Nrf2 controls the expression of the genes that participate in the antioxidant response, redox homeostasis, and the biogenesis of the mitochondria, *etc.* In addition, Nrf2 functions as a transcription repressor that inhibits the expression of inflammatory cytokines in the macrophages (*e.g.*, IL-1β, IL-6, and TNF-α)[95]. SARS-CoV-2 can interfere with the equilibrium between the transcription factor NF-κB involved in the expression of cytokines and in the activation of Nrf2, responsible for the expression of antioxidant enzymes[96], including hemoxygenase 1 (HO-1), superoxide dismutase 1 (SOD1), superoxide dismutase 3 (SOD3), glutathione S-transferase (GST), catalase (CAT), and glutathione peroxidase (GPx)[96]. Nrf2 also regulates the increase in the production of the antioxidant enzymes NAD(P)H and quinone oxidoreductase (NQO1), and enzymes needed for the biosynthesis of glutathione, which functions as the main cellular antioxidant[95]. In patients with SARS-CoV-2 infection, deficiencies in systems protection against free radicals, as well as deficits in superoxide dismutases (SODs), CAT, and reduced glutathione (GSH) have been described[94].

Oxidative stress is already increased in the elderly and people with diabetes and chronic cardiovascular diseases[90,91]. Increase in the stress level in response to viral infection affords a possible explanation of the severity of COVID-19 in such patients. In addition, elderly individuals may particularly vulnerable to infection by SARS-CoV-2 because the level and the activity of Nrf2 diminish with age[98]. Therefore, aging is not only associated with alterations in the response to adaptive immunity, but also to a proinflammatory state in the host[97].

NUTRITIONAL MANAGEMENT AND APPROACHES

Malnutrition in patients with COVID-19 infection

SARS-COV-2 infection and the resulting COVID-19 may cause multiorgan failure in addition to respiratory symptoms, including gastrointestinal (GI) and liver dysfunction, which can be complicated in the elderly or in the presence of comorbidities. There are complications associated with prolonged ICU stays; thus, the longer the ICU stay, the greater the risk of malnutrition. Malnutrition, mostly undernutrition, is the result of inadequate food intake or altered nutrient assimilation, and when it is caused by disease, different degrees of acute or chronic inflammation contribute to the state. Inflammation induces the elevation of resting expenditure, anorexia, and reduced intake. Such catabolic conditions modify body composition, with waste of muscle mass that alters functionality along and clinical outcomes[105]. Indeed, malnutrition may develop as a result of the physiological effects of SARS-COV-2, management procedures such as ventilation. Limited access of patients to direct consultations with healthcare professionals because of confinement impairs the identification of risk factors for malnutrition as well detection of the reduced food intake. Unplanned weight loss and the diminution of muscle mass induce a catabolic state in the patient, with an impact on mobility and, in turn, a poor quality of life and an increased risk of mortality, in addition to the complication of polymorbidities. As a consequence of malnutrition, immune function can be reduced, respiratory and muscle strength may be impaired, which delay recovery and result in longer hospital stays with poor outcomes. Thus, the additional use of healthcare services increases costs.

Based on the previous statement, malnutrition should be identified as an early step in the assessment of patients with SARS-CoV-2 infection, especially in patients with a high risk of mortality or of poor outcomes, such as older adults and polymorbid individuals. The identification of malnutrition is crucial for establishing effective nutritional support in order to improve food consumption, nutritional status, the patient's health prognosis, and even to prevent the occurrence of COVID-19 in the future. Particularly in the COVID-19 crisis, food and nutrient absorption is often impaired by nausea, vomiting, and diarrhea, the main GI symptoms, which lead to enhanced malnutrition. The international meta-analysis of McClave *et al*[106] of 47 studies in 10890 patients who were analyzed to determine the prevalence of liver and GI manifestations resulting from COVID-19 established consultative management of patients. Nausea/vomiting was a very frequent GI manifestation with a pooled prevalence of 7.8% (95%CI, 7.1%-8-5%) followed by diarrhea in 7.7% (95%CI, 7.2%-8.2%) and abdominal pain in 2.7% (95%CI, 2.0-3.4%). Moreover, ALT had a pooled prevalence of 15% (95%CI, 13.6%-16.5%) and AST had a prevalence of 15% (95%CI, 13.6%-15.4%) as manifestations of liver disorders. A cohort study of patients with COVID-19 in Hong Kong revealed that GI symptoms were present in 17.6% of patients and that diarrhea appeared to be the most common symptom. In the meta-analysis, the RNA virus was detected in 48.1% (95%CI, 38.3%-57-9%) of stool samples, and 70.3% (95%CI, 49.6%-85.1%) of the samples were collected after respiratory samples were found to be negative. Therefore, good management must be considered as a low risk of infection through endoscopic procedures or saving stool samples[107]. Thus, it is suggested that, prior to the administration of any treatment, it is necessary to evaluate the nutritional status of every infected patient.

In clinical practice, malnutrition is assessed with various tools (Table 1). The European Society for Clinical Nutrition and Metabolism (ESPEN) recommends using the Malnutrition Universal Screening Tool (MUST) for the identification of malnutrition in patients diagnosed with COVID-19[100]. The MUST instrument was designed for persons at risk of malnutrition, not only in those who are underweight but also in obese individuals. In patients with SARS-COV-2, loss of appetite is very frequent because of symptoms such as shortness of breath, loss of taste and smell, muscle pain, fatigue, and general discomfort. Related symptoms may contribute to insufficient achievement of energy and nutrient demands, thus promoting unplanned weight loss. To perform the MUST assessment, simple objective measurements of weight and height are needed to estimate the body mass index (BMI) in addition to weight at 3-6 mo previously. The acute disease effect denoted no nutritional intake for more than 5 d. However, even if conditions do not allow for obtaining objective measurements, screening can be carried out utilizing other measurement options, such as ulna length to estimate height and mid-upper-arm circumference. The latter are very useful for subjective BMI estimation in that healthcare personal and professionals, the patients' family members, or the patients themselves are able to obtain them. Nevertheless, if the patients are in the ICU or at home, and if it is not possible to obtain the measurements in any manner, the second step comprises the subjective

Table 1 Tools for malnutrition detection in patients with coronavirus disease 2019 and liver injury

Tool	Target patients	Criteria
MUST	Low weight	Objective criteria:
		Objective measures: weight and height to obtain BMI
		Other measures (optional): ulna length and mid upper arm circumference
		Weight loss in las 3-6 mo
	Obese patients	Subjective criteria:
		Reduced food intake in last 5 d: clinical management, psychological factors
		Weight loss appearance (clothes, jewelry)
NRS-2002	Hospitalized individuals	BMI
		Weight loss within 3 mo
		Reduced dietary intake in last week
NUTRIC score	Hospitalized patients at ICU	Age
		Days hospitalized or in the ICU
		Number of comorbidities
		IL-6 levels (optional)
		APACHE II score
		SOFA score
APACHE II score	Patients at ICU (predicting mortality)	Age
		Temperature
		Mean arterial pressure
		pH
		Heart rate/pulse
		Respiratory rate
		Sodium, potassium levels
		Creatinine
		Acute renal failure
SOFA score	Patients at ICU (estimation of mortality)	PaO_2
		FiO_2
		Medical ventilation
		Platelets level
		Glasgow Coma Scale
		Bilirubin levels
		Mean arterial pressure or administration of vasoactive agents required
		Creatinine levels
		Is a COVID-19 patient?
GLIM	Individuals at risk in general	Phenotypic criteria:
		Weight loss
		Low BMI
		Loss of muscle mass
		Etiologic criteria:

NRF-NPT	Detection of malnutrition in liver patients disease	Reduced food intake or assimilation
		Presence of disease or inflammation
		Unplanned weight loss in las 3-6 mo
		BMI
		Reduced dietary intake and uncompleted meals

BMI: Body mass index; GLIM: Global Leadership Initiative of Malnutrition; ICU: Intensive care unit; MUST: Malnutrition Universal Screening Tool; NRF-NPT: Royal Free Hospital-Nutritional Prioritizing Tool. NRS-2002: Nutrition Risk Screening-2002; NUTRIC: Nutrition risk in the critically ill; SOFA: Sequential Organ Failure Assessment.

criteria. The patient is asked to seek information related to reduced food consumption during the last 5 d or more, apparent weight loss visible in clothes and jewelry, changes in smell and taste perception if the cause of the reduced food intake is due to related symptoms in COVID-19 described previously, clinical management (ventilation, medication, and sedation), or because of the influence of physiological factors (social restriction, anxiety, and depression). The subjective criteria are useful to estimate a low, medium, or high risk of malnutrition under different circumstances, considering the limitations of infection-control restrictions instituted by local policies. It is highly recommended that patients remaining at home also perform a complete MUST assessment following progress after the implementation of nutritional strategies.

Several tools developed for assessment of hospitalized patients have been applied in COVID-19. Nutrition Risk Screening-2002 (NRS-2002) criteria, also recommended by ESPEN, predict malnutrition in hospitalized individuals and are recommended by the American College of Gastroenterology (ACG) guidelines for nutrition therapy[106]. NRS-2002 takes into account BMI; weight loss within the past 3 mo; reduced dietary intake in the previous week, and an ICU stay. In addition, the Nutrition Risk in the Critically ill (NUTRIC) score[108-111] is designed for patients, particularly for those in the ICU, and for those who can benefit from nutritional therapy considering their age, days hospitalized or time in the ICU, number of comorbidities, IL-6 Levels (optional). The Acute Physiology And Health Evaluation II (APACHE II) score[112,113], which is the most widely used tool for predicting mortality in the ICU, and the Sequential Organ Failure Assessment (SOFA) score[114,115], which estimates ICU mortality based on clinical data and laboratory results have both been used in COVID-19 clinical trials[116].

Recently, the Global Leadership Initiative on Malnutrition (GLIM), which includes the leading clinical nutrition societies worldwide, achieved a consensus with the purpose of establishing global criteria for the diagnosis of malnutrition in clinical practice. Such a consensus is a two-step approach. The first consists of the identification of "at risk" status by validated screening tools, and the second is the assessment for the diagnosis and categorization of the severity of the malnutrition[117]. According to this, three phenotypic criteria were highlighted: weight loss; reduced muscle mass, and low BMI, along with two etiological criteria, reduced food intake or assimilation and the presence of disease or inflammation. Therefore, the diagnosis of malnutrition requires at least one phenotypic and one etiologic criterion. The stratification of the phenotypic metric considers stage 1 (moderate) and stage 2 (severe) [117].

In patients with liver damage caused by COVID-19, the risk of malnutrition may be increased by the presence of GI-associated abnormalities. In severe cases of COVID-19 infection, liver injury has most commonly been observed. At the same time, patients with previous liver damage represent more critical cases of COVID-19[118]. The incidence of liver injury ranges from 14%-53%[8]. Approximately one-third of the infected population reported altered aminotransferase levels. Liver damage may affect glucose, amino acid, and lipid metabolism, and result in poor clearance of lactate and protein catabolism as a consequence of hyperaminoacidemia, and hyperammonemia, which contributes to malnutrition. On the other hand, it is crucial to determine whether the liver injury is a consequence of pre-existing liver injury (cirrhosis, viral hepatitis, NASH, and ASH) or the result of COVID-19 infection and/or the reported drug-induced liver injury. In conjunction with the MUST and NRS-2002 tools for malnutrition assessment, ESPEN recommends the Royal Free Hospital-Nutritional Prioritizing tool (RFH-NPT), which has been developed for the detection of malnutrition in patients with liver disease[119]. RFH-NPT is a validated tool very similar

to NRS-2002, but it has demonstrated greater sensitivity for the identification of malnutrition in liver diseases. The screening tool considers nearly the same indicators, namely unplanned weight loss in the previous 3-6 mo, BMI, reduced dietary intake, and uncompleted meals. The stratification scale is based scores of 1 (low risk), 2 (moderate risk), and 2-7 (high risk)[120]. Thus, in patients with COVID-19 and liver damage, the use of at least two of these options for the detection of malnutrition could be reasonable.

Nutrition strategies for liver injury in COVID-19

In COVID-19, disease complications are basically the result of a hyperinflammatory response mediated by cytokine storm and several immune-related stimuli mentioned above. Thus, nutrition treatment should be designed to strengthen the immune system during the COVID-19 crisis, providing nutrients that relieve inflammation and oxidative stress. Whether liver injury emerges as a consequence of COVID-19 or pre-existing before infection, nutrition strategies should also correct liver and GI manifestations as related symptoms to prevent or treat the associated malnutrition.

Energy and nutrient recommendations

Liver injury associated with COVID-19, as in any disease, could enhance inflammation, which alters the metabolic rate. In critically ill patients, it is recommended to estimate energy needs by means of indirect calorimetry considering all of the conditions for sterility during the measurement procedure. Significant increases in resting energy expenditure (REE) in patients with acute liver failure (ALF, 18%-30%)[121], alcoholic hepatitis (55%)[122] and alcoholic cirrhosis (26%)[123] have been reported. Hypermetabolism reported in patients with liver cirrhosis (> 30%)[124] could be related to effect of delay in the improvement of body composition on clinical outcomes. Hence, because of the individual variability in liver damage, REE should be measured by indirect calorimetry. Recently, the estimation of REE with a less-expensive handheld calorimeter method based on a respiratory quotient of 0.85, and which is very accurate for REE has been proposed[125]. However, when accessibility to calorimetric equipment is limited, prediction equations for the estimation of energy expenditure could be employed. A summary of caloric and nutrient recommendations is shown in Table 2. Caloric intake should be 1500-2000 kcal/d for normal maintenance by oral diets, with an increase of 400-500 kcals under conditions of stress or in an infection crisis[126]. ESPEN guidelines[100] suggest 27 kcal/kg body weight (Bw)/day in polymorbid patients and in patients > 65 years of age. For low-weight or older patients, it is suggested to achieve 30 kcal/kg Bw/day. In malnourished cirrhotic patients with muscle depletion, the energy supply must provide 30-35 kcal/kg Bw/day. Contrariwise, in overweight or obese patients with liver disease, the prognosis may be worse. In such cases, obesity has been associated with portal hypertension[127]. For that reason, an increased energy intake is not recommended. Nonetheless, all energy recommendations must be adjusted individually, taking into account disease severity, mobility, physical activity, and tolerance. In severely underweight patients, the energy supply must be carefully administered in order to prevent the refeeding syndrome, which is very common in such patients. Whenever possible, oral feeding should be the first energy and nutrient-supply option. When oral feeding is not feasible, support nutrition therapy by nasogastric tube through enteral nutrition (EN) or parenteral nutrition (PN) should be available as the next step.

Proteins in the diet are known to be crucial nutrients for gut-associated lymphoid tissue, as are active immunoglobulins, which act against infection in the gut mucosa[128]. The consumption of high-value proteins that contain essential amino acids is associated with immune responses, for example, adequate production of antibodies; activation of T and B lymphocytes, macrophages, and NK cells; and the production of cytokines and other immune elements that prevent infectious diseases[129]. In addition, in order to prevent body weight loss and muscle mass, > 1 g/kg Bw/day of protein intake is recommended for patients with anorexia or reduced food intake. In general, 1 g/kg Bw/day is sufficient to meet the requirement, but protein intake should be adapted to individual needs according to disease status, physical activity, and tolerance. Overall, 70-100 g/d of protein are acceptable in the oral diet, preferably consumed from animal (milk, yogurt, meat, fish, chicken, and cheese) and vegetable sources (beans, soy, nuts, and peas)[126]. Oral nutrition supplements (ONS) are a fairly good option when the goals of oral feeding are not fully achieved. In the latter cases, ONS are suggested to supply 150-400 kcals and 15-30 g of protein and should be consumed for at least 1 mo[100,126].

Table 2 Energy and nutrient recommendations for patients with coronavirus disease 2019 with or without liver injury

Energy/Nutrient	Criteria	Recommendation
Estimation of REE	All individuals with COVID-19	Estimation by indirect calorimetry
		Prediction equations
Calories	Normal oral diets	1500-2000 kcals/d
		Increase 400-500 kcals in stress or infection crisis
	Polymorbid, old patients > 65 yr	27 kcals/kg Bw/day
	Low weight, older patients	30 kcals/kg Bw/day
	Malnourish chronic patients and muscle depletion	30-35 kcals/kg Bw/day
	-Patients with COVID-19 outside ICU	ONS with low oral intolerance:
		150-400 kcals/service
		70-100 g protein/service
		Carbohydrates, fiber, PUFAs, vitamins, minerals, probiotics
		Consuming for a month
Protein	Normal individuals (prevent loss and muscle mass)	1 g/kg Bw/day
		70-100 g/d
		Form animal (milk, yogurt, meat, fish, chicken, cheese) and vegetable sources (beans, soy, nuts, peas)
	Patients with liver cirrhosis sarcopenic	1.2-1.5 g/kg Bw/day
	Obese sarcopenic	Oral supplementation of BCAA 0.20-0.25 g/kg Bw/day or 30 g/d
		Glutamine and arginine supplementation
Carbohydrates/fat	Patients with COVID-19 without respiratory impairment	Ratio 70:30 carbohydrates/fat
		Medium and low glycemic
		Fiber 25-30 g/d
		PUFAs: DHA, EPA, ALA
	Patients with ventilator support	Ratio 50:50 carbohydrates/fat
Vitamins	All individuals with COVID-19	A, C, D, E, folate, B_6 and B_{12} (monitoring in patients with liver abnormalities)
Minerals	All individuals with COVID-19	Zinc, copper, selenium (monitoring in patients with liver abnormalities)
	Critically ill patients	EN after 24-36 h. after ICU admission
		Initiate with trophic low-dose (10-20 mL/h.)
		Polymeric formula: 15-20 kcals/kg Bw and 1.2-2.0 g/kg Bw/day of protein vitamins, minerals, fiber, probiotics
		Provide 70%-80% needs in over 1 wk
	Sever obese patients BMI > 50	Energy 22-25 kcals/kg IBW
		Protein 2 g/kg per day (Class I, II) or 2.5 g/kg IBW/day of (Class III)
		Vitamins, minerals, fiber, probiotics
	Gastric intolerance individuals	Use prokinetics
		Post-pyloric feeding in persistence intolerance or at high risk of aspiration
	Patients with no GI feasible	PN recommended
	Poor nutrition status	Limit the use of omega-6 soy-based ILE during first week
	Prolonged stay at ICU	Mixture of lipids such as olive oil based ILE or SMOF (soy,

	medium chain triglycerides, olive oil, fish oil)

ALA: Alpha linoleic acid; BCAA: Branch chain amino acids; DHA: Docosahexaenoic acid; EN: Enteral nutrition; EPA: Eicosanoid acid; GI: Gastrointestinal; IBW: Ideal body weight; ICU: Intensive care unit; ILE: Intravenous lipid emulsion. ONS: Oral nutritional supplements; PN: Parenteral nutrition; PUFAs: Polyunsaturated fatty acids; REE: Resting energy expenditure.

In liver injury, nutritional approaches must be attended to according to the type and grade of the lesion(s). In patients with acute liver failure, nutrition therapy must be centered on providing sufficient energy in the form of glucose and fatty acids along with vitamins and mineral elements, preventing hypoglycemia and hypertriglyceridemia, and protein and amino acid sources adequate to avoid catabolism and to promote protein synthesis. Patients with liver cirrhosis are very likely to experience malnutrition and muscle wasting because of a decrease in protein synthesis and increased total protein breakdown. The recommendation is 1.2-1.5 g/kg Bw/day of protein to ameliorate protein synthesis in patients with sarcopenia, including those with obese sarcopenia, preferably with high-quality proteins from animal and vegetable sources in oral diets. In those with poor tolerance of protein, vegetable sources are acceptable[119]. It is preferable to distribute the intake in 3-5 meals a day, avoiding long starvation periods. A late evening snack of protein and carbohydrates has been shown to be very effective in improving nitrogen balance in cirrhotic patients[130, 131]. Oral supplementation with isoleucine, leucine, valine, and branched chain amino acids (BCAA) has been useful for patients with intolerance to protein with liver encephalopathy. In liver dysfunction, low BCAA levels are regularly observed in addition to high levels of tryptophan, aromatic amino acids, and sulfur-containing amino acids. The imbalance of amino acids may induce liver encephalopathy. Hence, the administration of 0.20-0.25 g/kg Bw/day or 30 g/d of BCAA has beneficial effects on the patient's mental state after episodes of encephalopathy and on improvement of protein metabolism[132,133]. In addition, BCAA supplementation in protein-restricted diets has been associated with improvement of the intestinal immune defense by increasing the levels of jejunal and ileal immunoglobulins and protecting duodenal villous morphology[134]. Some amino acids are responsible for modulating the immune response; for instance, glutamine activates protein participation with extracellular signal-regulated kinases (ERKs) and c-Jun N-terminal (JNKS) kinases in signal transduction, triggering transcription factor activation, and the expression of genes regulating the proliferation of lymphocytes, macrophages, and neutrophils. Moreover, glutamine induces the expression of some cytokines, including IL-6, TNF-α, and IFN-γ, and certain surface markers of lymphocytes[135]. Under catabolic and hypercatabolic conditions, glutamine has an essential role in metabolism; therefore, it is widely utilized in clinical nutrition under conditions of immunosuppression[135, 136]. On the other hand, arginine and its downstream metabolites citrulline and ornithine are involved in T cell activation, and promoting and modulating innate and adaptive immune responses[137].

During liver injury, the metabolism of glucose is altered, the glucose oxidation rate is reduced, and the glucose production rate in the liver is low because of the depletion of glycogen stores despite increased gluconeogenesis. Glucose deposition in skeletal muscle and liver as glycogen is impaired. At the same time, glucose uptake in tissues is reduced because of insulin resistance in response to high secretion and reduced degradation[138,139]. Lipid metabolism reflects an augmented rate of lipid oxidation parallel to insulin resistance. Additionally, the plasma levels of essential and polyunsaturated fatty acids are reduced in relation to the nutritional status and to the severity of the injury[140]. In patients with COVID-19, the ratio of carbohydrates to fat should fall within the range of 70:30 for patients without respiratory impairment and within 50:50 in patients on ventilatory support[141]. Nonetheless, it is noteworthy to take into consideration the previously mentioned changes in glucose and lipid metabolism in patients with liver disorders. In oral diets, low glycemic index foods, such as vegetables, whole grains, and legumes, are preferable rather than those with high glycemic/glycemic loads, which have been associated with the immediate increase of the inflammatory cytokines IL-6 and TNF-α[89] and CRP[142]. In parallel, fatty acids (FAs) have also been associated with the immune response, impacting on macrophages, epithelial cells, lymphocytes, neutrophils, dendritic cells, and lymphoid cells [143]. The consumption of saturated and trans-FAs from processed and fried foods has been correlated with the elevation of hs-CRP, IL-6, and TNF-α[144]. In influenza A virus infection, a diet rich in saturated FAs has been associated with impaired immune viral response, resulting in higher viral loads in the lung and heart, inducing inflam-

mation and tissue damage[145]. Contrariwise, polyunsaturated FAs, particularly omega-3 FAs, have a potent anti-inflammatory effect. Omega-3 FA eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), consumed mainly from fish and seafoods, including α-linolenic acid (ALA) consumed from plant sources, have been reported to initiate anti-inflammatory signaling[143]. In epithelial cells in the lungs, gut, and skin, omega-3 FAs are capable of activating nuclear and transmembrane receptors and can restore a compromised barrier defense and reducing the production of anti-inflammatory mediators such as IL-1β, TNF-α, interferon gamma (IFN-γ), and lipopolysaccharides (LPSs)[69]. Also, they reduce the expression of ERK1/2 MAPK, NF-κB, and COX-2, the main signaling pathways of the inflammatory response[69]. In viral infections, supplementation with omega-3 FAs appears to inhibit the production of TNF-α, IL-1β, IL-6, and IL-8 and reduce the production of ROS. In critically ill patients in the ICU, the addition of fish oil rich in omega-3/antioxidants in the enteral formula appears to enhance the response to oxygen therapy, improve clinical outcomes, and shorten ICU stays[146,147].

For patients outside the ICU, nutrition treatment should begin early, within 24-48 h of hospitalization, orally and mainly in older and polymorbid patients, whose nutritional situation may be compromised. The use of ONS could be fully applicable in patients with COVID-19 and liver injury in order to prevent or treat malnutrition and reestablish liver function. ONS are recommended to meet energy, macronutrient (carbohydrate, protein, and lipids) and micronutrient (vitamins and mineral elements) needs. Fiber and probiotics are suggested to promote optimal intestinal function. The increase of dietary fiber from whole grains benefits gut microbiome composition and is also correlated with reducing both systemic and gut inflammation by reducing IL-6, TNF-α, and hs-CRP, and by increasing short chain fatty acids (SCFAs)[74]. SCFA are produced by gut microbiota as a result of dietary fermentation. They are potential activators of anti-inflammatory signaling cascades and inhibitors of proinflammatory cytokines, as well as the reduced expression of NF-kB[72]. Furthermore, dietary fiber has been reported to promote healthy gut microbiota, which is related to inhibition of systemic inflammation and enhanced mucosal thickness, protecting the gut barrier from the infiltration of pathogens[77]. Dietary fiber is also thought to influence the gut microbiome and respiratory function, and it is noteworthy that, in some cases, the macrophage response to respiratory viruses is linked to the composition of the gut microbiome[148].

Vitamins and minerals in nutrition therapy

Some vitamins and mineral elements have attracted special attention because of the potential benefit that they may have during the COVID-19 crisis. In general, treatment with vitamins A, C, D, and E, folate, vitamin B_6 and B_{12}, and minerals including zinc, selenium, copper, iron, and calcium is recommended as ONS as well as by consumption of natural food sources in the diet. To date, there is no consistent evidence to support the idea that the previously mentioned vitamins and minerals possess a potential effect in preventing or treating the COVID-19. Nonetheless, in agreement with previous data regarding their effect on reducing flu symptoms and possessing antioxidant benefits, the consumption of vitamin C is suggested for consumption within a range of 1-2 g in persons at risk of respiratory infections[149]. Vitamin C exerts an influence on the immune system and on the production, development, and maturation of lymphocytes, and in the promotion of phagocytosis and chemotaxis of leukocytes during infection[82,150]. In pneumonia, vitamin C has been found to reduce ROS and inflammation by inhibiting the activation of NF-κB that, in turn, decreases IL-1, IL-8, IL-6, and TNF-α production, and reduces DNA damage and LPS-induced ROS[82]. In various trials that investigated the treatment of sepsis and ARDS vitamin C was found to reduce TNF-α and IL-1β and increase CAT, SOD, and glutathione levels[151]; in that regard, vitamin C supplementation could be beneficial in COVID-19.

Regarding vitamin D, recent investigations have pointed out its role in preventing infections, including COVID-19. Vitamin D has been described as possessing anti-inflammatory and immunomodulatory effects and may interfere with viral replication, probably by its effects on innate and adaptive responses by the modulation of defensins and cathelicidins and reduction of the Th1 helper cell response[152]. Furthermore, vitamin D participates in the activation of regulatory T cells and Th2 cells along with a decrease of proinflammatory cytokines, such as TNFα and IFNγ, which are involved in the pathogenesis of ARDS, by Th1 cells[153]. Vitamin D deficiency is correlated with an increase of susceptibility to infections and increased autoimmunity; its benefits are thus highlighted in persons with low levels of vitamin D[154]. One of the possible mechanisms by which vitamin D could impair the entry of COVID-19 into

host cells is by suppressing the adhesion molecule CD26/DDP4, a key element for viral entry[155]. Another possible mechanism of lung protection is through regulation of the renin–angiotensin system to inhibit viral entry and replication[156].

It appears that the role of vitamin A in preventing the effects of COVID-19 is not fully understood, but it is known that retinoic acid, the most active retinoid form of vitamin A, has an impact on the production of IL-1β and IL-1 receptor antagonists by means of alveolar macrophages and the consequent infiltration of neutrophils into the lungs during the course of ARDS. Retinoic acid contributes to surfactant production, which may be another way to protect against ARDS. Meanwhile, carotenes attenuate ROS production, diminishing the level of oxidative stress in the lungs. Under conditions of vitamin A deficiency, epithelial damage is often observed during viral infections, as is the increase of susceptibility of the host to respiratory viruses like influenza and SARS-CoV[156].

The most relevant activity of vitamin E is it antioxidant activity, which protects against free radicals like superoxides. In addition, the vitamin E effect is associated with the immune response of lymphocytes, NK cells, and neutrophils, which decline in the elderly[157]. Vitamin E supplementation in older adults was shown to enhance immune cell functions including neutrophil chemotaxis and phagocytosis, NK cell activity, and mitogen-induced lymphocyte proliferation[158].

With regard to the vitamin B group, vitamins B_6, B_9 (folate), and B_{12} are considered relevant to immune function in the context of the COVID-19 pandemic framework [159]. Low concentrations of B_6 influence on lymphocyte maturation, antibody responses, and the cytotoxic activity of NK cells. Folate intervenes in the response of Th1 and NK cells and in optimal antibody production[160]. Two mechanisms have been proposed by which folate may blunt the COVID-19 infection. The first is the significance of the homocysteine-mediated trans-sulfuration pathway and of ferroptotic stress that leads to cell death[88]. The second is the probable disruption of furin protease activity involved in SARS-CoV-2 spike protein cleavage, as mentioned previously[161]. Vitamin B_{12} also participates in antibody responses and circulating lymphocyte levels. In DNA synthesis, which is important for cell replication, B_{12} restores an abnormal ratio of CD4+/CD8+ T cells, and its deficiency may be associated with the impairment of the immune response to viruses and bacteria in conjunction with suppressed NK cells[86]. Hence, the consumption of folate, B_6, and B_{12}, is recommended, and they should be integrated within nutrition therapy.

The trace minerals zinc, copper, and selenium are intricately involved in immune function. Zinc is highlighted because of its immunomodulatory effects on NK cell activity and macrophage and neutrophil function, complementary activity, and T cell-mediated function. Antioxidant activity has been attributed to trace minerals because they are cofactors of antioxidant metalloenzymes such as SOD. Zinc deficiency is implicated in the systemic activation of NF-κB[162]. Zinc might reduce viral replication and attenuate GI and respiratory symptoms related to COVID-19. Additionally, zinc at low doses (2 μmol/L) can prevent SARS-CoV replication by inhibiting SARS RNA polymerase[163]. Increased intracellular levels of zinc enhance the therapeutic effect of some drugs employed in the treatment of COVID-19, such as chloroquine, disulfiram, and tetracycline[164]. Recent evidence supports the idea that maintaining optimal levels of zinc is fundamental for resistance in the host response in COVID-19 and for preventing other viral infections[165]. A clinical study of four patients treated with oral administration of a high dose of a zinc salt, based on previous data that zinc shortens the duration of a cold, reported rapid improvement of the symptomatology [166]. Therefore, alone or in combination with other drugs, zinc is being investigated in several trials to determine its effectiveness in the prevention or treatment of COVID-19.

Selenium is considered another important trace element with antioxidant and anti-inflammatory effects. Selenium, together with vitamin D deficiency, probably impairs immune responses to COVID-19 and increases the severity of the disease[167]. In contrast, other clinical studies reveal that the recovery rate in surviving patients was related to increased selenium levels in patients with COVID-19[168,169]. Selenium is intricately involved in a wide range of immune activities, such as T cell activation, maturation, differentiation, and proliferation. It exerts antiviral activity by regulating the TCD4+ response, modulating TCD8+ and NK cells with cytotoxic activity, and it has a crucial role in the production of antibodies[170]. It is thought that a selenium deficiency has an influence on the high incidence of thromboembolism in patients critically ill with COVID-19 in the ICU[171]. A possible explanation is that low selenium levels are correlated with an abnormal thromboxane A_2-to-prostacyclin I_2 ratio, which is implicated in vasoconstriction and coagulation[172]. However, further studies are needed for clarification[170].

Copper protects DNA integrity by reducing oxidative damage, and its deficiency alters the immune response and promotes infectious diseases. Copper appears to participate in immune cell differentiation and to inhibit viral replication. It exerts an influence on the optimal functioning of NK cells, lymphocytes, neutrophils, macrophages, and monocytes. Supplementation with high doses of copper (7.8 mg/d) was shown to improve the activity of antioxidant enzymes and to activate SOD, ceruloplasmin, and benzylamine oxidase. However, the high dose affected neutrophils, serum IL-2R, and the levels of anti-influenza virus antibodies[173]. In this framework, copper has been proposed as a target element, together with others, such as zinc, in the treatment of COVID-19[174]. The antiviral properties attributed to copper would act directly with the virus by blocking structural proteins or by improving immune cell functioning[159]. Following this line of reasoning, optimal plasma levels of copper can elevate innate and adaptive immune responses to promote best action against SARS-CoV-2. Therefore, it must be part of regimens for COVID-19 prevention and therapy[175].

Nutritional support in critically ill patients with COVID-19 and liver injury

The hyperinflammatory response is one of the main characteristics of patients critically ill with COVID-19. Accordingly, the GI tract could play a central role in modulation of the inflammatory response, as it is the largest immune organ in the body, with the greatest microbiome. Nutritional therapy through EN strengthens gut barrier defenses and the microbial burden by providing luminal nutrients that impair dysbiosis and stimulate the anti-inflammatory response[176]. EN nutrition should start early, within 24-36 h after admission to the ICU or within 12 h of mechanical ventilation. To avoid refeeding syndrome, EN should be initiated with low trophic doses (10-20 mL/h) of a standard isosmotic polymeric formula that supplies 15-20 kcal/kg Bw and 1.2-2.0 g/kg Bw/day of protein, considering the actual body weight. The goal is to provide 70-80% of energy needs during 1 wk. In obese individuals with a BMI of 30-50, EN provides 11-14 kcals/kg Bw/day; for patients with severe obesity with a BMI >50 energy 22-25 kcal/kg Bw and 2 g/kg/d (classes I and II) or 2.5 g/kg/d (class III), taking into account the ideal body weight (IBW)[102]. Various complications may occur in patients with EN, such as GI disorders (*e.g.*, diarrhea, vomiting, and nausea) and mechanical disorders related to intubation and metabolic disorders (*e.g.*, hyperglycemia and an electrolyte imbalance). Thereafter, close monitoring is required to prevent difficulties[177]. In patients with gastric intolerance, prokinetics may alleviate symptoms and promote motility, but post-pyloric feeding should be performed in the persistence of intolerance or in patients with a high risk of aspiration[118].

For patients in whom GI feeding is not feasible, PN should be considered. Patients with a poor nutrition status, significant intolerance to EN, or those with a prolonged length-of-stay in the ICU, are potential candidates for PN. To avoid proinflammatory infusion, it is suggested to limit the use of omega-6 soy-based intravenous lipid emulsion (ILE) in week 1 or to change to a mixture of lipids, such as olive oil-based ILE or to soy, medium chain triglycerides, olive oil, and fish oil (SMOF)[102]. PN complications include catheter-related bloodstream infections and PN liver-associated damage[99]. At present, there are no reported cases associated with these complications. Nevertheless, the background must be taken into account for patients with sustained PN[126].

Certain other aspects must be taken into consideration when determining nutritional support in the patient. For instance, in liver injury, the primary treatment goal is against the COVID-19 infection, using antivirals, antibiotics, symptomatic support, oxygen therapy, and anti-inflammatory drugs, *etc.* It has been reported that some of the antivirals and drugs employed to treat this infection did cause liver damage[55, 178], and clinicians should consider reducing the dose or discontinuing the drug(s). In patients with severe COVID-19, AST, ALT, total bilirubin, albumin, and certain other liver function indicators are significantly increased. However, the indices gradually returned to normal levels during recovery. With moderate liver damage, the organ function was restored without special treatment[179]. Consequently, moderate-to-severe cases require the regular monitoring of liver indicators, including AST, ALT, alkaline phosphatase, bilirubin, GGT, albumin, and prothrombin time. In severe cases, hepatoprotective drugs should be administered with caution[8] and the patient should probably be referred to the hepatology service for further specialized management. Mildly elevated indicators may not require specific liver treatment or hepatoprotective drugs[118].

ROLE OF PHYTOCHEMICALS IN COVID-19 THERAPY

The outbreak of COVID-19 has revolutionized medical science, and has been accompanied by the absence of a definitive treatment in addition to the unknown long-term effectiveness of recently approved vaccines. That has encouraged researchers to design target drugs in the fight against COVID-19 and also to seek further therapeutic options. Phytochemicals are molecules that are biologically active and that generally derive from plants or vegetable sources. Phytochemicals provide benefits when they are consumed in foods, supplements, or as medicinal ingredients. For several years, these compounds have been extensively studied from different perspectives. To date, 5000 bioactive compounds have been identified and classified into different groups depending their chemical features or biological activities. The groups include polyphenolic compounds, carotenoids, alkaloids, and sulfur/nitrogen compounds. Each group comprises a wide variety of molecules with high biological potential. The most predominant biological activities are the result of antioxidant, antitumor, anticancer, anti-inflammatory, antimutagenic, detoxifying, and immunomodulatory properties [180,181]. Moreover, various phytochemicals have antiviral activity that is shown to be more effective than that of antivirals, in addition to being generally better tolerated and having fewer adverse effects[182]. Two modalities have been proposed by which phytochemicals may induce protection against the virus, including (1) direct interaction with the structure of the virus and (2), enhancement of endogenous cytoprotective systems. In both cases, some of the compounds have proven to be effective. For the purpose of this review, some of these will be discussed briefly within the framework of COVID-19 and liver injury.

Direct interaction with the virus

From structural studies of SARS-CoV-2, it has been possible to determine the major drug targets, which include 3-chymotrypsin-like protease ($3CL^{pro}$), papain-like protease (PL^{pro}), RNA-dependent RNA polymerase, and spike (S) proteins. The S proteins are considered potential therapeutic targets because the virus attaches itself to the ACE2 receptor through these proteins, leading to fusion with the host cell. Subsequently, the virus releases its genetic material for RNA replication, building new viruses. As the proteins participate in the process, are attractive targets of antiviral drugs and phytochemicals[183].

Previous studies of SARS-CoV and Middle East Respiratory Syndrome provided relevant information for understanding the behavior of SARS-CoV-2 and the effectiveness of natural compounds that inhibit viral activity. Among the compounds that appear to possess effective antiviral activity against coronaviruses silvestrol, tryptanthrin, scutellarein, saikosaponin B2, quercetin, myricetin, caffeic acid, isobavachalcone, psoralidin, and lectins. The majority are extracted from natural herbs that are very commonly used in traditional medicines. Many of the bioactive compounds depend on enzyme inhibition for their antiviral effects[184]. It appears that polyphenols are the most effective antiviral compounds. For example, quercetin inhibits the protease $3CL^{pro}$, which has a crucial role in viral transcription. The inhibitory concentration (IC_{50}) of quercetin was reported to be 8.6 ± 3.2 μmol/L against SARS-CoV PL^{pro} [185]. Quercetin has shown to be effective in inhibiting the influenza virus, poliovirus, adenovirus, Epstein-Barr virus, and hepatitis C virus, among others[182].

A few computer modeling studies have been performed to screen the targeted biding sites of phytochemicals with SARS-CoV-2. Recently, Kurman *et al*[76] used molecular docking or molecular dynamics (MD) software to predict phytochemical interactions with Nps15, a nidoviral RNA uridylate-specific endoribonuclease (NendoU) protein commonly present in coronaviruses, and responsible for interfering with the innate immune response. It was found that 50 phytochemicals had the potential to bond with Nsp15 and obstruct viral replication. The phytochemicals with the effective bonding potential were sarsasapogenin, ursonic acid, curcumin, ajmalicine, novobiocin, silymarin and aranotin, piperine, gingerol, rosmarinic acid, and alpha terpinyl acetate, suggestive of potential use as inhibitors of SARS-CoV-2 replication. In another MD simulation study, phytochemicals from the Aryurvedic medicinal plants *Withania somnifera* (Ashwagandha), *Tinospora cordifolia* (Giloy), and *Ocimuvingm sanctum* (Tulsi), identified as anolide V, somniferine, tinocordiside, vicenin, ursolic acid, and isoorientin 4′-*O*-glucoside 2′′-*O*-*p*-hydroxybenzoagte, potentially inhibited the main protease M^{pro} or the $3Cl^{pro}$ of SARS-CoV-2. The authors suggested that such active compounds were safe, and that the drug-likeness test and their absorption, distribution, metabolism, excretion, and toxicity (ADMET) profile predicted their potential effectiveness[186]. In an in-silico MD study of 32 phytocompounds, Swargiary *et al*[187] found that amentoflavone and gallocatechin gallate were

potential inhibitors of $3CL^{pro}$ and PL^{pro} and might be promising drug candidates for the treatment of SARS-CoV-2. However, the findings of in-silico studies require support by in vivo research to determine their mechanism of action.

Activation of cytoprotective systems

In addition, phytochemicals can also induce protection against SARS-CoV-2 by activating cytoprotective systems. A variety of these compounds have been shown to trigger signaling pathways related to endogenous defenses such as Nrf2/Keap1/ARE. Nuclear factor erythroid 2-related factor 1 (Nrf2) is a nuclear transcription factor coded by the *NFE2L2* gene. It is known as the master regulator of cytoprotection and antioxidant responses[188]. Nrf2 impacts approximately 250 genes involved in antioxidant responses, detoxification, cell growth, proliferation, differentiation, energy metabolism, and apoptosis. Under homeostatic conditions, Nrf2 binds to its negative regulator Keap1 in the cytosol, but the electrophilic molecules that result, such as ROS, encourage Nrf2 dissociation from Keap1 and further translocation into the nucleus to bind the specific DNA sequence. The antioxidant response elements (ARE) elicit the expression of several genes involved in cell protection, including antioxidant enzymes, phase-II detoxifying enzymes, NAD(P)H quinone oxidoreductase 1 (NQO1), and the enzymes involved in glutathione synthesis and metabolism *via* musculo-aponeurotic fibrosarcoma proteins (s-Maf)[189]. The redox-sensitive Nrf2/Keap1/ARE signaling pathway has a fundamental role in preserving homeostasis caused by oxidative stress, inflammation, diabetes, cardiovascular diseases, cancer, neurodegeneration, liver-kidney injury, and aging[190]. According to the evidence, some phytochemicals possess the ability to activate the Nrf2/Keap1/ARE pathway. They are called "Nrf2 bioactivators", but few have been broadly studied. Sulphoraphane (SFN), an isothiocyanate found in *Brassica* species like broccoli, is the most potent Nrf2 bioactivator. Taking into account the "CD value", which refers to the amount of a certain compound necessary to double NQO1 activity in murine hepatoma cells (hepg2)[191], SFN requires 0.2 μmol/L, and other phytochemicals, such as quercetin, require, 2.5 μmol/L, with curcumin requiring 2.7 μmol/L, and silymarin, 3.5 μmol/L. It is important to bear in mind that the lower the amount required, the more potent the phytochemical is considered to be. Other phytochemicals have been found to activate Nrf2, including andrographolides, quercetin, β-carotene, genistein, lutein, resveratrol, and zeaxanthin [192]. SFN activates nuclear respiratory factor (NRF) by means of a direct reaction with the electrophilic isothiocyanate group, changing the covalent linking of the Keap1 cysteine residues. SFN has thus been extensively employed in several protocols for the treatment of inflammation, cancer, diabetes; and cardiovascular, neurodegenerative, lung, hepatic, and kidney damage. SFN is considered to be an anticancer, antiproliferative, antioxidant, and anti-inflammatory agent[193,194]. The Nrf2/Keap1/ARE pathway is ubiquitously active, which may be the reason why certain phytochemicals could be promising protectors under different clinical situations.

To our knowledge, silymarin (SM) could be one of the most remarkable phytochemicals from the COVID-19 and liver injury perspective. SM is a blend of seven flavonolignans (65%-80%) obtained from the extract of *Silybum marianum*. The main flavonolignan is silybin (50%-70%) and its isoforms silybin A and silybin B. Isosilybin, silychristin, isosilychristin, and silydianin and their isoforms are the remaining flavonolignan constituents. SM has been used as a traditional medicine since ancient times by physicians and herbalists to treat acute and chronic liver abnormalities because of its antioxidant, anti-inflammatory, and antibiotic activities[101]. The mechanisms of action of SM are not yet fully elucidated, but involve triggering the Nrf2/Keap1/ARE signaling pathway. Various in vitro and in vivo trials have demonstrated the efficacy of SM in Nrf2 activation. Likewise, in SFN, the reported benefits are not only found in liver injury models[195,196] but have also been described in lung[197], neurodegenerative[198], cardio–renal[199], gastric ulcer[200], and neurotoxicity[201] models, among others. Furthermore, an in-silico MD study revealed the affinity of six SM flavonolignans (silybin A, silybin B, isosilybin A, isosilychristin, taxifolin, and silydianin) for bonding Keap1 by electrostatic and van der Waals interactions, as well as hydrogen bonds. That could partially explain the ability of SM to induce the activation of the Nrf2/Keap1/ARE signaling pathway[202].

Moreover, recent investigations have identified SM antiviral activity against hepatitis C and B, dengue, influenza, Chikungunya, and HIV[203]. SM even proved to inhibit the entry and attachment of enterovirus 71 (EV-A71), which is responsible for causing hand, food, and mouth disease in childhood, more effectively than the positive control, balcalein[204]. Together with previously mentioned results of MD studies with regard to potential SM and COVID-19 inhibition, it is suggested that SM or its flavonolignans should be considered as very promising drugs for the treatment of

COVID-19 and liver injury.

Curcumin is another phytochemical with potential for treating SARS-CoV-2 and liver damage. Curcumin is the main polyphenol in turmeric, present the rhizome of *Curcuma longa* and other species. In traditional medicine, it is used as an anti-inflammatory, antiseptic, analgesic, antimalarial, and as an insect repellent[205]. Current evidence supports the ability of curcumin to attenuate oxidative stress produced by ROS and RNS. Curcumin induces the antioxidant enzymes GST and γ-Glutamyl cysteine ligase (γ-GCL) and, at the same time, inhibits ROS-producing enzymes (oxidases, lipooxygenase, xanthine hydrogenase, and cyclooxygenase) and removes peroxide radicals, hydrogen peroxide, hydroxyl radicals, oxygen, and nitric oxide. The activities are associated with regulation of the Nrf2/Keap1/ARE pathway in addition to the modulation of other transcription factors, such as NF-kB and AP1[206]. In rat hepatic stellate-T6 (HSC-T6) cells, curcumin reduced the levels of malonaldehyde (MDA), and ROS treated with glucose oxidase, upregulated the nuclear translocation of Nrf2, augmenting glutathione levels, and reduced the expression of smooth muscle α-actin and extracellular matrix molecules[207]. In a rat model of arthritis, curcumin reduced inflammation by increasing methionine sulfoxide reductase A and the antioxidant enzymes CAT, SOD, and GPx[208]. In macrophages and RAW264.7 cells, curcumin protected cells from stress by inducing H_2O_2, triggering the Nrf2/Keap1/ARE pathway and the expression of antioxidant enzymes, thus promoting cell survival [209]. Additional evidence that supports the effect of curcumin on Nrf2 activation, curcumin is also described as an antiviral. Curcumin interacts with viral proteins on the cell surface, impairing entry of the virus. It also interacts with RNA polymerase and other proteins to hamper replication and may also interact with protease M^{pro}[210, 211]. In the previously mentioned MD study, curcumin was an effective inhibitor of the SARS-CoV-2 Nps15 protein. The hyperinflammatory response initiated in the "cytokine storm" is also weakened by curcumin, which interferes in the NF-κB and MAPK inflammatory pathways to reduce the expression of the proinflammatory cytokines IFN-γ, monocyte chemoattractant protein 1 (MCP)-1, IL-6, IL-10, and TNF-α [212]. Curcumin appears to prevent apoptosis and lung fibrosis by inhibiting the TGF-β pathway[213]. The envelope protein of SARS-CoV-2 is the smallest of the four structural proteins of the virus and it is known to participate in the viral entry process. We have performed some in-silico studies to investigate that protein.

Molecular modeling of the SARS-CoV-2 envelope protein

The three-dimensional model of the SARS-CoV-2 envelope protein of was built using Modeller 9.23 Software and considering the crystal structure of the transmembrane region of the envelope protein of SARS-CoV (PDB: 5X29). The resulting model represents a homo-pentamer of the E protein of SARS-CoV-2.

Docking analysis of the compounds of interest

Docking studies were used to predict the binding affinity of the compounds of interest and the SARS-CoV-2 envelope protein. Results of the analysis of silibylin, curcumina, and sulfuraphane were performed with Autodock 4.2 (Table 3 and Figure 5). The input files were prepared with the AutoDock Tools 1.5.2 graphic interface[214]. A grid box of 120 Å × 120 Å × 120 Å and a grid spacing of 0.375 Å was used for the docking studies. The Lamarckian genetic algorithm was selected for the sampling score, considering a randomized initial population of 100 and a maximum number of energy evaluations of 10^7.

CONCLUSION

The current pandemic situation caused by COVID-19 infection has generated global changes in not only human health, but in all economic, political, and social levels. The lack of an effective vaccine that prevents COVID-19 infections and the absence of an effective treatment that reduces multiorgan consequences, only allows us to establish guidelines and recommendations based on direct experience with patients and observing what works and what does not and to make decisions supported by science. In this review, we attempted to provide an outline of how hyperinflammatory and oxidative stress responses to COVID-19 infection may cause liver injury or worsen a pre-existing one. GI-related symptoms, such as diarrhea, vomiting, nausea, and reduced food intake, along with a delay in medical attention, promote weight loss. Malnutrition increases mortality, hospital stay, and poor outcomes, in addition to high economic costs. The detection of malnutrition is thus crucial for establishing optimal

Table 3 Curcumina, silibylin, sulfuraphane evaluation by Autodock 4.2

Ligand	Binding energy (kcal/mol)	kI μmol/L	Residue interactions
Curcumine	-4.6	428.13	Phe 23, Val 25, Leu 28, Phe 26, Thr 30, Val 26
Silybin	-5.73	62.57	Phe 23, Phe 26, Val 29
Sulforaphane	-3.75	1.79	Val 29, Phe 26, Val 25, Ala 22, Phe 23, Leu 27

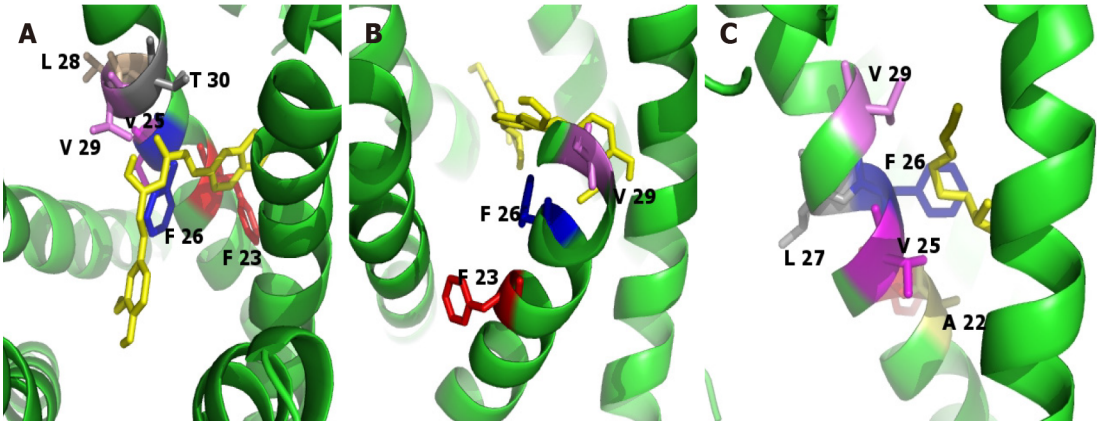

Figure 5 Graphic representation of the binding poses of the ligands on the envelope protein of severe acute respiratory syndrome-coronavirus-2. Images were carried out using Pymol. Homo-pentamer of the E protein of severe acute respiratory syndrome-coronavirus-2 is shown in green, and the ligand is shown in yellow. Surrounded residues are shown in different colors and labeled as indicated. A: Curcumine; B: Silybin; C: Sulforaphane.

nutritional therapy. the nutritional guidelines for patients with SARS-CoV-2 infection and liver injury are based on the statements of international clinical nutrition associations and the currently available evidence. Maintaining an optimal nutritional state is fundamental for preventing infection or overcoming SARS-CoV-2. Herein, the key role of providing sufficient energy, protein, lipids, and carbohydrates is clarified. Furthermore, the function of vitamins and trace minerals impacting the immune response is explained. To complete the nutritional approaches, we considered the use of phytochemicals as potential components of the therapy because of the possible benefits that they might offer during the COVID-19 crisis. The interactions (*i.e.* possible antiviral effects) of phytochemicals such curcumine, sulphoraphane, and silybin with the viral envelope protein have been demonstrated in-silico. The latter is an open door to researchers in the race to find tools to help overcome this pandemic in the best possible manner.

Abstract

Gastrointestinal (GI) cancers are among the most common cancer types and leading causes of cancer-related deaths worldwide. There is a tremendous clinical need for effective early diagnosis for better healthcare of GI cancer patients. In this article, we provide a short overview of the recent advances in GI cancer diagnosis. In the first part, we discuss the applications of blood-based biomarkers, such as plasma circulating cell-free DNA, circulating tumor cells, extracellular vesicles, and circulating cell-free RNA, for cancer liquid biopsies. In the second part, we review the current trends of artificial intelligence (AI) for pathology image and tissue biopsy analysis for GI cancer, as well as deep learning-based approaches for purity assessment of tissue biopsies. We further provide our opinions on the future directions in blood-based and AI-enhanced approaches for GI cancer diagnosis, and we think that these fields will have more intensive integrations with clinical needs in the near future.

Key Words: Liquid biopsy; Plasma cell-free DNA; Circulating tumor cell; Extracellular vesicle; Exosome; Artificial intelligence

INTRODUCTION

Gastrointestinal (GI) cancers, which include tumors from the colon, rectum, stomach, pancreas, esophagus, anus, gallbladder, liver, and bile duct, are among the most common cancer types and leading causes of cancer-related deaths worldwide[1]. Colorectal cancer (CRC), in particular, is the third most common cancer in men (9%) and women (8%) in the United States[1-3]. Most patients with GI cancers are in the advanced stage upon diagnosis and have relatively poor prognosis outcome. For example, the overall 5-year survival rate for patients with hepatocellular carcinoma (HCC) is around 20%[3], while the survival rate for early stage patients is as high as 70%[1,3]. This is because various efficient treatment strategies, such as surgical resection and organ transplantation, are feasible for early-stage patients only. Hence, early diagnosis is of high clinical significance for better healthcare of cancer patients.

Pathological analysis of the tumor tissue is currently the "gold standard" for clinical diagnosis of cancers[4,5]. In particular, image-based computed tomography (CT) colonography, optical colonoscopy, and endoscopic biopsy are mostly widely used in the diagnosis of GI cancers. Recent studies have demonstrated that blood-based approaches, also known as liquid biopsy, offer substantial advantages over conventional tissue biopsy-based diagnostic methods, including minimally invasive nature, cost-efficiency, clinical convenience for real-time monitoring, and the potential to promote higher patient compliance. Major analytes in current liquid biopsy studies include circulating cell-free DNA (cfDNA), circulating tumor cells (CTCs), as well as extracellular vesicles (EVs) that transport the biomolecules from tumor cells, such as lipids, proteins, DNA fragment, and RNAs[6-9]. Moreover, advances and integration of artificial intelligence (AI) have brought revolutionary changes to the clinical and translational cancer studies[10-12], especially in cancer diagnosis. The identification and utilization of disease-specific biomarkers, and development of exquisite diagnostic algorithms are both highly valuable for early diagnosis of cancers.

In this article, we provide an overview of current approaches for GI cancer diagnosis, especially in CRC and HCC. We focus on blood-based biomarkers, as well as AI algorithms for image-based tissue biopsies. We review the identification of biomarkers and development of diagnostic methods, and provide our opinions on future directions in early diagnosis of GI cancers.

BLOOD-BASED LIQUID BIOPSY APPROACHES

With the advantages of being highly efficient, minimally invasive, and cost-effective, liquid biopsy has become an emerging technique for early diagnosis of cancers. Tumor-derived cell-free DNA in peripheral blood provide a surrogate for researchers/clinicians to investigate the genomic and epigenomic landscape as well as dynamics during treatment of malignant tumors[13,14]. Conventionally, liquid biopsy approaches cover the analysis of various circulating components, including cfDNA, cfRNA, CTCs, and tumor-associated EVs (Figure 1)[15], and significant progress has been made in these areas in the past few years (Table 1).

Circulating cell-free DNA

cfDNA molecules in plasma originate from various tissues in human body. In cancer

Table 1 Biomarkers for blood-based liquid biopsy in gastrointestinal cancers

Cancer type	Biomarker type	Biomarkers	No. of patients /controls	Accuracy	Ref.
GC	cfDNA copy number	*HER2* gene	60/30	Sn = 73.3%, Sp = 93.3%	[19]
GC	cfDNA methylation	BARHL2	128/30	Sn = 90%, Sp = 100%	[104]

PC	Exosomal miRNA	miR-133a	110/64	Sn = 90.6%, Sp = 87.2%, AUC = 0.893	[115]
HCC	cfDNA methylation	cfDNA 5hmC	1204/958	AUC = 0.846	[30]
HCC	Exosomal miRNA	miR-10b-5p	90/28	AUC = 0.934	[75]
HCC	Exosomal mRNA	hnRNPH1	88/68	Sn = 85.2%, Sp = 76.5%	[80]
HCC	Plasma cfRNA	hsa_circ_0000976, hsa_circ_0007750 and hsa_circ_0139897	158/53	AUC = 0.863	[85]
HCC	Serum cfRNA	miR-143	131/122	Sn = 80.3%, Sp = 82.4%	[87]
HCC	Serum cfRNA	miR-132, miR-212`	80/42	Sn = 93.75%, Sp = 63.44%	[116]

GC: Gastric cancer; CRC: Colorectal cancer; PC: Pancreatic cancer; HCC: Hepatocellular carcinoma; Sn: Sensitivity; Sp: Specificity; AUC: Area under the

curve.

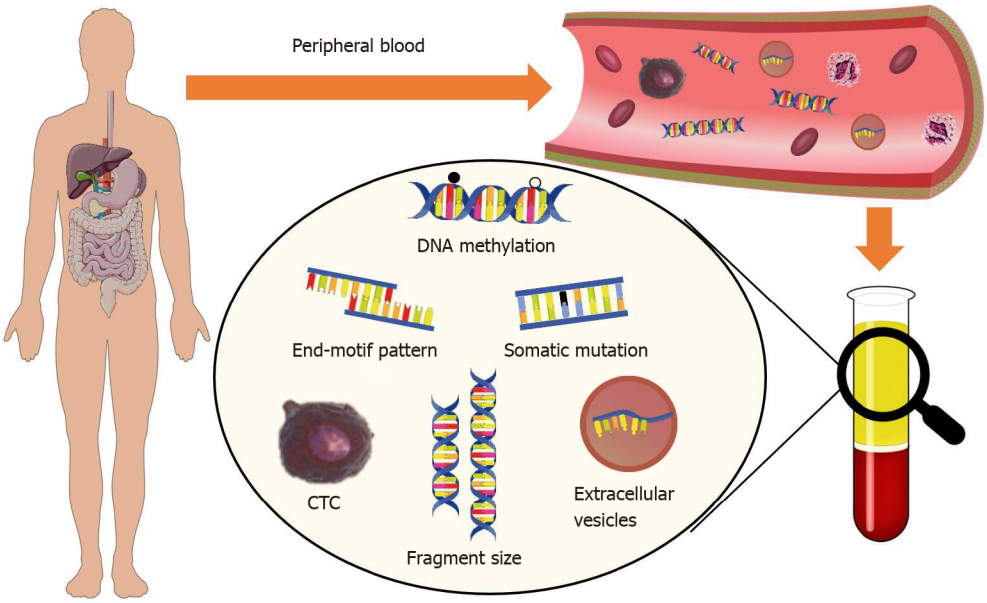

Figure 1 Blood-based liquid biopsy in cancer diagnosis. In the peripheral blood of cancer patients, circulating cell-free nucleic acids, circulating tumor cells, and extracellular vesicles carry the tumor-associated information, which allow noninvasive diagnosis of cancer patients.

patients, the dying tumor cells release their DNA, which contains the tumor-specific signatures, including somatic mutations, copy number aberrations (CNAs), and altered DNA methylation profiles, into the circulation (which is known as ctDNA). However, tumor-derived cfDNA usually account for a small fraction of the total cfDNA, and the concentration is even lower in early-stage cancer patients, which largely limits the accuracy of most cfDNA-based liquid biopsy assays. To this end, in recent studies, researcher have explored the application of extra-deep sequencing and discovered a broad range of tumor-related signals in cfDNA to further improve their performance in bother diagnosis and prognosis monitoring.

Conventional genomic and epigenomic alterations: Somatic mutations are one of the most widely studied tumor-associated genomic alterations. In a proof-of-concept study, through extra-high sequencing of cfDNA in HCC patients, researchers are able to non-invasively resolve the mutation landscape of the tumor with high accuracy[16], which would be informative in guiding the therapeutic strategies for cancer patients. The somatic mutations in cfDNA are widely utilized used as biomarkers for early diagnosis and prognosis monitoring. For example, in pancreatic cancer (PC), the overall survival of patients with detectable KRAS mutation in cfDNA was significantly shorter than that of patients without such mutations[17]. Notably, the somatic mutations detected in cfDNA may not solely come from the tumors. In fact, recent studies have proven that clonal hematopoiesis also introduces somatic mutations which are detectable in cfDNA. Hence, it is highly recommended to analyze the blood cells in parallel to cfDNA in somatic mutation-oriented studies.

CNA is another widely used biomarker in cancer diagnosis and prognosis monitoring. For example, Shoda *et al*[18] found that the copy number status of *HER2* gene in cfDNA is a potential biomarker for predicting the risk of recurrence and monitoring the effects of treatment for patients with gastric cancer (GC); Chen *et al*[19] showed that in GC, patients with stable chromosomes were sensitive to drug treatment while patients with detectable chromosomal instability in cfDNA were resistant to treatment, demonstrating the potential of cfDNA in predicting treatment responses.

DNA modifications, mostly 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC), are abundant epigenetic regulators in the human genome. These modifications are known to affect gene expression, and suffer from gross abnormalities in almost all kinds of tumors. In cancer patients, such modifications are detectable in cfDNA and could be used to point to the tissue origin of the tumor. For example, Chan *et al*[20] analyzed the CNA and 5mC profiles of cfDNA simultaneously using whole-

genome bisulfite sequencing technology, demonstrating that flexible combination of these two biomarkers would benefit in cancer diagnosis in various clinical scenarios; Li *et al*[21] showed that methylated *SFRP2* in cfDNA has the potential to serve as a non-invasive biomarker for CRC screening; Gai *et al*[22] reported the application of DNA methylation biomarkers in differentiating CRC patients with and without liver metastases. Eissa *et al*[23] reported that the methylation of *BNC1* and *ADAMTS1* gene promoters could be used for PC diagnosis and screening with an area under the curve (AUC) of 0.95. The hypermethylation of cysteine dioxygenase 1 gene (*CDO1*) could distinguish pancreatic ductal adenocarcinoma (PDAC) patients from healthy controls with a sensitivity of 95%[24]. Besides diagnosis, Kim *et al*[25] showed that low methylation of ST-alpha and L1 of cfDNA are associated with a shorter overall survival in GC patients; Harada *et al*[26] suggested that GC patients with a high methylation level in the promoter of *CDO1* gene in cfDNA had a significantly worse prognosis. Similarly, Zhang *et al*[27] found that, in PDAC patients, the methylation of *PCDH10* gene was associated with a shorter disease-free survival. On the other hand, recent studies have suggested that 5hmC-based biomarkers in cfDNA are highly predictive of colorectal, gastric, and liver cancers with superior performance over conventional protein-based biomarkers[28-30]. Through genome-wide profiling of 5hmC in cfDNA as well as genomic DNA (gDNA) of paired tumor and adjacent normal tissues from patients with colorectal, gastric, liver, and other cancers, Li *et al*[21] discovered robust cancer-associated 5hmC signatures in cfDNA for cancer diagnosis. In another study, Cai *et al*[29] utilized the highly sensitive 5hmC-Seal assay to profile the genome-wide 5hmC landscape in cfDNA samples from 2554 HCC patients and found that liver-related 5hmC biomarkers show a remarkable capacity for distinguishing early HCC from high-risk non-cancerous subjects with chronic hepatitis B virus infection or liver cirrhosis. These studies demonstrated that DNA methylation-based biomarkers have favorable clinical value in cancer diagnosis, molecular characterization of the tumor, and prognosis monitoring of the patients, especially in GI cancers.

Emerging cfDNA fragmentomic features: Plasma cell-free DNA is known as naturally fragmented, small molecules. Recent studies have revealed that the tumor-derived DNA possess a remarkable difference in fragmentation characteristics compared to the background DNA (which mostly comes from the hematopoietic system)[31], and demonstrated the clinical significance of these features in the diagnosis of various GI cancers.

CfDNA molecules show a dominant size peak at 166 bp and most of them are shorter than 200 bp, and this phenomenon is believed to correlate with the nucleosome structure[32]. In cancer patients, tumor-derived cfDNA is even shorter than the background DNA[33]. Hence, it is doable to enrich the tumor-derived cfDNA through selection of shorter cfDNA molecules in principle. Indeed, Mouliere *et al*[34] demonstrated the enrichment of tumor-derived cfDNA in fragment sizes between 90 and 150 bp in a cohort of 344 plasma samples from various cancer patients. They also showed that using an integrated analysis of cfDNA at different size ranges, they could classify CRC patients from healthy individuals with a high specificity of 94%[34].

Besides size pattern, recent studies further showed that the relationship between the fragmentation pattern and nucleosome structure could point to the tissue origin of cfDNA[35,36]. In particular, cfDNA of different origins tends to have different preferences on fragment ends. Jiang *et al*[16] compared the genome-wide fragment end patterns of cfDNA in one HCC patient and one non-cancerous control; they reported that many genomic loci show significantly higher chances to serve as fragment ends (which they called "preferred-ends") in the HCC patient, and the usage of such genomic loci could differentiate HCC patients from non-cancerous controls with a favorable accuracy. Moreover, the same team further showed that the nucleotide frequencies (or motifs) at the cfDNA end, which are believed to correlate with nuclease cutting preference, also change in various cancers[37,38]. In fact, they found a nuclease, DNAS1L3, which plays key roles in the apoptotic fragmentation process and shows strong sequence preferences when cutting the DNA[39]. Interestingly, this gene is significantly down-regulated in many cancers and thus affects the end motif pattern of the tumor-derived DNA[37]. The discovery of these novel biomarkers largely extends our knowledgebase on both the biology of cfDNA and cancer biomarkers; these novel biomarkers also promise the development of less complex and cheaper assays than those based on the conventional genomic/epigenomic biomarkers. However, most current studies are still in proof-of-principle stage, thus large-scale validation studies are essential to assure the performances before clinical investigations.

Circulating tumor cells

CTCs are released into the bloodstream of patients through the blood vessels and lymphatic vessels. When the primary cancer cells acquire an increased propensity for migration, invasiveness, and resistance, these tumor cells will invade through the tissue surrounding their site of origin and keep invading until they enter the blood or the lymphatic system, and become the CTCs[40,41]. Although most of CTCs will die within hours, only a small part of them can potentially form a new cancerous lesion at a distant site and grow into a new metastasis[42,43].

There are many commercial kits for CTC isolation and enrichments. CTC isolation and enrichment are mostly based on their physical and immunological properties. The physical features of CTCs, such as the size, density, and electric charge, are utilized to enrich CTCs from blood. For example, ISET (isolation by size of epithelial tumor cells) system and a microfluidic chip developed by Haber' lab filter CTCs from blood by the size of CTCs[44-46], CAP (centrifugal affinity plate) system isolates CTCs by the density gradient centrifugation[47], and ApoStream system enriches CTCs by dielectrophoretic field-flow fractionation[48,49]. Enriching CTCs based on the immunological properties of CTCs depends on the antigens expressed on the surface of epithelial cells, including epithelial cell adhesion molecule (EpCAM) and cytokeratin (CK). CellSearch is the first and only FDA-approved test for capturing CTCs that express EpCAM by using immunomagnetic beads[50,51]. There also are some methods that combine epithelial marker immunofluorescence staining with automated microscopy, such as NYONE[52]. At the protein level, fluorescence *in situ* hybridization (FISH) has been utilized for identifying chromosomal rearrangements in CTCs [53]. Immunocytochemistry (ICC) is the major technique that is used by several commercial kits for isolating CTCs, including ApoStream and OcoQuick. Flow cytometry is another protein analysis method employed for CTC isolation. The analysis of genetic information of CTCs is mainly based on PCR and next-generation sequencing (NGS), such as RNA-based digital PCR and single-cell sequencing[54,55]. Due to the low concentration and fragile property of CTCs and limitations of current methods, combination and further optimization may achieve better enrichment and detection for CTCs.

The clinical application of CTCs depends on the number of CTCs and the information about protein expression and gene mutation in CTCs. Kang *et al*[56] showed that for individuals with two or more CTCs per 7.5 mL of blood, 97.1% of them were GC patients in their cohort. The increased number of CTCs after treatment was also correlated with early recurrence[27]. Zhang *et al*[27] showed that in GC patients, the patients with five or more CTCs per 7.5 mL in postoperative blood had a significantly shorter overall survival and disease-free survival compared to those with less CTCs. The protein expression patterns in CTCs are also an important biomarker for cancer diagnosis. Around 50% GC patients with CK^+CD44^+ CTCs were diagnosed with distant metastases[57]. Wei *et al*[58] found that, in 76% of PDAC patients, vimentin was upregulated in CTCs, and a high level of vimentin in CTCs was associated with a shorter recurrence-free survival. Similarly, PDAC patients with CTCs that expressed high levels of mucin 1 (MUC-1) and cancer stem cell markers, such as ALDH, CD133, and CD44, were associated with a worse overall survival and tumor recurrence[59,60]. Chen *et al*[61] found up-regulated expression of ECT2 in CTCs from patients with CRC. Fang *et al*[62] found that CRC patients with liver metastasis showed a higher percentage of $^+CD133^+CD54^+$ $CD44^+$ cell subpopulations. Moreover, the upregulated genes in CTCs, such as *SHH*, *SMO*, *POU5F1B*, and *ALCAM*, were demonstrated as potential markers for therapeutic response and prognosis prediction in PC patients[63]. In HCC patients, Zhou *et al*[64] discovered that the presence of EpCAM $mRNA^+$ CTCs was associated with early recurrence when combined with Treg/$CD4^+$ T cell ratio.

Exosomes

Exosomes are membrane-bound extracellular nanovesicles (EVs) released by many types of cells, having a size ranging from 30 to 150 nm. Exosomes have been found in various bodily fluids, including plasma, urine, and malignant ascites[65]. Exosomes are involved in mechanisms of cell-cell communication in physiological and pathological tissues through transporting biomolecules, such as lipids, proteins, mRNA, microRNAs, and DNA fragments, and the intercellular transfer of signal components[66,67]. Tumor-associated exosomes are larger than those derived from healthy cells and are enriched with different types of mediators of tumorigenesis, including proteins, growth factors, immunomodulatory molecules, and nucleic acids that arise from the cytoplasm of donor cancer cells[68].

In the last decade, a significant number of studies have focused their attention on the exosome-mediated cross-talk which can promote the activation of signaling pathways and reprogram the functions of recipient cells through their cargo transfer that occurs between cancer and normal cells, especially in the tumor microenvironment[65,69-71].

Several examples of exosome biomarkers, such as proteins, microRNAs, and long non-coding RNAs (lncRNAs), have been shown to have the potential for the diagnosis and prognosis of specific types of cancer. For example, GPC-1 was identified as a diagnostic exosome marker for PC and CRC. CD9 and CD147 were found to be upregulated in exosomes derived from serum of CRC patients[72]. Previously, seven miRNAs including let-7a, miR-21, miR-23a, miR-155, miR-223, miR-1246, and miR-1229 were reported to be highly expressed in the serum exosomes of CRC patients and were significantly decreased after surgical resection[73]. MiR-103 was reported to be delivered from hepatoma cell-derived exosomes into endothelial cells, and induced metastasis[74]. In HCC patients, serum exosomal miR-10b-5p was fond to upregulated and could be used to distinguish HCC patients from healthy controls with an AUC of 0.934[75]. Nakamura *et al*[76] found that exosomal miR-21 and miR-155 were significantly upregulated in PDAC patients compared to chronic pancreatitis patients. In GC patients, exosomal lncRNA pcsk2-2:1 and lncRNA GNAQ-6:1 were significantly downregulated and could be served as biomarkers for early diagnosis for GC[77,78]. Yu *et al*[79] developed a panel of eight exosomal RNAs, which could distinguish PDAC patients from chronic pancreatitis patients with an AUC of 0.931. The exosomal mRNA *hnRNPH1* was found to have a high expression level in HCC patients and could be used to distinguish HCC patients from chronic hepatitis B patients with an AUC of 0.865[80]. Furthermore, lncRNAs, such as *LncRNA-ARSR*, *Lnc-sox2ot*, and *LncRNA-h19*, were showed to be associated with tumor progression[72,81].

Circulating cell-free tumor RNAs

Circulating cell-free RNAs (cfRNAs) are also present in the blood circulation and have the potential to serve as cancer biomarkers for cancer diagnosis. CfRNAs may be released into the blood through mechanisms of cell death or exosome-mediated signaling by living cells.

Historically, the study of cfRNA has focused on a small group of known cancer-related mRNA, miRNAs, and lncRNAs[76-78,82]. For instance, miR-21 showed an increased expression level in GC patients, which could serve as a classification biomarker with an 88.4% sensitivity and 79.6% specificity[83]. Huang *et al*[84] designed a panel of six miRNAs that were upregulated in the serum of GC patients, which showed an AUC of 0.702 in distinguishing GC patients from healthy controls. Shimura *et al*[85] found that three miRNAs (miR-30a-5p, miR-659-3p, and miR-3917) were overexpressed in GC patients who had peritoneal metastasis and could be used to distinguish patients with or without peritoneal metastasis with an AUC of 0.82. Yamada *et al*[86] showed that the expression of three serum miRNAs, including miR-21, miR-29a, and miR-125b, could discriminate CRC patients from healthy ones with an AUC of 0.827. In HCC patients, serum miR-143 was downregulated and could distinguish HCC patients from healthy controls with an AUC of 0.831[87]. Another study showed that a panel of three plasma circRNAs were found to distinguish HCC patients from healthy ones with an AUC of 0.863[88].

AI-ENHANCED ALGORITHMS FOR IMAGE-BASED AND TISSUE-BASED PATHOLOGY ANALYSIS

The early diagnosis and prognosis of a cancer type have become a necessity in cancer research. Image-based and tissue biopsy-based pathology analyses are considered to be the "gold standard" for their accuracy and effectiveness for cancer screening.

In recent years, AI has become an emerging field with the advances of computational power and massive amounts of learning data. Over the last two decades, different machine learning (ML) algorithms, such as support vector machines (SVM), random forest (RF), and artificial neural networks (ANNs), have been widely used in the field of medicine[89-91]. More recently, convolutional neural networks (CNN), a novel algorithm, show its great potential in processing and interpreting radiological and pathological images (Figure 2)[92,93]. Previous studies demonstrated that a multilayer CNN with pre-trained GoogleNet Inception v3 architecture on skin cancer level prediction could achieve comparable results to dermatologists[94]. Similarly, another image-based deep learning model proposed by Kermany *et al*[10] in analyzing optical

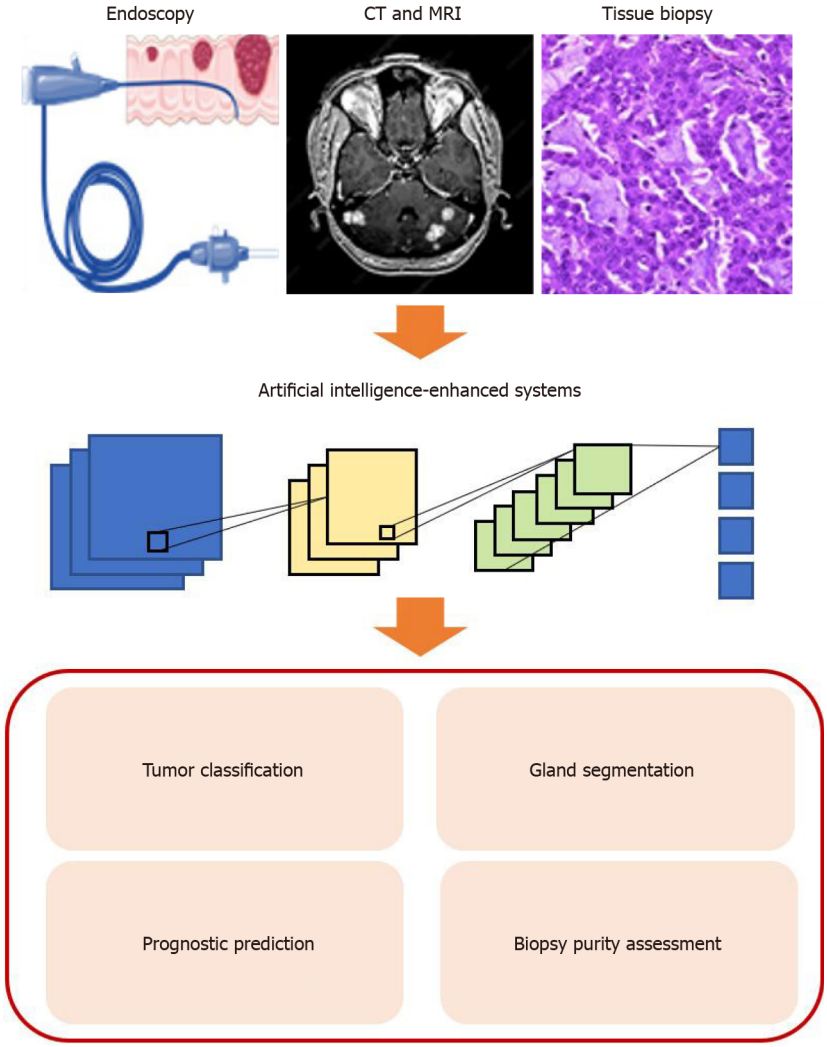

Figure 2 Applications of artificial intelligence in medical area. The effective combination of artificial intelligence and big data can provide efficient and accurate clinical-decision support for physicians. CT: Computed tomography; MRI: Magnetic resonance imaging.

coherence tomography (OCT) images of the retina is on par with the ophthalmologist, with an accuracy of 96.6%, sensitivity of 97.8%, and specificity of 97.4% on the four-class classification problem. Most importantly, both studies utilized transfer learning when training the model to save the training time, which is also a widely used technique in training an ML model in medical images due to the lack of training data in most cases[95].

Traditionally, the most effective and direct method of screening colorectal carcinoma is endoscopy, particularly colonoscopy[96]. Abdominal computerized tomography (CT) or abdominal magnetic resonance imaging (MRI) are employed when more precise and additional information is needed about the lesion to help assess cancer and look for any signs of spread. However, these methods are usually labor-intensive and time-consuming and require professional knowledge. In the era of big data, the number of colonoscopy examinations and radiology screening is enormously increasing[96]. To this end, the deep learning-based radiology and digital pathology workflow could assist the radiologists and pathologists to diagnose diseases in various aspects, such as tumor classification, gland segment, tumor microenvironment analysis, and prognostic survival prediction, to ease their ever-growing workload and improve their efficiency[92]. More recently, Luo *et al*[97] built a real-time Gastrointestinal Artificial Intelligence Diagnostic System (GRAIDS) for the diagnosis of upper GI cancer through analysis of imaging data from clinical endoscopies. The GRAIDS achieved a high diagnostic accuracy in detecting upper GI cancers and had a similar predicted sensitivity as expert endoscopies and outperformed the non-expert endoscopies. Besides, they performed a multi-center study and further validated the system from the other five primary care hospitals, thus indicating the general applicability of GRAIDS.

Apart from AI application in colonoscopy, CT, and MRI images, the digital pathology also drew much attention from researchers, in particular adopting deep learning on the whole slide images (WSIs)[92,98-100]. However, the WSIs are multi-gigabyte images, present high morphological variance, and contain various types of artifacts. Such circumstances prevent CNN directly from applying to the high-resolution images. On the other hand, typically small labeled datasets in pathological images impede the generality of the deep learning model[101]. Kermany *et al*[102] developed a multiple-instance learning-based deep learning system that only used the reported annotated datasets to tackle the limited number of labeled images and the AUCs were all above 0.98 when testing on multiple cancer types. Joseph *et al*[96] introduced a novel machine learning-based system on prediction of CRC outcome for whole digitized haematoxylin and eosin (HE) stained histopathology slides in learning heterogeneous and discriminant contents. They demonstrated the effectiveness of the method and presented a detailed analysis of its different elements which corroborate its ability to extract and learn salient, discriminative, and clinically meaningful content.

At present, pathological analysis of tissue biopsies is still the most widely approach in cancer diagnosis. Recent studies have shown that combination of molecular data and deep learning approach could predict the cancerous status and tissue origin of pan-cancer biopsies with high accuracy. For instance, Sun *et al*[103] developed GeneCT, which showed an overall accuracy of 98.2% in differentiating tumor samples from adjacent normal samples, and an overall accuracy of 98.6% in predicting the tissue origins of the biopsies. In addition, as tissue biopsy is one of the most widely materials in cancer studies, and the purity of the biopsies is crucial for appropriate project design and correct interpretation of the data. To this end, Fan *et al*[12] showed that the low prediction accuracy of GeneCT in some datasets suggested impurity of the samples. The performance of GeneCT was further evaluated using metastatic tumor samples, which is a common scenario in GI cancers. As a result, GeneCT shows potential as an accurate classification tool for tissue biopsy-based diagnosis, as well as an easy-to-use quality-control tool for cancer studies.

CONCLUSION

GI malignancies, especially CRC and HCC, are common cancers that lead to death of patients with cancers worldwide. Liquid biopsy plays an important role in early-stage GI cancer diagnosis as a noninvasive tumor detection strategy. Biomarkers including cfDNA, CTCs, and exosomes of liquid biopsy are widely used for the detection of tumor-associated molecules. The advantages of cfDNA, such as high amount, being relatively stable and easy for extraction and preservation, mostly representing the information from the major tumor clone, and the significant features including fragment sizes, the proportion of fragment, the end-motif, and genomic alterations, make it the preferential and accurate biomarker for the cancer diagnosis. CTCs are also important liquid biomarkers because they not only contain direct molecular information from the tumor clone but also can be cultured *in vitro*. However, CTCs are very rare and require fresh blood for isolation.

The potential of liquid biopsy in clinical practice is enormous in the future. However, there are several challenges that need to be resolved for the utility of liquid biopsy in clinical diagnosis. First, standardization should be established for the sample collection and storage conditions, and biomarker molecules and the suitable detection and analysis strategy depend on sample type. Second, tumor-associated molecule detection techniques require high sensitivity for early tumor detection and high specificity for early-stage tumor screening. At the same time, the low content of tumor biomarkers and the varied interference factors in the circulation make the high requirements for the high sensitivity and specificity of detection strategies. Reducing purification steps could shorten the time of sample treatment and reduce the cost, and optimization of the throughput platform could help to increase both the sensitivity and specificity of the biomarkers.

AI based on machine learning and deep learning is widely used in all walks of life. Recently, rapid developments have been made in the utility of AI in medicine areas and showed promising results in terms of accuracy for cancer diagnosis. However, the scale and quality of the training and validation datasets of most of the studies were relatively limited to apply this technique in clinical practice. Moreover, it also requires the external cross-validation, especially in tumor classification. Therefore, future studies with a larger number of datasets with high-quality annotations and external

cross-validation are required for routine practice-level validation.

ACKNOWLEDGEMENTS

We would like to thank Ms. Qi Wang from Shenzhen Bay Laboratory for her technical assistance.

Abstract

Varying degrees of liver injuries have been reported in patients infected with the severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2). In general, oxidative stress is actively involved in initiation and progression of liver damage. The liver metabolizes various compounds that produce free radicals. Maintaining the oxidative/antioxidative balance is important in coronavirus disease 2019 (COVID-19) patients. Antioxidant vitamins, essential trace elements and food compounds, such as polyphenols, appear to be promising agents, with effects in oxidative burst. Deficiency of these nutrients suppresses immune function and increases susceptibility to COVID-19. Daily micronutrient intake is necessary to support anti-inflammatory and antioxidative effects but for immune function may be higher than current recommended dietary intake. Antioxidant supplements (β-carotene, vitamin A, vitamin C, vitamin E, and selenium) could have a potential role in patients with liver damage. Available evidence suggests that supplementing the diet with a combination of micronutrients may help to optimize immune function and reduce the risk of infection. Clinical trials based on the associations of diet and SARS-CoV-2 infection are lacking. Unfortunately, it is not possible to definitively determine the dose, route of administration and best timing to intervene with antioxidants in COVID-19 patients because clinical trials are still ongoing. Until then, hopefully, this review will enable clinicians to understand the impact of micronutrient dietary intake and liver status assessment in COVID-19 patients.

INTRODUCTION

Since its first appearance in December 2019 in Wuhan, China, coronavirus disease 2019 (COVID-19), caused by the severe acute respiratory syndrome-coronavirus-2 (SARS-CoV-2), has spread swiftly around the world. The angiotensin converting enzyme 2 (ACE2) receptor has been identified as the target vehicle for the virus entrance into the host cell[1]. After binding of SARS-CoV-2, the bioavailability of ACE2 is reduced and angiotensin 2 becomes extremely available to promote oxidative stress cascades and inflammatory responses, which in turn contribute to the pathological host responses and the severity of disease[2,3]. The multiple organ involvement is mainly attributed to the wide distribution of ACE2 receptors[4]. Incidence of liver injury in SARS-CoV-2–infected patients is about 36% (range: 21%–52%)[1].

Any liver damage occurring during the COVID-19 course or treatment, in patients with or without previous liver diseases, could be considered as COVID-19-associated liver injury[4]. The presence of ACE2 receptors in hepatic cholangiocytes has pointed out the possibility of direct infection and active SARS-CoV-2 replication in the liver[5]. Many studies have also shown that COVID-19-associated liver injuries can be induced and/or exacerbated by the inflammatory response, endothelial changes, hypoxia and coagulopathy characteristic of severe disease course[4]. Accordingly, higher rates of liver dysfunction have been detected in critically ill COVID-19 patients[6]. In addition, compatibility between histological alternations and impaired blood flow has been found through the post-mortem analysis of COVID-19 patients' liver samples. Marked derangement of intrahepatic blood vessels, including portal vein fibrosis and wall inflammation, herniated portal vein with activated Kupffer cells containing large necrotic debris, and vascular thrombosis accompanied with high D-dimer (≥ 500 ng/dL) and high platelet count, have been observed[7].

In addition to impaired blood flow, more than a 50% of post-mortem liver samples of COVID-19 patients have shown the presence of large, small or mixed fatty droplets in hepatic parenchyma, a condition known as hepatic steatosis[7]. More recently, the hepatic steatosis, which is commonly associated with comorbidities such as metabolic syndrome, diabetes, obesity and hypertension, has also been recognized as an independent risk factor for severe disease in patients with COVID-19, significantly contributing to greater incidence of critical illness and lethality[8].

POSSIBLE MECHANISMS OF LIVER INJURY IN COVID-19

The main biochemical findings in COVID-19-affected liver are elevated transaminase aspartate aminotransferase (commonly referred to as AST) and alanine transaminase (ALT), which are above referent range in 20.0%-22.5% and 14.6%-20.1% COVID-19 cases, respectively. The increase of AST and ALT is followed by slightly increased total bilirubin in 35% of cases, as well as elevated alkaline phosphatase and gamma-glutamyl transferase in 6.1% and 21.1% of COVID-19 patients, respectively[4]. A meta-analysis of 25 relevant studies showed that COVID-19 survivors accounted for a lower percent of patients and lower increase of these parameters, compared with non-survivors. Moreover, cured patients had lower levels of total bilirubin and lactate dehydrogenase, higher level of albumin and lower proportion of markedly decreased albumin than patients who succumbed to the disease[9].

Until now, proposed mechanisms of COVID-19-associated liver injuries are: (1) Systemic inflammatory response; (2) Hypoxia–reperfusion injury; (3) Drug-induced liver injury; (4) Direct viral infection; and (5) Coexisting chronic liver disease [non-alcoholic fatty liver disease (NAFLD), alcoholic liver disease (commonly referred to as ALD), hepatitis B virus and/or hepatitis C virus infection, hepatocellular carcinoma, *etc.*] (Figure 1).

Systemic inflammatory response is an extensive body inflammatory activity. It begins when SARS-CoV-2 lung infection activates alveolar macrophages and lung epithelial cells to promote massive release of proinflammatory cytokines, particularly interleukin (IL)-6, tumor necrosis factor (TNF), and IL-1β[10]. Acting locally, these cytokines increase permeability of the lung endothelium and support further dissemination of the pathogen, but after reaching the circulation they spread through the body and induce excessive immune response, with deleterious impact on many organs (Figure 1). Proinflammatory cytokines further hyperactivate monocytes, macrophages and T lymphocytes, generating a self-producing loop which results in cytokines overwhelming the system [*i.e.* cytokine storm syndrome (also known as CSS)]. Thus, the cytokine storm can result in multiorgan damage, including to the liver[2].

In addition to CSS, hypoxia, as a consequence of pulmonary failure, is one of the most important factors causing secondary liver injury in COVID-19 patients[11]. Low or no circulation, reduced oxygen supply and lipid accumulation in hepatocytes during shock, and the hypoxic state lead to marked increases in reactive oxygen species (ROS) and their peroxidation products[12]. These hypoxia-induced products are directly involved in hepatic cell damage and death (Figure 1); while, on the other hand, they can act as second messengers to activate redox-sensitive transcription factors. They exaggerate the release of multiple proinflammatory factors and cause hepatocyte apoptosis, followed by further infiltration of inflammatory cells into hepatic tissue and consequent liver damage/failure[13]. However, the main part of liver injury caused by disturbed blood flow occurs during reperfusion, rather than at the time of the hypoxic state[14].

During the course of the COVID-19 epidemic, infected patients have been treated with different antipyretics (*e.g.*, paracetamol, ibuprofen), analgetics (*e.g.*, caffeine), anti-inflammatory agents (*e.g.*, aminosalicylates, corticosteroids), antirheumatics (*e.g.*, chloroquine, hydroxychloroquine) and antiviral agents (*e.g.*, baricitinib, abidol, lopinavir, ritonavir, remdesivir), and many of these drugs are hepatotoxic[15]. However, despite reports on more frequent liver injuries in critically ill COVID-19 patients[11,16,17], there is no evidence on liver dysfunction induced exclusively by drugs in severe SARS-CoV-2 infection.

Abundant expression of ACE2 receptors makes the liver susceptible to direct infection by SARS-CoV-2[1,11]. Up-regulated expression of ACE2 receptors in hepatocytes of COVID-19 patients that suffer from severe hypoxia has also been found. Yet, there is no evidence of viral replication inside hepatocytes. On the other side, the liver harbors the body's largest macrophage pool, indicating that the liver damage may be caused by lymphocytes recognizing infected hepatocytes and consequently inducing a cell death process[1].

OXIDATIVE STRESS, LIVER DISEASES AND COVID-19

Oxidative stress plays an important role in liver diseases. Although both ROS and reactive nitrogen species (RNS) are involved in normal physiological processes, excessive amounts of either can destroy the major cellular components, proteins, lipids, and DNA. Chronic liver diseases are one of the biggest risk factors for liver complications in COVID-19, and commonly these diseases are marked by increased oxidative stress[18]. In chronic liver diseases, function in all types of cells is altered including hepatocyte, stellate, endothelial and Kupffer cells and their impaired gene expression led to increased liver damage[19]. Oxidative stress and mitochondrial dysfunction have a key role in the development of NAFLD. Mitochondrial dysfunction implies not only the formation of ROS and RNS, glutathione (GSH) depletion, and protein oxidation but also inhibition of the β-oxidation of lipids, increased steatosis, and lipid accumulation in hepatocytes[18]. ROS are generated in a lipid-rich environment, leading to lipid peroxidation (LPO) and further production and release of very reactive products of LPO. These LPO products impair the respiratory chain in hepatocytes, leading to impaired oxidative phosphorylation, reduced ATP synthesis, and further increase ROS production[20]. Moreover, ROS, along with products of LPO, induce activation of several cytokines, including TNF-α, IL-6 and IL-8, as well as cell

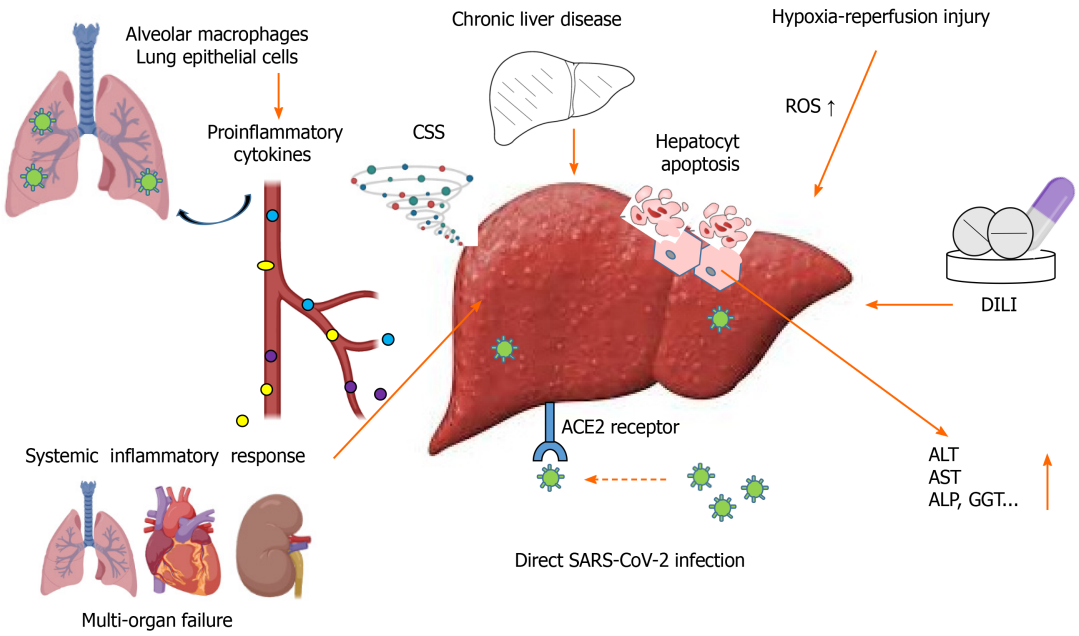

Figure 1 Pathophysiological mechanisms of coronavirus disease 2019-associated liver injuries. Created with BioRender.com. ACE2: Angiotensin converting enzyme 2; ALP: Alkaline phosphatase; ALT: Alanine transaminase; AST: Aspartate aminotransferase; CSS: Cytokine storm syndrome; DILI: Drug-induced liver injury; GGT: Gamma-glutamyl transferase; ROS: Reactive oxygen species.

death and fibrosis[21]. Furthermore, decreased activity of antioxidative enzymes, particularly superoxide dismutase and catalase, and lower level of coenzyme Q10 had been noticed in patients with liver diseases[22].

Most mechanisms of tissue damage due to SARS-CoV-2 infection are directly associated with oxidative stress[23]. Nevertheless, according to our knowledge, there are no studies about the parameters of oxidative stress in patients with SARS-CoV-2 infection. However, Polonikov *et al*[24] recently showed that people who had lower GSH levels before infection developed a more severe form of the disease than those with optimal GSH levels and suggested the crucial role of GSH in determining individual responsiveness to SARS-CoV-2 infection and disease pathogenesis.

In addition to producing $O_2$and H_2O_2, the cell infected by SARS-CoV-2 also produces IL-18 and IL-1β[2]. Besides, T lymphocytes and natural killer (NK) cells produce TNF-α, interferon (IFN)-γ, and IL-1β and stimulate the production of other proinflammatory cytokines, including IL-6 which contributes to the cytokine storm [25]. Additionally, IL-6 acts on liver cells, which in turn increase the synthesis of fibrinogen, plasminogen activator inhibitor-1, and C-reactive protein (CRP). The levels of these molecules rise consistently in COVID-19 patients[26]. Since liver diseases are associated with disturbed redox balance and inflammation, SARS-CoV-2 infection can lead to serious manifestations and lethality in COVID-19 patients.

Considering that the more recent studies recognize oxidative stress as a key player in COVID-19 severity, the free radical scavenging by specific natural and/or synthetic antioxidants would be beneficial in preventing the progression of COVID-19[23]. Among others, some natural plant compounds, such as polyphenols, are known to have anti-inflammatory, antioxidative and antiapoptotic properties[27,28] that make them potentially beneficial in the effort to improve therapies for the most vulnerable SARS-CoV-2-infected patients.

ANTIOXIDANT NUTRIENTS, DIET AND COVID-19

Vitamins and minerals are actively involved in neutralizing the harmful effects of oxidative species that induce liver damages. Their deficiency suppresses immune function and increases to the risk of infection. Patients with liver steatosis have increased LPO markers and proinflammatory cytokines as well as reduced total plasma antioxidant capacity (TAC)[29]. Literature data presented that vitamins (A, C, D, E, B6, B12, and folate), omega-3 fatty acids and minerals such as zinc, selenium, iron, magnesium and copper have important and common roles in maintaining the

immune system[30]. Inadequate dietary intake and/ or status of these micronutrients contribute to a decrease in resistance to infections, and consequently increased disease burden[31] Zhang and Liu[32] pointed out that in the assessment of micronutrients besides vitamins A, D, B, C and omega-3 fatty acids in COVID-19 patients, trace elements (selenium, zinc, and iron) should also be considered. Anti-inflammatory dietary index and dietary TAC are emphasized as a concept of the association between nutrients, dietary sources, eating habits, inflammation, and oxidative stress[33,34]. Omega-3 fatty acids, vitamin A and vitamin C, as well as polyphenols (widely present in plant-based foods) are known nutritional ingredients with anti-inflammatory and antioxidant properties[35]. There is evidence that supplementation with higher daily doses of nutrients (vitamins D, C, E, zinc and omega-3 fatty acids) than recommended might have a beneficial effect in patients with COVID-19, potentially reducing the viral load and the duration of hospitalization[31,36-38]. Oxidative stress contributes to the onset and progression of liver damage through related pathological mechanism[35]. According to a recent study by de Oliveira *et al*[39] NAFLD patients with lower hepatic injury have higher dietary TAC. It suggests a that increased consumption of foods with naturally high TAC leads to reduced production of LPO[39].

Vitamin A

Liver injury is associated with impaired vitamin A homeostasis. Vitamin A plays a role in regulating the production of IL-2 (promoting T cell growth) and proinflammatory TNF-α, which activates the microbial action of macrophages[31]. Also, vitamin A is involved in the phagocytic and oxidative explosive activities of macrophages activated during inflammation[40]. Vitamin A and some other retinoids show important immunomodulatory properties, by increasing the efficiency of actions of type 1 IFNs (*e.g.*, IFN-I), which are important antiviral cytokines[41]. Thus, retinoids promoted increase antiviral responses mediated by IFN-I. There is evidence that activation of retinoid signaling can strongly inhibit coronaviruses[42]. Thus, retinoids could possibly suppress viral replication in COVID-19 patients and may interfere with the cellular uptake of SARS-CoV-2 by inhibiting ACE2[43].

Dietary plant sources of vitamin A are carotenoids, such as β-carotene, while animal sources are rich in retinyl esters. Major food sources of vitamin A are presented in Table 1. β-carotene is known as a scavenger of ROS[44]. It also enhances T lymphocyte response, NK cell activity, and IL-2 production[45]. Liver represents the largest pool of retinyl esters in hepatic stellate cells. In hepatitis C-infected patients, vitamin A deficiency is associated with a lack of response to IFN as antiviral therapy[46]. Further, NAFLD is associated with declining circulating and hepatic retinol levels[30], and patients with NAFLD have higher risk for SARS-CoV-2 infections[47]. Adequate daily intake (about 650 μg/d for women and 750 μg/d for men) and liver storage below 80% in a healthy person are required to keep retinol levels in plasma around 2 μmol/L[45]. Data from 10 western European countries, demonstrated that low levels of vitamin A are associated with the incidence and mortality of COVID-19[41]. Vitamin A deficiency can occur during SARS-CoV-2 infection due to effects on the lung and liver body stores caused by inflammation process[48], suggesting importance of supplementation during this disease[49].

Vitamin D

Vitamin D is involved in several functions in the body, including increasing the oxidative burst potential of macrophages, and biosynthesis of superoxide dismutase. Furthermore, it suppresses the expression of proinflammatory cytokines, while promotes the expression of anti-inflammatory cytokines. In patients with chronic liver diseases, vitamin D deficiency is often reported[50], due to impaired synthesis of vitamin D–binding protein and hydroxylation of vitamin D. In spite of available *in vitro* and *in vivo* evidence, the therapeutic effect of vitamin D in liver disease still remain controversial[51]. Further studies will be required to clarify whether vitamin D have beneficial effects on liver diseases.

Vitamin D is actively involved in antioxidant, immunomodulatory, and antiviral responses. It induces the expression of enzymes involved in the antioxidant defense system. Also, it increases the levels of GSH, and suppresses the expression of NADPH oxidase. This way, vitamin D affects the reduction of oxidative stress and cellular oxidation[2]. Since deficiency of vitamin D is a global health challenge, the need for vitamin D supplementation has been a notable topic of research and discussion during the COVID-19 pandemic. Further, vitamin D deficiency elevates the vulnerability to acute viral respiratory infections[52]. Thus, supplementation with vitamin D enhances the innate immune responses to influenza and viral hepatitis C[53,54]. Vitamin D receptor is also expressed in pulmonary tissue.

Table 1 Ongoing clinical trials of antioxidant supplementation in coronavirus disease 2019 patients

Antioxidants and nutrients	Plant and/or animal sources	Potential target pathways	Recommended dietary intake; Effective dose for respiratory infection)	Registered clinical trials of COVID-19, rial number	Intervention dose	Primary outcome
Vitamin A	Carrots (raw); Cantaloupe; Mango; Salmon; Eggs	Role in immune competence; Immunomodulatory action	900/700 μg M/F	IRCT20200319046819N1[49]	25000 IU vitamin A and 600000 IU vitamin D per day, 300 IU vitamin E twice a week, 2000 mg vitamin C 4 times in a day, amp vitamin B; Soluvit in a day, for 1 wk	Weight, height, BMI; Severity of pulmonary involvement (CT scan); Respiratory support (invasive or non-invasive); WBC, CRP, IL6, TNF-α, IFN-γ, ESR; Body temperature; Organ involvement; Hospital duration; Mortality
Vitamin D	Portabella mushrooms; Dairy products; Eggs; Fish	Maintenance of cell physical barrier integrity; Increased antimicrobial protein production; Anti-inflammatory state; ACE2 and other members of the RAS expression	5- 15 μg; 20-50 μg[60]	NCT04334005[61]	25000 IU vitamin D	Mortality, all-cause mortality within 14 d
				NCT04344041[62]	400000 IU/or 50000 IU	Serum 25(OH)D3 changes during treatment
				NCT04636086[63]	50000 IU vitamin D ; 25000 IU vitamin D ; Days 1-4, 8,15, 22, 29 and 36	Vitamin D serum concentration, clinical improvement, biological markers
				NCT04621058[64]	D deficiency (< 30 ng/mL) 0.532 mg vitamin D (< 40 ng/mL): 0.266 mg vitamin D	Mortality reduction, lent of hospital reduction
				NCT04483635[65]	100000 IU vitamin D tab. baseline + 10000 IU/wk; 16 wk	Change in incidence laboratory-confirmed COVID-19 infection
				NCT04386850[66]	25 μg 25(OH)D3; 2 mo	Hospitalization, disease duration, death, mortality, ventilation
Vitamin C	Oranges; Lemon; Green and red peppers; Tomato; Broccoli; Brussel sprouts; Cabbage; Cauliflower; Spinach; Sweet potato; Winter squash	Antioxidant capacity; Immunomodulatory effects on interferon production; Cytokine production down-regulation	40-80 mg; 6–8 g[77]	NCT04323514[74]	10 g vitamin C infusion	Hospital mortality
				NCT04530539[75]	1000 mg vitamin C	Severity of symptoms
				NCT04682574[76]	30 g/d 2 d with standard treatment	Partial pressure of oxygen in arterial blood to fraction of inspired oxygen
Vitamin E	Sunflower seeds; Nuts; Almonds; Blueberries; Kivi; Broccoli	Antioxidant action; Immunomodulatory effects	7–10 mg; 30–200 mg[82]			
Zinc	Pumpkin and squash seeds nuts; Soybean; Beef; Mollusks; Lamb	Reduces ROS in viral infections; Replication inhibition; Immunomodulatory effects; Antibody production; NK cell activity; Cytokine production by mononuclear cells; Chemotaxis response reduction; Neutrophil respiratory burst reduction	8–14 mg; 30–50 mg[43]	NCT04335084[90]	Zinc, vitamin D, vitamin C 12 wk and hydroxychloroquine for 1 d	Prevention of COVID-19 symptoms recorded in a daily diary
Selenium	Sunflower seeds; Coconut meat; Mollusks; Salmon;	Antioxidant balanceROS balance in inflammatory processes	60–70 mg			

	Turkey; Ham					
Copper	Cashew nuts; Tofu; Mushrooms; Beef; Oyster; Cereals; Roots, tubers: Sweet potato; Quinoa	Role in immunity antimicrobial action due to copper toxicity; Enhance macrophage activity in lung infection	900 μg			
Curcumin	Rhizome of turmeric (*Curcuma longa*)	Antioxidant capacity; Virus-ACE2 interaction reduction; ACE2 level increase; Antiviral activities SARS-CoV-2 protease, spike glycoprotein-RBD and PD-ACE2 binding		IRCT20200611047735N1[114]	160 mg curcumin; 2 wk	Immune responses (IFN-γ, IL-17, IL-4 and TGF-β)
				IRCT20121216011763N46 [115]	1000 mg curcumin + 10 mg piperine twice/day, 2 wk	Clinical symptoms, duration, severity, inflammatory mediators
Silymarin	Milk thistle *(Silybum marianum)*	Antioxidant capacity; Anti-inflammatory; p38 MAPK pathway antiviral		NCT04394208[116]	420 mg/d; 3 divided doses	Clinical outcome duration of mechanical ventilation hospitalization

ACE2: Angiotensin converting enzyme 2; COVID-19: Coronavirus disease 2019; CRP: C-reactive protein; CT: Computed tomography; ESR: Erythrocyte sedimentation rate; IFN-γ: Interferon-gamma; IL: Interleukin; NK: Natural killer; PD: Protease domain; RAS: Renin-angiotensin system; RBD: Receptor binding domain; ROS: Reactive oxygen species; SARS-CoV-2: Severe acute respiratory syndrome-coronavirus-2; tab.: Tablet; TGF-β: Transforming growth factor-beta; TNF-α: Tumor necrosis factor-alpha; WBC: White blood cell.

The immunomodulatory effect of this vitamin are well established, and the supplements seems to be useful in the prevention or treatment of COVID-19. Vitamin D supplementation stimulates the binding of angiotensin-II to the ACE2 receptor, thereby diminishing the number of SARS-CoV-2 particles that can bind to ACE2 receptors and enter the cells[55,56]. Two meta-analysis reported that COVID-19 patients with a low blood vitamin D levels have worse prognoses[57] and that the risk of SARS-CoV-2 infection was significantly increased in patients with low levels of vitamin D[58]. CRP, as marker of inflammation and the cytokine storm, was highly expressed in COVID-19 patients with severe symptoms and correlate with vitamin deficiency[59]. Therefore, vitamin D could act as an adjuvant therapeutic for the treatment of this novel virus[60]. Ongoing clinical trials of vitamin D supplementation [61-66] in patients with COVID-19 are presented in Table 1.

Vitamin C

Vitamin C has a key antioxidant role, maintains cellular redox balance and protects against free radicals (ROS and RNS) during oxidative fight[67]. Also, vitamin C regenerates oxidized vitamin E, GSH and carotenoids, modifies pro-inflammatory cytokine production, and lower blood histamine. The meta-analysis reported that administration of high doses of vitamin C was associated with a reduction in-hospital mortality among patients with severe sepsis[68]. The hepatoprotective property of water soluble vitamin C is attributed to its antioxidant action, Animal models have lent strong evidence that vitamin C supplementation significantly decreases hepatic markers of oxidative stress, hepatocellular ballooning, and inflammation[69]. The prooxidant potential of vitamin C is enhanced with the presence of iron and copper catalysts *in vitro*. Through the Fenton reaction, the antiviral activity of vitamin C

increases, resulting in the formation of hydroxyl radicals from hydrogen peroxide. High intake of vitamin C may be an effective choice in the early treatment of COVID-19[70,71]. Several clinical studies evaluating vitamin C infusion in patients with COVID-19 are in progress (Table 1)[72-76]. It is indisputable that consumption of citrus fruits and vegetables that contain vitamin C is important in supporting the immune system during the COVID-19 pandemic[77].

Vitamin E

Vitamin E is a well-known fat-soluble vitamin, with a high antioxidant potential, which combats free radicals by a chain-breaking effect and protects cells from oxidative damage. Also, vitamin E enhances production of IL-2 and reduces production of prostaglandin E. Thus, vitamin E indirectly saves T cell function[32]. In addition, blood level of vitamin E inversely correlates with the number of products of oxidative stress, which is in line with the degree of liver injury. The potential mechanisms of action of vitamin E against COVID-19 involve the antioxidant properties of vitamin E derivatives that increase the integrity of the cell membrane and improve the adaptive response of the immune system to viral infections of the respiratory tract[78]. Natural isomers of vitamin E, α and γ tocopherols also have ROS scavenging potential. Taking vitamin E with vitamin C or alone, facilitates the removal of free radicals formed in the liver tissue[50]. The results of a meta-analysis[79] revealed that vitamin E supplementation significantly reduced AST, ALT, steatosis, inflammation, and hepatocellular ballooning. Vitamin E is also shown to be effective for normalizing ALT levels in patients with chronic liver injury in doses of 600 mg, while 800 IU is recommended for nondiabetic patients with nonalcoholic steatohepatitis (commonly known as NASH)[80,81]. As reviewed by Sahin *et al*[43], 200 IU vitamin E has no effect on lower respiratory infection but treatment with 800 IJ increases resistance to respiratory infections. Vitamins E and C in combination have been suggested as a useful antioxidant therapy in treating critically ill COVID-19 patients with gastric cardia complications. Major food sources of vitamin E and recommended dietary intake[82] are presented in Table 1.

Vitamins B6 and B12

Vitamin B6 is essential cofactor for metabolism of amino acids, which are structural components of cytokines. It has been shown that higher levels of the active form of vitamin B6, pyridoxal 5'-phosphate (PLP) in plasma with parallel reduction in liver PLP is linked to the lower inflammation rate[32]. Adequate vitamin B_6 (and B_{12}) supplementation in COVID-19 patients has been included in current protocols for the treatment[83], in order to regulate the altered homocysteine metabolism caused by the corona virus. Vitamin B6 administration at higher doses can decrease levels of inflammatory markers such as the TNF-α and IL-6, as well as D-dimer values, preventing coagulopathy in COVID-19 patients[84]. Methylcobalamin supplements may improve clinical deterioration during SARS-CoV-2 infection and decrease COVID-19-related symptoms and organ damage[85]. Combination of vitamin B_{12} (500 μg), vitamin D (1000 IU) and magnesium supplements was also shown to reduce COVID-19 severity symptoms and reduce the need for oxygen and intensive care support[86].

Zinc

Zinc enhances the function of antioxidant proteins and it is well known on its antioxidant activity, including protection against ROS and RNS[43]. It also has a strong anti-inflammatory action, reduces proliferation of proinflammatory Th17 and Th9 cells, and thus decreases release of proinflammatory cytokines such as TNF-α, IL-2 and IL-6. Zinc is potentially considered a major mineral during SARS-CoV-2 infection due to its dual immunomodulatory and antiviral effects. Indirect data suggest that zinc may decrease the activity of ACE2[43]. In NAFLD patients, with comorbidities such as old age, overweight, immune disturbance, diabetes and atherosclerosis, zinc deficiency and low body status may increase the risk of severe COVID-19 illness[34]. However, in the latest meta-analyses of 12 randomized control studies, the decrease of IL-6, increase of IL-2 and no ameliorative effects on TNF-α level due to zinc supplementation has been found[87].

Recent studies have shown that zinc supplementation is able to decrease SARS-CoV-2 infections, due to inhibition of viral uncoating, binding, and replication. It is reported by Finzi *et al*[88] that the clinical respiratory symptoms were improved in COVID-19 patients supplemented with high dose of zinc citrate, zinc gluconate or zinc acetate. Roy *et al*[89] suggested the combined use of curcumin and zinc treatment. The authors speculated that zinc in synergy with curcumin might promote the synthesis of

ionophore complexes, leading to the synchronized and improved antiviral activity. Curcumas exert an antiviral effect by inhibiting entry of the virus into the cell, while zinc inhibits the RNA polymerase. Major food sources of zinc, recommended dietary intake[43], and ongoing study that examines the effect of zinc supplementation in preventing COVID-19 symptoms[90] are presented in Table 1.

Selenium

As a part of selenoproteins, selenium has essential role in regulation of redox reactions, particularly in suppression of ROS produced during oxidative stress. Deficiency of selenium in the diet, concomitant with elevated oxidative stress in the host tissue, may lead to alteration of viral genome. The activity of selenoproteins in antioxidant defense, affects function of host leukocytes and NK cells[43], while selenium deficiency alters immune response by reducing proliferation of T cells, the lymphocyte-mediated toxicity, and NK cell activity[91]. Besides being pointed out as a promising treatment for COVID-19[92], crucial role of selenium in the SARS-CoV-2 emergence and spread has been suggested. Low selenium status in the host affects the viral genome[93], leading to the virus becoming more virulent[92]. Dietary supplementation of selenium can stimulate the activity of cytotoxic effector cells in COVID-19 [94].

The meta-analysis of antioxidants effects in COVID-19 patients revealed decreased mortality and the requirement of mechanical ventilation, but no shorter time in intensive care unit (ICU) due to antioxidant therapies (predominantly based in supplementation of selenium)[95,96]. However, in meta-analysis performed by Allingstrup and Afshari[97], no clear results supporting beneficial effect of selenium supplementation in critically ill patients, including less days on a ventilation and shorter ICU and hospital stay, was shown. The elevated ratio of thromboxane A2 to prostacyclin I2 followed by vasoconstriction and blood coagulation, has been found in animal models deficient in selenium[93]. The same mechanism possible explains the venous thromboembolism in COVID-19 patients with selenium deficiency.

Iron

Among many other physiological roles, iron is known to regulate production and action of cytokines. It is also involved in the generation of ROS in neutrophils, which presents pathogen-killing activity during oxidative burst[31]. In hepatitis C, enhanced hepcidin production favors viral persistence, while the inflammation during SARS-CoV-2 infection might be associated with promotion of hepcidin production. Elevated hepcidin reduces iron uptake in the gut, thus diminishing the effect of iron supplementation. Even more, the sequestration of iron in macrophages, hepatocytes and enterocytes, can be reduced by hepcidin[98]. When SARS-CoV-2 colonizes these cells, the accumulated iron is used for viral replication. Evidence in the context of SARS-CoV, based on the previous studies, indicates that iron is important for viral replication, which is why iron is a promising adjuvant therapeutic agent in treating the SARS-CoV-2 infection[99].

Copper

Being a part of copper/zinc-superoxide dismutase, an enzyme essential for anti-ROS defense, copper accumulates at sites of inflammation and acts as a free-radical scavenger[100]. Due to its activity in maintaining intracellular antioxidant balance, an important role for copper in the inflammatory response has been suggested. In general, it is important for IL-2 production and response, as well as for antibody production. Between 80% and 95% of copper is transported by ceruloplasmin, the levels of which are increased in response to inflammation and infection. Changes in copper homeostasis are a crucial component of respiratory burst. Copper has distinctive antimicrobial properties and helps to destroy a broad range of microorganisms[101]. It competes with zinc for the same absorption site, and the copper deficiency is likely to occur when zinc orally supplemented at high doses. Copper deficiency has been identified in liver disease, in NAFLD associated with insulin resistance, steatosis, and an accelerated progression of NASH[102,103]. Copper has proven to be capable of inactivating different types of viruses, such as influenza A/WSN/33 and recently SARS-CoV-2[104]. SARS-CoV-2 is very sensitive to the copper surface[105], thus copper may be proposed for supplementation during COVID-19 treatment[106].

Magnesium

Magnesium is involved in several functions in the body, including antioxidant

defense. It assists in DNA protection against oxidative damage and diminishes the production of superoxide anion radical[31]. It is hypothesized that a low magnesium status may encourage transition from mild to critical clinical manifestations of the SARS-CoV-2 infection[107]. Magnesium also maintains proper lung function and reduces the risk of airway hyper-reactivity. It has been noticed that magnesium deficiency is related to reduced activity of immune cells and increased levels of IL-6, which is recognized as a key player in the COVID-19 associated cytokine storm[108]. According to a recent study by Tan *et al*[86] , the concomitant oral supplementation of vitamin D, magnesium, and vitamin B12 decreases clinical deterioration in patients with COVID-19. It should be noted that magnesium has a relationship to vitamin D physiology. This suggests that magnesium could contribute to the beneficial effects of vitamin D on COVID-19 outcomes.

Polyphenols

Polyphenols are a large class of bioactive compounds from plants, which exert protective effects against oxidative stress, ultraviolet radiations, and different pathogens. Although there are more than 8000 polyphenolic compounds, all of them contain one or more phenolic rings with hydroxyl groups. The most common polyphenols are flavonoids (including, flavonols, isoflavones, flavones, flavanones, flavan-3-ols and anthocyanins), while nonflavonoids are phenolic acids (gallic, ellagic, chlorogenic or hydoxycinnamic), stilbenes (resveratrol), and lignans[109]. The antiviral activities of some polyphenolic compounds are well documented in the literature. Among the targeted viruses are hepatitis B and C viruses, herpes simplex virus-1, influenza A virus, and Epstein-Barr virus[110]. However, data on their effects on coronaviruses are still sparse.

Polyphenols could exert their anti-SARS-CoV-2 potential in several ways. The first one is inhibition of virus entry into the host cells. Since the spike (S) protein is the sole protein of coronaviruses responsible for its fusion with host cells, it is a meaningful target for antiviral therapies. Several polyphenols have demonstrated the interference with the S protein *in vitro*. In particular, luteolin and quercetin prevented SARS-CoV-2 infection of Vero E6 cells[111], while emodin interfered with the interaction between S protein and its receptor ACE2 in the same cells[112]. Hesperidin has shown a similar effect on the S protein-ACE2 interaction as emodin, and curcumin and several polyphenols from Citrus species also possess a high affinity to S protein[110].

The fusion of S protein and ACE2 could also be prevented by targeting ACE2. Some polyphenols, such as curcumin and resveratrol, down-regulate expression and function of ACE2, thereby affecting severity of COVID-19. Further, Jena *et al*[113] recently published a computational study that showed flavonoids such as catechin and curcumin could bind the ACE2, impeding its interaction with the virus, but these implications have not been confirmed *in vivo* so far. Ongoing studies that examine the effect of curcumin and silymarin supplementation on clinical outcomes in COVID-19 patients[114-116] are presented in Table 1.

Considering that ACE2 is abundantly expressed in the liver, this organ represents a potential target for direct infection and cytotoxicity caused by an active viral replication in hepatic cells[117]. Accordingly, persons with chronic liver disease can have serious consequences on health after SARS-CoV-2 infection, and polyphenols dietary intake could diminish these complications.

Aloe vera is one of the nutraceuticals with the strongest antiviral potential, with quercetin and kaempferol as the most active components against viruses. They both effectively reduce the viral replication of the influenza virus *in vitro*, and also reduce oxidative damage in the lungs and liver of infected mice[118]. Therefore, quercetin and kaempferol are good candidates for preclinical and clinical studies on the liver protection in SARS-CoV-2 infection.

Green tea and coffee are commonly consumed beverages worldwide and important sources of polyphenols. The polyphenols from green tea: Gallocatechin-3-gallate, epigallocatechin gallate, and epicatechingallate are recognized as potential weapon to battle SARS-CoV-2[119]. Moreover, both coffee and green tea have been shown to lower prevalence of metabolic syndrome, type 2 diabetes, and NAFLD[120].

Another mechanism for the beneficial effects of polyphenols in COVID-19 is the suppression of inflammatory response of the host. The above-mentioned cytokine storm, that has been responsible for lethal outcome in many patients worldwide, may be reduced by several polyphenols, including curcumin, resveratrol, emodin, epigallocatechin, gallate, naringenin, apigenin, and kaempferol[121]. All these polyphenols have shown potential to reduce level of proinflammatory cytokines *in vitro* and *in vivo*; although, their beneficial effects against SARS-CoV-2 need to be confirmed in clinical studies.

The severe inflammatory response could also lead to immune-mediated damage of the liver[118]. In line with this, polyphenol mediates the body's fight against the cytokine storm, which would protect the liver as well. Nevertheless, clinical studies on the hepatoprotective potential of different polyphenols in patients with COVID-19 are urgently needed to confirm this hypothesis.

Omega-3 fatty acids

Fatty acids are important players in hepatic lipid metabolism. Omega-3 fatty acids promote fat oxidation and decrease endogenous lipid synthesis by altering gene expression[122]. Patients with liver ALD have low levels of omega-3 fatty acids[123]. Despite genetic and anthropometric factors that could influence their benefits, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) possess a strong anti-inflammatory potential. Thus, a dietary intake of 250 mg/d is recommended for maintaining optimal health[36]. A study by Zheng *et al*[124] showed a statistically significant association between NAFLD and the severity of COVID-19 in obese patients and those with metabolic syndrome and fatty liver, while a study by Mahamid *et al*[47] showed that NAFLD is a significant risk factor for severe COVID-19 independently of both sex or metabolic syndrome. Also, NAFLD patients, in particular those with associated obesity, commonly have an impaired omega-3 fatty acid level and an increased omega-6/omega-3 ratio that can be ameliorated by a nutritional intervention[125,126].

The European Society for Parenteral and Enteral Nutrition has recently declared that omega-3 fatty acids can increase oxygenation in COVID-19 patients[127,128]. Bistrian[129] proposed parenteral supplementation with high doses of EPA and DHA (4–6 g/d), for treatment of patients with severe COVID-19, to inhibit cytokine storm and reduce the inflammation. The possible benefits and risk of omega-3 fatty acid intervention for patients with COVID-19 have been reviewed[130]. The authors concluded that although EPA and DHA may positively affect resolution of inflammation and recovery in patients with COVID-19, excess of EPA and/or DHA can induce LPO of cell membranes, resulting in cell damage due to elevated oxidative stress. This could be prevented by a concomitant supplementation with antioxidants, such as vitamin C and E[30,36]. However, based on the clinical trials that have been completed to date, it is still difficult to determine the optimal dose, route and timing of omega-3 fatty acids administration in COVID-19 patients. Until randomized clinical test data are validated, omega-3 fatty acid supplementation, especially at high doses, must be performed carefully in patients with COVID-19.

Dietary patterns

The COVID-19 pandemic provides nutrition researchers with new opportunities to keep the public, especially those in high-risk groups, constantly informed about the potential benefits of good nutrition and healthy eating habits for prevention and therapy in COVID-19[40,131]. The most vulnerable are the elderly, due to a declined gastrointestinal uptake of micronutrients and macronutrients[132]. Many studies have shown association between a high intake of plant foods, fruit and vegetables and low levels of inflammatory parameters.

There is strong evidence of a favorable impact of the Mediterranean diet on IL-6 and CRP values[133]. Traditionally, the Mediterranean diet is characterized by low intake of simple carbohydrates, high consumption of olive oil, fiber, fresh fruit and vegetables, legumes, whole grains, olives, nuts and fish, moderate consumption of dairy products and poultry, low intake of red meat, many condiments and spices, and regular but moderate wine intake. Oleic acid consumption, which is abundant in olive oil, is also a feature. These components directly affect the synthesis of various antioxidant enzymes and may reduce liver tissue damage generated by oxidative stress[134].

Numerous studies have also shown the anti-inflammatory effect of the dietary approach stop hypertension (referred to as DASH) diet[135]. The ability of nutrients rich in antioxidants (bayberry juice, chocolate, onion, lettuce, and tomato products) to increase TAC in plasma and thereby reduce NAFLD through modifications of oxidative stress is well documented[34]. However, proper nutrition and nutrition support can help battle against COVID-19 by improving immune responses and aiding inflammatory processes[40,136].

CONCLUSION

Foods rich in vitamins, minerals, polyphenols and other bioactive compounds may decrease inflammatory pathway activity and prevent liver damage in COVID-19 patients. An important additional aspect is their ability to control oxidative stress. Antioxidants supplementation during the COVID-19 pandemic crisis should respect nutritional status and serum levels of relevant nutrients in patients. It is essential to recognize nutritional deficiencies in COVID-19 patients, and to intervene to improve their status. Constant public informing about balanced diet and healthy eating habits is important in the prevention of SARS-CoV-2 infection.

Abstract

Incidental pancreatic cysts are commonly encountered with some cysts having malignant potential. The most common pancreatic cystic neoplasms include serous cystadenoma, mucinous cystic neoplasm and intraductal papillary mucinous neoplasm. Risk stratifying pancreatic cysts is important in deciding whether patients may benefit from endoscopic ultrasound (EUS) or surgical resection. Surgery should be reserved for patients with malignant cysts or cysts at high risk for developing malignancy as suggested by various risk features including solid mass, nodule and dilated main pancreatic duct. EUS may supplement magnetic resonance imaging findings for cysts that remain indeterminate or have concerning features on imaging. Various cyst fluid markers including carcinoembryonic antigen, glucose, amylase, cytology, and DNA markers help distinguish mucinous from nonmucinous cysts. This review will guide the practicing gastroenterologist in how to evaluate incidental pancreatic cysts and when to consider referral for EUS or surgery. For presumed low risk cysts, surveillance strategies will be discussed. Managing pancreatic cysts requires an individualized approach that is directed by the various guidelines.

Key Words: Pancreatic cyst; Intraductal papillary mucinous neoplasm; Endoscopic ultrasound-guided fine needle aspiration; Serous cystadenoma; Surveillance; Carcinoembryonic antigen

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Incidental pancreatic cysts are common, and some have malignant potential. magnetic resonance imaging of the pancreas should be used to risk stratify pancreatic cysts and decide whether patients may benefit from endoscopic ultrasound or surgical resection. Presumed low risk cysts should undergo surveillance unless the patient is not a surgical candidate or has a pseudocyst or serous cystadenoma. We discuss the approach to diagnosis and management of incidental pancreatic cysts.

INTRODUCTION

Pancreatic cysts are typically discovered incidentally with the increased use and quality of abdominal imaging. They are identified in up to 20% of magnetic resonance imaging (MRI) and 3% of computed tomography (CT) scans with older patients more likely to have pancreatic cysts[1-3]. The malignant potential of some pancreatic cysts creates consternation for patients and providers alike. A retrospective study of Veterans Administration patients with pancreatic cysts noted a hazard ratio of 19.64 for pancreatic cancer[4]. However, other studies of incidental pancreatic cysts demonstrated lower risk of malignancy with a hazard ratio of 3.0 for pancreatic adenocarcinoma[5]. The American Gastroenterological Association (AGA) technical review of incidental pancreatic cysts estimated incident risk of malignancy at 0.24% per year with a prevalent malignant risk of 0.25% at the time the cyst is identified[6].

The most commonly encountered benign pancreatic cysts include serous cystadenoma (SCA), mucinous cystic neoplasm (MCN), and intraductal papillary mucinous neoplasm (IPMN). MCN and IPMN have varying malignant potential. SCAs classically appear lobular with multiple septations and microcysts (Figure 1). If densely septated, the cyst can appear mass-like on imaging and endoscopic ultrasound (EUS). A central scar which may be calcified is pathognomonic for SCA but occurs in only 15-20% of all SCA. A surgical series reported 51% preoperative diagnostic accuracy mainly based on radiologic imaging studies for SCA[7]. On pathology, SCA are defined by glycogen-containing cuboidal epithelial cells. The natural history of SCAs may involve slow gradual growth, which occurs in less than half of all SCAs with cysts larger than 4 cm potentially growing faster[8,9].

MCNs are defined by the presence of ovarian-like stroma, which explains why they occur almost exclusively in women. On imaging, MCNs are usually characterized by unilocular cysts in the body and/or tail (Figure 2). Peripheral calcifications of the wall or septa can occur in about 25% of MCNs. Approximately 15% of resected MCNs contain invasive cancer, and risk factors for malignancy include size > 6 cm, enhancing nodule, thick irregular wall, and peripheral calcifications[6,10]. While MCNs have malignant potential, less than 0.4% of MCNs smaller than 3 cm without a nodule harbor high-grade dysplasia or invasive cancer[11]. This has led to the suggestion by some that not all MCNs must be resected.

IPMNs are more common with radiologic and histologic subtypes that confer different risks of malignancy. Main duct IPMNs (MD-IPMN) have the highest malignant potential (approximately 60%-80%) and are characterized by diffuse or segmental dilatation of the main pancreatic duct to > 5 mm from a cystic tumor producing mucus within the duct (Figure 3)[12]. Branch duct IPMNs (BD-IPMN) arise within the branches of a nondilated main pancreatic duct (Figure 4) with malignant risk ranging from 3% to 26%[6,12]. Mixed type IPMNs have features of both MD-IPMN and BD-IPMN with approximately 20% to 30% of BD-IPMN ultimately proven to be mixed type IPMN following surgical resection[13]. The malignant potential of mixed type IPMN is comparable to MD-IPMN although mixed type IPMN with only microscopic involvement of the main pancreatic duct may carry less malignant risk [14]. High risk features for malignant IPMNs include solid component, enhancing nodule, main pancreatic duct dilation > 1 cm, jaundice and cytology with high-grade dysplasia or cancer, which were associated with lower 5-year survival compared with size > 3 cm, main pancreatic duct 5-9 mm, pancreatitis and non-enhancing nodules[15]. Other findings potentially associated with development of risk features include rapid rate of growth > 2.5 mm per year, body mass index > 26.4, smoking, and history of extrapancreatic malignancy[15-17]. Gastric histology is associated with a more benign course and more commonly found with BD-IPMN and microscopic mixed type IPMN while intestinal histology tends to occur with MD-IPMNs[18]. The less common pancreatobiliary and oncocytic histologic subtypes are mainly associated with high-grade dysplasia[19].

Solid pseudopapillary neoplasms (SPEN) also have malignant potential with characteristic pseudopapillae and cystic spaces containing hemorrhage and cholesterol clefts in myxoid stroma alternating with solid tissue. Therefore, these lesions appear solid

APPROACH TO DIAGNOSIS OF THE INCIDENTAL PANCREATIC CYST

Evaluating a patient with an incidental pancreatic cyst should begin with a targeted history focused on acute or chronic pancreatitis and family history of pancreatic cancer or hereditary cancer syndromes associated with increased risk of pancreatic cancer. Patients at increased risk of pancreatic cancer due to family history should be managed differently and these patients are not the focus of this review. For those with incidental cysts, MRI pancreas with magnetic resonance cholangiopancreatography in 1.5 or 3 tesla should be performed. MRI has 55% to 76% accuracy for differentiating benign from malignant cysts while it is only 40% to 50% accurate for diagnosing the specific type of cyst[20]. MRI is superior for identifying communication between the main pancreatic duct and cyst, and thus better at diagnosing BD-IPMNs. If MRI cannot be performed, pancreatic protocol CT with contrast-enhanced images during the pancreatic and portal venous phases should be obtained. The imaging findings will help determine whether EUS is needed for further diagnostic evaluation, the patient should undergo surgical resection, or begin a surveillance program. The overarching questions when reviewing imaging are: (1) Is the cyst malignant; (2) If not, is it a mucinous cyst; and (3) If it is a mucinous cyst, what is the malignant potential[21-23]?

Before embarking on further evaluation for incidental pancreatic cysts, discussion should occur with select patients about whether ongoing management fits with the patients' overall clinical status. All pancreatic cyst guidelines agree that patients who are not surgically fit do not need ongoing surveillance. A study of 725 patients with IPMNs noted that patients with higher Charlson comorbidity index ≥ 7 were 11 times

more likely to die from non-IPMN related causes within 3 years of cyst diagnosis and had significantly shorter median survival (43 mo *vs* 180 mo)[24]. Another study used the Adult Comorbidity Evaluation 27 scoring system in 793 patients with IPMNs followed for over a year with similar conclusions that patients with higher scores were more likely to die from non-IPMN related causes[25]. These may help risk stratify patients with multiple comorbidities who likely will not need ongoing attention to their cysts. The other group of patients who do not need ongoing evaluation include those with pseudocysts or SCAs although the European cyst guideline suggests a one-time surveillance MRI one year after identification of SCAs[26].

The multiple guidelines that have been proposed to assist clinicians with managing pancreatic cystic lesions share many commonalities although the AGA guideline is the significant outlier (Table 1)[12,20,26-28]. The controversial AGA guideline increased the threshold for sending a patient to EUS-FNA as well as surgery from one to at least two risk features. While this may be expected to decrease the unnecessary resection of benign cysts, the impact on the negative predictive value has not been proven[29,30]. In our experience, we found similar rates of missing malignant cysts when comparing the International Association of Pancreatology Fukuoka and AGA guidelines (19% by Fukuoka, 25% by AGA) and preventing unnecessary surgeries (69% by Fukuoka, 74% by AGA)[29]. Therefore, the guidelines all serve as guides but cannot dictate management of patients with pancreatic cysts.

EUS

Following radiologic imaging, the role of EUS in the diagnostic work-up of pancreatic cysts includes evaluating cysts that are indeterminate or have risk features, or if EUS may change management. EUS-FNA is helpful in differentiating mucinous from nonmucinous cysts when imaging is indeterminate and in diagnosing suspected cystic neuroendocrine tumors and solid pseudopapillary neoplasms[31]. The Fukuoka and AGA guidelines offer guidance on whom to select for EUS-FNA based on presence of specific risk features. The Fukuoka guideline for suspected MCN and IPMN recommends EUS for patients with any one of these clinical or radiologic worrisome features (pancreatitis, size ≥ 3 cm, enhancing nodule < 5 mm, main pancreatic duct 5-9 mm, thick cyst wall, abrupt change in main pancreatic duct diameter with upstream parenchymal atrophy, lymphadenopathy, elevated serum CA 19-9, cyst growth ≥ 5 mm/2 years)[12]. On the other hand, the AGA guideline suggests EUS-FNA only for cysts with two high-risk imaging features (size ≥ 3 cm, solid component, or dilated main pancreatic duct) or if significant changes develop in the cyst during surveillance [27]. However, it is certainly reasonable to perform EUS-FNA in certain situations even with a single risk feature such as a solid component or significantly dilated main pancreatic duct given the relatively high risk of malignancy associated with these features.

EUS imaging is limited in diagnostic accuracy for identifying mucinous cysts with only 51% accuracy[32]. Moreover, among expert endosonographers there remains wide variation in interobserver agreement of neoplastic features[33,34]. Agreement is reportedly best for nodules, moderate for solid component and cystic communication with pancreatic duct, and fair for suspicion of malignancy[34].

Endosonographers can distinguish nodules from mucus by comparing the echogenicity relative to adjacent tissue and assessing the mobility of the structure with patient repositioning and probing with the needle. Nodules appear iso- or hypoechoic without a smooth edge or hyperechoic rim compared with mucus which have a smooth-edged hyperechoic rim surrounding a hypoechoic center[35]. Contrast-enhanced harmonic EUS, which involves intravenous injection of special contrast agents that highlight microvasculature differences between normal and abnormal tissue, appears helpful in not only diagnosing nodules, but also differentiating high-grade dysplasia and cancerous nodules from nodules with low-grade dysplasia[36]. Nodules taller than 5 mm have greater association with malignancy.

Cyst fluid analysis

Because of the inadequate diagnostic capabilities of EUS imaging alone, intense interest has focused on searching for the ideal cyst fluid marker whether protein, DNA, RNA, metabolite that would diagnose the cyst, distinguish a mucinous from nonmucinous cyst, and predict malignant progression of the cyst. Cyst fluid for cytology typically has low diagnostic yield with less than 50% sensitivity for mucinous lesions, however, it is helpful when positive for a specific diagnosis. Similarly, cytology is highly specific for malignancy with at best 60% sensitivity for malignancy [27,37]. Fluid cytology appears more useful for SPEN with 70-81% accuracy and cystic neuroendocrine tumors with 70%-89% diagnostic yield[38-41]. Cyst fluid from

Table 1 Key Features of pancreatic cyst guidelines

Specifics of Guidelines	2015 AGA	2017 Fukuoka	2017 ACG	2017 ACR	2018 European Study Group
Patient population	Incidental pancreatic cysts	Suspected MCN and IPMN	All pancreatic cysts	Incidental pancreatic cysts	All pancreatic cysts
Threshold for EUS and/or surgery	At least 2 risk factors	1 risk factor	1 risk factor	1 risk factor	1 risk factor
Surveillance recommendations in unresected cysts	MRI in 1 year, then every 2 yr	Surveillance based on cyst size	Surveillance based on cyst size	Surveillance based on cyst size and age	Surveillance based on cyst size and diagnosis
Stopping surveillance	(1) After 5 yr of stability without development of high-risk features; (2) Surgically unfit; and (3) Select resected cysts including BD-IPMN with no, low or moderate-grade dysplasia	(1) Surgically unfit; and (2) Following resection of serous cystadenoma and MCN without invasive cancer	(1) Surgically unfit; (2) Following resection of serous cystadenoma and MCN without invasive cancer; and (3) Individualize approach to patients > 75	(1) 9-10 yr and stop at age 80; and (2) For cysts discovered > age 80, limited surveillance for 4 yr only if stable	Surgically unfit

AGA: American Gastroenterological Association; ACG: American College of Gastroenterology; EUS: Endoscopic ultrasound; MRI: Magnetic resonance imaging; MCN: Mucinous cystic neoplasm; IPMN: Intraductal papillary mucinous neoplasm; BD-IPMN: Branch duct-intraductal papillary mucinous neoplasm.

pancreatic lymphangioma has a characteristic chylous appearance, elevated triglyceride levels, and numerous benign lymphocytes[42]. Improved diagnostic yield for mucinous or malignant cysts by 29% has been reported with cyst wall cytology, obtained by repeatedly passing the needle back and forth through the collapsed cyst wall[43]. Therefore, cyst wall cytology may be preferred over fluid alone, unless copious fluid is available for cytology. A small study suggests greater diagnostic yield with EUS-fine needle biopsy using a core biopsy needle[44].

If there is enough fluid, before sending it for analysis it should be evaluated for string sign, which is highly specific (95%) for a mucinous cyst[45]. This is defined as cyst fluid extending for at least 1 cm and 1 s from the tip of the EUS needle or between two fingers that are separated after placing a drop of fluid on them. The remaining fluid should be sent for carcinoembryonic antigen (CEA), amylase, glucose and potentially DNA analyses (Table 2).

While CEA is not predictive of malignancy, it remains the most widely used and accurate tumor marker for differentiating mucinous from non-mucinous pancreatic cysts[46]. However, it does not distinguish IPMN from MCN. Other limitations with CEA assays are they were validated for serum but not for cyst fluid, and significant CEA variation exists among different assays[47]. The appropriate CEA threshold is debated with CEA greater than 192 ng/mL having 73% sensitivity and 84% specificity for mucinous cysts[32]. Cyst fluid glucose may be more accurate than CEA for mucinous cysts with a recent meta-analysis reporting 91% sensitivity and 75% specificity for glucose compared with 67% sensitivity and 80% specificity for CEA[48]. A common cutoff used for cyst fluid glucose in diagnosing mucinous cysts is < 50 mg/dL. Very low CEA levels < 5 ng/mL are specific for SCA, pseudocyst, or cystic neuroendocrine tumor[49]. Amylase is helpful in excluding pseudocysts if less than 250 U/L[49].

DNA analysis of cyst aspirates may be helpful especially when less than 0.5cc of fluid is available as this precludes many chemistry and tumor marker analyses. A recent meta-analysis noted that KRAS and GNAS mutations were more accurate for diagnosing mucinous cysts and IPMNs than CEA alone[50]. Other studies have noted high specificity > 90% for mucinous cysts and IPMNs but lower sensitivity (65%) with KRAS and GNAS[51]. Using both CEA and KRAS may be increase sensitivity to 83% for mucinous cysts but at the expense of specificity (85%)[52]. How useful DNA mutations are for identifying cysts with high-grade dysplasia or cancer remains to be determined with some preliminary studies of various DNA mutation panels suggesting high sensitivity and specificity[53,54]. Our study found the addition of DNA analysis consisting of KRAS, loss of heterozygosity, DNA quantity and quality did not improve upon the Sendai guideline in detecting malignant cysts[55].

Table 2 Cyst fluid studies

Cyst fluid test	Test characteristics	Diagnosis
String sign ≥ 1 cm, ≥ 1 s	95% specificity, 94% positive predictive value	Mucinous
Cyst fluid cytology	63% sensitivity	-
Cyst wall cytology	29% increased diagnostic yield	-
CEA > 192 ng/mL	75% sensitivity, 84% specificity	Mucinous
CEA < 5 ng/mL	50% sensitivity, 95% specificity	Serous cystadenoma, pseudocyst, cystic neuroendocrine tumor
Amylase < 250 U/L	44% sensitivity, 98% specificity	Excludes pseudocyst
Glucose < 50 mg/dL	89% sensitivity, 78% specificity	Mucinous
KRAS/*GNAS* mutation	89% sensitivity, 100% specificity	Mucinous

CEA: Carcinoembryonic antigen.

Needle-based confocal laser endomicroscopy and microbiopsy forceps

Newer tools during EUS that may improve diagnosis of pancreatic cysts include needle-based confocal laser endomicroscopy (nCLE) (Mauna Kea Technologies, Paris, France) and microbiopsy forceps (Steris, Mentor, OH, Figure 6). Both require passing the nCLE probe or microbiopsy forceps through a 19-gauge needle, which limits the size and location of cysts eligible for these techniques. EUS-nCLE allows real-time microscopic imaging of the cyst wall. Visualizing a superficial vascular network pattern is consistent with SCA with 56% to over 90% sensitivity and 100% specificity (Figure 7)[56,57]. Sensitivity for mucinous cysts ranges from 66% to over 90% with finger-like papilla consistent with IPMN (Figure 8) and epithelial bands seen in MCN [56,58]. The most common complication with nCLE is pancreatitis which ranges from 1.2% to 12%. Recommended techniques to minimize pancreatitis include preloading the nCLE probe in the FNA needle, nCLE duration less than 10 minutes and avoiding brushing the tip of the nCLE probe along the cyst wall.

A systematic review of 9 studies with 463 patients undergoing EUS with microbiopsy forceps reported 68.6% diagnostic accuracy with near 10% complications [59]. A death has been reported in Europe following this procedure as well as up to 4% severe complications[60]. Therefore, while nCLE and microbiopsy forceps are exciting tools that may improve diagnosis of pancreatic cysts, further studies are necessary to understand their safety profile as well as the optimal place these tools have amidst the currently available cyst fluid markers.

SURGICAL RESECTION

Surgery should be considered for patients with cysts that are symptomatic, malignant, or at high-risk for malignancy. Stratifying the malignant risk of a pancreatic cyst is simplest when the diagnosis of the cyst is known, but also possible for indeterminate cysts by assessing for risk features. Surgical resection is recommended for symptomatic SCAs only[20,26]. On the other hand, resection of MCNs should be considered for all patients or select higher risk patients with symptoms, nodule or size ≥ 4 cm[12,26]. Similarly, due to higher malignant risk of MD-IPMN and mixed type IPMNs, surgical resection is suggested for these lesions[12,26]. Resection is recommended for select BD-IPMN with a risk feature. Absolute indications for resection include main pancreatic duct ≥ 1 cm, enhancing nodule ≥ 5 mm, solid mass, jaundice, or cytology suspicious or positive for malignancy. Relative indications for resection of BD-IPMN include main pancreatic duct 5-9 mm, cyst ≥ 4 cm, enhancing nodule < 5 mm, growth rate ≥ 5 mm/year, serum CA 19-9 ≥ 37 U/mL, acute pancreatitis, or new onset diabetes. SPENs are considered premalignant with up to 15% incidence of local invasion or metastatic disease[39]. Given their malignant potential, favorable post-resection outcomes, and occurrence in mainly young women, referral for surgical resection is most appropriate[20,26].

The AGA guideline is the outlier by requiring the presence of at least 2 risk features before sending a patient to surgery. In the AGA technical review, 15% of all resected pancreatic cyst specimens had invasive malignancy while the rate of high-grade

Figure 6 Microbiopsy forceps through endoscopic ultrasound needle.

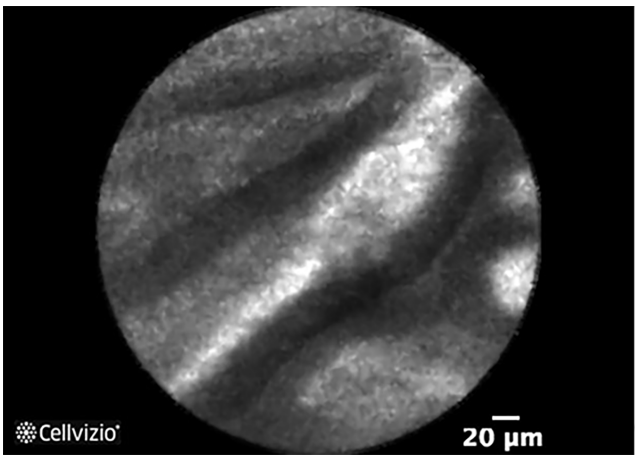

Figure 8 Papillary projections in intraductal papillary mucinous neoplasm. Courtesy of Mauna Kea Technologies.

dysplasia was not assessed[6]. Of surgically resected IPMNs, 25% had invasive malignancy and 42% had either high-grade dysplasia and/or invasive malignancy[6]. Whether resecting IPMN with low-grade dysplasia in 58% of cases is acceptable can be debated, but as a result, the AGA guideline increased the threshold for surgery to requiring 2 risk features (solid component, dilated main pancreatic duct, and/or concerning features on EUS-FNA) in the hopes of improving the positive predictive value for resecting pancreatic cysts[27]. However, this has not proven true from multiple studies including our experience[29]. A recent meta-analysis comparing the

Fukuoka and AGA guidelines reported they both had similarly modest sensitivity (67% and 59%, respectively) and specificity (64% and 77%, respectively) for detecting high-grade dysplasia and invasive cancer[61].

The AGA technical review identified the following as the greatest risk factors for malignancy in incidental pancreatic cysts: solid component [odds ratio (OR) 7.7], cyst size > 3 cm (OR 3), and dilated main pancreatic duct (MPD) (OR 2.4)[6]. One caveat is that the included studies used varying definitions for dilated main pancreatic duct ranging from ≥ 3mm to > 6 mm. Studies have suggested that the degree of main pancreatic duct dilation correlates with varying malignant potential with higher risk associated with duct > 7-8 mm[62,63]. Regarding cyst size, a study of 563 resected and radiologically diagnosed BD-IPMN noted that 18% of cysts > 3 cm had high-grade dysplasia or invasive cancer, while no malignancy was detected in cysts < 2 cm and no high-grade dysplasia was noted in lesions < 1 cm[64]. Larger cysts seem associated with development of high-risk features including nodule and main pancreatic duct dilation[16]. Assessment of cyst size and nodules may vary depending on the imaging modality. EUS may be more accurate than CT or MRI for cyst size measurements and for detecting nodules[35,65].

Careful surgical planning is important with MD-IPMN, and partial pancreatectomy is reasonable in cases with segmental dilation or diffuse dilation with focal lesions[12]. Resection should continue until the margins are negative for high-grade dysplasia and cancer. However, determining how much pancreas to resect in MD-IPMN with diffuse dilation without focal lesions can be challenging. ERCP with pancreatoscopy and/or intraductal ultrasound (IDUS) and EUS may help with surgical planning. Case series have suggested the utility of pancreatoscopy with or without IDUS in mapping IPMNs preoperatively leading to more or less extensive surgeries than previously planned in about 60% of patients[26,66,67]. Therefore, these tools may be used selectively to guide surgical planning. Regarding total pancreatectomy, some suggest this should be reserved for younger healthy patients who will tolerate brittle diabetes or exocrine insufficiency postoperatively while others advocate for this in all patients with diffuse main pancreatic duct dilation or those with family history of pancreatic cancer[12,26].

SURVEILLANCE

Patients with cysts at low risk for malignancy and following resection of certain cysts should undergo surveillance. MRI is preferred over CT for surveillance due to reduced radiation exposure and potentially improved ability to detect communication with the main pancreatic duct and nodules[20,26,28]. Recent reports of gadolinium deposition in the brain has raised concern over repeated injections of gadolinium during surveillance MRIs[68]. A few studies have suggested that MRI performed with *vs* without gadolinium did not change management decisions[69,70]. Non-contrast MRI scans have demonstrated similar efficacy to contrast-enhanced MRI in discerning benign from malignant disease[69]. Therefore, surveillance MRIs may be performed without gadolinium unless concerning findings are noted on the non-contrast MRI.

Surveillance is recommended at various intervals for unresected pancreatic cystic neoplasms depending on size and other criteria for different guidelines (Table 3)[12,20,26-28]. The surveillance interval may be lengthened if there are no concerning features or changes found on repeated testing[26,27]. If a cyst had been followed with imaging every 6 mo, this may be extended to every year while annual surveillance may be lengthened to biennial follow-up. Similarly, if new onset or worsening diabetes or concerning changes (risk features) develop on imaging, surveillance interval should be shortened and/or EUS performed and patient referred to a multidisciplinary pancreas center.

While the other gastroenterology guidelines suggest surveillance intervals based on cyst size and other factors without an explicit recommendation to stop surveillance except in surgically unfit patients, the AGA guideline endorses a simplified surveillance protocol of MRI in 1 year and then every 2 years for 5 years followed by stopping if the cyst remains stable without developing high risk features[27]. This is perhaps the most controversial aspect of the AGA guideline. Numerous long-term surveillance studies have been published following the release of the AGA guidelines, most of which noted low risk of malignancies developing after 5 years of surveillance. A Japanese study of 1404 patients with BD-IPMN excluding cysts with nodules or main pancreatic duct dilation > 1 cm noted gradually increasing incidence rates of cancer over time (3.3% at 5 years, 6.6% at 10 years and 15% at 15 years)[71]. Long-term surveillance of 1036 BD-IPMNs without worrisome or high-risk features in Italy found

1.1% developed cancer after median 62 mo follow-up[72]. Development of worrisome features or cyst size growth > 2.5 mm/year were associated with risk for cancer. Another study of 363 patients with BD-IPMN followed for over 5 years noted that cyst size > 1.5 cm was associated with higher risk of developing cancer (7.5% *vs* 0.9%)[73]. Therefore, surveillance should not be stopped for all patients after 5 years, and in fact, should continue for most patients except those who are no longer surgical candidates. As discussed earlier, various comorbidity scoring systems including the Charlson comorbidity index and Adult Comorbidity Evaluation 27 scoring system may serve as aides to identify patients at higher risk from their comorbidities than their pancreatic cyst[24,25]. These patients likely would not benefit from ongoing surveillance. The American College of Gastroenterology guideline also suggests individualizing surveillance in patients over 75 years old analogous to the United States Preventive Services Taskforce recommendations for colon cancer screening.

Following surgical resection of SCA or MCN without invasive features, surveillance is not necessary as resection is considered curative. This is because no recurrence of MCN without invasive cancer was noted in patients after nearly 5 years[74]. For higher risk IPMNs including high-grade dysplasia at the surgical margins, non-intestinal subtype, or family history of pancreatic cancer, the Fukuoka guideline recommends repeat imaging at least every 6 mo[12]. For other IPMNs, surveillance every 6-12 mo is suggested. Those with resected invasive cancer should continue surveillance as per patients with pancreatic ductal adenocarcinoma. The AGA guideline supports postoperative surveillance only following resection of high-grade dysplasia or invasive cancer with MRI every 2 years[27]. A concern with this recommendation is that early recurrences, especially in patients with invasive cancer, may be missed.

Unresolved questions remain regarding surveillance including the optimal surveillance interval and duration in unresected cysts.

CONCLUSION

While the various guidelines provide a foundation for managing pancreatic cysts, the approach to each patient with a pancreatic cyst should be individualized based on clinical status and comorbidities, risk of malignancy, and personal preferences. A good quality MRI of the pancreas may help identify malignant and mucinous cysts. If the diagnosis of the cyst remains uncertain or there are concerning features on imaging, EUS should be pursued although the ideal diagnostic markers and tools remain elusive. Surgical resection should be reserved for patients with high risk features including solid mass, nodule or dilated main pancreatic duct. The ongoing challenge with surgical referral remains accurately identifying signs predictive of malignancy that allow early surgery to improve long-term survival while sparing patients with low-risk cysts the morbidity and mortality of pancreatic surgery. High quality studies are necessary to discover better diagnostic markers and tools, to improve risk stratification of patients, and to understand the optimal interval and duration of

surveillance.

Abstract

Recently, increasing attention has been paid to the application of artificial intelligence (AI) to the diagnosis of diverse hepatic diseases, which comprises traditional machine learning and deep learning. Recent studies have shown the possible value of AI based data mining in predicting the incidence of hepatitis, classifying the different stages of hepatitis, diagnosing or screening for hepatitis, forecasting the progression of hepatitis, and predicting response to antiviral drugs in chronic hepatitis C patients. More importantly, AI based on radiology has been proven to be useful in predicting hepatitis and liver fibrosis as well as grading hepatocellular carcinoma (HCC) and differentiating it from benign liver tumors. It can predict the risk of vascular invasion of HCC, the risk of hepatic encephalopathy secondary to hepatitis B related cirrhosis, and the risk of liver failure after hepatectomy in HCC patients. In this review, we summarize the application of AI in hepatitis, and identify the challenges and future perspectives.

Core Tip: Currently, there is a need of a comprehensive review to introduce the applications of artificial intelligence (AI) in hepatitis. We first discuss the possible value of AI based data mining in predicting the incidence of hepatitis, classifying the different stages of hepatitis, diagnosing or screening for hepatitis, forecasting the progression of hepatitis, and predicting response to antiviral drugs in chronic hepatitis C patients. In addition, we introduce the applications of AI based on radiology in predicting hepatitis and liver fibrosis, grading hepatocellular carcinoma (HCC) and differentiating it from benign liver tumors, and predicting the risk of vascular invasion of HCC as well as the risk of hepatic encephalopathy secondary to hepatitis B related cirrhosis.

INTRODUCTION

Artificial intelligence (AI) is a new discipline that aims to simulate, extend, and expand human intelligence and integrates theory, method, and application research and development[1]. According to the different algorithms of AI, AI is usually divided into traditional AI (*e.g.*, traditional machine learning) and deep learning (based on neural network structure) in the medical field[2]. Compared with traditional AI, deep learning can directly apply the image to the learning process without manual feature extraction, while traditional machine learning needs manual recognition and extraction of different features. Therefore, deep learning has the advantage of no manual extraction of various features, which makes its learning process faster, intelligent, and accurate. In addition, deep learning can iterate and improve from past mistakes, but it needs more big data and more result analysis to fully show its robust and precise efficiency[3].

Lately, AI technology has been at the forefront of scientific research. The benefits of the AI model in various fields have triggered an upsurge in the use of this technology for data mining and analysis in more areas, and it has also attracted attention in the field of medicine and biological cognition[4]. For instance, AI has been widely used in the examination of superficial glands such as the thyroid and breast to assist radiologists to evaluate whether nodules are benign or malignant, with a high level of accuracy. The accuracy is lower than that of senior radiologists but higher than that of junior radiologists[5-7]. Some literature has reported the application of AI technology based on data mining or radiology in predicting hepatitis, evaluating fibrosis, and diagnosing benign and malignant liver masses[8-10].

This systematic review is intended to ascertain the clinical utility in routine practice of AI based on data mining, predict the incidence of hepatitis A, B, C, or E, categorize the different stages of hepatitis B, predict the progression of hepatitis C in veterans, and diagnose or screen for hepatitis B. Particularly, this review focuses on the application of deep learning or radiomics based on radiology to stage hepatic fibrosis, predict the occurrence of HCC, identify microvascular invasion, and predict the risk of liver failure after hepatectomy in HCC patients.

HEPATITIS DETECTION BASED ON DATA MINING

Predicting incidence of hepatitis

Newborn babies are required to be vaccinated with hepatitis B vaccine in numerous countries, which has reduced the incidence of hepatitis worldwide. However, viral hepatitis is still a serious health problem[11]. Hence, Guan *et al*[12] designed the AI model of artificial neural network (ANN) and autoregressive integrated moving average (ARIMA) with hepatitis data mined from Liaoning Disease Control and Prevention Center, which aimed to forecast the incidence of hepatitis A. They extracted data concerning the incidence of hepatitis A from 1987 to 2001 in the above-mentioned Disease Control and Prevention Center. The incidence of hepatitis A from

1981 to 1997 was taken as the training group and from 1998 to 2001 as the validation group. The forecasting statistical effect value and the correlation coefficient are summarized in Table 1. Intelligently mining hepatitis B-related medical record data from local health websites authorized by the local Health Commission, the AI model of ARIMA (0, 1, 1) and ElmanNN (Elman neural network) with eight neurons were established by Zheng *et al*[13]. From January 2012 to August 2019, the local health bureau reported 486983 cases of hepatitis B. Hepatitis B incidence from January 2012 to December 2018 was used to build and train ARIMA (0, 1, 1) model and ElmanNN model with eight neurons, and hepatitis B incidence from January 2019 to August 2019 was used to validate ARIMA (0, 1, 1) model and ElmanNN with eight neurons, with root-mean-square error (RMSE) and mean absolute error (MAE) applied to evaluate the prediction effect of the model. The RMSE and MAE of the above-mentioned ARIMA (0, 1, 1) model and ElmanNN with eight neurons are shown in Table 1. Gan *et al*[14] also tried to forecast the incidence of hepatitis B using a hybrid model combing Grey system and BP-ANN (back propagation artificial neural networks), with trained and validated data collected from National Health Commission. From 2003 to 2012, 10486959 cases of hepatitis B were reported by National Health Commission. Compared with the above data, the prediction effect of a hybrid model, Grey model (1, 1) and Grey model (2, 1), was calculated. The predictive results are summarized in Table 1. The results showed that the hybrid algorithm was superior to the Grey model algorithm in all assessment norms, and a better prediction effect was achieved. Intending to predict the incidence of hepatitis E, Guo *et al*[15] mined monthly incidence and cases of hepatitis E from the local Center for Disease Control and Prevention as samples. All above-mentioned data were collected from January 2005 to December 2017 in the local Centers for Disease Control. The monthly incidence and cases from January 2005 to June 2015 were used as the input variable to establish an AI model of the ARIMA, supporter vector machine (SVM), and long-short time memory neural network (LSTM), and those from July 2015 to December 2017 as the validating group. The assessment indexes of the ARIMA, SVM, and LSTM models were RMSE and MAE, whose corresponding values are given in Table 1.

Classifying different stages of hepatitis

According to the serological level of transaminase and serological titer of hepatitis B antigen or antibody, hepatitis B can be categorized into five stages: I, HBeAg (+) chronic infection; II, HBeAg (+) chronic hepatitis; III, HBeAg (-) chronic infection; IV, HBeAg (-) chronic hepatitis; V, HBsAg (-) stage. For young doctors, it can be difficult to accurately classify the clinical types of hepatitis. Therefore, with 52 patients included, an automated diagnosis of hepatitis B using multilayer mamdani fuzzy inference system expert system (ADHB-ML-MFIS) was established by Ahmad *et al*[16] to categorize the different stages of hepatitis B. In the ADHB-ML-MFIS expert system, there were two levels of input variables. The input variables of the first layer were transaminase, and the input variables of the second layer were serological markers of hepatitis B. The diagnostic accuracy of the ADHB-ML-MFIS expert system for differentiating stages of hepatitis B was 92.2% with the detailed results shown in Table 1.

Diagnosing or screening for hepatitis

Raman spectroscopy has been used to diagnose hepatitis B, showing a superior performance compared to traditional serological tests. Obtaining 119 confirmed hepatitis B virus (HBV) infected samples from histopathology department, Khan *et al*[8] combined Raman spectroscopy with pattern recognition technology, and established an AI model based on the SVM algorithm and radial basis function to diagnose hepatitis B. In the study, the AI model achieved high diagnostic performance for hepatitis B, with the data presented in Table 1. Collecting data from 1134 blood samples, Wang *et al*[17] proposed a method for promptly screening hepatitis B patients and non-hepatitis B patients using serum Raman spectroscopy combined with LSTM. Then, LSTM was used to train the spectral data. Several models can distinguish hepatitis B from non-hepatitis B, with the highest diagnostic efficacy acquired by serum Raman spectroscopy combined with LSTM. The accuracy of serum Raman spectroscopy combined with LSTM for screening hepatitis B from non-hepatitis B was 0.9732. About 50% of hepatitis C virus (HCV) infected persons worldwide have not been diagnosed or treated, and it remains a significant risk factor for human health [18]. Thus, it is vital that clinicians could find these undiagnosed patients with hepatitis C infection, a nowadays-treatable disease. With 120023 HCV patients and 9601900 non-HCV patients used as modeling data, Doyle *et al*[19]developed five kinds of AI models attempting to find undiagnosed hepatitis C infection: Logistic regression, gradient boosting trees, gradient boosting trees with temporal variables, stacked

Table 1 Hepatitis detection based on data mining

No.	Task	Algorithms	Sample size (type)	Evaluation index	Ref.
1	Predicting incidence of hepatitis A	ANN; ARIMA	N/A (CDC data)	ANN: Correlation coefficient 0.71; ARIMA: Correlation coefficient 0.66	[12]
2	Predicting incidence of hepatitis B	ARIMA; ElmanNN	486983 cases (data from health commission)	ARIMA: RMSE 0.94, MAE 0.81; ElmanNN: RMSE 0.89, MAE 0.70	[13]
3	Forecasting incidence of hepatitis B	Hybrid method (combing GM and BP-ANN)	10486959 cases (data from health ministry)	R 0.9495, RMSE 4.863 × 10^3, MAE 3.9704 × 10^4	[14]
4	Prediction of incidence of hepatitis E	ARIMA; SVM; LSTM	N/A (CDC data)	ARIMA: RMSE 0.022, MAE 0.018; SVM: RMSE 0.0204, MAE 0.0167; LSTM: RMSE 0.01, MAE 0.011	[15]
5	Automated classification of the different stages of hepatitis B	ADHB-ML-MFIS expert system	52 patients (serological data)	Overall accuracy: 0.922; No hepatitis accuracy: 1; Due to infection accuracy: 0.75; Acute HBV accuracy: 0.95; Chronic HBV accuracy: 0.91	[16]
6	Analyzing HBV infection from normal blood samples	Polynomial function; RBF	119 serum samples from HBV infected patients (Raman spectroscopy data)	Polynomial kernel (order-2): Quadratic programming/least squares: Accuracy 98%, precision 97%, sensitivity 100%, specificity 95%; RBF kernel (RBF sigma-2): Quadratic programming: accuracy 94%, precision 90%, sensitivity 100%, specificity 87%; RBF kernel (RBF sigma-2): Least squares: Accuracy 95%, precision 92%, sensitivity 100%, specificity 90%	[8]
7	Rapidly screening hepatitis B from non-hepatitis B	LSTM	1134 blood samples (Raman spectroscopy data)	Accuracy 97.32%, sensitivity 97.87%, specificity 96.77%, precision 96.84%	[17]
8	Finding undiagnosed patients with hepatitis C infection	Logistic regression; Gradient boosting trees; Gradient boosting trees with temporal variables; Stacked ensemble; Random forest	9721923 patients (data from the patient's medical history)	The stacked ensemble had a specificity of 0.99 and precision of 0.97 at a recall level of 0.50	[19]
9	Predicting hepatitis C virus progression among veterans	CS Cox modellongitudinal Cox model; CS boosting modelLongitudinal-boosting model	72683 CHC individuals (VHA data)	CS Cox model: Concordance 0.746; Longitudinal Cox model: Concordance 0.764; CS boosting model: Concordance 0.758; Longitudinal-boosting model: Concordance 0.774	[20]
10	Forecasting response to IFN plus RIB treatment in HCV patients	ANN	300 patients (serological data)	The diagnostic accuracy rose from 52% (ANN 2) to 70% (ANN 6)	[21]

ANN: Artificial neural network; ARIMA: Autoregressive integrated moving average; CDC: Centers for Disease Control; RMSE: Root-mean-square error; MAE: Mean absolute error; GM: Grey model, BP-ANN: Back propagation artificial neural networks; SVM: Supporter vector machine; LSTM: Long-short time memory neural network; ADHB-ML-MFIS: Automated diagnosis of hepatitis B using multilayer Mamdani fuzzy inference; HBV: Hepatitis B virus; RBF: Gaussian radial basic function; CHC: Chronic hepatitis C virus; VHA: National Veterans Health Administration; IFN: Interferon; RIB: Ribavirin, HCV: Hepatitis C virus.

ensemble, and random forest. All these models mined data from demographics, risk factors, symptoms, treatments, and procedures relevant to HCV from the patient's medical history. At different recall levels, the models had different diagnostic performances. For example, the stacked ensemble had a specificity of 0.99 and precision of 0.97 at a recall level of 0.50.

Forecasting progression of hepatitis

Liver biopsy is the gold standard for the evaluation of liver fibrosis and cirrhosis. However, liver biopsy is an invasive examination and carries the risk of causing liver bleeding. In clinical practice, aspartate aminotransferase-to-platelet ratio index (APRI) and radiology are often used to forecast hepatic fibrosis and cirrhosis. In Konerman *et al*[20]'s study, aiming to predict HCV progression among veterans, they developed the cross-sectional (CS) Cox model, longitudinal Cox model, CS boosting model, and longitudinal-boosting model with 72683 chronic hepatitis C (CHC) individuals and matched control data searched from National Veterans Health Administration between 2000 and 2016. The calculated value of APRI > 2 after time zero for two consecutive times indicated the progression of liver cirrhosis. The predictive

concordance of the above-mentioned four models is given in Table 1.

Predicting response to antiviral drugs in CHC patients

The combined administration of interferon-alpha (IFN) and ribavirin (RIB) is the first-line recommended treatment regimen for patients with CHC. However, the cure rate is still low and the incidence of side effects is high. Therefore, there is an urgent need for doctors in the hepatology or infection departments to evaluate the response of patients with CHC to the combinative administration of IFN and RIB. Hence, Maiellaro *et al*[21] retrospectively analyzed 300 patients treated with IFN plus RIB through an ANN, intending to predict the response to the treatment. The range of positive predictive value and negative predictive value of the ANN model for predicting the treatment response of patients with CHC to the combined administration of IFN and RIB was 57%-75% and 52%-71%, respectively.

HEPATITIS EVALUATION BASED ON RADIOLOGY

Radiology plays an important role in evaluating a range of hepatic diseases, such as hepatitis, hepatic fibrosis, HCC, vascular invasion of liver cancer, and even HE. With the rapid development of computer technology and AI, radiomics and deep learning have become hot topics in the field of medical imaging. Compared with traditional AI, deep learning is a more advanced and intelligent learning algorithm, which was based on a neural network structure inspired by the human brain[22,23]. Radiomics has also been developed recently. It can adopt a variety of methods to extract numerous quantitative features from ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) images, then select the quantitative features related to the task, finally providing clinicians with a model based on radiomics to evaluate diagnostic and prognostic information[24,25].

Predicting clinical severity in alcohol-associated hepatitis patients

Tana *et al*[26] included 34 patients with alcohol-associated hepatitis (AAH) and 35 control subjects in their study to extract texture features from computed tomography images based on random forest and deep learning convolutional neural network algorithms, which evaluated the diagnostic value of CT texture analysis for clinical severity (most notably aspartate aminotransferase) in AAH patients. Recursive feature elimination using random forest identified 23 top features for AAH categorizing, and the accuracy of deep learning for diagnosing AAH was 70% in the validation set.

Diagnosing or grading liver fibrosis

According to the METAVIR scoring system[27], hepatic fibrosis can be divided into five categories: F0, no fibrosis; F1, portal fibrosis without septa; F2, portal fibrosis and few septa; F3, numerous septa without cirrhosis; F4, cirrhosis. Significant fibrosis is defined as ≥ F2. Based on radiomics or deep learning algorithms, multifarious imaging modalities have been applied to diagnose or stage liver fibrosis, such as ultrasound, contrast or non-contrast CT, CT texture, MRI, or gadoxetic acid–enhanced hepato-biliary phase MR.

A study including 144 HBV infected patients, evaluated the performance of multiparametric ultrasomics for the diagnosis of significant hepatic fibrosis[9]. Conventional ultrasomics, original radiofrequency, and contrast-enhanced micro-flow features comprise the multiparametric ultrasomics for clinicians to diagnose diseases and monitor treatment regimens. Multiparametric ultrasomics used Adaboost, random forest, and SVM algorithms for predicting significant liver fibrosis, with results summarized in Table 2. With 466 patients (401 with chronic hepatitis B, 65 without fibrosis) undergoing partial hepatectomy used as the data of the training group and test group of transfer learning (TL) radiomics, Xue *et al*[28] discussed the diagnostic value of transfer learning radiomics based on multimodal ultrasound in the grading of liver fibrosis. As the name suggests, TL moves a network trained on a large data set on to other related tasks, thus avoiding the over fitting problem caused by insufficient training data in conventional deep learning. Results showed that the area under the curve (AUC) of TL was statistically higher than that of non-TL, and the AUC of multimodal ultrasound imaging was larger than that of single modality ultrasound imaging. Hence, multimodal ultrasound imaging based on TL could usefully be applied to the staging of liver fibrosis.

Table 2 Hepatitis or hepatitis associated lesion detection based on radiology

No.	Task	Algorithms (model)	Sample size (type)	Evaluation index	Ref.
1	Predicting clinical severity in AAH patients	Random forest; Convolutional neural network	69 cases (CT texture features)	Accuracy: 82.4% of RFE-RF in the test set; Accuracy: 70% of CNN in the test set	[26]
2	Assessing significant liver fibrosis by multiparametric ultrasomics data	Adaboost; Random forest; SVM (multiparametric ultrasomics)	144 HBV infected patients (multiparametric ultrasomics)	AUROC: 0.85 ± 0.01 of Adaboost, random forest, SVM in multiparametric ultrasomics including conventional ultrasomics, ORF and CEMF	[9]
3	Grading liver fibrosis	Inception-V3 network (transfer learning)	466 patients (multimodal ultrasound)	AUCs of TL in GM + EM reached 0.950, 0.932, and 0.930, respectively, for grading S4, ≥ S3, and ≥ S2an	[28]
4	Predicting cirrhosis	LASSO (radiomics nomogram)	144 cases of HBV patients (CT features and clinical factors)	AUROC: 0.915 in the training cohort, 0.872 in the validation cohort, overall correctly classified rate of 82.0%	[29]
5	Differentiating hepatic fibrosis' grade	RFC (CTTA-based models); SVM (CTTA-based models)	30 fibrosis patients (CT texture features)	Train AUC 0.95 in RFC (model 1); Test AUC 0.90 in RFC (model 1); Train AUC 0.88 in SVM (model 2); Test AUC 0.76 in SVM (model 2)	[30]
6	Assessing liver fibrosis severity	A prototype convolutional neural network	558 cases (CT images)	AUCs were 0.82, 0.85, and 0.88 of Vol_L/Vol_S in diagnosing advanced fibrosis, cirrhosis, and decompensated cirrhosis in the whole study population	[31]
7	Staging liver fibrosis	Convolutional neural network	634 fibrosis patients (MR images and MR/virus)	AUCs were 0.84, 0.84, and 0.85 of the model full for diagnosing F4, ≥ F3, and ≥ F2 in the test set, respectively	[34]
8	Assessing liver fibrosis in chronic hepatitis B	Convolution neural network (DLRE)	398 HBV patients (shear wave elastography)	AUCs of DLRE 1.00, 0.99, and 0.99 for classifying F4, ≥ F3, and ≥ F2 in the training set and 0.97, 0.98, and 0.85 in the validation set	[35]
9	Diagnosing FNH from HCC in the non-cirrhotic liver	LASSO (radiomics nomogram)	156 patients (CT images and clinical factors)	Accuracy: 92.4% in the training set, 89.2% in the validation set	[38]
10	Diagnosing HCC	LASSO (radiomics signature)	211 patients (MR images)	AUROC: 0.861 in the training set, 0.810 in the validation set	[39]
11	Preoperative prediction of HCC grade	LASSO (combined model with clinical factors and radiomics signature)	170 HCC patients (MR images and clinical factors)	AUROC: 0.742, 0.786, and 0.800 based on T1WI images, T2WI images, and combined T1WI and T2WI images in the combined model	[41]
12	Predicting MVI risk in HBV-related HCC preoperatively	LASSO (radiomics nomogram)	304 HCC patients (CT images and AFP)	AUROC: 0.846 in the training set, 0.844 in the validation set	[43]
13	Preoperative prediction of MVI in HCC patients	LASSO (combined model)	157 HCC patients (CT images and clinical factors)	AUROC: 0.835 in the training dataset, 0.801 in the validation dataset	[44]
14	Predicting risk of HE complicated by hepatitis B related cirrhosis	LASSO (integrated model of radiomics and clinical features)	304 cirrhosis patients (CT images and clinical factors)	Accuracy: 0.93 in the training cohort, 0.83 in the testing cohort	[45]
15	Predicting liver failure in cirrhotic patients with HCC after major hepatectomy	LASSO (integrated radiomics-based mode)	101 HCC patients (MR images and clinical factors)	Accuracy: 0.802 in radiomics-based model	[47]

AAH: Alcohol-associated hepatitis; CT: Computed tomography; RFE-RF: Recursive feature elimination using random forest; CNN: Convolutional neural network; SVM: Supporter vector machine; HBV: Hepatitis B virus; AUROC: Area under the receiver operating curve; ORF: Original radiofrequency; CEMF: Contrast-enhanced micro-flow; AUC: Area under curve; TL: Transfer learning; GM: Gray scale modality; EM: Elastogram modality; LASSO: Least absolute shrinkage and selection operator; RFC: Random forest classifier; CTTA: Computed tomography texture analysis; VolL: Liver volume; VolS: Spleen volume; MR: Magnetic resonance; DLRE: Deep learning radiomics of shear wave elastography; FNH: Focal nodular hyperplasia; HCC: Hepatocellular carcinoma; MVI: Microvascular invasion; AFP: Alpha-fetoprotein; HE: Hepatic encephalopathy.

In another study, Wang *et al*[29] included 144 HBV patients with hepatic fibrosis

confirmed by liver biopsy who underwent unenhanced CT examinations in their study and successfully extracted 25 cirrhosis-related CT features to construct a radiomics signature using the SVM algorithm. In addition to the CT features that were closely related to liver cirrhosis, the specific clinical factors (alanine transaminase, aspartate aminotransferase, globulin, and international normalized ratio) were also closely related to liver cirrhosis. Combining the radiomics signature and clinical factors, a radiomics-based nomogram was established, and the results demonstrated that the area under the receiver operating curve (AUROC) of the radiomics nomogram was 0.915 and 0.872 in the training and validation cohorts, respectively. CT texture analysis (CTTA) revealed the biological and pathological features of diverse liver diseases by analyzing the characteristics and distribution of pixels in medical images, and extracted texture features that were difficult to recognize by the naked eye. To explore the diagnostic value of CTTA in low- and high-grade hepatic fibrosis, Budai *et al*[30] included 30 patients with liver fibrosis in the study. They extracted 354 CT texture features and constructed a CTTA-based model using a random forest classifier (RFC) algorithm and SVM algorithm, respectively. The AUROC of the CTTA-based model based on the RFC algorithm in predicting fibrosis grade was 0.90 in both the first and second analyses. The AUC of the CTTA-based model using the SVM algorithm in predicting liver fibrosis in analysis I was 0.76, and 0.91 in analysis II that was the highest prediction rate. Son *et al*[31] also evaluated liver fibrosis severity using splenic volume (measured on portal venous phase CT images). They proposed a convolution neural network (CNN) based on a three-dimensional U-net, with 513 chronic liver disease patients and 45 healthy liver subjects taken as modeled data, dividing the liver and spleen into many segments. By using the calculus method, the volume of hepatic and splenic segments in each thin slice was first calculated, then the volume of the liver and spleen in each thin slice was calculated, and finally, the volume of the liver and spleen amounted to the volume of the liver and spleen in each thin slice multiplied by the thickness of each thin slice. Then, they evaluated the correlation between liver and spleen volume indexes [Vol_S (spleen volume), Vol_L (liver volume), and Vol_S/Vol_L] and liver fibrosis severity and their diagnostic value in liver fibrosis severity. The results demonstrated that the AUCs were 0.82, 0.85, and 0.88 of Vol_L/Vol_S for the diagnosis of advanced fibrosis, cirrhosis, and decompensated cirrhosis in the entire study population, which outperformed the Vol_L.

A variety of methods have been used to detect the stage of liver fibrosis, such as serological markers and elasticity scores based on ultrasound[32,33]. Yasaka *et al*[34] specifically included 534 patients with hepatic fibrosis into training datasets and 100 fibrosis patients into test sets, analyzing the diagnostic value of deep CNN using gadoxetic acid-enhanced hepatobiliary phase MR images and MR/virus model for liver fibrosis. The results showed that AUCs were 0.84, 0.84, and 0.85 of the model full (combined MR images and MR/virus model) for diagnosing F4, ≥ F3, and ≥ F2 in test sets, respectively, while 0.81, 0.84, and 0.83 of MR/virus model for diagnosing F4, ≥ F3, and ≥ F2 in test sets.

Previous studies have been limited to single-center studies to explore the diagnostic value of ultrasound, CT, or MRI images-based radiomics or deep learning model for liver fibrosis. Wang *et al*[35] subsequently carried out a prospective multicenter study based on deep learning radiomics of shear wave elastography (DLRE) to assess the diagnostic performance for evaluating liver fibrosis in chronic hepatitis B, and compare it with 2D-SWE (shear wave elastography) and serological biomarkers [APRI and fibrosis index based on four factors (FIB-4)]. A total of 398 patients from 12 hospitals in China with 1990 2D-SWE images were included in the study, and a DLRE model was established using the CNN algorithm. The results showed that the AUCs of DLRE were 0.97, 0.98, 0.85 for classifying F4, ≥ F3, and ≥ F2 in the validation set, which statistically outperformed 2D-SWE and serological biomarkers (APRI and FIB-4) except 2D-SWE in ≥ F2. Simplified structural flowchart of convolutional neural network architecture for staging liver fibrosis can be seen in Figure 1.

Diagnosing HCC

Typical focal nodular hyperplasia (FNH) has central cicatricial foci, which is enhanced in the arterial phase (AP), and the enhancement degree gradually decreases to low density in the portal venous phase (PVP). Atypical FNH has no central cicatricial foci and shows low perfusion, even hemorrhage, necrosis, and calcification on enhanced CT, which makes it difficult to differentiate atypical FNH from HCC[36,37]. Hence, Nie *et al*[38] aimed to establish a radiomics nomogram model based on CT for differentiating FNH from HCC. A total of 156 patients with FNH and HCC were divided into a training group and test group of the above-mentioned radiomics nomogram model. Initially, 4227 radiomics features were extracted from the regions of interest (ROIs) on

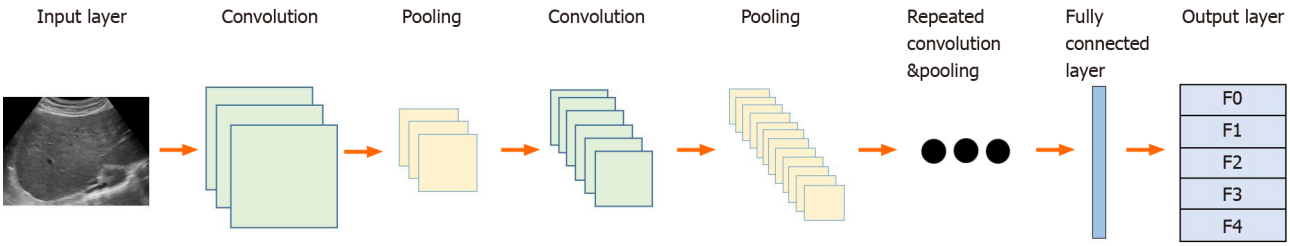

Figure 1 Simplified structural flowchart of convolutional neural network architecture for staging liver fibrosis. After repeatedly convoluting and pooling the input layer images, the extracted high-dimensional manageable features are fed into the fully connected layer and the classification task is performed by expressing the class probabilities through the output layer.

hepatic CT scan. After selection for inter- and intra-class correlation coefficients (ICCs) > 0.75 and statistical difference between the two groups, 764 radiomics features were entered into least absolute shrinkage and selection operator (LASSO) regression, and finally, ten features were used for the construction of a radiomics signature. After multivariate logistic regression calculation, old age, HBV infection, and early enhancement (with a washout pattern) were used to establish the clinical factors model. Three models were then established: Radiomics signature model, clinical factors model, and radiomics nomogram model (clinical factors and radiomics signature combined). The predictive performance of the radiomics nomogram model was superior to those of the other constructed models. The accuracy of the radiomics nomogram model for diagnosing HCC was 92.4% and 89.2% in the training and validation datasets, respectively.

To confirm the value of the AI model for predicting HCC, Jiang *et al*[39] implemented a prospective study to compare the diagnostic differences of the 2018 European Association for the Study of the Liver (EASL) criteria, Liver Imaging Reporting and Data System (LI-RADS) criteria, and a radiomics signature model for diagnosing HCC. They included 211 patients with surgically confirmed focal liver lesions (165 HCC patients, 30 non-HCC malignancies patients, and 16 non-HCC benign lesions patients) who were randomly divided into a training cohort (n = 133) and a validation cohort (n = 78). The results demonstrated that the AUROCs of HCC risk in all nodules calculated by EASL v2018 criteria, LR5/LR5V in LI-RADS v2018 criteria, and radiomics signature model were 0.811, 0.841, and 0.810, respectively. The benignity and malignancy of liver tumors are usually based on Edmondson grade. Generally speaking, low-grade liver tumors conform to Edmondson I/II, while high-grade liver tumors conform to Edmondson III/IV[40]. Wu *et al*[41] included 125 HCC patients in the training group and 45 HCC patients in the validation group to predict the grade of HCC patients based on unenhanced MRI radiomics. The MRI image was uploaded to ITK-SNAP software, and the ROI was depicted along the edge of the tumor on each TIWI and T2WI segment with radiomics features extracted from ROI. A total of 656 radiomics features were extracted. After LASSO regression selection, 14, 18, and 20 features were selected based on T1WI, T2WI, and combined T1WI and T2WI, respectively. Finally, the combined model was established with results summarized in Table 2.

Predicting microvascular invasion of HCC

The occurrence of microvascular invasion (MVI) often reduces the 5-year survival rate of HCC patients, which is closely related to the poor prognosis of HCC patients[42]. Peng *et al*[43] randomly assigned 304 cases of eligible HCC patients to the training group and validation group. IBEX software was used to extract radiomics features from the ROI of enhanced CT images in each of the HCC patients. In this study, 980 candidate radiomics features were generated from each patient, and after screening by LASSO with λ chosen smallest cross-validation error, eight radiomics features were selected to establish the radiomics signature. Radiomics signature, together with radiologic features (non-smooth tumor margin, internal arteries, and hypoattenuating halos) and alpha-fetoprotein > 20 ng/mL, was used to construct the radiomics nomogram, whose AUROC values for predicting MVI status were 0.846 and 0.844 in the training and validation sets, respectively. Ma *et al*[44] also discussed the value of preoperative radiomics nomogram for diagnosing MVI in HCC patients based on enhanced CT; 110 HCC patients were randomly assigned to the training cohort (MVI+ group 37 cases, MVI-group 73 cases), and 47 HCC patients to the validation cohort (MVI+ group 18 cases, MVI-group 29 cases). The ROI was drawn by an experienced

radiologist using ITK-SNAP software in AP, PVP, and delayed phase (DP) images on CT along the visible borders of the lesion. Initially, in the AP, PVP, and DP images, 647 radiomics features were extracted. After screening by ICC and concordance correlation coefficient ≥ 0.75 and LASSO method, finally, five AP features, seven PVP features, and nine DP features were selected. In predicting HCC invasion of MVI, PVP and radiomics signature outperformed AP and DP, hence, the PVP radiomics signature with the effective clinical factors constituted the combined model, whose AUCs were 0.835 and 0.801 in the training and validation groups, respectively for diagnosing MVI status in HCC.

Predicting HE secondary to hepatitis B related cirrhosis

Decompensated liver cirrhosis is often accompanied by multiple complications, of which HE is the most serious complication. Therefore, it is worthwhile to try to predict hepatic fibrosis patients who are susceptible to HE to provide early prevention and treatment[45]. A total of 304 cases of first-diagnosed hepatitis B-related cirrhosis were included in their study, 212 cases in the training group (HE = 38, non-HE = 174) and 92 cases in the validation group (HE = 21, non-HE = 71). Initially, 356 radiomics features were picked from the ROI of a patient's liver enhanced CT. After three times selection, 19 radiomics features were applied to construct a radiomics model. Three clinical factors related to HE, including serum albumin, ascites, and collateral circulation, were used to establish a clinical factor model. The results showed that, in the training and validation cohorts, the model combining radiomics and clinical features had an accuracy rate of 0.93 and 0.83 in predicting the risk of HE complicated by hepatitis B cirrhosis, respectively, while the corresponding values were 0.89 and 0.84 for radiomics model, and 0.83 and 0.77 for the clinical model.

Predicting liver failure in cirrhotic patients with HCC after major hepatectomy

Postoperative hepatic failure is the most serious complication in HCC patients after hepatectomy, which not only prolongs the hospitalization time of patients but also increases the mortality of patients[46]. Zhu *et al*[47] included 101 eligible HCC patients who had a major liver resection, to use preoperative gadoxetic acid-enhanced MRI for predicting liver failure based on the radiomics model. Removing the necessary structures, on the hepatobiliary phase image of the above-mentioned patient, experienced radiologists drew ROIs of the liver along the edge of the whole hepatic parenchyma. Through screening for ICC > 0.75 and LASSO regression, five features were employed to establish a radiomics signature. Then, the radiomics signature and ICG-R15 (a variable in the clinical factors model) were incorporated to establish a radiomics-based model. The results showed that the accuracy of the radiomics-based model in predicting postoperative liver failure was 0.802.

CONCLUSION

AI can mine data from patients' medical records, the Centers for Disease Control and Prevention in countries or regions, and serological markers. Raman spectroscopy can predict the incidence of hepatitis, classify the different stages of hepatitis, diagnose or screen hepatitis, forecast the progression of hepatitis, and predict response to antiviral drugs in CHC patients with a high level of diagnostic performance. AI, especially deep learning or radiomics, can predict hepatitis, predict liver fibrosis and its grade, differentiate HCC from the benign liver tumor, predict the risk of vascular invasion of HCC, predict the risk of HE complicated by hepatitis B related cirrhosis, and predict the risk of liver failure after hepatectomy in HCC patients, with good levels of accuracy.

Limitations and future perspectives

At present, all reviewed studies using AI are mostly single-center research, and the amount of data in the training sets may be insufficient. In the future, people should build an internet database or hospital, and disease-related information from various countries or regions could be uploaded to the internet database or hospital so that AI researchers can obtain more disease-related information with different demographics, geographic areas, *etc*., to carry out multicenter research, and establish a more robust and inclusive AI model for clinical use.

Abstract

The realm of extended criteria liver transplantation created the 'adjacent possible' for dynamic organ preservation. Machine perfusion of the liver greatly expanded donor organ preservation possibilities, reaching before unattainable goals, including the mitigation of ischemia-reperfusion injury, viability assessment, and organ reconditioning prior to transplantation. However, current scientific evidence lacks uniformity between studies, perfusion protocols, and acceptance criteria. Construction of collaborative research networks for sharing knowledge should, therefore, enable the development of high-level evidence and guidelines for machine perfusion utilization, including donor acceptance criteria. Finally, this approach shall guarantee conditions for further progress to occur.

static cold storage for these high-risk donors. However, controversy still exists between different machine perfusion modalities and even amongst studies employing the same method, compromising the strength of the available evidence. With the currently fragmented efforts, the development of collaborative networks will produce collective outcomes that will expand the boundaries of current knowledge.

INTRODUCTION

Previously disregarded and surpassed by the simplicity of static cold storage (SCS), dynamic organ preservation found the 'adjacent possible' in the realm of extended criteria donors (ECD) liver transplantation. Over the last few years, the liver transplantation community has experienced a surge in studies investigating the safety and efficacy of dynamic preservation[1-5]. This event is mainly a consequence of the increased use of ECD organs in order to attend to the growing demand for donor livers. The use of these high-risk organs exposed the limitations of SCS and posed a threat to recipients due to the risk of early allograft dysfunction and even primary non-function; thus, they are often discarded[6,7]. Therefore, at present, ECD liver transplantation has given the possibility to revisit and develop further machine perfusion techniques, previously hindered by the lack of appropriate conditions (*e.g.*, complexity, specific perfusates, and devices, costs). Figure 1 illustrates the evolution of conditions favouring the renewed interest in machine perfusion of the liver (MPL).

DYNAMIC ORGAN PRESERVATION AND ISCHAEMIA-REPERFUSION INJURY MITIGATION

The keystone of dynamic organ preservation is the mitigation of ischemia-reperfusion injury (IRI). IRI is responsible for the inflammatory-mediated tissue injury involved in transplantation and is ultimately associated with adverse results, such as early allograft dysfunction and primary non-function[8]. Dynamic preservation is characterized by a continuous flow of an oxygenated solution, preventing ischemic damage to the cells. In addition, the continuous flow of the perfusate provides nutrients and removes toxic metabolic waste products[7].

Diverse techniques of MPL are currently under research, while a few are currently clinically implemented. These include the *ex-situ* (normothermic, hypothermic, subnormothermic, controlled oxygenated rewarming), the *in-situ* modalities (normothermic regional perfusion, NRP), and the ischemia-free organ transplantation [2-4,6,9-12]. Furthermore, combinations of techniques have more recently gained the attention of the transplant community (*e.g.*, cold-to-warm, hypothermic plus normothermic, NRP plus hypothermic or normothermic *ex-situ* perfusion)[13-18]. Also, *ex-situ* normothermic machine perfusion (NMP) can be performed in a preservation approach during organ transportation or in an end-ischemic method, whereby the organ will be perfused after arrival at the transplant centre[7]. Hypothermic machine perfusion (HMP) can be done using an oxygen pre-charged perfusate or an actively oxygenated perfusate — with perfusion *via* portal vein exclusively (hypothermic oxygenated perfusion, HOPE) or in association with the hepatic artery (dual HOPE, D-HOPE)[3,5]. Although HMP is currently used in an end-ischemic approach, a device for hypothermic perfusion during organ transportation is under clinical investigation in the United States (clinical trials.gov, NCT number 03484455).

Albeit all these techniques hold the potential to benefit ECD livers, clearly controversy exists about the best strategy. Currently, the two most studied modalities are NMP and HMP. Both can be performed *ex-situ* in an end-ischemic approach for organs from donors after brain death (DBD) and donors after circulatory death (DCD). Furthermore, due to the need to increase DCD organ utilization avoiding its associated

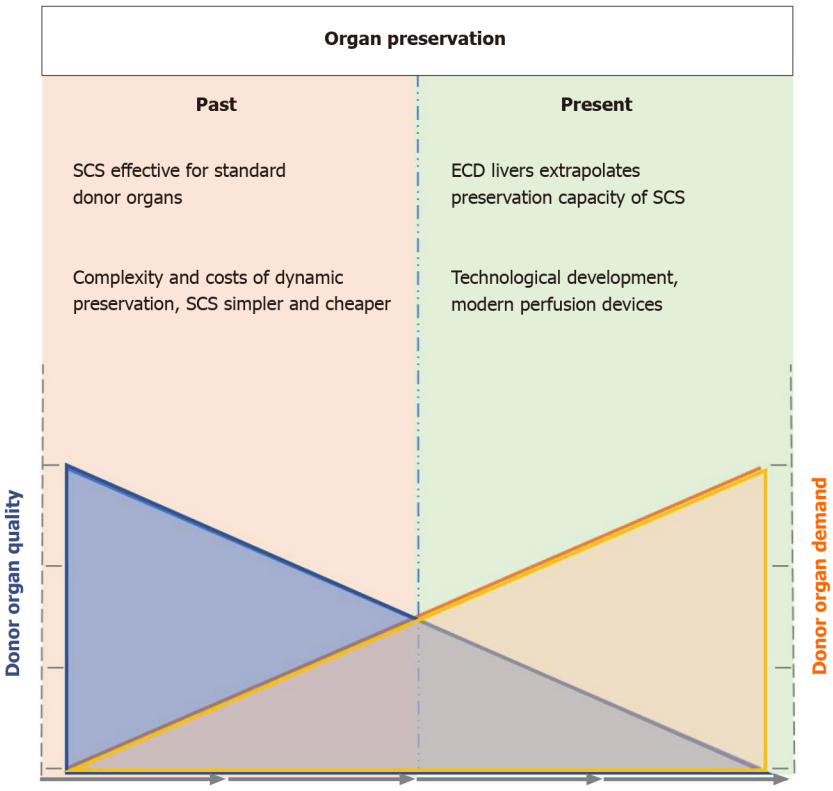

Figure 1 Conditions favouring the development of machine perfusion of the liver. At the start of transplantation, the utilization of good quality donor organs and the low price and simplicity of static cold storage (SCS) favoured its general use. However, the rise in demand for liver transplantation and the donor organ demographic change imposed a frequent utilization of extended criteria donor (ECD) organs. ECD liver transplantation presented inferior results, exposing the limitations of SCS. This scenario, allied to the technological development, created a favourable environment and renewed interest in dynamic organ preservation.

post-transplant complications, NRP is routinely applied in a few countries, including Spain, France, and Italy. NRP alleviates the warm ischemic injury to the organ and induces initial normothermic reperfusion in the donor. Thereby, it allows assessment of viability markers (most lactate and transaminases) which help to decide whether the organ must be declined or not. Several studies currently evidenced the benefits of this technique for DCD liver transplantation[11,19].

Despite consistently attending the primary aim to mitigate IRI, questions are still emerging about the mechanistic pathways involved in this process within each method[8,20]. In fact, benefits vary slightly between techniques mainly as a consequence of the physical properties employed by the methods and the moment of application. Table 1 describes the potential advantages of different MPL techniques in clinical studies. Notably, only three of the mentioned studies were randomized and the study of Ghinolfi *et al*[21] included only 10 patients[2,21,22].

ORGAN VIABILITY ASSESSMENT IN LIVER TRANSPLANTATION: CONTINUOUS FLOW FOR REAL-TIME ANALYSIS

Once inducing reperfusion, whilst NMP abbreviates the cold ischemia time, it results in full activation of the aerobic mitochondrial respiration with reactive oxygen species production and release. Further downstream processes are triggered with subsequent oxidative tissue damage and initiation of the inflammatory cascade[8,23]. The fully physiologically active organ allows real-time assessment of its metabolic functioning, which is currently mostly based on lactate clearance and bile production[6,24]. However, definitive viability criteria are not yet characterized and validated[25].

We are currently transitioning from a combination of hepatocyte function-based criteria to a more comprehensive assessment that incorporates cholangiocyte function. The Birmingham group developed pioneer clinical viability criteria, which included: Lactate clearance, evidence of bile production, perfusate pH stability, hepatic artery flow and portal vein flow, and homogeneous graft perfusion with soft consistency of parenchyma[6]. Later, Watson *et al*[24] advocated using changes in lactate, in glucose

Table 1 Potential benefits of the different modalities of machine perfusion of the liver on clinical studies

	Safety and feasibility	Prevention of early allograft dysfunction	Prevention of biliary complications	Prolonged preservation time	Viability assessment	Therapeutic interventions

and transaminases, and the ability to maintain a stable perfusate pH without bicarbonate supplementation to consider an organ viable. Most recently, the Groningen group highlighted the importance of bile composition analysis during viability assessment (biliary bicarbonate, pH, glucose, lactate dehydrogenase); and their viability criteria already included bile flow and its properties on the analysis[26]. Another study, evaluating discarded donor livers, demonstrated a low hepatocellular injury during NMP; with, however, an elevated bile duct injury on histology[27]. Notably, the impact of MPL on the peribiliary glands and peribiliary vascular plexus, rather than solely bile duct injury, deserves attention. This is because if damage to the bile duct cannot be avoided, establishing a healthy environment to the peribiliary glands contributes to the regenerative capacity of this structure, possibly preventing the development of nonanastomotic strictures[28-30]. The relevance of biliary biomarkers to assess cholangiocyte function and bile duct viability is currently a research topic in liver transplantation[31].

The importance of biliary analysis was indirectly reinforced by another study investigating discarded donor livers, the VITTAL (Viability testing and transplantation of marginal livers) trial[6]. Despite excellent synthetic function with isolated bile flow assessment, a significant proportion of organs developed biliary complications, even requiring retransplantation[6]. In accordance, recently, Eshmuminov *et al*[32] questioned the value of bile formation as a marker of a deteriorating liver function. These findings were paralleled by previous studies, concluding that continuous bile production alone appears not sufficient enough to evaluate liver viability during *ex-situ* machine perfusion[27]. In this study, porcine and human livers were perfused for up to 1 wk and the authors demonstrated good bile production once appropriate drug-induced stimuli were offered[27]. Finally, they suggest the response to vasoconstrictors and hormones as viability markers for liver function. Interestingly, part of the viable livers included in the study from Eshmuminov *et al*[27,33] was initially declined for transplantation based on elevated flavin mononucleotide (FMN) levels during HOPE[34].

Conversely, HMP —usually performed at temperatures between 4 °C and 12 °C — keeps the organ at a low metabolic rate, making the assessment of most of its function more challenging. Despite that, actively oxygenated HMP techniques act seemingly on the mitochondria, restoring the electron transport chain and enhancing the mitochondrial oxidative phosphorylation and adenosine triphosphate production[8,23]. Despite the different metabolic status during HMP, more than 2000 molecules can be quantified from perfusates[34]. Recent viability assessment during HOPE focused on mitochondria function and injury. Muller *et al*[34] identified the first biomarker of organ viability during HMP, the FMN. FMN is a molecule in mitochondria complex I, which is released during organ reperfusion concomitantly and from the same pocket

as reactive oxygen species[35,36]. The number of released FMN molecules was also assessed during different perfusion modalities and authors found a higher FMN release during normothermic liver perfusion[36]. Therefore, ultimately, it reflects the severity of IRI, the mitochondrial injury and dysfunction[36]. The authors from Zurich found a strong correlation between perfusate FMN levels' — fluorometric readings after 30 min of HMP — and post-transplant outcome parameters (hospital stay, cumulative complications, and 90-d graft loss)[34]. Importantly, based on the autofluorescence properties, FMN can be measured in real-time using a spectrometer [34]. This mitochondrial parameter was further validated during NRP and NMP in kidneys and livers. Data presented by Wang *et al*[36] supported the entire concept of mitochondrial injury quantification through FMN release and concluded that this marker appears useful during various preservation approaches.

Table 2 summarizes parameters tested in clinical studies to assess the viability of donor organs during MPL prior to transplantation. Importantly, current studies included different parameters within their viability criteria. In addition, even when the same parameters were investigated, thresholds and the timepoints analysed varied.

A WAY BEYOND PRESERVATION: ORGAN RECONDITIONING

Moving organ preservation forward, MPL extrapolates the simple concept of mitigation of donor organ damage before transplantation; in the interim, the dynamic preservation aims to improve the quality of the donated organs or, in other words, recondition them. This step further is fundamental to increase ECD organ utilization once they were exposed to more severe damage and carry a high risk to receptors if SCS is applied.

Non-randomized single-centre clinical studies have confirmed the ability of HMP to enhance the results of ECD liver transplantation[3,10,37]. Dutkowski *et al*[37] suggested that high-risk DCD organs — associated with most severe IRI, poor clinical outcomes, and a high rate of post-operative complications — submitted to the HOPE technique for 1-2 h prior to transplantation have similar outcomes to standard DBD organs, including the length of hospital stay and biliary complications. Later, the same group compared HOPE-treated DCD livers to a matched cohort of DCD organs without further intervention. The perfused livers presented lower post-transplant alanine aminotransferase levels, decreased biliary complication rate, and increased 1-year graft survival[3]. More recently, Schlegel *et al*[38] reported a 5-year graft survival of 94% for transplanted HOPE-treated DCD livers against 78% for untreated DCD organs. Similar benefits were also found in D-HOPE studies led by the Groningen group[30]. van Rijn *et al*[22] recently published a randomized clinical trial on HMP with 160 patients transplanted with DCD organs. The study reached its primary endpoint, D-HOPE-perfused DCD livers had a lower incidence of symptomatic non-anastomotic biliary stricture (6%) compared to 18% in the control group (P = 0.03). This study also demonstrated that D-HOPE reduced the occurrence of early allograft dysfunction post-transplantation[22].

Importantly, evolving evidence supports the safety of performing D-HOPE for up to 24 h, which may improve transplant logistics[39]. A recent study suggested that HOPE plays a protective role in preventing hepatocellular carcinoma recurrence after liver transplantation, which is possible due to protection from IRI, downstream inflammation, and subsequent pro-tumour-recurrence environment[40,41].

A large multicentre trial recently evidenced preservation NMP was able to reduce in 50% the hepatocellular enzyme releases post-operatively, increasing organ utilization rate and preservation time[2]. Nevertheless, NMP did not reduce biliary complications rate post-transplant and, also, did not impact on graft or patient survival[2]. Similar results were found in another study wherein end-ischemic NMP was used[42]. The Birmingham group applied NMP to discarded donor livers, 71% of the perfused organs were transplanted. Although this study reported 100% 90-d patient and graft survival, perfusion did not prevent non-anastomotic biliary stricture (incidence of 18%), and four recipients required retransplantation within 542 d[6]. Albeit the near-physiological conditions of donor organs during NMP favours the assessment of their metabolic functions, the ability of NMP per se to recondition ECD organs is still controversial. Whether a severely damaged organ would recover after activation of the damaging IRI machinery during NMP without any further intervention is not clear. Seemingly, additional support must be required[8,13,43,44].

The uncertainty about NMP reconditioning properties is counterbalanced by evident advantages. The organ's full metabolism facilitates its viability assessment,

Table 2 Parameters employed in clinical studies to assess the viability of donor organs before transplantation

Ref.	Method	Perfusate parameters	Bile parameters	Perfusion parameters
Watson *et al*[11]	NRP	Within 2 h of NRP: Alanine transaminase up to 500 IU/L, providing no continued rise between the first and second hours		
Muller *et al* [34]	HMP	At least 1 h of HMP: Threshold at 10000 A.U. (100 ng FMN/mL perfusate) to refuse livers regardless of the use of a DCD or DBD liver		
Watson *et al*[32]	NMP	No timepoint defined: Changes in lactate, glucose, and transaminase concentrations and the ability of the liver to maintain perfusate pH without supplemental bicarbonate		
Matton *et al*[26]	NMP		Within 2.5 h of NMP: Bicarbonate concentration > 18 mmol/L, pH > 7.48, glucose concentration < 16 mmol/L, bile/perfusate glucose concentration ratio < 0.67, and LDH concentration < 3689 U/L	
de Vries *et al*[14]	NMP	Within 150 min of NMP: Lactate concentration within "normal" values (0.5-1.7 mmol/L); pH within normal values (7.35-7.45), without continuing sodium bicarbonate supplementation	Within 150 min of NMP: Cumulative bile production of ≥ 10 mL and ≥ 4 mL in the preceding hour. pH > 7.45	
Mergental *et al*[6]	NMP	Within 4 h of NMP: Lactate ≤ 2.5 mmol/L; and two or more parameters: pH ≥ 7.30; Evidence of glucose metabolism	Within 4 h of NMP: Evidence of bile production	Within 4 h of NMP: HA flow ≥ 150 mL/min and PV flow ≥ 500 mL/min; and homogenous perfusion of the parenchyma
Cardini *et al*[50]	NMP	Within 2 h of NMP: Rapid decrease and maintenance of lactate to physiological levels, maintenance of physiological pH values without sodium bicarbonate supplementation, and glucose consumption. Remarkably high transaminases and LDH levels and a severe rise of these parameters are deemed warning signals	Within 2 h of NMP: Bile production and bile pH are indicators for bile duct viability and function	
Reiling *et al*[51]	NMP	Within 2 h of NMP: Lactate clearance to < 2 mmol/L. Within 4 h of NMP: Evidence of glucose metabolism. Maintenance of physiological pH without continuing administration of sodium bicarbonate	Within 4 h of NMP: Bile production (no lower limit)	Within 4 h of NMP: Stable hepatic arterial and portal venous flows. Homogeneous graft perfusion with soft consistency of parenchyma

DCD: Donation after circulatory death; DBD: Donation after brain death; HA: Hepatic artery; HMP: Hypothermic machine perfusion; LDH: Lactate dehydrogenase; NMP: Normothermic machine perfusion; NRP: Normothermic regional perfusion; PV: Portal vein.

increases the surgeon's confidence, and allows safe prolonged organ preservation[2,6]. This ambiguity opened up an opportunity for further additions to the technique, for example, combinations of perfusion modalities and pharmacological interventions[15,43]. Combinations of perfusion modalities may merge both techniques' benefits; experimental and clinical studies have already suggested the possibility to enhance the reconditioning of the most severely damaged organs with the realization of HMP before NMP[13-15,17]. Similarly, pharmacological interventions may mitigate IRI and improve donor organ metabolic recovery, which has been suggested in pre-clinical studies investigating discarded steatotic donor livers[43]. For a comprehensive review on pharmacological agents used in MPL, please refer to Resch *et al*[45].

FINAL CONSIDERATIONS

Although several studies currently have demonstrated the benefits of dynamic organ preservation, limitations of this evidence exist. This is because significant variability of technicalities occurs even between studies employing the same method. For example, for NMP, parameters such as the rewarming period, arterial and portal vein perfusion pressure, and perfusate constitution vary between studies. Similarly, studies diverge on the perfusion duration, either replacing SCS during organ transportation or performed as an end-ischemic approach at the recipient transplant centre. For HMP, similar challenges also occur. So far, most studies focused on organs with a short period of cold ischemia time and, also, the level of perfusate oxygenation differs

between them. Adopting standardized protocols might enable the construction of large perfusion databases, which may unveil further advantages of MPL.

In addition, the foundation of large networks to develop studies collaboratively must benefit even further the era of machine perfusion in liver transplantation. The development of large collaborative perfusion groups working collectively may allow reliable comparison between perfusion modalities and, even, identify which technology is most beneficial to each specific organ.

CONCLUSION

Over the last few years, machine perfusion in liver transplantation gathered momentum, though it seems the construction of definitive evidence is still needed. This is mainly because of current disjointed individual efforts with non-standardization of methods and publication of single-centre non-randomized small studies. Dynamic organ preservation must thrive on collaborative networks wherein collective outcomes must consolidate its actual benefits (viability assessment, prolonged organ preservation, and organ reconditioning) and create the conditions for further progress to occur. Pharmacological *ex-situ* treatments and investigation of the impact of this technology on specific donor organs are some possibilities within reach, lying in the realm of the possible.

ACKNOWLEDGEMENTS

This paper presents independent research supported by the Brazilian Ministry of Health *via* the Support Program for Organizational Development of the SUS (PROADI-SUS) at the Hospital Israelita Albert Einstein. The views expressed are those of the author(s) and not necessarily those of the Ministry of Health, the PROADI-SUS, or the Hospital Israelita Albert Einstein. We are extremely grateful to the staff from the Hospital Israelita Albert Einstein and Hospital Municipal Vila Santa Catarina, whose continued support provides resources and intellectual input that is shaping the thoughts and future strategies for the continuing development of our research.

Abstract

BACKGROUND

Identifying novel colorectal cancer (CRC) prognostic biomarkers is crucial to helping clinicians make appropriate therapy decisions. Melatonin plays a major role in managing the circadian rhythm and exerts oncostatic effects on different kinds of tumours.

(TSGHIRB approval number: 098-05-292 and 2-105-05-129).

AIM

To explore the relationship between *MTNR1B* single-nucleotide polymorphism (SNPs) combined with gene hypermethylation and CRC prognosis.

METHODS

A total of 94 CRC tumour tissues were investigated. Genotyping for the four *MTNR1B* SNPs (rs1387153, rs2166706, rs10830963, and rs1447352) was performed using multiplex polymerase chain reaction. The relationships between the *MTNR1B* SNPs and CRC 5-year overall survival (OS) was assessed by calculating hazard ratios with 95%CIs.

RESULTS

All SNPs (rs1387153, rs2166706, rs10830963, and rs1447352) were correlated with decreased 5-year OS. In stratified analysis, rs1387153, rs10830963, and rs1447352 risk genotype combined with CDKN2A and MGMT methylation status were associated with 5-year OS. A strong cumulative effect of the four polymorphisms on CRC prognosis was observed. Four haplotypes of *MTNR1B* SNPs were also associated with the 5-year OS. *MTNR1B* SNPs combined with *CDKN2A* and *MGMT* gene methylation status could be used to predict shorter CRC survival.

CONCLUSION

The novel genetic biomarkers combined with epigenetic biomarkers may be predictive tool for CRC prognosis and thus could be used to individualise treatment for patients with CRC.

Key Words: Colorectal cancer; Melatonin; Hypermethylation; Polymorphism; Prognosis; Biomarker

Core Tip: In this retrospective cohort study, we found that *MTNR1B* single-nucleotide polymorphism were associated with a significantly increased risk of colorectal cancer (CRC) 5-year overall survival. A strong cumulative effect of the four polymorphisms on CRC prognosis was observed. This study indicated the novel genetic biomarkers, *MTNR1B*, combined with *CDKN2A* and *MGMT* gene methylation statuses, maybe a predictive tool for CRC prognosis.

INTRODUCTION

Colorectal cancer (CRC) is the third most newly diagnosed cancer and second most frequent cause of cancer-related deaths worldwide[1]. The sudden increase in the incidence of CRC in Taiwan may be associated with obesity, a sedentary lifestyle, and unhealthy dietary habits resulting from improvement of the economy[2]. However, these well-known risk factors cannot wholly account for the increased incidence of CRC. Extensive studies have demonstrated that genetic and epigenetic variations influence personal CRC susceptibility and prognosis[3-6]. Finding novel CRC prognostic biomarkers is crucial because it would help clinicians in making appropriate decisions. Melatonin, which plays a central role in the management of circadian rhythm, has been identified in the pineal retina, lymphocytes, bone marrow, and gastrointestinal tract[7]. Several epidemiological studies have indicated that melatonin exerts oncostatic effects, including antioxidant activity, stimulation of apoptosis, regulation of prosurvival signalling and tumour metabolism, inhibition of

P-Editor: Liu JH

angiogenesis, metastasis, and induction of epigenetic alteration[8] on different types of tumours[9-11]. Melatonin prevents metastases, increases the 1-year longevity of patients with resected CRC, and enhances myelotoxicity, lymphocytopenia, and other undesirous haematological and immunological side effects. Furthermore, melatonin reduces neurotoxicity, weakness, insomnia, and psychological stress. These effects have been reported when melatonin is administered as a single pharmaceutical agent or coadministered with the usual first-line and second-line schedules for radiotherapy and chemotherapy[12]. The growing interest in understanding the association between melatonin and colorectal carcinogenesis has led to thorough studies regarding the presence of unique melatonin binding sites in the human colon's intestinal mucosa and submucosa. The melatonin receptor MT2, one of the largest superfamilies of G-protein linked receptors and encoded by *MTNR1B*, is generally responsible for mediating the downstream effects of melatonin[13]. In 2006, Ekmekcioglu *et al*[14] reported that MT2 was involved in the antiproliferative action of melatonin. Some research demonstrated that the levels of melatonin are regulated through its biosynthesis from the amino acid tryptophan, which is mediated by MT2[15]. Research analyses have demonstrated reduced expression of MT2 in tumour mucosa compared with the normal mucosa in patients with CRC[16,17]. This may be caused by MT2 downregulation, which reduces protection against CRC and facilitates the development of CRC tumours. In vitro findings indicate that melatonin triggers p53 phosphorylation through the activation of MT2[18].

Studies have reported an association between *MTNR1B* gene polymorphisms and impaired insulin secretion, higher fasting glucose level, increased risk of type 2 diabetes, and gestational diabetes[19,20]. However, the effect of *MTNR1B* gene polymorphisms on CRC sensitivity is little understood. Many studies have demonstrated that *CDKN2A* is more frequently methylated in poorly differentiated, lymphatic metastasis of CRC[21]. In addition, the hypermethylation state of DNA repair genes, *MGMT* and *MLH1*, which are silenced, and have been shown to be correlated with specific mutations in tumor DNA, such as *KRAS* mutations or microsatellite instability, respectively[22]. Furthermore, aberrant promoter methylation of the *CDKN2A, MGMT*, and *MLH1* genes has been reported to be related to adenoma-carcinoma sequence and could serve as a diagnostic prognostic marker of CRC[23,24].

In the present study, a hospital-based retrospective cohort study was conducted to evaluate the effects of *MTNR1B* gene polymorphisms rs1387153, rs2166706, rs10830963, and rs1447352 and their haplotypes on the 5-year overall survival (OS) of patients with CRC and to analyse interactions based on the methylation status of the *CDKN2A* and *MGMT* genes. We hypothesised that the influence of *MTNR1B* gene variation combined with the hypermethylation of *CDKN2A* and *MGMT* genes would predict the prognosis and provide clinical recommendations for optimal treatment of CRC.

MATERIALS AND METHODS

Samples and DNA extraction

A retrospective cohort study, described in detail elsewhere[24-27], was conducted to predict the OS of patients with CRC in Taiwan. Among this cohort, 94 tumour tissues were collected from patients with CRC, which was diagnosed in the Tri-Service General Hospital (TSGH), Taiwan, from 2006 to 2010. The 5-year prognosis was assessed using the tumour tissues. The TSGH Colon and Rectum Division's clinical practice guideline requires enrolees to return once every 3 mo in the first year after surgical resection and once every 3–6 mo thereafter. Written informed consent was obtained from all patients before participation in the study. The TSGH Institutional Review Board approved this study (TSGHIRB approval number: 098-05-292 and 2-105-05-129). Data regarding registered patients—including sex, surgical age (permanent variable), adjuvant chemotherapy, histologic grade and location of the tumour, and survival—were collected from the TSGH's cancer registry database and analyzed to investigate the association with *MTNR1B* genotyping. All methods were performed in accordance with the relevant guidelines and regulations. OS was defined as the time from the date of surgery to the date of death from any cause or the last follow-up date before December 31, 2010. Cellulose-coated magnetic beads were employed to extract genomic DNA from the tumour tissues stored at −80 °C in a liquid nitrogen tank by using the MagCore Compact Automated Nucleic Acid Extractor (catalogue no. MCA0801; RBC Bioscience, Taipei, Taiwan) and Genomic DNA Tissue Kit (catalogue

no. 69504; Qiagen, Taipei, Taiwan).

MTNR1B genotyping

The *MTNR1B* gene polymorphisms rs1387153, rs2166706, rs10830963, and rs1447352 were screened using the Agena MassARRAY platform with iPLEX gold chemistry (Agena, San Diego, CA, United States). The detailed genotyping protocols have been reported elsewhere[28,29]. Following the manufacturer guide, the specific polymerase chain reaction (PCR) primer and extension primer sequences were designed using the Assay Designer software package (v.4.0). A 1-μL genomic DNA sample (10 ng/μL) was employed in multiplex PCR in 5-μL volumes containing 1 unit of Taq polymerase, 500 nmol of each PCR primer mix, and 2.5 mmol/L of each dNTP (Agena, PCR accessory and Enzyme kit). Thermocycling was performed at 94 °C for 4 min, which was followed by 45 cycles at 94 °C for 20 s, 56 °C for 30 s, 72 °C for 1 min, and then 72 °C for 3 min. Unincorporated dNTPs were deactivated using 0.3 U of shrimp alkaline phosphatase. Single-base extension reaction was performed using iPLEX enzyme, terminator mix, and extension primer mix; this was followed by 94 °C for 30 s, 40 cycles at 94 °C for 5 s, 5 inner-cycles at 56 °C for 5 s, 80 °C for 5 s, and finally 72 °C for 3 min (Agena, iPLEX gold kit). After cation exchange resin was added to remove residual salt from the reaction, 7 nL of the purified primer extension reaction was loaded onto the matrix pad of a SpectroCHIP (Agena). The SpectroCHIPs were analysed using a MassARRAY Analyzer 4, and clustering analysis was performed using TYPER 4.0 software.

Methylation-specific-PCR

We analyzed *CDKN2A*, *hMLH1*, and *MGMT* DNA methylation in the promoter regions through methylation-specific polymerase chain reaction (MS-PCR), as described in our earlier study[25]. Perform MS-PCR with 1.2-μL aliquots of forward and reverse primers, with 12.5 μL HotStart Taq Premix (RBC Bioscience) and bisulfite-converted DNA according to the manufacturer's protocol. The sequences, annealing temperature of individual primer used for amplification, and MS-PCR product sizes are illustrated in Table 1. The MS-PCR procedures were in accordance with the previous study[25]: first, 10 min at 95 °C; then, 35 cycles of 30-s denaturation at 95 °C, 30-s annealing, and 48-s extension at 72 °C; finally, 4-min extension at 72 °C. After the amplification, MS-PCR products were mixed with a loading buffer, electrophoresed on 2% agarose gel by using 0.2-μL gel-stained dye for 25 min, and visualized using an ultraviolet transilluminator.

Statistical analysis

Student's *t*-tests were performed to analyse continuous variables, and χ^2 tests were performed for statistical analyses of categorical variables (IBM SPSS Statistics 22). The existence of a Hardy–Weinberg equilibrium per single-nucleotide polymorphism (SNP) was assessed using two goodness-of-fit tests. Linkage disequilibrium (LD) among genotyped SNPs was obtained using the Haploview 4.2 programme. The minor allele frequencies of four *MTNR1B* gene polymorphisms (rs1387153, rs2166706, rs10830963, and rs1447352) are higher than 5% in an ethnic Chinese population according to data in the dbSNP database.

The relationships between the *MTNR1B* SNPs and 5-year OS of patients with CRC and between the cumulative effect of *MTNR1B* SNPs and 5-year OS of CRC were assessed using adjusted hazard ratios (aHRs) with 95%CIs, calculated using Cox proportional-hazards analyses and adjusted for all the aforementioned patient-level and hospital-level characteristics.

Haplotype frequencies for these SNPs combinations were first estimated using haplo.stats (version 12.1) for the R statistical package and then verified using Haploview 4.2. These software programmes employ expectation–maximisation algorithms when constructing the haplotypes. All statistical tests were two-sided, and $P < 0.05$ was considered statistically significant.

RESULTS

In this study, 94 CRC tumor samples from the TSGH tumor bank were analyzed. LD was evaluated for all *MTNR1B* SNP pairs. The Lewontin's D' values of the pairs were 1.00 (rs1387153: rs2166706), 0.90 (rs1387153: rs10830963), and 0.88 (rs1387153: rs1447352); and the R2 values were 0.98, 1.00, and 1.00, respectively. Four haplotypes with frequencies of 0.034 (T-C-G-A), 0.011 (C-T-C-A), 0.011 (C-T-C-G), and 0.472 (C-T-

G-A) were selected for the haplotype association analysis. The relationship between the *MTNR1B* genotype and the demographic and clinicopathological features of patients with CRC was evaluated. Among the patients with CRC, 41.5% were men; the mean age at surgery was 64.2 ± 13.8 years; 51.0% were at stage III–IV; and 19.1% of the patients died during the study period. Table 2 and Table 3 show that certain possible CRC risk factors, such as age, sex, tumor-node-metastasis stage, and *CDKN2A*, *MLH1* and *MGMT* genes methylation status, were not significantly associated with the *MTNR1B* genotype. However, tumor location and survival were associated with a *MTNR1B* polymorphism. The relationships between each *MTNR1B* genotype were analyzed to determine their association with 5-year OS in patients with CRC using Cox proportional-hazards models adjusted for age, sex, stage, adjuvant chemotherapy, tumor location, and the methylation status of the *CDKN2A, MLH1* and *MGMT* genes (Table 4). All SNPs were associated with lower 5-year OS. The variant types of rs1387153 (TT *vs* CC + CT: aHR = 6.23, 95%CI = 2.01–19.3), rs2166706 (CC *vs* TT + TC: aHR = 6.40, 95%CI = 2.21–18.6), rs10830963 (GG *vs* CC + CG: aHR = 7.43, 95%CI = 2.63–21.1), and rs1447352 (AA *vs* GG + GA: aHR = 4.28, 95%CI = 1.32–13.9) decreased the 5-year OS in patients with CRC.

We further examined the relationship between each SNP and the 5-year OS, with data stratified by the methylation status of the *CDKN2A* and *MGMT* genes (Table 5). Particularly, 5-year OS was significantly reduced in the rs1387153 and rs1447352 polymorphism subgroups of unmethylation of the *MGMT* gene (aHR = 8.57, 95%CI = 1.67–44.1; aHR = 19.4, 95%CI = 2.94–128, respectively) compared with the opposite subgroups. In contrast, we determined that the rs1447352 polymorphism was related to a higher risk of mortality in the subjects with methylation of the *CDKN2A* gene (aHR = 9.40, 95%CI = 1.02 –86.8). Besides, rs10830963 exhibited a significant association with 5-year OS in the subgroups with hypermethylation of the *CDKN2A* gene (aHR = 27.2, 95%CI = 3.12–233). According to the small number of hypermethylation *MLH1* gene, we could not perform the *MLH1* gene methylation-stratified analysis.

The cumulative effects of four SNPs were then evaluated. We selected polymorphism to classify the risk based on genotypes, in accordance with the findings summarised in Table 4: TT *vs* CC + CT for rs1387153, CC *vs* TT + TC for rs2166706, GG *vs* CC + CG for rs10830963, and AA *vs* GG + GA for rs1447352. The subjects were classified into five groups on the basis of their genotypical risk score (0, 1, 2, 3, and 4), and the significance of the linear trend was then evaluated. The risk of poor CRC prognosis significantly increased with an increase in the SNP risk genotypes (P_{trend} < 0.001, Table 6). Furthermore, patients were divided into two groups on the basis of the number of risk genotypes, forming the < 2 and ≥ 2 SNP risk genotypes groups. The 5-year OS was significantly different between the group with two or more SNP risk genotypes and the comparison group (aHR = 5.81, 95%CI = 2.03-16.6).

[a]The total number of patients with colorectal cancer does not correspond because of missing data. CRC: Colorectal cancer.

Haplotype analysis was performed to determine the relationship between haplotypes of the studied SNPs (rs1387153, rs2166706, rs10830963, and rs1447352) and the 5-year OS. Four haplotypes were screened and two demonstrated significance. The T-C-G-A haplotype contributed to reduced 5-year OS (aHR = 2.75, 95%CI = 1.82–11.2), whereas the C-T-C-G haplotype reduced the risk of mortality (aHR = 0.21, 95%CI = 0.06–0.71, Table 7). No significant relationship with the 5-year OS was evident for the C-T-G-A haplotype (aHR = 1.96, 95%CI = 0.44–8.66) or the C-T-C-A haplotype (aHR = 0.70, 95%CI = 0.28–1.72).

DISCUSSION

In this retrospective cohort study, we examined the associations between four *MTNR1B* gene polymorphisms (rs1387153, rs2166706, rs10830963, and rs1447352) and CRC outcomes in terms of OS. Correlations between all SNPs and the 5-year OS were identified. In stratified analysis, the rs1387153 and rs1447352 risk genotypes were determined to be associated with 5-year OS in the unmethylation *MGMT* gene subgroup. In contrast, the rs10830963 and rs1447352 risk genotypes with hypermethylation *CDKN2A* gene had a higher risk of death in five years. Four haplotypes of *MTNR1B* SNPs were also determined to be associated with increased risk of mortality. This study is one of a few that has reported an association between *MTNR1B* SNPs and the 5-year OS in patients with CRC. The *MTNR1B* gene location of both rs1387153 and rs2166706 is > 11 kb upstream. The variant rs10830963 is located in an intronic region, whereas the variant rs1447352 is located at approximately 4.5 kb from the *MTNR1B* gene[30]. Qiu *et al*[31] indicated that these SNPs may influence the *MTNR1B* expression, causing a functional deficiency of melatonin. De Luis *et al*[32] demonstrated that rs10830963 was associated with an increased *MTNR1B* mRNA expression and the expression of other genes that may affect the energy balance role of melatonin[33]. However, the potential role and regulation of the other three SNPs in the *MTNR1B* expression are poorly understood[34].

[a]The total number of patients with colorectal cancer does not correspond because of missing data. CRC: Colorectal cancer.

Mechanisms involving the oncostatic effect of melatonin binding to MT1 and MT2 receptors in CRC have been reported in numerous studies. An *in vitro* study conducted by Karasek *et al*[35] determined that both MT1 and MT2 were part of the oncostatic action of melatonin on Colon 38 adenocarcinoma cells. Furthermore, activation of the tumour suppressor *p53* gene by melatonin is reportedly directly controlled by MT1 and MT2. Melatonin's suppression of cell proliferation and clonogenic activity is impaired because of the lack of either receptor[18]. León *et al*[16] demonstrated an association between reduced MT1 and MT2 expression and increased malignancy in CRC in 54 Spanish patients with CRC. Moreover, expression of the tumour markers CD44 and CD133 was negatively correlated with MT1 and MT2 expression in patients with CRC[17]. Furthermore, the role of the MT1 receptor in gastric adenocarcinoma was demonstrated in patients over the age of 50 years[36]. In the present study, we determined that four *MTNR1B* gene polymorphisms were significantly associated with the 5-year OS of patients with CRC, with a cumulative effect on prediction for poorer prognosis. Few studies have assessed the relationship between *MTNR1B* gene polymorphisms and CRC prognosis. However, some type 2 diabetes susceptibility genes are correlated with metastasis development[37]. Nasrabadi *et al*[38] indicated that high expression of MT2 was associated with gastric adenocarcinoma, because MT2 receptors enhance the secretion of bicarbonate by stimulating calcium release into the mucosa of enterochromaffin cells. Numerous reports have indicated that *MTNR1B* SNPs are associated with fasting glucose level, obesity, carbohydrate disorders, and type 2 diabetes, which are crucial metabolic risk factors for CRC[39,40]. Indeed, Johnson *et al*[41] reviewed the association between colorectal cancer and type 2 diabetes and indicated that there is a positive and observational correlation. Besides, the GG genotype of the variant rs10830963 was discovered to significantly increase the risk of breast cancer than the CC genotype[39,42]. Moreover, the AA genotype of the variant rs10765576 was correlated with lower risk of breast cancer compared with the GG or GA major allele among Chinese women[13].

Data concerning the effect of gene methylation modification on the association between *MTNR1B* gene polymorphisms and CRC prognosis are scarce. The case-only analysis performed by Das *et al*[43] assessed the potential interactions and associations between epigenetics, genetics, and the risk of oesophageal cancer. Das *et al*[43]

[a]Adjusted for age, sex, stage, adjuvant chemotherapy, tumor location and the methylation status of *CDKN2A, MLH1* and *MGMT* gene. HR: Hazard ratio; N/A: Not applicable.

determined that *CDKN2A* methylation and the *p53* polymorphism were significantly associated with oesophageal cancer risk. DNA methylation can regulate gene expression by modifying chromatin complexes and recruiting methyl-CpG domain-binding proteins around CpG islands, and this is the most common epigenetic alteration. There was a clinical study had revealed the feasibility of using specific gene methylation statuses as biomarkers for CRC prognosis[44]. For instance, the hypermethylation of *CDKN2A* and *MGMT* promoters has been suggested to be independently correlated with poorer prognosis (including metastasis, recurrence, and mortality) in patients with CRC[45,46]. Our findings demonstrated that the risk of mortality in *CDKN2A* hypermethylation patients with rs10830963 or rs1447352 risk genotype was higher than that in the opposing subgroups. However, SNPs−rs1387153 and rs1447352 with unmethylation of the *MGMT* gene were associated with poorer CRC prognosis. All these findings regarding the correlation with gene promoter methylation status and polymorphisms suggest an overlap and crosstalk between the involved pathways, adversely affecting cancer prognosis, and indicate a strong correlation between genetic and epigenetic factors in the Taiwanese population. Therefore, *CDKN2A* and *MGMT* methylation status and *MTNR1B* SNPs may be used as molecular targets for predicting CRC prognosis. The efficiency of any single polymorphic site for risk detection is usually limited because of the multistep model of colorectal carcinogenesis. The benefits of using a combination of several SNPs are well-documented[47]. Our analysis revealed a significant cumulative effect, which was observed as *MTNR1B* SNPs correlating with the 5-year OS, which indicates that using more risk genotypes may improve the accuracy of CRC prognoses. Furthermore, the risk of mortality in individuals with the TT genotype rs1387153, CC genotype rs2166706, and GG genotype rs10830963 may be 2.75-fold higher than that in other haplotypes.

Certain limitations to the present study should be considered. First, limitations are inherent in any retrospective cohort study. Second, our sample size was not sufficiently large enough to provide a more precise estimate of the association between *MTNR1B* SNPs and CRC prognosis. Third, our preliminary retrospective cohort study was not designed to clarify the pathophysiology of how the risk genotype of the *MTNR1B* gene reduces postoperative survival. In addition, data regarding registered patients were collected from the TSGH's cancer registry database. Other potential risk factors, such as dietary habits, obesity, and combined primary diseases were unavailable from the database. Furthermore, this study did not include normal colorectal tissues, *i.e.* we could not describe *MTNR1B* polymorphic variants in normal colorectal tissues. The results of the present study should be verified using a large-scale study that controls for confounding variables, such as lifestyle, carcinogen exposure, and diet, among others.

CONCLUSION

In summary, we conducted a retrospective cohort study to investigate the association between *MTNR1B* SNPs and CRC prognosis in those with different gene methylation statuses. All polymorphisms were correlated with 5-year OS. Three SNPs (rs1387153, rs10830963, and rs1447352) were associated with enhanced mortality risk when combined with different *CDKN2A* or *MGMT* gene methylation status. Furthermore, we observed a strong cumulative effect of *MTNR1B* SNPs on the 5-year OS of patients with CRC. Our findings indicate that *MTNR1B* SNPs combined with *CDKN2A* and *MGMT* gene methylation statuses may be predictive biomarkers for CRC prognosis. This study offers insights into novel genetic and epigenetic biomarkers for the prediction of CRC prognosis, and the findings could be used to individualise the treatment of patients with CRC.

ARTICLE HIGHLIGHTS

Research background

Melatonin plays a central role in the management of circadian rhythm and was identified in the gastrointestinal tract. Epidemiological studies demonstrated that melatonin has oncostatic effects including induction of epigenetic alteration on different types of tumours. The melatonin receptor MT2 encoded by *MTNR1B* is generally responsible for mediating the downstream effects of melatonin. The expression of MT2 in tumour mucosa is lower than the normal mucosa in patients with

colorectal cancer (CRC).

Research motivation

Growing studies have investigated the association between melatonin and CRC carcinogenesis. However, the relationship between *MTNR1B* gene polymorphisms and CRC sensitivity is not clear. To analyze the effects of *MTNR1B* gene polymorphisms on CRC prognosis and evaluate the interactions with aberrant promoter methylation of the *CDKN2A* and *MGMT* genes will be of great significance.

Research objectives

In our study, we aimed to explore the association between *MTNR1B* single-nucleotide polymorphism (SNPs) and the 5-year overall survival (OS) of CRC patients. To further assess the interaction between *MTNR1B* SNPs and *CDKN2A* and *MGMT* gene methylation, we examined the relationship between each SNP and the 5-year OS, with data stratified by the methylation status of the *CDKN2A* and *MGMT* gene.

Research methods

Ninety four CRC patients from Taiwan were enrolled to evaluate the association between *MTNR1B* SNPs, *CDKN2A*, *MGMT* gene hypermethylation and 5-year OS. The *MTNR1B* gene polymorphisms were screened using the Agena MassARRAY platform with iPLEX gold chemistry. The promoter methylation status of *CDKN2A* and *MGMT* was assessed using methylation-specific polymerase chain reaction. Associations of the genetic and epigenetic effect and 5-year OS were assessed using the Cox proportional hazards regression model.

Research results

In this retrospective cohort study, we found that *MTNR1B* SNPs was associated with a significantly increased risk of CRC 5-year OS. A strong cumulative effect of the four polymorphisms on CRC prognosis was observed. In stratified analysis, rs1387153, and rs1447352 risk genotype were determined to be associated with 5-year OS in the unmethylation *MGMT* gene subgroup. In contrast, rs10830963 and rs1447352 risk genotype with hypermethylation *CDKN2A* gene had a higher risk of death in five years. Four haplotypes of MTNR1B SNPs were also determined to be associated with increased risk of mortality.

Research conclusions

This study is one of few reports which demonstrated the association between MTNR1B SNPs and the 5-year OS in patients with CRC. Our data identified these novel genetic biomarkers combined with *CDKN2A* and *MGMT* methylation status for the prediction of CRC prognosis, and the findings could be used to individualise the treatment of patients with CRC.

Research perspectives

Based on our findings, the novel genetic biomarkers, *MTNR1B*, combined with *CDKN2A* and *MGMT* gene methylation statuses could be a predictive tool for CRC prognosis. The new set of markers may help physicians make treatment decisions based on the prognostic information and would improve the OS of patients with CRC. This study warrant further investigation of the underlying mechanisms related to oncostatic effects of *MTNR1B* on CRC.

Abstract

BACKGROUND

Non-invasive fibrosis scores are not yet validated in the newly defined metabolic associated fatty liver disease (MAFLD).

AIM

To evaluate the diagnostic performance of four non-invasive scores including aspartate aminotransferase to platelet ratio index (APRI), fibrosis-4 index (FIB-4), body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score (BARD), and nonalcoholic fatty liver disease fibrosis score (NFS) in patients with MAFLD.

METHODS

Consecutive patients with histologically confirmed MAFLD were included. The discrimination ability of different non-invasive scores was compared.

RESULTS

A total of 417 patients were included; 156 (37.4%) of them had advanced fibrosis (Metavir ≥ F3). The area under receiver operating characteristic curve of FIB-4, NFS, APRI, and BARD for predicting advanced fibrosis was 0.736, 0.724, 0.671, and 0.609, respectively. The area under receiver operating characteristic curve of FIB-4 and NFS was similar (P = 0.523), while the difference between FIB-4 and APRI (P = 0.001) and FIB-4 and BARD (P < 0.001) was statistically significant. The

enrollment.

best thresholds of FIB-4, NFS, APRI, and BARD for diagnosis of advanced fibrosis in MAFLD were 1.05, -2.1, 0.42, and 2. A subgroup analysis showed that FIB-4, APRI, and NFS performed worse in the pure MAFLD group than in the hepatitis B virus-MAFLD group.

CONCLUSION

APRI and BARD scores do not perform well in MAFLD. The FIB-4 and NFS could be more useful, but a new threshold is needed. Novel non-invasive scoring systems for fibrosis are required for MAFLD.

Key Words: Metabolic associated fatty liver disease; Non-invasive fibrosis scores; Fibrosis-4 index; Non-alcoholic fatty liver disease fibrosis score; Aspartate aminotransferase to platelet ratio index; BARD

Core Tip: Metabolic associated fatty liver disease (MAFLD) is a new concept proposed in 2020 to redefine fatty liver disease. The utility of non-invasive fibrosis scores as well as their optimal thresholds for MAFLD remains unknown. We validated the conventional non-invasive scores including aspartate aminotransferase to platelet ratio index, fibrosis-4 index, body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score, and nonalcoholic fatty liver disease fibrosis score in patients with MAFLD. The results indicate that the conventional scores may lead to a high rate of misdiagnosis in MAFLD. A novel scoring system for fibrosis is urgently needed.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD), defined as excessive fat accumulation in liver cells in the absence of other liver diseases, has become a new epidemic due to its growing prevalence[1,2]. To date, NAFLD is believed to affect more than a quarter of the global population[2,3]. The natural history of NAFLD is highly variable; however, it is believed to progress through various fibrosis stages to end up in liver cirrhosis in a significant number of patients. The development and grade of liver fibrosis are strongly related with the adverse outcomes of NAFLD[4-6]. Thus, it is critical to identify patients with advanced fibrosis to optimize the management of NAFLD.

Liver biopsy is currently regarded as the "gold standard" for the diagnosis of liver fibrosis. However, due to the high prevalence of NAFLD, it is impossible to perform a biopsy for each patient. Moreover, the inherent issues including safety, sampling errors, and the inter- and intraobserver variation limit its application[7,8]. These limitations warrant the need for non-invasive scores for assessing liver fibrosis.

Numerous non-invasive assessment tools have been developed for diagnosis of advanced fibrosis[9]. The most widely used non-invasive scores include aspartate aminotransferase (AST) to platelet ratio index (APRI), fibrosis-4 index (FIB-4), body mass index (BMI), AST/alanine aminotransferase (ALT) ratio, diabetes score (BARD), and NAFLD fibrosis score (NFS). Most of them have been tested in subjects with NAFLD, showing great diagnostic accuracy in predicting fibrosis[10-13].

Metabolic associated fatty liver disease (MAFLD) is a recently proposed concept to replace NAFLD[14]. Significantly different from NAFLD, the MAFLD definition does not require the exclusion of any chronic liver diseases; however, the presence of metabolic associated disease or dysfunction is required[15,16]. It is known that metabolic profiles are associated with a risk for severe fibrosis in patients with NAFLD [17]. The MAFLD population has been found to have higher non-fibrosis scores than

NAFLD individuals[18]. Thus, in the light of the new concept of MAFLD, which incorporates metabolic disorder, the performance of these non-invasive models requires re-evaluation and further validation. This study aimed to evaluate the utility of conventional non-invasive scoring systems in MAFLD.

MATERIALS AND METHODS

Ethics

The study protocol was approved by the Institutional Review Board of the First Affiliated Hospital of Fujian Medical University and was in accordance with the Declaration of Helsinki. Written consent forms were obtained from all patients. The data was anonymized prior to the analysis.

Patients

Consecutive patients with histologically confirmed MAFLD admitted to the First Affiliated Hospital of Fujian Medical University from 2005 to 2015 were retrospectively analyzed in this study.

Histologic evaluation

All patients enrolled in this study underwent percutaneous liver biopsy under ultrasonic guidance. The liver specimens were fixed in formalin, embedded in paraffin, and stained with hematoxylin and eosin and Masson's trichrome. The minimum biopsy length was 15 mm, and at least six portal areas were required[19]. Histopathological slides were reviewed independently by two pathologists experienced in reading liver histopathology slides and were blinded to the patient's clinical data.

Fatty liver was defined as the presence of steatosis in at least 5% of hepatocytes. The liver fibrosis was graded as 0 to 4 points according to the Metavir fibrosis stage[20], where 0 = absence of fibrosis; 1 = perisinusoidal or periportal; 2 = perisinusoidal and portal/periportal; 3 = bridging fibrosis; 4 = cirrhosis. Advanced fibrosis was defined as stage 3 or 4 fibrosis (bridging fibrosis or cirrhosis).

Diagnosis of MAFLD

The diagnosis of MAFLD was based on the following criteria[15]: A histological evidence of hepatic steatosis and the presence of one of the following three conditions: BMI ≥ 23 kg/m^2, presence of type 2 diabetes mellitus, or evidence of metabolic dysregulation. The metabolic dysregulation was defined by the presence of at least two of the following conditions: (1) Waist circumference ≥ 90 cm in men and 80 cm in women; (2) Blood pressure ≥ 130/85 mmHg or specific drug treatment; (3) Plasma triglycerides ≥ 1.70 mmol/L or specific drug treatment; (4) Plasma high-density lipoprotein cholesterol < 1.0 mmol/L for men and < 1.3 mmol/L for women or specific drug treatment; (5) Prediabetes (*i.e.* fasting glucose levels 5.6-6.9 mmol/L or 2 h post-load glucose levels 7.8-11.0 mmol/L or glycated hemoglobin 5.7%-6.4%; (6) Homeostasis model assessment-insulin resistance score ≥ 2.5; and (7) Plasma high-sensitivity C-reactive protein level > 2 mg/L.

According to the result of hepatitis B surface antigen (HBsAg) seropositivity, patients were divided into pure MAFLD group (HBsAg negative) and hepatitis B virus (HBV)-MAFLD group (HBsAg positive for > 6 mo) for the purpose of subgroup analysis.

Demographic and laboratory evaluation

The following data were collected at the time of biopsy from all patients: age, gender, BMI, waist circumference, history of diabetes, and hypertension. Laboratory parameters were as follows: Blood cell count, AST, ALT, γ-glutamyl transpeptidase, albumin, globulin, bilirubin, fasting plasma glucose, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglyceride, urea, creatinine, uric acid, fasting insulin, glycated hemoglobin, high-sensitivity C-reactive protein, and HBsAg.

All biochemical assessments were performed by standard laboratory methods. Non-invasive liver fibrosis assessment scores included APRI, FIB-4, BARD, and NFS, which were calculated based on previously published formulas as shown in Table 1[10,12,21,22].

Table 1 An overview of formulas and cutoffs for determining non-invasive marker panels for detection of liver fibrosis[10-12,21,22]

Formula	Equation	Lower cutoff	Higher cutoff
FIB-4	[Age (yr) × AST (IU/L)]/{platelet count (10^9/L) × [ALT(IU/L)]$^{1/2}$}	1.3	2.67[11]
		1.45	3.25[22]
APRI	[(AST/ULN)/platelet count (10^9/L)] × 100	0.5	1.5[21]
NFS	-1.675 + 0.037 × age (yr) + 0.094 × BMI (kg/m^2) + 1.13 × IFG/diabetes (yes = 1, no = 0) + 0.99 × AST/ALT-0.013 × platelet count (× 10^9/L) - 0.66 × albumin (g/dL)	-0.676	1.455[10]
BARD	Scale 0-4; BMI ≥ 28 kg/m^2 = 1 point; AST/ALT ≥ 0.8 = 2 points; Diabetes = 1 point	2[12]	

ALT: Alanine aminotransferase; APRI: Aspartate aminotransferase to platelet ratio index; AST: Aspartate aminotransferase; BARD: Body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score; BMI: Body mass index; FIB-4: Fibrosis-4 index; IFG: Impaired fasting glucose; NFS: Nonalcoholic fatty liver disease fibrosis score; ULN: Upper limit of normal.

Statistical analysis

Continuous variables are expressed as mean ± SD or median (interquartile range) and were compared using Student's *t* test in the case of normally distributed data or Mann-Whitney test in the remaining cases. Categorical variables are expressed as counts (percentages) and evaluated by χ^2 test or the Fisher's exact test. The diagnostic accuracy of conventional non-invasive scoring systems was evaluated by the receiver operating characteristic (ROC) curve. The best cut-off values to determine the presence of advanced fibrosis were chosen based on Youden's index. The discrimination ability of the different models was compared using area under ROC curve (AUROC), positive predictive value (PPV), negative predictive value (NPV), sensitivity, specificity, and accuracy. Statistical analyses were performed using the SPSS software, version 18.0 (SPSS, Chicago, IL, United States) and MedCalc software version 15.2.2 (MedCalc Software, Mariakerke, Belgium). A P value < 0.05 was considered statistically significant.

RESULTS

Baseline characteristics of the patients

A total of 417 patients with biopsy-proven MAFLD were included in this study (Figure 1). All patients were treatment-naïve and did not receive nucleosides analogue treatment before biopsy. The mean age was 40.54 ± 10.95 years, and the BMI was 25.48 ± 2.66 kg/m^2. Of them, 354 (84.9%) were male, 82 (19.7%) had type 2 diabetes mellitus, 42 (10.1%) had hypertension, and 156 (37.4%) had advanced fibrosis (Table 2). Liver histological examination showed that 272 (76.0%) HBV-MAFLD patients had significant inflammation (grade ≥ 2). Antiviral therapy was initiated when chronic hepatitis B was diagnosed with the presence of significant inflammation (grade ≥ 2) or significant liver fibrosis (stage ≥ 2). Patients with advanced fibrosis were significantly older and had higher AST and lower albumin, triglyceride, and platelet counts. In addition, the FIB-4 (P < 0.001), NFS (P < 0.001), APRI (P = 0.003) and BARD (P < 0.001) scores were all significantly higher in patients with advanced fibrosis compared with patients with no/mild fibrosis.

Performance of FIB-4, NFS, APRI, and BARD for advanced fibrosis in MAFLD

The ROC curves were used to evaluate the utility of non-invasive scoring systems to identify advanced fibrosis (Figure 2). The AUROC was greatest for FIB-4 [0.736; 95% confidence interval (CI): 0.691-0.778] followed by NFS (0.724; 95%CI: 0.679-0.767), APRI (0.671; 95%CI: 0.623-0.715), and BARD (0.609; 95%CI: 0.560-0.656). The comparison between AUROCs showed that the discrimination abilities of FIB-4 and NFS were similar (P = 0.523). Similar results were also noted in NFS and APRI (P = 0.080). The differences between FIB-4 and APRI (P = 0.001), FIB-4 and BARD (P < 0.001), as well as NFS and BARD (P < 0.001) were statistically significant.

Table 3 summarizes the best cutoff values developed for prediction of advanced fibrosis by the four non-invasive models and the validation of previously reported cutoffs (for NAFLD) in this MAFLD cohort[10-12,21,22]. The best cutoff scores of FIB-4,

ALB: Albumin; ALT: Alanine aminotransferase; APRI: Aspartate aminotransferase to platelet ratio index; AST: Aspartate aminotransferase; BARD: Body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score; BMI: Body mass index; Cr: Creatinine; FIB-4: Fibrosis-4 index; FPG: Fasting plasma glucose; GGT: γ-Glutamyl transpeptidase; GLO: Globulin; HDL-C: High-density lipoprotein cholesterol; NFS: Non-alcoholic fatty liver disease fibrosis score; PLT: Platelet; TG: Triglyceride; UA: Uric acid.

APRI, NFS, and BARD for the diagnosis of advanced fibrosis in MAFLD were 1.05, 0.42, -2.1, and 2, respectively. Most cutoff scores were lower than the prior reported thresholds for each model. Using the newly developed thresholds, the sensitivity, specificity, PPV, and NPV of the above four models ranged from 41.7%-81.4%, 44.4%-78.2%, 46.7%-55.8%, and 69.2%-80.0%, respectively (Table 3).

With the previously reported cutoff value of 1.30 (lower) and 2.67 (higher) of FIB-4 for advanced fibrosis, the PPV was only 57.3% and 69.2%, and the NPV was 74.6% and 65.9%, respectively. Similar results were found for the NFS score; the PPV and NPV of the well-accepted threshold (-1.455) were only 56.0% and 70.6% (Table 3).

The accuracy of the FIB-4 and NFS scores, irrespective of the numerical value of cutoff used, was only 63.8%-68.8%. The accuracy was even lower for APRI and BARD (58.3%-64.5%). On the other hand, 20%-35% patients with biopsy-proven advanced fibrosis were misdiagnosed as no advanced fibrosis by these four scores (Table 3).

Performance of the non-invasive scores in HBV-MAFLD and pure MAFLD subgroups

According to the result of HBsAg, patients were divided into HBV-MAFLD (359, 86.1%) and pure MAFLD (58, 13.9%) subgroups. The difference in the baseline characteristics between HBV-MAFLD and pure MAFLD had been presented in our previous

Best cutoff value in bold.

[1]The percentage was calculated as the number of advanced fibrosis being missed diagnosed/the number of patients who were diagnosed as no advanced fibrosis by the non-invasive score × 100%. APRI: Aspartate aminotransferase to platelet ratio index; AUROC: Area under the receiver operating characteristic curve; BARD: Body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score; FIB-4: Fibrosis-4 index; NFS: Nonalcoholic fatty liver disease fibrosis score; NPV: Negative predictive value; PPV: Positive predictive value.

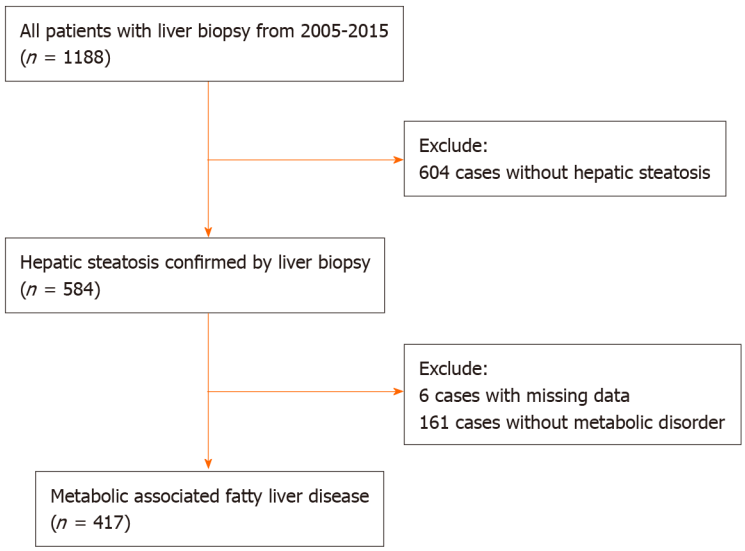

Figure 1 Flow chart of case selection.

work[23] and is shown in Supplementary Table 1. Briefly, the HBV-MAFLD group had higher ALT (135.82 ± 210.31 U/L *vs* 119.76 ± 118.19 U/L) and AST (71.70 ± 88.63 U/L *vs* 65.55 ± 63.28 U/L) levels and lower platelet (198.59 ± 60.33) × 10^9/L *vs* (237.47 ± 76.97) × 10^9/L levels than the pure MAFLD group. The AUROCs of FIB-4, NFS, and APRI in the HBV-MAFLD group was 0.738, 0.725, and 0.671, respectively, which were all higher than in the pure MAFLD group (FIB-4 0.658, NFS 0.692, and APRI 0.633). The AUROC of BARD was lower in the HBV-MAFLD group than in the pure MAFLD group (0.609 *vs* 0.644). Using different thresholds mentioned above, the overall performance of the FIB-4, APRI, and NFS, including sensitivity, specificity, PPV and

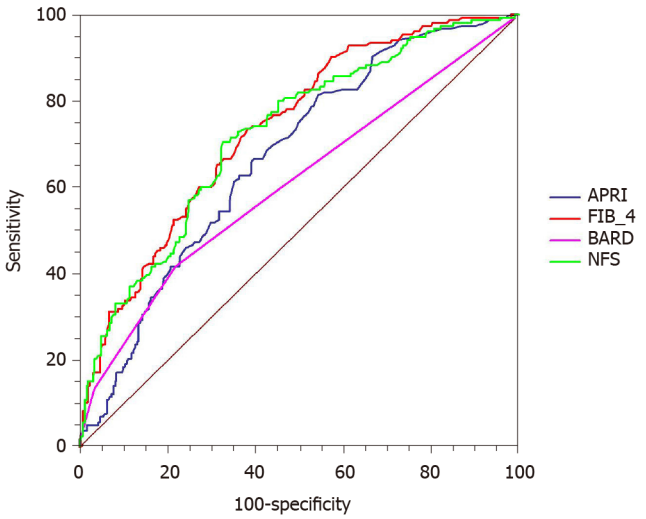

Figure 2 Receiver operating characteristic curves of different scores for advanced fibrosis. APRI: Aspartate aminotransferase to platelet ratio index; FIB-4: Fibrosis-4 index; NFS: Nonalcoholic fatty liver disease fibrosis score.

NPV, was better in the HBV-MAFLD group. The BARD score performed better in the pure MAFLD population (Table 4).

DISCUSSION

Non-invasive scoring systems are widely used to identify or exclude advanced fibrosis in patients with chronic liver disease. The main finding of our study is that FIB-4 and NFS performed better than APRI and BARD in MAFLD patients. These scores are more useful in HBV-MAFLD than in pure MAFLD population. However, the performance of all above models was not as good as previously reported in NAFLD.

The non-invasive fibrosis scoring systems are derived from widely available clinical, laboratory, and anthropometric parameters. Although the APRI and BARD scores are more user-friendly, their discrimination ability in prediction of advanced fibrosis is not satisfactory in this group of MAFLD patients. The AUROC of BARD was 0.609, and the accuracy was less than 65%. It is not a surprising result as the two variables for calculating BARD score (BMI and diabetes) were also variables for the diagnosis of MAFLD. This led to lower sensitivity and higher false positivity for detecting advanced fibrosis in MAFLD patients, thus the BARD score should not be recommended for MAFLD patients in clinical practice. Although APRI score was easy to calculate, it did not perform well in MAFLD as well. The NPV did not exceed 80%, and the PPV was only around 50% at any cutoff value tested. Thus, APRI should not be used for assessment of advanced fibrosis in the MAFLD population either.

The calculations of FIB-4 and NFS require the use of more complex formulas and may not be easy to use. Even though the results of our study indicate that both FIB-4 and NFS significantly outperform APRI and BARD for the prediction of advanced fibrosis in MAFLD, the NPV and PPV of these two models did not reach the similar values reported by previous studies using the cohort of NAFLD patients[10,11,24]. According to the previously reported studies on patients with NAFLD[10,11,24], when the cutoff of the FIB-4 and NFS was set at 1.3 and -1.455, respectively, the NPV increased from 90% to 93%. When the cutoff of the FIB-4 was set at 2.67, the PPV could reach 80%. However, in our cohort of MAFLD patients, by using the aforementioned cutoffs, or the new threshold found in the present study, the NPV did not exceed 75%, and PPV did not exceed 70%. This finding is of utmost clinical importance and indicates that in the light of the new concept of MAFLD, newer non-invasive fibrosis scores need to be developed and validated to assess the presence of advanced fibrosis in patients with MAFLD. Another worrying yet important finding of our study is that the use of these non-invasive fibrosis scores, even with the new cutoffs, led to a misdiagnosis of no advanced fibrosis in 20%-35% of the patients in this cohort (Table 3) when the histology actually showed the presence of advanced fibrosis.

The occurrence of HBV infection and fatty liver disease is frequently seen in Asian countries[25]. As our cohort consisted of 359 (86.1%) patients with chronic HBV

Table 4 Comparison of the diagnostic value among fibrosis-4 index, non-alcoholic fatty liver disease fibrosis score, aspartate aminotransferase to platelet ratio index, and body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score in hepatitis B virus-metabolic associated fatty liver disease (group A) and pure metabolic associated fatty liver disease (group B) subgroups

APRI: Aspartate aminotransferase to platelet ratio index; AUROC: Area under the receiver operating characteristic curve; BARD: Body mass index, aspartate aminotransferase/alanine aminotransferase ratio, diabetes score; FIB-4: Fibrosis-4 index; NFS: Non-alcoholic fatty liver disease fibrosis score; NPV: Negative predictive value; PPV: Positive predictive value.

infection, we performed a subgroup analysis to test the performance of the non-invasive scores in a pure MAFLD group, which is very close to previous NAFLD and HBV-MAFLD group. Three of the four non-invasive models (FIB-4, NFS, and APRI) performed even worse in the pure MAFLD group than in the HBV-MAFLD group. We speculate that the higher levels of ALT and AST and lower platelets in HBV-MAFLD might result in higher scores of the non-invasive models and make them easier to discriminate the advanced fibrosis. As MAFLD is a new entity, this result further reinforces the need to develop and validate novel scoring systems for fibrosis in the MAFLD population.

The strength of our study is that, to our knowledge, this is the first validation of conventional non-invasive fibrosis scoring systems in a large sample of histology-proven MAFLD. However, this study has some limitations. Firstly, a large proportion of included patients (86%) had concomitant chronic HBV infection, which could be a potential limitation as the western MAFLD population differs substantially from Asia's population in the HBsAg seropositivity rates, the results may only be applicable to a subset of the entire MAFLD pool namely HBV-MAFLD, which is the most important subtype of MAFLD in clinical practice in Asia. Secondly, as our study is a single-center study with only an Asian population, the findings will need further validation in other Asian and western cohorts.

CONCLUSION

APRI and BARD scores do not perform well and are not suitable for the diagnosis of advanced fibrosis in MAFLD. The FIB-4 and NFS could be more useful, and we propose a new threshold of 1.05 and -2.1, respectively, which had the best diagnostic performance for advanced fibrosis. There is an urgent need of a novel non-invasive scoring system for predicting advanced fibrosis in patients with MAFLD including its subtypes.

ARTICLE HIGHLIGHTS

Research background

Metabolic associated fatty liver disease (MAFLD) is a new concept proposed in 2020. The clinical features of MAFLD would be different from nonalcoholic fatty liver disease.

Research motivation

Non-invasive fibrosis scores have been tested in subjects with nonalcoholic fatty liver disease showing great diagnostic accuracy in predicting fibrosis. But the utility of non-invasive fibrosis scores, as well as their optimal thresholds, needs re-evaluation in MAFLD.

Research objectives

This study aimed to evaluate the diagnostic performance of four non-invasive scores including aspartate aminotransferase to platelet ratio index (APRI), fibrosis-4 index (FIB-4), body mass index, aspartate aminotransferase/alanine aminotransferase ratio, and diabetes score (BARD), and nonalcoholic fatty liver disease fibrosis score (NFS) in patients with MAFLD.

Research methods

Consecutive patients with histologically-confirmed MAFLD admitted to a single medical center were included. The discrimination ability of different non-invasive scores was compared.

Research results

A total of 417 patients were included; 156 (37.4%) of them had advanced fibrosis. The area under receiver operating characteristic curve of FIB-4, NFS, APRI, and BARD for predicting advanced fibrosis were 0.736, 0.724, 0.671, and 0.609, respectively. The area under receiver operating characteristic curve of FIB-4 and NFS was similar (P = 0.523), while the difference between FIB-4 and APRI (P = 0.001) and FIB-4 and BARD (P < 0.001) was statistically significant. The best thresholds of FIB-4, NFS, APRI, and BARD for diagnosis of advanced fibrosis in MAFLD were 1.05, -2.1, 0.42, and 2, respectively. A subgroup analysis showed that FIB-4, APRI, and NFS performed worse in the pure MAFLD group than the HBV-MAFLD group.

Research conclusions

APRI and BARD scores do not perform well in MAFLD. The FIB-4 and NFS could be more useful, but a new threshold is needed.

Research perspectives

MAFLD is a new entity. The results of this study indicate the conventional scores may lead to misdiagnosis, and the development of novel scoring systems to assess fibrosis in the MAFLD population is urgently needed.

Abstract

BACKGROUND

Gastric cancer remains a leading cause of cancer death worldwide. In Taiwan, gastric cancer is the sixth leading cause of cancer mortality in both males and females.

AIM

To evaluate secular trends in gastric cancer incidence according to age, sex, and *Helicobacter pylori* (*H. pylori*) treatment in Taiwan.

METHODS

In this population-based study, we used the national Taiwan Cancer Registry database. Annual percent changes in incidence rates were used to describe secular trends in incidence rates and sex ratios of gastric cancer in Taiwan. Pearson's product-moment correlation coefficients were used to analyze the correlation between annual age-adjusted incidence rates and the annual number of patients treated with antibiotic therapy for *H. pylori* infection.

RESULTS

The annual percent changes showed continuously decreasing rates of gastric

cancer among both males and females. However, the decreasing trends differed by sex, with an annual percent change of -2.58% in males and -2.14% in females. The age-specific incidence rates increased with age. Within the same age group, more recent time periods showed lower incidence rates than greater time periods. Similarly, the sex ratio was lower in later birth cohorts than in earlier birth cohorts. Age-adjusted incidence rates substantially decreased with increasing numbers of patients being treated with antibiotic therapy for *H. pylori* infection during 2005 to 2016 (r = 0.72).

CONCLUSION

We observed steadily decreasing trends with differential sex ratios in the incidence of gastric cancer in Taiwan. These results support *H. pylori* eradication programs in Taiwan.

Key Words: Gastric cancer; Population-based study; Taiwan Cancer Registry; Sex difference; *Helicobacter pylori*; *Helicobacter pylori* eradication

INTRODUCTION

Gastric cancer is one of the leading causes of cancer death worldwide. Data from GLOBOCAN 2020 shows an age-standardized incidence rate of gastric cancer of 15.8 per 100000 persons for males and 7.0 per 100000 persons for females, with a mortality rate of 11.0 per 100000 persons in males and 4.9 per 100000 persons in females[1]. In Taiwan, gastric cancer was the sixth leading cause of cancer death for both males and females in 2018[2].

Gastric cancer is a multifactorial disease; its risk factors include alcohol drinking, tobacco smoking, gastric ulcer, and atrophic gastritis, whereas the intake of fresh fruits and vegetables is probably protective[3]. A previous study demonstrated that anti-*Helicobacter pylori* (*H. pylori*) treatment has the potential to decrease the risk of gastric cancer[4]. Moreover, a study by Chiang *et al*[5] showed that the effectiveness of *H. pylori* eradication in reducing gastric cancer incidence and mortality was 53% [95% confidence interval (CI): 30% to 69%, P < 0.001] and 25% (95%CI: -14% to 51%, P = 0.18), respectively. This study aimed to investigate secular trends in the incidence of gastric cancer and its association with *H. pylori* eradication programs in Taiwan.

population-based Taiwan Cancer Registry (TCR) database. The TCR database has been collecting data on newly diagnosed cancer cases since 1979. The TCR's accuracy was such that the percentage of death certificate only cases was 0.91%, and the proportion of morphologically verified cases reached 92.23%[6]. In addition, the completeness of the TCR database was reported to be 98.44% in 2016[6]. All cases of primary gastric cancer in this analysis were classified based on the International Classification of Diseases for Oncology, third edition (codes C16.0–C16.9)[7]. We identified subjects who received anti-*H. pylori* treatment from 2005 to 2016, based on Anatomical Therapeutic Chemical Classification codes from Taiwan's National Health Insurance Research Database, which included treatment with clarithromycin, amoxicillin, metronidazole, and tetracycline[8].

Statistical analysis

Age-specific and age-adjusted incidence rates per 100000 person-years were calculated according to the 2000 World Health Organization standard population[9]. The incidence data were divided into ten 5-year age groups (25-29, 30-34, 35-39, 40-44, 45-49, 50-54, 55-59, 60-64, 65-69, and 70-74) and seven 5-year time periods. Birth cohorts were divided into five 10-year age groups (25-34, 35-44, 45-54, 55-64, and 65-74). We calculated age-adjusted incidence rates for the period from 1979 to 2016 and age-specific incidence rates for the period from 1981 to 2015, for birth cohorts representing the years 1906 to 2005.

To describe linear trends by time period, we computed the annual percent change (APC) in incidence rate and tested whether the corresponding changes in rates were significant. We also used the Pearson's product-moment correlation coefficient to analyze the correlation between the annual age-adjusted incidence rate and the annual number of patients treated with antibiotic therapy for *H. pylori* infection. The research protocol was approved by the Institutional Review Board of Fu-Jen Catholic University (C107034).

RESULTS

Age-adjusted incidence rates

The age-adjusted incidence rates of gastric cancer show that rates for males were volatile between the years of 1981 to 2002 but steadily decreased from 2002 to 2016, with an average APC (AAPC) of -2.58% (Figure 1). However, the incidence rates for females slightly increased between the years of 1979 to 1997 and then gradually decreased from 1997 to 2016, with an AAPC of -2.14% (Figure 1).

Age-specific incidence rates

Looking at age-specific incidence rates by sex for the years of 1981 to 2015, we found that age-specific incidence rates of gastric cancer increased with age, with the highest incidence rate occurring among the oldest age group across all time periods (Figure 2). Among the same age group, more recent time periods showed lower incidence rates than earlier time periods. For example, among males aged 60-64 years, the incidence rate per 100000 persons during 2011-2015 was 44.42, which was lower than the incidence rate for 1996-2000, which had an incidence rate of 62.41. Moreover, among the same age group, the decreasing trend in age-specific incidence was more evident in males than in females (Figure 2).

The age-specific incidence rates by birth cohort for both males and females are shown in Figure 3. In both males and females, older birth cohorts had higher incidence rates than younger birth cohorts within the same age group. Moreover, among the same birth cohort, incidence rates increased more significantly by age in males than in females (Figure 3).

Sex ratios of age-adjusted incidence rates

We also found that the sex ratios of age-adjusted incidence rates decreased from 1981 to 2016 (Figure 4A). Males had higher age-adjusted incidence rates than females, with sex ratios ranging from 2.5 in 1979 to 1.9 in 2016, with an AAPC of -0.67% during the study period. During time periods prior to 1990, age-specific sex ratios were higher in older age groups, whereas the sex ratios were more consistent during time periods after 1996 (Figure 4B). Sex ratios of age-specific incidence rates by birth cohort showed that among the same age group, sex ratios were higher in earlier birth cohorts than in later birth cohorts. Whereas the sex ratios were close to 1 in the 35-44 age group, the

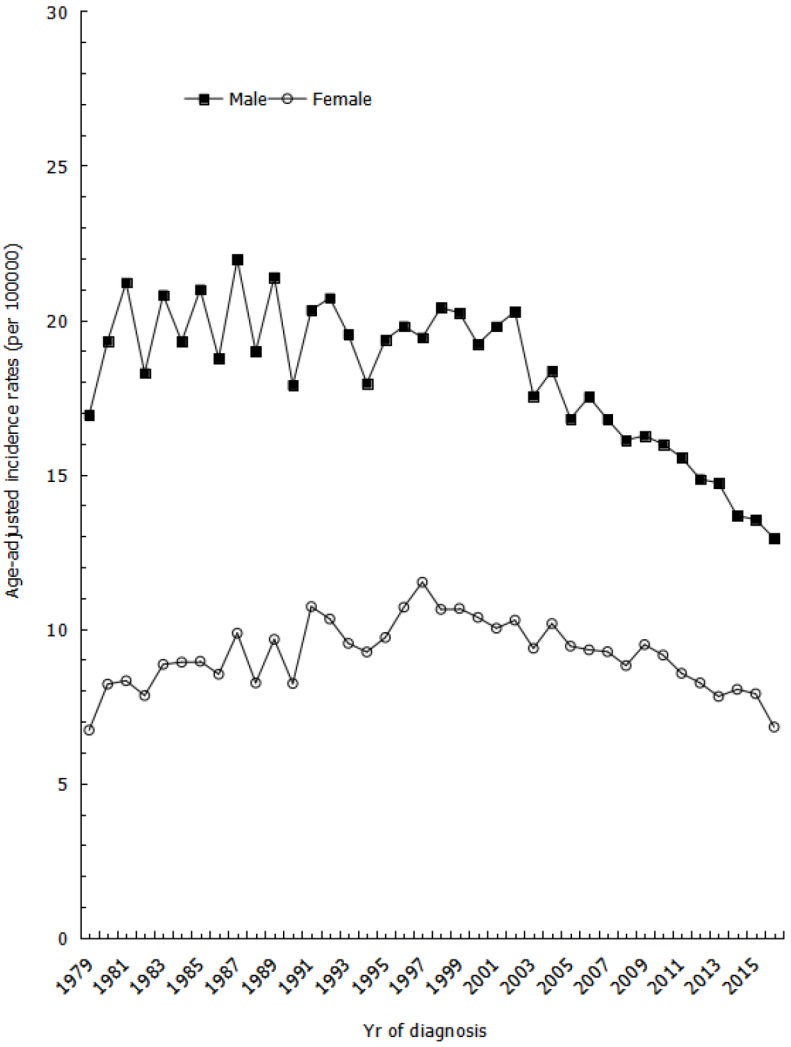

Figure 1 Secular trends in age-adjusted incidence rates of gastric cancer in Taiwan. 1979-2016, showing steadily decreasing rates in males from 2002 to 2016, with an Average Annual Percent Change (AAPC) of -2.58%, and gradually decreasing rates in females from 1997 to 2016, with an AAPC of -2.14%.

sex ratios were all less than 1 in the 25-34 age group (Figure 4C).

Association with H. pylori treatment

Furthermore, we also investigated the association between gastric cancer incidence and *H. pylori* treatment (Figure 5). During 2005 to 2016, the age-adjusted incidence rates decreased substantially along with increasing numbers of patients newly treated with antibiotic therapy for *H. pylori* infection (r = 0.72).

DISCUSSION

This population-based study found an overall secular trend of declining gastric cancer incidence in Taiwan from 1979 to 2016. Age-adjusted incidence rates decreased after 2002, with a statistically significant trend in both males and females; although, our results were slightly lower than estimates from other East Asian countries in terms of proportion changes. For example, one study from Japan found a decreasing trend with an AAPC of -1.4%, while another study from China found an AAPC of -3.7%[10]. Meanwhile, Taiwan showed an AAPC in incidence rate of -1.62% from 1996 to 2013 [11]. The downward trend in incidence was greater in males during earlier years, but this difference has since diminished in recent years. Furthermore, the downward trend observed from 2002 to 2016 was higher in males than in females, with an AAPC of -2.59% in males and -2.40% in females. Our proportion changes were slightly lower than estimates from other Asian countries, as shown in a study by Bertuccio *et al*[12]. One possible reason for the discrepancy may be that our study period began in the 1980s, after the incidence of gastric cancer had already been steadily declining for

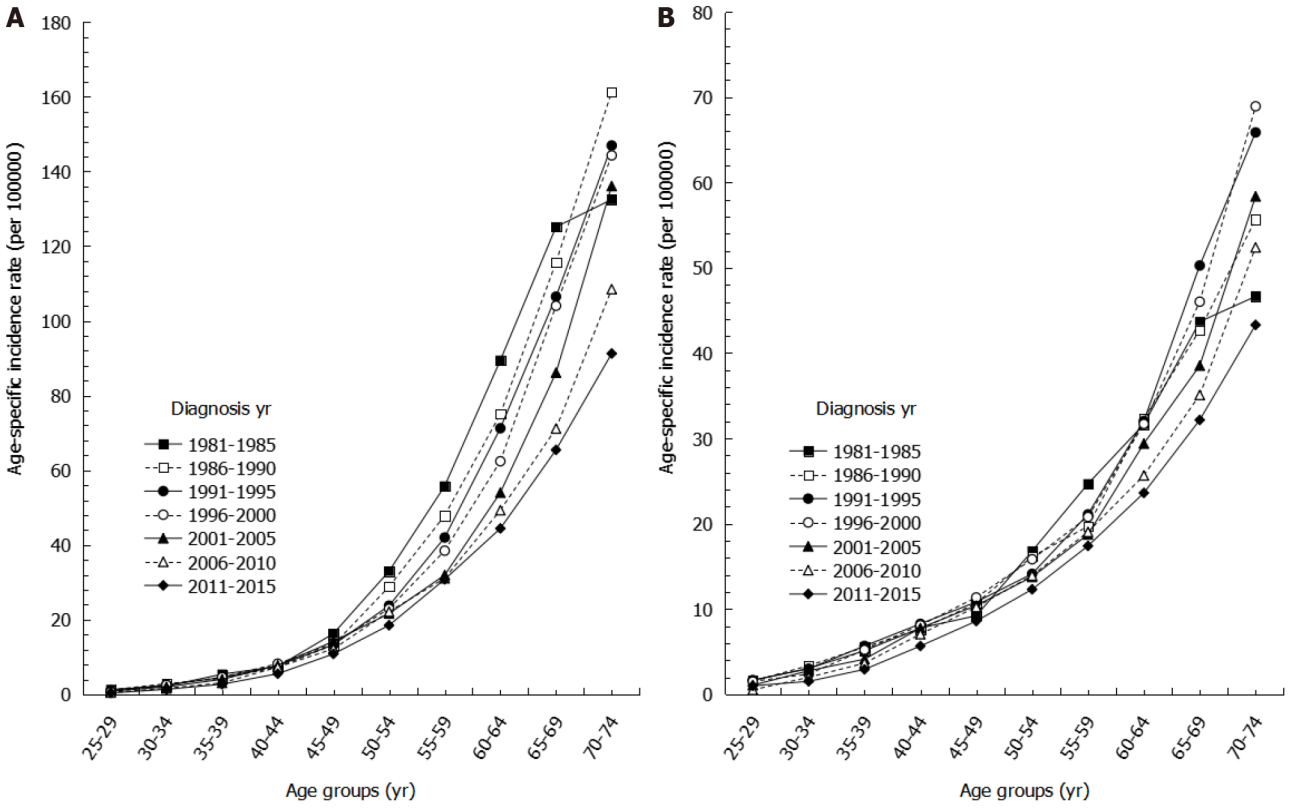

Figure 2 Age-specific incidence rates of gastric cancer in Taiwan by time period during 1981-2015. A: Among males; B: Females, showing lower incidence rates in more recent time periods than in earlier time periods. The decreasing trend was more evident in males than in females.

several decades.

As the development of gastric cancer is a multistage process arising from different risk factors, the decline in incidence rates in Taiwan may be attributable to the following reasons. First, the Taiwanese government launched an *H. pylori* eradication program in 1997[13]. Although anti-*H. pylori* treatments started in 1997, the number of patients treated with antibiotic therapy was unstable during the first decade. Therefore, we show results ranging from 2005 to 2016, which show a strong association between the number of patients treated with *H. pylori* treatment and age-adjusted incidence rates (r = 0.72) (Figure 5).

Several clinical studies have demonstrated the prophylactic role of *H. pylori*-eradication in the prevention of gastric cancer. For instance, in a Swedish study[14] of 39154 patients undergoing hip replacement, prophylactic antibiotic treatment conferred a reduction in gastric cancer risk after 5 years (odds ratio: 0.6; 95%CI: 0.3 to 1.2). In addition, another Japanese study reported that *H. pylori* eradication inhibited the development of gastric cancer after endoscopic resection during a follow-up period of 3 years[15]. Ever since the government approved *H. pylori* eradication, there has been a decreasing trend in peptic ulcers in Taiwan[13,16]. The mass eradication of *H. pylori* infection was launched in 2004 among a high-risk Taiwanese population with prevalent *H. pylori* infection that were living on the Matsu Islands, and continued until 2018. As a result of this effort, the prevalence rates of *H. pylori* decreased from 64.2% to 15.0%, with reinfection rates of less than 1% per person-year[5]. In one Taiwanese study of 80255 peptic ulcer patients, early *H. pylori* eradication conferred a reduction in early gastric cancer risk (hazard ratio: 0.77)[17]. In addition, this study also showed that early *H. pylori* eradication reduced the standardized incidence ratio of gastric cancer from 1.60 to 1.05 (95%CI: 0.96 to 1.14). Together with results from these studies, our findings provide supportive evidence that the eradication of *H. pylori* infection may be associated with a substantial reduction in gastric cancer incidence.

Second, dietary and lifestyle habits in Taiwan have improved in the past few decades. Earlier studies showed that the consumption of foods containing nitrosamine [18] and cigarette smoking[19] were risk factors for gastric cancer. However, the increased use of refrigerators as a method of food preservation led to a decreased consumption of preserved foods containing nitrosamine and provided the constant availability of fresh food[20]. In Taiwan, a national public survey claimed that the

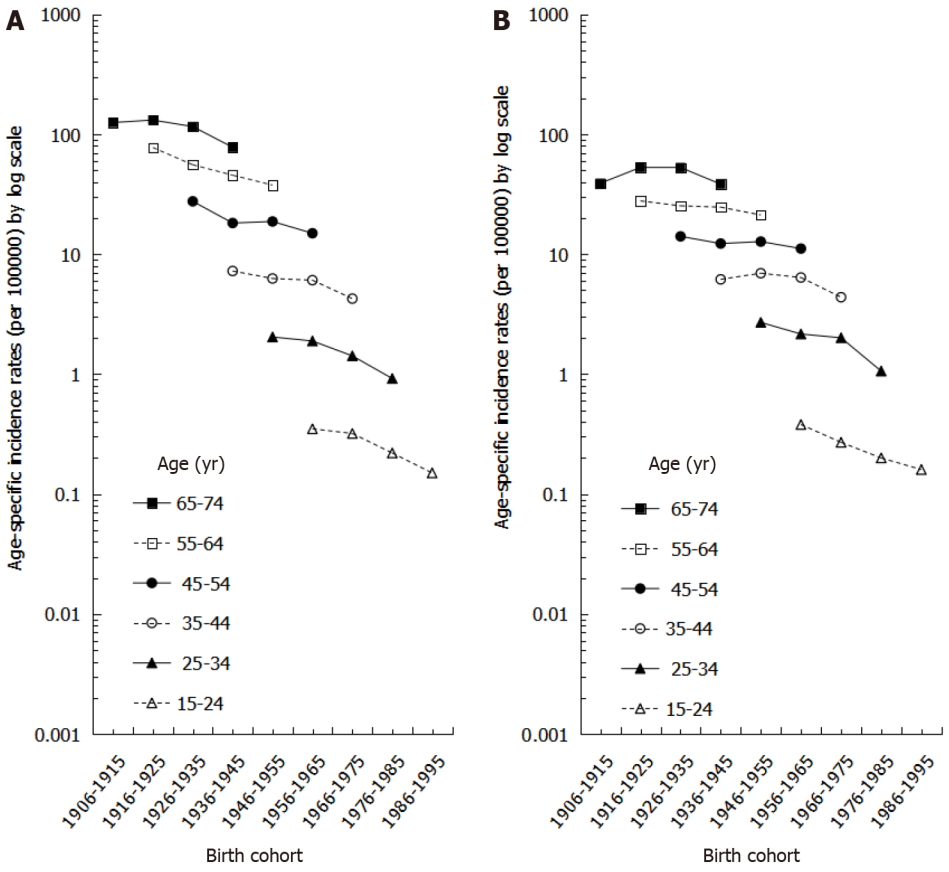

Figure 3 Age-specific incidence rates of gastric cancer in Taiwan by birth cohort during 1906-2005. A: Among males; B: Females, showing higher incidence rates in older birth cohorts than in younger birth cohorts within the same age group. Within the same birth cohort, incidence rates increased by age more evidently in males than in females.

popularization rate of refrigerators was approximately 99.14% in 1991 compared to a popularization rate of only 74.19% in 1976, with 3.6% of families even owning two refrigerators[21]. In regard to cigarette smoking, the Tobacco Hazards Prevention Act was implemented in January 2009, and the prevalence of smoking in adults over 40 years of age dropped from 12.25% in 2001 to 8.18% in 2013[22].

Our age-adjusted incidence rates were slightly lower than estimates from other East Asian countries in terms of proportion change. The reason may be that there has been no evident decline in alcohol consumption, another known risk factor for gastric cancer[23]. Surveys in Taiwan showed that the prevalence of alcohol drinking among males was 38.2% in 2001 and 24.2% in 2013, while the prevalence among females was 9.2% in 2001 and 9.3% in 2013[24]. Furthermore, obesity is also associated with an increased risk of gastric cancer[25-27]. The body mass index of the Taiwanese population has increased over time. The prevalence of having a body mass index ≥ 24 kg/m^2 among males rose from 33.4% during 1993-1996 to 52.1% during 2013-2016 and among females, rose from 33.0% during 1993-1996 to 37.4% during 2013-2016[28].

We also showed a steady decrease in sex ratios. In our results examining sex ratios by birth cohort, younger age groups had lower sex ratios, especially in the 25-34 age group, which had a ratio lower than 1, indicating that males accounted for a lower incidence of gastric cancer. The trends in sex ratios by birth cohort are similar to the intestinal type of gastric cancer based on histopathology and non-cardia site based on anatomic site[29]. We speculate that the decreasing trend in gastric cancer may be mainly attributed to declines in the intestinal type histology because the intestinal type of gastric cancer affects males and older age groups more frequently[30], leading to a greater decrease in incidence among males than among females. Furthermore, the dominant risk factors for gastric cancer, especially for non-cardia cancer, are diet, cigarette smoking, and *H. pylori* infection, whereas the risk factors for cardia cancer are obesity, gastroesophageal reflux, and Barrett's esophagus[31]. This may explain why the corresponding decrease in Taiwan is mainly in non-cardia gastric cancer, as the prevalence of risk factors such as poor diet, smoking, and *H. Pylori* infection are decreasing in Taiwan.

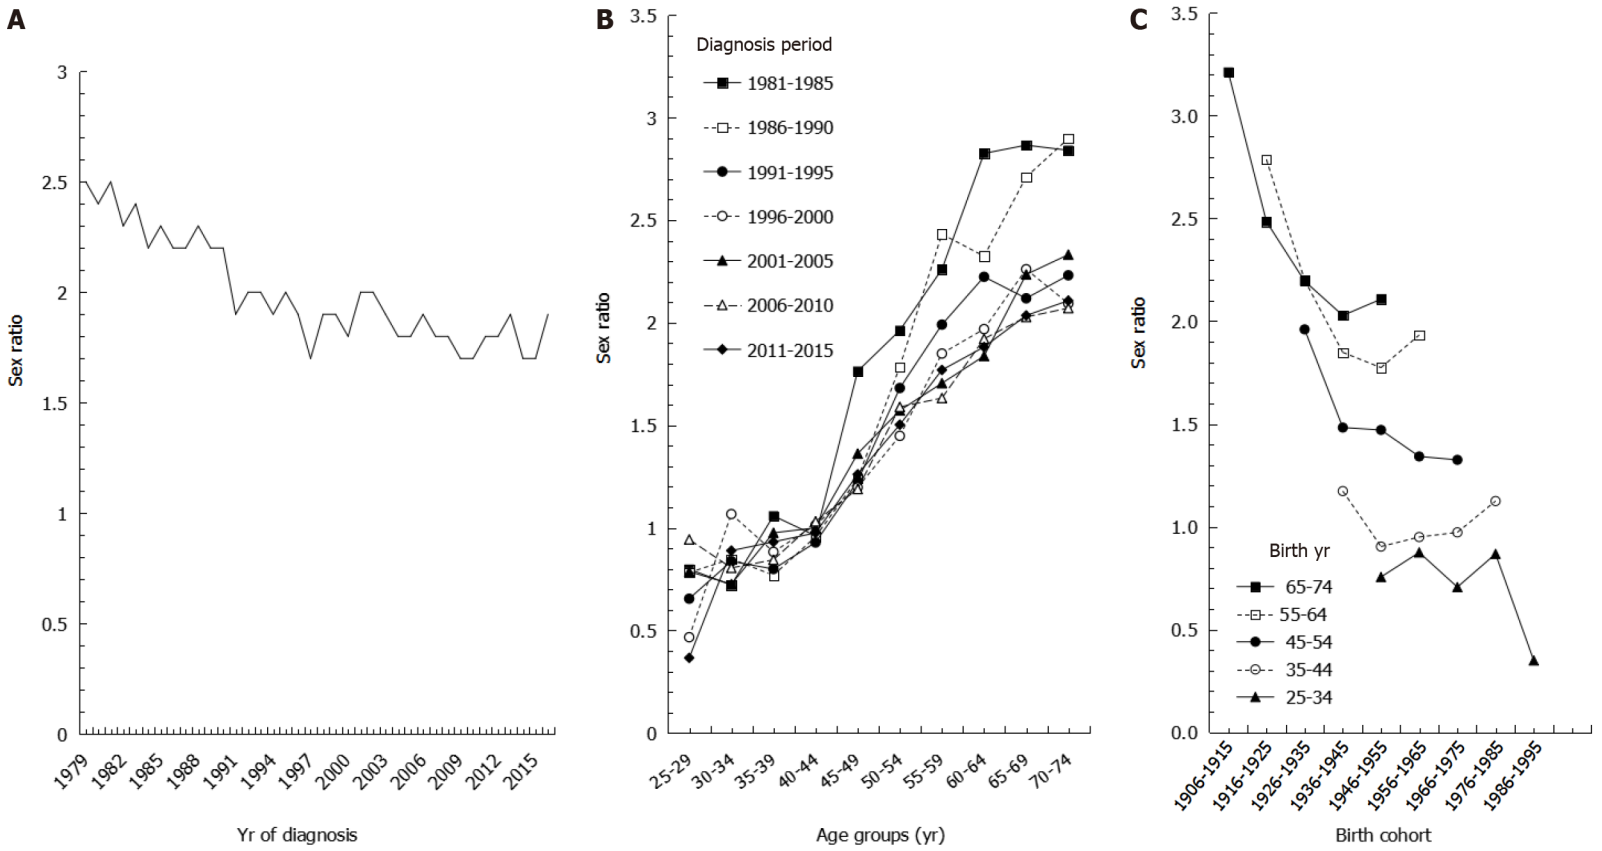

Figure 4 Sex ratios of gastric cancer in Taiwan during 1979-2016. A: Decreasing trends in age-adjusted incidence rates; B: Sex ratios by time period, showing a more consistent trend after 1996; C: Sex ratios in earlier birth cohorts were higher than later birth cohorts.

Regarding the sex ratios in age-specific incidence, we found a large curve in sex ratios around 45-59 years of age. Lindblad *et al*[32] indicated that estrogen may prevent gastric cancer, and our results are in accordance with females in this age group being exposed to some protective factors against gastric cancer, such as estrogen and reproductive factors. The growth of gastric cancer cells may be stimulated during low concentrations of estrogen, such as in young females and postmenopausal women, while the growth of cancer cells may be inhibited in females with high concentrations of estrogen[33,34].

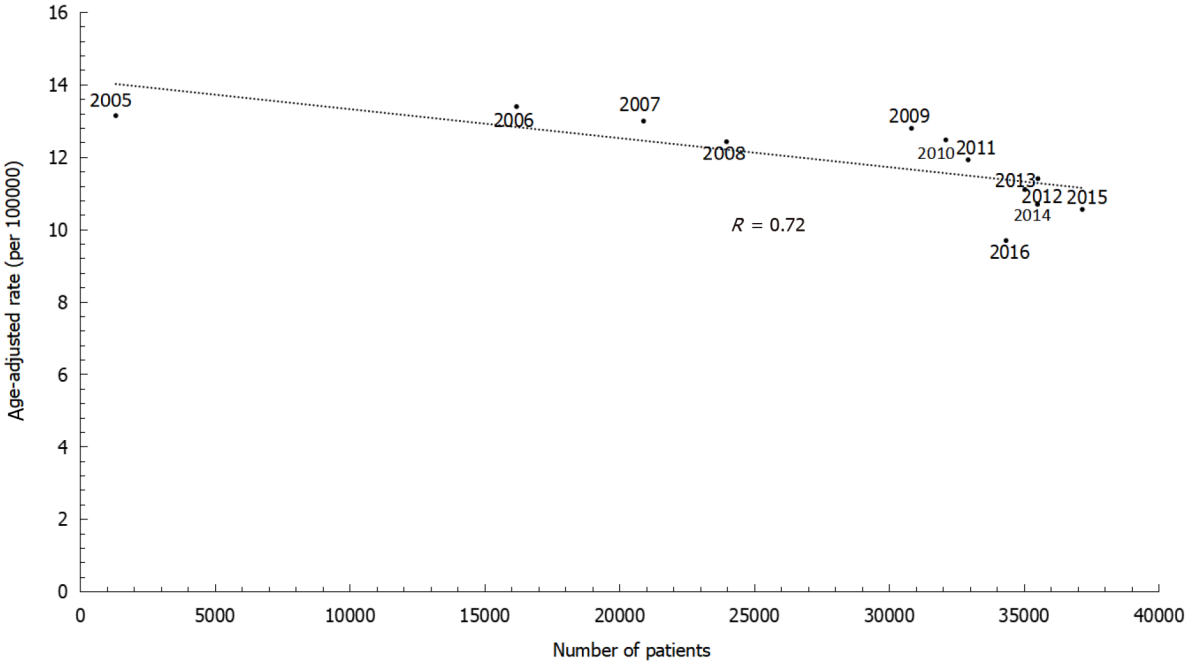

Figure 5 Correlation between numbers of patients with *Helicobacter pylori* infection newly treated with antibiotic therapy and age-adjusted incidence rates showed a substantial decrease with an *r* coefficient of 0.72 in Taiwan, 2005-2016.

In this study, we summarize the descriptive epidemiology of gastric cancer incidence in Taiwan during a period of almost 40 years and show that gastric cancer incidence has steadily declined during this period. However, there are several limitations to our study. First, due to limitations of the database, we were unable to confirm whether the declines in gastric cancer incidence are attributable to differential histologic types and anatomic sites. An earlier study showed a decreased standardized incidence ratio of non-cardia gastric cancer after *H. pylori* eradication, but this eradication did not influence the overall risk for cardia gastric cancer[35]. Also, as for pathological patterns, another study in Taiwan showed significantly decreasing trends in the incidence of adenocarcinoma. However, there was no evident decrease in the incidences of mucosa-associated lymphoid tissue lymphoma and diffuse large B-cell lymphoma[11]. Therefore, further studies are needed to investigate the relationship between *H. pylori* and the histologic type and anatomic site of gastric cancer. Second, this study did not investigate ecological correlations since there was no adjustment for other confounders, such as dietary and lifestyle habits, due to the limitations of the databases.

CONCLUSION

In conclusion, we show continuously decreasing rates of gastric cancer in both sexes, increasing age-specific incidence rates with age, lower sex ratios in later birth cohorts, and decreasing age-adjusted incidence rates with increasing anti-*H. pylori* treatment. The results support the need to further address the issue of mass anti-*H. pylori* treatment in areas with a high prevalence rate of *H. pylori* infection in order to eliminate the threat of *H. pylori*-associated gastric cancer.

ARTICLE HIGHLIGHTS

Research background

Gastric cancer is a multifactorial cancer and is a leading cause of cancer death worldwide. In Taiwan, gastric cancer is the sixth leading cause of cancer mortality.

Research motivation

We desired to discover the association between gastric cancer incidence and potential

factors, including anti-*Helicobacter pylori* (*H. pylori*) treatment.

Research objectives

The objective of this study was to observe secular trends in gastric cancer incidence according to age, sex, and the implementation of a nationwide *H. pylori* treatment program in Taiwan.

Research methods

We used the national Taiwan Cancer Registry database in this population-based study. Annual percent changes in incidence rates were used to describe secular trends in incidence rates and sex ratios of gastric cancer in Taiwan and to study the relationship between its incidence and potential risk factors, including anti-*H. pylori* treatment. Pearson's product-moment correlation coefficients were used to analyze the correlation between annual age adjusted incidence rates and the annual number of patients treated with antibiotic therapy for *H. pylori* infection.

Research results

The annual percent changes showed steadily decreasing rates of gastric cancer in both sexes. However, the decreasing trends differed by sex, with an annual percent change of -2.58% in males and -2.14% in females. The age-specific incidence rates increased with age. Among the same age group, more recent time periods showed lower incidence rates than earlier time periods. Within the same age group, the sex ratio was lower in later birth cohorts than in earlier birth cohorts. In addition, age-adjusted incidence rates decreased substantially with increasing numbers of patients newly treated with antibiotic therapy during 2005 to 2016 for *H. pylori* infection (r = 0.72).

Research conclusions

We observed steadily decreasing trends with differential sex ratios in the incidence of gastric cancer in Taiwan. The results also support the association between trends in gastric cancer incidence and the implementation of *H. pylori* eradication programs in Taiwan.

Research perspectives

Further long-term cohort studies are needed to investigate the relationship between *H. pylori* treatment and gastric cancer histologic type and anatomic site and should include adjusting for other confounders, such as dietary and lifestyle habits and genetic susceptibility.

Abstract

BACKGROUND

A progressive reduction in the secretion of pancreatic enzymes in patients with chronic pancreatitis (CP) results in malabsorption and ultimate malnutrition. However, the pathogenesis of malnutrition is multifactorial and other factors such as chronic inflammation, alcohol excess and poor dietary intake all contribute. Patients may restrict their dietary intake due to poor appetite or to avoid gastrointestinal symptoms and abdominal pain. Whilst up to half of patients with chronic pancreatitis are reportedly malnourished, the dietary intake of patients with CP is relatively understudied and has not been systematically reviewed to date.

AIM

To perform a systematic review and meta-analysis of the dietary intakes of patients with CP compared to healthy controls, and to compare the dietary intake of patients with alcohol-related CP and non-alcohol-related CP.

METHODS

Conflict-of-interest statement: The authors declare no conflicts of interest.

PRISMA 2009 Checklist statement: The authors have read the PRISMA 2009 checklist and the manuscript was prepared and revised according to the PRISMA 2009 checklist.

A systematic literature search was performed using EMBASE, MEDLINE, and Cochrane review on studies published between 1946 and August 30th, 2019. Adult subjects with a diagnosis of CP who had undergone dietary assessment were included in the systematic review (qualitative analysis). Studies on patients with other pancreatic diseases or who had undergone pancreatic surgery were not included. Studies comparing the dietary intake of patients with CP to that of healthy controls were included in the meta-analysis (quantitative analysis). Meta-analysis was performed using Review Manager 5.3. Newcastle Ottawa Scale (NOS) was used to assess quality of studies.

RESULTS

Of 6715 studies retrieved in the search, 23 were eligible for qualitative analysis while 12 were eligible for quantitative analysis. In the meta-analysis, the total energy (calorie) intake of patients with CP was similar to that of healthy controls [mean difference (MD): 171.3; 95% confidence interval (CI): -226.01, 568.5; P = 0.4], however patients with CP consumed significantly fewer non-alcohol calories than controls [MD: -694.1; 95%CI: -1256.1, (-132.1); P = 0.02]. CP patients consumed more protein, but carbohydrate and fat intakes did not differ significantly. Those with alcohol-related CP consumed more mean (standard deviation) calories than CP patients with a non-alcohol aetiology [2642 (1090) kcal and 1372 (394) kcal, respectively, P = 0.046], as well as more protein, fat, but not carbohydrate.

CONCLUSION

Although patients with CP had similar calorie intake to controls, studies that analysed the contribution of alcohol to energy intake showed that patients with CP consumed fewer non-alcohol calories than healthy controls. A high calorie intake, made up to a large degree by alcohol, may in part contribute to poor nutritional status in CP.

Key Words: Systematic review; Meta-analysis; Chronic pancreatitis; Dietary intake; Undernutrition; Alcohol-related chronic pancreatitis

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Patients with chronic pancreatitis appear to have a similar dietary intake to heathy controls, however, this diet may be made up of alcohol-derived calories to a considerable degree. This may account for the poor nutritional status frequently observed in this population.

INTRODUCTION

Chronic pancreatitis (CP) is a progressive, inflammatory disease of the pancreas, causing progressive fibrosis and eventual destruction of the gland[1]. Along with a gradual loss of pancreatic endocrine and exocrine function, a chronic hyper-inflammatory state increases the risk of undernutrition[2,3]. Almost 50% of CP patients are known to be undernourished[4], the reasons for which are multifactorial.

Maldigestion and malabsorption commonly co-exist with suboptimal dietary intake. Patients may self-restrict to ease symptoms of malabsorption, nausea, early satiety, and abdominal pain. Misleading dietary instructions or selective over-restriction of diet, for instance a fat-free diet to manage steatorrhea, may further cause suboptimal intake[5,6]. For some, chronic excess alcohol consumption may displace food resulting in reduced intake of dietary nutrients[7], while heavy smoking may further reduce appetite[8]. Further complications, including type 3c diabetes and chronic pain, and

maldigestive symptoms including nausea, steatorrhoea, abdominal bloating and or discomfort may worsen already poor dietary intake in the latter stages of the disease [9].

In patients with CP, the prevalence of nutrient deficiencies and their consequences have been widely reported[10-14] however little is known regarding the dietary intake of patients with CP. One study on dietary intake in CP reported that 52% of the patients lost weight following diagnosis of CP, with those who lost weight consuming significantly fewer calories than those who did not[15]. Conversely in another study, patients with calcifying CP consumed higher amount of fats and proteins[16]. Therefore, despite being a digestive disease, no study has systematically reviewed dietary intake in CP.

To address this gap, we undertook a systematic review of published observational studies reporting dietary intake in patients with CP. Specifically, the primary objective was to compare energy (calorie) and macronutrient intake in CP patients with that of healthy controls. The secondary objectives were to determine if dietary intake in CP differed according to aetiology, and to determine and compare the micronutrient intakes of patients with CP with that of controls.

MATERIALS AND METHODS

This study adhered to the Preferred Reporting Items for Systematic Reviews (PRISMA) guidelines[17]. No ethical approval was required due to the nature of the study.

Under the guidance of medical librarian (J.M), Ovid Medline (1946 to August 30th, 2019), Embase (1980 to September 30th, 2019) and Cochrane Review were searched. The search strategy was developed for MEDLINE and translated for use in EMBASE. Finally, we searched the Cochrane central register of control trials to assess for any available trials on our search. We searched for articles with a combination of exploded versions of Medical Subject Headings (MeSH) and keywords as follows: ("Pancreatitis, Chronic", chronic pancreatitis) AND "diet", "dietary intake", "food intake", "food quality", "nutrient intake", "nutritional assessment", "nutrition intake", "nutrition survey", "nutritional survey", "nutritional surveys", "food", "diet history", "dietary history", "food frequency questionnaire", "food diary", "food diaries", "calorie intake", energy intake", "carbohydrates", "dietary protein", "dietary fats", "vitamins", "minerals", "macronutrient intake", "micronutrient intake", "eating", "diet pattern", "dietary pattern", "diet records", "dietary records", "diet quality", "dietary quality", "diet assessment", "dietary assessment".

Boolean operator "OR" was used to assess between each Mesh term and "AND" was used to combine the searches for chronic pancreatitis and dietary intake. Additionally, bibliographies of included studies, and abstracts of pertinent scientific conferences were also manually reviewed for other relevant articles. The search was not limited by language.

Criteria for inclusion/exclusion

To be included, studies had to have quantified the dietary intake of patients with chronic pancreatitis. The PICO[18] model was used to determine the inclusion criteria as follows: patient population (adults of both sexes with a confirmed diagnosis of CP) with the data of interest (studies that measured dietary intake by any recognised means, including food-frequency questionnaires (FFQs), diet histories, food diaries, electronic ('app') measurement, or any other validated technique. Data on controls (healthy or non-pancreatitis) were recorded, if available. Publications had to be available in full text. Studies on patients with active acute pancreatitis, pancreatic carcinoma, cystic fibrosis, and total pancreatectomy were excluded. Data from children under the age of 18, those on enteral/parenteral nutrition, elemental diet or additional supplementation *via* parenteral routes were excluded. Duplicates, case-reports, reviews, editorial/comments, abstracts only, and animal studies were also excluded. Intervention studies where the diet was modified before assessment were excluded, unless baseline unmodified dietary assessment was available. However, data from patients that may have received dietary advice as part of routine clinical care were not excluded.

Study selection

Two reviewers (QS and YB) independently reviewed abstracts and titles of the citations to determine suitability for final inclusion. Disagreement was resolved with discussion or if required, consultation with the third reviewer (SND). Once potentially

relevant studies were identified, full publications were sought, and the selection criteria were applied.

Quality assessment

Quality and risk of bias was assessed using the Newcastle-Ottawa scale (NOS)[19]. A total score of 9 stars can be awarded to each study based on: Up to four stars for the patient selection criteria, two stars for comparability of participants on the basis of design or analysis, and three stars for ascertainment of exposure. The study was deemed to be low quality (0-3 stars), moderate quality (4-6 stars), or high quality (7-9 stars) according to this scoring system.

Data extraction

For each eligible study, the following data were extracted: study details, patient characteristics (age, ethnicity, gender, smoking status, alcohol consumption, BMI), clinical details (disease status, diagnostic criteria, complications, duration of disease, controls if included), dietary intake (energy intake (calories), macronutrient intake (carbohydrate, fat, protein), vitamin intake (vitamins A, B, C, D, E and K), and mineral intake (iron and calcium). We attempted to contact study authors to clarify data where required.

Statistical analysis

Data were analysed using Review Manager (RevMan, version 5.3.5, The Copenhagen Nordic Cochrane Center, The Cochrane Collaboration, 2014). Data were presented as mean (g/d for macronutrients and kcal/d for caloric intake) and corresponding standard deviation (SD). Data were pooled using a random-effects model to give the most conservative estimates. Statistical heterogeneity was calculated as I^2 (presented as 0%-100%). Values < 40% were considered as relatively unimportant, 40%-60% moderate heterogeneity and > 60% indicated substantial heterogeneity. P values < 0.05 were considered statistically significant. Publication bias was assessed using Egger's test. Subgroup analysis for statistical associations were done using SPSS (version 20, IBM, United States).

RESULTS

Study identification and characteristics

The PRISMA flow diagram is shown in Figure 1. Table 1 summarises the 23 articles retrieved in the search, representing 1,577 patients with confirmed CP (based on clinical symptoms and/or radiology). Of these, 12 studies comparing dietary intake of CP patients to that of controls were eligible for meta-analysis, representing 1048 patients with CP and 1,965 control subjects. Most case-controlled studies[6,7,15,20-29] recruited healthy controls, while five studies compared CP patients to patients with alcoholic cirrhosis[6,7,23,25,30], and one study[31] compared patients with pancreatic steatorrhea to those with intestinal steatorrhea. Nine studies originated from Asia (predominantly India), seven from Europe (predominantly France), five from the United States, two from South/Central America, and one each from Africa and Australasia. Most studies were done in the out-patient setting (22 studies)[6,7,15,20-30,32-34] while two studies[31,35] assessed hospitalised patients, and one study[36] assessed dietary intake by means of an international survey. All but three studies[26,29,36] were single centre.

Dietary assessment methods

Regarding dietary assessment, a variety of methods were used (some studies used combined methods to estimate intake). Four studies used food diaries (between 3 and 7 d diaries), 9 studies used food frequency questionnaires (FFQ, of which one used a software technology VioScreen), six studies used a 24-h recall method, one study used a 7-d recall method, three studies employed a diet history method, four studies (all conducted in the 1970s or 1980s) referenced a particular dietary assessment technique, and attempts to obtain the original references were not successful, and five studies did not report the exact dietary assessment method employed. Twenty-two out of the 23 included studies used an a posteriori or data- driven approach to assess diet quality, while one study used a priori measure of diet quality (diet indices)[24], specifically the healthy eating index (HEI) and Mediterranean diet score (MED). Dietary assessment was performed by a dietitian (n = 15) or nutritionist (n = 2) in most cases, and 6 studies

[1]No demographic or additional clinical details were provided for the n = 20 subgroup of patient with additional dietary assessment.
CP: Chronic pancreatitis; NOS: Newcastle Ottawa scale; FFQ: Food frequency questionnaire; BMI: Body mass index; M: Male; F: Female; NR: Not reported; RCT: Randomised controlled trial; PC: Pancreatitis cancer.

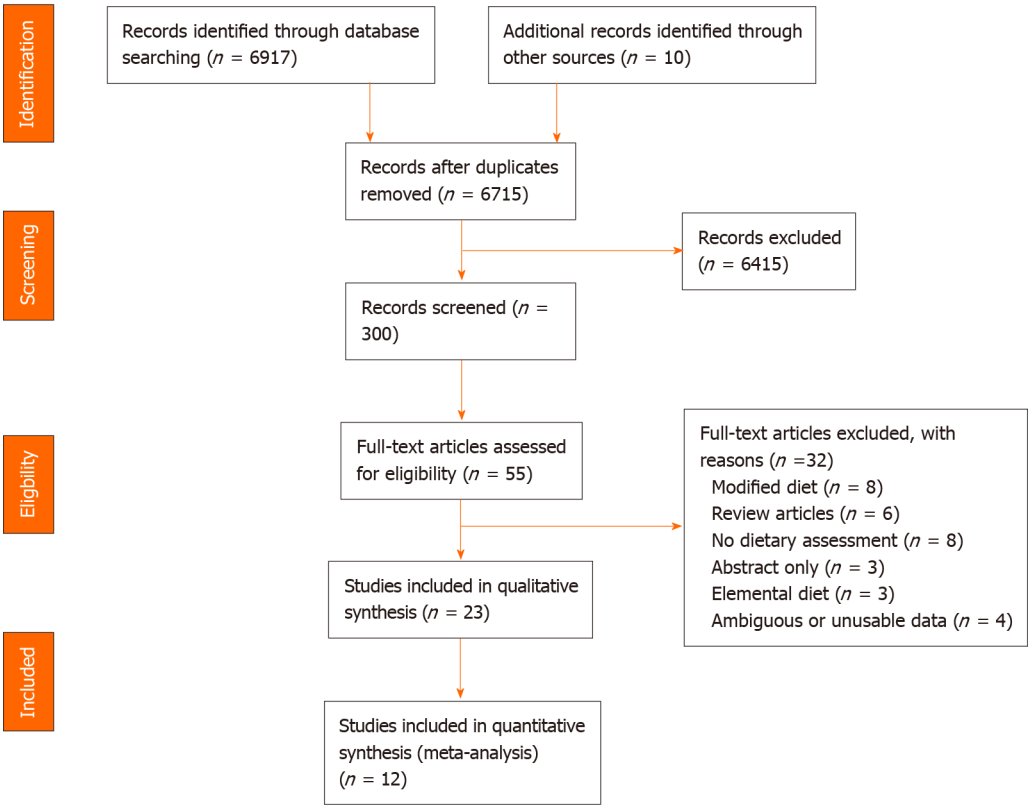

Figure 1 PRISMA flowchart: Preferred reporting items for systematic review and meta-analysis.

did not characterise the individual conducting the assessment. Only six of the 23 studies were published in the last 10 years (2010 or later). Seven studies had been published more than 30 years ago (earlier than 1990).

Participants

Patients with CP had a pooled average age of 43 years (range 29-57.6 years), while healthy controls had a pooled average age of 45 years (range 24.7-54 years). 19 studies reported gender distribution, 1152 (86.8%) of CP patients were male while 175 (13.2%) were female. Thirteen studies reported the BMI of CP patients (pooled mean BMI 21.5 kg/m^2, range 16.2-25.7 kg/m^2), while the reported mean BMI of controls was 24.8 kg/m^2 (range 18.4-27.3 kg/m^2). The average BMI of CP patients from studies conducted on subjects from Eastern/African countries was lower than those conducted on subjects from Western countries (US, Europe) (BMI 18.2 and 22.5 kg/m^2 respectively, P = 0.042). When comparing control subjects from studies from Eastern and Western countries the BMIs did not differ (20.5 and 25 kg/m^2 respectively, P = 0.066).

Study quality

According to the NOS for quality assessment, one study[36] was deemed to be "high-quality" while no studies were deemed to be "low-quality", with the remainder being medium-quality.

Quantitative analysis

Meta-analysis was used to combine study results. Ten studies reported energy (calorie) intakes for both patients with CP and healthy controls, and two studies reported data for geographic groups separately, which were reported independently in the forest plot. There was no difference between the energy intakes of patients with CP and healthy controls (MD: 171.3; 95%CI: -226.01, 568.5; P = 0.4) (Figure 2A), however when analysing data from four studies reporting the intake of non-alcohol calories (five separate study groups), patients with CP consumed significantly fewer non-alcohol calories than healthy controls [MD: -694.1; 95%CI: -1256.1, (-132.1); P = 0.02] (Figure 2B). From 13 studies (16 separate study groups), patients with CP had a higher intake of protein than healthy controls (MD: 14.2; 95%CI: 7.99, 20.49; P < 0.001, Figure 2C). From 11 studies (15 separate study groups), the consumption of carbohydrate (MD: 14.05; 95%CI: -34.03, 62.12; P = 0.57, Figure 2D) did not differ between groups. Similarly, from 12 studies (16 separate study groups) the intake of dietary fat (MD: 8.69; 95%CI: -0.21, 17.59; P = 0.06, Figure 2E) did not differ between the groups. Heterogeneity was considerably high for all outcome measures.

Qualitative analysis

Energy intake and macronutrient composition: Macro- and micronutrient intakes of patients and controls in all studies included in the systematic review are summarised in Table 2. For patients with CP, energy (calorie) intake ranged from 842 to 4178 kcal/d, while the energy intake of controls ranged from 810 to 4178 kcal/d. Where there was higher energy intake among patients with CP, the reasons varied between studies. High calorie consumption was due to higher fat and protein intake in one study[23], higher carbohydrate intake in one study[21], and due to a high intake of all macronutrients in another[35]. In one study[7], the calorie intake was high due to excessive alcohol consumption, with alcohol comprising 50% of total caloric intake. The percentage of energy intake consumed as carbohydrate ranged from 22.1% to 73%, the percentage of energy consumed as protein ranged from 9.1% to 21.3%, and the percentage of energy consumed as fat ranged from 16 to 35%. For controls, the corresponding percentages were 27.5% to 61% (carbohydrate), 10.5% to 16.8% (protein) and 19.8% to 36.6% (fat). In the majority of studies reporting lower energy intake among patients with CP, those with poor energy intake showed some form of malnutrition (defined by lower BMI/loss of weight) after onset of disease when compared to controls. In one study that compared subtypes of CP[37], patients with tropical CP had the lowest intake of energy, attributable to a low intake of dietary fat.

Protein intake: Twenty studies[6,7,15,20-27,29,30,32,33,35-40] determined the protein intake of patients with CP, 15 of which were controlled[6,7,20-26,29,30,32,35-37,40]. Of those, 13 studies[6,7,20-26,29,35-37,40] compared the protein intake of CP patients to that of healthy controls, while one study compared to patients with alcoholic cirrhosis [30] and another to patients with acute pancreatitis[32]. The protein intake of patients with CP ranged from 35 to 145 g/d, compared to 45 to 117g/d among healthy controls. Five studies[20,26,29,35,40] reported that patients with CP consumed a higher intake of protein than healthy controls. In one of these studies[40], the relative risk of developing CP increased as a function of the quantity of protein (and alcohol) consumed. Another study on African patients[26] reported that high protein intake

was mostly derived from high bean consumption. Eight studies[6,7,15,27,32,33,36,37] reported the opposite: that patients with CP consumed less protein than controls, with protein intake being 20% lower than the recommended daily allowance in two studies [33,37]. Five of these eight studies were conducted in Eastern countries, specifically India and Japan. One study[36] compared protein intake in patients with India with that of patients in France, finding that intake was lower in the former. Three studies considered the source of dietary protein[6,20,23]. Of these, two studies[6,23] reported that patients with CP consumed more animal-based protein than controls.

Carbohydrate intake: Eighteen studies[6,7,15,21-27,29,32,33,35-37,39,40] analysed the carbohydrate intake of patients with CP, of which 13 studies[6,7,21-26,29,32,35,36,40] were controlled. In the 13 controlled studies, there were 17 separate groups studied. Among controlled studies, carbohydrate intake ranged from 89 to 533 g for patients with CP, and 116 to 386 g for controls. Of the controlled studies, three[21,26,35] reported that patients with CP had a higher intake of carbohydrates than controls (in one of those studies[26], only one of the study arms reported that patients with CP consumed significantly more carbohydrate than controls). Four studies reported the opposite[6,7,26,32], stating that patients with CP consumed lower amounts of carbohydrates than controls (in one of those studies[26], only the African group reported that patients with CP consumed significantly less carbohydrate than controls). The other controlled studies reported no significant difference in carbohydrate intake between patients with CP and controls.

Fat intake: Seven studies[18,21,23,24,33,34,38] reported a higher intake of dietary fat in patients with CP than in controls. In several studies, a higher intake of fat was associated with the development of CP[18,21,24,33,38] and earlier onset of disease[18,38]. Three studies provided details on the source of dietary fat[6,20,23]. In one study[6] conducted in Japan, CP patients had statistically lower fat intake from both animal and plant sources, but significantly higher intake of marine fat (fish oil). Two studies analysed patients' intake of saturated fat, monounsaturated and polyunsaturated fat [20,23], reporting that patients with alcohol-associated CP consumed significantly more dietary fat than both control patients with cirrhosis[20,23] and healthy controls [20].

Alcohol intake: Noel-Jorand and colleagues[20] noted that patients with CP had reached the same threshold of alcohol consumption as patients with alcoholic liver cirrhosis prior to diagnosis of their respective diseases (204-232 g/d per subject), however those who developed CP consumed alcohol over a shorter time-frame than those who developed cirrhosis. Lévy *et al*[23] similarly reported that patients with CP had a lower mean duration than those with alcoholic cirrhosis. Durbec *et al*[40] reported that the total quantity of alcohol consumed, as well as the duration of consumption, prior to diagnosis was lower in women than in men. This was mirrored in a study from the United States in which women with CP had a lower duration of alcohol consumption than men with CP[7]. Three studies compared patients with alcohol-related CP to those with CP of other causes. Patients with alcohol-related CP consumed more calories[35,37], carbohydrate[35] and protein[29]. Table 3 compares intake between those with alcohol-related CP and CP of other causes. Those with alcohol-related CP had a higher overall energy intake than those with non-alcohol-related CP, along with a higher protein and fat intake, but not carbohydrate intake.

Table 3 Energy (calorie), protein, carbohydrate, and fat intake of patients with alcohol-related chronic pancreatitis[7,18,21,23,24,28,33] compared to those with non-alcohol-related chronic pancreatitis[14,20]

Fat, g/d (SD)	91 (43)	29 (13)	0.01[1]

[1]Statistically different.
SD: Standard deviation.

Geographical differences: Studies reporting a higher consumption of energy were mostly conducted in Western countries (United States, Europe, Mexico), and the majority were published over 20 years ago. Studies reporting a lower consumption of energy tended to arise from Eastern countries (mainly India and Japan), and the majority had been published more recently. The consumption of carbohydrate and protein appeared to be similar in Western and Eastern countries, while the average intake of fat was lower in eastern/African countries (mean 35.8 g/d) compared to Western countries (mean 75 g/d).

Micronutrient intake: Only four studies measured micronutrient intake (Table 4), of which two studies were controlled (both recruited healthy controls). Vitamin A was expressed in various forms and it was not clear which specific form was presented in some cases. In a controlled study from Japan[6], controls consumed more vitamin A, vitamin B1, vitamin B2, calcium and iron, but not vitamin C.

DISCUSSION

This is the first systematic review to quantify the nutritional intake of patients with CP. While total calorie consumption was not different between patients with CP and healthy controls, patients with CP consumed significantly fewer non-alcohol calories than controls. Those with CP also consumed significantly more protein than healthy controls, however the intake of carbohydrate and fat did not differ. When comparing patients with alcohol-related CP to those with a non-alcohol aetiology, patients with alcohol-related CP consumed more calories, protein and fat than controls, but consumed a similar amount of carbohydrates. This review has highlighted the dearth of research on this topic in general. Only five of the studies retrieved in the search were published in the ten years preceding this paper.

The contribution of alcohol to overall energy intake is an important finding. Five studies were meta-analysed to compare non-alcohol caloric intake to that of healthy controls. In one study from the US on alcohol-related CP, as much as half of all calories consumed were derived from alcohol[7]. In another study conducted both in France and Africa, percentage calories from alcohol were as high as 31% and 39% respectively [24]. The contribution of alcohol to weight is not straightforward. Each gram of alcohol provides 7.1 (29.7 kJ) kcal whereas each gram of carbohydrate approximately provides 4 kcal/g[41], therefore, those consuming large amounts of alcohol should eventually gain excess weight. However, in a Brazilian study comparing asymptomatic alcohol-aetiology CP patients to non-pancreatitis patients with excessive alcohol consumption and healthy controls, patients with CP had lower BMI, body fat and lean body mass, despite a higher alcohol-derived caloric consumption. They also had magnesium and vitamin deficiencies, as well dyslipidaemia and increased risk of cardiovascular disease[25]. Calories derived from alcohol have no nutritive value. Where the same amount of calories was consumed by two groups of non-pancreatic healthy subjects (one receiving calories from carbohydrates and the other receiving the same calories from alcohol), those obtaining energy from alcohol did not gain weight, even when alcohol-derived calorie consumption was increased[42]. Malnutrition secondary to alcohol consumption is multi-factorial and not just due to non-nutritive calorie provision. One study reported that patients consuming high levels of alcohol (23% of

Table 4 Studies analysing micronutrient intake in patients with chronic pancreatitis and controls

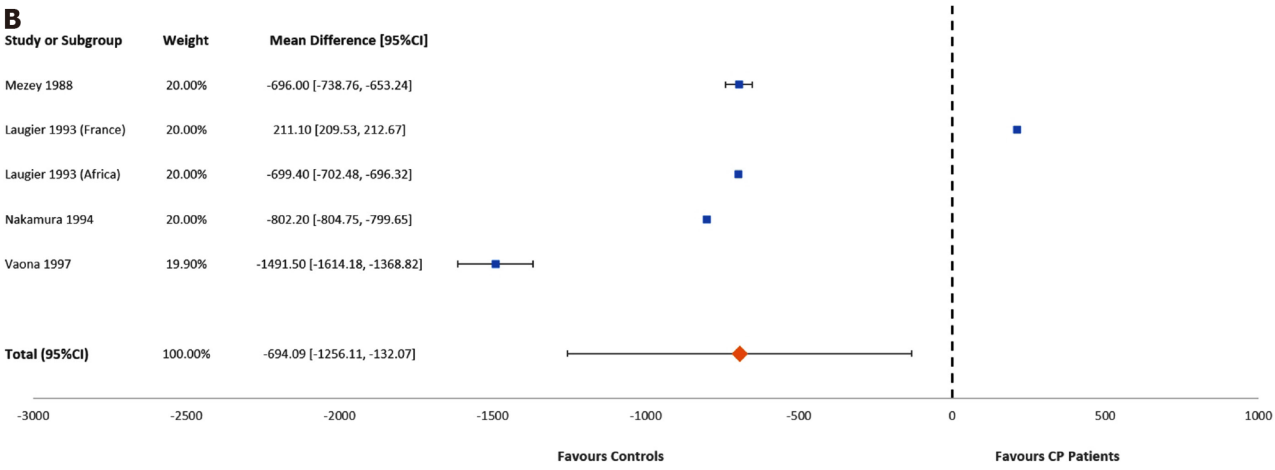
total calories) tended to displace carbohydrate intake. However, where alcohol intake was higher than 30% of total calories, the intake of proteins, fat and vitamins declined considerably[43].

As well as being responsible for the development of CP and the progression of disease, and aside from the effects of nutrient displacement, a high intake of alcohol is known to directly contribute to malnutrition. Alcohol has direct toxic effects on the gastrointestinal tract and liver, leading to impaired digestion, reduced absorption of nutrients into the blood, and impaired utilisation or increased degradation of those nutrients. As well as causing malabsorption, alcohol also increases systemic inflammation increasing energy requirement, and leading to weight loss[44]. All these effects occur independently and parallel to the decreased secretion of pancreatic enzymes and chronic inflammation that occur as a consequence of CP, hence, cumulative damage occurs in CP patients with excessive alcohol consumption. Patients with CP may reduce their intake of alcohol following diagnosis[24], however most studies show that they continue to consume high quantities of alcohol[45].



Patients with CP may not be classically underweight, however they may be sarcopenic, defined as low skeletal muscle mass, low muscle strength, and low muscle function leading to impaired physical performance[46,47]. A systematic review[47] reported that sarcopenia is prevalent in 17%-64% of patients with CP, and negatively affects outcomes such as quality of life, hospitalisation, mortality and may be associated with a lower islet yield following total pancreatectomy with islet autotransplantation. Sarcopenic obesity describes the state where excess body weight and reduced muscle mass or strength occur simultaneously. In the 12 studies meta-analysed for total calorie intake, only seven reported BMI. Of those, all reported a mean BMI in the underweight or normal BMI range for patients with CP. Only two of the five studies meta-analysed for non-alcohol calorie intake reported BMI, with both reporting BMI to be in the normal range. Crucially, BMI alone is a poor indicator of individual nutritional status and body composition, with sarcopenia being present independent of BMI[47-49]. In addition, impaired measures of functional capacity (such as hand-grip strength) have been reported in patients with CP, independent of weight or BMI[12,50]. Contrary to the 'textbook' description of an underweight patient, those with CP are frequently overweight or obese[12]. In the present review, whilst none of the studies measured sarcopenia or sarcopenic obesity, patients with CP appeared to have an adequate or high caloric consumption. However, a high percentage of calories as alcohol might explain the nutritional deficits reported in some.

The issue of the macronutrient composition of the diet is more complex. In our meta-analysis of 12 studies (investigating 16 different study populations), we showed that patients with CP consumed significantly more dietary protein compared to

healthy controls. Recently-published consensus guidelines state that patients with CP do not need to follow specific restrictions on protein, fat or carbohydrate intake, but instead should follow a "well-balanced" diet, except for those who are malnourished, where a high protein, high calorie dietary pattern is warranted[9,51]. It is not known if patients included in the meta-analysis had received dietary counselling at any time preceding their inclusion in the studies. Several studies have examined the role of protein intake in the development of CP. In a paper published in 1973, Sarles *et al*[16] reported the results of an international study of dietary intake in CP in 16 countries across 4 continents. The study, which did not meet the criteria for inclusion into the systematic review, reported that subjects with alcoholism who developed chronic calcific pancreatitis had higher protein and fat intakes than controls. Conversely in a subgroup from India, chronic calcific pancreatitis was found in 'occasional alcoholics' who were deficient in protein. In a study published in the same decade by the same author[40], two study groups were assessed, including a group from France, and a second group of Caucasian patients from 9 international centres. This study also recruited controls and was eligible for inclusion in the systematic review and meta-analysis. It found that there was a small increase in the relative risk of developing chronic pancreatitis with increased protein intake, although the study counselled

against a "protein-poor" diet due to the risk of malabsorption and protein deficiency. Most studies reporting a high protein intake for patients with CP had recruited patients with an alcohol aetiology[7,21,23,24,28]. Studies on patients with non-alcohol aetiology appeared to report a lower protein intake[20].

Regarding fat intake, the study by Durbec and Sarles[40] reported that both a low-fat and high-fat diet increased the relative risk of developing chronic pancreatitis, suggesting consumption of an "average fat" diet (85-110 g fat per day). Perhaps unexpectedly, our meta-analysis showed that there was no difference in fat intake between patients with CP and healthy controls. The forest plot (Figure 2E) shows that most studies reported that patients had a higher intake than controls, and the p-value was just above the arbitrary 0.05. Patients were traditionally advised to follow a low-fat (or even fat-free) diet in an effort to reduce the symptom burden associated with pancreatic exocrine insufficiency. The most recent guidelines[9,51] recommend against restricting fat intake for all but the most severe cases of intractable malabsorption. This is in part because protein and carbohydrate are similarly malabsorbed, resulting in adverse symptoms, and simple fat restriction does not address this fact. Furthermore, achieving protein requirement is also more difficult with a restrictive diet. Treatment with optimal dosage of PERT treats malabsorption of all macronutrients and allows for a more "normal" dietary intake. The studies described above, suggesting that higher dietary intakes of protein and fat might be related to the development of CP, were published during the 1970s, before the importance of adequate treatment with PERT was appreciated. The relationship between the development of CP, the macronutrient composition of the diet, along with the interplay between nutritional status and alcohol intake are therefore not well understood.

There is a clear gap in the literature on the dietary intake of micronutrients in CP. Only four studies[6,24,32,37] have investigated this, one of which was uncontrolled [32]. Only one study measured the dietary intake of fat-soluble vitamins D, E and K [24]. However, this is a critical issue for patients with CP, who are known to have micronutrient deficiency. Again, a high intake of calories with little nutritive value is certain to exacerbate nutritional deficiencies[12,52-58].

This study was also the first to systematically review the methodology of dietary assessment techniques for this patient group, finding considerable heterogeneity, which presented a clear challenge for the interpretation of data, and thereby limits the generalisability of results. A notable number of studies did not report the methods used, while others utilised retrospective techniques and some used prospective methods such as food diaries. Each method carries its own risk of bias. For example, retrospective techniques such as FFQs and dietary recall may be affected by recall bias, as well with problems with subject memory, cognition and motivation. The reported nutrient intake in some studies appeared to be considerably high compared to contemporaneous national surveys. For example, Lévy *et al*[23] reported the dietary intake of newly diagnosed alcoholic CP patients from 1995 and reported an intake for both groups in excess of 4,000 kcal and 100 g protein per day. This is considerably higher than values reported by other national surveys around that time, including the French national dietary study from 1993-94 [mean energy intake in males of 2,390 kcal of which 16.6% came from protein (approximately 99g)[59]]. Similarly, the Irish North-South Food Consumption Survey 1997-99 found that men aged 18-64 years had a mean energy intake of 2,632kcal and 100g protein[60]. FFQs, used in the French study, have been shown to overestimate energy intake[59]. However, this study was not eligible for inclusion in the meta-analysis due to incompatible data.

Limitations and strengths

This systematic review was limited by the heterogenous nature of the included studies. More importantly, the method of dietary assessment differed considerably between studies, which may account for the wide range of intakes reported and may have resulted in both under- and over-estimation of actual intake. However, the meta-analysis was designed to report the differences in intake between patients with CP and controls rather than absolute values (and the methodology for patients and controls was the same within each individual study), which should minimise this error. In addition, the meta-analysis compared patients with CP to healthy controls only, and excluded studies with other types of controls. Hence, despite inter-group heterogeneity, intra-group diversity was minimal. Furthermore, as heterogeneity is high in large scale studies, this may have further added to the heterogeneity observed, as most of our included studies recruited large patient numbers. Only 12 of the 23 studies retrieved were deemed eligible for meta-analysis, and fewer were suitable for some of the analyses, such as non-alcohol calories. This was in part due to the inclusion of studies that recruited healthy controls only.

Only six studies were published within the last ten years. Nonetheless, we believe that the results are applicable to present-day patients. A potential variable was the inclusion of a wide range of ethnic groups. The differences in nutrient intake reported may have been a consequence of geographic location rather than the effect of CP. However, the inclusion of healthy controls from the same geographic region as the patients with CP would have minimised this limitation. In addition, most patients with CP recruited to the various studies were male, but the same restriction wasn't applied for controls. Therefore, the gender differences might explain higher caloric intake by CP patients in some studies. No study had compared dietary intake by gender. As with all systematic reviews, this study was inherently limited by the quality of the studies included, although only one study was deemed to be of low quality. In some cases, different units and methods of reporting were used, necessitating extrapolation or recalculation.

CONCLUSION

This systematic review and meta-analysis supports the notion that while patients consume apparently adequate energy, the quality of the dietary intake is poor, in part due to the contribution of alcohol to overall energy intake. This review has also highlighted the critical lack of recent studies on this topic. Further studies should aim to characterise the dietary intake of patients with CP, with robust study designs and adequate sample size. Longitudinal research would help to determine the effects of various dietary patterns and alcohol abuse on diet. Intervention studies of therapeutic dietary strategies as well as early dietetic consultation in patients with CP are sorely needed.

ARTICLE HIGHLIGHTS

Research background

Patients with chronic pancreatitis (CP) are a high risk of developing malnutrition due to progressive exocrine insufficiency, malabsorption, and adverse gastro-intestinal symptoms. Poor dietary intake and excess alcohol consumption may exacerbate malnutrition.

Research motivation

Although CP is a digestive disease, little is known regarding the dietary intake of patients with this condition, and no systematic reviews or meta-analyses have been undertaken to date.

Research objectives

The purpose of this systematic review and meta-analysis was to compare the macronutrient and micronutrient intake of patients with CP to that of healthy subjects, and to determine if there was a difference in dietary intake according to aetiology.

Research methods

With the guidance of a medical librarian, we conducted a search of multiple databases including Ovid Medline, EMBASE and Cochrane Review.

Research results

Twenty-three studies were retrieved in the search and included in the systematic review (representing 1577 patients with CP), of which 12 were eligible for meta-analysis (representing 1048 patients with CP and 1965 healthy controls). There was no statistical difference in the energy (calorie) intakes of patients with CP and controls. However, when analysing studies reporting non-alcohol calorie consumption, patients with CP consumed significantly fewer calories than health control subjects. Those with CP consumed more protein than healthy controls, but there was no difference in the consumption of carbohydrate and fat. Heterogeneity was considerably high for all outcome measures. A broad variety of methods was used in the various studies to estimate dietary intake, and most had been published more than ten years prior to this review.

Research conclusions

This was the first meta-analysis to evaluate the dietary intake of patients with CP. Although the calorie intake of patients with CP did not differ from that of healthy controls, studies that analysed the contribution of alcohol to energy intake showed that those with CP consumed fewer non-alcohol calories than controls. This may contribute to the poor nutritional status of patients with CP.

Research perspectives

The considerable heterogeneity made it difficult to make general conclusions, and the broad range of dietary assessment methods used means that under-or over-estimation of intake may have occurred. There were few data for micronutrient intake, a considerable research gap considering the common occurrence of biochemical deficiency in this patient group. There were few recently-published studies. Future studies should aim to characterise the dietary macronutrient and micronutrient intakes of patients with CP with robust methodology and study design.

Abstract

The relationship between nonalcoholic fatty liver disease (NAFLD) and chronic kidney disease (CKD) has gained considerable scientific interest in adults over the past few years. However, this association has recently emerged in children. Several published studies have suggested a role for NAFLD as a risk factor for CKD from the earliest age, with a potential influence of the major NAFLD risk polymorphisms, resulting in an increased risk of both cardiovascular and metabolic diseases. In view of the progressive course and increased cardio-metabolic risk closely related to NAFLD and CKD, we focused on the link between these diseases in childhood.

Key Words: Nonalcoholic fatty liver disease; Chronic kidney disease; Children; Liver

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Nonalcoholic fatty liver disease has been linked to chronic kidney disease in childhood. Due to the intrinsic cardiometabolic burden related to both diseases, we highlighted the importance of knowledge of this relationship in pediatric patients.

TO THE EDITOR

We read with interest the review by Mantovani *et al*[1] on the challenging association of nonalcoholic fatty liver disease (NAFLD) with chronic kidney disease (CKD)[1]. The authors provided a comprehensive overview on this association, linking two chronic diseases with a serious cardiometabolic burden and potentially leading to end-stage organ injury, by discussing both pathophysiological and therapeutic aspects.

In our opinion, it is important to underline that the relationship between NAFLD and CKD already occurs in childhood. Parallel to the increasing prevalence of childhood obesity, NAFLD has become the most common chronic liver disease in pediatric patients[2-4]. As demonstrated in adults, there is convincing evidence in children indicating NAFLD as a risk factor for CKD later in life[5-9]. Owing to the shared metabolic pathogenesis (including ectopic lipid accumulation and insulin resistance)[10], NAFLD has been found to be closely inter-related with renal dysfunction in childhood[9,11-14]. There is compelling evidence of a significant reduction in estimated glomerular filtration rate (eGFR) in obese children with NAFLD[8,12,14], as well as possible modulation of the main NAFLD genes (including the I148M *PNPLA3* variant[5,15-17], the E167K allele of *TM6SF2,* and *HSD17B13*)[5, 15]. Early impairments in renal function (such as reduced eGFR and/or abnormal albuminuria) have been observed in children with obesity and NAFLD and linked to the severity of liver disease[8,12-14].

We wish to draw readers' attention to the early subclinical renal involvement in children with obesity and NAFLD. In view of the greater cardiometabolic risk (including type 2 diabetes, cardiovascular disease, and metabolic syndrome)[18-21] of these patients and the potential genetic influence of NAFLD polymorphisms, findings from these studies might have important clinical and prognostic implications at an early age. In our opinion, all children with obesity should undergo abdominal ultrasound to detect fatty liver[22], and careful monitoring with intensive lifestyle-dietary intervention programs. In the future, NAFLD management may also include genetic characterization, which could represent a crucial step to counteract the development of cardiovascular and metabolic disorders already occurring in childhood.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Haruhiko Sugimura, PhD, MD, Vice President, Hamamatsu University School of Medicine; Professor and Chairman of the Department of Tumor Pathology, Hamamatsu University School of Medicine, 1-20-1 Handayama, Higashi-ku, Hamamatsu 431-3192, Japan. hsugimur@hama-med.ac.jp

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Drug-induced pancreatitis is a gastrointestinal adverse effect concerning about 2% of drugs. The majority of cases are mild to moderate but severe episodes can also occur, leading to hospitalization or even death. Unfortunately, the mechanisms of this adverse reaction are still not clear, hindering its prevention, and the majority of data available of this potentially life-threatening adverse effect are limited to case reports leading to a probable underestimation of this event. In particular, in this editorial, special attention is given to thiopurine-induced pancreatitis (TIP), an idiosyncratic adverse reaction affecting around 5% of inflammatory bowel disease (IBD) patients taking thiopurines as immunosuppressants, with a higher incidence in the pediatric population. Validated biomarkers are not available to assist clinicians in the prevention of TIP, also because of the inaccessibility of the pancreatic tissue, which limits the possibility to perform dedicated cellular and molecular studies. In this regard, induced pluripotent stem cells (iPSCs) and the exocrine pancreatic differentiated counterpart could be a great tool to investigate the cellular and molecular mechanisms underlying the development of this undesirable event. This particular type of stem cells is obtained by reprogramming adult cells, including fibroblasts and leukocytes, with a set of transcription factors known as the Yamanaka's factors. Maintaining unaltered the donors' genetic heritage, iPSCs represent an innovative model to study the mechanisms of adverse drug reactions in individual patients' tissues not easily obtainable from human probands. Indeed, iPSCs can differentiate under adequate stimuli into almost any somatic lineage, opening a new world of opportunities for researchers. Several works are already available in the literature studying liver, central nervous system and cardiac cells derived from iPSCs and adverse drug effects. However, to our knowledge no studies have been performed on exocrine pancreas differentiated from iPSCs and drug-induced pancreatitis, so far. Hence, in

this editorial we focus specifically on the description of the study of the mechanisms of TIP by using IBD patient-specific iPSCs and exocrine pancreatic differentiated cells as innovative *in vitro* models.

Key Words: Induced pluripotent stem cells; Therapy personalization; Patient-specific cells; Drug-induced pancreatitis; Thiopurines; Inflammatory bowel disease

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: About 5% of inflammatory bowel disease patients develop pancreatitis after thiopurine administration. The mechanism of this adverse effect is still not clear making it difficult to prevent. By differentiating induced pluripotent stem cells into their pancreatic exocrine counterpart, it is possible to set up innovative personalized *in vitro* models to study this adverse effect in a more effective way.

INTRODUCTION

Gastrointestinal adverse effects are common especially with orally absorbed drugs and may result in undesirable consequences leading to the reduction of treatment efficacy and, in the most serious cases, to therapy interruption with associated healthcare costs. To better study and prevent these adverse events there is the need for dedicated clinical investigation[1]. Over the past years, adverse drug reactions (ADRs) have been widely studied also for their negative effect on the development of new drugs[2,3].

Among the different ADRs, drug-induced pancreatitis has become increasingly recognized as an important cause of acute pancreatitis with a wide range of drug classes involved in its development[4]. Unfortunately, the majority of data available of this potentially life-threatening ADR are principally limited to case reports, leading to a probably underestimated incidence, reported to be around 2%[4]. Furthermore, the mechanisms of drug-induced pancreatitis of many drugs are still not clear, making it difficult to determine a definitive association of causality between specific medications and acute pancreatitis, and in only less than 10% of cases the real cause has been determined. Drugs known to induce pancreatitis have been classified considering the number of case reports, the recurrence of pancreatitis with a re-challenge with the drug, consistent latency between the drug assumption and the onset of acute pancreatitis and the exclusion of alternative causes such as alcohol assumption or gallstones [4,5] (Table 1).

Interestingly, certain types of ADRs are reported to be more frequent in patients affected by specific diseases. An important example is thiopurine-induced pancreatitis (TIP), an idiosyncratic ADR affecting more frequently inflammatory bowel disease (IBD) patients taking thiopurines, such as azathioprine and mercaptopurine[6]. In the vast majority of cases, TIP is manageable, however patients have to stop the treatment and to be sometimes hospitalized until the symptoms are resolved[7]. The higher incidence of this adverse event in IBD patients, especially in the pediatric population, suggests that molecular mechanisms involved in the disease may contribute to TIP predisposition[6]. However, mechanisms determining TIP predisposition are still unknown and only hypotheses have been postulated. In particular, the mechanisms proposed can be divided into three different groups: genetic predisposition[8,9], alteration in thiopurine biotransformation[7] and abnormalities in innate or adaptative immunity[10].

The thiopurines azathioprine, mercaptopurine and thioguanine undergo an extensive biotransformation catalyzed by several enzymes[11]. Regarding genetic predisposition, TIP seems unrelated to candidate variants on important genes of the thiopurine biotransformation pathway, such as *TPMT, ITPA* and *NUDT15*, well-known to induce severe ADRs, including myelosuppression and hematologic toxicity[12,13].

Table 1 Classification system of drugs related to pancreatitis development[4,5]

Class	
Class Ia	At least one case report with positive rechallenge, excluding other possible causes such as alcohol, gallstones and other drugs
Class Ib	At least one case report with positive rechallenge but not excluding other possible causes
Class II	At least four cases in the literature without rechallenge but with consistent latency in greater than 75% of cases
Class III	At least two cases in the literature without rechallenge and consistent latency
Class IV	Single case reported in the literature not fitting the previous described classed without rechallenge

Recently, two different research groups have found a strong association between the Class II *HLA* gene region polymorphism rs2647087 and TIP[8,9], but more efforts are needed to translate these variants into clinical practice. TIP development may be also related to direct damage to the exocrine pancreatic cells or to an accumulation of toxic metabolites (biotransformation hypothesis). However, pancreatitis frequently occurs early after thiopurine administration, making the accumulation of toxic metabolites unlikely, while more probably immunological reactions are involved. However, direct toxicity of thiopurines or their metabolites on patients' pancreatic cells cannot be completely excluded[7,10].

To study and discover TIP mechanisms and predisposition, innovative patient-specific *in vitro* models could be helpful and decisive. In this regard, induced pluripotent stem cells (iPSCs) and their differentiated counterpart are widely used to set up groundbreaking personalized *in vitro* models representative of patients' genetic background. The peculiar characteristics of these cells allow to set up *in vitro* models to study disease mechanisms and ADRs with the purpose to personalize patients' therapy, improving the disease outcome. The iPSC model can be a great tool to better understand, and thus prevent, ADRs in particular in comparison to animal models and immortalized cells. Indeed, the predisposition to a specific ADR may be related to the individual genetic patients' background, leading to a wide range of toxicities of different severity[14]. Therefore, the iPSC technology, matching the donor's genetic background, can be extremely helpful for developing patient-specific assays. Indeed, by using iPSCs, it seems reasonable to precisely mimic the patients' susceptibility to an abnormal response to a specific drug, setting up powerful assays useful to identify predictive biomarkers. In the last years, many different models[15] have been developed using the iPSC technology, including the differentiation into pancreatic exocrine cells[16].

PATIENT-SPECIFIC IPSCS AS AN IN VITRO MODEL TO STUDY DRUG-INDUCED PANCREATITIS

Patient-specific iPSCs can be obtained by reprogramming patients' fibroblasts or peripheral blood mononuclear cells using the four Yamanaka's factors OCT4, SOX2, KLF4 and MYC, forcing somatic cells to an embryonic-like state[17,18]. Differentiation of iPSCs allows to generate almost any kind of somatic cells using appropriate protocols. In the literature it is possible to find a wide range of differentiation possibilities including neural-like cells, hepatocytes, enterocytes, pancreatic endocrine cells and many others as recently reviewed by our group[15]. These cells, being patient-specific, have been frequently used to model and study individual susceptibility to develop ADRs. For example, regarding gastrointestinal toxicity, some groups have already tried to model hepatocytes[19-21] and enterocytes[22,23] to study drug-induced liver injury and intestinal toxicity, respectively. However, in comparison to other ADRs, drug-induced pancreatitis has not been deeply studied yet. A limited number of protocols[16,24-26] are available in the literature to generate pancreatic exocrine cells starting from iPSCs in comparison to the endocrine counterpart[15]. To the best of our knowledge, our group recently evaluated for the first time the mechanisms behind TIP predisposition using iPSCs and pancreatic differentiated cells of pediatric patients affected by IBD that developed or not TIP. Differentiation of iPSCs in pancreatic exocrine cells was performed using the protocol developed by Takizawa-Shirasawa *et al*[16]. Briefly, different stimuli were added to the culture medium in 4 different steps (Figure 1). To characterize cells obtained during each differentiation step, genetic expression of specific genetic markers was analyzed and confirmed:

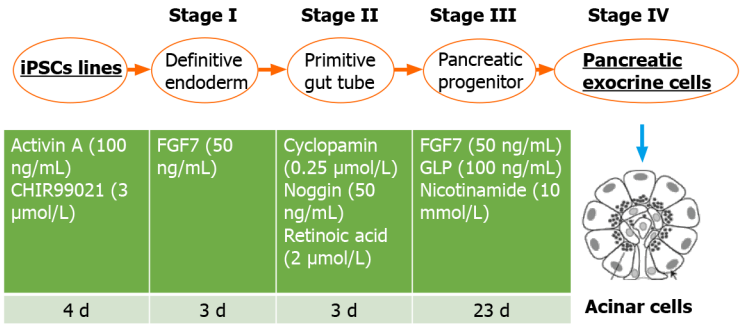

Figure 1 Differentiation of induced pluripotent stem cells into pancreatic cells towards a 4 steps protocol. iPSCs: Induced pluripotent stem cells; d: Days of culture.

OCT4 for undifferentiated cells (iPSCs), *FOXA2* and *SOX17* for definitive endoderm (stage I), *PDX1* for pancreatic progenitors (stage III) and amylase, in particular its pancreatic isoforms *AMY2A* and *AMY2B* for pancreatic exocrine cells (stage IV).

The gold standard of cytotoxicity assay showed an almost double *in vitro* sensitivity of TIP cases cells to thiopurines, more marked in iPSCs rather than in the differentiated counterpart, after mercaptopurine and thioguanine exposure. *TPMT* variants (rs1142345, rs1800460 and rs1800462) were excluded as a possible cause of this different sensitivity because all patients resulted wild-type.

The results obtained are encouraging, however some limitations have to be overcome in the next future. For instance, the differentiation protocol to obtain exocrine pancreatic cells could be further improved in terms of efficiency based on the more recent studies performed by Hohwieler *et al*[24] and Ito *et al*[25] which used 3D culture methods and the distinction between acinar and ductal cell type, by analyzing the expression of different genetic and protein markers such as amylase and chymotrypsin C for acinar cells, and SOX9 and cytokeratin 19 for ductal cells[24,25]. An important point to consider is if the amylase markers are sufficient to reflect terminal differentiation. Beside studies considering the mRNA levels of these markers[24,25], more functional studies, evaluating the amylase protein concentrations and enzyme activity, should be implemented. These comparisons would allow to ensure that terminal differentiation is as representative as possible of the *in vivo* models. Another important point to focus, linked to pancreatic cell generation, is the time necessary that is too long for a clinical application of this *in vitro* model for TIP predisposition screening. Studies are now ongoing to partially resolve this limitation trying to develop more efficient and faster ready-to-use patient-specific pancreatic exocrine differentiated cells. The cost of hospitalization after a pancreatitis event has been recently calculated, resulting in around 8000 € *per* patient[27]. Considering an incidence of pancreatitis of 5%, we can estimate that every 20 patients treated with azathioprine one will be at risk of pancreatitis. Therefore, to be cost-effective, the analysis should amount to 400 €, considering only the cost of the analysis, without evaluating the health benefit[28]. Current costs are still higher but there is a trend toward reduction; indeed, the iPSC technology is still expensive and costs have to be reduced before they can be introduced into clinical practice. In particular, characterization costs are high, but several suggestions to address this limitation have been already proposed such as SNP microarray technology for the routine karyotyping and cost-effective methods such as innovative flow cytometry analyses to assess cell surface expression of pluripotent markers[29].

Beyond technical limitations, it is conceivable that thiopurines do not directly reach the pancreatic tissue unmodified, but rather as metabolites. Therefore, to improve the clinical relevance of the *in vitro* model, patient-specific pancreatic cells would need to be exposed to a representative mixture of thiopurine metabolites or to conditioned media of other thiopurine metabolizing cells such as hepatocytes[30]. Moreover, it is important to keep in mind that TIP predisposition could be influenced by the contribution of the immune system that, in predisposed patients, could be activated for unknown reasons after thiopurine administration attacking the pancreatic tissue. This aspect has to be considered, modeled and studied as well[7,31]. Finally, data obtained have to be confirmed in a larger cohort of patients that now includes 3 cases and 3 controls already analyzed while 2 cases and 2 controls still have to be analyzed.

CLINICAL IMPLICATIONS

Drug-induced pancreatitis represents an important clinical issue for different reasons including therapy interruption, reduction of treatment efficacy, the need for unnecessary diagnostic procedures and treatment for the adverse effect resolution[1] with associated healthcare costs. Moreover, in recent years an increasing number of drugs have been associated with pancreatitis development although its recognition by clinicians is still limited because of the lack of biomarkers useful to prevent this ADR.

CONCLUSION

Drug-induced pancreatitis is a growing problem related to several drugs and TIP recapitulates well all complications related to the development of this ADR. The possibility of studying TIP by an iPSC-based model seems a great opportunity to investigate TIP mechanisms that still remain not clear. The *in vitro* model established in our laboratory has proven to be suitable for studying and investigating TIP predisposition in a personalized way in pediatric IBD patients. Alongside thiopurines, several other drugs such as asparaginase, nilotinib and pazopanib can cause pancreatitis. Therefore, the *in vitro* model developed in this study could be applied also to study the sensitivity of other drugs with the purpose of pancreatitis prevention.

Abstract

Nonalcoholic fatty liver disease (NAFLD) is becoming a frequent liver disease, especially in patients with metabolic syndrome and especially in Western countries. Complications of NAFLD comprise progressive fibrosis, cirrhosis and hepatocellular carcinoma. NAFLD also represents an independent risk factor for cardiovascular disease, extrahepatic neoplasia and other organ damage, such as renal insufficiency. Given the epidemiological importance of the disease, new developments in specific treatment of the disease and the wide availability of noninvasive techniques in estimating steatosis and fibrosis, NAFLD should be subject to screening programs, at least in countries with a high prevalence of the disease. The review discusses prerequisites for screening, cost-effectiveness, current guideline recommendations, suitability of techniques for screening and propositions for the following questions: Who should be screened? Who should perform screening? How should screening be performed? It is time for a screening program in patients at risk for NAFLD.

Key Words: Screening; Nonalcoholic fatty liver disease; Diabetes; Liver fibrosis; Cirrhosis

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Nonalcoholic fatty liver disease (NAFLD) is becoming more important in Western countries and leads to serious complications in patients with progressive disease. The epidemiological, clinical and technical requirements for screening for this disease are fulfilled and are outlaid in this review. It is time to consider a screening program for NAFLD.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease worldwide, with rising prevalence to an estimate of 25% in Western populations[1]. NAFLD is regarded as one component of metabolic syndrome, including obesity, insulin resistance or type 2 diabetes mellitus (T2DM), hypertension, and dyslipidemia. Recently, the new term metabolic dysfunction-associated fatty liver disease has been proposed to emphasize this association[2]. Over the next decade, the number of patients with advanced fibrosis stages is expected to rise further together with an increasing incidence of complications [nonalcoholic steato hepatitis (NASH)-related end stage liver disease, *e.g.* hepatic decompensation, liver cancer and mortality][3]. In this recent modeling, the number of NAFLD patients in the United States, the EU5 (France, Germany, Italy, Spain, United Kingdom) and China was estimated to be 85.3 million, 72.2 million and 211 million, respectively, whereby in the same countries, more than 17.3 million, 12.6 million and 32.6 million patients were predicted to have NASH[3]. The number of NASH patients with advanced fibrosis is expected to more than double until 2030. Similar but slightly more conservative calculations have been obtained with different modeling methodologies but confirm the extent of the clinical problem[4]. In addition to liver-related morbidity and mortality, it is important to emphasize that NAFLD patients have increased cardiovascular mortality, which together cause an enormous socioeconomic impact in industrialized countries[4]. The fact that NAFLD has become the most frequent disease entity on the liver transplant waiting list in the UNOS network documents the need for early detection and intervention in the future[5]. Given the sheer frequency of patients with obesity, metabolic syndrome and NAFLD worldwide, it is remarkable that this disease entity has been overlooked by clinicians and the pharmaceutical industry for a considerable period of time, and no widely established algorithms for screening exist. The global burden of disease documents the burning need to establish clinical care structures and diagnostic algorithms to cope with the increasing number of patients at risk.

A multistep diagnostic screening algorithm is recommended in current guidelines in Western countries and combines an initial ultrasound (US) examination with subsequent risk prediction tools such as the Fibrosis-4 (FIB-4) or NAFLD fibrosis score (NFS) followed by transient elastography (TE) stratification for liver biopsy[6,7]. Increasing public and professional awareness as well as the implementation of screening algorithms in primary and secondary care will lead to a more frequent diagnosis of NAFLD patients at different stages of the disease (NAFL, noncirrhotic NASH, NASH with cirrhosis) in the near future. For the histological assessment of NAFLD, different systems are used for scoring in clinical practice [*e.g.*, NAFLD activity score (NAS)][8]. The definite histopathological diagnosis of NAFL *vs* NASH is based on the simultaneous presence of steatosis, ballooning and inflammation, which are required for the diagnosis of "NASH" in the European SAF/FLIP algorithm[9].

Of the different histologic features of NASH, fibrosis has been identified as the strongest predictor of adverse clinical outcomes, including decompensation and liver-related death[10-14]. The latest meta-analysis showed that the stage of biopsy-confirmed liver fibrosis is a strong predictor of future all-cause mortality and morbidity in NAFLD with and without adjustment for key potential confounding variables[15]. It became clear that evaluation of the fibrosis stage is even more fundamental than scoring necroinflammation or diagnosing NASH. Several options for the noninvasive evaluation of liver fibrosis in NASH, such as elastography devices and blood tests, are available[16]. Despite recent progress in noninvasive tests (NITs) for the evaluation of liver fibrosis in NAFLD, the diagnosis of NASH is still often based on liver biopsy, an invasive procedure not suitable for the large proportion of the general population affected by NAFLD. To identify patients with an increased risk, the NFS was introduced in 2007 as a simple scoring system to distinguish NAFLD with and without advanced fibrosis (fibrosis stages 3 and 4)[17]. Subsequently, further fibrosis tests, including the FIB-4 index, Fibrotest/Fibrosure, enhanced liver fibrosis (ELF) test, and liver stiffness measurement (LSM) by vibration-controlled TE, have entered clinical practice[18-21]. Of relevance for fibrosis screening, these NITs show excellent

AUROCs for the diagnosis of advanced fibrosis and cirrhosis[22]. Furthermore, repeated testing of FIB-4 within 5 years improved the identification of individuals at an increased risk of severe liver disease in the general population[23]. In light of a multistep screening algorithm, the performance has been further improved by the sequential combination of different NITs for advanced fibrosis, thereby refining the patient referral pathway between primary care or diabetologists and liver specialists [24]. Sequential combinations of FIB-4 (or NFS) and TE with a lower cut-off to rule-out advanced fibrosis and a higher cut-off to rule-in cirrhosis can increase the specificity and thereby reduce the need for liver biopsies from 33% to 19%[25]. The ultimate goal of screening measures is to identify patients at high risk for liver-related events and unfavorable overall outcomes. Longitudinal retrospective studies have demonstrated that NITs calibrated on liver fibrosis are prognostic markers to stratify the risk of liver-related outcomes and mortality in NAFLD patients[26].

Comparative diagnostic accuracy studies for established and novel biomarkers and combinations thereof are ongoing in the European LITMUS and United States NIBLE consortia[27]. It will be interesting to learn whether and which of the novel biomarkers outperforms the established freely available routine scores NFS and FIB-4. At the same time, biomarker screening strategies are currently being tested to establish validated numbers of patients to test to identify NASH patients with advanced fibrosis suitable for specific treatment.

The following review gives an overview of current guideline recommendations and answers the question of when, whom and how to screen in the different clinical settings.

RECOMMENDATIONS FOR NAFLD SCREENING IN RECENT GUIDELINES

Several guidelines worldwide have already taken a position on screening for NAFLD. The consensus is that screening in the general population is not recommended[6,7,28,29]. AASLD also discourages screening in high-risk groups because of the current lack of treatment options, unclear value of screening tests, and unclear cost-effectiveness. However, "a high index of suspicion" for the presence of NAFLD in diabetes mellitus type 2 patients is advised[7]. The Asian guideline takes a similarly noncommittal view, which also does not explicitly recommend screening in risk groups (here T2DM and obesity) but merely describes it as worth considering[29].

In contrast, specific screening recommendations can be found in the Latin American and European guidelines. Here, NAFLD screening is recommended for patients with repeatedly altered liver enzymes, features of metabolic syndrome, or obesity [body mass index (BMI) > 30] according to Latin American guidelines[28]. In the same direction, patients with insulin resistance and metabolic syndrome, especially manifest type 2 diabetes, should also be screened for the presence of NAFLD according to the European recommendation, regardless of the level of liver enzymes[6]. Both guidelines primarily recommend abdominal US as the initial examination to determine the presence of steatosis. Serum fibrosis tests are considered appropriate for further risk stratification[6,28], with the Latin American guideline decidedly recommending determination of FIB-4 and NFS. Elastography, as a more reliable method, is also mentioned[28] but is considered secondary due to its lack of availability in many places.

The guidelines differ in their treatment of patients in whom serum fibrosis scores indicate intermediate fibrosis risk. While the European algorithm recommends both high-risk and intermediate-risk patients for referral to the hepatologist[6], the Latin American guidelines suggest that this should only be the case for patients > 50 years of age with diabetes or obesity[28].

The basis of the differing recommendations is an ultimate lack of data on the efficacy and efficiency of structured screening and on the effectiveness of the therapeutic efforts that begin after NAFLD has been diagnosed in the context of screening. There are also discrepancies between the lack of widespread availability of specific examination procedures and the desire for screening results that are as sensitive and specific as possible and avoid overloading specialists by referring numerous false-positive screened patients.

SCREENING–WHEN? IS IT TIME FOR A NAFLD SCREENING PROGRAM?

Prerequisites for a disease to justify screening

In 1968, Wilson and Jungner formulated basic criteria for the usefulness of screening procedures for a particular disease in a paper by the WHO[30,31]. These criteria include peculiarities of the disease (significant burden of disease in the population and knowledge of etiology and stages of disease) and of reaching a diagnosis (simple test acceptable to patients) as well as organizational requirements (available facilities for diagnosis and therapy). In general, these criteria already apply for NAFLD for some time.

However, the authors also point out that efficient therapy as well as cost-effectiveness of screening must be present[30]. Here, important new developments have occurred in recent years that make screening for NAFLD much more justified than in the past.

The general progress in diagnosing and treating liver disease led an expert group 2016 to the proposal that screening for liver fibrosis (independent from the underlying disease) may now be feasible even for the general population[32].

For a long time, missing therapeutic options were a major argument against NAFLD screening, since lifestyle changes could only be maintained in a minority of patients and NASH-specific drugs were not even developed. In the meantime, several new drugs acting on various pathophysiological processes in NASH have entered clinical development. Current drug classes being investigated for NASH treatment are agonists of nuclear receptors such as FXR agonists (including FGF19), peroxisome proliferator-activated receptors agonists, chemokine receptor inhibitors, thyroid hormone receptor-β agonists and analogs of enterohepatic hormones such as GLP-1 and FGF21 or SGLT2 inhibitors[33]. Despite disappointment by negative interim results from three out of four recent phase 3 trials, the process of approval is ongoing for obeticholic acid as the only drug with a significant benefit in the phase 3 interim analysis. Obeticholic acid is an obvious candidate for the first conditional approval as a NASH therapeutic in the near future. However, even before approval of new drugs, NAFLD patients "at risk" should be offered to participate in ongoing clinical trials, particularly those with drug combinations, since the future will putatively be a more efficient combination therapy of two different drug classes with complementary effects[33].

Cost-effectiveness of NAFLD screening

Decisions on the target population for screening are mostly driven by cost-effectiveness and depend on the prevalence of the disease in the target population and health outcomes measured as quality-adjusted life-years (QALYs). Unfortunately, the cost-effectiveness of noninvasive liver tests in NAFLD is scarcely available in the literature.

However, the cost-effectiveness of noninvasive screening for alcohol-related liver fibrosis has been investigated in more detail[34]. For low prevalence populations, a screening strategy involving a blood-based noninvasive fibrosis test (ELF) in the first-line follow-up with LSM in intermediate- or high-risk individuals in the second-line follow-up was most cost-effective, both short- and long-term, depending on whether diagnostic testing had lasting or temporary effects on abstinence rates. The study documents that the effect of screening measures strongly depends on the therapeutic options and the size of the treatment effect. Moreover, for high-prevalence populations, direct referral to LSM was highly cost-effective.

In contrast to the growing burden of disease, a cross-sectional study of the public health response to NAFLD among experts in 29 European countries in 2018 and 2019 revealed a general lack of national policies, awareness campaigns and civil society involvement and only a few epidemiological registries[35]. Only one-third of the countries reported having national recommendations for NAFLD screening in all patients with diabetes, obesity and/or metabolic syndrome.

Data on cost-effectiveness need to be interpreted in the context of the national health system, economy and availability of treatment. Nevertheless, available data for certain diagnostic measures allow at least some general insight and can be used as part of evidence-informed decision making. As the most basic diagnostic method, ultrasonography screening for NAFLD has been found to be cost-effective in Thailand for patients with metabolic syndrome participating in an intensive weight reduction program when compared with no screening[36]. Differences in the age of the target population have been observed, since screening before 45 years was cost saving, while screening at 45 to 64 years was cost-effective.

The cost-effectiveness of LSM by TE has only been assessed in comparison to liver biopsy as the invasive reference method. In a systematic analysis covering four cost-effectiveness and four cost-utility studies[37], high-quality cost-effectiveness studies suggested that TE is less costly but also less accurate than liver biopsy (which is not surprising since histology is still regarded as the diagnostic gold standard). The incremental cost-effectiveness ratio (ICER) of TE improves with a greater level of diagnostic accuracy and a higher degree of liver fibrosis. Similar data have been obtained in a Canadian systematic review of existing TE cost-effectiveness studies from the perspective of the Ontario Ministry of Health and Long-Term Care[38]. For a primary economic evaluation, decision analytic models were used to compare short-term costs and outcomes of TE compared to liver biopsy. Again, data suggested that TE leads to cost savings but is less effective than liver biopsy in the diagnosis of liver fibrosis. Of note, TE became more economically attractive in a high-risk population with a higher degree of liver fibrosis. No studies have assessed the cost-effectiveness of TE with controlled attenuation parameter (CAP)-based fat quantification for the diagnosis of liver steatosis.

It remains open whether NAFLD screening can become cost-effective in the near future with a further increasing number of at-risk NAFLD patients in Western countries. Investigators from six prospective cohorts in Europe and Asia used patients with mostly alcohol-related liver disease to explore the cost-effectiveness of TE as a screening method to detect liver fibrosis against standard of care in a primary care pathway[39]. In 6295 participants, TE with the proposed cutoffs for the diagnosis of significant fibrosis (≥ F2) of 9.1 kPa in general population settings and 9.5 kPa in at-risk populations outperformed fibrosis scores in terms of accuracy. Screening with TE was cost-effective, with mean ICER ranging from 2570 €/QALY for a population at risk of alcohol-related liver disease (age ≥ 45 years) to 6217 €/QALY in the general population [39]. Overall, there was a 12% chance of TE screening, even though it was cost saving across countries and populations. This study clearly documents that screening for liver fibrosis with TE can be a cost-effective intervention for European and Asian populations, even in primary care, and may even be cost saving.

For various other screening tools, a comparative cost-utility model analysis of different annual noninvasive screening strategies has been conducted in Canada using a third-party payer perspective in a general population compared to screening in a high-risk obese or diabetic population[40]. The investigated screening algorithms involved the NFS, cytokeratin-18, TE and acoustic radiation force impulse (ARFI) imaging for detecting advanced fibrosis (≥ F3). Liver biopsy and magnetic resonance elastography were compared as confirmation methods. Compared with no screening, screening in high-risk obese or diabetic populations was more cost-effective than in the unselected general population. Interestingly, liver biopsy confirmation was not found to be cost-effective. These data suggest that annual NASH screening can be cost-effective in high-risk obese or diabetic populations in a Western country.

Using a different simulation model in the United States, the effectiveness and cost-effectiveness of US screening for NAFLD followed by liver biopsy has been assessed for type 2 diabetic patients[41]. In this more basic NASH screening strategy, all patients received a one-time screening US, individuals with hyperechogenicity on US underwent subsequent liver biopsy, and those found to have NASH received medical therapy to decrease disease progression. Screening for NASH decreased the number of individuals who developed cirrhosis by 12.9% and resulted in an 11.9% reduction in liver-related deaths. However, the screening strategy resulted in only 0.02 fewer QALYs due to the disutility associated with treatment and was dominated by the "no screening" strategy[41]. The impact of treatment efficacy and treatment-related side effects became clear in this study because when the model excluded the treatment-related quality-of-life decrement, screening became cost-effective. This study documents that treatment-associated side effects are relevant for quality of life and impact QALYs and the suitability of screening.

Referral strategies between primary care and secondary care by specialists have also been investigated. Given the high prevalence of NAFLD in Western countries, the optimal evaluation of NAFLD likely involves triage by a primary care physician (PCP) with advanced disease managed by gastroenterologists or hepatologists. Screening in a cohort of 10000 simulated United States-American patients with NAFLD performed in either PCP or referral clinics was simulated[42]. Risk stratification by the PCP using the NFS alone costs approximately 20% more *per* QALY than usual care costs. In the microsimulation, at a willingness-to-pay threshold of $100000, the NFS alone in the PCP setting was the most cost-effective strategy in 94.2% of samples, followed by the combination NFS/vibration-controlled transient elastography in the PCP setting (5.6%) and usual care in 0.2%[42]. This study indicates that risk stratification of pa-

tients with NAFLD in primary care is a cost-effective strategy that should be further explored in clinical practice.

Finally, the outcome of the entire diagnostic chain is relevant for decision making upon screening. This certainly includes the likelihood of referral to the specialist after obtaining a risk surrogate (which is often moderate at best), the availability of effective drugs for the target disease (in case of NASH to be established) and relevant side effects of the treatment impacting quality of life. Taking into account the emerging awareness campaigns among the public and PCPs and ongoing phase 3 treatment studies for NASH patients, it is likely that the impact of screening on the overall outcome could improve over the near future.

WHO TO SCREEN?

NAFLD is an asymptomatic disease in the early phase, often leading to a late diagnosis [43]. In a large population-based, cross-sectional study from Barcelona, the authors found elevated liver stiffness (as defined with TE > 6.8 kPa) in 9% of the participants, and NAFLD was the leading etiology (followed by alcohol risk consumption)[44]. Risk factors for elevated liver stiffness included obesity, type 2 diabetes and the presence of metabolic syndrome (each with a prevalence of elevated liver stiffness in 20%–30%). This study convincingly underlines the importance of NAFLD in the general population but especially in the known risk groups. While the prevalence of NAFLD in the general population is quite high (20%-30%), only approximately 7%-10% of NAFLD patients develop relevant complications of this disease, such as advanced fibrosis, cirrhosis or hepatocellular carcinoma (HCC)[45,46] (Figure 1). Thus, screening the entire population cannot (yet) be justified because too many patients would suffer overdiagnosis and possibly overtherapy. For advanced testing or invasive diagnostic measures such as liver biopsy, which applies to a selected patient population of still 3%-5%, primary testing to rule out low-risk individuals appears mandatory.

These numbers from the general population, however, do not apply to patient groups with increased NAFLD prevalence and increased risk for advanced disease. In the presence of the risk factors diabetes and obesity, the prevalence of NAFLD increases to 75%[47,48]. Diabetes and obesity are clear independent risk factors for the development of NASH-related fibrosis[46,47] and other factors of the metabolic syndrome are closely associated[49]. In addition, patients with these underlying diseases are more likely to develop complications of NAFLD[48]. Consequently, screening in the group of patients with these risk factors for complications is particularly important[50]. Elevated liver enzymes alone are sufficient as a reason for screening but are not sufficient as a sole decision criterion, as relevant NAFLD with fibrosis or cirrhosis may be present even with normal transaminases[51-53].

These facts warrant screening of this risk population[54], especially at higher HbA1c levels[54]. In some cohorts, patients with NAFLD also had an older age > 50 years in addition to the above risk factors[55-57], and an increased prevalence of NAFLD and advanced fibrosis has been shown in men[57]. These risk factors reflect quite well the collective for which screening for NAFLD is repeatedly discussed in the current literature or even concrete recommendations exist[6,7,28,29].

NAFLD is linked to several other diseases and is connected to metabolic disturbances. It is straightforward to consider the presence of NAFLD in patients with such concomitant diseases, one of the most important being coronary heart disease. Additionally, NAFLD should also be considered, depending on the advancement of the respective disease, in diseases such as polycystic ovary syndrome, sleep apnea, hypothyroidism, depression, renal insufficiency or psoriasis[7,58-60]. Making a specific screening recommendation for these patients is probably not warranted at this time; further risk profiles are needed here to justify such screening in selected patient groups with these diseases.

General screening of close relatives is also not reasonable despite some familial clustering and genetic factors (*e.g.*, *PNPLA3*[61]) that may influence the course of NAFLD. The penetrance of these genetic risk factors is too low to justify screening in the presence alone (RR 3.26 for the histological presence of NAFLD *per* effect allele [62]). However, relatives with the presence of the abovementioned risk factors should definitely be screened for the presence of NAFLD[6]. Screening with diabetes type 2 as a central risk factor again has very recently been shown to be cost effective in the United States by avoiding advanced liver-specific disease and endpoints (all calculated screening models based on US and AST, with an ICER between $17000 and $35000/QALY[63], see also ***Cost-effectiveness of NAFLD screening***).

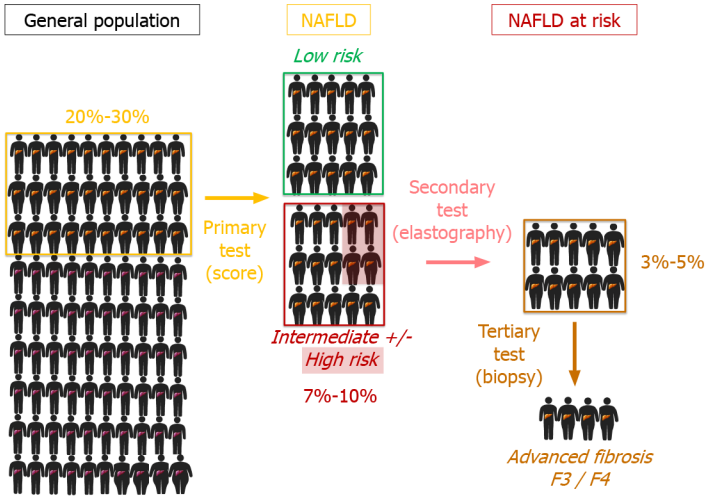

Figure 1 Nonalcoholic fatty liver disease patient proportions according to risk assessment. Stepwise enrichment of nonalcoholic fatty liver disease (NAFLD) patients at risk for advanced fibrosis using a three-step strategy with score-based primary testing in a subgroup of the general population at risk for NAFLD and elastometric secondary testing to identify candidate patients for liver biopsy represents the third and final step in most algorithms. Patients with a diagnosis of NAFLD by either surrogate scores or ultrasound (20%-30% of the general population) are divided into low-risk *vs* intermediate-to-high-risk subgroups (the latter 7%-10% of the general population). After elastometry testing, half of these subjects can be assigned to a high likelihood of advanced fibrosis F3/F4 and should be subjected to liver biopsy. NAFLD: Nonalcoholic fatty liver disease.

WHO SCREENS?

A decision about who carries out screening is determined by the care structures of a particular health care system rather than by the efficacy of particular screening procedures. Even if certain diagnostic procedures proved to be cost-efficient for screening (*e.g.*, LSM as shown above in section 3), the lack of a broad availability of LSM-determining procedures may preclude its application. Consequently, more broadly available blood-based tests are needed, and the design of a screening algorithm must then be aligned with the capabilities of those performing the screening[64-66].

In many countries, almost all patients are primarily cared for by PCPs. A certain proportion of patients defined in the at-risk population (see above) are assigned to specialists (diabetologists/endocrinologists, cardiologists), but numerous patients with diabetes mellitus, obesity, and arterial hypertension are also treated exclusively by PCPs (*e.g.*, in the context of so-called disease management programs). In Europe, screening algorithms are implemented in a total of only 5 countries and are located in the primary health care sector in all of these countries (Belgium, Denmark, Czech Republic, Slovakia, and United Kingdom[35]). However, there are sometimes considerable structural differences in the health care systems of these countries.

Due to access to patients, comprehensive risk population screening in many countries can only be in the hands of PCPs, possibly supported by diabetologists and cardiologists. This group of physicians is particularly suited to broadly identify the major risk diseases for NAFLD and thus to determine the individual NAFLD risk in these patients[67]. This assessment is also in line with existing EASL recommendations [6] and a recently developed algorithm for general practitioners and diabetologists [68]. Direct referral of all patients at risk to hepatologists is not feasible. The need for a screening filter at the primary care level to prevent unnecessary referrals to specialists is shown by data from England ("Camden and Islington NAFLD pathway"[69]) and the United States[70]. In both studies, almost 90% of unnecessary referrals could be avoided by structured screening at the primary care provider level. On the other hand, in an American study, more than 25% of NAFLD patients referred to a hepatologist without screening already had advanced fibrosis (characterized as at least F3 with TE measurement[54]).

Data on awareness of NAFLD at GP level are rare. In the United States, data from the United States Veteran Affairs Database showed that NAFLD is significantly underdiagnosed in primary care patients[71]. Patients with abnormal alanine aminotransferase (ALT)/glutamate pyruvate transaminase (GPT) without other known liver disease (viral hepatitis and alcohol use were largely excluded by data analysis) were detected in only 40% of cases in this study, received a suspected diagnosis of NAFLD in only 21%, received therapeutic counseling in only 15% and were referred to a specialist in only 3% of cases. Initially, there is no reason to assume that the situation

in other countries differs significantly from these results. A study by the professional association of gastroenterologists in private practice in Germany (bng) showed for a cohort of NAFLD patients in secondary care that approximately 10% of these patients already had advanced fibrosis according to FIB-4 screening, but even these patients were not consistently counseled or guided regarding therapy[55]. Only 27% of patients with presumed advanced fibrosis in this study received nutritional counseling. In this respect, education and training activities for PCPs are definitely necessary to increase awareness of the presence and risks of NAFLD and to create acceptance for screening. Diabetologists and cardiologists should also be included by these measures, as they should also be involved in screening due to their spectrum of patients they treat.

Integration of primary care identification of patients at risk for the presence of NAFLD, particularly with advanced fibrosis, into secondary testing facilities at a specialist setting is a crucial issue for the overall efficacy of a screening algorithm (Figure 2). Dedicated elastography platforms have been established at several places, such as in our own center[72]. The likelihood of referral of "intermediate or high risk" individuals to secondary care, the proportion of subjects with "indeterminate" test results (the so-called "gray zone" of respective score-based tests) and the availability of advanced testing platforms for referral are relevant factors at this interface. As pointed out, existing or emerging networks between PCPs and specialists are key to optimizing a bidirectional transition into secondary testing and, in case of "low risk", back to long-term observation and basic treatment in a primary setting.

HOW TO SCREEN?

Value of transabdominal ultrasonography of the liver in NAFLD

US is a widely available, cost-effective, radiation-free method that allows assessment of hepatic fatty degeneration[73]. Hepatic fatty degeneration results in an increase in the echogenicity of the liver parenchyma (*e.g.*, compared with the renal parenchyma). US is thus suitable as a screening method for NAFLD. However, steatosis below 10% of hepatocytes is not detected, and up to 20% is unreliably detected[74] (especially with microvesicular fatty degeneration). In moderate and severe hepatic steatosis, good sensitivity (85%-96%) is achieved with specificity up to 98%[75]. The best results are seen above a liver fat content of 12.5%, where AUROC values under consideration of different echographic parameters reached comparable results to H-magnetic resonance spectroscopy (MRS)[76]. With the above referenced threshold, exclusion of steatosis by US is not completely possible. With regard to possible fibrosis of the liver, US diagnostics do not allow reliable determination and staging[73].

Noninvasive measurement of hepatic steatosis and fibrosis by elastography

US-based shear wave elastography techniques are well suited as a method for measuring liver stiffness to detect or exclude advanced liver fibrosis and cirrhosis in NASH. In addition, FibroScan, for example, now also offers the possibility of quantifying the fat content of the liver *via* the measurement of additional parameters.

The CAP measurement integrated in the FibroScan achieved AUROC values between 0.7[77] and 0.84[78] in studies with more than 400 patients each for (histologically confirmed) steatosis of > 33% and > 66%.

Different elastography techniques are now available on the market, and a differentiated overview cannot be given here but is available elsewhere[79]. While TE using FibroScan requires the purchase of a dedicated device, other techniques, such as ARFI imaging (Siemens), Elast-PQ (Philipps), and supersonic shear-wave elastography (SWE, Aixplorer), offer the advantage of being integrated into routine US equipment [73].

In large cohorts from Europe and Asia, the reliability of TE, its superiority over fibrosis scores, and even its cost-effectiveness have been demonstrated, at least for certain at-risk populations, in determining liver fibrosis of different origins[39]. TE is also well suited for quantifying fibrosis in NAFLD. Here, sensitivity, specificity, and AUROC values improve as fibrosis progresses, reaching values of approximately 92% and 0.89 for cirrhosis (F4), respectively[77,80]. Difficulties in estimating fibrosis in obese patients with the normal (M) probe[81] were countered by the company's introduction of an XL probe for particularly obese patients, which provides reliable values and is automatically chosen if the patient has appropriate physical conditions [82,83].

Apart from slight differences in patients with different body types, the diagnostic value of the different elastography methods in determining liver fibrosis in NAFLD

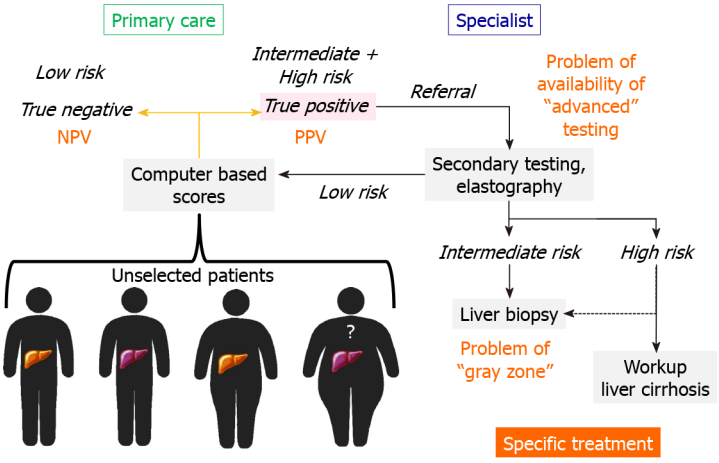

Figure 2 Linking primary care to hepatology. Unselected patients from the general population are most likely in contact with primary care. In primary care, patients at risk for the presence of nonalcoholic fatty liver disease and according to computer-based scores at risk for advanced fibrosis should be transferred into secondary testing facilities at a specialist setting. Critical for the overall efficacy of a screening algorithm are the likelihood of referral of "intermediate or high risk" individuals to secondary care, the proportion of subjects with "indeterminate" test results ("gray zone" of score-based tests) and the availability of advanced testing platforms for referral. NPV: Negative predictive value; PPV: Positive predictive value.

patients appears to be similar. Several studies with different populations and study designs yielded similar AUROC values for TE, SSI, ARFI, and 2D-SWE[84-86]. However, problems with a tendency to overestimate fibrosis occurred in bariatric, extremely obese (median BMI 47 kg/sqm) patients for both TE and ARFI, where the ELF score was actually superior to these two elastography methods[87]. Nevertheless, the procedures should also be well suited for screening most patients. The availability of the methods is very heterogeneous, so broad screening with elastography is currently not possible.

Value of magnetic resonance imaging and computed tomography in the diagnosis and screening of NAFLD

The availability of computed tomography (CT) is bound to institutions with large medical devices but is well reproducible and reliably determines the fat content of the liver by measuring organ density[73]. In a meta-analysis comparing different radiological methods, CT performed rather modestly with a sensitivity of 46%-72%[88]. At least moderate hepatic fatty degeneration can be diagnosed if the density ratio of the liver and spleen on native CT has a cutoff value > 1.1[89]. Dual-energy CT has been able to show promising results for quantifying fat content in the liver in smaller cohorts, even in comparison with magnetic resonance imaging[90]. However, such techniques are poorly validated and not widely available. Overall, CT should not be used as a primary screening method for detecting NAFLD because of its cost, lack of broad availability, and substantial radiation exposure.

Magnetic resonance imaging (MRI), though also a large medical device, is a radiologic imaging modality without any radiation exposure. Certain modalities of MRI can be used to determine both the fat content of the liver and the fibrosis stage quite reliably[73]. MR-based quantification of liver fat content using proton density fat fraction (PDFF) has high linearity and precision with simple postprocessing[91], but it is also not suitable for screening large risk groups because of cost and effort[92]. Compared with histology as a reference standard and in comparison to CAP, PDFF-based determinations have a higher diagnostic accuracy for detecting steatosis (histological grade 1-3) with an AUROC of 0.96 up to 0.99, a sensitivity of 96%, and a specificity of 100%[93,94]. MRS has the highest accuracy for fat assessment in the literature[88,92,95] but is currently limited to research centers due to a lack of standardization of methodology and high costs for hardware and software requirements [73].

MR elastography measures liver stiffness significantly more reliably than US-based elastography techniques[85,96]. In a biopsy-controlled study of 100 patients, an AUROC of 0.98 was achieved at 40 Hz[97]. A joint analysis from 12 studies with over 900 patients still showed summary AUROC values of 0.93-0.95[98]. MR elastography also correlated better to clinical fibrosis parameters and scores than TE[99] but remains restricted to specialized centers[92].

Multiparametric MRI with determination of fat content (by PDFF or spectroscopy) and fibrosis (by MR elastography) was superior to the respective FibroScan-based non-MR methods (CAP for steatosis and TE for fibrosis) in a comprehensive new study [100] and cost-effective for risk stratification of NAFLD in a United Kingdom study [101]. Nevertheless, these methods are not (yet) suitable for broad screening due to lack of availability and high costs.

Laboratory chemistry scores

Because screening must be performed primarily by PCPs, screening tools must be widely available, inexpensive, and noninvasive[58,66,67]. This allows screening to be performed on a day-to-day basis and, more importantly, increases the acceptance of screening by the physicians performing it. The two-step design with the verification of steatosis and fibrosis risk improves the specificity (and in some cases even the sensitivity) of screening[65,102]. Positively screened patients must be transferred to a hepatologist for further evaluation. In this context, the proportion of positively screened patients should not be too large to avoid overloading hepatologists[65,103]. The extent of the diagnostic "gray zone" is of particular importance in this regard and can vary substantially from test to test. In any case, however, patients with prolonged or repeated elevations of GPT/ALT should be referred for further evaluation (as is usually the case), as they are generally at increased risk for liver disease or injury[51, 104,105].

There are significant differences between different countries and health care systems in the availability and cost-effectiveness of different screening tools. However, despite the limited sensitivity of US, this procedure is an attractive screening option for PCPs because of its ease of performance. More technically sophisticated and sensitive procedures such as CAP or elastography are generally not available at this level of care.

Steatosis scores correlate with insulin resistance. Their diagnostic performance for steatosis depends on the degree of fatty degeneration, fibrosis, and inflammation[106]. Assuming at least moderate steatosis is relevant, the performance of the fatty liver index (FLI) and NAFLD liver fat score is best, with the highest AUROC values with a positive predictive value of 99%, but without safe exclusion of steatosis below the cutoff[106-108]. Only the FLI can easily be obtained from routine values in family practice (see Table 1) and should therefore be used when US is not feasible[109].

Fibrosis scores also vary in both availability and quality of information. In this regard, the sensitivity and specificity of each score for significant fibrosis, advanced fibrosis, and cirrhosis are quite different and additionally vary depending on the population screened (population screening *vs* high-risk screening *vs* screening of confirmed NAFLD)[110]. Scores that require the determination of expensive specialty laboratory parameters are not suitable for primary care screening, nor are scores that include, at least in part, unavailable laboratory parameters or instrumental procedures. Although these special scores are superior to routine scores, as expected[111], and would also improve specificity in combination with them[112], the lack of availability and the lack of acceptance of these special scores by general practitioners, based in part on complicated determination, hinder their widespread use. This applies, for example, to the ELF test[113] (hyaluronic acid, TIMP-1, and procollagen peptide), which is of similar prognostic value to liver biopsy[114], and the fibrometer VCTE test (with elastography), which is also superior to purely laboratory chemistry-clinical indices [24].

Scores with readily available routine parameters for fibrosis risk include NFS, FIB-4 score, APRI score, Forns score, and BARD score. The first two (NFS, FIB-4) are superior to the last three (APRI, Forns, BARD) in screening fibrosis in the NAFLD cohort[115,116]. In a recent systematic review, this could be confirmed, especially for the hardest endpoint (mortality)[117]. These two scores (FIB-4 and NFS) are also suitable for screening patients with normal ALT[118] and can be easily determined *via* internet-based calculators.

In population screening, all scores have significant weaknesses and are therefore of limited use for this question[110]. However, the discriminatory performance of all tests is significantly better in high-risk collectives[110]. Although the FIB-4 score was initially developed for the detection of hepatitis C virus fibrosis[119], it has since been validated[120] and compared[121] in NAFLD collectives and may be considered suitable in principle for liver fibrosis of other etiologies. The FIB-4 score has an additional advantage over the NFS in that no albumin value is needed and that the proportion of intermediate tested patients is somewhat smaller[65,116]. However, both scores have lower specificity in patients > 65 years of age[122], which may increase the referral rate to the specialist due to a higher proportion of false-positive screened

Table 1 Scores for diagnosing steatosis and fibrosis with parameters used

	Routine parameters											Special parameters

NIKEI	X	X				X			X					

New fibrometer versions (V2G, V3G) and their respective parameters labeled with brackets: (V2G) and ((V3G)). AST: Aspartate-aminotransferase; ALT: Alanine-aminotransferase; yGT: gamma-glutamyltransferase; TG: triglycerides; BMI: Body mass index; Diab.: Diabetes; A2M: Alpha-2-microglobulin; HA: Hyaluronic acid; Gluc: Glucose; PIIINP: Procollagen-III-peptide; TIMP-1: Tissue inhibitor of metalloproteinases I; Apo-A1: Apo-A1-lipoprotein; FLI: Fatty liver index; HIS: Hepatic steatosis index; NAFLD-LFS: Nonalcoholic fatty liver-liver fat score; VAI: Visceral adiposity index; TyG: Triglyceride and glucose index; NFS: NAFLD fibrosis score; FIB-4: Fibrosis-4; APRI: AST-platelet-ratio index; ELF: Enhanced liver fibrosis; NIKEI: Noninvasive Koeln-Essen-index.

patients. Data from a screening study of type 2 diabetes patients show that the use of age-adjusted cutoffs on FIB-4 (in delineating negative *vs* intermediate) reduces the number of patients tested intermediate (from 38.3% to 15.4%[65]). Repeated measurements of laboratory scores could also help to identify patients at risk of severe liver disease in the general population, as was recently shown for repeated measurements of FIB-4 within 5 years[23].

The screening strategy proposed in Figure 3 relies on recent proposals and takes into account the aforementioned prerequisites of high-risk screening by PCPs but may not currently be evidence-based in several areas. In particular, this concerns the handling of the intermediate-risk group, the screening interval in low-risk patients, and the cost-effectiveness of the entire algorithm. In addition, the screening recommendation given requires further education and possibly training of PCPs about the prevalence and prognosis of NAFLD.

CONCLUSION

It is time for NAFLD screening. NAFLD is hard to diagnose in the early phase of the disease. The prevalence of this disease is increasing in countries with Western lifestyles, and the complication rate (inflammation, fibrosis, cirrhosis and HCC) is high in patients with metabolic dysfunction. Additionally, there are inexpensive noninvasive tools for the diagnosis of steatosis and fibrosis, leading to a reliable identification of persons at risk who can be referred to hepatologists. Apart from lifestyle modification, there are evolving drug treatments shortly before approval or in the late phases of clinical trials.

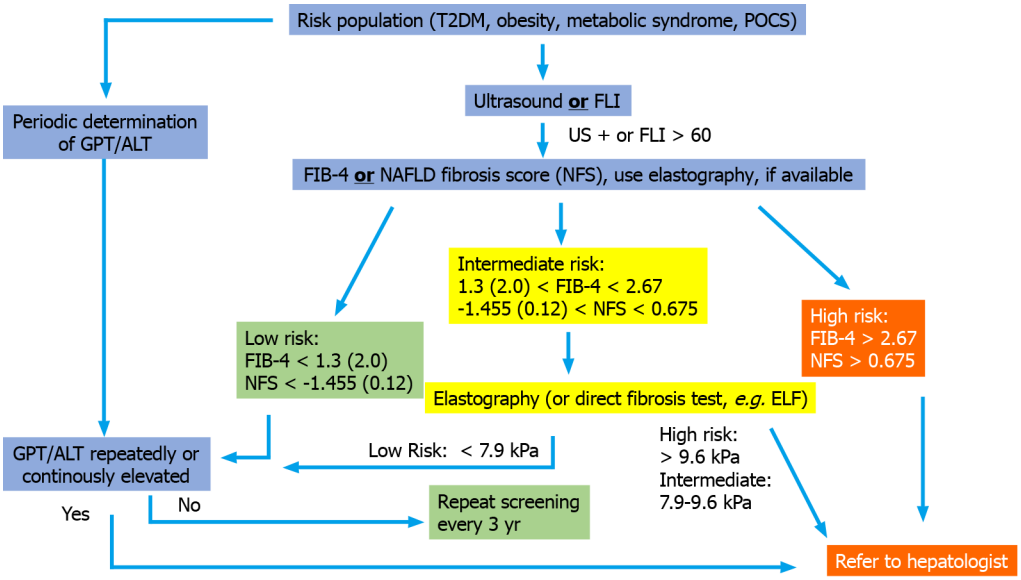

Figure 3 Possible screening algorithm that can be modified according to availability but contains the two main elements (detection of steatosis and fibrosis risk) and can be performed in the primary care physician's office. The algorithm corresponds well to the so-called European algorithm of the EASL-EASD-EASO Clinical Practice Guidelines[6] and to a recently proposed approach for family physicians and diabetologists[68] but is simpler to use. The sequences of fatty liver index and Fibrosis-4 (FIB-4) have been decisively studied for screening in a high-risk population of type 2 diabetes patients[65]. The use of age-adjusted cutoff values (in parentheses) is reasonable to reduce the high proportion of intermediate tested individuals. The sequential use of FIB-4, nonalcoholic fatty liver disease fibrosis score or enhanced liver fibrosis in the intermediate group has not been investigated in studies so far, but there are first studies on the basic sequential use of noninvasive fibrosis scores[123]. FLI: Fatty liver index; FIB-4: Fibrosis-4; T2DM: Type 2 diabetes mellitu; NFS: Nonalcoholic fatty liver disease fibrosis score; GPT: Glutamate pyruvate transaminase; ALT: Alanine aminotransferase.

Studies show that screening for NAFLD, at least for a risk population, is cost effective and will help to prevent serious hepatic consequences of pandemic metabolic dysfunction. However, it will not be easy to implement comprehensive screening programs in all countries since there are large structural differences between national health systems. For example, the extent of availability of elastography will decide in each country, whether this promising technique can be used in broad screening approaches or whether US and lab scores will be necessary for PCPs to conduct screening for NAFLD. Therefore, each screening algorithm (as the one depicted in Figure 3) should be adapted locally depending on the broad availability of methods for detecting steatosis and fibrosis. Additionally, the screening population (*i.e.* the patients with an amount of risk factors high enough for qualifying for the screening program) has to be determined in each country individually depending on the epidemiology of NAFLD in this country.

So what is to be done? We have to increase awareness for NAFLD and its consequences in the population and in primary care. National professional gastroenterology and hepatology societies have to develop guidelines for screening programs depending on the structure of the population and health care system of their respective country. National health systems must implement reimbursement for the tools needed for reliable screening. Hepatologists should prepare for rising numbers of patients referred for risk stratification and specific counseling.

Abstract

The coronavirus disease 2019 (COVID-19) pandemic, caused by the novel virus severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), began in December 2019 in China and has led to a global public health emergency. Previously, it was known as 2019-nCoV and caused disease mainly through respiratory pathways. The COVID-19 outbreak is ranked third globally as the most highly pathogenic disease of the twenty-first century, after the outbreak of SARS-CoV and Middle East respiratory syndrome in 2002 and 2012, respectively. Clinical, laboratory, and diagnostic methodology have been demonstrated in some observational studies. No systematic reviews on COVID-19 have been published regarding the integration of COVID-19 outbreaks (monitoring, fate and treatment) with environmental and human health perspectives. Accordingly, this review systematically addresses environmental aspects of COVID-19 outbreak such as the origin of SARS-CoV-2, epidemiological characteristics, diagnostic methodology, treatment options and technological advancement for the prevention of COVID-19 outbreaks. Finally, we integrate COVID-19 outbreaks (monitoring, fate and treatment) with environmental and human health perspectives. We believe that this review will help to understand the SARS-CoV-2 outbreak as a multipurpose document, not only for the scientific community but also for global citizens. Countries should adopt emergency preparedness such as prepare human resources, infrastructure and facilities to treat severe COVID-19 as the virus spreads rapidly globally.

Key Words: COVID-19; SARS-CoV-2 virus; Environmental perspectives; Epidemiological characteristics; Public health; Emergency preparedness

Core Tip: This review is the first attempt to integrate coronavirus disease 2019 (COVID-19) outbreaks (monitoring, fate and treatment) with respect to environmental and human health perspectives. Briefly, the paper systematically addresses the environmental aspects of the COVID-19 outbreak such as the origin of severe acute respiratory syndrome coronavirus 2, epidemiological characteristics, diagnostic methodology, treatment options and technological advancement for the prevention of COVID-19 outbreaks.

INTRODUCTION

A series of patients with unidentified pneumonia, caused by β-coronavirus, was reported in late December 2019 in Wuhan (Hubei Province), China. Coronavirus disease 2019 (COVID-19) outbreaks are clinically very similar to viral pneumonia. A number of experts from the PRC Centers for Disease Control declared that this respiratory disorder (alternatively known as novel coronavirus pneumonia, NCP) was caused by a novel coronavirus[1]. The World Health Organization (WHO) initially named the disease as 2019-nCoV (2019-novel coronavirus) on January 12, 2020. It was officially later named COVID-19 on February 11, 2020 by the WHO. On the same date, the International Committee on Taxonomy of Viruses named the virus as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) after developing the genome sequence from a COVID-19 patient in Wuhan on January 7, 2020. The virus belongs to the β-coronavirus family, which is very prevalent in nature among other families. Similar to other viruses, the SARS-CoV-2 also has many natural hosts including different intermediate and final hosts, which makes it challenging for scientific communities to treat and prevent COVID-19 outbreaks. It has higher transmission and infection potential but causes a lower mortality rate compared with SARS-CoV and Middle East respiratory syndrome (MERS-CoV)[2]. The genomic sequence of SARS-CoV-2 revealed that it has 79.5% and 96% similarity with SARS-CoV and bat coronavirus, respectively[1], which implies that bats might be the source of SARS-CoV-2. Although the COVID-19 outbreak started in China, the virus has spread to over 213 countries with the highest rate of infection in the United States, Italy, France, and Spain among others as per data published by the WHO on December 13, 2020 (Figure 1). There are approximately 202608306 confirmed SARS-CoV-2 cases and 4293591 deaths worldwide. Consequently, COVID-19 has emerged as a global threat to public health and is steadily growing due to human-to-human transmission. Moreover, this transmission also spreads in different environmental sectors such as water, air, soil, sewage and fecal matter[3]. Additionally, this process is accelerated by a number of meteorological factors namely temperature, weather, humidity and air quality parameters including particulate matter, SOx, NOx and carbon, *etc*. Therefore, a better understanding of the global consequences of COVID-19 is required with regard to environmental perspectives. Accordingly, this review will address the origin of SARS-CoV-2, route of transmission, pathogenesis, epidemiological characteristics, diagnostic methodology, treatment options and technological advancement for the prevention of COVID-19 outbreaks with regard to environmental perspectives in order to acquire the latest understanding of this new infectious disease of which certain immediate as well as long-term remedial measures can be explored.

EPIDEMIOLOGY OF THE COVID-19 OUTBREAK

Origin of the COVID-19 outbreak

SARS-CoV-2 is a β-coronavirus and is enveloped with non-segmented Orthocoronavirinae subfamily RNA[4]. Among the four genera, γ- and δ-CoV infect birds while α- and β-CoV infect mammals including humans (Table 1). The α- and β-CoV have six

Table 1 Details of coronavirus (genus, species and receptor)

Genus	Species	Targets	Receptor
α-CoV	Alphacoronavirus 1:	Mammals

variants. Among them α-CoVs variants (HCoV-229E and HCoV-NL63), and β

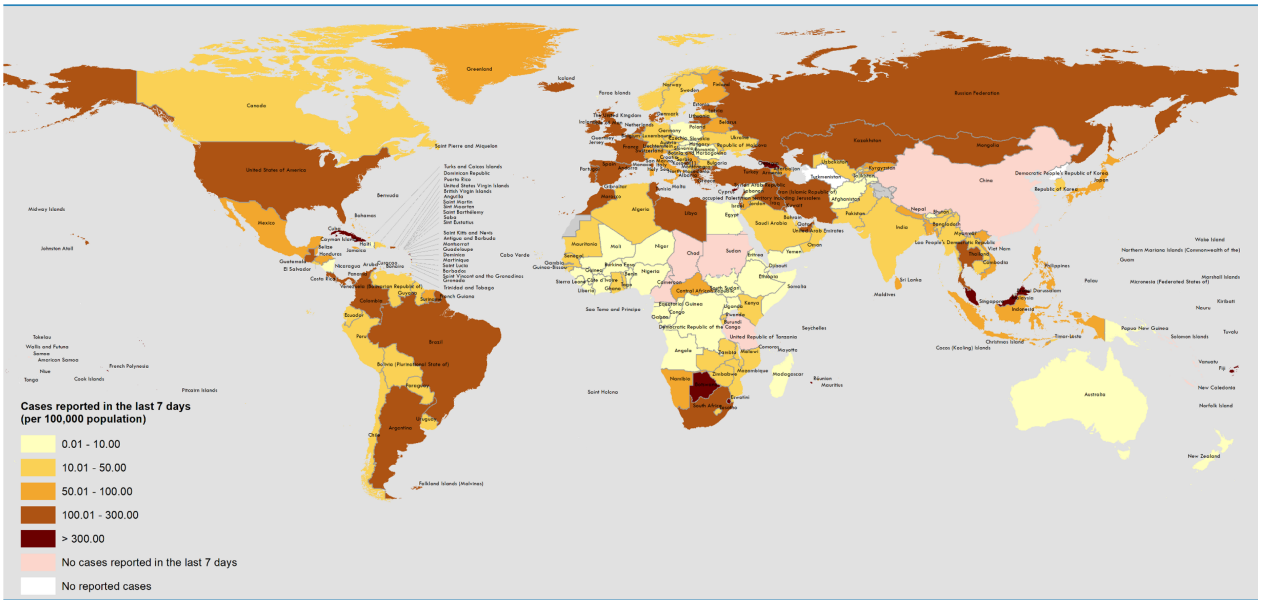

Figure 1 Geographical distribution of coronavirus disease 2019 outbreaks. Source: https://www.who.int/publications/m/item/weekly-epidemiological-update-on-covid-19---10-august-2021 (data as reported at 4:58 pm CET on August 10, 2021).

-CoVs variants (HCoV-HKU1 and HCoV-OC43) have lower pathogenic capability in humans and cause mild respiratory symptoms similar to the common cold. Only β-CoVs variants (SARS-CoV and MERS-CoV) have severe pathogenic capability in humans. This pandemic started in Wuhan specifically in a seafood wet market, on December 12, 2019. Several studies have demonstrated that bats are natural hosts of SARS-CoV-2 and animals such as snakes, turtles and pangolins are intermediate hosts of SARS-CoV-2.

Previously, snakes were thought to be involved in COVID-19 outbreaks by Ji *et al*[5] but this hypothesis was rejected by Zhang *et al*[6] who did not find any similarity in genome sequence between snakes and COVID-19 patients. In another study, researchers found an approximately 96.2% genome sequence similarity between SARS-CoV-2 and bat coronavirus (CoV RaTG13)[7]. In addition, the genomic sequence of SARS-CoV-2 matched with 79.5% of the genome sequence of SARS-CoV[8]. These findings implied that bats were the suspected source of COVID-19 outbreaks as well as the natural host of this virus. The virus was finally transmitted to humans *via* unknown intermediate hosts from bats. However, few bats are sold in the Wuhan seafood market[9]. Accordingly, scientists are trying to determine the intermediate sources such as snakes, turtles and pangolins. Xu *et al*[10] found approximately 99% genomic similarity between SARS-CoV-2 and pangolins. Furthermore, they revealed that pangolins are the potential intermediate host of SARS-CoV-2. Apart from these studies, to date there is no adequate evidence on the virus origin regarding potential intermediate hosts and the natural host of SARS-CoV-2. Therefore, SARS-CoV-2 could use angiotensin-converting enzyme 2 (ACE2), similar to SARS-CoV receptor for human infection[7]. However, there is controversy regarding the infectious potential of COVID-19 patients to transmit the disease during the incubation period. Recently, the WHO reported that cats may be the carrier of this virus, whereas other domestic animals like ducks, hens and dogs may not be carriers of this deadly virus.

Transmission of COVID-19

The animal-human interface is not a new concept. Zoonotic diseases with a wildlife reservoir have long been recognized as significant public health problems. Indeed, up to three-quarters of infectious diseases that cause human infections are known to be zoonotic[11]. Apart from this, the complexity of animal, human, and environmental factors is thought to play a critical role in its emergence[12]. On the other hand, contact with infected patients and droplets are considered to be major transmission routes of COVID-19. Aerosol transmission is another important route of SARS-CoV-2 infection. By contrast, SARS-CoV and MERS-CoV transmission are mainly reported through nosocomial transmission. However, human-to-human SARS-CoV-2 transmission occurs mainly through close contact between COVID-19 patients or friends or carriers and between family members including relatives. It can be spread rapidly in

healthcare workers (up to 50%) and patients (62–79%) similar to SARS-CoV and MERS-CoV and is considered the most common route of infection[13]. It is also assumed that consumption of wild animals who are the hosts of SARS-CoV-2 and humans in close contact with these animals are suspected to be the route of entry of SARS-CoV-2 and its mode of transmission. However, this route of SARS-CoV-2 transmission remains controversial and requires further study.

To date, 1 million people around the world have tested positive for this virus, but only 4 cases have so far been reported in which pets showed positive for SARS-CoV-2. These involved 2 dogs and 2 cats, the owners had COVID-19 and are believed to be the most likely source of transmission to their pets. The dogs showed clinical signs, but one of the cats did not have signs of illness. In late March 2020, health officials in Belgium reported that a cat from Liège province had also tested positive for SARS-CoV-2. Nevertheless, the US Centers for Disease Control and Prevention (CDC), WHO, and key animal health organizations have all issued statements aiming to calm people's fears about their pets being a source of the novel virus[14-16]. In this regard, the World Organization for Animal Health has emphasized that "there is no justification in taking measures against companion animals which may compromise their welfare". Furthermore, given the speculation that wild live animal species may be linked to this pandemic, this collaborative approach will also require the expertise of wildlife forensic specialists.

SARS-CoV-2 has also been detected in saliva, the gastrointestinal tract, urine and stool. In particular, the gastrointestinal tract or digestive tract has been recognized as another route of SARS-CoV-2 infection based on a bioinformatics study[17]. SARS-CoV-2 has been detected in gastrointestinal mucosal tissue of COVID-19 patients[18]. In addition, it has also been detected in tears and conjunctival secretions of COVID-19 patients[19]. Intrauterine vertical transmission from pregnant women to the newborn is temporarily excluded due to a lack of adequate data on pregnant women infected with SARS-CoV-2[20].

Prevalence of COVID-19

A number of researchers estimated the basic reproduction number (R_0) to calculate the number of people affected by secondary infections. Generally, it represents the number of people with COVID-19 but in a completely susceptible population without intervention[21]. Using the SEIR model, Wu *et al*[22] recorded an R_0 value for SARS-CoV-2 in the range of 2.47-2.86, while Majumder and Kenneth[23] estimated the R_0 value to be 2.0–3.3 based on the IDEA model. By contrast, other β-CoV viruses namely SARS-CoV and MERS-CoV showed an R_0 value in the range of 2.2–3.6 and 2.0–6.7, respectively[24,25], which indicated that SARS-CoV-2 has higher transmissibility than SARS-CoV and MERS-CoV. In China, 87% of cases were in the age group 30 to 79 years and 3% cases were noted to be aged ≥ 80 years, while female cases were only 41.9%[26,27]. Additionally, 81% of cases were classified as mild, 14% cases were severe and 5% cases were very critical. In another study, it was reported that the overall case-fatality rate (CFR) was 2.3%; however, in the age groups 70-79 and ≥80 years, the CFRs were 8.0% and 14.8%, respectively[22]. These findings clearly indicated that elderly males are more susceptible to SARS-CoV-2 compared with other groups. In addition, the virus affected those elderly males with chronic diseases such as diabetes, hypertension, heart disease, *etc*.[20]. In summary, the prevalence of COVID-19 is very high, and it can spread very rapidly within countries and outside countries.

Virus susceptibility and incubation period

Generally, elderly people aged between 55 and 75 years are more susceptible to SARS-CoV-2 infection. Currently, it has been found that the virus is also infecting middle-aged people aged between 25 and 50 years. The average age of patients across 18 studies was 51.97 years (95%CI: 46.06%-57.89%), 55.9% were male (95%CI: 51.6%–60.1%). Additionally, 36.8% cases showed comorbidities (95%CI: 24.7%-48.9%), the most significant being hypertension (18.6%; 95%CI, 8.1–29.0%), cardiovascular disease (14.4%; 95%CI: 5.7%–23.1%), and diabetes (11.9%; 95%CI: 9.1%-14.6%), among others[28]. Children account for 1% to 3% of COVID-19 cases across countries and likely experience an asymptomatic infection (mild or no symptoms on infection) compared with adults. Zhong *et al*[29] demonstrated that the virus has an average median incubation period of about 3 d but it can range between 0 and 24 d, and the average median time from symptomatic onset to death is 14 d. They also found that mortality rises in patients with comorbidities or a surgical history before virus infection. Generally, the average median latency period for SARS-CoV-2 infection was 4 d, the average interval to hospital admission after onset of symptoms was 3.8 d, and the average time to death after admission to hospital was 17.4 d[30]. Another study

reported that the time to appearance of COVID-19 symptoms to death ranged between 6 and 41 d with a median period 14 d[22]. They also showed that this period was age-dependent and related to the patient's immune system status. The prevalence was greater in patients aged over 70 years compared with those less than 70 years. According to the WHO, the incubation period for COVID-19 ranged from 2 to 10 d. By contrast, for MERS-CoV infection the average median latency was 7 d[31]. However, in COVID-19, the maximum latency was observed to be 24 d, which was high compared with SARS and MERS. This indicated that SARS-CoV-2 has a higher risk of transmission. Accordingly, in comparison with SARS and MERS, SARS-CoV-2 has a shorter median incubation period. Recent data showed that elderly people (aged above 75 years) have a shorter median interval, *i.e.*, 11.5 d from symptom onset to death in comparison to COVID-19 patients (20 d). This finding indicated that disease progression is more rapid in elderly people compared to younger people[1].

GENOMIC STRUCTURE AND PATHOPHYSIOLOGY

Genomic structure

SARS-CoV-2, a β-coronavirus, is a single-stranded RNA virus with a diameter ranging between 80 nm and 120 nm. Currently, four types of coronavirus are present in nature: α-, β-, δ- and γ- coronavirus. The γ- and δ-CoV infect birds, while α- and β-CoV infect mammals. Details of these coronaviruses are presented in Table 1. There are six coronaviruses causing human infection including SARS-CoV and MERS-CoV. The complete genome sequence of SARS-CoV-2 is closest to SARS-like bat CoV (MG772933). There is approximately 79% homology in genome sequence between SARS-CoV-2 and SARS[9]. In addition, the complete genomic sequence of SARS-CoV-2 is approximately 29.9 kb, while SARS-CoV and MERS-CoV have a genome length of 27.9 kb and 30.1 kb, respectively[8,32]. The SARS-CoV-2 genome contains a variable number of open reading frames (ORFs) ranging between 6 and 11[33]. Two-thirds are located mainly in the first ORF (ORF1a/b) which encodes 16 non-structural proteins (NSP) and translates polyproteins (pp1a and pp1ab), while the remaining ORFs encode accessory and structural proteins. The remainder of the RNA virus encodes four essential structural proteins, including the spike (S) glycoprotein, small envelope (E) protein, matrix (M) protein, and nucleocapsid (N) protein, and several accessory proteins, that interfere with the host innate immune response[34]. Frameshift mutation between ORF1a and ORF1b is mainly responsible for the production of pp1a and pp1ab polypeptides that are regulated by chymotrypsin-like protease (3CLpro) or main protease (Mpro), and this process produces 16 non-structural proteins (NSPs) with the help of papain-like proteases[35]. Therefore, SARS-CoV-2 pathophysiology and virulence are thought to be linked with NSPs and structural protein functions.

Pathophysiology

The pathophysiology of COVID-19 produces pneumonia which seems to be very complex. The pathological mechanism is presented in Figure 2. A group of researchers claimed that viral infection is caused by an immune reaction through the "cytokine storm"[36,37]. The main protagonist of this "cytokine storm" is interleukin 6 (IL-6). Generally, activated leukocytes are primarily responsible for IL-6 production and IL-6 acts on a number of cells and tissues. It stimulates acute phase protein production and regulates thermoregulation, bone structure and central nervous system functions[36,37]. However, its main role is pro-inflammatory actions. COVID-19 enhances IL-6 level, which is implicated in the pathogenesis of the cytokine release syndrome (CRS), which is an acute systemic inflammatory syndrome characterized by fever and multiple organ dysfunction[36,37].

Another group of researchers demonstrated that SARS-CoV-2 uses angiotensin converting enzyme 2 (ACE2) receptor for both cross-species and human-to-human transmission[1,38]. The virion S-glycoprotein present on the virus surface interacts with ACE2 receptors on human cells to spread the infection[39]. S-glycoprotein contains two subunits, S1 and S2. The S1 determines the virus-host range and cellular tropism in the key function domain – RBD (receptor-binding domain), while S2 is responsible for cell membrane-virus fusion by two tandem domains, heptad repeats 1 (HR1) and HR2[40,41]. Following membrane fusion, viral RNA is released into the cytoplasm, and the uncoated RNA is induced to produce pp1a and pp1ab polypeptides with the help of either chymotrypsin-like protease (3CLpro) or main protease (Mpro), which encode 16 non-structural proteins (NSPs) in the presence of papain-like proteases, and finally form a replication-transcription complex (RTC) in double-

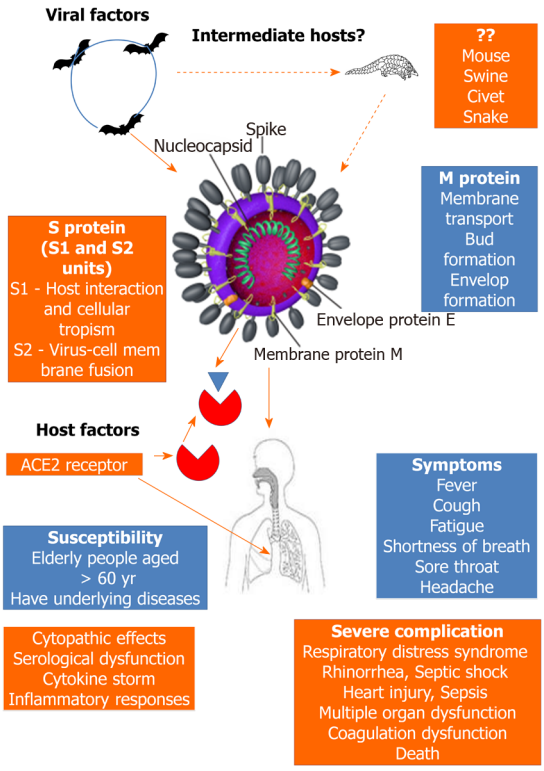

Figure 2 Pathogenesis of severe acute respiratory syndrome coronavirus 2 (viral and host factors). ACE2: Angiotensin-converting enzyme 2.

membrane vesicles[8]. Subsequently, the RTC replicates continuously and synthesizes sub-genomic RNAs[42] to encode accessory proteins and structural proteins. This newly formed genomic RNA, envelopes glycoproteins and nucleocapsid proteins mediated through the endoplasmic reticulum (ER) and Golgi[43] are assembled together to form viral buds. Finally, these newly formed virion-containing vesicles are fused with plasma membrane to release the virus and cause infection through mucous membranes, especially nasal and larynx mucosa, and then enter the lungs through the respiratory tract.

These ACE2 receptors are very important in the spread of COVID-19. They are mainly found in the lower respiratory tract of humans. After entry through mucous membranes, especially nasal and larynx mucosa, the virus enters directly into the lungs through the respiratory tract. In the next step, the virus attacks other target organs which contain ACE2 receptors, such as the lungs, heart, renal system and gastrointestinal tract[36,37]. Accordingly, the binding affinity of this virus-receptor has been intensively studied using different approaches. Systematic detection analysis showed that SARS-CoV-2 S-glycoprotein binding capacity with ACE2 was 10-fold higher than SARS-CoV as shown under cryo-electron microscopy of the SARS-CoV-2 S protein in pre-fusion conformation[39]. Recently, Wu *et al*[9] demonstrated moderate genomic and phylogenetic similarity with SARS-CoV but higher similarity with bat CoV genome sequence, particularly in the S-glycoprotein and RBD. They also found that there were no amino acid substitutions occurring in the NSP7, NSP13, envelope, matrix, or accessory proteins p6 and 8b at the protein level, except in NSP2, NSP3, spike protein, underpinning the subdomain, *i.e.*, RBD. Another recent study demonstrated that mutation of NSP2 and NSP3 plays an important role in infection and SARS-CoV-2 differentiation. However, this mechanism of SARS-CoV-2 infection in humans *via* S-protein binding with ACE2 is unclear, as is the interaction strength for risk transmission. Accordingly, the WHO was also unable to clarify the mechanism of COVID-19. This has led to further investigations regarding potential human-to-human transmission and the pathophysiological mechanisms of COVID-19 outbreaks.

CLINICAL CHARACTERISTICS OF COVID-19 INFECTION

Being an acute respiratory infection, COVID-19 is initiated in the respiratory tract, primarily by droplets, respiratory secretions, and direct contact. After entry, the virus

affects a number of organs or systems (Figure 3). The clinical symptoms of COVID-19 vary from asymptomatic or paucisymptomatic forms to clinical conditions. In particular, all patients are divided into general, severe, and critical patient groups. The most common clinical symptoms of COVID-19 are fever (87.9%), cough (67.7%), fatigue (38.1%), sputum production (33.4%), shortness of breath (18.6%), sore throat (13.9%), and headache (13.6%)[27,44]. The development of these symptoms may occur within 3 d of viral infection. On the other hand, other symptoms may occur 9 d after virus infection. Of these, fever and cough are the dominant COVID-19 symptoms. The incidence of diarrhea (3.7%) and vomiting (5.0%) is very rare[27,44]. However, it is very difficult to accurately distinguish COVID-19 from other viral respiratory infections. The CDC included loss of taste or smell, pink eye, muscle pain, intense chills, headache and sore throat as COVID symptoms. In severe cases, symptoms such as acute respiratory distress syndrome, rhinorrhea, dyspnea, gastrointestinal disorders, septic shock, mental stress, acute heart injury, sepsis, multiple organ dysfunction syndrome (MODS), secondary infection and even death may occur[8,34]. Critical COVID-19 patients with severe respiratory failure require an intensive care unit (ICU) or ventilation support. However, the occurrence of upper respiratory symptoms and gastrointestinal symptoms are very rare compared with other symptoms. In addition to this, the elderly and those who have underlying diseases (*i.e.*, chronic obstructive pulmonary disease, hypertension, diabetes, cardiovascular disease) are very prone to COVID-19 and develop symptoms such as metabolic acidosis, acute respiratory distress syndrome, coagulation dysfunction and even death [8,45]. Sometimes, COVID-19 patients experience acute heart injury, arrhythmia, impaired renal function and abnormal liver function such as the formation of microvesicular steatosis (50.7%) at the time of admission[1,45,46].

Hematological assays revealed that most patients had decreased white blood cell counts, and lymphocytopenia[27]. In the case of critical patients, neutrophil count, D-dimer, blood urea, creatinine and lymphocyte levels decreased markedly. In another study, a reduction in albumin level (75.8%; 95%CI, 30.5%-100.0%), higher C-reactive protein (58.3%; 95%CI: 21.8%-94.7%) and lactate dehydrogenase (LDH) levels (57.0%; 95%CI: 38.0%-76.0%), higher lymphopenia level (43.1%; 95%CI, 18.9%-67.3%), and higher erythrocyte sedimentation rate (ESR) (41.8%; 95%CI: 0.0-92.8%) and other clinical manifestations were recorded[28]. Additionally, inflammatory factors, which indicated the immune status of patients, namely IL-6, IL-10, and tumor necrosis factor-α (TNF-α) are also markedly increased. In critical patients (admitted to the ICU), higher IL-2, IL-7, IL-10, granulocyte colony-stimulating factor (GCSF), 10 kD interferon gamma-induced protein (IP-10), monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein 1-α (MIP-1α), and TNF-α levels in plasma were observed[8,45]. In patients with severe COVID-19 [admitted to the ICU; 20.3% cases (95%CI, 10.0–30.6%)], 32.8% of patients experienced ARDS (95%CI: 13.7%–51.8%), 13.0% patients had acute cardiac injury (95%CI: 4.1%-21.9%), 7.9% patients experienced acute kidney injury (95%CI: 1.8-14.0%), 6.2% cases (95%CI: 3.1%-9.3%) developed shock and 13.9% cases (95%CI 6.2%-21.5%) experienced fatal outcomes[28]. Furthermore, 96.8% of all patients (95%CI: 94.9%-98.7%) had RNAemia in blood and nasopharyngeal aspirates (NPA)[28].

IMMUNOPATHOLOGICAL RESPONSES

Immunological symptoms are generally caused due to binding of virus S proteins with ACE2 at the receptor, usually in the endosome Toll-like receptor (TLR) 3, TLR7, TLR8, and TLR9[8,47]. Retinoic-acid inducible gene I (RIG-I) of the virus, melanoma differentiation-associated gene 5 (MDA5) of the cytosol and nucleotidyltransferase cyclic GMP-AMP synthase (cGAS) are generally responsible for the spread of COVID-19[8, 48,49]. Viral infection activates nuclear factor-κB (NF-κB) and interferon regulatory factor 3 (IRF3) to produce type I interferons (IFN-α/β) and pro-inflammatory cytokines as immune mediators (*i.e.*, innate immunity) to prevent infection[8,50]. As a result, the plasma levels of some cytokines and chemokines are elevated in COVID-19 patients such as IL-1, IL-2, IL-4, IL-7, IL-10, IL-12, IL-13, IL-17, GCSF, macrophage colony-stimulating factor (MCSF), IP-10, MCP-1, MIP-1α, hepatocyte growth factor (HGF), IFN-γ and TNF-α[20,45,51]. Generally, these inflammatory responses were noted in the lower airway and lung[52]. Consequently, these trigger immune signaling and produce the "cytokine storm' within the body leading to a very critical condition in COVID-19 patients.

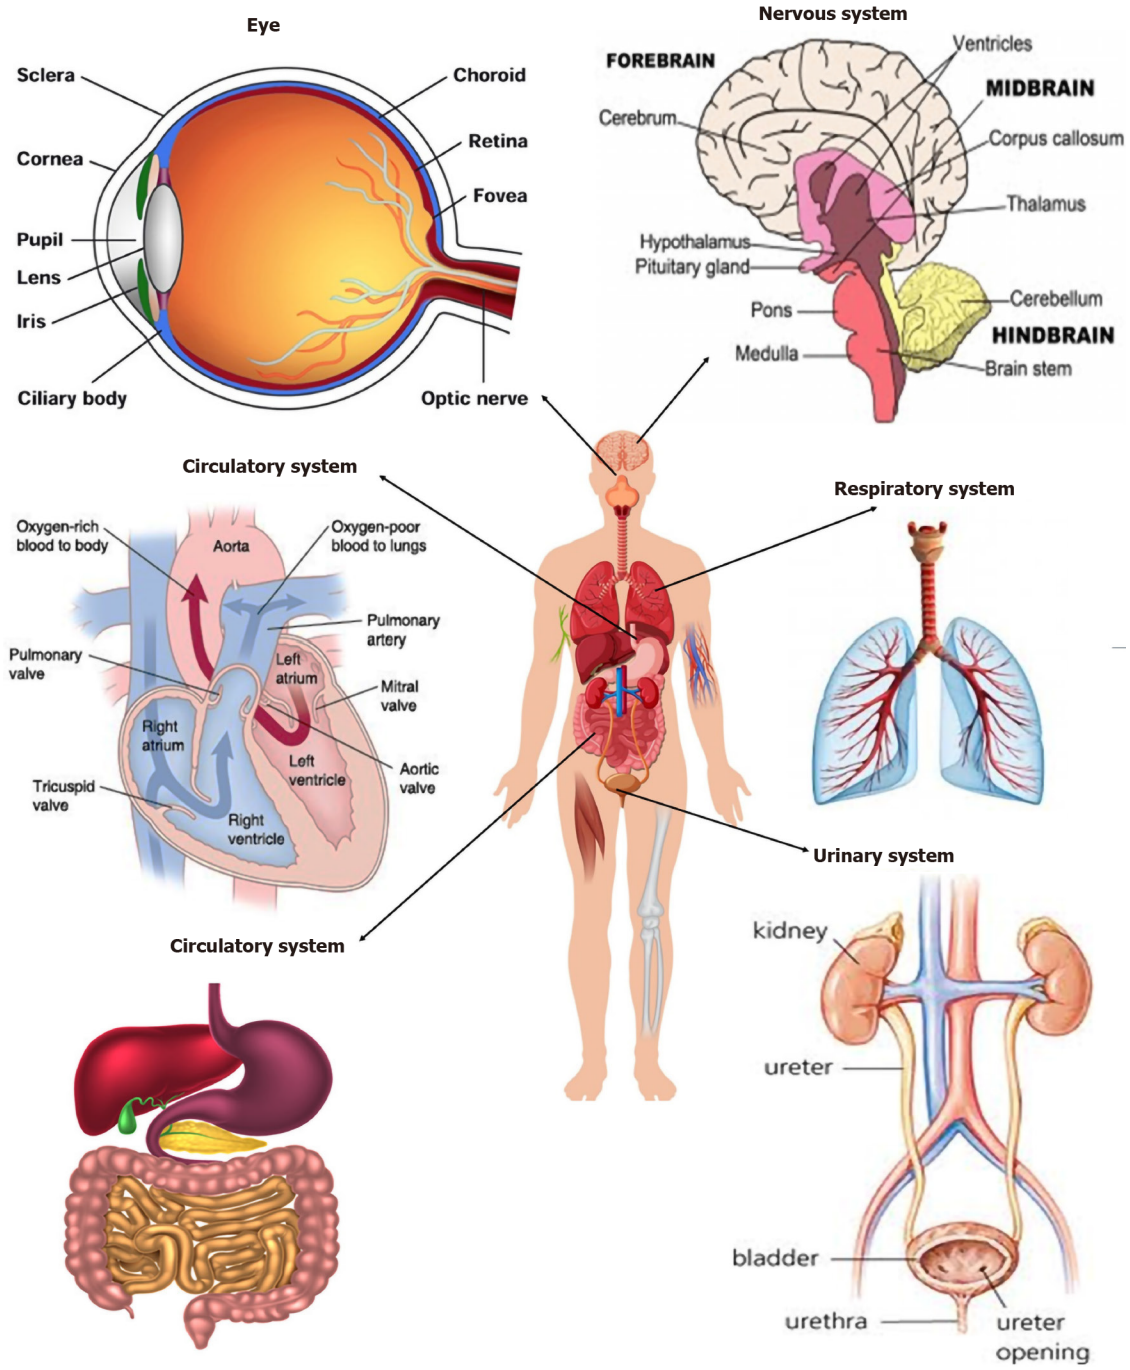

Figure 3 Coronavirus disease 2019 in organs or systems (Images were taken www.google.com).

DIAGNOSIS OF COVID-19

Since the outbreak of COVID-19, a number of diagnostic tools have been used to detect the infection. The classical Koch's postulates method was used to detect the infection in Wuhan[22]. This method is very expensive and time-consuming as it uses electron microscopy. In some countries, radiography was used to detect the viral infection such as a chest computed tomography (CT) scan. CT scan is an important tool in diagnosing COVID-19 pneumonia. Typical COVID-19 pneumonia features were observed by CT. and CT imaging showed ground-glass opacities (56.4%-65%), an air bronchogram (47%), bilateral patchy shadowing (51.8%), consolidations (50%), smooth or irregular interlobular septal thickening (35%), thickening of adjacent pleura (32%), sometimes rounded morphology, peripheral and lower lobe involvement and a peripheral lung distribution in COVID patients[27,53,54]. A very recent study recorded bilateral chest CT findings in 90% patients, and proved its sensitivity (97%) in detecting COVID-19 [55]. However, in another study clinical scientists found that some patients with

confirmed COVID-19 had normal CT scans[53]. Therefore, the diagnosis of COVID-19 is very confusing. Moreover, this technique mainly determines pneumonia. Accordingly, scientists are looking for an alternative method which is more reliable and confirmative. The detection of viral nucleic acid from nasal and throat swab samples, cough, sputum or other respiratory tract samples is the golden diagnostic method for COVID-19 detection. This method uses RT-PCR technology to detect viral infection. Although, this method has high specificity, false-negative results may occur due to low sensitivity and the testing time is too long. In the case of false-positive tests, the WHO recommends resampling and further testing. In this regard, serologic testing is an important diagnostic tool to detect patients who have either current or previous infection but have a negative PCR test[56,57]. In this technique, basic parameters are tested to detect the COVID-19, namely white blood cell count, neutrophil and lymphocyte count, D-dimer, blood urea, and creatinine estimation to identify the appearance of leukopenia, leukocytosis, and lymphopenia as COVID-19 symptoms[58, 59]. In another study, it was demonstrated that 82.1% of COVID patients are lymphopenic, 33.7% patients are leukopenic and 36.2% patients are thrombocytopenic [1]. In addition, another group of researchers recommended elevated plasma levels of C-reactive protein, lactate dehydrogenase, creatinine kinase, transaminase, abnormal myocardial enzyme spectrum or creatinine as COVID-19 indicators[27,45]. They also showed that cytokine release syndrome is an important vital indicator of disease progression. On the other hand, Wan *et al*[60] demonstrated higher IL-6 and IL-10 levels, and lower CD4+T and CD8+T levels as indicators of COVID-19.

Currently, a number of technological inventions are ongoing to detect COVID-19 in a simplistic pathway. Different technological inventions such as the more organized sequencing library (SHERRY) in China, SHERLOCK technology in China, FELUDA in India *etc.*, have been developed as testing tools for rapid detection of COVID-19[6,61]. However, clinical verification of these technological inventions has not been undertaken to date, and once approved, they will be a major breakthrough in technology to diagnose COVID-19 rapidly and economically.

GLOBAL SCENARIOS OF COVID-19 OUTBREAKS

Since its outbreak in Wuhan, China in late December 2019, SARS-CoV-2 infection is spreading very rapidly across the globe. COVID-19 has affected 202608306 people and caused around 4293591 deaths (Table 2). The inter-continental spread is described in Table 2. Figure 4 shows COVID-19 outbreaks in different countries. In the beginning, the Asian countries namely China and South Korea were the epicenter of COVID-19 until the first week of February. Up to August 10, 2021, there have been 93826 confirmed cases and 4636 deaths in China (WHO). In Korea the first COVID case was recorded on January 20, 2020. Since then, about 212448 cases have been confirmed and 2125 deaths recorded in Korea. The epicenter then moved from Asian countries to European countries mainly Italy and Spain. COVID-19 was recorded in Italy on January 30, 2020, and was found in France and Spain on January 24, 2020 and January 31, 2020, respectively. In particular, in Italy, the United Kingdom, France, Germany and Spain it affected people more seriously; approximately 4400617, 6094243, 6310933, 3800048, and 4627770 confirmed cases and 128242, 130357, 112288, 92291, and 82125 deaths were recorded in these countries, respectively, up to August 10, 2021. Among the European countries, mortality rate was highest in Italy due to its travel connection with China. In the middle of March, the virus epicenter moved to the United States and other American countries. The United States and Canada were the most affected countries during this phase. Although the first COVID-19 patient was recorded in late January, 2020 the first death was confirmed in February. In the USA, the first COVID-19 patient died in the middle of March. On August 10, 2021, the USA had recorded the greatest number of confirmed cases and deaths worldwide. The death rate is 206 per million people, which is the tenth highest rate globally. The first COVID-19 patient in Canada was reported on January 27, 2020. On August 10, 2021 there have been 36780480 and 1442087 confirmed cases in the USA and Canada, respectively, and 633799 and 26678 deaths, respectively. In the middle of April, the virus epicenter moved to Russia and India. As of August 10, 2021, there have been 6469910 and 31997017 confirmed cases in Russia and India, respectively, and the number of deaths is 165650 and 428715, respectively. However, the first confirmed COVID-19 case was recorded on January 30, 2020 in Kerala state and January 31, 2020 in Russia. The virus infection in these countries took a very long time to spread due to the implementation of different control measures. The details of COVID-19 cases in India are presented in

Table 2 Coronavirus disease 2019 outbreaks based on the World Health Organization (data as reported at 7.07 PM CEST on August 10, 2021)

Items	Confirmed cases	Deaths
Globally	202608306	4293591

Table 3. However, according to fatality rate data, Belgium (15% fatality) is highest, followed by the United Kingdom (15%), France (14.7%), Italy (13.6%) and the Netherlands (12.3%) (John Hopkins Bulletin).

TREATMENT OF COVID-19

Antiviral drug treatment

Presently, COVID-19 treatment is based on symptomatic findings. To date, there is no precise treatment method, but currently the WHO, CDC and Food and Drug Administration have recommended certain drugs for COVID-19 treatment. The effectiveness

and limitations of each drug are summarized in Table 4[62]. The existing drugs for treating COVID-19 patients are remdesivir, chloroquine, hydroxychloroquine, tocilizumab, lopinavir-ritonavir, azithromycin, baloxavir, favipiravir, *etc.*[63]. Remdesivir, is most prominent for treating COVID-19 patients[64]. The efficacy of remdesivir in treating patients has been reported globally[63-65]. Recently, the ChAdOx1 vaccine developed by the University of Oxford's Jenner Institute and the Oxford Vaccine Group has proved effective in combatting COVID-19. More recently,

Table 4 Recommended drugs for coronavirus disease 2019 treatments (Food and Drug Administration and World Health Organization)

Common drugs	Dose	Mechanism
Chloroquine; Antimalarial	50% for GFR < 10 mL/min	*In vitro* activity and has immunomodulating properties Inhibits viral enzymes or processes such as viral DNA and RNA polymerase, viral protein glycosylation, virus assembly, new virus particle transport, and virus release ACE2 inhibition due to acidification at cell membrane surface, inhibits fusion of virus, and cytokine release
Hydroxychloroquine; Antimalarial	800 mg orally on day one, followed by 400 mg/d orally for four to seven days	Same as chloroquine
Chloroquine phosphate; Antimalarial	1 g orally on day one, followed by 500 mg/d orally for four to seven days	Same as chloroquine
Remdesivir; Nucleoside Analogue	200 mg IV on day 1 followed by 100 mg IV daily on days two to five or 200 mg IV on day 1 followed by 100 mg IV daily on days two to ten	*In vitro* activity; Inhibitor of RNA-dependent RNA polymerases (RdRps) Remdesivir-TP competes with adenosine-triphosphate for incorporation into nascent viral RNA chains Once incorporated into the viral RNA at position i, RDV-TP terminates RNA synthesis at position i+3 Because RDV-TP does not cause immediate chain termination (i.e., 3 additional nucleotides are incorporated after RDV-TP), the drug appears to evade proofreading by viral exoribonuclease (an enzyme thought to excise nucleotide analogue inhibitors)
Azithromycin; Macrolide Antibacterial	500 mg on day one, followed by 250 mg daily for four days	Prevents bacterial superinfection, has immunomodulatory action on pulmonary inflammatory disorders Downregulates inflammatory responses and reduces excessive cytokine production associated with respiratory viral infections; however, its direct effects on viral clearance are uncertain Immunomodulatory mechanisms include reducing chemotaxis of neutrophils (PMNs) to lungs by inhibiting cytokines (*i.e.*, IL-8), inhibition of mucus hypersecretion, decreased production of ROS, accelerating neutrophil apoptosis, blocking activation of nuclear transcription factors
Lopinavir; Ritonavir; HIV protease inhibitor	400 mg/ritonavir 100 mg orally twice daily for up to 21 d	*In vitro* animal model studies show potential activity for other coronaviruses (SARS-CoV and MERS-CoV) Lopinavir and ritonavir may bind to Mpro, a key enzyme for virus replication and suppress virus activity
Tocilizumab; Interleukin-6 (IL-6) Receptor-InhibitingMonoclonal Antibody	4-8 mg/kg infused over more than 60 min (additional dose after 12 h)	Cytokine release syndrome; Inhibits IL-6-mediated signaling by competitively binding to both soluble and membrane-bound IL-6 receptors. IL-6 involved in T-cell activation, immunoglobulin secretion induction, hepatic acute-phase protein synthesis initiation, and hematopoietic precursor cell proliferation and differentiation stimulation
Baloxavir; Antiviral	80 mg orally on day 1 and on day 4, and another dose of 80 mg on day 7 (as needed); not to exceed 3 total doses	Active against influenza viruses; *In vitro* antiviral activity against SARS-CoV-2 demonstrated in one trial
Favipiravir; Antiviral	1600 mg twice daily on day 1, then 600 mg twice daily for 7-10 d; Severe: 1600 mg every 12 h on day 1, then 600 mg every 12 h days 2-10	*In vitro* activity against Vero E6 cells

SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2.

Russia has reportedly developed a coronavirus vaccine named Sputnik V.

Chinese medicine treatment

A number of Chinese medicines have been used to treat COVID-19 patients. According to the Academy of Sciences, Shuanghuanglian oral liquid is most prominent and inhibits SARS-CoV-2. Several studies reported that baicalin, chlorogenic acid and forsythin present in Shuanghuanglian oral liquid have certain inhibitory effects on various viruses and bacteria including SARS-CoV-2[66]; however, the detailed mechanism is not yet known. Lianhuaqingwen capsules have also been used to treat

SARS-CoV-2 infected people as well as other diseases such as influenza viruses, including H7N9 by reducing inflammatory factors[1,17].

Unani medicine treatment

These are plant-based treatments, called Ayurvedic treatments, and these treatments are nontoxic and have no side effects. Different plant parts are used to treat anti-viral activities[67]. The most important plants are *Glycyrrhiza glabra, Allium cepa, Allium sativum, Ocimum sanctum, Ocimum tenuiflorum, Piper nigrum, Cinnamomum verum, Daucus maritimus, Curcuma longa, etc.* Administration of the aqueous extracts of these plants along with lemon juice and honey is very effective for flu and the common cold [68]. According to Fiore *et al*[69] *Glycyrrhiza glabra* plant extract is effective in treating viruses such as SARS related coronavirus, HIV-1, respiratory syncytial virus, varicella zoster, hepatitis A, B, C, and cytomegalovirus herpes. Similarly, Wang *et al*[70] indicated that *Glycyrrhiza glabra* also has antiviral and antimicrobial activities. Therefore, *Glycyrrhiza glabra* plant extract along with other plants may be useful in controlling COVID-19. Accordingly, the Government of India has recommended Ayurveda treatment methods to improve immunity (Table 5).

Homeopathic treatment

Arsenic album-30 is considered beneficial for viral infections. Recently, the Directorate of AYUSH, New Delhi, India has issued an order on January 30, 2020 to take prophylactic medicine to avoid coronavirus infection. Dr Rajan Sankaran has recommended Camphor 1M as a potential medicine for COVID-19 (https://www.boomlive.in/coronavirus-outbreak/homoeopathy-can-be-used-as-adjuvant-to-covid-19-treatment-dr-anil-khurana-7997). They recommended 4 pills of Arsenic album-30 medicine once daily on an empty stomach for 3 d. It is highly diluted arsenic trioxide and works as a homeopathic prophylaxis. Accordingly, the Homeopathy Department of Kerala Government is administering *Arsenicum Album* 30C as a preventive medicine to boost immunity in COVID-19 patients and it was approved by the Department of AYUSH, GoI (https://gulfnews.com/world/asia/india/covid-19-kerala-government-distributes-homeopathy-medicine-to-boost-immunity-1.1588091249686). However, to date, there is no clinical evidence that Arsenic album-30 is an effective medicine. As a result, the use of these medicines to manage COVID-19 has been criticized globally. Mathie *et al*[71] reported that *Arsenicum album* medicine is effective in reducing fever, runny nose, headache, and sore throat in patients with swine flu. Therefore, the use of homeopathy in COVID-19 management is debatable and requires further scientific study.

Immuno-booster treatment

Boosting the body's immunity is a potential individual protocol as COVID-19 pathogenesis is caused by a disproportionate immune response. Therefore, it is important to take supplements to boost both innate and adaptive immune response. Interferon is reported to inhibit viral infection and in particular, recombinant interferon α is effective for SARS-like viruses. Additionally, interferon was reported to be an effective inhibitor of MERS-CoV replication[72]. These findings indicated that interferon could be used to treat COVID-19 infection. Intravenous immunoglobulin might be the safest immune modulator for all age groups, and could help to inhibit pro-inflammatory cytokine production and to increase anti-inflammatory mediators[1,73]. Moreover, thymosin alpha-1 (Ta1) is used as an immune booster for SARS patients to effective control the disease[74]. Accordingly, intravenous immunoglobulin and Ta1 may also be used for the treatment of COVID-19. Recently, different immune-booster drugs have been used to treat COVID-19 such as neuraminidase inhibitors (*e.g.*, oseltamivir used to treat influenza). Apart from these, citrus fruits, dry fruits (almonds, walnuts, and dates) are very effective in improving the immune system. Vitamin A, C, D and E, and zinc supplements are effective in older patients. Additionally, adequate sleep, regular exercise and stress avoidance is essential to boost the immune system[68].

Plasma therapy

Due to lack of appropriate vaccines and specific drugs, plasma therapy could be an effective way to treat COVID-19. Previously, convalescent plasma therapy was proved to be an effective treatment option for SARS patients and those with H1N1 influenza [75,76]. From an immunological perspective, it was observed that recovered COVID-19 patients produced specific antibodies against SARS-CoV-2, and therefore their serum could be used to prevent re-infection. Additionally, these antibodies can limit the

Table 5 Unani drugs for coronavirus disease 2019 treatment (Source: Department of AYUSH, Government of India)

Unani drugs	Doses
Symptomatic treatments	
SharbatUnnab	10-20 mL twice a day
TiryaqArba	3-5 g twice a day
TiryaqNazla	5 g twice a day
KhamiraMarwareed	3-5 g once a day
ArqAjeeb	4-8 drops in fresh water and four times a day
Habb e IkseerBukhar (fever)	2 pills with lukewarm water twice daily
SharbatNazla	10 mL mixed in 100 mL of lukewarm water twice daily
Qurs e Suaal	2 tablets to be chewed twice daily
Decoction	
Behidana	3 g
Unnab	7 nos
Sapistan	7 nos
Darchini	3 g
Banafsha	5 g
Berg-e-Gaozabaan	7 g
Sore throat	
Khashkhash; Bazrulbanj; Post Khashkhash; Barg e Moard (Habbulaas); Tukhm e kahuMukashar; GuleSurkh	Any of them @12 g (each)

production of virus in the acute phase and help to clear the virus if injected during the first week of the viremia peak. Therefore, plasma globulin specific to SARS-CoV-2 has to be prepared from recovered COVID-19 patients. Recently, the Delhi Government successfully applied plasma therapy to treat COVID-19 patients.

In summary, in addition to the abovementioned treatments for COVID-19, auxiliary blood purification treatment (mainly used for severe NCP patients) could be used as an alternative therapy. According to Zarbock *et al*[77] the ACE2 receptor, the key receptor of SARS-CoV-2, is highly expressed in human kidney (100 times higher than in the lung). Kidney is one of the target organs for SARS-CoV-2; therefore, continuous blood purification could reduce renal recovery during COVID-19. Additionally, the kidney suffers from cytokine storms under severe COVID-19 infection. Therefore, blood purification technology could be an alternative method for removing inflammatory factors, eliminating cytokine storms, correcting electrolyte imbalances and maintaining acid–base status[1]. In addition, randomized double-blind clinical trials should be used as standard methodology for large sample sizes to determine antiviral drug efficacy in clinical practice. Currently, in India the discharge policy for COVID-19 recovered patients is based on 3 tier COVID-19 facilities and the categorization of patients is based on clinical severity. The revised discharge policy is indicated in Figure 5.

PREVENTION OF COVID-19 OUTBREAKS

COVID-19 has affected all sectors of society. Therefore, prevention is the best practice to reduce the impact of COVID-19 considering the lack of effective treatments. This can be achieved through a variety of means as follows:

Individual measures

Individual measures are essential in reducing the spread of COVID-19 at the community level. Community level spread is mainly caused when an infected person is in close contact with other healthy individuals. According to the WHO, the following individual measures should be taken to reduce the contamination level such

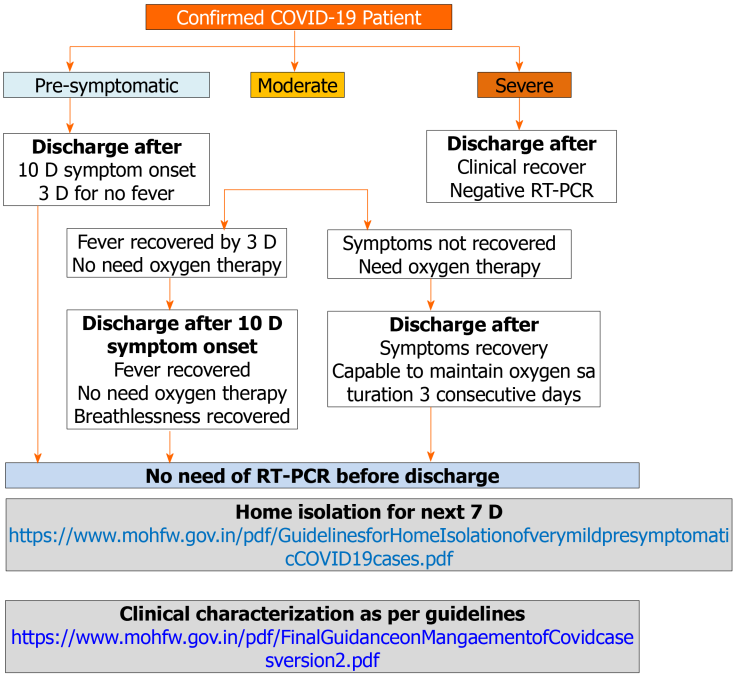

Figure 5 Discharge policies adopted by the Indian government. COVID-19: Coronavirus disease 2019.

as the use of face masks; respiratory hygiene by covering the mouth and nose with a bent elbow or tissue during coughing or sneezing; washing hands regularly with soap or disinfectant (containing at least 60% alcohol); avoiding contact with infected people, maintaining an appropriate distance (at least 2 m) from coughing or sneezing people; refraining from touching eyes, nose, and mouth with unwashed hands and finally, following advice from the healthcare provider.

Community level measures, social lockdown

Social lockdown is the restriction of inter-individual physical contact. Generally, it is a community level measure. The prime objective of social lockdown is to avoid two people from different families or nearby inhabitants coming in close contact with each other[78]. However, minimal and emergency movement of the general public is allowed under this condition. The emergency services (medical care, food security, general security and medicine supply) vary in different countries. However, in severe situations, emergency services such as the food and medical supply chain can also be closed as external or internal body fluid discharges such as coughs, sneezes, saliva *etc.* from COVID-19 patients infect healthy persons due to its easy transmissibility. Another objective of social lockdown is to allow the community to develop mild or full resistance to a mutated virus[78]. Moreover, it provides researchers more time to work on medicine or vaccines production. Considering the advantages of social lockdown, many nations across the globe have started different degrees of social lockdown to prevent SARS-CoV-2 infection.

International social lockdown progress

Some of the international social lockdown campaigns have been addressed here to understand COVID-19 preventive measures. Since the outbreak of COVID-19, China was the first country to implement social lockdown, which occurred in the last week of January 2020 in Wuhan city, the epicenter of the COVID-19 outbreak. During lockdown, buses and cars were allowed to run but domestic flights and trains were cancelled in various cities, and around 760 million people were under lockdown[29]. Accordingly, the WHO praised China as they had taken "perhaps the most ambitious, agile and aggressive disease containment effort in history"[79-81]. After China, Italy was the second country to adopt social lockdown. In Italy, social lockdown was declared on February 21, 2020 in northern Italy covering only 50000 people. Considering the disease incidence, the Federal government of Italy declared whole country lockdown on March 9, 2020. Only public transport was partially allowed, and a public pass system was initiated to ride buses or board flights on an emergency basis [82].

COVID-19 in the USA was spreading very rapidly with a high death rate since its first official COVID-19 case. Higher infection was mainly due to either higher migrant movement or a higher rate of clinical diagnosis[83]. Hence, following the high death and infection rate in the USA, the Trump government implemented the first lockdown on March 19, 2020 but to achieve total control of COVID-19, the American government extended the lockdown period to April 30, 2020 on March 30, 2020. The Trump government explained the second lockdown as follows "The better you do, the faster this whole nightmare will end. Therefore, we will be extending our guidelines to April 30th to slow the spread." Accordingly, the Director of NIH recommended the people of the USA to adapt to the lockdown voluntarily and stringently[84]. Most of the African countries had started to implement social distancing in the middle of March and ended it between May 10 and May 20, 2020. The same window was also used by most European countries. Social distancing in Bangladesh was implemented by Prime Minister Sheikh Hasina very late on March 25, 2020 and ended on May 16, 2020. Other countries such as Pakistan and Sri Lanka started to implement social distancing on March 24, 2020 which ended on May 9, 2020. Additionally, Sri Lanka declared a curfew to maintain strict social distancing.

Social lockdown status in India

Being a populous country, a large portion of the population lives in places of high density and their unhygienic lifestyle results in frequent infectious and epidemic diseases[85]. Therefore, as World Bank data have indicated India is still struggling to improve its health care system and is unable to provide sufficient hospital beds for its citizens. India can only afford 0.7 hospital beds per 1000 people, the doctor: population ratio is 1:1800 (standard is 1:1000), and the total number of ventilators available is 48000[86]. Considering this, the Government of India under Prime Minister Narendra Modi declared a Janata Curfew for 14-h (from 7 a.m. to 9 p.m.) on March 22, 2020 prior to total lockdown. Except for 'essential services' (police, medical services, media and home delivery) everyone took part in the curfew. According to Swiss firm IQAir, at least 75 Indian districts took part and helped to control the spread of SARS-CoV-2, which had an immediate positive effect, especially in Delhi, which is known as one of the world's most polluted capital cities. This resulted in a massive change in New Delhi's Air Quality Index (AQI). This was mainly due to a huge reduction in vehicular traffic; during lockdown there was a 70% reduction in the demand for petroleum oil. India is the third largest user of oil, after the USA and China. After that a nationwide lockdown for 21 days (except emergency services) was declared on March 24, 2020. The government implemented the following restrictions: (1) ban on people from stepping out of their homes; (2) closed all services and shops except pharmacies, hospitals, banks, grocery shops and other essential services; (3) closed all commercial and private establishments (only work-from-home allowed); (4) suspended all educational, training, and research institutions; (5) closed all places of worship; (6) suspended all non-essential public and private transport; (7) prohibited all social, political, sports, entertainment, academic, cultural, and religious activities; and (8) suspended entry of all international commercial flights from March 22. During the first phase of lockdown, the infection rate was not as high as that in the USA, Spain and Italy. It was previously reported that temperature may adversely affect virus infection [87]. Considering the influence of the upcoming Indian hot and humid summer, the health experts urged the Government to extend the lockdown. Many international news agencies described this strict lockdown by the Indian government as harsh, intensive and mismanaged[88,89]. However, the WHO declared that "the measures taken by India to break the community spread of COVID-19 by the lockdown was a very early, scientific and timely decision"[90]. In the words of Dr. David Nabarro, special envoy on the disease, WHO "*The lockdown in India was quite early on, when there was relatively a small number of cases detected. This was really a far-sighted decision because it gave the whole country the opportunity to come to terms with the reality of this enemy. People understood that there is a virus in our midst. It gave time to develop capacities at the local level for interrupting transmission and sorting out hospitals. Of course, there is a lot of debate and criticism, and inevitably with a lot of frustration and anger that life is being disturbed in this way. It is very, very upsetting. I think it is courageous of the government, honestly, to take this step and provoke this enormous public debate and let the frustration come out, to accept that there will be hundreds of millions of people whose lives are being disrupted. For poor people on daily wages, this is a massive sacrifice they are making. And to do it now at an early stage as opposed to waiting three or four weeks later when the virus is much more widespread was very courageous*[91]."

In the second phase, PM Modi extended the nationwide lockdown on April 14, 2002 until May 3, with a conditional relaxation after April 20. On April 16, lockdown areas

were classified as "red, orange and green zones", indicating the presence of infection hotspots, some infection, no infections, respectively. On April 20, the government announced relaxations in different sectors such as agriculture including dairy, aquaculture and plantations, selling of farming products, cargo transportation including trucks, trains and planes following social distancing norms[92]. On April 25, the government allowed the opening of small retail shops with half-staff following social distancing norms. On April 29, the Ministry of Home Affairs allowed inter-state movement of migrant people following the guidelines laid down by the government. An additional extension (May 4 – May 17) was granted by Government of India on May 1, 2020 with additional relaxation to curb the infection.

In this phase, the whole country was categorized into three zones namely red zones (130 districts), orange zones (284 districts) and green zones (319 districts). Red zones were areas with high infection and a high doubling rate, orange zones had comparatively fewer cases and green zones had no cases in the past 21 days. Normal movement was allowed in green zones with buses (50% capacity). In orange zones, only private and hired vehicles but no public transportation was allowed, while red zones were under complete lockdown. The government then implemented a fourth phase of lockdown to prevent COVID-19 between May 18 and May 31, 2020. On May 30, the government extended the ongoing lockdown until June 30 for only containment zones with services resumed in a phased-manner from 8 June. This was termed "Unlock 1.0". The second phase of unlock, called Unlock 2.0, was announced for the period of 1 to 31 July, followed by the easing of restrictions. Currently, Unlock 3.0 has been announced for August.

ENVIRONMENTAL PERSPECTIVES: INFLUENCE AND IMPACTS

The lockdown period has greatly helped the environment to rejuvenate, simply due to a reduction in pollution level to a large extent.

Longevity of SARS-CoV-2 in the environment

SARS-CoV-2 can remain suspended for approximately 30 min as an aerosol (< 5 μm). SARS-CoV-2 remained viable in aerosols for up to 3 h, with a reduction in infectious titer from $10^{3.5}$ to $10^{2.7}$ $TCID_{50}$ per L of air. SARS-CoV-2 is more stable on plastic and stainless steel than on copper and cardboard[78]. The virus has the longest life on plastic and steel, surviving up to 72 h but the total number of virus particles decreases sharply over this time ($10^{3.7}$ to $10^{0.6}$ $TCID_{50}$ per mL of medium after 72 h on plastic and $10^{3.7}$ to $10^{0.6}$ $TCID_{50}$ per mL after 48 h on stainless steel). On copper, it survives up to 4 h [78]. On cardboard, it survives up to 24 h, which suggests packages that arrived in the mail should have only low levels of the virus. On copper and cardboard, the virus is undetectable by 8 and 48 h, respectively[78]. The half-life of SARS-CoV-2 is similar to SARS-CoV-1 in aerosols, with a median of approximately 1.1 to 1.2 h and 95% credible intervals of 0.64 to 2.64 for SARS-CoV-2 and 0.78 to 2.43 for SARS-CoV-1[78]. The half-life of these two viruses is also similar on copper. On cardboard, the half-life of SARS-CoV-2 is longer than SARS-CoV-1. The longest viability was detected on stainless steel and plastic; the estimated median half-life of SARS-CoV-2 is 5.6 h on stainless steel and 6.8 h on plastic[78].

Meteorological influence

The COVID-19 pandemic is spreading globally irrespective of meteorological influence. Meteorological factors such as temperature, weather conditions and humidity are thought to play a vital role in COVID-19 transmission. At the beginning of the outbreak, it was speculated that COVID-19 may decrease with increasing air temperature as the outbreak occurred in the winter months[93]. Additionally, air temperature was relatively low in those months in comparison with Spring and/or Summer months. Accordingly, Zhou and Xie[94] demonstrated there is no concrete evidence of a decrease in COVID-19 when ambient temperature increases. Recently, Ma *et al*[95] indicated the positive influence of temperature and humidity on COVID-19 *i.e.*, increase in temperature and humidity decreases the number of COVID-19 deaths. This study was also conducted in same time period (January-February) as the study by Zhou and Xie[94]. A similar positive influence of meteorological factors on COVID-19 in various countries[96,97] was demonstrated. In addition to meteorological factors, Ramadhan[96] highlighted very high mobility and high density of people resulted in fast transmission of COVID-19 in Jakarta.

Influence on air quality

COVID-19 transmission has a direct impact on air quality namely particulate matter, SOx, NOx and carbon, *etc*. Standard air quality is essential in maintaining human health. However, almost 91% of the world's population lives in very poor air quality that exceeds the permissible limits[98], resulting in approximately 8% of deaths globally mainly in Asia, Africa and parts of Europe[98]. Coccia[99] demonstrated that cities (North Italy) with poor air quality (PM_{10} or ozone) increased the probability of COVID-19, mainly due to air pollution-to-human rather than human-to-human transmission. Another study from the same city indicated that prolonged exposure to poor air quality (PM_{10}, $PM_{2.5}$, O_3, SOx and NO_2) boosts COVID-19 incidence and even death in elderly people who have severe respiratory and cardiovascular disorders[97].

On the other hand, COVID-19 has significantly improved the air quality globally, particularly during lockdown periods due to the cessation of social activity, industrial activity, institutional activity, *etc*. Columbia University reported that the amount of carbon monoxide and carbon dioxide in New York City was reduced by 5% and 10%, respectively. During February 2020, carbon emission was decreased by 25% in China, which was last recorded during the economic crisis of 2008-2009. NASA's OMI instrument measured a 36% reduction in NO_2 concentration in China as well as in Italy, Spain, and France during February 2020 (these countries declared lockdown before other European nations). The level of particulate matter ($PM_{2.5}$) in London, Cardiff, and Bristol was less following the implementation of lockdown. PM induces inflammation in lung cells and exposure to PM increases the susceptibility and severity of COVID-19 symptoms.

In China, there was a profound decline in air pollution (greenhouse gases) during January and February as recorded by NASA using satellite images due to the decrease in industrial, business and transportation activity. Accordingly, the China's Ministry of Ecology and Environment declared that it is 'good quality, air days'.

An approximately 43%, 31%, 10%, and 18% decrease in $PM_{2.5}$, PM_{10}, CO, and NO_2 levels, respectively, were observed in India during COVID-19 lockdown compared to previous years[100]. The AQI was reduced by 44%, 33%, 29%, 15% and 32% in north, south, east, central and western India, respectively. In New Delhi, the AQI was reduced to as low as 93, and in Mumbai it decreased to 90 from 161 and 153, respectively.

Due to quarantine, NO_2 level was reduced by 22.8 μg/m^3 and 12.9 μg/m^3 in Wuhan and China, respectively. $PM_{2.5}$ level dropped by 1.4 μg/m^3 in Wuhan but in another 367 cities it was decreased by 18.9 μg/m^3[103]. After two weeks of lockdown in Spain, the black carbon and NO_2 level decreased markedly (-45 to -51%)[102]. However, O_3 level increased (+33 to +57%, 8 h daily), probably due to lower titration of O_3 by NO due to lower NOx level[102]. Additionally, the Copernicus Atmosphere Monitoring Service (CAMS) of the European Union observed a drop in $PM_{2.5}$ level during February 2020 in comparison with the previous three years. In China, according to CAMS[103], an approximately 20%–30% decrease in $PM_{2.5}$ was recorded in different parts of China during February 2020 compared with monthly averages in February 2017, 2018 and 2019. It is likely that the improvement in air quality around the globe was recorded due to COVID-19 control measures mainly by lockdown and quarantine[104-108]. During this period the demand for petroleum oil was reduced by 20% worldwide.

Furthermore, different national and international media on 10th February reported increased SO_2 concentration of approximately 1,350 μg/m^3 in Wuhan and Chongqing cities due to mass cremation of COVID-19 victims based on a screenshot image from *windy.com*. These were the results of the GEOS-5 Model. On the other hand, The Sun showed that this was not certain but mainly due to the cremation of virus-infected victims. Accordingly, The Sun (https://archive.is/ShAfz), *WION* (https://archive.is/Cdz4d) and IndiaTimes (https://timesofindia.indiatimes.com/times-fact-check/news/fact-check-satellite-images-showing-high-levels-of-sulphur-dioxide-indicate-mass-cremations-in-china/articleshow/74130633.cms) demonstrated that the mass cremations in Wuhan and Chongqing cities could be the prime reason for increased SO_2 concentration. Dr Arlindo M da Silva, from the Global Modeling and Assimilation Office, stated that GEOS-5 sulfur dioxide models do not "assimilate real satellite data" to confirm the image of *windy.com*. The China National Environmental Monitoring Center and the Center for Satellite Application on Environment and Ecology and the Chinese Academy of Sciences explained that the SO_2 data fluctuated between 4 and 8 μg/m^3, which was over 200 times less than the data shown on the website.

Influence on noise level and water quality

Environmental noise produced mainly by industrial or commercial operations, transit

vehicles, and many other sources cause serious health problems in the population [109]. The implementation of quarantine and lockdown due to COVID-19 preventive measures by most governments around the globe has compelled people to stay at home. The use of private and public transportation including trains and planes decreased significantly. Additionally, all commercial activities, shopping complexes and industrial operations stopped almost entirely. Accordingly, it is thought that noise level should have reduced; however, there are currently no studies on this issue. Most studies are confined to air quality assessment. Therefore, more attention should be focused on this environmental aspect.

Water quality in freshwater and marine ecosystems is also expected to improve globally. The lack of tourists, as a result of social distancing, has caused a significant change in beaches around the world. Coastal areas are important natural assets, which provide recreation and tourism, and fishing activities. These services are crucial for the nutrition and survival of coastal animals and human communities, and impart intrinsic values[110]. The lack of tourists has resulted in less pollution, especially plastics and wastes as well as reduced drainage volume into water bodies. A lower pollution level in aquatic ecosystems improves the health of the ecosystem by improving the health of aquatic organisms. In undisturbed habitats, olive ridley turtles were able to lay their eggs in Odisha's Gahirmatha beach and Rushikulya roockery. A number of dolphins were observed jumping in the water at the Marine Drive of Mumbai in the Arabian Sea, and the Canals of Venice are now full of fish and dolphins, as the water has sufficient time for sediments to settle to the bottom. According to Sunita Narain, the environmental activist, also the Director General of the Centre for Science and Environment (CSE), explained that, "*Right after this health crisis subsides, it is imperative to get the economy back in shape. People need to get back to work and continue leading their lives. This is just a phase. People can learn from it. However, we require long-term solutions like that of the utilization of clean energy, conservation of forests, and efficient waste management systems in order to see real impact.*" According to R. Ramamurthy, COVID-19 is an eye-opener. For example, beaches such as those of Acapulco (Mexico), Barcelona (Spain), or Salinas (Ecuador) are now cleaner with crystal clear waters[101]. This aspect also needs further study to understand the impact of COVID-19.

Influence on waste generation and waste recycling

A number of environmental issues such as air and water pollution, soil erosion, and deforestation are responsible for direct or indirect generation of organic and inorganic waste[111]. Home quarantine measures, established across most countries as COVID-19 measures, have expanded online shopping dramatically. Accordingly, online procurement systems enhanced the generation of inorganic waste due to packaging, in addition to enhanced organic waste generation by households. Furthermore, medical waste generation is also high. In Wuhan, around 240 metric tons of medical waste is generated per day since the COVID-19 outbreak, which is too high compared with previous years (average 50 tons)[45]. Calma[112] reported that in countries like the USA garbage generation due to personal protective equipment such as masks and gloves have increased significantly compared with previous years.

Waste recycling is a common and effective way to prevent pollution, save energy, and conserve natural resources; simultaneously, it is a major environmental problem across the globe[113,114]. Although wastes are generated in high volume globally, at present it is impossible for all countries to recycle these wastes due to the further spread of SARS-CoV-2 infection. Accordingly, the USA has closed waste recycling totally due to COVID-19. Affected European countries have also restricted waste management during this outbreak[101]. For example, Italy totally prohibited infected residents from sorting their waste. Industry also seized the use of reusable bags, as single-use plastic can harbor viruses[115]. China has implemented the use of additional disinfectant in wastewater treatment plants to strengthen their disinfection process to prevent the new coronavirus spreading *via* wastewater. However, to date, there is no evidence of the survival of SARS-CoV-2 in drinking water or wastewater [116].

Other indirect influences on the environment

Wildlife is also affected by SARS-CoV-2. In a USA sanctuary, one tiger was reported to be coronavirus positive. In a Chinese sanctuary, two pangolins died due to the virus infection. It also affected the movement of migratory birds. Different migratory birds are now visiting places where they never visited before due to high pollution levels. It has also forced the UN organization to postpone the Annual Climate Change Conference, *i.e.*, COP-26, which was scheduled to be held at Glasgow in the UK in

November 2020.

SOCIAL IMPACTS

COVID-19 outbreaks have adversely affected different sectors of society with big losses globally in terms of both monetary and personal loss, which cannot be accurately estimated. However, some aspects can be addressed here. Globalization is a chain process; therefore, it will collapse if a single chain stops working. In particular, the economy of countries is adversely affected. Functions, especially business meetings, sports events, scientific conferences, running educational institutes, fashion shows, and wedding parties are to be avoided, which has a big social impact on society. In the educational sector, many countries banned the running of schools, colleges and universities as well as students attending classes, which has deprived the students of a good quality education. This loss poses a large problem not only in monetary matters but also a big disadvantage to the students and their families mainly due to psychological stress. Apart from this, the tourism sector and industrial sectors are facing a major problem due to lack of labor. Prices of commodities are increasing, which has had a negative impact on poor people worldwide. Implementation of lockdown has had an enormous negative impact on poor people especially their daily wage as they are unable to earn. According to the ILO, half of permanent employees will be deprived of work, particularly in the Asia and Pacific regions. In India, 90% of workers from unorganized sectors were highly affected. In addition, production in eight major sectors was reduced by 6.5%, which obviously affected the industrial production index. According to an estimate by the IATA there was a loss of about $113 billion during the lockdown period so far. However, the positive effect of social lockdown is spending more time with family members as well as friends but without physical meetings. It has positive effects on health and accordingly improves immunity.

This pandemic has had a serious impact on major festivals around the world, which may lead to secondary epidemic burnout and stress-related absenteeism. The Public Health Department of England has mentioned 14 ways to protect mental health during the pandemic. The WHO has recommended two most effective protocols, the R-TEP (Recent Traumatic Episode Protocol) and G-TEP (Group Traumatic Episode Protocol) to treat the invisible and psychological wounds of trauma in these situations. *'The Lancet'* documented the psychological impact of quarantine in people which included low mood, insomnia, stress, anxiety, anger, irritability, emotional exhaustion, depression and post-traumatic stress symptoms. Some people have a higher risk because of long-term absenteeism from work due to illness and burnout, which has led to a loss of productivity of approximately 35% in these workers (America's State of Mind Report). In the case of patients who are in quarantine with their children they are facing major mental disorders such as trauma-related health disorder.

It is obvious that this pandemic has both long- and short-term implications on public mental health. Poor mental health may be the result of social isolation and loneliness. It is reported that 47% cases showed negative mental health effects due to worry or stress related to coronavirus, in particular, the situation is very pronounced among older adults and households with adolescents. Research has shown that older adults are at higher risk of poor mental health due to loneliness and bereavement. It also showed that job loss enhances depression, anxiety, distress, and low self-esteem and a higher rate of disorders. In the USA, 30 million students and subsequently their families face physical, social, and mental health impairment. During this pandemic, mental health illness among adolescents has been exacerbated, and over 12% of adolescents aged between 12 and 17 years have depression and/or anxiety. Closures of non-essential businesses and disruption to livelihood have a negative impact on mental health. It has been observed that people with low incomes (about 26%) experience major negative mental health impacts (worry, 17% and stress, 14%) compared with high income groups. Presently, the Coronavirus Aid, Relief, and Economic Security Act (CARES Act) endorsed the need for emergency services to improve the mental health conditions of remote people. According to the CDC, people who suffer from chronic illness such as chronic lung disease, asthma, chronic cardiovascular disease, and diabetes are at high risk of severe illness due to COVID-19.

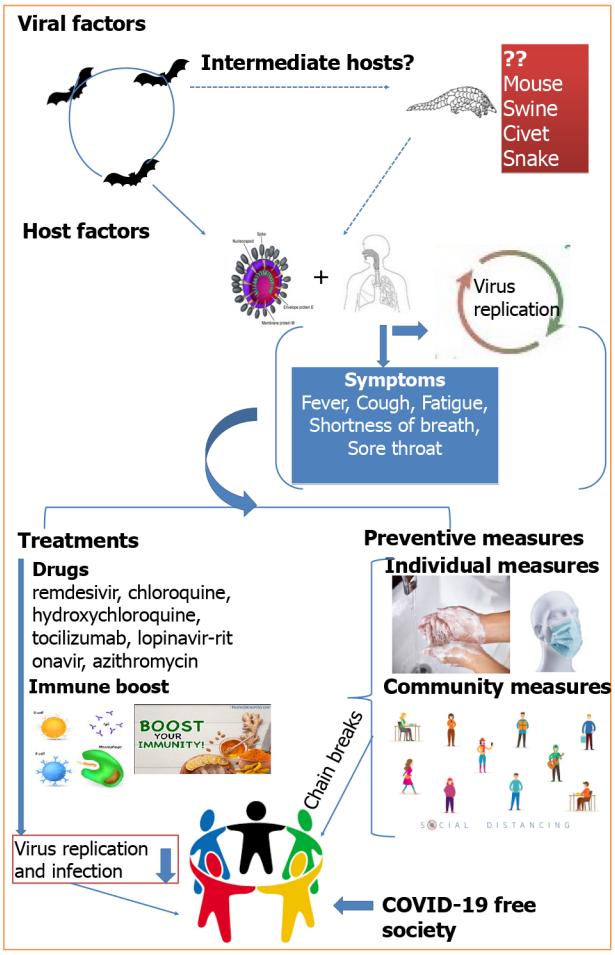

Figure 6 Schematic presentation of the management of coronavirus disease 2019 outbreaks. COVID-19: Coronavirus disease 2019.

RECURRENCE OF COVID19

Although a large number of individuals recover from COVID-19, the incidence of SARS-CoV-2 RNA recurrence has been recorded in various countries. To date, the incidence of recurrent SARS-CoV-2 in recovered individuals ranges from 7.35 to 21.4% [117]. Bonifácio *et al*[118] reported the recurrence of COVID-19 in a female nurse from Brazil. Following her recovery, two family members developed flu-like symptoms and tested positive for COVID-19 by RT-PCR. The next day, the nurse experienced malaise, myalgia, severe headache, fatigue, weakness, feverish sensation, sore throat, anosmia and dysgeusia. Hoang[119] estimated that 15% (95%CI, 12% to 19%) of patients (among 3,644 patients, recovering from COVID-19) tested positive for SARS-CoV-2. In addition, Hoang[119] documented that the proportion was 14% (95%CI, 11% to 17%) in China and 31% (95%CI: 26%-37%) in Korea. Furthermore, he demonstrated that among recurrent cases, 39% (95%CI: 31%-48%) experienced at least one comorbidity. The estimates for times from disease onset to admission, from admission to discharge, and from discharge to RNA positive conversion were 4.8, 16.4, and 10.4 d, respectively [119]. Loconsole *et al*[120] reported the recurrence of COVID-19 in a 48-year-old man from Italy who developed dyspnea and chest pain. The recurrence of COVID-19 has been reported around the world, and raises questions about the durability and quality of immune protection from SARS-CoV-2 as well as the quality of treatment options.

FUTURE PERSPECTIVES

COVID-19 has been an unprecedented disaster around the globe in every aspect, especially environmental health, social and economic aspects. This pandemic originated from bats. People worldwide are consuming different animals including bats, cats, snakes, mice, rats, pigs, dogs, *etc*., as food stuff. Accordingly, our future generation must be provided with substantial knowledge before consuming these

animals as food. Furthermore, people should be informed about the negative impact of these foods as they may harbor dangerous microbes. Emphasis should be given to providing adequate health care facilities to all people across countries including a greater number of health care systems, health insurance *etc.* This pandemic has highlighted the lack of health care facilities across the globe. Therefore, investment is needed in science and technology to establish specialized research centers to fight against such disasters in the future. In addition, more scientific studies are needed especially on viral diseases, mosquito-and insect-based diseases, bacterial infections, cancer, *etc.*, to combat any future pandemics. Currently, no medicine or vaccines have been identified to treat or eradicate COVID-19. Therefore, efforts should be focused on developing effective medicine or vaccines to treat COVID-19 through technological advancements.

CONCLUSION

This review provides an insight into the current status of COVID-19 (to date) from an environmental perspective. COVID-19 is a zoonotic disease, which originated from bats in Wuhan, China and was declared a pandemic by the WHO. The main symptoms are high fever, cough, shortness of breath and fatigue, which are similar to those of SARS. COVID-19 is highly infectious and transmissible through either aerosol droplets or close contact. The virus has spread to 213 countries/territories with approximately 202608306 confirmed cases and 4293591 deaths up to August 10, 2021. SARS-CoV-2 binds to human ACE2 and infects humans. Elderly people are more prone to SARS-CoV-2 compared to other age groups. To date, there is no specific medicine or vaccines for COVID-19. Currently, drugs such as remdesivir, chloroquine, hydroxychloroquine, tocilizumab, lopinavir-ritonavir, azithromycin, *etc.*, are used to treat SARS-CoV-2 infection. However, no drug is able to induce full recovery in COVID-19 patients. Remdesivir is effective in treating the virus. Recently, the ChAdOx1 vaccine was developed by the University of Oxford's Jenner Institute and the Oxford Vaccine Group. More recently, Russia has developed a coronavirus vaccine, named Sputnik V but these are still in the testing phase. Therefore, boosting the immune response could be an effective way to improve viral resistance. Accordingly, prevention and management are currently the best solution to control COVID-19. Therefore, it is essential that we follow the preventive measures, management and quarantine strictly laid down by the concerned government (Figure 6). Source reduction as an individual protective measure is the best way to control the infection. Lockdown as a social strategy is considered an indirect, but effective alternative tool to control spread of the virus. Additionally, the pandemic has had a direct impact on the environment, society and economy. Therefore, we should promote science and technology to develop vaccines or specific drugs to combat COVID-19.

ACKNOWLEDGEMENTS

The authors would like to thank the Department of Environmental Science of Sukanta Mahavidyalaya and The University of Burdwan for allowing working from home during the lockdown period.

Abstract

Pancreatic cancer is one of the solid tumors with the worst prognosis. Five-year survival rate is less than 10%. Surgical resection is the only potentially curative treatment, but the tumor is often diagnosed at an advanced stage of the disease and surgery could be performed in a very limited number of patients. Moreover, surgery is still associated with high post-operative morbidity, while other therapies still offer very disappointing results. This article reviews every aspect of pancreatic cancer, focusing on the elements that can improve prognosis. It was written with the aim of describing everything you need to know in 2021 in order to face this difficult challenge.

Key Words: Pancreatic cancer treatment; Advanced pancreatic cancer; Metastatic pancreatic cancer; Pancreatic cancer surgery; Pancreatic cancer chemotherapy; Pancreatic cancer screening

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Pancreatic cancer is a very dangerous enemy and the results are still very unsatisfactory. But we have not given up. Research is running fast on many paths, without losing its enthusiasm.The number of articles published on this subject in the last two years is impressive. I have tried to summarize all the most significant data from the different lines of research, ranging from screening and early diagnosis to new developments in surgery and associated therapies. I hope I have succeeded in the task of describing as comprehensively as possible the most promising fields of research available to us today, in order to achieve the improved results we desire.

INTRODUCTION

Pancreatic cancer is currently the seventh leading cause of cancer death worldwide and the fourth following lung, colorectal and breast cancers in the United States and Europe. It will become the third by 2030. It is an age-related neoplasm and this trend is similar between males and females. In particular the number of both deaths and incident cases peaked at the ages of 65-69 years in males, whereas the peak in females was observed at the ages of 75-79 years[1-4]. The commonly used term "pancreatic cancer" usually refers to ductal adenocarcinoma (PDAC), which represents 85% of all pancreatic tumor[4]. Complete surgical resection significantly prolongs survival, but the tumor is often diagnosed at an advanced stage and only a small percentage of patients are therefore candidates for surgery. Moreover, surgery is still associated with high post-operative morbidity. Despite ongoing developments, PDAC remains one of the most difficult tumors to treat, and the five-year survival rate is less than 10%[5]. There are four fundamental challenges that underlie the high mortality. First, the retroperitoneal location of the pancreas, deep in the abdomen, protects growing tumors from detection. The symptoms are late and therefore the diagnosis is made when the tumor is already in an advanced stage. Second, PDAC has an aggressive biology characterized by early metastasis and 50% of patients has metastatic disease at presentation. In addition, a large number of patients undergoing surgery develop metastases within 4 years. This suggests the presence of micrometastasis in apparently localized cases[6]. Third, pancreatic cancer dramatically weakens patients, limiting their ability to withstand aggressive treatments. Finally, it shows resistance to many antineoplastic therapies[7,8]. Advances in prevention, screening, early detection, and therapy, particularly on new frontiers, are essential to improve outcomes. This article has been written with the aim of describing everything you need to know in 2021 in order to face this difficult challenge.

NON-FAMILIAL RISK FACTORS AND PREVENTION

Identification of risk factors, high-risk populations and early detection markers is the first and crucial step to change the pancreatic cancer horizon[9]. PDAC incidence rates are nearly four times higher in high-income countries such as the United States and Western European countries than in middle- and low-income countries[3]. The different incidence seems to be related with different lifestyles.

Obesity, smoking, alcohol consumption and type 2 diabetes are considered non-familial risk factors for pancreatic cancer. Chronic pancreatitis, cystic fibrosis and intraductal papillary mucinous neoplasm (IPMN) should also be considered. An increased risk of pancreatic cancer has been observed following gastrectomy[10-17].

One-third of all cancers could have been prevented through lifestyle correction[18]. A 2020 European prospective study (EPIC) evaluated the association between the healthy lifestyle index score and PDAC[19-22]. Healthy lifestyle habits were inversely related to the risk of PDAC. Adherence to healthy behaviors, corresponding to a three-point increase in the score, was associated with a 16%-23% lower risk. The result summarizes many previous studies[23-29] and support the adoption of healthy lifestyles in PDAC prevention.

A recent nutrigenomic study has highlighted nutrients capable of preventing cancer through epigenetic modifications. An optimal diet should include omega 3 fatty acids, polyphenols, folic acid, selenium and zinc. Particularly important for PDAC prevention could be the epigallocatechin, a polyphenol from tea and green tea[30,31].

Data linking type 2 diabetes with pancreatic cancer suggest that the new onset of diabetes in a lean older adult should prompt consideration of PDAC. This is even more valid if new-onset diabetes is associated with unintentional weight loss[32-34]. A Mayo Clinic study evaluated the use of computed tomography (CT) at the time of diabetes diagnosis in otherwise asymptomatic patients. A higher likelihood of showing potentially resectable tumors was observed compared with scans performed six months later[32]. However, CT screening of all elderly subjects with new-onset

diabetes is not feasible[33]. With the identification of these characteristics that differentiate pancreatic cancer-associated diabetes from other cases of new-onset diabetes, perhaps the guidelines will updacate[35].

HEREDITARY RISKS FACTORS

PDAC can be hereditary. There are two categories of inherited risk for PDAC: Genetic syndromes (20% of cases) and familial pancreatic cancer (80%). Familial pancreatic cancer is defined as a predisposition that is based on familial clustering in families in which there is at least one pair of first-degree relative (FDR) relatives with PDAC in the absence of a known genetic syndrome. Genetic syndromes that predispose to pancreatic cancer are listed in Table 1. Table 1 also shows in parentheses the frequencies of mutated genes in PDAC patients[36-42].

Knowledge of inherited risk factors is important because it allows us an effective stratification and management of patients. According to American Society of Clinical Oncology and National Comprehensive Cancer Network guidelines, all patients diagnosed with PDAC should be evaluated to understand if there is a risk of familial predisposition to cancer. All patients should undergo risk assessment for syndromes associated with an increased risk of PDAC. Germline genetic testing is recommended for patients with PDAC and an unremarkable family history[43,44].

SCREENING

Screening aims to detect preinvasive lesions (IPMNs and pancreatic intraepithelial neoplasias) with high-grade neoplastic changes and early invasive tumors that are more amenable to potentially curative resection[45-49].

Candidates for screening

(1) Patients with Peutz-Jeghers syndrome or CDKN2A mutation, regardless of family history; (2) BRCA2 mutation with at least one affected FDR or at least two affected relatives of any degree; (3) BRCA1, partner and localizer of BRCA2 (PALB2), ataxia-telangiectasia mutated (ATM), and Lynch syndrome mutation carriers with one or more affected FDRs; (4) Hereditary pancreatitis with a PRSS1 mutation; and (5) Regardless of gene mutation status: (a) At least three affected relatives on the same side of the family, of whom at least one is an FDR of the individual being considered for surveillance; (b) At least two affected relatives who are FDRs of each other, of whom at least one is an FDR of the individual being considered for surveillance; and (c) At least two affected relatives on the same side of the family, of whom at least one is an FDR of the individual being considered for surveillance.

General population-based screening for average-risk patients is not recommended [33] because the average lifetime risk for developing PDAC is too low[49].

Screening modality

The current recommendation provides for the execution of endoscopic ultrasonography (EUS) or magnetic resonance imaging (MRI)/magnetic resonance cholangiopancreatography (MRCP). It has been demonstrated that they detect more lesion as compared with CT scan[50]. Screening is recommended at age 50 years or 10 years younger than the youngest relative with PDAC in familial pancreatic cancer relatives. In other cases, screening is carried out between 35 and 45 years. For patients with a normal pancreas on imaging, repeat the procedure every year alternating EUS and MRCP. The age for stopping screening should be individualized based on each patient's medical status, life expectancy, and preferences.

SURGICAL RESECTION FOR IPMNS AND OTHER CYSTIC LESIONS

Surgical resection is indicated in patients with any of the following[45]: (1) Solid pancreatic lesion ≥ 5 mm of indeterminate pathology or if additional evaluation does not yield a definitive preoperative diagnosis; (2) Any positive fine-needle aspiration (FNA) result, except for a pancreatic neuroendocrine tumor; (3) Main-duct IPMNs with any one of the following: (a) Main pancreatic duct dilation of ≥ 10 mm; (b) Main pancreatic duct stricture; or (c) Mural nodules; (4) Branch duct IPMNs (BD-IPMNs)

Table 1 Genetic syndromes predisposing to pancreatic cancer (the frequency of mutated genes among patients with pancreatic ductal adenocarcinoma is indicated in brackets)

Genetic syndrome	Mutated genes
Hereditary breast/ovarian cancer syndrome[36,37]	*BRCA1* (0.7%), *BRCA2* (1.4%), *PALB2* (1%)
Familial atypical multiple mole melanoma syndrome[38]	*CDKN2A* (0.7%)
Peutz-Jeghers syndrome[39]	*STK11*
Familial adenomatous polyposis	*APC* (0.4%)
Lynch syndrome[40]	*MLH1*, *MSH2* (0.4%), *PMS2* (0.3%)
Hereditary pancreatitis[41]	*PRSS1*, *SPINK1*
Ataxia telangectasia[42]	*ATM* (1.4%)
Li-Fraumeni syndrome[42]	*P53* (0.4%)

with any one of the following: (a) Rapid growth (> 5 mm over six months); (b) Mural nodules or an enhancing solid component; (c) Abrupt main pancreatic duct caliber change with distal atrophy (even if no mass is visible); (d) Main pancreatic duct dilation of ≥ 10 mm; (e) Positive cytology; or (f) Associated symptoms of pancreatitis, jaundice, or pancreatic-type pain; or (5) Asymptomatic main pancreatic duct stricture with an associated suspicious mass.

For patients who do not meet these criteria for surgery, repeat imaging in three months if worrisome features are present[47,51]. Worrisome features include the following: (1) Solid lesion with main pancreatic duct size of 5 mm to 9 mm in diameter; (2) Main pancreatic duct stricture and/or dilation ≥ 6 mm of unknown etiology without an associated mass; and (3) Solid lesion < 5 mm of uncertain significance.

Repeat imaging in six months is recommended for patients who have the following imaging abnormalities: (1) Cystic lesion (presumed BD-IPMN) ≥ 3 cm in size; (2) Cystic lesion with associated main pancreatic duct 5 mm to 9 mm; (3) Cystic lesion associated with lymphadenopathy; (4) Cyst growth rate of ≥ 5 mm in two years; and (5) Increased serum carbohydrate antigen 19-9 (CA 19-9).

Individuals without worrisome features of malignancy should undergo repeat imaging in 12 mo[47,51].

Screening/surveillance should be continued until the patient is no longer a surgical candidate.

A 2020 paper analyzed the benefits of screening. Nine out of 10 screen-detected PDAC were resectable, with a three-year survival of 85%, compared with 25% in PDAC detected outside surveillance. With continued follow-up of patients with resectable PDAC, the five-year overall survival (OS) rate was 60%[49].

BIOMARKERS AND EARLY DETECTION

Different biomarkers are being evaluated to improve early diagnosis of tumor not detectable by imaging and to differentiate cancer and high-grade dysplasia from benign disease[52].

Blood tests

The most useful serum tumor marker for PDAC is CA 19-9. It is recommended adding this test when there are worrisome features on abdominal imaging. The sensitivity and the specificity of elevated CA 19-9 to detect PDAC are 79% and 82%, respectively[53-55]. It becomes more precise when used in combination with CA 125[56,57]. Other carbohydrate markers, such as CA 50, CA 72.4 and CA 242, were extensively analyzed in PDAC patients. Although they exhibited less sensitivity than CA 19-9 for the diagnosis, they improved specificity[58-61]. Satake and Takeuchi[62] also studied SPan-1 and DUPAN-2. SPan-1 has a high sensitivity for PDAC (81.4%), but the specificity (67.5%) and diagnostic accuracy (71%) are lower than those of CA19-9. SPan-1 may be considered as an additional useful serum marker, but it does not significantly improve the diagnostic accuracy obtained with CA 19-9. In contrast, DUPAN-2 has a high specificity (85.3%) and low sensitivity (47.7%). Furthermore, it seems that serum levels of DUPAN-2 are influenced by liver function. SPan-1 and DUPAN-2 unfortunately have not yet shown the sensitivity and specificity needed to

be used for early detection[62,63].

A huge step forward in the early detection of pancreatic cancer could come from studying cell-free DNA (cfDNA), which consists of circulating double-stranded DNA molecules that can be found in plasma or blood serum. From the analysis of these molecules, it is possible to understand if we are in the presence of a tumor DNA and to go back to the tissue of origin. By analyzing the methylation status of two genes in cfDNA, ADAMTS1 and BNC1, early stage cancer can be identified with a sensitivity of 94.8% and a specificity of 91.6%[64].

Innovative discoveries have also been made in the field of RNA. Abnormal microRNA expressions are potential diagnostic markers for several cancers, including PDAC. Multiple microRNA tests performed in combination with CA 19-9 can improve diagnostic accuracy, particularly miR-216[65-69]. Permuth *et al*[70] demonstrated that a combination of eight lncRNAs helps in the differential diagnosis between malignant and non-malignant IPMNs. Furthermore, three lncRNAs (HAND2-AS1, CTD-2033D15.2, and lncRNA-TGF) could be exploited as early diagnostic biomarkers of IPMN[71,72].

Pancreatic juice and pancreatic cyst fluid

Pancreatic juice collected at the time of ERCP and cyst fluid obtained by EUS-guided FNA can be analyzed for molecular markers. These procedures also have broad potential in terms of early diagnosis of PDAC. Next-generation sequencing can be performed at low cost to detect low-frequency mutations. Potential markers include mutant GNAS (specific for IPMNs) and mutant KRAS. TP53, SMAD4, PIK3CA, PTEN, and AKT1 mutants are also useful as they correlate with IPMN-associated tumors[73-75]. According to Suenaga *et al*[76], a pancreatic juice collection, to ensure optimal yield of mutations for pancreatic screening assays, should be performed 10 min after secretin administration. The authors detected 40 patients with KRAS mutations in pancreatic juice out of 45 undergoing surveillance with EUS, reconfirming the usefulness of these analysis[76].

There are many other biomarkers that are currently being validated for clinical use, such as mucins (MUC). Normal pancreatic ductal epithelium expresses low levels of MUC, while an upregulation of MUC occurs in BD-IPMNs and more pronounced changes in expression in PDAC. Normal pancreatic ductal epithelium expresses low levels of MUC, while upregulation of MUC occurs in BD-IPMN and PDAC[77-83]. The analysis of mucin changes in the fluid of pancreatic cysts allows us to differentiate mucinous from non-mucinous pancreatic cysts with high sensitivity and specificity and to diagnose PDACs associated with IPMN at an early stage[84]. MUC4 and MUC16 have been reported to be 100% specific for PDAC, while associated with sensitivities of 63% and 67%, respectively[85].

Interesting data were reported about interleukins (IL). Higher concentrations of IL-1b, IL-5, and IL-8 have been identified in cystic lesions with high grade dysplasia or malignancy[86]. IL-1b is a potentially useful factor in differentiating high-risk from low-risk pancreatic cysts.

The Das-1 monoclonal antibody is also capable of detecting pancreatic cysts at risk of malignancy with high levels of sensitivity (88%) and specificity (98%)[87,88]. Das-1, IL and MUC could be used in conjunction with clinical guidelines to identify patients at risk for malignancy.

Saliva

Saliva is a suitable substance for screening because it is obtained in a simple and noninvasive manner. In addition, salivary mRNA is relatively stable and informative for disease diagnosis, including cancer. Zhang *et al*[89] identified 7 up-regulated genes (MBD3L2, KRAS, STIM2, DMXL2, ACRV1, DMD, and CABLES1) and 5 down-regulated genes (TK2, GLTSCR2, CDKL3, TPT1, and DPM1) in subjects with PDAC compared with healthy controls or those with chronic pancreatitis. A combination of 4 mRNAs (MBD3L2, KRAS, ACRV1, and DPM1) can discriminate diseased patients from healthy ones with sensitivity and specificity over 90%[89]. Xie *et al*[90] worked on miR-3679-5p and miR-940. The former is down-regulated, while the latter is up-regulated in PDAC patients compared to controls. The combination of the two miRNAs identifies diseased subjects with sensitivity and specificity of 70%. The same group evaluated the expression of salivary long non-coding RNAs (lincRNAs). They identified HOTAIR and PV1T as significantly up-regulated lincRNAs in the PDAC group compared with controls and benign pancreatic tumors. The combination of salivary HOTAIR and PVT1 differentiated PDAC from healthy controls with a sensitivity of 78.2% and specificity of 90.9% and PDAC from benign tumors with a sensitivity of 81.8% and specificity of 95%[90,91]. Another important mRNA studied in

serum, urine, and saliva is MIR1246. Salivary expression of miR-1246 is related to serum CA19-9 levels[92]. Significantly higher expression of MIR1246 in serum and urine was observed in patients with cancer compared with healthy controls. Ishige *et al* [93] observed an AUC for MIR1246 in serum of 0.87 (sensitivity, 92.3%; specificity, 73.3%), for MIR1246 in urine of 0.90 (sensitivity, 90.2%; specificity, 83.3%). Combining the expression of MIR1246 in serum and urine resulted in a sensitivity of 85%. These results indicate that MIR246 may be a useful diagnostic biomarker for pancreatic cancer. The accuracy further increases if we consider miR-1246 and miR-4644 simultaneously[92].

Urine

Several biomarkers have also been evaluated in urine. Radon *et al*[94] used three protein biomarkers (REG1A, TFF1 and LYVE1) to form a powerful urinary panel that can detect patients with stages I-II PDAC, with over 90% accuracy. Brezgyte *et al*[95] found four miRNAs (miR-143, miR-204 and miR-223) in significantly higher amounts and one miRNA (miR-30e) in lower amounts in the urine of PDAC Stage I patients compared to the healthy population. These miRNAs (except for miR-204) also showed a decreased expression in Stage II-IV compared to Stage I[95]. However, more studies are needed to validate the clinical utility of these biomarkers.

CLINICAL FEATURES

The presenting symptoms in patients with PDAC varies according to location. Tumors in the body and tail present with pain and weight loss, while tumor of the head cause jaundice and steatorrhea[96]. Pain associated with PDAC is usually insidious, visceral, generally epigastric, radiating to the sides or straight through to the back. It is worse by eating or lying supine at night. Rarely, it develops acutely on account of acute pancreatitis due to tumoral occlusion of the main pancreatic duct[97]. Pancreatic cancer may result in an onset of diabetes mellitus[98,99]. The hypercoagulable state that accompanies PDAC can result in Trousseau syndrome, which consists of superficial, sometimes migratory thrombophlebitis[100]. Thromboembolic complications occur more commonly in patients with tumors arising in the tail or body of the pancreas[101]. Skin manifestations could occur as paraneoplastic phenomena[102]. Rarely, erythematous subcutaneous areas of nodular fat necrosis (pancreatic panniculitis), typically located on the legs, may be evident. It is more frequent in patients with the acinar cell variant of PDAC. It is not pathognomonic for an PDAC, because it has also been described in associated with pancreatic neuroendocrine tumors, IPMNs and chronic pancreatitis[103].

When assessing symptoms, it should be borne in mind that PDAC tends to infiltrate nearby organs and structures and to give distant metastases very early. Local extension typically involves adjacent structures, such as the duodenum, the portal vein (PV), or the superior mesenteric vessels. PDAC also show a striking tendency toward perineural invasion, both within and beyond the pancreas. The difficulty in achieving a wide resection margin due to the proximity to the vessels accounts for the fact that the retroperitoneal tissue behind the head of the pancreas represents the most common site of disease recurrence. Sometimes the tumor extends to the spleen, adrenal glands, vertebral column, transverse colon, and/or stomach. In these cases, tumors are not resectable. Tumor may metastasize to regional peripancreatic lymph nodes or less often to distant lymph node, peri-gastric, mesenteric, omental or porta-hepatic nodes. Distant metastasis may affect the liver, peritoneum, lungs, and less frequently, bone. Signs of advanced, incurable disease include an abdominal mass, ascites, Virchow's node, Sister Mary Joseph's node or a palpable rectal shelf. Pancreatic cancer is the origin of a cutaneous metastasis to the umbilicus in 7% to 9% of cases[104].

DIAGNOSIS

CT

CT is considered the gold standard for pancreatic cancer's diagnosis. Protocol pancreatic CT is performed for evaluation of suspected PDAC or if a routine CT scan was not sufficient for initial staging[105,106]. This protocol consists of evaluating the patient at different stages of contrast injection. The arterial phase provides excellent opacification of the celiac axis, superior mesenteric artery (SMA), and peripancreatic

arteries. An attenuation difference between tumor and normal pancreas is best achieved after peak enhancement of the aorta in the arterial phase but before the one of the liver, in the portal venous phase. This is sometimes termed the "pancreatic phase". The portal venous phase provides better enhancement of the superior mesenteric vein (SMV), splenic and PVs. In addition, peak hepatic enhancement, which optimizes the detection of hepatic metastases, also occurs in the portal venous phase[107,108].

The typical CT appearance of a PDAC is an ill-defined hypoattenuating mass within the pancreas. Smaller lesions may be iso-attenuating, making difficult their identification[109]. Secondary signs of PDAC include a dilatation of the pancreatic duct or common bile duct, parenchymal atrophy, and contour abnormalities. Dilation of both the pancreatic duct and the common bile duct, commonly referred to as the "double duct sign" is not diagnostic for a pancreatic head malignancy[110]. Routine preoperative CT helps to identify hepatic vascular anatomy and prepares the surgeon for any potential vascular anomalies. It can detect hemodynamically significant arterial stenosis[111]. The contrast-enhanced CT scan is the best technique for PDAC staging [112] and it is essential to detect vascular invasion. CT criteria for vascular invasion include arterial embedment in the tumor mass or venous obliteration, tumor involvement exceeding one-half the circumference of the vessel, vessel wall irregularity, vessel caliber stenosis, or a "teardrop" sign of the SMV[113]. Classic CT criteria for vascular involvement are not reliable in patients who have undergone neoadjuvant therapy with a highly active chemotherapy combination such as mFOLFIRINOX (mFFX). In such cases, surgical exploration may be the only method to assess resectability[114].

MRI

Contrast-enhanced MRI of the pancreas may be useful in staging patients at initial presentation. MRI is the best technique for detection of small liver metastases[115]. The importance of MRI also lies in the ability to diagnose pancreatic cancer by identifying changes in the body that indicate systemic effects of PDAC. It has been well recognized that anorexia, sarcopenia, and weight loss are hallmarks of PDAC. Consequently, it can be used to measure adipose and muscle mass in high-risk populations to identify early disease[116-118].

EUS

EUS is considered the most sensitive method to detect early neoplasia in the pancreas. PDAC on EUS appears as a hypoechoic mass, typically with dilation of the proximal pancreatic duct and the border of the lesion may have an irregular contour. This is the best accurate technique for local T and N staging, and for predicting vascular invasion. However, EUS is inferior to CT for evaluation of distant metastases. In addition, the specificity of EUS for excluding vascular invasion in small tumors is limited, particularly when inflammatory changes are present[119].

EUS is mainly used as part of the workup to obtain fine needle aspiration or biopsy material in patients suspected of having a PDAC[120]. EUS is not readily accessible and as a result is considered a complementary modality to the pancreatic protocol CT. Emerging area for endoscopic ultrasound includes the incorporation of elastography. Elastography shows significantly lower elasticity values for PDAC than for normal pancreatic tissue[121]. Incorporation of elastography in the evaluation of solid pancreatic lesions improves diagnostic accuracy[122,123].

Endoscopic retrograde cholangiopancreatography

A meta-analysis demonstrated a 92% sensitivity and 96% specificity of endoscopic retrograde cholangiopancreatography (ERCP) in the diagnosis of PDAC[124]. Findings suggestive of a malignant tumor of the pancreatic head include stenosis or obstruction of the common and pancreatic bile ducts (the "double duct" sign), a pancreatic duct stenosis greater than 1 cm in length, and pancreatic duct obstruction. In addition, ERCP provides an opportunity to collect tissue samples for cytohistologic analysis [124].

Some early-stage pancreatic tumors are not detected by CT, MRI, or EUS. Especially for carcinoma in situ, localized stenosis of the main pancreatic duct is often the only imaging finding. Pancreatic duct imaging evaluation by ERCP and subsequent pancreatic juice cytology are critical for diagnosis.

On the other hand, ERCP is an invasive procedure that can cause acute pancreatitis, bleeding, and cholangitis. Consequently, it has purely therapeutic value for patients with cholestasis due to tumor obstruction of the biliary system and require placement of a biliary stent[125].

Positron emission tomography

The role of positron emission tomography (PET) is limited for PDAC due to the high number of false positives and false negatives[126]. However, the degree of fluorodeoxyglucose (FDG) uptake correlates with histopathology, aggressiveness, and metastatic potential[127,128]. According to a meta-analysis, PET/CT is more accurate than CT in detecting distant metastases. Preoperatively, it may therefore be useful in avoiding unnecessary resection if unexpected metastases are found[129,130]. After treatment, FDG-PET is instead used to detect residual or recurrent cancer. It can also be applied to assess and monitor response to therapy in unresectable or metastatic disease[127,131].

Other molecular imaging agents including overexpressed proteins, signaling pathways, and tumor stroma may also be used[132]. Among these, promising results appear to involve 68Ga-cicratide, an integrin αvβ6-specific radiotracer, which has favorable pharmacokinetics and is capable of detecting pancreatic cancer lesions and monitoring response to therapy[133]. Another molecular imaging method that is of interest for early detection is hyperpolarized MRI. It can identify metabolic aberrations in the pancreas that indicate preneoplasia[134].

Staging laparoscopy

Sub-centimeter metastases of the liver or peritoneum that are rarely visible by CT, MRI or PET may be visualized laparoscopically. Up to one-third of patients thought to be resectable by imaging will be found to be unresectable based upon laparoscopic findings[135,136].

Some experts suggest a selective approach to staging laparoscopy, limiting the procedure to those with the highest likelihood of occult metastatic disease[137,138]. First, this includes tumors of the body or tail of the pancreas that appear potentially resectable by CT scan. Second, it includes large (> 3 cm) primary tumors and patients with a high initial CA 19-9 level (> 100 units/mL)[139].

Biopsy

Biopsy of a pancreatic mass can be performed either percutaneously or *via* EUS. EUS-guided FNA is the best modality for obtaining a tissue diagnosis. EUS-FNA is a safe method with a 0.98% morbidity and a 0.02% mortality. Although the most common adverse events of EUS-FNA include pancreatitis and postprocedural pain, there is also some concern regarding tumor cell seeding[140]. According to a study by Yane *et al* [141] the cumulative needle tract seeding rate at five years was 3.8%. However the preoperative EUS-FNA has no negative effect on recurrence-free survival and OS.

In many cases, the diagnosis will not yet be histologically confirmed. Once PDAC is suspected on imaging studies, the next step is generally a staging evaluation rather than biopsy. Patients who are fit for major surgery and who appear to have potentially resectable PDAC, they do not necessarily need a biopsy before surgery. Biopsy could be indicated if there is evidence of systemic spread or local evidence of unresectability on staging studies. It is also indicated if the patient is unfit for major surgery or if other diagnoses need to be excluded[142,143].

Pancreatic incidentaloma

A 2014 systematic review[144] evaluated 5 studies enrolling patients with incidentalomas and concluded that most solid lesions are malignant. Histologic definition of a solid lesion of the pancreas should be the first option, as opposed to radiologic monitoring alone. It is important to avoid operating on benign solid lesions such as chronic focal pancreatitis or autoimmune pancreatitis.

In case of cystic lesion, surgery is the first option for cystadenomamucinous and IPMN with high-risk stigmata. A recent review defined high-risk stigmata as the presence of obstructive jaundice, vascularized mural nodules ≥ 5 mm, main duct diameter ≥ 10 mm[145].

STAGING

The goal of the staging workup is to delineate the extent of disease spread and to identify patients who are eligible for resection with curative intent. Patients with PDAC can be staged according to the eighth edition of TNM system of American Joint Committee on Cancer (AJCC). However, most clinicians use a four-tiered staging system including resectable, borderline resectable, locally advanced (LA), and

metastatic cancer[146,147] (Table 2). In 2017, a classification was published, by the International Association of Pancreatology, which redefines the concept of resectability in relation to biological risk and patient conditions[148]. Table 3 summarizes the different resectability criteria assumed by the different scientific societies.

SURGERY

Surgical resection is the only potentially curative treatment. Unfortunately, PDAC is often diagnosed at an advanced stage and radical surgery could be performed in a very limited number of patients. The surgical interventions that can be performed are different depending on the tumour location and extension. In all cases the operation involves the removal of the tumour with free margins and at least twelve lymph nodes, which are necessary for staging. Tumors of the head require more complex operations, which still have a high operative morbidity. In high-frequency surgical centres mortality after pancreatoduodenectomy (PD) is now less than 2%, but post-operative morbidity remains high, 30%-50%. Anastomotic dehiscences, are the most serious post-operative complication. They are difficult to manage and are unfortunately associated with a still high mortality rate. Tumors of the tail and body require easier operations than head tumors, with a low operative morbidity and mortality. Unfortunately, because of their late symptomatology, they are more frequently unresectable.

Pancreaticoduodenectomy

PD is the classic operation performed for pancreatic tumors of the head or uncinate process. Conventional pancreaticoduodenectomy involves removal of the pancreatic head, duodenum, first 15 cm of the jejunum, common bile duct, gallbladder, and a partial gastrectomy. It is a complex procedure and patients may experience several complications. These complications could be intra-operative or post-operative[149,150].

The most important intraoperative complication of PD is bleeding. Most patients undergoing PD for PDAC have an obstructive jaundice with associated coagulopathy. Bleeding can occur from multiple sites during the various phases of mobilization and resection, so hemostasis must be monitored and assured before reconstruction begins.

Postoperative complications can be further divided into short-term and long-term complications. The short-term ones are pancreatic fistula, delayed gastric emptying, and postoperative bleeding. The long-term ones are biliary stenosis and cholangitis, pancreatitis, peptic ulcer disease, small bowel obstruction, and incisional hernia[149,150].

Modifications of the conventional PD procedure have been developed in an attempt to improve outcomes or minimize the morbidity associated with this operation. The pylorus-preserving pancreaticoduodenectomy preserves the gastric antrum, pylorus, and proximal 3 cm to 6 cm of the duodenum. It can decrease the incidence of post-operative dumping, marginal ulceration, and bile reflux gastritis, without negative effect on the morbidity, mortality and long-term survival[151]. Instead, the subtotal stomach-preserving pancreaticoduodenectomy is performed with the aims to preserve as much stomach as possible, minimizing the delayed gastric emptying that are associated with preserving the pyloric ring in the face of vagal denervation. In this procedure, the duodenum, pylorus, and 1 cm to 2 cm of stomach are resected with the pancreatic specimen. Although described, this modification has yet to be validated, and it is uncommonly performed[152].

The "Artery-first" approach is a surgical technique or set of techniques that have in common the dissection of the main arterial vasculature involved in pancreatic cancer, prior to performing any irreversible surgical step (transection of the pancreatic neck or bile duct division). The "Artery-first" approach has the potential to reduce blood loss and increase R0 resection rates and OS, as demonstrated in a recent meta-analysis[153].

Modified child reconstruction aims to reduce the incidence of cholangitis due to digestive reflux through hepatic-digiunal anastomosis. In case of pancreatic-digiunal anastomosis, the hepatic-digiunal anastomosis is made downstream of the previous one. In case of pancreatico-gastric anastomosis, the hepatico-digiunal anastomosis is made near the previously closed loop. Whatever the type of pancreatico-digestive anastomosis, the digestive anastomosis (gastro-digiunal or duodeno-digiunal) is made 60 cm downstream of the hepatico-digiunal anastomosis, to reduce digestive reflux into the biliary tract.

Table 2 Resectability criteria

Resectability status		Resectable	Borderline resectable	Locally advanced
Arterial involvement	Celiac artery	None	≤ 180°; > 180°, without involvement of aorta o GDA (body/tail)	>180° (head/uncinate); Solid tumor contact with CA and aorta
	SMA common hepatic artery	None	≤ 180°; Solit tumor contact without extension into CA or hepatic artery biforcation	> 180°
Venous involvement (portal vein/smv)		None; ≤ 180° contact without contour irregularity	> 180°; ≤ 180° with contour irregularity or thrombosis, with reconstructible PV/SMV; Solid tumor contact with IVC	Unreconstractible PV/SMV due to tumor involvement or occlusion

CA: Celiac artery; GDA: Gastroduodenal artery; IVC: Inferior vena cava; PV: Portal vein; SMA: Superior mesenteric artery; SMV: Superior mesenteric vein.

Table 3 Resectability criteria and societies

Vessel involvement	NCCN 2019	MDACC	ACTO	AHPBA/SSAT/SSO
CA abutment (≤ 180°)	Borderline	Borderline	Borderline	Unresectable
CA encasement (> 180°)	Borderline (body/tail); locally advanced (head/uncinate)	Unresectable	Unresectable	Unresectable
SMA abutment (< 180°); SMA encasement (> 180°); CHA abutment or encasement	Borderline; Locally advanced; Borderline	Borderline; Unresectable; Borderline	Borderline; Unresectable; Borderline	Borderline; Unresectable; Borderline
PV/SMV encasement (> 180°) or abutment (≤ 180°) with contour abnormality	Borderline	Borderline	Borderline	Borderline

ACTO: Alliance for Clinical Trials in Oncology; AHPBA: American Hepato-Pancreato-Biliary Association; CA: Celiac artery; CHA: Common hepatic artery; MDACC: The University of Texas MD Anderson Cancer Center; NCCN: National Comprehensive Cancer Network; PV: Portal vein; SMA: Superior mesenteric artery; SMV: Superior mesenteric vein; SSAT: Society for Surgery of the Alimentary Tract; SSO: Society for Surgical Oncology.

Post-operative pancreatic fistula (POPF) is the main and most frequent complication after pancreatic resection surgery. It is caused by leakage of pancreatic juice into the abdominal cavity, which is collected and conveyed to the outside by the drains normally placed at the end of surgery or during postoperative care if necessary. The diagnosis is made on the basis of the quality of the drainage fluid (varying from transparent to coffee-colored to brown) and the value of amylase in the fluid itself, greater than three times the normal limit of serum amylase[149,150].

POPFs are classified into three grades based on clinical impact. Grade A fistulas do not involve any special intervention and do not significantly modify the postoperative hospital stay. Grade B fistulas require a longer postoperative stay, the retention of surgical drains, the possible placement of additional drains under radiological guidance, antibiotic therapy and the use of artificial nutrition (enteral or parenteral). In grade C fistulas, reoperation is required to resolve the complication.

Several methods have been used to reduce the risk of pancreatic fistula, including the use of octreotide, pancreatic duct occlusion, pancreatic duct stenting, pancreaticojejunostomy, anastomosis modification, and pancreaticogastrostomy. The efficacy of octreotide in preventing POPF is still a hotly debated topic. According to a 2020 meta-analysis[154], somatostatin analogs did not affect POPF after PD, but rather appeared to be associated with a lower rate of POPF after distal pancratectomy. Therefore, reconstruction technique is the most important factor in reducing the risk of this complication. Recently, interesting results concern the blumgart anastomosis (BA), which combines the duct-mucosal principle with the transpancreatic U-suture technique. Unlike other duct-mucosal anastomoses such as Cattell-Warren anastomosis and Kakita anastomosis, U-shaped sutures and horizontal mattress suture technique are used in BA. The difference is that Blumgart's technique involves the placement of 3 to 6 transpancreatic and digestive seromuscular U-sutures to bring the pancreatic stump and jejunum closer together. A meta-analysis conducted by Ricci *et al* [155] demonstrated the ability of BA to reduce the risk of pancreatic fistula compared with non-blumgart duct-to-mucosal anastomoses (non-BA DtoM). The reduction seems clinically significant, with a number needed to treat of 9 which means that one pancreatic fistula can be avoided every ten patients treated with BA instead of non-BA

DtoM[155,156].

Indications for the preoperative treatment of jaundice in patients who are candidates for surgery are still under debate. It increases post-operative complications and should be reserved to patients with cholangitis or with bilirubin levels greater than 15 mg/dL[157].

Distal pancreasectomy

Distal pancreasectomy with splenectomy is the conventional operation for PDAC located in the body or tail of the pancreas. It can provide a margin-negative resection and ensure a sampling of at least 12 regional lymph nodes. A systematic review, that included 29 observational studies, found less blood loss and reduced length of hospital stay in patients operated with laparoscopic approach. However, the laparoscopic technique has some disadvantages that may lead to inadequate resection margins: Technical difficulties, inability to palpate the gland, difficulty in closing the pancreatic stump. Generally, surgeons advocate an open approach when the concern for malignancy is high, reserving laparoscopic resection for benign or premalignant indications[158-160].

Petrucciani *et al*[161] evaluated the prognosis of patients with positive surgical margin (R1). A better OS was observed in patients with R0 margin *vs* R1. However, an extension of the surgical resection following R1 pancreasectomy did not improve long term survival.

Total pancreasectomy

Sometimes, because of the extent or location of the tumor, a total pancreasectomy is required to achieve microscopically negative resection margins[162,163]. However, the metabolic consequences of this procedure, which include permanent exocrine insufficiency and brittle diabetes, have a detrimental impact on the quality of life and long-term survival[164]. A recent study showed a moderately reduced summary score of 76%, compared with a general population score of 86% using the EORTC QLQ-C30 questionnaire to evaluate the overall quality of life. Diarrhea is the most important symptom[165].

Lymphadenectomy

Tomlinson *et al*[166] evaluated the minimum number of lymph nodes removed during pancreasectomy that are essential for proper staging. They consider a number of 15 Lymph nodes as the optimal cut-off. Therefore, the cut-off of 12 lymph nodes reported by Schwarz, represents a more easily threshold value, but sufficient for correct staging.

Standard lymphadenectomy should strive to resect lymph node stations 5, 6, 8a, 12b1, 12b2, 12c, 13a, 13b, 14a, 14b, 17a, and 17b[167].

In some centres, mainly in Japan, surgeons routinely perform extensive lymph node dissection, including all 8, 9, all 12, all 14, 16a2, and 16b1 lymph nodes. A systematic review comparing standard *vs* extended lymphadenectomy demonstrated that there are no differences in OS between the two groups at one, three, or five years. However, the risk of complications was significantly increased after extended lymphadenectomy [168].

Vascular resection

If the pancreatic tumor involves the PV or SMV, pancreatic resection with PV or SMV resection may be considered: (1) When the vascular resection allows for adequate vascular flow; (2) When the tumor does not involve the SMA or hepatic artery; and (3) When an R0 resection can be accomplished. Nevertheless, many surgeons prefer to treat patients with PV or SMV involvement with neoadjuvant systemic chemotherapy before surgery.

A systematic review of 12 single-center reports concluded that pancreasectomy with PV/SMV resection is a safe and feasible procedure. It increases the number of patients who can undergo curative surgery and improves long term prognosis in a selected group of patients[169]. However, post-operative morbidity and mortality increase markedly when arterial resections are performed and few data are available to support these procedures[170-172].

Open vs minimally invasive approach

A systematic review identified 27 retrospective studies, including close to 7000 patients who underwent pancreasectomy (1306 minimally invasive, 5603 open)[173]. The laparoscopic approach was associated with longer operative times [mean difference (MD) 71 min], but lower intraoperative blood loss (MD -300 mL). The rate of

lymph node retrieval was significantly higher in the minimally invasive group (MD 1.34 nodes), and the likelihood of an R0 resection was also higher (odds ratio 1.45). Hospital stay, postoperative hemorrhage and wound infection were significantly lower in the laparoscopic group, while the rate of overall mortality, reoperations, vascular resection, pancreatic fistula, delayed gastric emptying and bile leak were similar between the two groups[174-176].

In some high-volume surgical centres, robotic-assisted pancreatic resection has been adopted. Experienced surgeon reported the same morbidity and mortality of open surgery. Decreased blood loss, higher number of adequate lymphadenectomy and improved gastric emptying are reported in some studies. These results may improve OS, but, because robotic-assisted pancreasectomy is still in its infancy, available long-term oncologic outcomes are limited[177-181].

CHEMOTHERAPY FOR RESECTABLE AND BORDERLINE RESECTABLE PANCREATIC CANCER

The only treatment with curative potential for pancreatic cancer is surgery. Five-year survival ranges from 10% to 25%.

For patients with PDAC resectable or borderline resectable, surgical resection is followed by adjuvant chemotherapy. Some high-volume centers also use neoadjuvant therapy in these categories of patients[182,183].

Adjuvant chemotherapy

Several adjuvant chemotherapy regimens have been evaluated in randomized controlled trials[184-190]. Currently, mFFX is the recommended therapy for patients with a good performance status. Gemcitabine (+/- capecitabine) remains a treatment option for patients not sufficiently fit or with contraindications to mFFX[182,191]. Because mFFX has a high toxicity, Brown University Oncology Research Group suggests FOLFOX + nab-paclitaxel (FOLFOX-A) as an alternative[192].

According to a meta-analysis[193], S1 was ranked best for overall and disease-free survival followed by mFFX. Whilst there was no significant difference between S1 and mFFX for OS, S1 had significantly longer disease-free survival (MD 2.8 mo) and was ranked best for lowest overall and haematological grade 3/4 toxicities[194]. However, the results should be interpreted with care, as S-1 has shown good results in the Asian population, but its performance in Caucasians remains unclear due to the different expression of cytochrome P-450.

Adjuvant chemotherapy should be administered between 28 and 59 d after surgery. This timing appears to provide better survival than administering before 28 or after 59 d[182,194].

A 2020 study compared the efficacy between adjuvant chemotherapy and chemoradiation therapy in relation to AJCC stage. Monochemotherapy and combination chemotherapy + chemoradiotherapy (CRT) showed better OS and disease free survival than CRT alone in patients with AJCC stage III, whereas there was no significant difference in OS in patients with AJCC stage I/II[195].

Neoadjuvant chemotherapy

The main purpose of neoadjuvant chemotherapy (NACT) differs according to the stage. For patients with BR-PDAC the objective of the therapy is to decrease tumor size and to control the micro metastases. For patients with primary resectable PDAC the purpose is to increase the proportion of patients receiving chemotherapy, because half of patients undergoing surgery, do not receive adjuvant chemotherapy due to postoperative morbidity or poor general condition[196].

In 2020, important advances were made in this field. For patients with BR-PDAC several studies confirmed the benefits on R0 resection rates and survival of NACT with mFFX[197-200] or multi-agent gemcitabine[201]. Moreover, in the PREOPANC-1 trial, patients receiving neoadjuvant CRT with gemcitabine obtained the same benefits of mFFX[202]. A study of the University of Texas showed that patients who received neoadjuvant CRT had significantly improved R0 resection rates, lymph node resection rates, and locoregional recurrence rates, compared with those who received NACT [203]. Although early data suggest the importance of integrating both NACT and CRT into the treatment, large prospective trial data are lacking[204]. New evidence for a standard regimen for BR-PDAC will be established by the result of the ESPAC-5F trial (ISRCTN89500674)[205].

For primary resectable cancer, the potential benefit of NACT has been validated, particularly when initiated within 6 wk of diagnosis[206]. The SWOG S1505 study observed that patients who received gemcitabine and nab-paclitaxel had a greater pathologic response and median survival comparable to those who received mFFX [207]. Several chemotherapeutic agents for resectable pancreatic cancer are currently being studied in several RCTs[208]. The NorPACT-1 study[209] and the Panache-01 study[210] are evaluating the effect of NACT with mFFX, and the NEONAX study [211] of NACT with 2 cycles of nab-paclitaxel/ gemcitabine.

In the Asian population, treatment regimens differ. The Prep-02/JSAP-05 study study demonstrated, in patients with resectable PDAC, that NACT with gemcitabine plus S-1 (GS therapy) improves median OS compared with initial surgery (37 mo vs 27 mo). The resection rate and morbidity of surgery remain the same[212].

Based on these results, the latest Japanese guidelines recommend GS therapy as standard neoadjuvant therapy for patients with resectable PDAC. In this regimen, patients receive intravenous gemcitabine at a dose of 1000 mg/m2 on days 1 and 8, plus oral S-1, twice daily, at a dose based on body surface area (80, 100, 120 mg/d) on days 1-14 every 3 wk for 2 cycles. For patients with BR-PDAC, they recommend NACT, but have refrained from recommending any specific regimens[212-214]. Among several ongoing RCTs on treatments for borderline resectable pancreatic cancer, a Japanese trial is comparing neoadjuvant therapy with gemcitabine plus nab-paclitaxel and CRT therapy with S-1[215].

A subset of patients does not respond to NACT. There is therefore a need to find markers that can predict response to NACT. At the moment the best ones seem to be GRP78, CADM1, PGES2 and RUXF[216] (Table 4).

CHEMOTHERAPY FOR LA PANCREATIC CANCER

Thirty to forty percent of patients with PDAC are initially diagnosed LA PDAC[182, 215]. LA PDAC is still nonmetastatic, but due to the local growth, curative resection is not possible at the time of diagnosis. Treatment involves chemotherapy with regimens that are also used in the metastatic setting, such as mFFX or gemcitabine plus nab-paclitaxel[217-219]. A small percentage of patients, with excellent response to chemotherapy, may become eligible for surgical resection. The majority have incurable disease. A systematic review of studies investigating mFFX in LA-PDAC revealed a median OS ranging from 10.0 mo to 32.7 mo[220], while in the LAPACT study, about the Nab-Paclitaxel + Gemcitabine regimen, OS 18.8 mo[221]. Recently, Kunzmann *et al* [222] compared two different NACT regimens, mFFX and gemcitabine plus nab-paclitaxel. The mFFX was superior in both the conversion rate to surgery (45.0% *vs* 30.6%) and the rate of R0 resections achieved (74% *vs* 68%). A subsequent study confirmed that mFFX patients had greater tumor size reduction, fewer positive lymph nodes, longer OS and distant metastasis-free survival compared to the nab-P/G patients[223].

The role of CRT for LA disease is still unclear. According to the LAP07 study, CRT improves the rate of local control but does not prolong survival in patients with LA PDAC after treatment with chemotherapy (gemcitabine with or without erlotinib) [224]. It is unclear whether these conclusions still hold true in the setting of newer combination chemotherapy regimens and improved radiation therapy techniques, such as stereotactic radiation therapy and proton therapy. The PAULA-1 study compared two cohorts of LAPDAC patients treated with stereotactic body radiotherapy (SBRT) ± chemotherapy *vs* CRT ± chemotherapy in terms of local control, distant metastases-free survival (DMFS), progression-free survival (PFS), OS, and toxicity. Patients treated with SBRT showed higher local control rate and similar OS, DMFS, PFS and toxicity compared to CRT[225].

CHEMOTHERAPY FOR METASTATIC PDAC

Half of patients have metastatic disease at the time of diagnosis. The primary treatment is systemic chemotherapy, with the goal of increasing survival and palliating cancer-related symptoms. Both mFFX and gemcitabine plus nab-paclitaxel improve median OS compared to gemcitabine monotherapy[226,227]. In clinical practice, for patients who are fitter, mFFX is generally preferred, reserving gemcitabine plus nab-paclitaxel as a second-line option if they have adequate performance status[228,229]. For patients who have received first-line gemcitabine and

have progressed, a good option might be the combination of fluorouracil plus leucovorin with nanoliposomal irinotecan[230]. Golan *et al*[231] evaluated patients with metastatic PDAC and BRCA1-2 germline mutation. In these patients, disease progression had not occurred during at least 4 mo of first-line platinum derivative-based chemotherapy. Patients were randomized to receive olaparib or placebo. Olaparib showed a benefit in terms of PFS and a relatively safe toxicity profile. Although AIFA has not yet approved the indication, this study suggests a role for olaparib as maintenance therapy[231].

Finally, we look forward to the results of the AVENGER 500 trial (NCT03504423) to evaluate the efficacy of mFFX with or without CPI-613. CPI613 (devimistat) is an inhibitor of pyruvate dehydrogenase and a-ketoglutarate, key enzymes of the Krebs cycle. It has already shown good results in a phase I study[232].

STROMA-TARGETING THERAPY

Although chemotherapy is the recommended treatment for patients with advanced PDAC, its efficacy is not satisfactory. The major hurdle is considered the dense dysplastic stroma. The stroma components occupy more than 70% of the total tumor volume. The dense desmoplastic stroma of PDAC leads to vascular compression and a hypoxic microenvironment, which in turn influences drug pharmacokinetics/pharmacodynamics. It also prevents proper action of immune system cells, which are unable to reach the target site. The result is a chemoresistant and immunoresistant tumor[233,234].

One of the major components of the PDAC stroma is hyaluronic acid (HA). HA promotes the survival, proliferation, and migration of tumor cells[235]. HA is a potential therapeutic target using pegylated hyaluronidase (PEGPH20). The HALO-109-202 study demonstrated that PEGPH20, combined with Abraxane (nab-paclitaxel) and gemcitabine, improves progression-free and OS in patients with high HA levels [236]. However, poor results were obtained from the subsequent HALO-109-301 study (NCT02715804). Another element to be acted upon is the Hedgehog signaling pathway, which is generally overactivated in pancreatic cancer. Vismodegib, in combination with gemcitabine or erlotinib, was studied for this purpose. It did not significantly affect survival compared with these two drugs administered as monotherapy[237,238].

In tumors, Angiotensin II activates transforming growth factor-β through the AT1R and stimulates proliferation, so several angiotensin system inhibitors have been used to target PDAC stroma[233]. One study evaluated the efficacy of mFFX combined with losartan in a neoadjuvant regimen in patients with LA PDAC. The therapy was associated with an increased R0 resection rate[239].

A clinical trial evaluated the efficacy of focused ultrasound combined with gemcitabine microbubble delivery in PDAC patients. Patients treated with the combination tolerated multiple chemotherapy cycles of gemcitabine. A prolongation of median survival by almost 9 mo and, in 50% of cases, a reduction in tumor size were observed[240].

Poor results were obtained from stroma depletion in clinical settings. They are due to the fact that, although stroma-targeting therapy enhances the delivery of chemotherapeutic agents, it might also promote tumor chemoresistance and metastasis (a double-edged sword)[241]. According to several experts, future research should focus on the tumor ECM biology, biomarkers correlated with treatment benefit (as ADAM12)[242] and pharmacological agents able to alter the tumor microenvironment (TME). One of the most interesting discoveries in this regard involves clodronate liposomes. They prevent metastasis formation by inhibiting the activity of PDAC-associated macrophages and altering the microenvironment of key organs that are sites of metastatic invasion. They are therefore valuable candidates to be evaluated in combination with target therapy against stroma[243].

IMMUNOTHERAPY

Immune checkpoint inhibitors

Checkpoint inhibitors activates the function "kill the tumor" of the immune system, targeting immune checkpoint molecules (PD-1, PD-L1, CTLA-4) that negatively regulate T-cell function. Although they resulted in remarkable successes in other cancers, ipilimumab, BMS-936559 and tremelimumab showed little efficacy in PDAC [244-247]. The reasons of failure of immune checkpoint inhibitors are the low baseline PD-1+ T-cell infiltration into the tumor and a paucity of neoepitopes[248,249]. Indeed, in a very small subset of PDAC patients with a high burden of microsatellite instability (MSI-high) PD-1 inhibitor is effective and was recently FDA approved[250,251].

Currently, the development of immune checkpoint inhibitors for PDAC is focused on combination therapy with chemotherapeutic agents[252-255].

Therapeutic cancer vaccines

Therapeutic cancer vaccines present of immunogenic tumor antigens to the immune system, resulting in activation of the anti-cancer response. GVAX is an allogeneic vaccine irradiated with tumor cells engineered to express GM-CSF. It was studied alone and in combination with CRS-207 and cyclophoshamide, however it didn't correlate with improved survival[256,257].

More promising results were instead obtained with KIF20A-66[258-260].

K-RAS vaccines have been tested in the past, but data remain unclear and with no prominent advantages in metastatic patients[261-264].

We are currently awaiting the results of some studies: (1) TLP0-001, a phase III study of a dendritic cell (DC) vaccine loaded with WT1 peptides in patients with advanced PDAC refractory to standard chemotherapy[265,266]; (2) A clinical trial using GV1001 with GM-CSF in patients with LA-PDAC in combination with gemcitabine chemotherapy, tadalafil and radiation therapy (NCT01342224); and (3) NCT01836432, NCT02405585 and NCT01072981 evaluating algenpantucel-L in combination with chemotherapy and CRT therapy. They involve patients with borderline resectable and LA unresectable PDAC.

CAR-T cell

CAR-T cell therapy is a type of adoptive cell therapy. CAR-T cells are T lymphocytes that are extracted from a patient's blood sample or from a donor by apheresis, genetically modified to express the receptor for chimeric antigen (CAR), and cultured in the laboratory. They are then re-infused into the patient. The resulting T cells are able to recognize tumor cells and activate the immune system response against the disease[267]. The target antigens of CAR-T cells include mesothelin, prostate stem cell antigen (PSCA), CEA, HER2, MUC-1, and CD133[268,269]. In a study of metastatic PDAC, autologous mesothelin-specific T lymphocytes improved PFS in two patients of the six examined. An additional patient had complete remission of all liver metastases

[270].

Combination of immunotherapy drugs was experienced and showed good results over time. Le *et al*[271] compared the efficacy of Ipilimumab as monotherapy (arm 1) and Ipilimumab in combination with GVAX (arm 2) in patients with already treated PDAC. Combination therapy showed an increase in median OS (5.7 mo *vs* 3.6 mo) and 1-year OS (27% *vs* 7%). Chung *et al*[272] evaluated the combination of Pembrolizumab with modified p53-expressing Ankara vaccinia virus (p53MVA). Three of eleven patients experienced disease stabilization by 30, 32, and 49 wk. Good OS and PFS results were also obtained using DC and cytokine-induced killer cell immunotherapy in combination with S-1 chemotherapy, compared with chemotherapy or supportive care alone[256].

Several trials of immunotherapy-based treatment combinations with targeted agents are ongoing for patients with pancreatic cancer[273-275].

Oncolytic viruses

Oncolytic viruses are modified therapeutic drugs that selectively infect and self-replicate in tumor cells with tumor-dissolving effect. They also activate the anti-tumor immunity and change the TME from an immunosuppressed state to an immune-activated state. Futhermore, oncolytic viruses have the advantages of specificity, low toxicity, and low drug resistance[276]. Adenovirus, Herpes Simplex Virus, Protoparvovirus, Reovirus and Vaccinia Virus have been tested. However most of the studies have shown unsatisfactory results. The only positive results derive from ParvOryx02 (NCT02653313). A single-arm study published in 2020 showed an encouraging efficacy of pembrolizumab in combination with Pelareorep and chemotherapy in patients progressed after first-line treatment[277-281] (Table 5).

GENETIC MUTATION AND TARGET THERAPY

Some genetic alterations produce cellular changes in neoplastic cells that are potentially therapeutically targetable. BRAF mutations occur in 1%-3% of PDAC. They showed to be targetable in metastatic colon cancer where the combination of Encorafenib and Cetuximab has recently been approved[282,283]. Encorafenib and Cetuximab should also be evaluated in PDAC. Furthermore, pancreatic tumors with NTRK gene fusions can be treated with tropomyosin receptor kinase inhibitors[284, 285]. Similarly, some wild-type Kras pancreatic tumors hosting somatic NRG1 gene fusions respond to treatment with a kinase inhibitor of the HER family[286,287].

However, the results of the targeted therapies have been unsatisfactory, mainly due to the low life expectancy. There is no time to sequence the tumors and develop a treatment based on mutations[288].

The exceptions were the germline alterations. Patients with mutations of BRCA1, BRCA2 or PALB1 are remarkably sensitive to treatment with DNA cross-linking agents, such as platinum-based drugs, and poly(ADP-ribose) polymerase (PARP) inhibitors[289-291]. Patients with Lynch syndrome (MSI-high) respond well to treatment with immune checkpoint inhibitors[292-294] and those with ATM mutations could respond to the drugs, targeting the ATR-checkpoint kinase 1 (Chk1) pathway [295,296].

The elephant in the targeted therapy room remains Kras[297]. It has been considered "undrinkable"[297-299] because the protein lacks an efficient small-molecule binding pocket and has a high affinity for cellular guanosine triphosphate (GTP), which is highly concentrated in the cytoplasm. Furthermore, other than the GTP/GDP binding pocket, KRAS has no other pockets for small-molecule inhibitor binding. A druggable variant of Kras appears to be G12C. Enormous progress has been made in this regard and several drugs (AMG 510, MRTX849, JNJ-74699157 and LY3499446) are currently in clinical trials[299]. The importance of these can be deduced from the fact that 95% of pancreatic cancers harbor mutations in the Kras gene (the four Kras mountains, TP53, CDKN2A and SMAD4 present in > 50% of tumors)[300,301]. Although Kras G12C mutations are only a small fraction of Kras mutations in PDAC, these drugs represent a chance to take down a previously thought invincible adversary.

PANCREATIC CANCER AND GUT MICROBIOTA

Recent studies have shown the gut microbiota (GM) may play a role in the

development of PDAC and its response to therapy. GM alterations result in reduced mucus thickness, leading to decreased antimicrobial defenses and increased exposure to bacterial components such as LPS, flagellin, single or doubled DNA and CpG DNA. These agents activate Toll-like-receptors and trigger chronic inflammation that are related to carcinogenesis. Moreover, inflammation and dysbiosis lead to mutation of Kras, that accelerates carcinogenesis, activating nuclear factor-κB pathway[302-304].

Several bacterial products are considered potential carcinogens. Cyclomodulins promote tumorigenesis through active interference with host cell cycles. Colibactin and Bacteroides fragilis toxin act synergistically with Escherichia coli to create double-stranded DNA damage[305]. E. coli cytotoxic necrotizing factor and CagA lead to uncontrolled cell proliferation, while cytolytic distending toxin and cycle inhibitory factor participate in genetic alterations and induce hyperploidy even in the absence of cell division[306]. The presence of an *Helicobacter pylori* infection and high concentrations of Fusobacterium spp and Porphyromonas gingivalis (bacteria generally present in the oral cavity) are associated with an increased risk of pancreatic cancer [307-310].

Moreover, other studies correlated a large number of microbes with immune suppression, downregulation of tumor suppressive pathways and the upregulation of oncogenic pathways[311].

Dysbiosis is also related to obesity, chronic pancreatitis and diabetes, well-established risk factors of PDAC[312,313].

Because it participates in drug metabolism and biotransformation and immune regulation, the GM is implicated in the efficacy of chemotherapeutic agents[314]. The innate immune response activated by the GM potentiates the action of oxaliplatin [315]. Gentamicin activity may be reduced by the enzymes pyrimidine nucleoside phosphorylase and cytidine deaminase, which are produced by Gamma-proteobacteria and mycoplasmas within PDAC. Thus, these data suggest the possibility of modulating GM to counteract the chemoresistance characteristic of pancreatic cancer [316].

Intratumoral microorganisms can play a key role in anticancer therapy[317]. Indeed, they can stimulate host immune responses with positive or negative impacts on therapy. *Gammaproteobacteria*, *Escherichia Coli* and *Fusobacteria* are most commonly present in PDAC. Gamma proteobacteria contain the enzyme CDD which could be responsible for the ineffectiveness of gemcitabine[318]. Escheria Coli is capable of inducing chemical changes in the structure of gemcitabine, fludarabine, cladribine, and CB1954[319]. The desmoplastic response induced by tumor cells is dependent on MyD88. It is activated by Fusobacterium species.

The intratumoral microbiota thus emerges as a major proponent of the chemo-immunoresistant phenotype of pancreatic cancer and is related to long-term survival in PDAC patients.

PROGNOSIS

The most important prognostic factor is tumor stage. The median survival time after resection for patients with stage IA, IB, IIA, IIB, and III was 38, 24, 18, 17, and 14 mo, respectively[320]. Other factors may influence the prognosis of PDAC after surgery: Surgical margin status, tumor grading, presence of lymphatic invasion, preoperative and postoperative serum levels of CA 19-9, and cigarette smoking[321-329]. Squamous subtypes have a poor prognosis. They are enriched with TP53 and KDM6A mutations, upregulation of TP63ΔN transcriptional network, hypermethylation of pancreatic endoderm cell fate determining genes[330].

Several studies have investigated novel factors influencing prognosis: (1) Increased expression of CDK1 and CCNA2 is associated with poor prognosis, although they may be potential therapeutic targets[331]; (2) The autophagy regulatory genes MET and RIPK2 play a prognostic role in PDAC[332]; (3) High expression of GPDAC2, GPDAC3 and GPDAC5 has been significantly associated with favorable survival[333]; (4) High expression of Hic-5 is negatively correlated with postoperative survival time, as Hic-5 stimulates tumor proliferation, migration, and invasion[334]; (5) PRMT1 promotes pancreatic cancer growth by increasing cellular β-catenin levels and predicts poor prognosis[335]; (6) Patients with first recurrence in the lung have a better prognosis than patients with first recurrence in the liver[336]; (7) Increased levels of ZIP4 correlate with poorer survival. ZIP4 inhibits the expression of the gemcitabine transporter ENT1, so that cells take up smaller amounts of the drug. Activation of this pathway participates in the chemoresistance of pancreatic cancers[337]; (8) The highly upregulated in liver cancer (HULC) lncRNA distinguishes patients with pancreatic cancer, patients with benign pancreatic disease, and healthy subjects and correlates with TNM stage. Subjects with low HULC expression have significantly higher 3- and 5-year OS than those with high expression. Therefore, HULC lncRNA could be considered an effective marker for the diagnosis and prognosis of PDAC[338]; (9) Upregulation of TYMS leads to unfavorable OS and RFS[339]; and (10) The GINS complex has four subunits, encoded by the GINS1, GINS2, GINS3, and GINS4 genes, all of which are overexpressed in PDAC. The expression of each member is associated with the histological grade of PDAC and is a negative prognostic marker[340].

CONCLUSION

Pancreatic cancer is a very treacherous, dangerous enemy and the results are still very unsatisfactory. But we have not given up. Research is running fast on many paths, without losing its enthusiasm. It is proof that we are encircling it, and at the end, we

will win. The success of a fight is linked to the ability to move from one failure to another without losing one's enthusiasm.

Abstract

Zollinger-Ellison syndrome (ZES) associated with pancreatic or duodenal gastrinoma is characterized by gastric acid hypersecretion, which typically leads to gastroesophageal reflux disease, recurrent peptic ulcers, and chronic diarrhea. As symptoms of ZES are nonspecific and overlap with other gastrointestinal disorders, the diagnosis is often delayed with an average time between the onset of symptoms and final diagnosis longer than 5 years. The critical step for the diagnosis of ZES is represented by the initial clinical suspicion. Hypergastrinemia is the hallmark of ZES; however, hypergastrinemia might recognize several causes, which should be ruled out in order to make a final diagnosis. Gastrin levels > 1000 pg/mL and a gastric pH below 2 are considered to be diagnostic for gastrinoma; some specific tests, including esophageal pH-recording and secretin test, might be useful in selected cases, although they are not widely available. Endoscopic ultrasound is very useful for the diagnosis and the local staging of the primary tumor in patients with ZES, particularly in the setting of multiple endocrine neoplasia type 1. Some controversies about the management of these

tumors also exist. For the localized stage, the combination of proton pump inhibitory therapy, which usually resolves symptoms, and surgery, whenever feasible, with curative intent represents the hallmark of gastrinoma treatment. The high expression of somatostatin receptors in gastrinomas makes them highly responsive to somatostatin analogs, supporting their use as anti-proliferative agents in patients not amenable to surgical cure. Other medical options for advanced disease are super-imposable to other neuroendocrine neoplasms, and studies specifically focused on gastrinomas only are scant and often limited to case reports or small retrospective series. The multidisciplinary approach remains the cornerstone for the proper management of this composite disease. Herein, we reviewed available literature about gastrinoma-associated ZES with a specific focus on differential diagnosis, providing potential diagnostic and therapeutic algorithms.

Core Tip: As symptoms of Zollinger-Ellison syndrome are nonspecific and overlap with other gastrointestinal disorders, most of these patients are usually referred to general gastroenterologists, leading to a diagnostic delay. A better disease awareness together with the maintenance of a high index of suspicion are necessary to make the final diagnosis. The proper management of Zollinger-Ellison syndrome due to a gastrinoma include both the medical treatment for symptom's relief and surgery whenever feasible with curative intent; the multidisciplinary approach, with close cooperation between gastroenterologists and surgeons, and the referral to tertiary centers with great expertise in the neuroendocrine field are mandatory.

INTRODUCTION

Zollinger-Ellison syndrome (ZES) was firstly described in 1955 as associated with a neuroendocrine neoplasm (NEN) capable of ectopic gastrin secretion (namely gastrinoma)[1], resulting in gastric acid hypersecretion, which typically leads to gastroesophageal reflux disease (GERD), recurrent peptic ulcers, and chronic diarrhea. The terms gastrinoma and ZES have been frequently used as synonymous, although gastrinoma refers to the NEN secreting gastrin, whereas ZES refers to the clinical manifestations of the disease. ZES has an incidence of 1-1.5 cases/million per year[2]. Gastrinomas are NENs located in the duodenum (70%), pancreas (25%), and rarely (5%), in other sites, including stomach, liver, ovary, and lung. Gastrinoma is the most frequent functioning duodenal NEN and the second most frequently occurring functional pancreatic NEN (pNEN), following insulinoma; in turn, 15% of functioning pNENs is represented by gastrinoma. It may be sporadic, which is generally diagnosed between the ages of 50 and 70 years with a male to female ratio of 1.5-2:1 [3], whilst 20%-30% of the patients develop ZES in the context of a genetic syndrome known as multiple endocrine neoplasia type 1 (MEN-1)[4].

The diagnosis of ZES is not always straightforward due to both non-specific symptoms and confounding factors including proton pump inhibitor (PPI) therapy, which might temporarily relieve symptoms. Furthermore, as these patients tend to be referred to gastroenterologists because of diarrhea and/or reflux disease disorder, despite a better awareness of the disease, the diagnosis might be challenging for those

gastroenterologists with low experience in the neuroendocrine setting as well as for many oncologists who are less used to dealing with diarrhea and reflux disease. As a consequence, the average time between the onset of symptoms and the final diagnosis is often longer than 5 years[5,6], and nearly 25% of patients are metastatic at the first diagnosis and show a worse prognosis when compared to non-metastatic patients in whom the surgical management is associated with a promising 15-year survival rate of > 80%[7].

Furthermore, some controversies about the management of these tumors still exist, particularly regarding the exact role of surgery or medical treatment and the possible role of somatostatin analogs (SSAs)[3]. Given that gastrinoma and ZES need both a proper medical treatment for symptom relief and a surgical procedure whenever feasible, the multidisciplinary approach, with close cooperation between clinicians and surgeons, remains the cornerstone for proper management of this composite disease, which should be always referred to tertiary centers.

Herein, we review from a critical point of view current knowledge about gastrinoma-associated ZES, also providing potential diagnostic and therapeutic algorithms based on both evidence from literature and own personal experience.

METHODOLOGY

Bibliographical searches were performed in PubMed using the following keywords: Gastrinoma; Zollinger Ellison syndrome; neuroendocrine neoplasms; pancreatic neuroendocrine neoplasm; duodenal neuroendocrine neoplasm; diagnosis; therapy; guidelines. We searched for all relevant articles published over the last 10 years. The reference lists from the studies returned by the electronic search were manually searched to identify further relevant reports. The reference lists from all available review articles, primary studies, and proceedings of major meetings were also considered. Articles published as abstracts were included, whereas non-English language papers were excluded.

CLINICAL PRESENTATION

ZES is characterized by gastric acid hypersecretion and consequent hyperchlorhydria resulting in severe acid-related peptic disease and diarrhea. The symptoms usually resolve when gastric acid secretion is controlled pharmacologically with PPIs[8,9]; of note, the disappearance of diarrhea following PPI treatment is typical of ZES and represents one of the factors contributing to the diagnostic delay. According to data from the literature, common symptoms include abdominal pain (75%), diarrhea (73%), heartburn (44%), and weight loss (17%)[6,8,10]. As these symptoms are both not specific and often less severe due to concomitant PPI treatment, the final diagnosis is often delayed and patients are diagnosed with irritable bowel syndrome or reflux disease by gastroenterologists with low or no knowledge of the disease[8,11].

The endoscopic features are also not specific and might include erosions and ulcers [12], however, ZES patients often present with multiple ulcers located at unusual sites, *e.g.*, beyond the first or second portion of the duodenum[8,13]. Furthermore, enlarged gastric folds can be present in more than 90% of patients with ZES[11].

One should keep in mind that approximately 25% of gastrinomas occur in the context of MEN-1, which is characterized by the presence of parathyroid, pancreatic-duodenal, and pituitary tumors[14]; thus the occurrence of unexplained hypercalcemia might be a sign for possible MEN-1 syndrome-associated ZES[15,16], also taken into account that primary hyperparathyroidism is generally the presenting feature in the majority of cases of MEN-1 syndrome[8,16,17]. Of note, parathyroidectomy usually improves gastrin levels and basal acid output[16]. Finally, in ZES/MEN-1 patients, type 2 gastric NENs might occur[3].

DIFFERENTIAL DIAGNOSIS

Symptoms of ZES are nonspecific and overlap with other gastrointestinal (GI) disorders, which explains the frequent diagnostic delay.

As concerns chronic diarrhea in ZES, this is sustained by hyperchlorhydria and sodium and water malabsorption due to hypergastrinemia[18]. As afore-mentioned,

diarrhea is one of the most frequent symptoms in ZES; up to 75% of patients manifest diarrhea[19], and this could be the sole presenting symptom in 3%-10% of the patients [20]. Moreover, chronic diarrhea is one of the most frequent symptoms requiring gastroenterologist referral; its diagnostic workup could be challenging because many different causes could cooperate to diarrhea development and recurrence (*e.g.*, dietary habits, drugs). Recent British Society of Gastroenterology (BSG) guidelines for chronic diarrhea[21] tried to classify different causes of chronic diarrhea (Table 1) and to standardize a diagnostic work-up in these patients. Since hormone-secreting tumors are considered rare causes of chronic diarrhea, BSG guidelines suggest testing patients for these tumors only when other causes of diarrhea have been excluded. From a clinical point of view, the association between chronic diarrhea with both other ZES suggestive symptoms (*e.g.*, chronic peptic ulcer disease) and clinical response to PPIs may be helpful in diagnosing this challenging syndrome, taking into account that the delay in diagnosis of ZES remains between 6 to 9 years from the first clinical presentation[9,19].

Abdominal pain and heartburn are frequently reported as symptoms of ZES[9]. As well as diarrhea, they are sustained by hyperchlorhydria, which directly damages GI mucosa, causing ulcers and erosions. Abdominal pain could be associated with peptic ulcers, which, differently from *Helicobacter pylo*ri or non-steroidal anti-inflammatory drug-related ulcers, are multiple, located at unusual locations (*e.g.*, the third part of the duodenum, small bowel) and complicated by bleeding, penetration, perforation, or strictures[8,13,19].

Similar to peptic ulcer disease, chronic GERD is one of the most frequent manifestations of ZES[13]. Heartburn and regurgitation are the most typical symptoms, which are super-imposable to symptoms associated with typical GERD; differently from the typical syndrome, patients with ZES often present esophageal strictures due to over-exposition to acid reflux.

Again, the association between these symptoms and chronic diarrhea, after exclusion of other common GI etiologies, might raise the suspicion of ZES, which requires specific tests in order to get the final diagnosis.

DIAGNOSIS

The diagnosis of ZES is quite challenging, also considered that the critical point is the initial suspicion of ZES. A suggested diagnostic algorithm is represented in Figure 1.

ZES is a clinical syndrome characterized by the following triad: (1) gastric acid hypersecretion, sustained by (2) fasting serum hypergastrinemia causing (3) peptic ulcer disease and diarrhea[1]. Hypergastrinemia is sustained by a gastrinoma, a rare NEN (located primarily in the duodenum or pancreas) that secretes gastrin.

Since ZES symptoms can be explained almost entirely by acid hypersecretion, PPIs, which significantly decrease acid secretion, can mitigate or resolve ZES symptoms, making ZES diagnosis even more challenging than in the past[9,22], but avoiding severe ZES complications.

Hypergastrinemia is the hallmark of ZES; however, hypergastrinemia might recognize several causes, which should be ruled out in order to make a final diagnosis of ZES[23]. In detail, it can be distinguished between (1) appropriate hypergastrinemia, due to atrophic gastritis (with or without pernicious anemia), anti-secretory therapy (PPIs or high-dose histamine H2-receptor antagonist, namely famotidine), chronic renal failure, *Helicobacter pylori*-related pan-gastritis, vagotomy, and (2) inappropriate hypergastrinemia that can be observed in ZES (sporadic or associated with MEN-1), antral-predominant *Helicobacter pylori* infection, retained-antrum syndrome, gastric-outlet obstruction, extensive small-bowel resection.

The diagnosis of ZES requires the demonstration of inappropriate gastrin secretion associated with gastric hyperchlorhydria, which corresponds to a gastric pH < 2[5]. Normal fasting gastrin levels are < 100 pg/mL; levels > 300 pg/mL are highly suspicious, and levels > 1000 pg/mL together with a gastric pH below 2 are considered to be diagnostic for gastrinoma[2,9,24]. Naso-gastric tube aspiration has classically been used to estimate gastric pH, but it can be uncomfortable for patients and can underestimate gastric acid output; alternatively, gastric pH can be measured during upper GI endoscopy, by aspiration of gastric juice for pH determination using either pH paper or a pH meter; while endoscopic sampling was shown to overestimate total acid volume, it provided more reproducible results and offered greater patient tolerance than nasogastric tube placement[5,23,25,26]. To avoid false-negative results, fasting serum gastrin levels and gastric pH should be measured after PPI withdrawal

Table 1 Differential diagnosis of chronic diarrhea[21]

Common	Infrequent	Rare
IBS-diarrhea	Small bowel bacterial overgrowth	Small bowel enteropathies (*i.e.* Whipple's disease, tropical sprue, amyloid, *etc.*)
Bile acid diarrhea	Mesenteric ischemia	Hypoparathyroidism
Diet (artificial sweeteners, caffeine, FODMAP malabsorption, *etc.*)	Lymphoma	Addison's disease
Colonic neoplasia	Surgical causes (small bowel resection, incontinence, *etc.*)	**Hormone secreting tumors** (*i.e.* VIPoma, gastrinoma, carcinoid)
IBD	Chronic pancreatitis	Autonomic neuropathy
Celiac disease	Radiation enteropathy	Factitious diarrhea
Drugs (antibiotics, NSAID, *etc.*)	Pancreatic carcinoma	Brainerd diarrhea
Overflow diarrhea	Hyperthyroidism	
	Diabetes	
	Chronic infections (*i.e.* giardiasis)	
	Cystic fibrosis	

FODMAP: Fermentable Oligosaccharides, Disaccharides, Monosaccharides, and Polyols; IBS: Irritable bowel syndrome; NSAID: Nonsteroidal anti-inflammatory drugs.

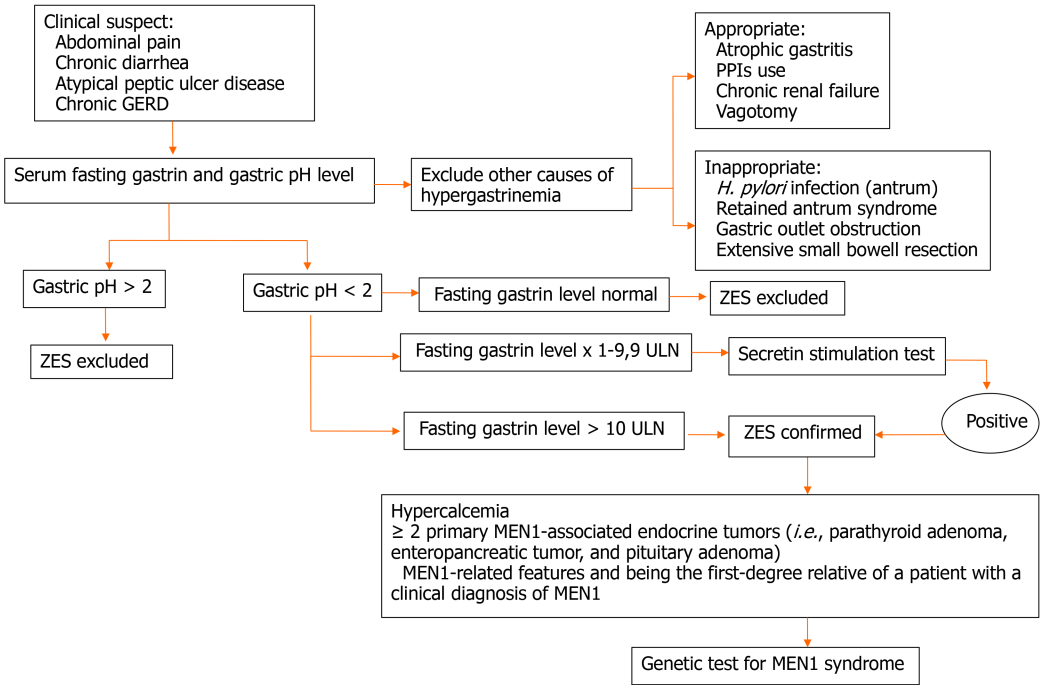

Figure 1 A suggested diagnostic algorithm is depicted. GERD: Gastroesophageal reflux disease; *H. pylori*: *Helicobacter pylori*; MEN-1: Multiple endocrine neoplasia type 1; PPIs: Proton pump inhibitors; ULN: Upper limit of normal; ZES: Zollinger Ellison syndrome.

[2,6,27]. However, PPI withdrawal could be dangerous for ZES patients, because it could bring a dramatic increase in gastric acid secretion, hence causing severe peptic ulcer disease and its complications[23], thus the decision to stop the treatment should be tailored to every single patient. Then, it is usually suggested to start histamine H2-receptor antagonists (*i.e.* famotidine) as soon as PPIs are stopped in order to prevent complications due to gastric acid hypersecretion. Having a shorter duration of action compared to PPIs, H2-antagonists could be used until the evening before serum gastrin and gastric pH tests[23].

Imaging and ultrasound endoscopy (endoscopic ultrasound)

Localization of the primary tumor and its metastases is the first diagnostic step when ZES associated with gastrinoma is suspected.

Contrast-enhanced computed tomography (CT) scan is useful to identify primary tumor > 1 cm, pancreatic head tumors, and liver metastases, with a sensitivity between 59% and 78% and a specificity between 95% and 98%, respectively. Conversely, sensitivity decreases for tumor size < 1 cm and extra-pancreatic locations[28,29].

Contrast-enhanced magnetic resonance imaging (MRI) showed high specificity (namely 100%) in detecting small pancreatic tumors and liver metastases, whereas sensibility is sub-optimal varying from 25% to 85%. Of note, MRI showed a higher sensibility for liver metastases detection when compared to CT scan[28,30].

Somatostatin receptor scintigraphy (Octreoscan®) has been used to localize gastrinomas[8,31]. This test involves the administration of indium radio-labeled octreotide, which binds selectively to somatostatin receptors found on gastrinoma cells. It showed quite good sensitivity (between 77% and 78%) and a good specificity (93%-94%) for primary tumor detection and its metastases, although sensitivity decreases for small tumors (< 1 cm)[32]. Diagnostic accuracy of somatostatin receptor scintigraphy (Octreoscan®) can be improved by performing it in combination with single-photon emission CT (SRS-SPECT)[28]. Different studies showed higher sensitivity and specificity in primary tumor detection, 78%-88% and 97%, respectively, when compared to Octreoscan® alone[33-35].

In more recent years, somatostatin receptor positron emission tomography (PET) techniques have shown great promise for improving the localization of gastrinomas as well as other NENs[36-39] and for the detection of distant metastases, including bone lesions. The radioisotope ^{68}Ga can be ligated to peptides that bind to somatostatin receptors found in abundance on the NEN surface[36]. This technique showed a higher sensibility and specificity (72%-100% and 83%-100%, respectively) when compared to the aforementioned diagnostic techniques in localizing the primary tumor, especially small size tumors[36,37,40]. Combining ^{68}Ga-radiotracers with traditional CT scans (PET/CT) further enhances diagnostic accuracy compared to PET alone, showing a sensitivity of 93% and a specificity of 96% in primary tumor detection [41]. Gallium-^{68}PET-scan should be always included in the diagnostic pathway of all NENs, including gastrinoma, in order to both identify the primary tumor and stage the disease.

Endoscopic ultrasound (EUS) has become an important diagnostic tool to localize gastrinomas, particularly small (*i.e.* < 2 cm) pancreatic lesions; its sensitivity and specificity are 75%-100% and 95%, respectively, for pancreatic tumors. Unfortunately, its sensitivity dramatically decreases in cases of duodenal localization, ranging from 38% to 63%[28,42]. A further advantage of this technique is the possibility of taking cytologic/histologic samples through a fine needle aspiration/biopsy (FNA/B) to confirm the diagnosis of NEN, even if false-negative results are possible mainly due to poor sampling adequacy. EUS-FNA/B is now considered the primary sampling technique for pancreatic tumors, with a sensitivity ranging between 80% and 90%, specificity at 96%[43], and a sampling adequacy rate of 83%-93%[44].

When used as a screening modality in asymptomatic patients with MEN-1, EUS has been reported to be more accurate than CT scan to detect smaller tumors[45]. Therefore, its diagnostic ability has led experts to recommend it as an annual screening modality for all patients with MEN-1, although recent evidence suggests that the growth rate of small pNENs (*i.e.* < 2 cm) is low and that EUS screening frequency can likely be extended[14,46].

Esophageal pH-recording

Since one of the most common symptoms of ZES is GERD, it could be argued that esophageal pH-monitoring could be a useful tool to diagnose ZES. Recent BSG guidelines for esophageal manometry and esophageal pH monitoring[47] stated indications to perform esophageal pH-monitoring, also including as an indication GERD symptoms that did not respond to double dose of PPIs. This technique allows to diagnose an increased acid exposure, to evaluate the association between symptoms and acid or non-acid reflux, and to identify different phenotypes of upper symptoms (*i.e.* non-erosive reflux disease, hypersensitive esophagus, and functional heartburn).

ZES is not usually included in diagnosis performed by esophageal pH-monitoring, and, consequently, ZES reference standard for esophageal pH-monitoring is lacking. However, evidence of a high number of acidic reflux episodes (*i.e.* esophageal pH < 4), a high number of long (*i.e.* > 5 min) reflux episodes, a high percentage of time with esophageal pH < 4, both on a double dose of PPIs and off PPIs, could raise the

suspicion of abnormal gastric acid secretion. This hypothesis should be confirmed by prospective studies; however, considering the rarity of this syndrome, it would be very difficult to obtain standard values to use in clinical practice; therefore, despite its potential utility, this test is not currently included in the standard diagnostic workup of gastrinoma.

Secretin provocative test

Secretin provocative test in ZES diagnosis founds its application in controversial cases, that is patients with suspected ZES, gastric pH < 2 but fasting serum gastrin < × 10 upper limit of normal[9]. To perform a secretin stimulation test, fasting gastrin levels are obtained before intravenous (IV) administration of secretin and then 2, 5, and 10 min after infusion[25]. Patients with gastrinomas exhibit an inappropriate increase in gastrin production in response to secretin infusion[9]. This mechanism can be explained in part by the fact that secretin receptors are expressed directly on the gastrinoma cell surface[48]. Different cut-offs for positive tests have been proposed, including an absolute increase in gastrin concentration ≥ 110 pg/mL or ≥ 200 pg/mL or a 50% increase in gastrin concentration[49]. However, previous data suggested that a positive secretin-provocative test (≥ 120 pg/mL increase) has a sensitivity of 94% and specificity of 100%, respectively[50]. According to data from the literature, a false-negative response can occur in 6% to 20% of patients[51,52], whereas false-positive responses, ranging from 15% to 39% in different studies[52,53], are found in patients with pernicious anemia or chronic PPI use.

In order to reduce the risk of false-positive results, PPI treatment should be withdrawn, but, again, the decision should be discussed in a case-by-case manner to limit the risk of severe complications (*e.g.*, perforation or bleeding). This might partially explain the reason why the secretin test can be difficult to be performed and should be reserved for strictly selected cases when the diagnosis is not straightforward.

MEN-1

MEN-1 is an autosomal dominant disorder, whose incidence has been estimated from random postmortem studies to be 0.25%, and to be 1%-18% in patients with primary hyperparathyroidism, 16%-38% in patients with gastrinomas, and less than 3% in patients with pituitary tumors[14]. From a clinical point of view, MEN-1 syndrome includes the occurrence of parathyroid adenoma (90%), entero-pancreatic tumor (30%-70%), being gastrinoma the most frequent (40%), and pituitary adenoma (30%-40%). Other tumors that might occur in MEN-1 patients are adrenal cortical tumor (40%), pheochromocytoma (< 1%), bronchopulmonary NEN (2%), thymic NEN (2%), gastric NEN (10%), lipomas, (30%), angiofibromas (85%), collagenomas (70%), and meningiomas (8%)[14].

In patients with an established diagnosis of gastrinoma-related ZES, MEN-1 syndrome might be present in approximately 25% of the cases. The presence of hypercalcemia due to hyperparathyroidism is one of the first signs. However, the diagnosis might be challenging in this specific setting as ZES does not usually develop in the absence of primary hyperparathyroidism, and hypergastrinemia has also been reported to be associated with hypercalcemia as a confounding factor[15]. Furthermore, parathyroidectomy leads to restoration of normocalcemia and improvement in clinical symptoms and biochemical abnormalities in as many as 20% of MEN-1 patients with ZES[14]. Moreover, staging and localization with CT or MRI is even more challenging in the setting of MEN-1 due to the presence of numerous small tumors < 1 cm in size[27,28]. A high index of suspicion must be maintained if a patient with chronic diarrhea and unexplained peptic ulcer disease presents with primary hyperparathyroidism. The genetic test for MEN-1 syndrome should be performed in a selected subgroup of patients, namely (1) in patients with two or more primary MEN-1-associated endocrine tumors (*e.g.*, parathyroid adenoma, entero-pancreatic tumor, and pituitary adenoma) or hypercalcemia associated with an endocrine tumor; and (2) patients showing MEN-1-related features and being the first-degree relative of a patient with a clinical diagnosis of MEN-1[14].

THERAPY

The management of gastrinoma and ZES includes both a proper medical treatment for symptom's relief and surgery with curative intent whenever feasible. A proposed therapeutic algorithm is represented in Figure 2.

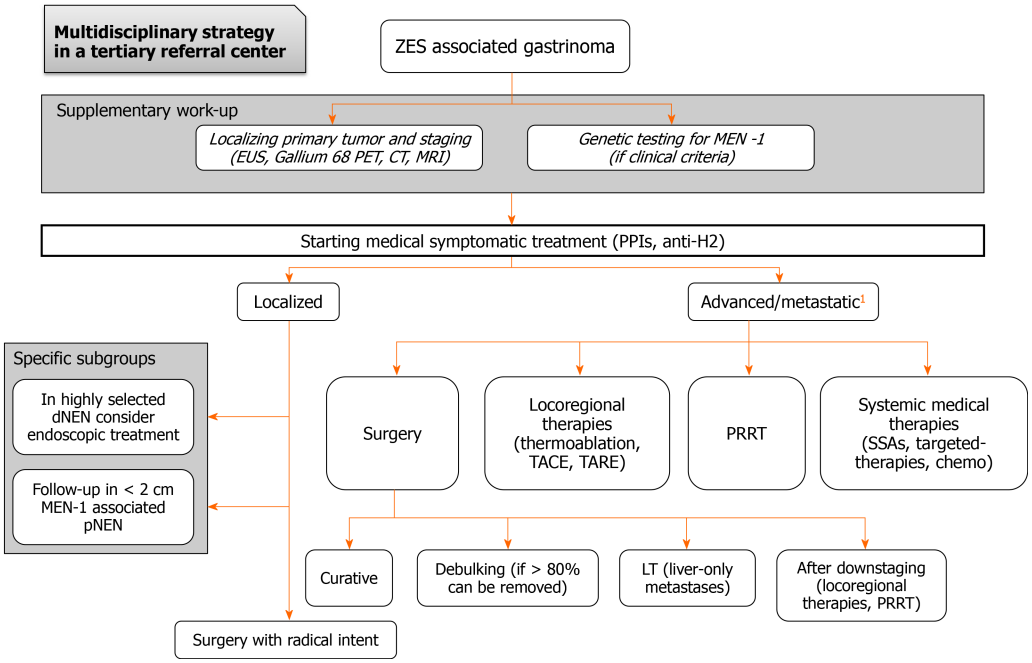

Figure 2 A proposed therapeutic algorithm is represented based on both evidence from literature and personal own experience. [1]Allocation driving prognostic factors are performance status, age, metastatic disease burden and pattern, comorbidities. CT: Computed tomography; dNEN: Duodenal neuroendocrine neoplasm; EUS: Endoscopic ultrasound; H2: Histamine receptor 2: LT: Orthotopic liver transplantation; MEN-1: Multiple endocrine neoplasia type 1; MRI: Magnetic resonance imaging; PET: Positron emission tomography; pNEN: Pancreatic NEN; PPIs: Proton pump inhibitors; PRRT: Peptide-radioreceptor therapy; SSAs: Somatostatin analogs; TACE: Transarterial chemoembolization; TARE: Transarterial radioembolization; ZES: Zollinger Ellison syndrome.

Surgery

The role of surgery in the treatment of gastrinoma has changed completely from the introduction of PPIs in the 1980s. In fact, before the advent of an effective anti-secretory therapy, surgery was performed to control acid hypersecretion, mainly removing the target cells of gastrin through total gastrectomy. These operations were, by the way, affected by a high mortality rate due to acid-related complications in the postoperative course. With the use of PPIs, gastric hypersecretion was no longer a problem, and the main determinant of prognosis became the gastrinoma itself because of its malignant potential and surgical excision started to be proposed as a potentially curative therapy. From 1981, the National Institute of Health began a prospective study recruiting patients with ZES for surgical therapy, with a well-designed surgical protocol in order to capture the long-term results of the best available surgical approach. The study reported a 10-year overall survival (OS) and disease-free survival (DFS) of 94% and 34%, respectively[54]. Therefore, surgery has gradually changed its role and gastrinoma resection has started to be increasingly proposed to patients eligible for resection. Currently, across the most important guidelines, surgical excision is generally recommended either for sporadic gastrinoma or for MEN-1 associated gastrinoma if complete tumor removal is possible[2,55-58]. Subsequent studies reported a 20 year OS of 58%-71%, a 20-year disease-related survival of 73%-88%[59], and a 10-year DFS of 25%-50%[60]. Surgery of the primary tumor also demonstrated to reduce the occurrence of liver metastases[61-63], which are one of the main determinants of prognosis, and to improve DFS in comparison with non-surgical management[62].

The majority of gastrinomas (from 60% to 90% depending on the series)[42,60] occur in the duodenum, and, since these are often very small lesions (less than 1 cm) and located at the submucosal layer, tumor detection is not so straightforward. Therefore, the surgical technique should follow a stepwise approach to search for the tumor even in case of negative preoperative imaging. In this context, surgery has firstly a diagnostic purpose, which is quite uncommon in modern surgery and, given the peculiarity of this technique and the rarity of the disease, it should be performed by experienced surgeons in tertiary referral centers. After a complete abdominal exploration, the duodenum and the pancreatic head are mobilized (Kocher maneuver) and carefully palpated. Intra-operative ultrasound with a linear probe is then performed on the duodenum and pancreas looking for the primary tumor and on the liver in search for liver metastases. Intra-operative endoscopy is performed thereafter

advancing the scope into the duodenum; duodenal gastrinomas may be found through trans-illumination of the bowel wall as non-trans-illuminated spots. If a lesion is identified, it should be marked with a suture and the duodenum opened around it for a full-thickness excision. If the described steps fail to reveal any lesion, a 3 cm longitudinal incision is made on the anterior aspect of the second portion of the duodenum, and the entire duodenal wall is palpated. Suspicious lesions are excised with a full-thickness rim of normal tissue and sent for pathology. The duodenum is then closed transversally, if possible, to minimize the risk of strictures[64,65]. In the hands of an experienced surgeon, lesions could be found in 98% of imaging-negative ZES patients, with a 50% curative rate[59], similar to that of imaging-positive patients. These findings suggest that surgery should be performed as soon as possible in sporadic ZES, despite negative imaging findings. Pancreatic gastrinomas should be enucleated if located 3 mm or farther from the main pancreatic duct. Conversely, lesions that are closer to the pancreatic duct require distal pancreatectomy with or without splenectomy if located in the body or tail of the gland and pancreaticoduodenectomy if located in the head/neck. Pancreaticoduodenectomy or distal pancreatectomy may be necessary also for local recurrence after enucleation[66].

Regional lymph nodes should always be removed because nodal metastases are present in almost half of the patients[54,67] and lymphadenectomy has been associated with increased DFS[68], as reported also for other pNENs[69-71]. The presence of primary gastrinoma located in a lymph node is controversial, however, several studies reported long disease-free survivors after resection of only a positive lymph node[72, 73], and this supports the role of routine lymphadenectomy.

Since pancreaticoduodenectomy provides complete removal of the regional lymph nodes of the pancreatic head, the results in terms of DFS are better with respect to enucleation because of the higher chance of radicality[54,67]. However, given the high postoperative morbidity and the good prognosis also of patients with small residual disease, pancreaticoduodenectomy is not recommended as the standard operation for these patients[2,55-58]. Generally, the indication for surgery should always follow a thorough risk/benefit assessment within a multidisciplinary tumor board aiming at maximum radicality and minimum morbidity. This is particularly the case for MEN-1 patients; in these patients, who have generally an earlier age of onset, pNENs should be resected in low-risk patients, and surgery is generally recommended for tumors larger than 2 cm[14,58]. However, according to most authorities, as well as all guidelines, surgical resection for an attempted cure should be performed in ZES patients whenever possible[2,27,58]. This is particularly true for functioning duodenal NENs, including gastrinomas, which have been reported to express a high metastatic potential[74], thus a radical surgical approach should be the first choice in this specific setting. However, in highly selected cases (*i.e.* duodenal lesions ≤ 1 cm, limited to the submucosal layer and without lymph nodal involvement), endoscopic resection might also be considered, although the risk of undetected micro-metastases might represent an issue.

Another controversial issue is laparoscopic surgery; while it is widely adopted for pNENs, its role for gastrinomas is limited to patients in whom preoperative imaging gives an accurate definition of tumor location. Unfortunately, as already mentioned, extensive exploration is often needed for diagnostic purposes. In these cases, laparoscopy is inadequate, and laparotomy is mandatory.

The role of surgical resection in ZES patients with advanced metastatic disease or even with extensive invasive localized disease is not well-defined. In this setting, the possibility of surgical removal of all resectable tumors (cytoreductive surgery, debulking surgery) should be considered, and surgery is generally recommended if ≥ 80% of all disease can be removed (generally feasible in 5%-15% of all metastatic gastrinomas), although only a few reports containing primarily gastrinomas treated with this approach are currently available[10,72].

Finally, in highly selected metastatic gastrinomas, with liver-only metastases and fulfilling strict inclusion criteria, liver transplantation might be considered, even if its use remains controversial and the risk of tumor recurrence represents an issue[58].

Liver-directed therapies

Studies specifically focused on liver-directed therapies in the context of gastrinomas are scant; however, as for other NENs, the embolization approaches in the setting of gastrinoma are generally reserved for patients with metastatic unresectable hepatic metastases either limited to the liver or with a liver-predominant disease, particularly if locally symptomatic[10,58]. Of note, liver-directed therapies are used less frequently in ZES than in other metastatic NENs, because in ZES, the hormone excess-state can be well-controlled medically.

Medical treatment

Among functioning NENs, gastrinoma is the most frequent type. There are two therapeutic goals in the management of patients with gastrinoma: The control of gastric acid hypersecretion and the treatment of the tumor itself.

Antisecretory medications

The therapy for syndrome control is based on PPI (*e.g.*, omeprazole, esomeprazole, lansoprazole, pantoprazole, *etc.*), which are highly effective drugs and considered the drugs of choice for suppressing acid secretion. PPIs effectively block gastric acid secretion by irreversibly binding to and inhibiting the hydrogen-potassium ATPase pump on the luminal surface of the parietal cell membrane. Theoretically, the choice and titration of anti-secretory therapy should be guided by the parameters of gastric acid secretions such as basal acid output (to reduce it below 10 mEq/h)[75], since using symptoms alone as a signal of efficacy might be misleading, even if in many centers these methods are not available. Therefore, in most cases, PPI therapy is started at an empirical maximized dosage. The recommended initial dose of omeprazole is 60 mg/daily or esomeprazole 120 mg/daily, lansoprazole 45 mg/daily, rabeprazole 60 mg/daily, pantoprazole 120 mg/daily, divided, twice-a-day[75-78]. The type of PPI used seems not to be of relevance and a systematic review of 12 randomized trials examining the relative effectiveness of different PPI doses and dosing regimens found no consistent differences in symptom resolution and esophagitis healing rates[79]. IV PPIs are indicated in patients with clinically significant upper GI bleeding from a suspected peptic ulcer. Omeprazole, pantoprazole, and esomeprazole are the only PPIs available as an IV formulation. The other patients can be treated with oral preparation.

As concerns efficacy, PPIs have significantly decreased the morbidity and mortality resulting from severe ulcer disease[80]. In 60% of patients, ulcer healing occurs within 2 wk; in 90%-100% of patients, healing occurs within 4 wk. PPIs are generally safe, even when used in high doses.

Once an effective clinical control of the peptic disease has been achieved, a gradual dose reduction is generally suggested[81,82]. In a study by Metz *et al*[83], 37 patients received high-dose omeprazole for almost 2 years, and nearly 50% were able to lower the dose down to 20 mg once daily, with 95% of patients experiencing safe long-term reductions in their medication dose. PPIs are generally well tolerated and can control hypergastrinemia in ZES for > 10 years (although some patients experience low vitamin B12 levels)[84].

No tachyphylaxis has been described. Therefore, the long duration of action, the fewer adverse effects, and the high potency make them superior to H2 blockers.

Regarding the use of H2-receptor antagonists in ZES, the dose usually is 4-8 times higher than the dose administered to patients with peptic ulcer disease. Although a good success rate exists, this treatment has been reported to fail in 50% of patients. Therefore, these drugs are never the first choice.

Only when PPIs are unable to control gastric acid secretion, SSAs can be considered, as they reduce gastrin secretion, even if they do not represent a first-line treatment at least for symptom control.

Even if this is not a treatment currently approved in localized gastrinoma, it is worth mentioning that in animals, the cholecystokinin-2 receptor antagonist YF476 has been shown to inhibit the development of enterochromaffin-like cell-tumors in susceptible animals with induced hypergastrinemia. Therefore, this drug could represent a potential option in ZES, not only to inhibit hypergastrinemia but also to prevent gastric NEN type 2 (*e.g.*, associated with ZES/MEN-1). Furthermore, there continues to be interest in the development of cholecystokinin-2 receptor antagonists as anti-secretory agents[85]. However, strong evidence supporting the role of these molecules in this specific setting is lacking.

Anti-proliferative treatment

Approximately one-third of ZES patients present with metastatic disease to the liver [10,86]. There are several systemic therapeutic options for advanced gastrinoma, not substantially different from the ones for other NENs, however, studies evaluating specific response rates in gastrinomas alone are limited.

SSAs like octreotide and lanreotide are highly effective in controlling the symptoms associated with hormone hypersecretion in all functioning tumors[87,88]; furthermore, they can reduce gastrin levels and their anti-proliferative effect has been demonstrated in PROMID and CLARINET studies[89,90]. However, in these studies only a few cases of gastrinoma were included, and, even if different case reports and case series suggested the role of SSAs in controlling gastrin secretion and symptoms in ZES

patients[91-94], to date only a few studies with a very low number of patients investigated specifically the role of SSAs in ZES[3].

The multitargeted tyrosine kinase inhibitor, sunitinib, has demonstrated an improved progression-free survival from 5.5 mo to 11.4 mo in metastatic pNENs[95]. Moreover, based on the results of two randomized, double-blind, prospective, placebo-controlled studies, the mammalian target of rapamycin-inhibitor everolimus has been approved in advanced both pancreatic[96] and extra-pNENs[96]. However, there are no specific studies on the effects of sunitinib/everolimus in the specific setting of gastrinomas.

Streptozocin, 5-fluorouracil, and doxorubicin have been used, with the response rate reported to be as high as 69%[97]. Despite these reported response rates, the true radiologic response rate is more probably between 10% and 40%[98,99]. More recently, anti-proliferative activity has also been shown for temozolomide. Data came from retrospective studies[100] as well as from a prospective randomized study comparing capecitabine plus temozolomide to temozolomide alone in pNENs that revealed a median progression-free survival longer in the combination arm (22.7 mo *vs* 14.4 mo, hazard ratio 0.58, $P = 0.023$), but satisfactory in both[101]. Moreover, a recent real-world analysis confirmed the combination of capecitabine and temozolomide as an active treatment for metastatic NENs[102]. Because of these studies, the use of capecitabine plus temozolomide has become routine for advanced pNENs, including gastrinomas.

Lastly, peptide receptor radionuclide therapy (PRRT) may be the most promising systemic therapy, and it has been repeatedly reported as particularly useful for symptom relief in functioning forms, even if this aspect might be less important in the setting of gastrinomas due to concomitant PPI treatment which is considered to be the first-line approach for symptoms' control[10]. Two different isotopes have been used in most studies: ^{90}Yttrium (^{90}Y)- or ^{177}Lutetium (^{177}Lu)-labeled SSAs[103]. The approval of PRRT treatment comes from the promising results of a double-blinded, control phase 3 trial (NETTER-1)[104] in patients with advanced unresectable, midgut carcinoids and the results of treatment of 510 patients with advanced pNENs and other NENs[105,106]. According to data from the literature, gastrinomas are one of the malignant pNENs that were most responsive to PRRT; however, they also had one of the highest recurrence rates leading to a poorer prognosis[103,105]. In detail, in one study including 11 patients with metastatic ZES[107] treated with either ^{90}Y-and/or ^{177}Lu-labeled SSAs, the mean serum gastrin decreased by 81%, complete response occurred in 9%, partial tumor response in 45%, tumor stabilization in 45%, with a persistence of the antitumor effect for a median period of 14 mo in 64% of the cases. Another study[108] involving 30 gastrinoma patients treated with ^{90}Y-labeled SSAs reported a partial response rate of 33% with a mean OS time of 40 mo.

CONCLUSION

As the diagnosis of ZES is challenging; the maintenance of a high index of suspicion is necessary to get the final diagnosis. Better disease awareness is useful to reduce the diagnostic delay, particularly due to the improper referral of patients to physicians with low or no expertise in the neuroendocrine field. The association between typical symptoms including chronic diarrhea, reflux disorder, and recurrent peptic disease particularly at unusual sites should raise the suspicion of ZES after exclusion of alternative and more common GI etiologies. The possibility of an underlying MEN-1 syndrome should be always considered, particularly in young patients with concomitant hypercalcemia suggestive of hyperparathyroidism and/or familiar history of MEN-1. A fasting gastrin level is generally the first step and confounding factors such as PPI use need to be considered. Gastric pH, esophageal pH-recording, and possibly a secretin stimulation test might be necessary as well, although the decision to perform them should be tailored to every single patient, considered both the need to withdraw PPI treatment and the limited availability of these tests in routine clinical practice. Tumor localization must be performed and EUS with the possibility of getting a sampling through FNA is considered to be a more accurate technique than conventional imaging for small lesions. Given the high expression of STTRs in gastrinomas, gallium-68PET-scan should be always included in the diagnostic pathway of all NENs, including gastrinoma, in order to both identify the primary tumor and to stage the disease.

Regarding the treatment of the localized disease, the two milestones are represented by PPIs for symptoms' control and surgery with curative intent. The role of surgery in

the treatment of gastrinoma has changed completely from the introduction of PPIs. In the past, total gastrectomy represented the sole effective treatment to treat ZES by removing the end-organ target of gastrin. With the use of PPIs, gastric hypersecretion was no longer considered a problem and surgical excision started to be proposed as a potentially curative therapy. Surgical removal of the primary tumor (and possibly its metastases) with curative intent should be, indeed, always performed. Unfortunately, the diagnosis is often made when the disease is too advanced for a surgical approach. The first step, again, is represented by syndrome control, based on PPIs, which are considered to be the drugs of choice for suppressing acid secretion. In order to achieve tumor growth control, SSAs constitute a viable option; studies specifically focused on advanced gastrinomas are scanty and often retrospective, however, according to data from the literature, treatments for the advanced disease are super-imposable to other NENs and include targeted therapies, chemotherapy, and PRRT. As there is a need for both a proper medical treatment for symptom's relief and a surgical procedure whenever feasible with curative intent, the multidisciplinary approach, with close cooperation between clinicians and surgeons, remains the cornerstone for proper management of this composite disease. Due to the risk of overlapping ZES with other GI common disorders, referral to tertiary centers with great expertise in the neuroendocrine field is mandatory.

Abstract

Colonoscopy remains the gold standard investigation for colorectal cancer screening as it offers the opportunity to both detect and resect pre-malignant and neoplastic polyps. Although technologies for image-enhanced endoscopy are widely available, optical diagnosis has not been incorporated into routine clinical practice, mainly due to significant inter-operator variability. In recent years, there has been a growing number of studies demonstrating the potential of convolutional neural networks (CNN) to enhance optical diagnosis of polyps. Data suggest that the use of CNNs might mitigate the inter-operator variability amongst endoscopists, potentially enabling a "resect and discard" or "leave in" strategy to be adopted in real-time. This would have significant financial benefits for healthcare systems, avoid unnecessary polypectomies of non-neoplastic polyps and improve the efficiency of colonoscopy. Here, we review advances in CNN for the optical diagnosis of colorectal polyps, current limitations and future directions.

Core Tip: A convolutional neural network (CNN) is a specific type of artificial intelligence deep learning. These networks may play an important role in the coming years in assisting endoscopists to optically diagnose colorectal polyps. CNNs can mitigate the inter-operator variability amongst endoscopists, potentially enabling a "resect and discard" or "leave in" strategy to be adopted. This would improve the efficiency of colonoscopy, reduce healthcare costs and reduce adverse events for patients by avoiding unnecessary resections of non-neoplastic polyps. In this article, we expand on the most relevant studies in this field and discuss limitations and future directions that will determine fulfilment of the potential of CNN in the optical diagnosis of colorectal polyps.

INTRODUCTION

Colorectal cancer (CRC) is the third most commonly diagnosed cancer worldwide[1] and thus, a significant burden on global healthcare systems. Most CRCs develop in a relatively predictable, stepwise sequence from mutation-accumulating neoplastic polyps, such as adenomas and sessile serrated lesions (SSL)[2]. Current evidence-based societal guidelines unequivocally accept colonoscopy to be the gold standard tool for screening of CRC[3]. Colonoscopy offers the opportunity to both detect and resect neoplastic polyps[4] and its implementation, especially as part of bowel cancer screening programs, has been linked to a significant reduction in the incidence of the CRC and CRC-related mortality[5].

Over 90% of polyps detected at colonoscopy are either small (6-9 mm) or diminutive (≤ 5 mm), entities that are thought to harbour a very low risk for developing into CRC [6]. Furthermore, almost half of these polyps are non-neoplastic in nature; and frequently hyperplastic[7]. Accurate differentiation of neoplastic from non-neoplastic polyps can prevent the unnecessary resection of the latter, avoiding an intervention which is not cost-effective and which carries risks of significant morbidity[8].

Recent years have seen significant research activity in the use of artificial intelligence (AI), particularly convolutional neural networks (CNN), to optically diagnose colorectal polyps. The field is gaining increasing momentum. The aim of this review article is to summarise and critically appraise the available medical literature related to advances in CNN for optical diagnosis of colorectal polyps and highlight the field's current limitations and future directions.

OPTICAL DIAGNOSIS

The term "optical diagnosis" refers to the use of advanced imaging techniques for real-time, *in-vivo* polyp characterisation and evaluation to guide therapeutic decisions[9]. Accurate optical diagnosis of diminutive polyps would enable identification of hyperplastic polyps in the rectosigmoid region, where they are commonly found, and allow the endoscopist to confidently take a "diagnose and leave" approach instead of resecting the lesion. Equally, for diminutive adenomas, accurate optical diagnosis would prompt the endoscopist to remove the lesion on the spot and discard the specimen without the need for histological assessment ("resect and discard"strategy) [9].

The American Society of Gastrointestinal Endoscopy established the Preservation and Incorporation of Valuable endoscopic Innovations (PIVI) to provide thresholds that are required of endoscopic technology in order to implement a "resect and discard"(PIVI 1) and "diagnose and leave" (PIVI 2) strategy[9]. PIVI 1 requires ≥ 90%

concordance in post-polypectomy surveillance intervals when comparing the combination of optical diagnosis for diminutive adenomas with histopathology assessment of all other polyps against decisions based solely on histopathology evaluation of all identified polyps[10]. PIVI 2 requires a technology to achieve a negative predictive value (NPV) of ≥ 90% for diminutive adenomatous polyps in the rectosigmoid region[9].

There has been extensive research in image enhanced endoscopy (IEE), such as narrow band imaging (NBI), to assist endoscopists in optical diagnosis to characterise diminutive polyps[11-13]. Using IEE, expert endoscopists in academic centres have consistently demonstrated an optical diagnosis accuracy that exceeds PIVI thresholds [14-16], however, studies have often found community and non-expert endoscopists to fall short of these minimal thresholds[17]. An example is the multi-centre DISCARD-2 study which evaluated the optical diagnosis accuracy of 28 community endoscopists using NBI. Disappointingly, the endoscopists' optical diagnosis derived colonoscopy surveillance intervals only matched 68% of the histopathology derived intervals[18]. Although widely available, technologies for optical diagnosis has not been incorporated into routine clinical practice with one of the main barriers being the inter-operator variability amongst endoscopists[19].

WHAT IS A CONVOLUTIONAL NEURAL NETWORK?

AI is the ability of computers to perform tasks that traditionally require human intelligence (Figure 1)[20]. Machine learning (ML) is a subset of AI, whereby computers continuously learn from data without explicit human programming[21]. This can be used to predicate a polyp's histology. ML models can be trained using unsupervised or supervised techniques. Unsupervised learning is when the input and output data are not paired. Supervised ML is more labour intensive as it requires paired input and output data for training. An example of a supervised ML model for optical diagnosis is to annotate a bounding box around a polyp (input data), commonly referred to as a region of interest, and label it with the histology of the polyp (output data). The model automatically learns to extract features that allow it to differentiate polyp subtypes and output a diagnosis based on the histology classification system it was trained with but the annotation process is time consuming for the clinician.

Deep learning is a subset of ML, whereby algorithms use multiple layers within a neural network[22], mimicking the human brain, to extract high level features from input data. CNNs are the most commonly used network in the application of deep learning to optically diagnose polyps. They provide an objective output, bypassing the human inter and intra-operator variability, and can develop classification algorithms without exhaustive effort as they do not require human-crafted feature extraction or extensive pre-processing of data[23].

Building a CNN model typically involves three separate datasets; a training set, a validation set and a test set[24]. The training set is used to develop the model so that it predicts a label (*e.g.*, adenomatous or hyperplastic polyp for polyp characterisation) based on features extracted from the endoscopic image by the algorithm itself. The validation set is used to avoid over-fitting into the training dataset through fine tuning of the hyperparameters of the model. Finally, the testing set is used as an independent dataset to evaluate the generalisability of the CNN. With smaller datasets, cross-validation can be used to assess the model's robustness. In cross-validation, the data is split into equal parts (*e.g.*, 4 parts), with one part held out as a validation dataset. This process is repeated multiple times, with the results of each split eventually pooled together to decide how robust the model is[24]. CNNs evaluated using cross-validation should still be assessed against an independent test set to examine their generalisability[24].

CONVOLUTIONAL NEURAL NETWORKS AND OPTICAL DIAGNOSIS

It is only in the last few years that the use of CNNs in optical diagnosis of colorectal polyps has been extensively investigated, with various studies emerging (Table 1). Many of these studies have in fact demonstrated the capability of CNNs to surpass the PIVI 2 threshold in order to support a "leave in" strategy for rectosigmoid hyperplastic polyps (Table 2). This was first demonstrated by Chen *et al*[25], who used a single centre, retrospective, still image dataset of 2157 polyps to train a CNN and reported a

imaging (NBI) data. This recently developed modality is not yet readily available in most endoscopy departments, although it will become more widely used with time.

Byrne *et al*[23] further advanced the field by training a CNN with NBI-near focus (NBI-NF) which is more commonly used in Europe and North America. It was trained with 220 polyp positive videos and when tested against 125 diminutive polyps which were collected prospectively, the model diagnosed 106 polyps with high confidence, achieving a sensitivity for identifying NBI International Colorectal Endoscopic (NICE)

type 1 polyps of 98%, specificity 83% and NPV of 97%. A novelty worth highlighting in this study was the use of images derived from videos, an approach that reduces selection bias compared to retrospective still images as endoscopists usually capture high quality polyp views that are free from motion blur and surface artifact. An additional advantage of this CNN is that it simplified the clinical workflow as it automatically diagnoses polyps without requiring a still image of the polyp to be captured. Limitations of the study are that SSLs, normal tissue and lymphoid aggregates were excluded from the final analysis and the videos used to train and test the CNN were captured from colonoscopies performed by a single expert endoscopist and hence, potentially less generalisable to novice users.

The most commonly used imaging modalities amongst community endoscopists are white light imaging (WLI) and NBI without magnification. Using a large retrospective still image training set of 5278 polyps and tested against 634 polyps, Zachariah *et al*[26]'s CNN fell short of ***PIVI*** 2 in WLI (NPV of 88.9% and accuracy 92.8%) but achieved the threshold in NBI without magnification (NPV of 90.8% and accuracy 93.1%). This study advanced the field as it demonstrated the capabilities of CNNs to optically diagnose polyps in standard NBI modality and also to differentiate adenomas from serrated polyps through the inclusion of SSLs in its dataset.

Whilst the majority of CNNs have been trained and tested using Olympus data, studies are emerging using data from other manufacturers. van der Zander *et al*[27] recently developed a CNN using Fujifilm data in high definition white light (HDWL) and blue light imaging (BLI). The CNN was more efficacious when it used a unique multimodal imaging approach where it combined both HDWL and BLI images of the same polyp in its decision process compared to a single imaging modality. When evaluated against 60 prospectively collected diminutive polyps, it did not reach the ***PIVI*** 2 threshold with a NPV of 87.5% but did achieve an optical diagnosis accuracy of 95% (sensitivity for identifying pre-malignant polyps 95.6% and specificity 93.3%) and demonstrated superiority to both expert and novice endoscopists in human benchmark testing.

In comparison to PIVI 2, there are fewer studies evaluating the performance of CNNs against PIVI 1. The CNN presented in Zachariah *et al*[26] reached PIVI 1 thresholds in both WLI and NBI with normal magnification, achieving concordance with histology-based colonoscopy surveillance intervals in 90.9% and 98.3% of patients, for each respective modality. Rodrigues-Diaz *et al*[28] used a single centre retrospective still image dataset to train a CNN with 607 polyps and tested against 90 diminutive polyps where it achieved a high confidence diagnosis in 78% of cases, with a 94% agreement with histology-based colonoscopy surveillance intervals. Tested against 68 rectosigmoid polyps, the model diagnosed 88% of polyps with high confidence, achieving PIVI 2 thresholds with a NPV of 97%.

There is also potential to expand the use of optical diagnosis CNNs outside of the "resect and discard" and "leave in strategy". A dilemma that can complicate issuing post-polypectomy surveillance intervals is discrepancies between endoscopic and histological diagnosis and classification of polyps with tissue fragmentation in the specimen retrieval process playing an important role. Shahidi *et al*[29]'s proof of concept study used a CNN to resolve discrepancies in polyps ≤ 3 mm in size. Tested against 900 polyps that were ≤ 3 mm and optically diagnosed as adenomatous by an expert endoscopist, the CNN diagnosed the adenomas with high confidence in 644 polyps, with 256 polyps deemed to be of sub-optimal imaging quality. However, of these high confidence diagnoses, the pathologists diagnosed 15.4% as normal mucosa, 13.2% as hyperplastic polyp and 0.3% as SSL. In this context, a CNN could help to mitigate against the risk of under-surveillance.

Whilst CNN's diagnostic accuracy excels in many studies, without real-time capabilities, they would have no clinical utility. Prior to the era of deep learning, computer aided diagnosis algorithms lacked real-time capability, but most CNNs do not share this problem and often process data at a rate that exceeds the 25 frames per second that is generated in a video recording of a colonoscopy procedure. Given the excellent performance in ex-vivo studies and the real-time capabilities displayed by CNNs, the future appears promising for their integration in colonoscopy.

TRANSPARENCY OF CONVOLUTIONAL NEURAL NETWORKS

The complexity of CNN models' decision process is often referred to as a "black box" and represents an important barrier to its acceptance by both clinicians and patients [30]. Opening the ''black box'' to display the raw features which informed the CNN's

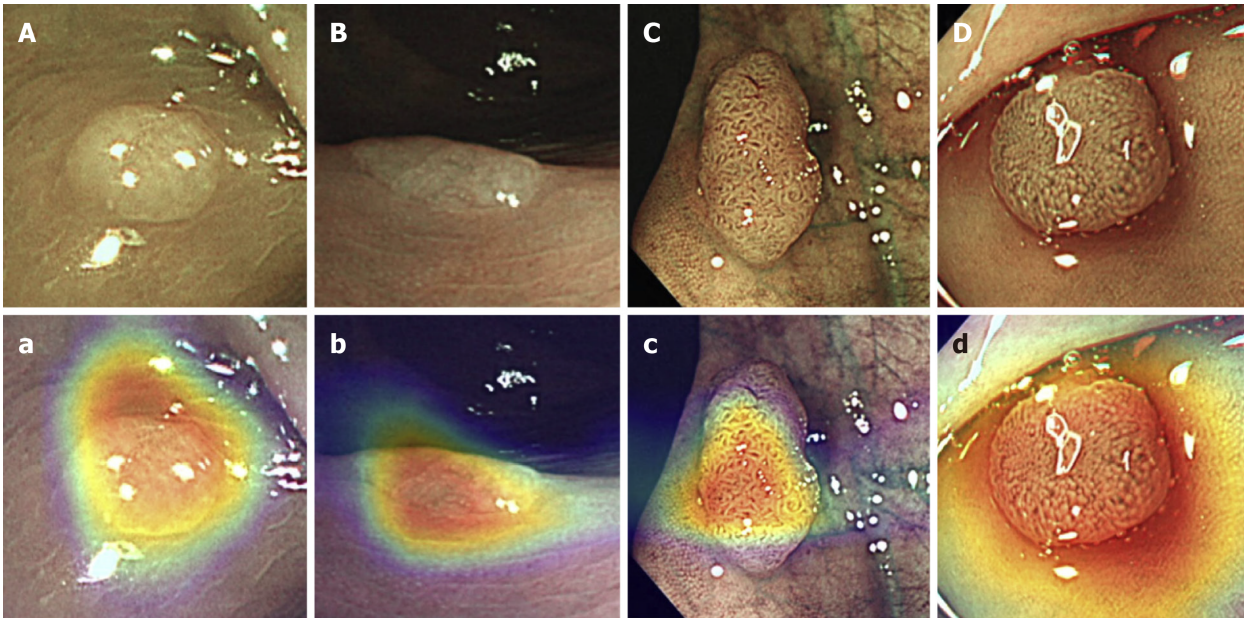

Figure 2 Illustration of coloured heatmaps, overlaid to the polyp, which demonstrates the regions that most likely contributed to the convolutional neural networks's diagnosis. A, B, C, D: Original narrow band imaging (NBI) of polyps; a, b, c, d: Coloured heatmap overlaid on the NBI image; Red: Higher probability that this region informed the convolutional neural networks (CNN)'s diagnosis; Blue: Lower probability that this region informed the CNN's diagnosis. Images adapted and modified with permission from the publisher[31]. decision is important for transparency especially from a safety standpoint[28]. Transparency can help identify biases within the neural network and aid root-cause analyses in cases of patient harm, for example, if a neoplastic polyp that subsequently develops into a CRC is originally misdiagnosed as non-neoplastic by the CNN model.

For polyp characterisation, important steps have been taken to open the black box. Jin *et al*[31] developed a CNN that generated a coloured heat map, overlaid to the polyp, to help the endoscopist comprehend the specific aspects of the image that contributed to the CNN's prediction (Figure 2). This could help the endoscopist to decide which information is relevant and which decisions are truly based on appropriate image analysis. If, for example, the heatmap is overlaid to normal mucosa, then the endoscopist would quickly be able to appreciate this and disregard the CNN's diagnosis.

More recently, in order to further enhance CNN transparency, Rodriguez-Diaz *et al*[28] developed a colour coded segmentation model (Figure 3). In this model, the CNN divides the polyp into distinct segments to allow the endoscopist to identify the specific regions within the image that is informing the CNN's decision. The CNN predicts the histology of each subregion of the segmented polyp, with high confidence neoplastic diagnoses coloured in red, high confidence non-neoplastic in green, and low confidence/indeterminate diagnoses in yellow, with the final predication resulting from an aggregate of all the analysed regions. The end result is a detailed spatial colour coded histology map of the polyp surface, which the endoscopist can visualise and incorporate into their decision process[28], enhancing the interpretability of this CNN model in comparison to others. However, an important limitation to this advanced CNN is that it currently lacks the ability to operate at a video rate.

Further research in the interpretability of CNN models is required to improve its acceptance[32] and accelerate its translation to clinical practise.

LIMITATIONS AND FUTURE DIRECTIONS

Despite the promise shown by CNNs this far, it is crucial to recognise that there are various limitations that need to be overcome before they can become part of the endoscopic clinical workflow. The most significant limitations are the reliance on retrospective datasets[33], which are inherently subject to selection bias, and the lack of prospective studies and randomised controlled trials[34]. Most studies train and test

CNNs using high quality images of polyps, free from "noise" such as motion blur and polyp surface artifact (*e.g.*, mucus, stool or blood). The extent to which CNNs pre-clinical results are reproducible in the real-world setting, where 'noise' is frequently encountered, remains to be seen.

To the best of our knowledge, there have been no prospective randomised controlled clinical trials evaluating optical diagnosis CNN *in-vivo*. This is partly due to clinical trials being time consuming and expensive, and an alternative pragmatic approach could be the use of a benchmark test in the form a publicly available external dataset to compare different CNN models[35]. No such datasets currently exist for polyp characterisation and therefore the generalisability of CNN models remains poorly understood. Generalisability refers to the CNN performance with different endoscope models and clinical settings from the site that the data was generated to train the CNN. To date, only one study[36] has evaluated generalisability, and this was limited to a small testing set of 69 polyp images from two population cohorts (Australian and Japanese) using two separate endoscope manufactures (Olympus and Fujifilm). Despite the small test-set, this study highlighted the concerns of generalisability as the operator area under the curve fell from 94.3% for the internal set, to 84.5% and 90.3% for the external testing sets (NBI and BLI respectively).

Another important limitation is that studies often exclude polyps that are not adenomas or hyperplastic polyps, restricting the possible classification outputs of CNNs. This, in turn, limits their clinical utility as polyps such as SSL and inflammatory polyps would be misclassified due to limitations in the initial training phase of the CNNs when the categorisation system is established.

Research in this field is likely to continue to expand and future directions to consider include: (1) Guidelines to identify the role of CNNs in the clinical workflow, specifically, whether it is a second reader, a concurrent reader or a provider of an independent diagnosis[30]; (2) Prospective multi-centre randomised clinical trials; (3) Publicly available external datasets for benchmark testing and evaluation of the generalisability of CNN models in different clinical settings and population cohorts; and (4) Acquiring datasets inclusive of all polyp sub-types to advance CNN classification systems.

CONCLUSION

In summary, this is an exciting time for the endoscopy community. CNNs diagnostic performance has excelled in ex-vivo studies and in human benchmarking testing. CNNs are likely to be a key adjunct in optically diagnosing polyps and have renewed optimism that implementation of a "resect and discard" and "leave in" strategy is feasible due to the potential to alleviate the inter-operator variability amongst endoscopists. This would bring significant financial benefits to healthcare systems, avoid unnecessary polypectomies of non-neoplastic polyps and improve the efficiency of colonoscopy. However, prospective multi-centre randomised controlled trials and publicly available datasets for benchmark testing are required to further evaluate the efficacy and generalisability of CNNs. Furthermore, with these models now emerging in endoscopy units, it's imperative that guidelines are developed to establish their role in the clinical workflow.
