Core Tip: Artificial intelligence-based (AI) methods have demonstrated high performance in classification, object detection, and segmentation tasks. Through multidisciplinary and collaborative work between clinicians and technicians, the advantages of AI have been successfully applied in automatic polyp detection and classification. The new AI-based systems present a better polyp detection rate and contribute to better clinical decision-making for preventing colorectal cancer (CRC). This article provides an overview of recent research focusing on AI and its applications in the early detection of CRC and adenomatous polyps.

INTRODUCTION

Colorectal cancer (CRC) is a common malignancy. Worldwide, in 2020, it ranked third among neoplasms, with incidences of 1931590 cases, representing 10% of neoplasms. However, in terms of mortality, it ranked second for the same year after lung cancer due to the crude mortality rate of 12.0 per 100000 inhabitants, prevailing in the male population[1].

Although CRC remains among the ten most frequent cancers, in a retrospective description, it was observed that at a global level, between 2000 and 2019 its ranking was stable in high-income countries, in which it maintained second place as a cause of death from neoplasia. However, in the remaining countries, it gradually increased; hence, in 2019, CRC was the 3rd leading cause of cancer death in upper-middle-income countries, the 4th leading cause in lower-middle-income countries, and the 5th leading cause in countries where income was low[2]. It is expected that by 2035, in those countries where it remains stable, the CRC mortality rate will decrease due to the application of early detection programs that are being implemented, the active participation of the population, and the prioritization of education on this matter. Nevertheless, it is expected that by 2035, in countries with low incomes, the mortality rate will continue to increase due mainly to late diagnosis and limited access to treatment if these indicators are not strategically addressed in time[3].

The risk of CRC in the general population is not uniform, and it is associated with factors such as a family history of CRC, lifestyles and eating habits and above all, the presence of polyps, either isolated or associated with genetic polyposis syndromes[4]. CRC can then be prevented by modifying diet and lifestyle, as well as early detection and timely treatment. Various studies have shown that screening tests facilitate the detection of precursor lesions in early stages. This, added to their subsequent elimination, promotes a reduction in CRC incidence and mortality[5-7].

Colonoscopy is the gold standard procedure for the diagnosis of large intestine (colon) and rectal diseases. The World Gastroenterology Organization establishes that both the sensitivity and the specificity of colonoscopy for the detection of polyps and colon cancer is 95%[4]. The United States Preventive Services Task Force determined that colonoscopy has a sensitivity between 89% and 98% for detecting adenomas of 10 mm and larger. For adenomas of 6 mm or more, the sensitivity ranges from 75% to 93%, while the specificity found was 89%[8], in which case a screening test for CRC is recommended. Additionally, in joint work between the American Cancer Society, the United States Multisocial Working Group and the American College of Radiology in 2008, colonoscopy was strongly recommended as a screening test designed to detect both early cancer and adenomatous polyps if resources were available and patients were willing to undergo an invasive test[5]. Similarly, the National Comprehensive Cancer Network recommends and promotes the application of colonoscopy for the detection of adenomatous polyps and early stages of CRC[9]. It should be noted that colonoscopy is a procedure that depends fundamentally on physician observation. In recent decades, technology has been incorporated into the inspection procedure, known as computer-aided systems.

Computer-aided detection/diagnosis systems (CADe/CADx) have been proposed, developed, and clinically used since 1966, especially in thoracic and breast imaging as well as in the cancer risk assessment[10]. The progress of computational resources and medical imaging devices has enabled CADe/CADx systems to support tasks in other areas, such as endoscopic examination[11]. CADe aims to find or localize abnormal or suspicious regions, increasing the detection rate while reducing the false negative rate (FNR). Additionally, CADx provides a second objective opinion regarding the assessment of a disease from image-based information. In the early stages of both systems, their algorithms were predominantly based on feature extraction methods engineered by domain experts[12]. However, the widespread progress of diseases and variability of cases have rendered these methods obsolete and have opened the research to new and improved methods. In particular, artificial intelligence (AI) has provided tools and algorithms capable of achieving high performance in terms of accuracy, sensitivity, and specificity to face tasks related to feature extraction, classification, detection, and region segmentation.

This work focuses on the main contributions of AI in gastroenterology, in particular, to the early detection of CRC through polyp detection and classification. We focus on those works that enhance the performance of endoscopic tests, which allow for direct visualization of existing lesions in the mucosa of the colon and rectum. With the numerous applications of AI and the growing interest in AI-related topics, some misconceptions have been discovered that are worth analysing.

WORLD OF AI

Since the term AI was first used in 1956, it has been a thriving field with relevant applications in several areas, including medicine[10]. The term AI refers to technology that allows computer systems to perform tasks that normally require human skills. The field of AI is broad and includes different fields, such as robotics, computer vision, natural language processing and machine learning, as shown in Figure 1. Often, such areas overlap to deliver more advanced features and capabilities. In medicine, robotic devices are increasingly being used in minimally invasive surgical procedures, such as robotic-assisted surgery for patients with CRC[13]. Natural language processing is another crucial AI area used to make the machine read, understand, and interpret human language. In the treatment of CRC, natural language processing has been useful for extracting relevant clinical information from scanned colonoscopy and pathology reports that would otherwise have to be extracted manually[14]. Computer vision and image processing have also been helpful in colonoscopy exploration, enhancing the visualization of lesion tissues[15]. However, from all AI fields, machine learning is the most widely used in three areas of medicine: Early detection and diagnosis, treatment, and outcome prediction and prognosis evaluation[16]. Gastrointestinal endoscopy has advanced in all three areas, but there is a clear trend in the detection and classification of polyps (see Wang *et al*[11], Nogueira-Rodríguez *et al*[17] and the references therein).

The following subsections focus on analysing the most prominent AI-based works on endoscopic tests without ignoring a brief review of the most commonly used machine learning algorithms (including deep neural networks) and evaluation metrics.

MACHINE LEARNING

Machine learning, a subset of AI, refers to a set of computer algorithms that learn from the input data provided, adjust a model through a training process, and perform predictions in novel situations by using the trained model[18]. According to the type of learning strategy, machine learning algorithms can be classified into two categories: Supervised and unsupervised learning. In supervised learning, a training set that contains the input data with the correct response (targets) must be previously available. The model is trained using the training set until it is generalized to respond correctly to all possible inputs. In the case of unsupervised learning, the correct answers are not provided, and the model attempts to group the data into categories identifying similarities between such data[19,20]. In medicine, supervised learning is the most commonly applied strategy because the goal is predicting a known outcome by mimicking a physician or health professional.

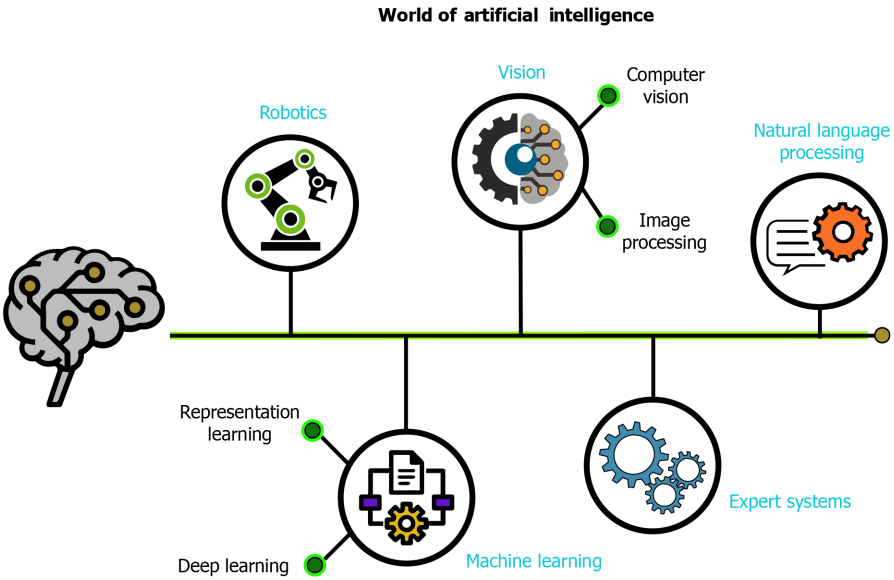

Figure 1 Artificial intelligence is a set of fields that are combining to improve tasks that involve human cognitive functions such as learning, reasoning and self-correction.

In the context of machine learning, healthcare data can be categorized as structured and unstructured. Imaging, genetic data, and electrophysiological data are some examples of structured data, whereas physical examination notes or clinical laboratory results that contain large portions of narrative texts are unstructured data[19]. The major digital data sources in medicine are images resulting from the development and improvement of different medical imaging techniques (*e.g.*, computer tomography, magnetic resonance imaging, ultrasound, X-ray and endoscopy)[10].

In gastroenterology, most computer-aided diagnosis/detection systems use images or videos, enabling the use of machine learning techniques to enhance their outcomes. In early works, CADe/x systems combined feature extractor methods and classical machine learning techniques such as random forest, decision trees, and support vector machines[21-23]. More recent works have shown applications that use deep learning algorithms such as convolutional neural networks (CNNs), in part due to the high performance and low latency of the systems[20].

The selection of one machine learning algorithm over another should be guided by analysing the available data as well as the task to be performed with it. Table 1 summarizes the main characteristics of the algorithms used in the last 5 years of state-of-the-art polyp detection and/or classification. We narrowed the analysis to the four most commonly used methods according to the Scopus and PubMed databases applied to medicine namely, support vector machines, random forest, decision trees and deep neural networks. Both support vector machines and random forests present high performance even if the data have high dimensionality. However, support vector machines are not recommended when the database is large because they increase training and inference time without improving performance[24]. Conversely, random forest presents high performance when working with large databases[25]. Deep neural networks outperform classical machine learning algorithms in almost all criteria but require large quantities of labelled data that may not be available, or the acquisition and labelling process may be very expensive or time consuming.

EVALUATION METRICS OF MACHINE LEARNING ALGORITHMS

Evaluation metrics are tied to the tasks (*e.g.*, classification, detection, localization, and segmentation) performed by the machine learning models. In gastroenterology in applications such as automatic polyp detection or classification, the evaluation metrics can be computed considering different levels: Video sequence, image, or region (pixel level).

Table 2 summarizes the terms and formulation of metrics commonly used for performance evaluation of machine learning models. In particular, those used in AI-based applications for colonoscopy. Some terms are key to understanding the

Table 1 Comparison between different types of machine learning approaches used in studies focused on polyp detection and classification

Characteristics	Support vector machine	Random forest	Decision trees	Deep neural networks	Context	Ref.
High dimensional data	High	High	Moderate	High	Performance	Shen *et al*[12]; Goodfellow *et al*[26]
Overlapped classes	Low	Low	Low	High		
Imbalance datasets	Moderate	High	Low	Moderate		
Non-linear data	Moderate	High	Moderate	High		
Larger dataset	Moderate[1]	High[1]	Low	High

Interpretability	Moderate	Moderate	High	Low		

[1]Consider that it leads to slow response time.

Table 2 Most common evaluation metrics found in the state of the art for detection, segmentation and classification tasks

Term	Symbol	Description
Positive	P	Number of real positive cases in the data
Negative	N	Number of real negative cases in the data
True positive	TP	Number of correct positive cases classified/detected
True negative	TN	Number of correct negative cases classified/detected
False positive	FP	Instances incorrectly classified/detected as positive
False negative	FN	Instances incorrectly classified/detected as negative
Area under curve	AUC	Area under the ROC plot
Term	**Task**	**Formulation**
Accuracy	C, D, S	(TP + TN)/(TP + TN + FN + FP)
Precision/PPV	C, D, S	TP/(TP + FP)
Sensitivity/Recall/TPR	C, D, S	TP/(TP + FN)
Specificity/TNR	C, D, S	TN/(TN + FP)
FPR	C, D, S	FP/(TN + FP)
FNR	C, D, S	FN/(TP + FN)
f1-score/DICE index	C, D, S	2 · (precision · recall)/(precision + recall)
f2-score	C, D, S	4 · (precision·recall)/(4·precision + recall)
IoU/Jaccard index	D, S	(target ∩ prediction)/(target ∪ prediction)
AAC	D, S	(detected area ∩ real area)/(real area)

C: Classification; D: Detection; S: Segmentation. PPV: Positive predictive value; TPR: True positive rate; TNR: True negative rate. AAC: Annotated area covered.

evaluation metrics in algorithms used for automatic polyp detection and/or classification. There are two well-defined cases: Images with polyps (positive cases) and images without polyps (negative cases). In both cases, some authors[15,27,28] define a true positive (TP) when the algorithm output finds the correct region of the polyp

(detection) or labels the image as a polyp (classification). In the case of detection, only one TP is considered per polyp, avoiding over-detection. Any detection or classification as a positive case outside the region of polyp or images without polyps is considered false positive. The absence of positive output in detection or classification in images with a polyp is considered a false negative. If the algorithm does not provide any positive output in images without polyps, it is considered a true negative. Positive polyp detection is a common evaluation metric that can be computed as a true positive rate (see Table 2) or polyp-based analysis by defining a threshold of the positive frame-level predictions[29].

The most widely used evaluation metric is accuracy (see formulation in Table 2). It works well in datasets with an equal number of samples belonging to each class (*i.e.*, balanced dataset), but it is not recommended for imbalanced datasets[30]. Evaluation metrics such as sensitivity, specificity, and positive predictive value are not dependent on the class distribution; therefore, they are not biased by imbalanced datasets[31]. The use of evaluation metrics also depends on the task to be performed. In detection tasks, metrics such as the f1-score (or DICE index) and f2-score of the Jaccard index are widely used[17]. We analyse each evaluation metric below.

Accuracy represents the overall effectiveness of the algorithm when comparing the number of correctly classified/detected samples with the total number of samples[17].

Precision (positive predictive value) represents the proportion of predicted positive cases that are real positives[17].

Sensitivity (recall or true positive rate) measures the ability of the algorithm to correctly identify the positive cases[17].

Specificity (true negative rate) measures the ability of the algorithm to correctly identify the negative cases[17].

The false positive rate (FPR) represents the proportion of negative cases incorrectly identified as positive cases in the data. In statistics, the FPR is equivalent to the type I error[26].

The FNR represents the proportion of positive cases incorrectly identified as negative cases in the data. In statistics, the FPR is equivalent to the type II error[26].

The DICE index (f1-score) determines the similarity between two different areas whether the algorithm is performing segmentation or detection tasks. In classification, the f1-score is a metric to evaluate a trade-off between precision and recall[32].

The f2-score is a metric to evaluate a trade-off between precision and recall but lowers the importance of precision and increases the importance of recall[17].

The Jaccard index (IoU) is a metric mostly used in detection/segmentation algorithms and quantifies overlap between the target area and the area predicted by the algorithm[32].

Annotated area covered is an evaluation metric mostly used in detection or segmentation tasks. It represents the proportion of the real area detected/segmented by the algorithm[33].

The area under the curve (AUC) is a metric obtained from the receiver operating characteristic curve that relates to the sensitivity *vs* specificity of a binary classifier[31]. The best classifier is the one with the AUC closest to 1.

ENHANCING COLONOSCOPY OUTCOMES *VIA* AI

Colonoscopy exploration is performed through a flexible tube (endoscope) that contains a tiny video camera at the tip. The camera allows the physician to see the inside of the entire colon by displaying the image on a digital screen, as shown in Figure 2. During the process, the physician detects (or not) the presence of lesions on the colon and polyps, and then, depending on the shape, colour and texture of the polyp, determines whether to remove it[15]. The outcome of colonoscopy exploration depends on several factors. On the one hand, the procedure is intrinsically dependent on the technology used, such as the camera resolution, screen size and resolution, frame rate, and capability to deal with blurriness, among other issues[15]. On the other hand, the results can be affected by the cognitive capabilities of the physician (*e.g.*, tiredness, fatigue or concentration) during the exploration procedure[34]. Other factors, such as bowel preparation and the percentage of the colon explored, can also affect the outcome of the exploration[35].

Traditional colonoscopy has been shown to be successful when detecting polyps larger than 10 mm, which are easily detected by physicians during inspection. However, the miss rate of polyp detection increases with smaller sized and/or flat polyps[36]. There are both clinical and technical efforts to improve colonoscopy

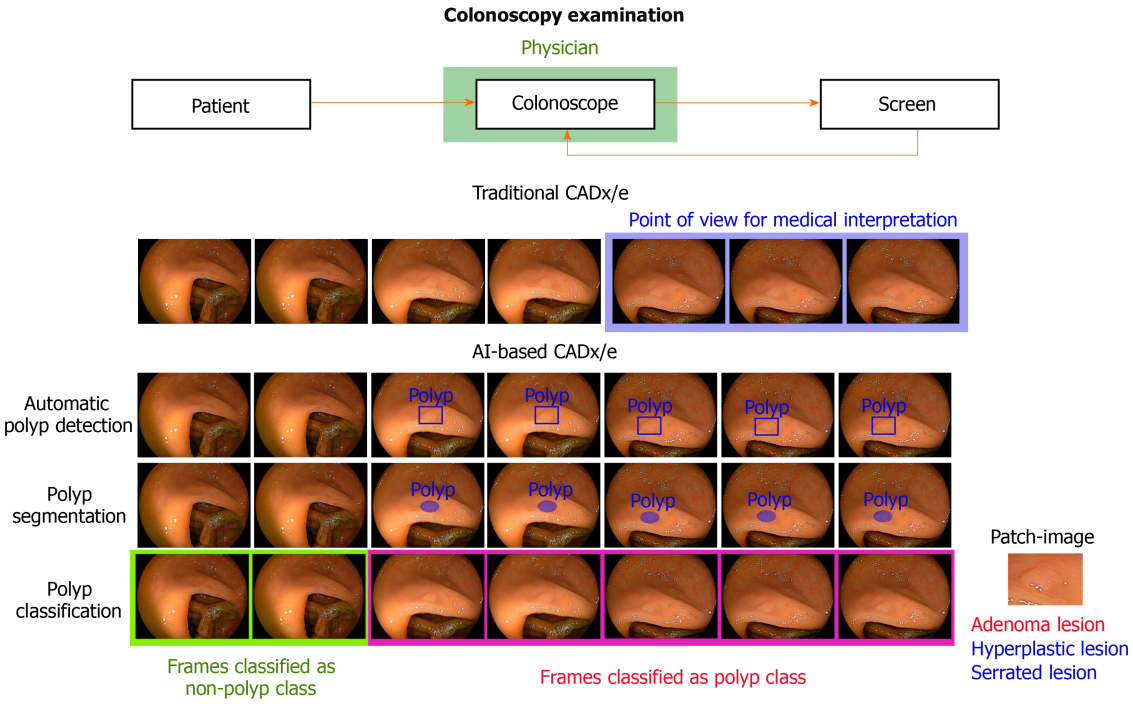

Figure 2 Comparison of traditional and AI-based computer-aided systems on colonoscopy examination.

results. For example, continuous improvement of the skills of physicians through training and practice[37] and the improvement of image/video acquisition devices combined with the development of clinically applicable CADx/e systems have been reported. Another technique used to make fine details of the mucosal surface more visible (evidencing small or slight lesions) on endoscopy tests is chromoscopy (also known as chromoendoscopy or chromocolonoscopy)[38].

Initially, chromoscopy consisted of spraying contrast dyes on the mucosa with the aim of outlining the mucosal morphology (dye-based chromoendoscopy DCE)[39]. The most frequent contrast dye used is indigo-carmine in concentrations varying from 0.2% to 2%[38]. DCE has been demonstrated to be a useful tool for endoscopists to detect and characterize lesions more accurately. A study presented by Brown *et al*[38] found that the rate of detection of small polyps was improved by DCE by approximately 90%. Such analysis was conducted on 2727 patients and showed that the detection of small polyps that could potentially develop into cancer was increased by 30% when chromoscopy was used. Although the DCE technique is simple to use and safe, it is labour intensive and time consuming, and the outcomes highly depend on bowel preparation[38,39]. Over the years, with the introduction of electronics and the improvement in technology, a new era of chromoscopy called virtual chromoendoscopy (VCE) has been adopted. VCE includes pre-processing optical imaging techniques, such as Olympus' narrow-band imaging (NBI) and autofluorescence imaging, as well as the post-processing techniques Pentax's i-SCAN and Fujinon intelligent chromoendoscopy[15]. Of all VCE techniques, NBI has been studied most frequently for assessing gastroenterology diseases[40]. This pre-processing technique uses light of specific wavelengths (green - 540 nm and blue -415 nm) to enhance detail on the mucosal surface. Although VCE techniques such as NBI can detect small-size or flat polyps, they suffer from some drawbacks, such as interobserver and intraobserver variability[41]. Such drawbacks refer to expertise, levels of distraction, or stress. However, the use of CADx/e systems may increase standardization in the process and, perhaps most importantly, more widespread adoption by non-experts in the field [41].

In this context, the new developments of CADx/e systems have focused on systems to assist in the detection and/or localization of polyps and the classification of the different types of polyps, both fundamental tasks to help clinicians at all stages of CRC diagnosis. AI has emerged as a powerful tool in two well-differentiated tasks: Polyp detection (including localization and segmentation) and polyp classification. By including an AI-based algorithm in the CADx/e systems that attend colonoscopy exploration, they can predict whether there are one (or more) polyps in a given video frame using white light alone, without the aid of advanced endoscopic imaging

modalities. If the purpose is also to locate the polyp, the algorithm predicts the position of the polyp in the image, as shown in Figure 2. If the physician requires a finer analysis, segmentation tools can allow isolation of the polyp region at the pixel level on the image. Once a polyp is detected, polyp classification aims to catalogue the type of polyp. The latter is particularly important because it allows the clinician to make a better decision as to whether to remove the polyp depending on whether it seems to be a benign, pre-malignant, or malignant polyp. Currently, to confirm if a polyp is malignant, the suspected polyp must be removed, and then a pathology test must be performed. However, an expected advance in the future is that AI can assist clinicians in differentiating polyps.

Colorectal polyps are anatomically pathologically classified as adenomatous, hyperplastic, or serrated and inflammatory, hamartomatous, juvenile, the latter being synthesized terminologically as miscellaneous, given their low prevalence (10%-20%) [42]. Adenomatous polyps are the most frequent (60%-70%). Depending on their histological characteristics, they can be tubular, villous, or tubulovillous. They can be of different degrees of dysplasia, which constitutes one of the elements for the diagnosis or the presumption of CRC[8,42]. Hyperplastic polyps have a prevalence between 10% and 30%. Although they are not usually neoplastic, there is a type of serrated polyp, the sessile serrated adenoma, which is considered a CRC precursor lesion through what is known as the serrated pathway of carcinogenesis[8,42,43].

ADVANCES IN AI FOR DETECTING AND CLASSIFYING COLORECTAL POLYPS

Automatic polyp detection—including classification and segmentation—in colonoscopy videos has been an active research topic during the last two decades. After analysing approaches reported in the literature, there are three well-defined methods: Hand-crafted, feature-based machine learning, and end-to-end learning approaches. Each method is discussed in more detail below. At the end of the analysis, we summarize the works in Table 3, showing the screening test, imaging modality and contribution for each one.

Hand-crafted approach

Hand-crafted methods refer to those based on exploiting low-level image processing techniques to obtain candidate polyp boundaries. This method considers the polyp as a protruding surface, with its boundaries detected using intensity valleys[37], Hessian filters[44], or the Hough transform[45].

Feature-based machine learning approach

Feature-based methods encompass the first era of machine learning: Designing a feature extractor and then training a classifier to predict a given class (*e.g.*, polyps or non-polyps). In early works, a texture descriptor was used to provide relevant features about the region of the image containing polyps using wavelet sub-band information in the work of Wimmer *et al*[46], Haralick co-occurrence matrix in the work of Hu *et al* [21], or Gaussian-kernel low pass filtering in the work of Mamanov *et al*[47]. Other features, such as shape, colour, and edge geometry, have also been used to create more robust detection systems that include polyp segmentation[32]. Glasmachers[33] proposed a CAD system that combines context-based image information to remove non-polyp information and shape features to reliably localize polyps.

After generating a feature vector using descriptors of texture, colour and/or shape, a classifier is required to predict whether polyps are present in the colonoscopy image, distinguishing between the different types of polyps or whether the region characterized on the image is a polyp (localization). The most commonly used classifiers are k-nearest neighbours[46], decision trees[22], random forests[22,32], and support vector machine[23].

End-to-end learning approach

The end-to-end (E2E) learning approach refers to training a learning system represented by a single model (generally a deep neural network)[33]. As the technology evolved and the computational capabilities increased, the use of convolutional neural networks as a key part of CADx/e systems is increasingly frequent in automatic polyp detection[48] and/or polyp classification tasks[49]. The advantage of the E2E approach is the possibility of designing more complex multitasking systems:

Table 3 Summary of studies focused on artificial intelligence applications for automatic polyp detection, classification, and segmentation

Study	Screening test	Imaging modality	Data type	AI-based algorithm	Contribution	Acc	Sen	Spe
Wimmer *et al* [46]	Colonoscopy	WL, NBI	Images	k-nearest neighbours	Polyp classification: non-neoplastic, neoplastic	80%	-	-
Tajbakhsh *et al* [22]	Colonoscopy	WL	Images	Decision trees; Random forest	Automatic polyp detection	-	88%	-
Hu *et al*[21]	CT Colonography	Greyscale	Images	Random forest	Polyp classification: non-neoplastic, neoplastic	-	-	-
Zhang *et al*[50]	Colonoscopy	WL, NBI	Images	CNN: Caffenet	Polyp detection and classification: benign from malignant	86%	88%	-
Shin *et al*[23]	Colonoscopy	WL	Images	Support vector machine	Whole image classification: polyps from non-polyps	96%	96%	96%
Sánchez-González *et al*[32]	Colonoscopy	WL	Images	Random forest; CNN: Bayesnet	Polyp segmentation	97%	76%	99%
Tan *et al*[52]	CT Colonography	Greyscale	Images	Customized CNN	Polyp classification: adenoma from adenocarcinoma	87%	90%	71%
Fonolla *et al*[51]	Colonoscopy	WL, NBI, LCI	Images	CNN: EfficientNet	Polyp classification: benign from pre-malignant	95%	96%	93%

Viscaino *et al* [54]	Colonoscopy	Greyscale	Images	Support vector machine; Decision treesk-nearest neighbours; Random forest	Whole image classification: polyp and non-polyp	97%	98%	96%

WL: White light; NBI: Narrow-band imaging; LCI: Linked colour imaging; Acc: Accuracy; Sen: Sensitivity; Spe: Specificity.

Detecting polyps and then identifying whether the detected polyp is hyperplastic or adenomatous[50]. Information about whether a polyp can be malignant will assist the clinician in making a better clinical decision (to remove or not the polyp)[51].

There are other alternatives to colonoscopy; colonography or wireless capsule endoscopy are also used as screening techniques to detect polyps. Both alternatives are less invasive and do not present a risk of perforation to patients as colonoscopy does. AI-based algorithms have also been used to enhance the analysis *via* CT colonography. In particular, the use of greyscale information in the image (using a grey-level co-occurrence matrix in the work of Tan *et al*[52] or texture information in the work of Hu *et al*[21]) combined with CNN has been useful for differentiation of polyps: Adenoma from adenocarcinoma[53], non-neoplastic from neoplastic polyp[21], or images with polyps and without polyps[54].

MICCAI 2015 POLYP DETECTION CHALLENGE

MICCAI proposes a common validation and evaluation framework of new algorithms published in the field of biomedical image analysis (Bernal *et al*[15] and the references therein). Each year MICCAI launches international competitions (challenges) that allow for benchmarking algorithms on publicly released datasets and offers a basis to discuss validation strategies[22]. In 2015, the MICCAI sub-challenge on automatic polyps was launched and represented a significant advance in the area. As a result of this competition, three large endoscopic image databases were published, establishing a benchmark for new algorithms[22,37,55].

Colonoscopy datasets

To successfully train classical machine learning models, it is necessary to have reasonably sized databases[22]. However, to train deep learning models, large databases are required because the quantity of data is related to the network

performance. The most famous public databases used in computer science are ImageNet[56], with more than 14 million natural images hand-annotated in 20000 categories, or Microsoft's COCO[57], with more than 2500000 images. The state-of-the-art reports better than 90% accuracy in classification, object detection and localization tasks with deep neural networks pre-trained with these databases. In medicine, creating large databases represents a challenge because the data and the expertly annotated ground truth are required. In the case of colonoscopy, some publicly available datasets for polyp detection and classification have been released in the last few years. In particular, efforts such as the MICCA 2015 sub-challenge have prompted different groups to create and make available the databases summarized in Table 4.

Three datasets annotated for automatic polyp detection have been very popular in the scientific community: CVC-ClinicDB[37], ETIS-Larib[55], and ASU-Mayo Clinic Colonoscopy Video[22]. Both datasets CVC-ClinicDB and ETIS-Larib are composed of annotated frames, whereas the ASU-Mayo Clinic dataset is composed of 38 fully annotated videos selected to show maximum variation in colonoscopy procedures. All public databases are summarized in Table 4, as well as their characteristics.

MISCONCEPTIONS IN AI

Deep learning-based AI models offer promising results for medical image analysis. Nevertheless, a thorough understanding of the available data and its limitations and proficient curation of suitable training, testing, and validation subsets are required to successfully train these models responsibly and use them in a clinical setup, *e.g.*, as a diagnostic support tool. Following are some of the most common misconceptions.

Imbalanced datasets

In medicine, obtaining samples to create datasets can be a time consuming and expensive process[15]. This becomes even more complicated when samples are obtained from invasive procedures such as colonoscopy. Another important aspect is that as a result of data scarcity (*e.g.*, due to the low incidence of a medical condition), an intrinsic imbalance in the data can occur. Therefore, the available colonoscopy datasets mostly do not contain the same number of samples per class (also known as an imbalanced dataset)[29,63,64]. If a deep learning model is trained on such a dataset, the result will present a high risk of exhibiting bias against the minority classes and, in extreme cases, ignoring it altogether.

Moreover, the dataset structure needs to be considered when studying the performance metrics of deep learning models, such as accuracy and/or error rate, which are the most frequently used metrics when evaluating classification results. However, both are insufficient when working with an imbalanced dataset, as the relative contribution of the minority classes to these metrics is negligible[30]. Best practice is to be aware of the limitations of each metric and evaluate the performance of the algorithm with a set of complementary metrics (see Table 2).

The time and effort required to curate balanced datasets for intrinsically imbalanced problems have led researchers to develop techniques to enable AI models to be successfully trained on an imbalanced dataset[30]. Currently, the proposed methods can be grouped into data-level techniques and algorithm-level methods, which can be combined in hybrid approaches.

Data-level techniques aim to decrease the level of imbalance by modifying the class distribution within the available dataset. On the one hand, under-sampling methods voluntarily discard data from the majority classes, reducing the total information available to train the model. The simplistic approach to under-sampling is random under-sampling, which discards random samples from the majority classes. Notwithstanding, valuable information might be lost in the process. Intelligent under-sampling methods select removal candidates using more elaborated criteria, such as redundancy within each class in the majority group, known as one-sided selection[65], or their distance from minority samples, known as near-miss algorithms, as the several alternatives presented in Mani *et al*[66]. On the other hand, over-sampling methods artificially increase the quantity of available data in the minority classes. One technique, random over-sampling (ROS), which randomly duplicates samples from the minority classes, is the naive approach to over-sampling and is known to cause overfitting[67]. The model memorizes particular training samples instead of learning the underlying characteristics of the corresponding class and is then unable to generalize to novel data [26]. Several methods have been proposed to reduce over-fitting while over-sampling, such as the synthetic minority over-sampling technique introduced in Chawla *et al*[68]

Table 4 Summary of publicly available colonoscopy datasets

Dataset	Year	Description	Data type	Ground truth
CVC-ColonDB[29,58]	2012	380 sequential WL images from 15 videos	Images (574 × 500 pixels)	Binary mask to locate the polyp
CVC-PolypHD[58,59]	2012	56 WL images	Images (1920 × 1080 pixels)	Binary mask to locate the polyp
ETIS-Larib[55]	2014	196 WL images from 34 video sequences (44 different polyps)	Images (1125 × 966)	Binary mask to locate the polyp
CVC-ClinicDB[37]	2015	612 sequential WL images from 31 videos sequences (31 different polyps)	Images (388 × 284 pixels)	Binary mask to locate the polyp
ASU-Mayo[22]	2016	38 short video sequences (NBI, WL)	Video (SD and HD video)	Binary mask for 20 training videos
Colonoscopic dataset[49]	2016	76 short video sequences (NBI, WL)	Video	Labels: hyperplastic, adenoma and serrated
Kvasir-SEG[60]	2017	1000 images with polyps	Images	Binary mask to locate the polyp
CVC-ClinicVideoDB[61]	2017	18 sequences	Video (SD video)	Binary mask to locate the polyp
CP-CHILD-A, CP-CHILD-B[62]	2020	10000 images	Images (256 × 256)	Labels: polyp and non-polyp

WL: White light; NBI: Narrow-band imaging.

and its variants Han *et al*[69], Jo *et al*[70], or the cluster-based over-sampling method proposed in Jo *et al*[70].

Algorithm-level methods comprise cost-sensitive learning algorithms[71], which assign penalties to each majority class, increasing the importance of the minority classes, and decision process adjustments, which shift the decision threshold such that bias towards the minority classes is reduced.

Correlated data

Another dataset structure aspect to consider when inspecting performance metrics is the presence of correlation between dataset splits (most commonly training, testing and validation)[26]. We consider the task of analysing images obtained from a recorded colonoscopy to classify detected colorectal polyps as malignant or benign. If the training and validation dataset splits contain frames from the same video or patient, the correlation introduced by this situation will affect validation metrics, resulting in over-optimistic results and the risk of hidden generalization or over-fitting problems.

Interpretability

Machine learning, and more broadly AI, are essentially statistical models. During the training process, a set of parameters that define the specific behaviour of the base model is adjusted so that model predictions match expert annotations for elements in the database. Notwithstanding, commonly used models do not consider domain-specific expert knowledge in their predictions. Hence, it is possible for the trained model to learn features that are undesirable or incorrect, such as unintended patterns or visual artefacts present in the database, instead of constraining the feature space to medically relevant features only. To avoid this problem, manual assessment of the database elements is advised, along with internal feature visualization techniques[72]. See Deng *et al*[73] for a review of different strategies proposed to incorporate expert knowledge as prior information to machine learning (ML)/AI models.

FUTURE PROSPECTS

The results obtained from AI-based models are promising and establish an advantage compared to traditional methods. However, there are some limitations to be overcome by future research to propose clinically useful methods.

Overcoming real-time constraints: Videos in a colonoscopy exploration are generally acquired at 25 frames per second[15], which means that the maximum time

available to process each image (frame) must be less than 40 ms.

Increasing the variability of polyp cases, including studies with data from multiple medical centres if possible. However, given the scarcity of data on less common lesions (serrated adenomas) and knowing that deep learning approaches require vast numbers of labelled training samples, new research may include techniques such as few-shot learning introduced by Vinyals *et al*[74]. This technique focuses on learning a class from one or a few labelled samples and has been successfully applied in other medical areas, such as cervical cancer cell classification[75], breast cancer classification [76], and metastatic tumour classification[77].

Including in the polyp detection scheme the ability to detect other elements such as folds or blood vessels that can appear in a real exploration and can affect current methods' performance.

Tests were performed on complete video sequences to analyse the performance of the model under temporal consistency constraints and high variability in polyp appearance due to camera progression. Both conditions might impact the models' performance in a real clinical environment.

The ability to obtain uncertainty estimates from ML/AI model predictions is key to a responsible adoption of these techniques in clinical setups, as biased recommendations from CADx/e can have adverse effects on the final diagnosis. Bayesian deep learning has been proposed as a framework to address this problem, where deep learning models can deliver uncertainty information along with classification results [78] at the expense of an increased number of training parameters (and hence more training data required) or a more restricted model structure, *e.g.*, the need to incorporate dropout units within the mode architecture, as in Gal *et al*[79] 2016. Both of the abovementioned techniques have been successfully combined with active learning algorithms that enable incremental dataset labelling and/or training of the model parameters as new data become available (see Gal *et al*[80], 2017, and Woodward *et al* [81], 2016).

CONCLUSION

AI is a promising area in gastroenterology. With the processing power and high performance of algorithms such as deep learning, a new era of AI-based computer-aided systems can assist physicians in essential tasks such as colorectal polyp detection and classification. To achieve clinically useful systems, both clinicians and technicians must cooperate to mitigate AI drawbacks. Although most of the current technological effort has been focused on creating more precise polyp detection and classification tools, it remains a long path to be covered before adopting AI-based technology into the physician's daily work as an assistive tool for diagnosis decisions.

Abstract

Faecal immunochemical tests (FITs) are the most widely colorectal cancer (CRC) diagnostic biomarker available. Many population screening programmes are based on this biomarker, with the goal of reducing CRC mortality. Moreover, in recent years, a large amount of evidence has been produced on the use of FIT to detect CRC in patients with abdominal symptoms in primary healthcare as well as in surveillance after adenoma resection. The aim of this review is to highlight the available evidence on these two topics. We will summarize the evidence on diagnostic yield in symptomatic patients with CRC and significant colonic lesion and the different options to use this (thresholds, brands, number of determinations, prediction models and combinations). We will include recommendations on FIT strategies in primary healthcare proposed by regulatory bodies and scientific societies and their potential effects on healthcare resources and CRC prognosis. Finally, we will show information regarding FIT-based surveillance as an alternative to endoscopic surveillance after high-risk polyp resection. To conclude, due to the coronavirus disease 2019 pandemic, FIT-based strategies have become extremely relevant since they enable a reduction of colonoscopy demand and access to the healthcare system by selecting individuals with the highest risk of CRC.

biomarker used widely in CRC screening programmes. In recent years, a large body of evidence has appeared that enables recommending its use in different scenarios. For the evaluation of symptomatic patients in primary healthcare, FIT improves use of available endoscopic resources, avoiding unnecessary colonoscopies, predicts the risk of CRC and may have an impact on prognosis. Furthermore, although endoscopic surveillance after adenoma resection is widely extended, there are relevant doubts over its efficiency in the context of high-quality baseline colonoscopies and a FIT-based surveillance strategy could be an alternative.

INTRODUCTION

Colorectal cancer (CRC) is a relevant health problem in the Western world. In 2018, almost half a million new cases were diagnosed in Europe and 250000 patients died due to CRC[1]. Health authorities have devised two main strategies to reduce the impact of CRC: screening in average- and high-risk populations and early detection in symptomatic patients[2-4].

All preventive and diagnostic strategies are based either on invasive or non-invasive techniques. Colonoscopy is the cornerstone of all techniques, due to its diagnostic yield, the capacity of histological sampling, and especially, its ability to perform therapeutic procedures. However, colonoscopy is time and resource consuming, there is limited capacity with potential waiting lists and it is associated with side effects. Among the non-invasive techniques either imaging techniques or several diagnostic biomarkers have been evaluated[5].

Faecal occult blood tests (FOBTs) are the most widely CRC diagnostic biomarker available. FOBTs detect either blood or blood products (such as globin) in faeces with different methods. There are two main types of FOBTs: Chemical (cFOBT) or immunological (faecal immunochemical test, FIT). cFOBTs demonstrated its effect on reducing CRC mortality in CRC screening in large-scale randomized controlled trials[5]. However, they have been gradually replaced by semiquantitative FITs due to their advantages. FITs are based on the reaction of monoclonal or polyclonal antibodies specific for human faecal haemoglobin (f-Hb), albumin, or other faecal blood components. Thus, they do not require any dietary or pharmacological restriction, as long as they do not react with blood from the upper digestive tract or with any food component. The greatest advantage is determined by its ability to detect and quantify f-Hb concentrations 7 to 15 times lower than those detected by chemical tests. This significantly improves CRC and advanced adenoma detection sensitivity. Moreover, FITs enable reliable and accurate automated analyses, which prevents subjective interpretation[6]. For this reason, most CRC mass screening programmes have opted for FIT. Moreover, there is a large amount of evidence on the diagnostic accuracy of FITs for CRC and adenoma detection in asymptomatic patients[7].

In recent years, a large amount of evidence has been produced on the use of FITs to detect CRC in patients with abdominal symptoms[8-10] as well as in the surveillance of high-risk subjects (surveillance after adenoma resection)[11,12]. Furthermore, due to the coronavirus disease 2019 (COVID-19) pandemic, FIT has become extremely relevant due to the limited endoscopic resources available and access to healthcare systems[13]. The aim of this review is, therefore, to update the evidence and recommendations available on use of FIT outside the scope of CRC screening. This topic is structured into the following sections: Evidence on FIT in the evaluation of symptomatic patients; risk prediction models for CRC incorporating FIT in symptomatic patients; a combination of FIT with other non-invasive biomarkers in patients with abdominal symptoms; recommendations on the use of FIT in primary healthcare; effect of FIT on CRC prognosis; and FIT for surveillance after adenoma resection.

EVIDENCE ON FIT IN THE EVALUATION OF SYMPTOMATIC PATIENTS

Despite the implementation of CRC screening programmes, most CRC cases are still diagnosed after symptomatic presentation[14]. A large number of studies have been performed on the effectiveness of FIT for triaging referrals; also in symptomatic patients, which have been summarized in a number of recent systematic reviews[8-10, 15]. The first systematic review assessing the value of immunochemical-based FOBTs as first-line investigation in symptomatic patients was completed in 2008[15]. This review included nine studies evaluating several FIT assays using different methods and reported that FIT had better diagnostic performance than cFOBTs. However, the studies included had a small sample size and a high degree of clinical heterogeneity (*i.e.* different populations, use of quantitative and qualitative FITs), which limits the conclusions of the meta-analysis.

This work was supplemented by another systematic review[10], conducted to inform the development of a new National Institute for Health and Care Excellence (NICE) diagnostics guidance (DG) 30[16]. This review included nine studies, which provided data about clinical evaluations of three quantitative FIT assays and showed that when the FIT result is based on a single sample with a cut-off point of 10 μg Hb/g of faeces, the sensitivity for detecting CRC was 92.1% (95% confidence interval [CI]: 86.9-95.3) and 100% (95%CI: 71.5-100) for OC-Sensor (Eiken Chemical Co. Ltd., Tokyo, Japan) and HM-JACKarc (Kyowa-Medex Co. Ltd., Tokyo, Japan) FIT assays, respectively, indicating that both could be useful to rule out CRC. In that review, specificity was estimated to be 85.8% (95%CI: 78.3-91) and 76.6% (95%CI: 72.6-80.3) for OC-Sensor and HM-JACKarc FIT assays, respectively. The systematic review also included results from a study evaluating the diagnostic accuracy of the FOB Gold (Sentinel Diagnostics, Milan, Italy) FIT assay to detect a significant colonic lesion (SCL) using a f-Hb cut-off of 9 μg Hb/g faeces, defined as bleeding, cancer or polyp (sensitivity 45.2%; specificity 92.3%). As a result of this evidence,[10] NICE recommended use of the OC Sensor®, HMJACKarc®, and FOB Gold® FIT assays in primary healthcare to assess people who have accounted low risk symptoms (without rectal bleeding) who do not meet the criteria for a suspected cancer pathway referral, using a threshold of 10 μg Hb/g faeces[16,17]. However, important clinical concerns have been raised related to this recommendation[18].

Applicability of quantitative FITs in the assessment of patients with abdominal symptoms in primary healthcare

The systematic review supporting DG 30 only included one study performed in a primary healthcare setting[19], and none of the reviewed studies assessed FIT accuracy in real practice. Hence, the assessment of FIT accuracy to detect CRC in a cohort of symptomatic patients recruited from primary healthcare could lead to different results when compared to another comprised by symptomatic patients referred to secondary healthcare[8]. This could happen for reasons unrelated to CRC prevalence[20]. In this sense, high-risk symptoms (*i.e.* rectal bleeding) are shared between CRC and other benign conditions (*i.e.* anorectal disease, diverticular disease, colorectal polyps, inflammatory bowel disease or non-steroidal anti-inflammatory drug related enteropathy) which are more prevalent, thus reducing FIT specificity to detect CRC[21].

A subsequent meta-analysis was aimed at solving these problems[8]. The authors performed subgroup analyses according to the characteristics of the studies (100% symptomatic cohorts/mixed cohorts of symptomatic/asymptomatic subjects) and CRC prevalence. In this respect, the pooled estimates of sensitivity for studies comprised solely by symptomatic patients and studies made up of mixed cohorts was 94.1% (95%CI: 90.0-96.6) and 85.5% (95%CI: 76.5-91.4), respectively. Conversely, there were no statistically significant differences between the pooled sensitivity of studies with CRC prevalence < 2.5% (84.9%, 95%CI: 73.4-92.0) and ≥ 2.5% (91.7%, 95%CI: 83.3-96.1).

Since then, many studies assessing the diagnostic accuracy of FIT have been performed in primary healthcare. However, some have limitations, mainly due to their retrospective nature[9] or the criteria used for CRC diagnosis. Several studies have not used colonoscopy or a sufficient follow-up time (at least 2 years) to detect incident CRC. These two criteria have been used as "reference tests" in the systematic reviews available to select high-quality studies[8,10,15,22]. Furthermore, they have been confirmed in a different meta-analysis which detected similar diagnostic accuracy among the studies that used these criteria[7]. This evidence has been summarized in a recently published meta-analysis that has evaluated the diagnostic accuracy of FIT in patients presenting lower abdominal symptoms in primary healthcare. The results

confirmed previous findings. Twenty-three studies (69536 participants) were included with a CRC prevalence ranging between 0.3% and 6.2%. Six studies (n = 34691) evaluated FIT as rule in test (threshold of ≥ 150 μg Hb/g faeces) showing moderate sensitivity (64.1%, 95%CI: 57.8-69.9) and high specificity (95.0%, 95%CI: 91.2-97.2). A threshold of 10 μg/g (15 studies; n = 48872) resulted in sensitivity and specificity of 87.2% (95%CI: 81.0-91.6) and 84.4% (95%CI: 79.4-88.3) for CRC, respectively[9].

In this meta-analysis, the number needed to scope to detect a CRC as well as the number of missed CRC per 1000 patients according to expected CRC prevalence in primary care was calculated. The number of missed CRC per 1000 patients if a patient has a 'negative' FIT result in a population with a CRC prevalence of 2% is expected to increase from four to five when using the threshold of 20 μg Hb/g faeces instead of 10 μg Hb/g faeces. However, at the same CRC prevalence, the number needed to scope is expected to decrease from 10 to 4 if the 150 μg Hb/g faeces threshold is used instead of 10 μg Hb/g faeces[9].

Accuracy of FIT in detecting SCL and gastrointestinal cancer in patients with abdominal symptoms

As previously discussed, abdominal symptoms are non-specific and shared among benign and malignant diseases. Thus, the aim of a physician is not only to rule out CRC as long as other benign conditions may also present with the same symptoms and may benefit from diagnosis. In this sense, a previous meta-analysis revealed that FIT may not be sensitive enough to rule out all SCL[8]. Unfortunately, there is a high degree of heterogeneity among the studies evaluated due to the FIT brands used, the threshold selected, and especially, the differences in SCL definitions. The definitions used vary among inflammatory bowel disease, cancer, or high-risk adenoma; plus any type of colitis; plus any advanced adenoma, polyposis, complicated diverticular disease, colonic ulcer and bleeding angiodysplasia or even any colonic lesion detection regardless of its importance[8]. In a recently published meta-analysis, the overall pooled sensitivity and specificity of FITs for SCL for studies that used the limit of detection as a threshold (seven studies; n = 22624 patients) was 70.4% (95%CI: 68.4-72.3) and 78.4% (95%CI: 77.8-78.9), respectively. At the ≥ 10 μg Hb/g faeces threshold (seven studies; n = 20407 patients), the sensitivity and specificity were 69.1% (95%CI: 60.5-76.5) and 87.2% (95%CI: 83.4-90.2), respectively. Furthermore, three studies (n = 20528 patients) evaluated the diagnostic accuracy of FIT with a threshold of ≥ 150 μg Hb/g faeces showing sensitivity and specificity of 35.9% (95%CI: 33.8-38.1) and 97.5% (95%CI: 97.3-97.8), respectively[9].

Gastrointestinal (GI) symptoms are non-specific and could be related to different GI diseases. A relevant question is whether symptomatic patients with a completely normal colonoscopy after a positive FIT require further evaluation. In a recently published study, the risk of GI cancer detection (upper GI cancer and CRC) after a complete colonoscopy without CRC was evaluated according to the FIT result (threshold 10 μg Hb/g faeces). During a mean time of 45.5 ± 20.0 mo, GI cancer was detected in 57 (2.1%) patients: upper GI cancer in 35 (1.3%) and CRC in 14 (0.5%). FIT-positive subjects revealed a higher CRC risk (hazard ratio [HR] 3.8, 95%CI: 1.2-11.9] with no differences in GI (HR 1.5, 95%CI: 0.8-2.7) or upper GI cancer risk (HR 1.0, 95%CI: 0.5-2.2). Upper GI cancer was detected in 22 (0.8%) patients during the first year. Two variables were independently associated: anaemia (odds ratio [OR] 5.6, 95%CI: 2.2-13.9) and age ≥ 70 years (OR 2.7, 95%CI: 1.1-7.0)[23].

Does one sample with a cut-off point of 10 μg Hb/g of faeces fit everybody?

NICE recommends a single f-Hb cut-off of 10 μg Hb/g faeces to be used in the evaluation of symptomatic patients at all ages regardless of sex. However, using FIT with the same cut-off for asymptomatic populations has been associated with a higher accuracy for advanced adenoma detection in males[24]. However, a recently published meta-analysis on the diagnostic accuracy for CRC detection in asymptomatic patients did not show any differences between males and females[7]. These variations may be related to the differences in advanced adenoma prevalence and location as well as colonic transit.

One key question is what threshold is used to determine a positive result in the evaluation of symptomatic patients. Most studies have evaluated the 10 μg Hb/g of faeces threshold to triage symptomatic patients as this cut-off approximates to the quantitation limit documented by the manufacturers of most FIT analytical systems[8, 10]. Nonetheless, a recent study showed that using a cut-off point of 20 μg Hb/g of faeces could reduce the number of colonoscopy examinations without missing more than 1 CRC per 1000 patients evaluated belonging to the low-risk group defined by

NICE DG 30[9]. Moreover, other thresholds have also been proposed: limit of determination, and recently, 150 μg Hb/g of faeces[25]. Thus, while patients with a concentration below the limit of determination had a risk of detecting a CRC less than 0.2%; in patients with a Hb greater than 150 μg/g of faeces the risk of detecting a CRC was greater than 31.1%.

In fact, the choice of threshold is a trade-off among the number of patients required to be referred to colonoscopy, the number of missing CRC, and CRC prevalence. In our meta-analysis, we calculated the number needed to scope to detect a CRC as well as the number of missed CRC per 1000 patients according to expected CRC prevalence in primary care. The number of missed CRC per 1000 patients if a patient has a 'negative' FIT result in a population with a CRC prevalence of 2% is expected to increase from four to five when using the threshold of 20 μg Hb/g faeces instead of 10 μg Hb/g faeces. However, at the same CRC prevalence, the number needed to scope is expected to decrease from 10 to 4 if the 150 μg Hb/g faeces threshold is used instead of 10 μg Hb/g faeces[9]. With respect to colonoscopy, we must take into account not only the resources required to evaluate patients and waiting lists but also the risks associated with colonoscopy. In a recently published meta-analysis, they were estimated at 5.8 perforations per 10000 colonoscopies (95%CI: 5.7-6.0) and 2.4 cases of relevant bleeding per 1000 colonoscopies (95%CI: 2.4-2.5)[26]. In this sense, it also seems reasonable to use a higher cut-off than that recommended by NICE, if there is well-planned safety netting to evaluate symptomatic patients with a negative result if symptoms persist. Furthermore, results could also be closely monitored locally to enable the rapid adjustment of cut-offs to optimize each area's resources[27]. However, because f-Hb correlates directly with the severity of colorectal lesions, raising the f-Hb cut-off will lead to losing a higher number of SCLs. However, those are less urgent for diagnosis and could easily be subsequently rescued in an environment whose colonoscopy resources are preserved through the appropriate use of FIT as a first line triage test.

There is the option of using more than one FIT determination. Two studies included in a previous meta-analysis[8,10] examined the utility of one *vs* two faecal samples for detecting advanced neoplasia (CRC plus advanced adenoma). The diagnostic yield of the two samples using a cut-off of 20 μg Hb/g faeces was attained with only one sample using a cut-off of 10 μg Hb/g faeces. This highlights the need for further investigation to verify the efficiency of using different strategies to triage not only advanced adenoma but also any SCL, if the use of a higher cut-off than that recommended by NICE (10 μg Hb/g faeces) is conditioned to a "safety netting", which requires more than one FIT sample.

RISK PREDICTION MODELS FOR CRC INCORPORATING FIT IN SYMPTOMATIC PATIENTS

A number of predictive models have been developed to improve clinical judgement in patients with abdominal symptoms, and some have included quantitative FITs[28]. In recent years, two prediction models (COLONPREDICT and the FAST score) have been developed and were externally validated, not only to identify people at higher risk of CRC but also to define a subgroup whose CRC risk is so low that we can ensure that no further evaluation is required[29,30]. For that purpose, both prediction models defined two cut-offs. The first (COLONPREDICT< 3.50 and FAST score < 2.12 respectively) was evaluated to identify a low-risk population with a negative predictive value (NPV) of having CRC higher than 99%. In this subgroup, no further evaluation should be recommended as the risk of performing a colonoscopy is similar to the risk of severe complications associated with this exploration[26]. A second cut-off (COLONPREDICT ≥ 5.60, FAST score ≥ 4.50) was calculated to define a high-risk subgroup in which at least 90% of CRC would be detected.

Despite COLONPREDICT, the model has shown a high diagnostic performance, with an area under the curve (AUC) of 0.92 in both derivation and validation cohorts, it has been criticized as too complex for routine primary healthcare practice due to considering too many clinical (age, sex, acetylsalicylic acid treatment, previous colonoscopy, rectal mass, benign anorectal lesion, rectal bleeding and change in bowel habit) and laboratory (serum carcinoembryonic antigen, faecal and blood haemoglobin) variables[29]. Conversely, the FAST score combines only three variables (f-Hb, sex and age). In addition to being easier, this model has also shown high accuracy to predict the individual risk of CRC and SCL in symptomatic patients (AUC = 0.88)[30]. To date, none of these prediction models have been validated in primary

healthcare.

A similar risk score was developed by Rodríguez-Alonso *et al*[31] for advanced neoplasia detection. A score between 0 and 11 is calculated for each patient according to three variables (sex, age, and FIT), and a risk score ≥ 5 is considered the optimal cut-off point for colonoscopy referral. More recently, the COLONOFIT score aims to assess the risk of advanced neoplasia (CRC plus advanced adenoma) in symptomatic patients with indication of a fast-track colonoscopy[32]. This model is based on age, colonoscopy (in the previous 5 years), tobacco use, and variables related to FIT (maximum f-Hb value and number of samples with FIT > 4 μg Hb/g faeces). A COLONOFIT score > 10 points enables diagnosis of 98% of CRC (NPV = 99.7%) and 77% of advanced adenomas, and has been shown to classify patients 3% to 4% better than the FAST score in this study. However, COLONFIT needs the submission of three FIT samples, which could reduce adherence and compromise its successful implementation in primary healthcare.

COMBINATION OF FIT WITH OTHER NON-INVASIVE BIOMARKERS IN PATIENTS WITH ABDOMINAL SYMPTOMS

Although many biomarkers have been evaluated for the detection of CRC in a screening setting[33], they have shown little applicability in clinical practice. A few studies have explored the possibility of improving the diagnostic performance of FIT in combination with other non-invasive biomarkers, mainly faecal calprotectin, M2-piruvate kinase and volatile organic compounds, in symptomatic patients[19,34-36]. In general, adding a second biomarker either improves sensitivity reducing specificity and increasing the number of patients referred to colonoscopy, or by contrast, increases specificity reducing sensitivity and the number of patients with a positive result. Only one study has evaluated the concomitant analysis of FIT and faecal calprotectin. This has shown mixed results, presumably due to heterogeneity of both targets, FIT assays, and cut-offs used. Mowat *et al*[19] reported the diagnostic accuracy of FIT (OC-Sensor®) and faecal calprotectin to detect SCL (CRC plus higher risk adenoma plus inflammatory bowel disease) using different cut-offs. The sensitivity of one sample of the OC-Sensor to detect CRC and SCL was 89.3% and 68.6% respectively (cut-off 10 μg Hb/g faeces). Furthermore, when using the limit of haemoglobin detection as a cut-off, the sensitivity to detect CRC and SCL improved by 100% and 88.2%, respectively. Finally, when adding the measurement of faecal calprotectin, the sensitivity to detect SCL increased by 91.2% and 96.1% using the 200 μg Hb/g faeces and 50 μg Hb/g faeces cut-offs, respectively[19].

RECOMMENDATIONS ON USE OF FIT IN PRIMARY HEALTHCARE

Not many international clinical guidelines have opted for the potential advantages of introducing FIT in daily clinical practice. The available literature was reviewed by van Melle *et al*[37], which identified a limited number of countries with clinical guidelines that explicitly recommended use of FIT in symptomatic patients: Australia[38], Spain [5], United Kingdom[16,17] and Denmark (limited to specialized healthcare). We searched most guidelines mentioned by van Melle *et al*[37], in addition to others such as the Italian[39], Colombian[40] and English versions of the Chinese guideline[41]. However, only the 2019 update of the Scottish guideline[42] raised the possibility of including FIT, after completion of several pilot studies currently being developed in Scotland (Table 1).

As previously noted, the NICE recommended that FIT be performed in primary healthcare in symptomatic patients with a positive predictive value below 3%[16,17] after performing a systematic review[10]. Specifically, in the National Institute for Health and Care Excellence guideline, 12 FIT is recommended in patients without rectal bleeding aged under 60 with altered bowel habits or iron deficiency anaemia, patients without rectal bleeding aged over 50 with abdominal pain or weight loss (in which the combination of both symptoms would have been a fast-track criterion); and patients older than 60 with anaemia[17]. Patients with a positive FIT should be referred through the fast-track pathway for further evaluation. In the DG 30, FIT is recommended in any symptomatic patient that does not meet any of the fast-track criteria[18]. The Australian guideline[38] includes the indications of the NICE guidelines to recommend FIT in patients aged under 60 without overt bleeding with a

Table 1 Clinical guidelines and recommendations on colorectal cancer diagnosis that include the use of faecal immunochemical test in primary healthcare

Guideline	Year	Criteria to use FIT
NICE DG 30 United Kingdom [16]	2017	People without rectal bleeding who have unexplained symptoms but do not meet the criteria for a suspected cancer pathway referral outlined in NICE's guideline on suspected cancer
Australia[38]	2018	In people with symptoms other than overt rectal bleeding, FIT can be used as part of the diagnostic assessment in primary healthcare. It is of particular use in the following circumstances to support diagnostic assessment and notify the urgency of colonoscopy: people over 50 yr with either unexplained weight loss or abdominal pain; and people under 60 yr with either altered bowel habit or anaemia
Spain[5]	2018	Patients with lower gastrointestinal symptoms of recent onset who do not meet criteria for referral without delay to a specialist service due to high suspicion of CRC (rectal or abdominal mass, rectal bleeding or iron-deficiency anaemia) should undergo a FIT
NICE NG12 United Kingdom [17]	2021	Offer FIT to assess for CRC in adults without rectal bleeding who: Are aged 50 and over with unexplained abdominal pain or weight loss, or are aged under 60 with changes in their bowel habit, or iron-deficiency anaemia, or are aged 60 and over and have anaemia even in the absence of iron deficiency

CRC: Colorectal cancer; DG: Diagnostics guidance; FIT: Faecal immunochemical test; NG: National Institute for Health and Care Excellence guideline; NICE: National Institute for Health and Care Excellence.

change in bowel habit or anaemia; and in those over 50 with abdominal pain or weight loss. Based on the article published by Mowat *et al*[19], the recommendation justified performing FIT to rule out SCL.

The Spanish guideline on CRC diagnosis and prevention[5] is based on the NICE DG 30 (including the 10 μg Hb/g of faeces cut-off) and the systematic review performed by Westwood *et al*[10]. FIT is recommended for the evaluation of any patient with lower GI symptoms if they do not meet the criteria for urgent referral to colonoscopy (tumour or mass on examination or imaging tests, rectal bleeding associated with CRC or iron deficiency anaemia). Therefore, this guide includes non-suspicious rectal bleeding as a FIT application criterion. In the event of a positive result, the guide recommends requesting a colonoscopy and in case of negative result, to monitor symptoms and refer the patient to a specialized level if symptoms persist.

On the other hand, guidelines that do not recommend FIT in primary healthcare generally propose referral to specialized healthcare for all high-risk symptoms and only recommend observation in patients with low-risk symptoms such as loss of appetite, constipation or mucus in the faeces[37]. The specialist will probably finally request the colonoscopy and decide priority himself. The New Zealand guide, updated in 2014[43], explicitly advises against its use, due to the lack of evidence in its favour and compares it with carcinoembryonic antigen. The Ontario clinical guidelines[44] withdrew the recommendations that included cFOBTs in 2017, to avoid a possible conflict with its screening programme. In 2019, this exclusion was extended to FITs. Other clinical guidelines only contemplate cFOBTs[45].

EFFECT OF A FIT-BASED STRATEGY ON RESOURCES

As we have seen, the guidelines that recommend FIT in primary healthcare are intended to identify a subgroup of patients at high risk of CRC detection despite presenting mild symptoms. Otherwise, these patients would not have been included in the fast-track colonoscopy. However, a negative FIT result in these patients would reduce the number of colonoscopies performed with no relevant findings[10]. This strategy may avoid colonoscopy-related risks in subjects with a low CRC risk and facilitate better prioritization on colonoscopy waiting lists. In this sense, an estimation performed based on the results obtained in the Pin-Vieito study[8] with a 3% CRC estimated prevalence and 10 μg Hb/g and 20 μg Hb/g of faeces cut-off (cohorts 100% symptomatic) highlights that FIT will avoid approximately 2/3 of the colonoscopy with two missed CRC out of 1000 patients evaluated (Figure 1). If we take the SCL into consideration with 12% and 10 μg Hb/g of faeces cut-off, the positive predictive value would be 24.8%, and the number of undetected SCL would be 24 out of 1000 subjects, mainly advanced adenomas.

Due to the COVID-19 pandemic, the risk stratification of subjects with GI symptoms has become of the utmost relevance. A modelling study has recently been published.

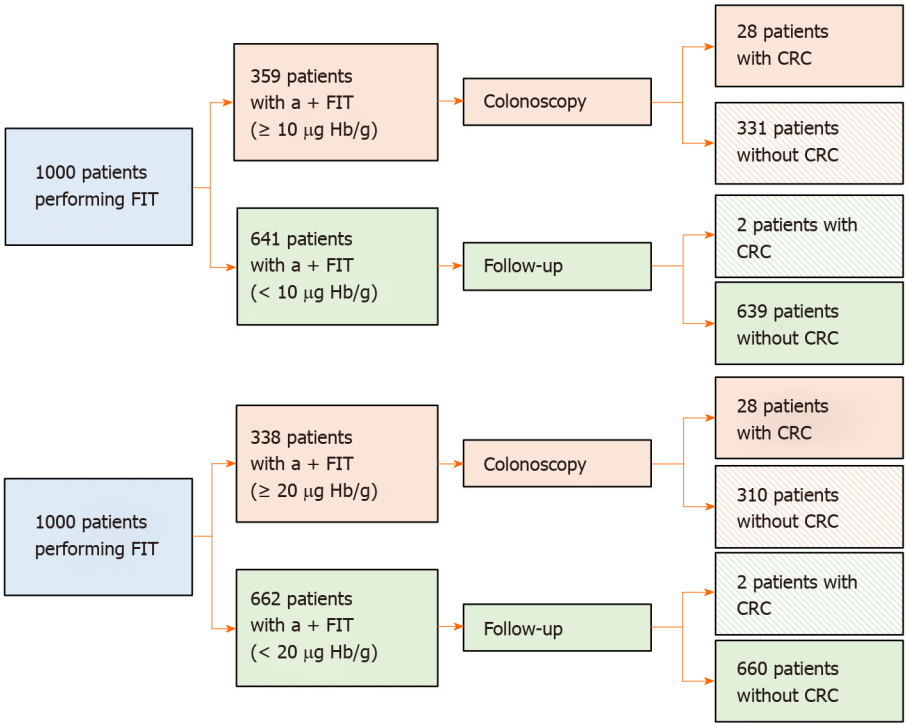

Figure 1 Estimation of the number of patients who need to be referred for colonoscopy, and the diagnostic yield for colorectal cancer in the 10 and 20 μg Hb/g of faeces thresholds[8]. CRC: Colorectal cancer; FIT: Faecal immunochemical test.

This model evaluated the effect of delays for colonoscopy on CRC mortality due to lack of endoscopic capacity and prioritization of colonoscopy in patients with a f-Hb ≥ 10 μg Hb/g of faeces. A delay higher than 6 mo would lead to 2250 attributable deaths and loss of 32799 life-years. In contrast, using FIT to stratify only 18% of symptomatic patients would be referred to colonoscopy; 89% of these deaths would be avoided and the requirements for colonoscopy would be reduced by > 80%[13]. This information has been confirmed in a recently published retrospective study in primary healthcare with a sample size of 14487 consecutive patients who underwent a FIT due to low-risk symptoms without fast-track criteria[46]. Using a ≥ 10 μg Hb/g faeces threshold, 10% of adults would be investigated to detect 91% of cancers with a number needed to scope of ten to detect one cancer and three to detect a SCL. Only 12 CRCs (< 2/1000 subjects) would be missed in the subjects evaluated. This proportion is similar to the colonoscopy-associated side effects[26] and CRC prevalence in asymptomatic adults aged 50-69[47].

A relevant topic is the strategy in subjects with a negative FIT result. Unfortunately, the information is limited. Hypothetically, symptoms in patients with CRC and a negative FIT will persist or even worsen, so they would require additional medical healthcare. In the Spanish guidelines, follow-up and request for colonoscopy are recommended if symptoms persist[5]. The results of the study performed by Nicholson *et al*[46] support this strategy because seven out of the 12 FIT-negative CRC were detected within 1 mo after FIT. A better understanding of the characteristics of patients with false negative results and their clinical course, is key to guide the most effective diagnostic tests to perform during follow-up.

Westwood *et al*[10] published a cost-effectiveness analysis to inform NICE about the use of FIT in symptomatic patients. For the effectiveness analysis, a meta-analysis was performed and for the cost analysis, a model based on quality-of-life-adjusted life years (QALYs) was devised. Researchers compared three strategies: triage with FIT, triage with cFOBT and no triage (direct referral to colonoscopy). The cost of a colonoscopy and the FIT was estimated at £372 and £4.53, respectively. The differences in QALYs between the three strategies were minimal. The triage strategy using FIT demonstrated a higher cost, but also higher efficacy and cost-effectiveness than cFOBT. It would only be surpassed in cost-effectiveness by placing the cut-off point at the detection threshold of 2 μg/g of Hb in faeces. The FIT also demonstrated greater cost-effectiveness compared to no triage, with an incremental cost of £258.09 per patient. Taking into account the lost QALYs due to FIT false-negatives, saving of £2578.543 per lost QALY was calculated using triage with FIT.

EFFECT OF FIT ON CRC PROGNOSIS

The main objective of any diagnostic strategy is to improve the prognosis of the disease detected. We have evidence that FIT-based CRC screening improves CRC prognosis through early detection[48]. However, the information regarding CRC prognosis detected after a positive FIT in symptomatic subjects is still limited. In this sense, a Polish retrospective analysis of 535 CRC detected in symptomatic subjects evaluated the effect of the pathway to CRC diagnosis on prognosis. CRC detected after a positive FIT (HemCheck-1) result revealed better prognosis than CRC detected on the basis of clinical evaluation (40 ± 47 mo *vs* 25 ± 38 mo; $P < 0.001$)[49].

In a recently published Spanish population-based study[14], a significantly longer 3-year survival was observed in patients with CRC diagnosed after a positive FIT in comparison with CRC detected after a negative result or without a FIT (HR 1.50; 95%CI: 1.22-1.84). These differences in prognosis were related to an earlier CRC stage at diagnosis in the positive FIT group. The reason for these findings is unclear; it is hypothesized that requesting a FIT could reduce diagnostic delay. However, there is a risk of bias, since in one-third of the positives the reason for the FIT request could not be confirmed and they could be related to opportunistic CRC screening.

Although these two retrospective studies have limitations and risk of bias (ignorance of comorbidities, circumstances of the CRC diagnosis, indications for FIT, single-centre, *etc.*), they support the hypothesis that evaluation of symptomatic patients with FIT could modify CRC prognosis. The causes of these differences are not clear and may include diagnostic delay, severity of the onset symptoms and characteristics of the general practitioner. Prospective studies need to be performed that evaluate the effect of a FIT-based diagnostic strategy on CRC prognosis to fully identify the strengths and weaknesses and thus find their ideal place in clinical practice guidelines.

FIT IN SURVEILLANCE AFTER ADENOMA RESECTION

Colorectal polyps are precursor lesions for CRC. Therefore, their removal during colonoscopy reduces CRC risk[5]. These patients have an increased risk of developing more polyps and eventually CRC over the years, so adopting surveillance strategies is recommended[5]. In recent years, mainly motivated by the implementation of the CRC populations screening programmes, there has been an increase in the number of patients with resected colorectal polyps that require surveillance. This has meant that colonoscopies have also undergone a major increase, which require large amounts of resources and highlights the currently overloaded endoscopy services[50,51]. However, we must keep in mind that colonoscopy is an invasive and expensive procedure, with a risk of adverse events, associated both with the procedure itself and with the sedation necessary for it to be performed correctly[26]. For these reasons, it seems reasonable that surveillance colonoscopy for patients after polyp removal should be targeted at those most likely to benefit[51].

The aim of surveillance after colorectal polyp resection is to reduce CRC incidence [51]. In order to make decisions on surveillance, there are two questions that need to be answered: what is the long term (10 years) risk of CRC without surveillance, and does endoscopic surveillance reduce CRC risk compared with no surveillance/participation in a CRC screening programme?

Until recently, the information available was limited and referred to the short-term risk of advanced adenoma detection, an intermediate lesion[52]. Several long-term studies with CRC incidence as the main endpoint have recently been published (Table 2)[53-58]. They reveal that subjects with low-risk lesions (mainly 1-2 non-advanced adenomas or serrated lesions) have a long-term CRC risk similar to the control group (general population or subjects with normal colonoscopy). In contrast, CRC risk is increased in subjects with high-risk lesions (mainly advanced adenomas/serrated lesions and/or multiple adenomas). Taking into account these results, the available practice guidelines recommend in the low-risk group a surveillance strategy equivalent to that recommended in the general population: participation in a CRC screening programme[2,5,59-61].

However, the evidence regarding the benefits of endoscopic surveillance in high-risk lesions is limited to cohort studies. In the study published by Cottet *et al*[62] in 2012, the standardized incidence ratio was 1.10 (95%CI: 0.62-1.82) and 4.26 (95%CI: 2.89-6.04) in those patients with and without colonoscopy follow-up, respectively. In a recently published study including 6239 patients with high-risk lesions, endoscopic

Table 2 Colorectal cancer risk in patients with high risk adenomas or low risk adenomas

surveillance was associated with a reduction in CRC risk (HR 0.71, 95%CI: 0.49-1.03 for 1 visit; 0.44, 0.28-0.70 for ≥ 2 visits)[57]. Atkin *et al*[63] also showed in a study including 12000 patients with high-risk lesions (1-2 adenomas ≥ 10 mm or 3-4 adenomas < 10 mm), that performing at least one endoscopic surveillance reduces the incidence of CRC (HR 0.57, 95%CI: 0.40-0.80). However, this risk reduction was limited to a subgroup of patients: low-quality colonoscopy, large (≥ 20 mm), high-grade dysplasia and proximal adenomas. In this respect, available guidelines recommend performing baseline colonoscopy with full exploration of the colonic mucosa and resection of all polyps detected[2,5,59-61]. CRC detection during surveillance depends not only on the characteristics of the polyps but also on the endoscopist's technical ability. A recently published Polish study revealed that long-term risk of CRC is increased (HR 2.69, 95%CI: 1.62-4.47) if baseline colonoscopy is performed by low-performing endoscopists (adenoma detection rate < 20%)[64].

One limitation of FIT is its limited diagnostic accuracy for adenomas at a single determination. In asymptomatic subjects, at a single determination FIT detects 31% and 21% of advanced adenomas at the 10 μg Hb/g and 20 μg Hb/g of faeces thresholds, respectively, with specificity higher than 90%[7]. There are several characteristics of the adenomas associated with a positive FIT: number, location, morphology and size[5]. However, the strength of a FIT-based CRC screening is that it is based on periodic (annual or biennial) determination. Furthermore, the threshold used can be tailored according to colonoscopy capacity and long-term objective. The evidence available on a FIT-based surveillance is limited. A prospective British study published in 2019 investigated whether faecal FIT could reduce the surveillance burden on patients and endoscopy services. The study population was patients with intermediate risk of CRC after polyp removal (1-2 adenomas ≥ 10 mm or 3-4 adenomas < 10 mm). Subjects were offered an annual FIT and all subjects underwent a 3-year scheduled colonoscopy. The number of patients that required work-up colonoscopy using the 10 μg Hb/g threshold was 28.8%. The 3-year programme sensitivity for CRC and advanced adenoma was 72.4% and 56.6% with a specificity of 71.1% and 73.7%, respectively. Incremental cost-effectiveness of colonoscopy *vs* FIT surveillance was £7354 per additional advanced adenoma detected and £180778 per additional CRC detected[11].

Similar results were obtained in a diagnostic accuracy study that evaluated FIT (2 μg Hb/g) in a cohort of high-risk patients who underwent endoscopic surveillance. A total of 593 patients were included, including 41 (6.9%) with advanced neoplasia (4 CRC, 37 higher-risk adenoma). Of the 238 patients (40.1%) who had detectable FIT, 31 (13.0%) had advanced neoplasia (2 CRC, 29 higher-risk adenoma) compared with 10 (2.8%) with undetectable FIT (2 CRC, 8 higher-risk adenoma). A detectable FIT gave NPV of 99.4% for CRC and 97.2% for CRC plus higher-risk adenoma. According to these results, a FIT determination can provide an objective estimate of the risk of advanced neoplasia, and could enable tailored scheduling of colonoscopy[65].

In the absence of results from randomized clinical trials evaluating a FIT-based surveillance strategy, we have information from a simulation study[66]. This study evaluated the additional benefit in terms of cost-effectiveness of adding colonoscopy surveillance to a CRC screening programme. Based on the information obtained from the Dutch CRC screening programme, FIT screening without colonoscopy surveillance after adenoma removal reduces CRC mortality by 50.4% compared with no screening or surveillance. Adding colonoscopy surveillance after adenoma resection to FIT screening would reduce mortality by an additional 1.7% to 52.1% but would increase

lifetime colonoscopy demand by 62% at an additional cost of €68000, for an increase of 0.9 life-year. Despite the reduction in mortality provided by endoscopic surveillance compared to FIT follow-up, this study concludes that it is not a cost-effective strategy based on the incremental cost-effectiveness ratios, which exceeds the Dutch willingness-to-pay threshold of €36602 per life-year gained and also substantially increases colonoscopy demand[66].

CONCLUSION

In conclusion, we have enough evidence to recommend use of FIT to triage symptomatic patients in primary healthcare. FIT improves use of available endoscopic resources, avoids unnecessary colonoscopies, accurately predicts the risk of CRC and may have an impact on CRC prognosis. On the other hand, although endoscopic surveillance after adenoma resection is widely extended, there are relevant doubts about its efficiency in the context of high-quality baseline colonoscopies. Moreover, in terms of evaluating the effect on CRC incidence, endoscopic surveillance should be compared with participation in a CRC screening programme. In this sense, we require a randomized controlled trial comparing endoscopic with FIT-based surveillance after high-risk polyp resection.

Abstract

BACKGROUND

Colorectal cancer (CRC), the third most common cause of death in both males and females worldwide, shows a positive response to therapy and usually a better prognosis when detected at an early stage. However, the survival rate declines when the diagnosis is late and the tumor spreads to other organs. Currently, the measures widely used in the clinic are fecal occult blood test and evaluation of serum tumor markers, but the lack of sensitivity and specificity of these markers restricts their use for CRC diagnosis. Due to its high sensitivity and precision, colonoscopy is currently the gold-standard screening technique for CRC, but it is a costly and invasive procedure. Therefore, the implementation of custom-made methodologies including those with minimal invasiveness, protection, and reproducibility is highly desirable. With regard to other screening methods, the screening of fecal samples has several benefits, and metabolomics is a successful method to classify the metabolite shift in living systems as a reaction to pathophysiological influences, genetic modifications, and environmental factors.

AIM

To characterize the variation groups and potentially recognize some diagnostic markers, we compared with healthy controls (HCs) the fecal nuclear magnetic resonance (NMR) metabolomic profiles of patients with CRC or adenomatous polyposis (AP).

METHODS

Proton nuclear magnetic resonance spectroscopy was used in combination with multivariate and univariate statistical approaches, to define the fecal metabolic profiles of 32 CRC patients, 16 AP patients, and 38 HCs well matched in age, sex, and body mass index.

RESULTS

NMR metabolomic analyses revealed that fecal sample profiles differed among CRC patients, AP patients, and HCs, and some discriminatory metabolites including acetate, butyrate, propionate, 3-hydroxyphenylacetic acid, valine, tyrosine and leucine were identified.

CONCLUSION

In conclusion, we are confident that our data can be a forerunner for future studies on CRC management, especially the diagnosis and evaluation of the effectiveness of treatments.

Key Words: Colorectal cancer; Adenomatous polyps; Nuclear magnetic resonance metabolomics; Fecal samples; Fecal metabolomics

Core Tip: Colorectal cancer (CRC) is the third leading cause of cancer-related death worldwide. Fecal occult blood and serum tumor markers are indicators currently used in the clinic, but their lack of sensitivity and precision limit their use for CRC diagnosis. Colonoscopy is the gold-standard screening technique for CRC, but it is costly and invasive. Using readily accessible biological samples such as stool specimens, in conjunction with high-throughput molecular profiling techniques, could significantly contribute to diagnosing and understanding the patient's relationship with CRC. We compared with healthy subjects the fecal nuclear magnetic resonance metabolomic profiles of patients with CRC or adenomatous polyposis.

INTRODUCTION

Colorectal cancer (CRC) is globally the third most common cause of cancer-related death in both men and women[1]. Many CRC cases are attributable to changeable (and therefore potentially preventable)[2] risk factors including diet, smoking, high alcohol consumption, physical inactivity, and being overweight. If diagnosed at an early stage, CRC shows a good response to therapy and usually a better prognosis, while survival decreases when the diagnosis is late, and the tumor spreads to other organs[3]. In addition, it is well documented that about 95% of CRCs are adenocarcinomas and begin as colonic adenomatous polyps (AP)[4] or adenomas. A series of molecular alterations and mutations induce CRC development. Tumors can be prevented with polyps excision and adequate treatment[5]. The fecal occult blood test and evaluation of serum tumor markers are commonly used in the clinic[6]; however, the lack of sensitivity and specificity of these markers limits their application in CRC diagnosis[6-8]. Currently, colonoscopy represents the gold-standard screening procedure for CRC due to its high sensitivity and specificity, but it is an expensive and especially invasive procedure[9,10]. Therefore, it is highly desirable to introduce custom-made methodologies combining minimal invasiveness, safety, and reproducibility. The screening of fecal samples has many advantages with respect to other screening techniques. In fact, stool screening is certainly non-invasive and primarily reflects the colorectal status. Moreover, the use of easily accessible and non-invasive biological samples, such as

stool specimens, combined with high-throughput molecular profiling techniques, can significantly contribute to the diagnosis of CRC and to the understanding of its interaction with the patient.

Metabolomics is an omics science that is an efficient approach to characterizing the change of metabolites in living systems as a response to pathophysiological stimuli, genetic modifications, and environmental factors. Metabolites are low molecular weight organic molecules that take part (as substrates or products) in the biochemical processes essential for sustaining life. Thus, the comprehensive evaluation of metabolites and their changes are fundamental to observe and measure the response of the organism to diverse conditions.

Nuclear magnetic resonance (NMR) spectroscopy is one of the most useful high-throughput techniques to obtain metabolomics information from biological samples [11,12]. NMR-based metabolomics has been successfully applied for disease classification[13-18] and prognosis. Starting from these premises, we compared the fecal NMR metabolomic profiles of patients with CRC or AP with those of healthy controls (HCs) to characterize the differences among the groups and possibly identify diagnostic markers.

MATERIALS AND METHODS

Patients and biological samples

A total of 86 patients including 32 CRC patients, 16 AP patients, and 38 HCs were enrolled for different studies between January 2016 and February 2019 at the Careggi Hospital and University of Florence, Italy. The Ethics Committee Area Vasta Toscana Centro (Italy) approved the studies. All fecal samples were taken at diagnosis, before starting any treatment (*e.g.*, surgical resection, chemotherapy, probiotic intake). Moreover, patients with evidence of serious illness, immunodeficit, autoimmune or infectious diseases were excluded. CRC patients, AP patients, and HCs were well matched in age, sex and body mass index. Table 1 summarizes the clinical characteristics of the enrolled patients.

Stool samples were collected in pre-labeled collection cups. Fecal water was extracted to ratios of 1:2 (g/mL, weight of unthawed feces-to-buffer) in 0.75 M phosphate-buffered saline (PBS, pH 7.4)[19]. The buffered samples where homogenized by whirl mixing for 30 s and sonicated for 15 min. Then each sample was centrifuged at 10000 g for 10 min at 4 °C, and 700 μL supernatant was transferred to 1.5 mL Eppendorf tubes and centrifuged again at 14000 rpm for 5 min at 4 °C. The clear supernatant was used for NMR analyses.

NMR sample preparation and analyses

A total of 70 μL buffer solution (1.5 M KH_2PO_4/d_2O, pH 7.4; 2 mmol/L NaN_3; 0.1% TMSP) was added to 630 μL of each fresh fecal water sample, and a total of 600 μL of this mixture was transferred to a 5 mm NMR tube.

One-dimensional proton NMR (^{1}H-NMR) spectra for all samples were acquired using the Bruker 600 MHz spectrometer (Bruker BioSpin srl; Rheinstetten, Germany) operating at 600.13 MHz proton Larmor frequency and equipped with a 5 mm PATXI ^{1}H-^{13}C-^{15}N and ^{2}H-decoupling probe including a *z* axis gradient coil, an automatic tuning-matching, and an automatic and refrigerated sample changer (SampleJet, Bruker BioSpin srl; Rheinstetten).

The BTO 2000 thermocouple served for temperature stabilization at the level of approximately 0.1 K at the sample. Before measurement, samples were kept for at least 3 min inside the NMR probe head for temperature equilibration.

Two one-dimensional ^{1}H-NMR spectra, namely one-dimensional (1D) NOESY and Carr-Purcell-Meiboom-Gill (CPMG), were acquired at 310 K with different pulse sequences: a standard nuclear Overhauser effect spectroscopy pulse sequence 1D NOESY PRESAT (noesygppr1d.comp; Bruker BioSpin) pulse sequence, using 64 scans, 98304 data points, a spectral width of 18028 Hz, an acquisition time of 2.7 s, a relaxation delay of 4 s, and a mixing time of 0.1 s; and a standard spin echo CPMG[20] (cpmgpr1d.comp; Bruker BioSpin) pulse sequence applied to a standard 1D sequence, with 64 scans, 73728 data points, a spectral width of 12019 Hz, and a relaxation delay of 4 s.

Spectral processing and statistical analysis

Free induction decays were multiplied by an exponential function equivalent to 0.3 Hz line-broadening factor before applying Fourier transform. Transformed spectra were

Table 1 Clinical characteristics of colorectal cancer patients, adenomatous patients, and healthy controls

Code	Gender ratio M/F	Median age, yr	Range of age, yr	Tumor staging T0/T1/T2/T3/T4 (*n* of patients)	Diet	Race
CRC	22 M-10 F; M/F = 2, 2	72	36-85	2/6/10/6/8	Mediterranean	Caucasian
AP	9M-7F; M/F = 1, 3	59	41-79	-	Mediterranean	Caucasian

AP: Adenomatous patients; CRC: Colorectal cancer; HCs: Healthy controls.

automatically corrected for phase and baseline distortions and fecal spectra calibrated to TMSP singlet at 0 ppm using the TopSpin version 4.1.0 (Bruker BioSpin GmbH).

NMR spectra were segmented into bins of 0.02 ppm in the spectral range between 0.2 and 10.00 ppm. Regions containing residual water signal (between 4.6 and 4.9 ppm) were removed from the binning. The spectral intensity within each bin was integrated using Assure NMR 2.2, and the corresponding area was calculated to obtain the variable used as input for the statistical methods.

Before analysis of the generated data matrix, probabilistic quotient normalization [21] normalization and mean centering of the variables were performed.

Statistical analyses of the data were performed using R[22]. On processed NMR spectra, multivariate data analyses were performed. Principal component analysis (PCA) was used as unsupervised technique for exploratory analyses to check the homogeneity of the acquired spectra and to visualize the presence of outliers. As a supervised technique, orthogonal projections to latent structures-discriminant analysis (OPLS-DA) was applied. The OPLS-DA method is a multivariate projection approach that is commonly used to model spectroscopic data. Compared to PCA or partial least squares projection to latent structures (PLS), OPLS is able to distinguish between "response-related" and "response-orthogonal" fluctuations in data, delivering benefits in terms of model interpretation[23]. All of the accuracies reported and the confusion matrix for different classifications were assessed by means of 100 cycles of the Monte Carlo cross-validation scheme (MCCV, R script developed in-house). In this case, 90% of the data were randomly chosen at each iteration as a training set to build the model. Then the remaining 10% was tested, and the sensitivity, specificity, and accuracy of the classification were assessed. Metabolite identification was performed manually based on previous literature[19,24], the human metabolome database public database, and a library of pure organic compounds (BBIOREFCODE; Bruker BioSpin). The relative metabolite concentrations (expressed in arbitrary units) were calculated integrating and calculating the peaks area[25].

To determine the discriminating molecules among all classes under study, the Wilcoxon test was chosen to infer differences between two groups of subjects[26]. False discovery rate (FDR) correction was applied using the Benjamini & Hochberg method, and adjusted $P < 0.05$ was considered statistically significant[27]. The effect size, using the Cliff's delta (Cd) formulation[28], was also calculated to aid in the identification of the meaningful signals giving an estimation of the magnitude of the separation between the different groups. The magnitude was assessed using the thresholds provided in Romano and Coll[29], *i.e.* $|Cd| < 0.147$ "negligible," $|Cd| < 0.33$ "small," $|Cd| < 0.474$ "medium,"and otherwise "large."

Changes in metabolite levels were calculated as the $\log_2$ (fold change) ratio of the normalized median intensities of the corresponding signals in the spectra of the two groups. MetaboAnalyst 4.0 free online software was used for pathway analysis[30].

RESULTS

Metabolic fingerprint of CRC and AP patients

The NMR spectra of 86 fecal extract samples (32 CRC, 16 AP, and 38 HC) were acquired. Because of the suboptimal shimming quality of 7 spectra, only 79 spectra (1D NOESY: 26 CRC, 15 AP and 38 HCs; CPMG: 27 CRC, 14 AP, and 38 HCs) were used in subsequent analyses.

PCA was initially carried out to generate an overview of the variation among the different groups of patients (CRC, AP, and HCs) using bucketed spectra of fecal extracts. Some trends could be detected in the score plots of the first two principal components as shown in Supplementary Figure 1. Indeed, both score plots reveal that

CRC and AP patient groups tend to spread in the plots more than HCs that are more grouped. However, no net clustering seems to appear in the metabolomic profiles of the groups of patients neither with respect to HCs using this unsupervised approach.

Comparative analyses among the groups have been performed to test the capability of ^{1}H-NMR fecal water spectra to classify the samples of the patients according to the diagnosis. Several models have been built using a MC cross-validated supervised OPLS-DA approach. First, all three groups (CRC, AP, and HCs) were used in the same model to test the accuracy of the approach in the prediction of the healthy or the patho-logical state using a single bucketed NMR fecal spectrum (Supplementary Figure 2). As is shown in the score plots of Supplementary Figure 2, the AP samples occupied the middle metabolomic space between HCs and CRC. Indeed, the resulting true AP-positive percentages of the OPLS-DA NOESY and CPMG models were 37.7% and 18%, respectively (Supplementary Figure 2), and most of the AP patients were misclassified within the metabolomic space of HCs or CRC.

Prognostic data about patients are not available therefore was impossible to assess whether the AP patients predicted within the metabolomic space of CRC were more predisposed to developing cancer.

The capability to correctly classify HCs provides another important challenge for clinical screening. Indeed, other OPLS-DA models have been attempted to distinguish the fecal water spectra of HCs compared to AP + CRC patients yielding an overall predictive accuracy of 85.3% using 1D NOESY binned spectra (Table 2, Supplementary Figure 3A).

Furthermore, separated models were established comparing separately the ^{1}HNMR binned spectra of HCs *vs* CRC, HCs *vs* AP, and CRC *vs* AP patients (Table 2, Supplementary Figure 3B-D). As reported in Table 2, all models built on 1D NOESY bucketed spectra are better performing than those built on CPMG spectra. Supplementary Figure 3 shows the score plots related to the higher predictive accuracy among the models listed in Table 2. The reported models suggest the existence of a metabolomic fingerprint in fecal extracts of CRC and AP compared with HCs, confirming what was previously suggested by PCA and the literature available[24,31-33].

In most biofluids, low mass metabolites coexist with high mass biomolecules such as lipids, proteins, and lipoproteins. Here, two NMR pulse sequences were used to selectively observe the different components: 1D NOESY pulse sequence yields a spectrum in which both signals of metabolites and high molecular weight molecules (*e.g.*, lipids, lipoproteins, and albumin) are visible; the CPMG pulse sequence enables the selective observation of small molecule components in solutions containing macromolecules (*via* T2 filtering). Representative one-dimensional ^{1}H-NMR spectra of fecal extracts obtained with the mentioned pulse sequences are shown in Supplementary Figure 4. Indeed, NOESY experiments, which are sensitive to both low and high molecular weight compounds, resulted more accurate classifiers of all of the cases considered in this study and are described in Table 2 (HCs *vs* AP and CRC: sensitivity 84.9%, specificity 85.7%, predictive accuracy 85.3%; HCs *vs* CRC: sensitivity 85.0%, specificity 88.6%, accuracy 86.8%; HCs *vs* AP: sensitivity 71.7.8%, specificity 83.8%, predictive accuracy 77.8%: AP *vs* CRC: sensitivity 87.4%, specificity 71.6%, predictive accuracy 79.5%).

Metabolic profiles of CRC and AP patients

With the aim of identifying metabolite-level variations characteristic for each group, univariate analyses were applied to the identified fecal metabolites. Marked changes were observed in the metabolic profiles of fecal samples between CRC patients and HCs. Indeed, the first were characterized by a significantly lower content of 3-hydroxyphenylacetate, methanol, galactose, acetate, xylose and isobutyrate and a higher content of glycerol and phenylalanine (Figure 1A). Compared to HCs, AP patients had significantly lower amounts of 3-hydroxyphelylacetate, butyrate, acetate, propionate, isobutyrate and lactate+threonine (considered together because of the overlapping doublets at 1.33 ppm) as reported in Figure 1C. In CRC fecal extract profiles, when compared to AP patients, only leucine, tyrosine, and valine remained statistically significant and were present in higher amounts (Figure 1B). The complete list of fecal extract metabolites identified is reported in Supplementary Table 1. The most relevant pathways identified are reported in Table 3 and Supplementary Figure 5.

The top six identified metabolomic pathways in CRC ($P < 0.05$) were aminoacyl-tRNA biosynthesis, phenylalanine, tyrosine and tryptophan biosynthesis, valine, leucine and isoleucine biosynthesis, phenylalanine and galactose metabolism and valine, leucine and isoleucine degradation. Among them, valine, leucine and isoleucine biosynthesis, aminoacyl-tRNA biosynthesis, valine, leucine and isoleucine

Table 2 Summary of orthogonal projections to latent structures-discriminant analysis models built fecal water spectra acquired using selective one-dimensional proton nuclear magnetic resonance pulse sequences, sensitivity (%), specificity (%) and predictive accuracy (%) assessed following 100 runs of Monte Carlo cross-validation are reported for each model

An integrated analysis based on MetaboAnalyst 4.0 software built on significantly altered metabolites in colorectal cancer (CRC); and adenomatous patients (AP): View of most contributing pathways; *P* is the original *P* value calculated from the enrichment analysis; Holm *P* is the *P* value adjusted by Holm-Bonferroni method; the false discovery rate is the *P* value adjusted using false discovery rate (FDR); Impact is the pathway impact value calculated from pathway topology analysis.

degradation and phenylalanine, tyrosine and tryptophan biosynthesis pathways were also altered in AP patients (Table 3).

DISCUSSION

In this study, we evaluated the fecal metabolomic profiles of CRC and AP patients

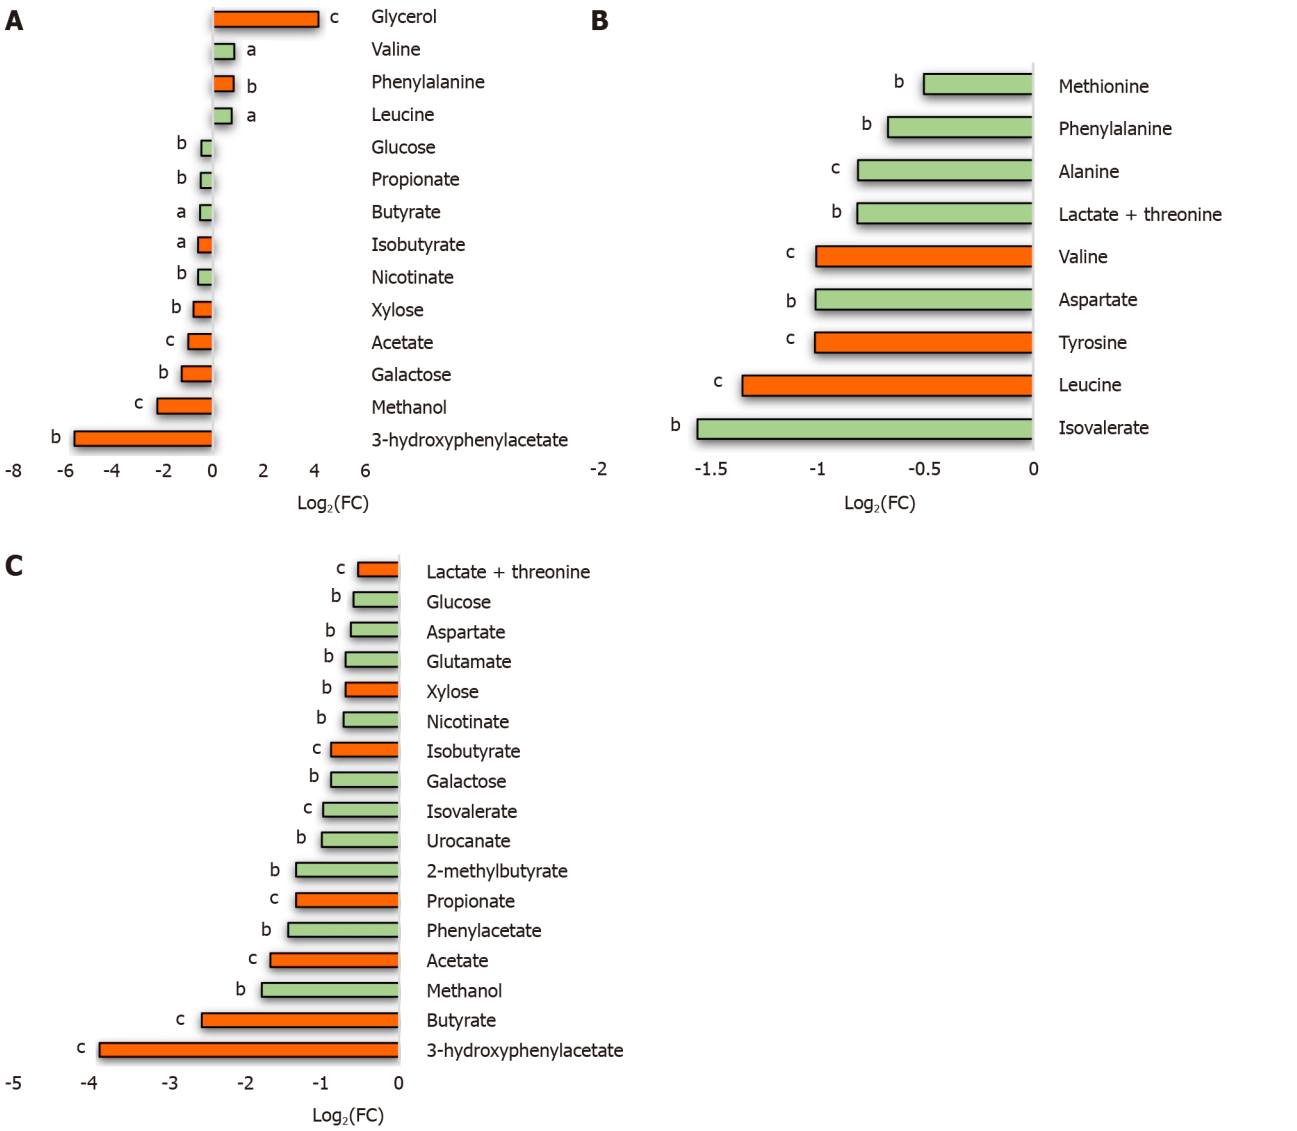

Figure 1 Fecal water metabolite levels of colorectal cancer, polyps' patients and healthy controls. Boxplots of fold-change (FC) values for the significantly altered metabolites. Red bars represent metabolites levels that remain significant after the false discovery rate (FDR) correction (FDR $P < 0.05$), green bars are the metabolites that are no more significant after the FDR correction ($P < 0.05$). Cliff's delta effect size is also reported for each metabolites in the comparisons (a: Small effect, b: Medium effect, c: Large effect). A: Comparison between healthy controls (HCs) and colorectal cancer (CRC) patients, negative $\log_2$ (FC) values mean lower metabolite levels in CRC fecal samples, positive $\log_2$(FC) values report higher content in CRC compared to HCs; B: Negative $\log_2$(FC) represent higher metabolite levels in CRC patients compared to polyp patients; C: Comparison between HCs and polyp patient-negative $\log_2$(FC) values mean lower metabolite levels in polyp patients fecal water.

with respect to HCs using NMR spectroscopy. The metabolome is a quantitative collection of low molecular weight compounds generated by metabolism[34]. Metabolomics is an emerging field of research downstream from genomics, proteomics, and transcriptomics. The metabolic screening of stool samples, which reflects the colorectal status, might contribute to the development of non-invasive screening tests[35,36]. The power of metabolomics consists in the capacity to detect and characterize tumors because cellular metabolism alterations represent a key hallmark of cancer[37]. To date, studies evaluating fecal metabolic changes associated with CRC are still lacking. Notably, no study has described fecal metabolomic changes associated with adenoma. Despite the high variability in fecal water profiles, reliable metabolic differences between patients and HCs were observed by preliminary analyses of the spectra. First, the PCA of the ^{1}H-NMR spectral data was carried out to identify some trends and outliers, showing some separation among cancer, adenoma, and HC groups. However, this unsupervised approach does not seem to clearly characterize the groups. These results were not surprising in light of the inter-individual variability introduced with diet, lifestyle, sex *etc.*

To optimize the separation among groups, we used OPLS-DA MCCV models, which were effective in discriminating the fecal metabolomic fingerprints of CRC patients and HCs (overall predictive accuracy of 93.7%). From the above analyses we can conclude that both low and high molecular weight molecules, visible using the 1D NOESY pulse sequence, are important to characterize at metabolic level the two pathological profiles. Moreover, the capability to accurately predict HCs when compared to patients with colonic AP or adenomas and CRC patients (showed predictive accuracy of 85.3%) using ^{1}H-NMR fecal water spectra, could be tested on a larger number of subjects to develop fast screening following a positive fecal occult blood test in order to spare colonoscopy in some patients who have bleeding due to other reasons[38,39].

In detail, the short-chain fatty acids (SCFAs) were found to be significantly decreased in CRC and AP patients, and in particular, lower levels of acetate were observed with respect to the HCs. SCFAs are microbial-derived metabolites, produced through gut bacteria fermentation of complex carbohydrates. SCFAs can be absorbed by the colonic epithelium, suppling energy and playing a crucial role in the regulation of fatty acids, glucose, and cholesterol metabolism[40-43]. A decrease in SCFA abundance is strictly linked to an unhealthy gut microbiota status, and alterations in the fecal SCFA profile may be the result of gut microbiota dysbiosis, inflammatory changes, or both[44]. Our data confirmed what has been previously reported by other studies. In particular, the analyses by Lin *et al*[45] demonstrated a high diagnostic performance of fecal acetate in CRC patients with respect to HCs.

In contrast with previous data, we did not find decreased levels of butyric acid in CRC patients with respect to HCs; however, we observed significantly decreased levels in AP. Butyric acid has an important homeostatic role in the human colon, and *in vitro* and *in vivo* studies have demonstrated its ability in preventing CRC[46-48]. However, other studies have showed contrasting results, suggesting a pro-cancer role of butyric acid, and low levels of butyrate usually seem to be linked with CRC development[31,35]. This double-edged role is named "butyrate paradox"[49,50]. Our results could be very interesting in this respect, suggesting that low levels of butyric acid in adenoma could lead to CRC development, while "normal" levels of butyrate in CRC could support cancer progression and promote the differentiation of regulatory T cells, which show a pro- tumorigenic role[51], especially in advanced CRC.

In addition, we found significantly low levels of 3-hydroxyphenylacetic (3-HPAA) acid in both CRC and AP patients. 3-HPAA acid is a weak acid and one of the most abundant products of polyphenol degradation in the large intestine[52,53]. Food polyphenols are broken down into other phenolic compounds by colonic bacteria action. In this way, poorly absorbable large-size polyphenols are converted to small-sized bioavailable metabolites, including 3-HPAA, which could be more biologically active[54,53]. Polyphenolic colon metabolites could be important endogenous antioxidants able to scavenge excess of free radicals, suppressing their effects on protein, lipid, and DNA damage[55]. A recent study demonstrated that polyphenol metabolites produced by colonic microbiota reduce some enzymatic activities involved in human tumorigenesis[56]. 3-HPAA can act as a CRC preventive agent by inhibition of cyclooxygenase-2 (COX-2)[57], a mediator of inflammation that is significantly overexpressed in a variety of human malignancies. Moreover, some studies have reported that COX-2 inhibitors not only prevent tumor formation but also decrease the number of already established polyps in patients with familial AP[58]. Accordingly, our results suggest that low levels of 3-HPAA are insufficient to inhibit COX-2, and consequently COX-2 expression can promote the development, tumor growth, immune suppression, angiogenesis, and metastasis of cancer cells.

Furthermore, higher amounts of amino acids such as leucine, tyrosine and valine, were present in the stool of CRC patients (compared to AP), probably resulting from malabsorption due to large epithelial inflammation and damage associated with CRC [59]. Previous metabolomic studies on fecal water have suggested that amino acid concentrations mirror the malabsorption of nutrients caused by the malfunction of epithelium barrier protection[60]. In agreement with previous studies, we documented higher levels of amino acids in the fecal water of CRC patients[31,35,61]. Alterations of amino acid levels can be associated with altered cancer cell activities, including the synthesis of proteins or catabolism to provide energy and/or other metabolite substrates.

CONCLUSION

In summary, our NMR metabolomics investigation revealed for the first time that fecal sample profiles can discriminate among CRC AP, AP patients and HCs, and some discriminatory metabolites were identified including acetate, butyrate, propionate, 3-HPAA acid, valine, tyrosine, and leucine. These altered metabolites suggest that changes in CRC and adenoma are associated with different pathway perturbations including valine, leucine and isoleucine biosynthesis, aminoacyl-tRNA biosynthesis, valine, leucine and isoleucine degradation phenylalanine, tyrosine and tryptophan biosynthesis, phenylalanine metabolism and galactose metabolism. In conclusion, we are confident that our data can be a forerunner for future studies on CRC management, especially the diagnostics and evaluation of the effectiveness of the treatments.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is globally the third most common cause of death. If diagnosed at an early stage, CRC shows a good response to therapy and usually a better prognosis. Unfortunately, despite its invasiveness, colonoscopy represents the gold-standard screening procedure for CRC.

Research motivation

Considering that colonoscopy is an expensive and invasive procedure, it seems to be essential to introduce custom-made methodologies combining minimal invasiveness, safety, and reproducibility. Fecal sample screening has many advantages with respect to other screening techniques.

Research objectives

The main objective of our study was to compare with HCs (HCs) the fecal nuclear magnetic resonance (NMR) metabolomic profiles of patients with CRC or adenomatous polyposis (AP) to characterize the variations among the groups and potentially identify some diagnostic markers.

Research methods

In order to define the fecal metabolic profile of 32 CRC, 16 AP patients and 38 HCs we used proton nuclear magnetic resonance spectroscopy in combination with multivariate and univariate statistical approaches.

Research results

The NMR spectra of 86 fecal extract samples have been acquired. With the aim of identifying metabolite level variations characteristic for each group, univariate analyses were applied to the identified fecal metabolites. The most marked changes were observed in the metabolic profiles of fecal samples of CRC patient *vs* HCs. AP patients, compared to HCs show significant lower amount of 3-hydroxyphelylacetate, butyrate, acetate, propionate, isobutyrate and lactate+threonine. In CRC fecal extract profiles, when compared to AP patients, only leucine, tyrosine, and valine remained statistically significant and present in higher amounts.

Research conclusions

The metabolic screening of stool samples might contribute to the development of non-invasive screening tests. To date, studies evaluating fecal metabolic changes associated with CRC are still lacking. Furthermore, no study has described fecal metabolomic changes associated with adenoma. The short-chain fatty acids were found to be significantly decreased in CRC and AP patients, and in particular, lower levels of acetate were observed with respect to HCs. In contrast with previous data, we did not find decreased levels of butyric acid in CRC patients compared to HCs; however, we observed significantly decreased levels in AP patients. We showed significantly low levels of 3-hydroxyphenylacetic (3-HPAA) acid in both CRC and AP patients. Finally, higher amounts of amino acids such as leucine, tyrosine, and valine were present in the stool of CRC patients (compared to AP), probably resulting from malabsorption due to large epithelial inflammation and damage.

Research perspectives

For the first time, we showed that fecal sample profiles can discriminate among CRC patients, AP patients and HCs, and some discriminatory metabolites were identified including acetate, butyrate, propionate, 3-HPAA acid, valine, tyrosine, and leucine. We believe that our data will be a starting point for future studies on CRC management, especially the diagnostics and evaluation of the effective of the treatments.

Abstract

BACKGROUND

We hypothesized that thermal damage accumulation during endoscopic submucosal dissection (ESD) causes the pathogenesis of post-ESD electrocoagulation syndrome (PECS).

AIM

To determine the association between Joule heat and the onset of PECS.

METHODS

We performed a retrospective cohort study in patients who underwent colorectal ESD from May 2013 to March 2021 in Japan. We developed a novel device that measures swift coagulation time with a sensor adjacent to the electrosurgical coagulation unit foot switch, which enabled us to calculate total Joule heat. PECS was defined as localized abdominal pain (visual analogue scale ≥ 30 mm during hospitalization or increased by ≥ 20 mm from the baseline) and fever (temperature ≥ 37.5 degrees or white blood cell count ≥ 10000 μ/L). Patients exposed to more or less than the median Joule heat value were assigned to the high and low Joule heat groups, respectively. Statistical analyses included Mann-Whitney U and chi-square tests and logistic regression and receiver operating characteristic curve (ROC) analyses.

RESULTS

We evaluated 151 patients. The PECS incidence was 10.6% (16/151 cases), and all

patients were followed conservatively and discharged without severe complications. In multivariate analysis, high Joule heat was an independent PECS risk factor. The area under the ROC curve showing the correlation between PECS and total Joule heat was high [0.788 (95% confidence interval: 0.666-0.909)].

CONCLUSION

Joule heat accumulation in the gastrointestinal wall is involved in the onset of PECS. ESD-related thermal damage to the peeled mucosal surface is probably a major component of the mechanism underlying PECS.

Key Words: Post-endoscopic submucosal dissection electrocoagulation syndrome; Joule heat; Colorectal endoscopic submucosal dissection; Colorectal neoplasms; Electrocoagulation; Gastrointestinal tract

INTRODUCTION

Colorectal endoscopic submucosal dissection (ESD), a minimally invasive operation, is the best endoscopic procedure for *en bloc* resection of superficial colorectal tumors[1-4]. However, ESD is associated with severe complications, with rates of perforation and bleeding of 2% to 14% and 0.7% to 3.1%, respectively[4-10]. Post-ESD electrocoagulation syndrome (PECS) is another notable adverse event that can occur after colorectal ESD. The incidence of PECS is 9% to 40%, although most cases improve with conservative therapy[11-15]. In addition, PECS sometimes manifests as a delayed perforation. Therefore, physicians require clinically useful PECS predictors to identify patients who are at risk[12,16].

Currently, two main hypotheses explain the mechanism underlying PECS. One suggests that ESD exposes the mucosa, which is then infected by intestinal bacteria, resulting in inflammation[13,17]. The other proposes that the peeled mucosal surface is inflamed by thermal damage during ESD[13,18]. Interestingly, a clipping closure method performed to prevent intestinal bacteria from infecting the exposed mucosa did not reduce the onset of PECS[19]. In contrast, few studies have examined the impact of thermal damage during ESD on the onset of PECS.

We have often encountered patients with PECS who underwent a lengthy colorectal ESD, and previous studies of PECS risk factors implicated prolonged ESD procedures [20,21]. We hypothesized that electrocoagulation is associated with Joule heat capable of causing thermal damage to the gastrointestinal wall during long ESD operations. Therefore, we aimed to determine the association between Joule heat and the onset of PECS.

statement: The Hitachi General Hospital Institutional Review Board approved this study (2019-97, 2020-1), and it was performed according to the ethical guidelines of the 1964 Declaration of Helsinki and its later amendments.

Informed consent statement: Informed consent was obtained using an opt-out option on the Hitachi General Hospital's website (see institution website uniform resource locators: http://www.hitachi.co.jp/hospital/hitachi/infor/opto-out/index.html).

Conflict-of-interest statement: All the authors have no conflict of interest related to the manuscript.

Data sharing statement: The original anonymous dataset is available on request from the corresponding author at maochi-tei@umin.ac.jp.

STROBE statement: The authors have read the STROBE Statement - checklist of items, and the manuscript was prepared and revised according to the STROBE Statement -checklist of items.

MATERIALS AND METHODS

Study design and patient selection

We performed a retrospective study in patients who underwent colorectal ESD at Hitachi General Hospital in Japan from May 2013 to March 2021. Case selection was according to the indications for colorectal ESD established by the Japan Gastroenterological Endoscopy Society guidelines[22]. Therefore, our inclusion criteria were as follows: (1) Laterally spreading tumors of the non-granular type with the Vi-type pit pattern, carcinomas with shallow T1 submucosal (SM) invasion, large depressed-type tumors, and large protruded-type tumors that are difficult to remove en bloc by endoscopic mucosal resection; and (2) Mucosal tumors with SM fibrosis. Patients with multiple colorectal neoplasms or apparent deeply invasive T1 SM carcinoma were excluded. R0 resection was defined as no cancer cells seen microscopically at the primary tumor site. We converted the swift-coagulation mode time, measured by an electrosurgical-coagulation unit with a high-frequency generator (VIO 300D, ERBE Co. Ltd., Tubingen, Germany), to Joule heat.

The Hitachi General Hospital Institutional Review Board approved the study (No. 2019-97, 2020-1), and our research was performed according to the ethical guidelines of the 1964 Declaration of Helsinki and its later amendments. The study is registered on the University Hospital Medical Information Network (ID: UMIN000038704, UMIN 000041580). Although our ethics committee waived the requirement for informed consent from each patient because we used anonymized data, we obtained informed consent using an opt-out option on our facility's website (uniform resource locator below).

PECS definition

PECS was defined as localized abdominal pain and fever without apparent perforation after colorectal ESD. We used a visual analog scale (VAS) to evaluate localized abdominal pain. Nurses who were not research participants administered the VAS. The pain criteria were defined as a score ≥ 30 mm from the postoperative day (POD) 1 to discharge or increased by ≥ 20 mm from the hospital admission VAS score. Our fever criteria were body temperature ≥ 37.5 degrees or white blood cell count ≥ 10000 μ/L from POD 1 to discharge.

Colorectal ESD procedures

All patients underwent bowel preparation (polyethylene glycol, 2 L) before colorectal ESD. Then, the patients were sedated in the endoscopy room using intravenous injections of pentazocine (15-30 mg/kg body weight). We added midazolam (1-3 mg/session) if pentazocine was insufficient for sedation. Electrocardiogram monitoring was performed in each case. The procedures were performed by 10 endoscopists (one expert colorectal endoscopic surgeon and 9 less experienced colorectal endoscopic surgeons). An expert was defined as an endoscopist who performed more than 40 colorectal ESDs[23]. We used a water-jet system colonoscope (PCF-Q260JI, Olympus Corporation, Tokyo, Japan) with a transparent hood (DH-29CR for scope tip, Fujifilm, Tokyo, Japan) attached to the scope tip. Marking, mucosal incision, and mucosal detachment were performed with a dual knife (KD-655Q, Olympus Corporation). We injected 0.4% sodium hyaluronate acid diluted in physiological saline into the SM layer directly below the lesion before mucosal detachment. A coagrasper (FD-411QR, Olympus Corporation) and an endoscopic clip (HX-610-090, Olympus Corporation) were used to obtain hemostasis.

Calculating Joule heat

We used the electrosurgical-coagulation unit to detach the lesion's colorectal mucosa. We changed the setting mode according to the procedure step and used dry-cut, swift-coagulation, and soft-coagulation modes. We calculated the power applied using the diagram in the manufacturer's technical manual that shows the relationship between resistance (Ω) and power (W) in the swift-coagulation mode (Supplementary material). As human internal resistance is 1000-1600 Ω[24], the lesion resistance was defined as 1300 Ω. Thus, lesions are detached while the electrosurgical-coagulation unit automatically adjusts the power output. However, this automatic power adjustment is difficult to monitor.

The curve describing the relationship between power (vertical axis) and resistance (horizontal axis) in the manufacturer's technical diagram (we used effect 4 in our study) showed that the power corresponding to 1300 Ω is 50 W (Supplementary material). Therefore, we obtained the formula: power consumption (J) = power (W) ×

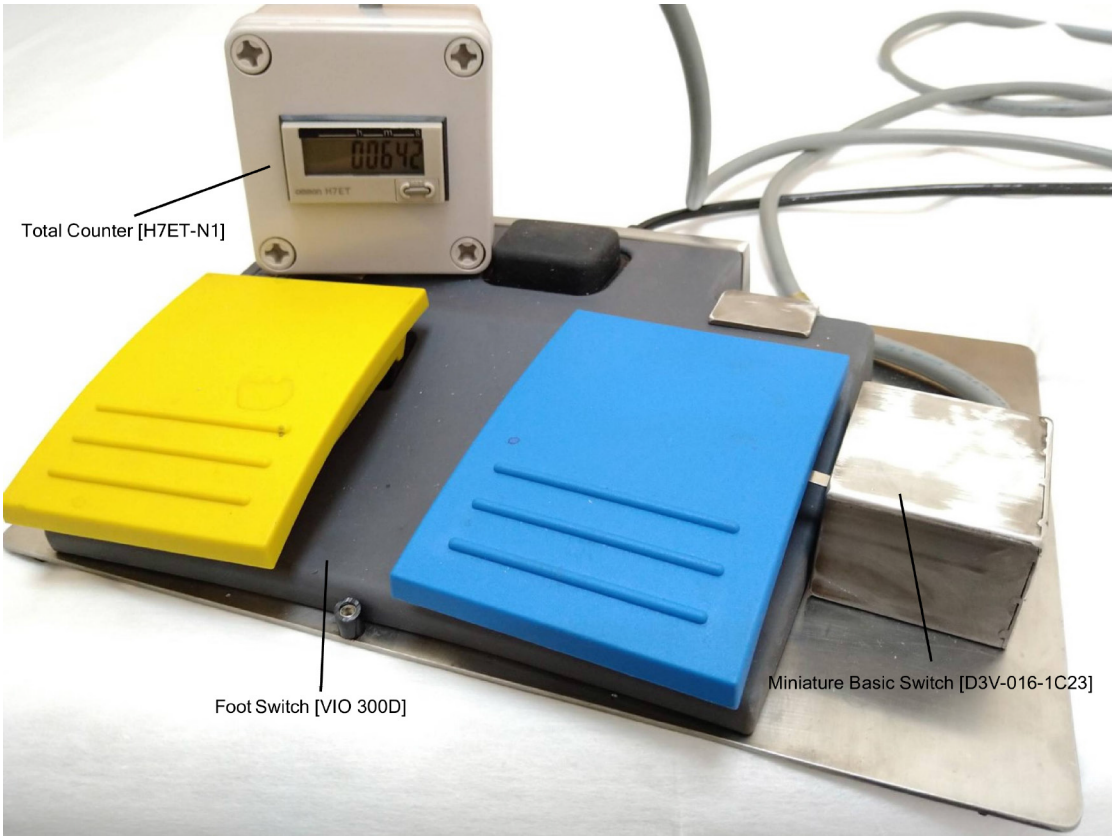

Figure 1 A novel device for measuring the swift-coagulation mode time with a sensor adjacent to the foot switch of the electrosurgical coagulation unit.

time (s) from the relationship between power and power consumption. We used this formula to calculate the total Joule heat applied to the lesion.

We developed a novel device to measure the swift coagulation time with a sensor [Miniature Basic Switch (D3V-016-1C23), OMRON Corporation, Kyoto, Japan] adjacent to the foot switch of the electrosurgical coagulation unit (Figure 1). This sensor was activated when the operator stepped down on the foot switch, and the swift-coagulation mode time was recorded by a counter [Total Counter (H7ET-N1), OMRON Corporation]. In cases where the swift-coagulation time was not measured, we retrospectively calculated the time using the data (swift-coagulation mode time/procedure time: Mean 3%) obtained from the measured cases. Patients exposed to more or less than the median Joule heat value (8460 J) were assigned to the high and low Joule heat groups, respectively.

Post-ESD hospitalization

In all patients, on POD 1, the vital signs and a blood sample were examined to check for bleeding, the pain VAS was administered, and radiography was performed to check for free air. We considered a fever, localized abdominal pain, or increased C-reactive protein suspicious for delayed perforation associated with PECS. If the pain or fever criteria were satisfied, we performed computed tomography. In the absence of adverse findings, patients resumed eating, starting with dinner on POD 1. If no fever, localized abdominal pain, or bleeding occurred after eating resumed, patients were discharged on POD 6.

Statistical analysis

We analyzed continuous and categorical variables using Mann-Whitney U and chi-square tests, respectively. In our multivariate analysis, we performed logistic regression analyses using important factors identified by univariate analysis. We determined the cutoff of the total Joule heat value that predicted the onset of PECS using receiver operating characteristic (ROC) curve analysis. A P value less than 0.05 was considered statistically significant. All statistical analyses were performed using SPSS software (version 26, IBM Corp., Armonk, NY, United States). The statistical methods of this study were reviewed by Masanori Ochi from the Department of

Gastroenterology, Hitachi General Hospital, Japan.

RESULTS

Baseline characteristics

Of 170 patients admitted for colorectal ESD, 19 met the exclusion criteria (multiple lesions, *n* = 6; post-ESD infection, *n* = 2; perforation during ESD, *n* = 7; ESD discontinuation, *n* = 4) (Figure 2). We analyzed the remaining 151 patients [mean age, 67.3 years (range 39-92); male, 62.3%]. Tumors occurred in the right colon (*n* = 59, 39.1%), left colon (*n* = 41, 27.2%), and rectum (*n* = 51, 33.8%); R0 and *en bloc* resections were achieved in 115 patients (76.2%) and 135 patients (89.4%), respectively; and PECS occurred in 16 patients (10.6 %) (Table 1).

Primary outcome

The high (*n* = 76) and low (*n* = 75) Joule heat groups showed no statistically significant difference in sex; tumor morphology, location, or depth of pathological invasion; R0 resection rate; or incidence of SM fibrosis (Table 2). Univariate analyses revealed that patient age was significantly greater, and the PECS incidence was significantly higher in the high Joule group than in the low Joule group; the specimen size was also significantly larger in the high Joule group. Compared to the low Joule heat group, the high Joule heat group included more patients who had undergone ESD performed by a trainee, and the difference was significant. In addition, the R0 resection rate was significantly higher in the low Joule group. Multivariate analysis showed that the R0 resection rate [odds ratio (OR), 3.27; 95% confidence interval (CI): 1.26-8.45; $P = 0.01$] and PECS incidence (OR, 4.83; 95%CI: 1.08-21.50; $P = 0.03$) were significantly higher and the specimen size (OR, 1.07; 95%CI: 1.03-1.11; $P < 0.01$) and number of ESD procedures performed by a trainee (OR, 5.30; 95%CI: 2.32-12.10; $P < 0.01$) were significantly larger in the high Joule heat group than in the low Joule heat group (Table 3).

PECS and Joule heat correlation analysis

The area under the ROC curve showing the correlation between PECS and total Joule heat was 0.788 (95%CI: 0.666-0.909), and the PECS onset cutoff value was 15390 J (sensitivity, 0.625; specificity, 0.822) (Figure 3).

DISCUSSION

To our knowledge, this study, performed using our novel device, is the first to indicate high total Joule heat exposure during colorectal ESD as a PECS risk factor. Additionally, PECS and Joule heat were highly correlated, and the Joule heat cutoff value where PECS occurred was 15390 J.

PECS is a state of temporary inflammation resulting from transmission of electrocoagulation heat to the resection site muscle layer and serous membrane during endoscopic therapy[18,25,26]. Previously reported PECS risk factors include tumor location[11,13,20,27], SM fibrosis[27], long procedure time[20,21], and specimen diameter[11,13]. Long procedures lead to the occurrence of PECS due to increased electrical current load on the gastrointestinal wall[11]. Additionally, ischemic changes occur in the gastrointestinal wall due to excessive current during incision, dissection, and hemostasis[28]. These reports suggest that Joule heat of the peeled mucosal surface is associated with the occurrence of PECS.

A study of lengthy procedures (mean, 90 min) demonstrated that long procedure time is a PECS risk factor[20]. However, several studies that did not include long procedure time as a PECS risk factor showed that the procedures were short (range, 52-67 min)[11,28,29]. Our study revealed that ESD procedures performed by trainees are associated with the onset of PECS. A previous study showed that ESD procedures performed by trainees are longer than those performed by experienced endoscopists [23]. Because the swift-coagulation mode time probably increases as the procedure time lengthens, high Joule heat accumulation is likely to occur during long ESDs, causing severe damage to the peeled mucosal surface, leading to PECS. Previous studies were limited in that they did not consider the impact of the ESD procedure time on the Joule heat delivered to the lesion. In this study, measurement of swift-coagulation mode time allowed us to investigate the association between PECS and

surface is involved in the development of PECS. Furthermore, using the total Joule heat cutoff value of PECS occurrence could allow the introduction of PECS prevention measures, including online measurement of swift-coagulation mode time during colorectal ESD. For example, an online PECS alert system is promising.

Limits of the study

First, because this was a retrospective cohort study, we could not rule out poor endoscope operability as a confounding factor. Second, as this was a single-center study, selection bias cannot be excluded. Nevertheless, we imposed strict inclusion and exclusion criteria to mitigate selection bias to the greatest extent possible. Last, the sample size was small. In the future, a prospective study should be performed to establish the validity of our results.

CONCLUSION

We found that Joule heat accumulation within the gastrointestinal wall is involved in the onset of PECS. ESD-related thermal damage to the mucosal peeled surface is probably a major component of the mechanism underlying PECS.

ARTICLE HIGHLIGHTS

Research background

Few studies have examined the impact of endoscopic submucosal dissection (ESD)-related thermal damage on the onset of post-ESD electrocoagulation syndrome (PECS).

Research motivation

We hypothesized that electrocoagulation is associated with Joule heat capable of causing thermal damage to the gastrointestinal wall during long ESD operations.

Research objectives

We aimed to determine the association between high Joule heat and the onset of PECS.

Research methods

We developed a novel device to measure the swift coagulation time with a sensor adjacent to the electrosurgical coagulation unit foot switch, which enabled us to calculate total Joule heat. PECS was defined as localized abdominal pain (visual analogue scale ≥ 30 mm during hospitalization or increased by ≥ 20 mm from the baseline) and fever (temperature ≥ 37.5 degrees or white blood cell count ≥ 10000 μ/L). Patients exposed to more or less than the median Joule heat value were assigned to the high and low Joule heat groups, respectively.

Research results

We evaluated 151 patients. The PECS incidence was 10.6% (16/151 cases), and all patients were followed conservatively and discharged without severe complications. In multivariate analysis, high Joule heat was an independent PECS risk factor. The area under the ROC curve showing the correlation between PECS and total Joule heat was high [0.788 (95% confidence interval: 0.666-0.909)].

Research conclusions

Joule heat accumulation in the gastrointestinal wall is involved in the onset of PECS. ESD-related thermal damage of the peeled mucosal surface is probably a major component of the mechanism underlying PECS.

Research perspectives

Future prospective studies should be performed to establish the validity of our results.

Abstract

BACKGROUND

Acute kidney injury (AKI) is one of the most common acute pancreatitis (AP)-associated complications that has a significant effect on AP, but the factors affecting the AP patients' survival rate remains unclear.

AIM

To assess the influences of AKI on the survival rate in AP patients.

METHODS

A total of 139 AP patients were included in this retrospective study. Patients were divided into AKI group (n = 72) and non-AKI group (n = 67) according to the occurrence of AKI. Data were collected from medical records of hospitalized patients. Then, these data were compared between the two groups and further

GD, and Gao Y performed manuscript review; All authors have read and approved the content of the manuscript; and Shi N and Sun GD contributed equally to this work.

analysis was performed.

RESULTS

AKI is more likely to occur in male AP patients (P = 0.009). AP patients in AKI group exhibited a significantly higher acute physiologic assessment and chronic health evaluation II score, higher Sequential Organ Failure Assessment score, lower Glasgow Coma Scale score, and higher demand for mechanical ventilation, infusion of vasopressors, and renal replacement therapy than AP patients in non-AKI group (P < 0.01, P < 0.01, P = 0.01, P = 0.001, P < 0.01, P < 0.01, respectively). Significant differences were noted in dose of norepinephrine and adrenaline, duration of mechanical ventilation, maximum and mean values of intra-peritoneal pressure (IPP), maximum and mean values of procalcitonin, maximum and mean serum levels of creatinine, minimum platelet count, and length of hospitalization. Among AP patients with AKI, the survival rate of surgical intensive care unit and in-hospital were only 23% and 21% of the corresponding rates in AP patients without AKI, respectively. The factors that influenced the AP patients' survival rate included body mass index (BMI), mean values of IPP, minimum platelet count, and hospital day, of which mean values of IPP showed the greatest impact.

CONCLUSION

AP patients with AKI had a lower survival rate and worse relevant clinical outcomes than AP patients without AKI, which necessitates further attention to AP patients with AKI in surgical intensive care unit.

INTRODUCTION

Acute pancreatitis (AP) is an excessive inflammatory response caused by digestion of the pancreas itself, which can further lead to local and distant organ damage, or even single or multiple organ failure. In the wake of continuous in-depth understanding of pathophysiological mechanism of AP and improvement of treatment measures, AP-related mortality rate is annually declining, whereas AP-associated hospitalization rises year-by-year worldwide[1,2]. In clinical practice, about 80% of the common etiologies are attributed to gallstones and alcohol consumption[3], however, the proportion of different etiologies significantly varies among different countries. In addition, hypertriglyceridemia is a high-risk factor for AP, and may lead to direct damage to pancreas and pancreatic exocrine function[4,5]. Thus, identification of

etiologies is highly essential to manage better AP patients. AP can be categorized into mild acute pancreatitis (MAP), moderately severe acute pancreatitis (MSAP), and severe acute pancreatitis (SAP) according to the presence and duration of organ failure presented in the revised Atlanta classification (2013)[6]. The mortality rate is high among SAP patients, reaching 15%-30% or even higher[7], due to persistent organ failure. Therefore, earlier identification and appropriate use of intensive care support can be conducive to prevent further disease progression, thereby improving AP patients' prognosis[8].

Acute kidney injury (AKI) is one of the most common AP-associated complications, resulting from uncontrolled inflammatory response, release of pancreatic amylase, hypovolemia, insufficient renal perfusion, micro-circulatory disturbance, intra-abdominal hypertension, and reactive oxygen species[9]. At present, AKI is mainly diagnosed based on the criteria presented by the Kidney Disease Improving Global Outcomes (KIDGO) guidelines[10,11]. The incidence of AKI has gradually, while steadily, increased year-by-year worldwide[12]. AKI can deteriorate AP patient's medical status and is an independent risk factor for increased mortality and development of chronic kidney disease (CKD). When AKI and AP occur simultaneously, a worse clinical prognosis is expected[13,14], involving longer period of hospitalization and higher mortality rate. However, in clinical practice, there is no an effective therapeutic approach for AKI except for renal replacement therapy (RRT)[15]. AKI has imposed a huge medical burden in China as well as in the world. Therefore, development of early detection and prevention measures is highly significant to avoid adverse outcomes associated with AKI[16].

Although previous studies have confirmed that concurrent AKI is associated with a poor prognosis[17], there is no reliable research assessing the influences of AKI on Chinese AP patients' survival rate who were hospitalized at surgical intensive care unit (SICU). Hence, to address this scientific gap, the current retrospective study was conducted.

MATERIALS AND METHODS

Study design

This retrospective study enrolled 139 AP patients who were admitted to the SICU of The Second Affiliated Hospital of Harbin Medical University (Harbin, Heilongjiang Province, China) between January 2014 and March 2019. Baseline and clinical data were collected during hospitalization. The enrolled AP patients were divided into AKI group (n = 72) and non-AKI group (n = 67) according to occurrence of AKI. This study was approved by the Ethics Committee of The Second Affiliated Hospital of Harbin Medical University.

Study population

The inclusion criteria for this retrospective study were as follows: Patients who were admitted to the SICU of The Second Affiliated Hospital of Harbin Medical University; patients who were diagnosed with AP; patients' age > 18-years-old. The exclusion criteria were as follows: Pregnant or breastfeeding women; patients with CKD; patients with recurrent pancreatitis; patients who received renal transplantation; incomplete medical data.

Diagnosis of AP

A combination of medical history, symptoms and physical examinations, laboratory tests, and radiographic examinations (*e.g.*, abdominal ultrasound, contrast-enhanced computed tomography, or magnetic resonance imaging) was applied to confirm the diagnosis of AP. A limited number of diagnosed AP patients were eventually confirmed by undergoing exploratory laparotomy.

Diagnosis and classification of AKI

Diagnosis and classification of AKI were conducted based on the criteria presented by the KIDGO guidelines (2012)[18], in which serum creatinine criteria was defined as an increased absolute value in serum creatinine level of ≥ 0.3 mg/dL (≥ 26.4 μmol/L) or a percentage increase in serum creatinine level of ≥ 50% within 48 h. Baseline serum creatinine level was defined as the lowest serum creatinine level measured within 2 d prior to admission to SICU. If no serum creatinine level was measured, the serum creatinine level recorded in the first measurement within 2 d after admission to SICU

was considered as baseline serum creatinine level.

RRT

In the present study, all AP patients who needed to undergo RRT were managed with continuous veno-venous hemofiltration (CVVH), anti-coagulation with heparin, and fixed pre- and post-dilution strategies. Blood flow rates, amount of substitute fluid, and dehydration volume were individually adjusted according to each patient's medical status.

Measurement of serum procalcitonin level and intra-peritoneal pressure

Serum procalcitonin (PCT) level was intermittently measured after AP patients' admission to SICU through Mini-VIDAS (Hain Lifescience GmbH; Nehren, Germany). Intra-peritoneal pressure (IPP) was indirectly reflected *via* measuring intravesical pressure with Freund's catheter.

Data collection

Baseline and clinical data, including patients' age, gender, body mass index (BMI), Acute Physiologic Assessment and Chronic Health Evaluation II (APACHE II) score, Sequential Organ Failure Assessment (SOFA) score, Glasgow Coma Scale (GCS) score, duration of mechanical ventilation (MV), abdominal puncture drainage, gallbladder puncture drainage, infusion of vasopressors, demand of RRT, IPP, body temperature, PCT, creatinine, platelet count, hospital day, and prognosis were collected from medical records of hospitalized patients. APACHE II score and SOFA score were calculated by the first 24 h clinical data after SICU admission.

Statistical analysis

Variables conforming to normal distribution were described as mean ± SD, while those abnormally distributed variables were expressed as median (range). Normality analysis was applied to continuous data. SPSS 22.0 software (IBM, Armonk, NY, United Sates) was used to carry out statistical analyses. Independent-samples *t*-test was used to perform inter-group comparison for normally distributed data, while Mann-Whitney *U* test was employed for inter-group comparison for abnormally distributed data. Classification data were expressed by the number of samples, and χ^2 test was adopted. The prognosis of AP patients who were admitted to SICU was analyzed by binary logistic regression analysis, while the remaining indicators were analyzed by the *t*-test or Mann-Whitney *U* test. P value < 0.05 was considered statistically significant.

RESULTS

Patients' baseline and clinical data

A total of 139 AP patients were enrolled in this retrospective study. The enrolled AP patients were divided into AKI group (n = 72) and non-AKI group (n = 67) according to occurrence of AKI. As shown in Table 1, AKI was more likely to occur in male AP patients (P = 0.009). AP patients with AKI exhibited a significantly higher APACHE II score, higher SOFA score, lower GCS score, and higher demand for MV, infusion of vasopressors, and RRT than non-AKI AP patients (P < 0.01, P < 0.01, P = 0.01, P = 0.001, P < 0.01, P < 0.01, respectively). No significant difference was observed in the remaining baseline and clinical data, including patients' age, BMI, proportion of abdominal puncture drainage, and gallbladder puncture drainage.

Vasopressor infusion

There were significant differences in types of vasopressors and proportion of norepinephrine, adrenaline, and vasopressor infusion between the two groups (Table 2).

Analysis of prognostic indicators

Significant differences were noted in dose of norepinephrine and adrenaline, duration of MV, maximum and mean values of IPP, maximum and mean values of PCT, maximum and mean serum levels of creatinine, minimum platelet count, prognosis of AP patients admitted to SICU, and hospital day between the two groups (Table 3). Among AP patients with AKI, the survival rates of SICU and in-hospital were only 23% and 21% of the corresponding rates in AP patients without AKI, respectively.

AKI: Acute kidney injury; APACHE II: Acute Physiology and Chronic Health Evaluation II; BMI: Body mass index; GCS: Glasgow Coma Scale; MV: Mechanical ventilation; RRT: Renal replacement therapy; SOFA: Sequential Organ Failure Assessment.

Analysis of the related factors influencing AP patients' survival rate

The factors influencing the AP patients' survival rate who were hospitalized at SICU included BMI, mean values of IPP, minimum platelet count, and hospital day. Among these factors, mean values of IPP showed the greatest effect (Table 4). The values of area under the receiver operating characteristic (ROC) curve for the four factors related to patients with or without AKI were calculated to predict the AP patients' survival rate, and were 0.896 and 0.891, respectively (Figure 1 and Table 5; $P > 0.5$). However, there was no significant different in values of the area under the two ROC curves. The sensitivity and specificity of the two ROC curves were approximately the same [sensitivity (80.6%) *vs* specificity (88.0%)].

Risk thresholds of the related factors

Risk thresholds of BMI, mean values of IPP, minimum platelet count, and hospital day were ≥ 24, ≥ 23, ≤ 77, and ≤ 4, respectively, which indicated that BMI ≥ 24, mean values of IPP ≥ 23, minimum platelet count ≤ 77, and hospital day ≤ 4 were risk factors for AP patients' survival rate who were hospitalized at SICU.

DISCUSSION

Excessive secretion and/or poor drainage of pancreatic juice are the essence of AP onset. With the increasing incidence of gallstones and alcohol abuse, AP had become a

AKI: Acute kidney injury.

common gastrointestinal disorder. The majority of cases with AP are MAP characterized by no new onset of organ dysfunction, whereas SAP not only leads to new onset of organ dysfunction, but also lasts for more than 48 h[6]. With aggravation of the condition from MAP to SAP, the length of stay at SICU and mortality rate significantly increased. Hence, SAP patients should be managed in SICU for multiple organ support therapy and surgical interventions to avoid further disease progression [19]. When AP happens, hemodynamic status should be assessed immediately to avoid hypovolemia or volume overload caused by excessive fluid resuscitation[20], which might cause detrimental influences[21]. Routine use of prophylactic antibiotics in SAP or necrotizing pancreatitis was not clinically recommended in the guidelines [22], because of no mortality benefit or reduction in the incidence of infected necrosis [23]. The ability to penetrate pancreatic necrotic tissue is of great significance in the selection of antibiotics. Less than 50% of necrotizing pancreatitis patients need surgical interventions, in which step-up approach and minimally invasive strategies were advocated[24-27], involving endoscopic nasobiliary drainage, percutaneous transhepatic gallbladder drainage, percutaneous transhepatic biliary drainage, endoscopic retrograde cholangiopancreatography, endoscopic transgastric/transduodenal drainage, and video-assisted retroperitoneal debridement.

During AP, kidney is the most vulnerable organ and is typically sacrificed to protect other important organs, such as heart, lung, brain, and liver. As a consequence, AKI is a common complication of AP, which is ordinarily associated with adverse outcomes, including risk of subsequent CKD, end-stage renal disease, RRT dependence, in-hospital and post-discharge mortality, and even healthcare cost-containment concerns [28-30]. It was generally believed that the incidence of AKI was about 20% in critically ill adult patients[31]. More than 50% of SAP patients would develop into AKI according to previous literature[3,17,32]. Different organs interact with each other in the whole body, and the deteriorated kidney function can inevitably cause or aggravate damage to other organs without early intervention. Diuretics had been demonstrated to be an independent risk factor for AKI[33], and thus, were no longer recommended for routine use in clinical practice. When RRT is required, the mortality rate may even exceed 75%[34]. Compared with developed countries, AKI is typically substantial underdiagnoses and undertreatment in developing countries[35], especially in African countries, which may be partially explained as seriously inadequate repeated serum creatinine assay[36].

At present, about 20% of AKI patients require to undergo RRT[37], and this rate continues to increase worldwide. Some eligible patients for RRT may decline to undergo this intervention because of resource constraints, high costs of therapy, or severe comorbidities[38], which significantly increase mortality rate compared with those cases who received it[39]. RRT involves different treatment modalities, such as

hemodialysis, hemofiltration, hemodiafiltration, and peritoneal dialysis. It has been suggested that continuous RRT has several advantages over intermittent RRT, including better hemodynamic stability (blood pressure control and blood circulation), improved survival, and greater likelihood of renal recovery[38,40,41]. Thus, CVVH had occupied the mainstream of RRT, particularly for AP patients who were hospitalized at SICU, because of its outstanding effectiveness and safety. Although it has been suggested that early application of RRT in patients with severe sepsis, irrespective of the presence of renal failure, might be beneficial, CVVH did not limit further organ damage and even prolonged the need for organ support. RRT is a non-selective method, which can simultaneously remove detrimental and beneficial substances. In clinical practice, in spite of great advances in RRT development, there is still a lack of uniform standards for RRT-associated strategies, such as optimal timing

for initiation of RRT, anti-coagulation, and optimal dosage[42,43].

Among several scoring systems, APACHE II score and SOFA score are commonly used to reflect timely and accurately illness severity and predict prognosis of AP patients[44]. It is well known that GCS score is a simple and valuable tool for indication of nervous system function and prediction of short- and long-term mortality [45], in which its discriminative power is similar to other more complex scoring systems[46]. Therefore, these three scoring systems were selected to assess the severity of AP in the present research. A number of scholars pointed out that demand for MV, infusion of vasopressors, and RRT could be risk factors for increased mortality in AP patients[47]. PCT level may contribute to earlier and better stratification of septic patients who are at risk of death and admitted to SICU[48]. To our knowledge, the increased IPP and decreased platelet count are closely associated with the severity and prognosis of AP in clinical practice[49]. Hence, the above-mentioned indicators were employed in the current study.

The present retrospective study provided a comprehensive description about the influences of AKI on AP patients' survival rate who were hospitalized at SICU in accordance with the criteria presented by the KIDGO guidelines. Our findings revealed that AP patients with AKI had more severe degree of illness than AP patients without AKI, as evidenced by higher APACHE II score, higher SOFA score, and lower GCS score, and the survival rates of SICU and in-hospital were only 23% and 21% of the corresponding rates in AP patients without AKI, respectively, which were roughly consistent with previously reported rates[10,31]. These gaps can be partially explained by the increased emphasis placed on AP and improvement of diagnostic methods and standardized therapeutic bundles. For AP patients with AKI, other influences were found to be associated with demand for MV, infusion of vasopressors and RRT, dosages of norepinephrine and adrenaline, duration of MV, maximum and mean values of IPP, maximum and mean values of PCT, maximum and mean serum levels of creatinine, and minimum platelet count. It was revealed that AKI negatively and seriously affected AP patients who were hospitalized at SICU.

The factors that influenced AP patients' survival rate who were hospitalized at SICU included BMI, mean values of IPP, minimum platelet count, and hospital day. With every unit change in BMI, mean values of IPP, minimum platelet count, and hospital day, the AP patients' survival rate was 4.4387, 14.1211, 0.1561, and 0.3730 of the original rates, respectively. Therefore, mean values of IPP had the greatest influence on the AP patients' survival rate who were hospitalized at SICU. Risk thresholds of BMI, mean values of IPP, minimum platelet count, and hospital day were ≥ 24, ≥ 23, ≤ 77, and ≤ 4, respectively, which indicated that BMI ≥ 24, mean values of IPP ≥ 23, minimum platelet count ≤ 77, and hospital day ≤ 4 were risk factors for the AP patients' survival rate who were hospitalized at SICU.

The present study contains a number of limitations. First, although significant differences were detected, this was only a small sample-size, single-center, retrospective study, which might reduce the reliability of our conclusion and its application to AP patients in clinical practice. Second, clinical data were obtained only on the basis of the medical records during hospitalization, which might lead to research bias. Last but not least, the etiology of AP had not been further differentiated. It is noteworthy that different etiologies may induce different clinical manifestations and prognosis, necessitating conducting further studies in the future.

CONCLUSION

In conclusion, this study attempted to clarify the influence of AKI on AP patients' survival rate who were hospitalized at SICU. Results showed that AP patients with AKI exhibited lower survival rate and worse relevant clinical outcomes than AP patients without AKI. Besides, BMI, mean values of IPP, minimum platelet count, and hospital day may play significant roles in predicting the AP patients' survival rate who were hospitalized at SICU. Our findings suggest that prevention of AKI is clinically important.

ARTICLE HIGHLIGHTS

Research background

Acute kidney injury (AKI) is common in acute pancreatitis (AP) patients, but the risk factors are not clear.

Research motivation

This study tried to explore the associated risk factors of AKI in AP patients.

Research objectives

This study aimed to assess the influences of AKI on the survival rate in AP patients.

Research methods

Patients were divided into two groups based on AKI status, and comparisons between the groups were calculated for diverse variables.

Research results

AKI is more likely to occur in male AP patients.

Research conclusions

AP patients with AKI exhibited lower survival rate and worse relevant clinical outcomes than AP patients without AKI in SICU.

Research perspectives

This study provided clinical evidence for prevention of AKI in AP patients.

ACKNOWLEDGEMENTS

We highly appreciate the contribution of participants and co-workers from surgical intensive care unit of The Second and First Affiliated Hospital of Harbin Medical

University to this research.

Abstract

BACKGROUND

Synchronous liver metastasis (SLM) is an indicator of poor prognosis for colorectal cancer (CRC). Nearly 50% of CRC patients develop hepatic metastasis, with 15%-25% of them presenting with SLM. The evaluation of SLM in CRC is crucial for precise and personalized treatment. It is beneficial to detect its response to chemotherapy and choose an optimal treatment method.

AIM

To construct prediction models based on magnetic resonance imaging (MRI)-radiomics and clinical parameters to evaluate the chemotherapy response in SLM of CRC.

METHODS

A total of 102 CRC patients with 223 SLM lesions were identified and divided into disease response (DR) and disease non-response (non-DR) to chemotherapy. After standardizing the MRI images, the volume of interest was delineated and radiomics features were calculated. The MRI-radiomics logistic model was constructed after methods of variance/Mann-Whitney *U* test, correlation analysis, and least absolute shrinkage and selection operator in feature selecting. The radiomics score was calculated. The receiver operating characteristics curves by the DeLong test were analyzed with MedCalc software to compare the validity of all models. Additionally, the area under curves (AUCs) of DWI, T2WI, and portal phase of contrast-enhanced sequences radiomics model (Ra-DWI, Ra-T2WI, and

appendix, statistical code, and dataset available from the corresponding author at email address. Participants informed consent was not obtained but the presented data are anonymized and risk of identification is low.

Ra-portal phase of contrast-enhanced sequences) were calculated. The radiomics-clinical nomogram was generated by combining radiomics features and clinical characteristics of CA19-9 and clinical N staging.

RESULTS

The AUCs of the MRI-radiomics model were 0.733 and 0.753 for the training (156 lesions with 68 non-DR and 88 DR) and the validation (67 lesions with 29 non-DR and 38 DR) set, respectively. Additionally, the AUCs of the training and the validation set of Ra-DWI were higher than those of Ra-T2WI and Ra-portal phase of contrast-enhanced sequences (training set: 0.652 *vs* 0.628 and 0.633, validation set: 0.661 *vs* 0.575 and 0.543). After chemotherapy, the top four of twelve delta-radiomics features of Ra-DWI in the DR group belonged to gray-level run-length matrices radiomics parameters. The radiomics-clinical nomogram containing radiomics score, CA19-9, and clinical N staging was built. This radiomics-clinical nomogram can effectively discriminate the patients with DR from non-DR with a higher AUC of 0.809 (95% confidence interval: 0.751-0.858).

CONCLUSION

MRI-radiomics is conducive to predict chemotherapeutic response in SLM patients of CRC. The radiomics-clinical nomogram, involving radiomics score, CA19-9, and clinical N staging is more effective in predicting chemotherapeutic response.

Key Words: Radiomics; Synchronous liver metastasis; Colorectal cancer; Chemotherapy; Magnetic resonance; Nomogram

Core Tip: Synchronous liver metastasis (SLM) indicates poor prognosis for colorectal cancer. Nearly 50% of colorectal cancer patients develop hepatic metastasis, with 15%-25% of them presenting with SLM. It is beneficial to detect the response of SLM to chemotherapy. Magnetic resonance imaging-radiomics could provide a non-invasive approach to predict the risk of SLM. The logistic model of DWI sequence behaved the best in evaluating the chemotherapeutic response in SLM compared with T2WI, DWI, and portal phase of contrast-enhanced sequences. Moreover, the radiomics-clinical nomogram containing radiomics score, CA19-9, and clinical N staging is more effective in predicting the chemotherapeutic response of SLM patients.

INTRODUCTION

Colorectal cancer (CRC) is the fourth most common malignancy worldwide[1], accounting for approximately one-third of cancer related deaths in western countries [2]. Nearly 50% of CRC patients developed hepatic metastasis throughout the course of disease, and 15%-25% of them were associated synchronous liver metastasis (SLM) [3]. SLM is confirmed as an indicator of poor prognosis for CRC, which was defined as a lesion identified within 90 d after the diagnosis of the primary tumor[4]. Currently, the standard guideline for the treatment of CRC patients with SLM remains undetermined. Conventional treatment for this condition is colectomy, followed by chemotherapy and liver resection[5]. Preoperative chemotherapy has superiority on early treatment of metastatic disease, which may help to achieve a negative resection margin[6] and reduce the risk of local recurrence[1]. However, liver injuries can be induced by chemotherapy, such as vascular changes and chemotherapy-associated steatohepatitis[7]. Previous studies have reported that administration of more than 12

cycles of preoperative chemotherapy increased the risk of re-operation and prolonged hospital stay[8]. Excessive cycles of preoperative chemotherapy may result in increased damage to the liver and lost potential opportunity to receive surgery[7] since progression of chemotherapy is irreversible. Therefore, precise and non-invasive assessment of the response of SLM patients to preoperative chemotherapy is a critical step in individualized treatment. In addition, SLM patients who were predicted as non-responders could benefit from alternative therapies to avoid dispensable chemotherapy.

Radiomics is a promising and non-invasive method to analyze conventional imaging features and incorporate them into predictive models to evaluate tumor behaviors[9]. Previous work has concluded that the nomogram combining radiomics and clinical factors exhibited favorable ability and accuracy in evaluating metastatic pulmonary nodules in CRC patients[10]. Analysis of liver texture is potentially a supplement to routine computed tomography examination and may provide prognostic markers for CRC patients[11]. A radiomics signature was validated to be a complementary predictor for preoperative staging of CRC patients[12]. It has been suggested that magnetic resonance imaging (MRI)-radiomics of CRC patients could provide a non-invasive approach to predict the risk of SLM[13].

To the best of our knowledge, little attention has been paid to predict the response of chemotherapy in SLM patients. This retrospective study examined the emerging role of MRI-radiomics signature in order to detect the prediction efficiency of models in chemotherapeutic response of SLM patients and avoid ineffective chemotherapy.

MATERIALS AND METHODS

Patient selection

This retrospective study was approved by the institutional review board of our hospital. For the characteristics of retrospective study, formal written consent is not applicable. Research methods were carried out in accordance with the Declaration of Helsinki.

A total of 102 CRC patients with 223 SLM lesions were identified from 2017 to 2020 in our hospital. SLM was a histopathologically confirmed intrahepatic lesion within 90 d of the diagnosis of CRC[4]. Inclusion criteria included: (1) Patients were histopathologically diagnosed as classical adenocarcinoma in CRC, excluding mucinous and signet ring adenocarcinoma[14]; (2) Patients have at least one SLM lesion; (3) For patients with multiple SLM lesions, the top three largest ones were selected to analyze; (4) Patients underwent baseline and 3 mo follow-up MRI examination after the start of chemotherapy; and (5) Patients underwent mFOLFOX7 chemotherapy regimen. Exclusion criteria included: (1) Patients underwent anti-tumor treatments such as chemotherapy, radiotherapy, or transarterial chemoembolization before baseline MRI examinations; (2) Patients were diagnosed with CRC with biopsy but not with surgery; (3) History of other malignancies; and (4) Patients were diagnosed as mucinous or signet ring adenocarcinoma. The general characteristics involved gender, age, tumor markers, and clinical T/N staging were recorded. The tumor markers encompassed alpha-fetoprotein (normal range: 0.0-20.0 μg/L), carcinoembryonic antigen (normal range: 0.0-5.0 μg/L), and CA19-9 (normal range: 0.0-37.0 U/mL) that all were divided into normal and abnormal subgroups.

The response to chemotherapy was assessed after 3 mo from the start of chemotherapy by MRI examinations. The response of lesions was categorized into four subgroups according to the Response Evaluation Criteria in Solid Tumors (version 1.1) criterion[15]: (1) Complete response refers that all target lesions disappeared; (2) Partial response is defined as lesions having at least a 30% decrease in the sum diameters of lesions; (3) Progressive disease is defined as lesions having at least a 20% increase in the sum diameters of lesions; and (4) Stable disease is defined as tumors with neither sufficient shrinkage nor sufficient increase in the lesions. None of the patients in this study belonged to complete response. Patients with partial response were classified as disease response (DR) group (Figure 1), while patients with progressive or stable disease were merged into disease non-response (non-DR) group.

MRI examination and image processing

All examinations were performed using 3.0-T MRI (Discovery 750, GE Healthcare, Waukesha, WI, United States). The axial T2WI, DWI, and portal phase of contrast-enhanced sequences (CE_{PP}) were taken. CE-MRI was performed with gadobenate dimeglumine being injected *via* a dual head pressure injector at a rate of 2 mL/s and

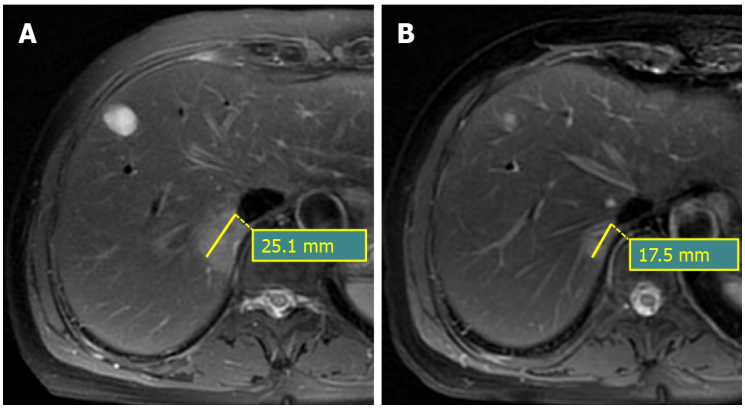

Figure 1 Magnetic resonance imaging examinations. A: A 48-year-old female had a synchronous liver metastasis with baseline long diameter of 25.1 mm; B: After chemotherapy, the lesion a had 30.3% decrease in long diameter of 17.5 mm, which belonged to the disease response group for analysis.

followed by 20 mL saline flush at the same rate. Post-contrast image acquisition was done in the axial plane in arterial phase (AP), PP, and equilibrium phases (EP). The imaging parameters were as follows: T2WI (TR 10000-12000 ms, TE 85 ms; FOV 36 cm × 40 cm, matix 320 × 320, thickness 5.0 mm, interval 1.0 mm), CE (TR 3.7 ms, TE 2.2 ms; FA 12°, matix 260 × 260, thickness 5.0 mm, interval 1.0 mm, 0.2 mL/Kg), and DWI (TR 3500 ms, TE 75 ms; FOV 32 cm × 32 cm, matix 128 × 128, thickness 3.0 mm, interval 0.6 mm, *b* value 0 and 800 s/mm^2).

The process of image standardization included resampling images into a 1.0 mm × 1.0 mm × 1.0 mm voxel size of X/Y/Z-spacing, denoising images by Gaussian, and normalizing the gray level of images to a scale from 1 to 32, which is automatically performed with the software of AK (Artificial Intelligence Kit, version 3.0.0, GE Healthcare).

Then, the three-dimensional volume of interest (VOI) was manually delineated in all the images by software of "ITK-SNAP" (version 3.4.0, http://www.itksnap.org/) by two radiologists with 9 and 12 years of experience in MRI diagnosis, respectively. Finally, the radiomics features of two radiologists were automatically calculated in AK software.

MRI-radiomics signature construction

A total of 396 radiomics features were automatically calculated by AK software, including 42 histogram parameters, 54 texture parameters, 9 form factor parameters, 100 gray-level co-occurrence matrices parameters, 180 gray-level run-length matrices parameters (RLM), and 11 gray-level size zone matrices parameters. The specific description of radiomics features is presented in the Supplemental Material. These radiomics features have underlying relationships with pathophysiological characteristics[16], intracellular heterogeneity[17], as well as genotypes[18], and so on.

Five steps were carried out to select radiomics features. First, the intra-class correlation coefficient (ICC) for all features by two radiologists was analyzed. Features with ICC greater than 0.80 were selected[19], and the mean values of radiomics features from two radiologists were calculated as robust features for further analysis. Second, we normalized the selected radiomics features by replacing the abnormal values with mean and converting the features into non-dimensional values *via* subtracting by mean and dividing by standard deviation value to eliminate discrepancies. Third, we randomly grouped the cohort into a training set and a validation set with a proportion of 7:3 (156 lesions in the training set with 68 non-DR and 88 DR lesions, 67 lesions in the validation set with 29 non-DR and 38 DR lesions). Fourth, we applied analysis of variance/Mann-Whitney *U* test, correlation analysis, and least absolute shrinkage and selection operator to select optimal features. The specific explanation of the methods to select radiomics features is summarized in the Supplemental Material. Last, the MRI-radiomics logistic model to differentiate DR and non-DR patients was constructed in the training set and verified by the validation set. The workflow of the radiomics signature in differentiating DR and non-DR patients was illustrated in Figure 2.

The calibration curves were depicted to compare the consistency between predicted and actual ability to evaluate response to chemotherapy, accompanied by Hosmer-Lemeshow test. The receiver operating characteristic curve was constructed by DeLong test, and the area under curve (AUC) was calculated to evaluate the validity of

MRI-radiomics logistic models.

Statistical analysis

Analysis of variance/Mann-Whitney *U* test /MW, correlation analysis, least absolute shrinkage and selection operator, the logistic model construction, the calibration curve establishment, and radiomics-clinical nomogram development were performed with R software V4.0.1 to select features that potentially predict chemotherapeutic response. The calibration curves were depicted with Hosmer-Lemeshow test to compare the consistency between predicted and actual ability of evaluating response of chemotherapy. The receiver operating characteristic curves were constructed to calculate the AUC with a 95% confidence interval (CI), and the DeLong test was made to evaluate the validity of models in MedCalc V18.2.1. The general information, such as gender, age, tumor index, and T/N stage, was analyzed with IBM SPSS V22.0, using χ^2 or independent samples *t*-test. A two-tailed $P < 0.05$ was considered statistically significant.

RESULTS

Patients' general information

General information of patients were listed in Table 1. A total of 102 patients with 223 lesions were enrolled. There were 53 patients with 97 lesions in the non-DR group and 49 patients with 126 lesions in the DR group. The mean age of non-DR was 63.2 ± 9.5-years-old, and that of DR was 59.9 ± 11.6-years-old. In general, baseline demographics and tumor characteristics were balanced in the DR and non-DR groups, with exceptions of CA19-9 ($P = 0.045$) and clinical N staging ($P = 0.030$). Higher ratios of patients with normal CA19-9 levels were enrolled in the non-DR group (non-DR was 56.6% *vs* DR was 36.7%). In regard to clinical N staging, patients in the non-DR group primarily were staged to be N1 (52.8%), while stage N2 (73.5%) ranked the top in the DR group.

MRI-radiomics logistic model construction

Among the total 1188 radiomics features from T2WI, DWI, and CE_{PP} sequences of MRI examination, 893 features with ICC greater than 0.80 between two radiologists remained for the following analysis. After decreasing redundant features with the methods of analysis of variance/Mann-Whitney *U* test, correlation analysis, and least absolute shrinkage and selection operator, 12 features were selected to construct the MRI-radiomics logistic model for predicting responses of chemotherapy (Figure 3) and the radiomics score (rad-score) was calculated accordingly. The 12 optimal features included four DWI features , six T2WI features , and two CE_{PP} features. The AUC of

Table 1 Baseline patient characteristics

General characteristics	non-DR, *n* = 53	DR, *n* = 49	*P* value
Demographics			
Gender (female/male)	28/25	17/32	0.065
Age (mean ± SD)	63.3 ± 11.1/63.2 ± 7.5	58.6 ± 11.2/59.7 ± 14.1	0.117
Tumor markers			
AFP (normal/abnormal)	51/2	47/2	0.936
CEA (normal/abnormal)	14/39	14/35	0.807
CA19-9 (normal/abnormal)	30/23	18/31	0.045
Clinical T/N staging			
T1/T2/T3/T4	0/1/48/4	0/10/33/6	0.136
N0/N1/N2	3/28/22	5/8/36	0.030

The characteristics of age and clinical T/N staging were analyzed by independent-samples *t*-test. The data of gender and tumor markers of AFP/CEA/CA19-9 were analyzed by Pearson χ^2. A $P < 0.05$ was viewed as statistically significant. Non-DR: Disease non-response group; DR: Disease response group; SD: Standard deviation; AFP: Alpha-fetoprotein; CEA: Carcinoembryonic antigen.

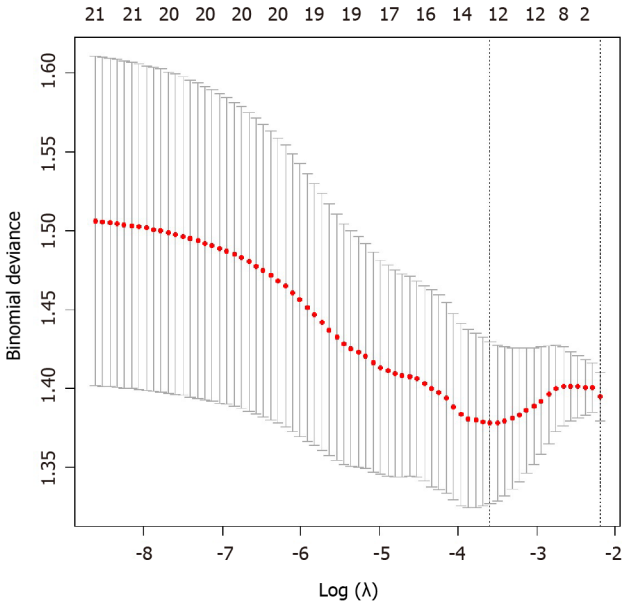

Figure 3 The feature selection method of least absolute shrinkage and selection operator. A total of 12 optimal features were selected.

this model was 0.733 (95%CI, 0.656-0.800) in the training set and was 0.753 (95%CI, 0.633-0.849) in the validation set. The calibration curves showed good consistency in the predicted and the actual ability to evaluate chemotherapy responses in both training and validation sets. The non-significant Hosmer-Lemeshow test suggested goodness-of-fit for the MRI-radiomics logistic models in the training ($P = 0.858$) and validation ($P = 0.374$) set.

Furthermore, we also compared prediction efficiency in chemotherapeutic response between different radiomics models of single DWI, T2WI, or CE_{PP} sequence (Ra-DWI, Ra-T2WI, Ra-CE_{PP}). The AUCs of these models were listed in Table 2. The AUCs of the training set and validation set of Ra-DWI were 0.652 (95%CI, 0.571-0.726) and 0.661 (95%CI, 0.536-0.772), which were higher than those of Ra-T2WI and Ra-CE_{PP} (Table 2). Then we compared the radiomics features of DWI between the baseline and after chemotherapy in the DR group. There were 105 lesions enrolled, as the post-chemotherapy images of another 21 lesions were not satisfactory. By features selection, 11 significant delta-radiomics features were left. The remaining features included histogram (Quantile 0.025), texture (ClusterShade_angle90_offset1), gray-level co-occurrence matrices Entropy (GLCMEntropy_angle135_offset7/_angle90_offset1, and

Table 2 The area under the curve of radiomics model of DWI sequence, radiomics model of T2WI sequence, and radiomics model of portal phase of contrast-enhanced sequences models in the training set and the validation set

Sequence	Training set	*P* value	Validation set	*P* value
Ra-DWI	0.652 (95%CI, 0.571-0.726)	0.001	0.661 (95%CI, 0.536-0.772)	0.018
Ra-T2WI	0.628 (95%CI, 0.547-0.704)	0.005	0.575 (95%CI, 0.450-0.695)	0.291
Ra-CE_{PP}	0.633 (95%CI, 0.552-0.709)	0.003	0.543 (95%CI, 0.418-0.664)	0.544

A $P < 0.05$ of the DeLong test was considered statistically significant. The DeLong test of validation set in radiomics model of T2WI sequence and radiomics model of portal phase of contrast-enhanced sequences had no statistical significance. Ra-DWI: Radiomics model of DWI sequence; Ra-T2WI: Radiomics model of T2WI sequence; Ra-CE_{PP}: Radiomics model of portal phase of contrast-enhanced sequences; CI: Confidence interval.

differenceEntropy), RLM (LongRunHighGreyLevelEmphasis_AllDirection_offset1_SD/_angle45_offset7, ShortRun Emphasis_angle45/90_offset1/HighGreyLevelEmphasis_angle90_offset7), and size zone variability. The top 4 of the 11 delta-radiomics features belonged to RLM parameters.

Radiomics-clinical nomogram analysis

For clinical characteristics, tumor marker CA19-9 ($P = 0.045$) and clinical N staging ($P = 0.030$) were demonstrated to be statistically different between DR and non-DR groups. Thus, CA19-9 and clinical N staging, together with rad-score were integrated into the logistic model to construct the radiomics-clinical nomogram (Figure 4). The formula of the logistic model was: Y = -2.141 + 1.018 × [rad-score] + 0.893 × [CA19-9] + 1.042 × [N staging]. The AUC of the radiomics-clinical nomogram was 0.809 (95%CI, 0.751-0.858).

DISCUSSION

The standardized treatment for SLM patients is unascertained, and early detection of patients with DR or non-DR is crucial for personalized treatment planning. In order to predict patients' responses to chemotherapy, we generated a MRI-radiomics based model in this study. The AUC of this model was 0.733 in the training set and was 0.753 in the validation set. Non-significant Hosmer-Lemeshow test and the calibration curve of the MRI-radiomics model showed good consistency between the predicted and actual probability. Although the AUC value was not ideal enough, the non-invasive MRI examination is still beneficial to differentiate non-DR and DR in clinical practice. There were 156 lesions with 68 non-DR and 88 DR lesions in the training set and 12 radiomics features to construct MR-radiomics logistic model. The sample size of the logistic model often relies on an events per predictor variable[20]. Vittinghoff *et al*[21] conducted a large simulation study of other influences on relative bias, confidence interval coverage, and type I error and found that the events per predictor variable between 5 to 9 could achieve acceptable results. In our study, the events per predictor variable were 5.7 in non-DR group and were 7.3 in the DR group, which were both in the range of 5 to 9. Therefore we believed that the MRI-radiomics model based on 156 lesions in the training set was valid.

As for the selection of MRI sequences, a recent investigation in reproducibility and robustness of MRI radiomics has suggested that caution should be taken in the interpretation of clinical studies using T1WI features to delineate VOI[22]. Meanwhile, after making some attempt in the exploration stage, we realized that it was difficult and inaccurate to depict VOI in AP and EP of CE sequence. Thus, we selected DWI, T2WI, and PP of CE sequences to do future research. Features with ICC more than 0.80 identified by two radiologists were selected, and the mean values of selected features were calculated as robust features for further analysis. After comparing the predictive efficiency between Ra-DWI, Ra-T2WI, and Ra-CE_{PP}, Ra-DWI demonstrated outstanding predictive value compared with Ra-T2WI and Ra-CE_{PP} (AUCs in the training set: 0.652 *vs* 0.628, 0.633; AUCs in the validation set: 0.661 *vs* 0.575, 0.543). We should think highly of DWI due to its potential for evaluating DR and non-DR in clinical practice. As has been investigated that delta-radiomics analysis explored the change of radiomics features between baseline and follow-up computed tomography images can improve the differentiation of pre-invasive ground glass nodules from invasive ground glass nodules[23].

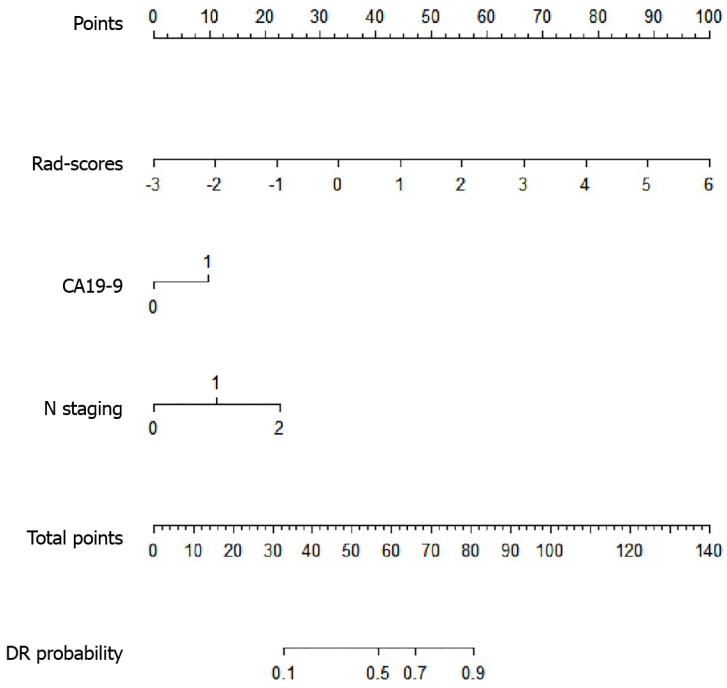

Figure 4 The nomogram of radiomics-clinical analysis to differentiate patients with disease non-response group from disease response group. The zero in CA19-9 represented normal and one referred to abnormal. DR: Disease response group; Rad-score: Radiomics score.

After comparing the delta-radiomics of DR between baseline and post-chemotherapy MRI examination, we obtained the top 4 of 11 delta-radiomics features of post-chemotherapy belonging to RLM parameters. Kim *et al*[24] analyzed the association between pathological characteristics and gray-level run-length matrices features of pancreatic cancer and revealed that gray-level non-uniformity values of RLM were powerful indicators for prognosis. RLM is more sensitive to reflect changes of regional heterogeneity since it analyzes radiomics changes through the whole length of the run [25]. These results suggested that DWI helped to discriminate patients with DR from non-DR in clinical practice.

The nomogram of incorporated independent risk factors for clinical events, such as differentiation[26], survival[27], and recurrence[28], has been widely applied in the field of oncology. The radiomics-clinical nomogram contained rad-score, CA19-9, and clinical N staging demonstrated better predictive accuracy compared with MRI-radiomics signature (AUC: 0.809 *vs* 0.733 in the training set, and 0.753 in the validation set). In patients with SLM, elevation of CA19-9 and carcinoembryonic antigen is a prognostic indicator and can predict response to treatment[29]. A previous study identified that CA19-9 was the best prognostic indicator of metastatic CRC[30] and also was a significant prognostic indicator for CRC patients treated with neoadjuvant chemoradiotherapy[29]. Similar to a previous study[31], we demonstrated that more patients (63.3%) with DR had elevated levels of CA19-9 than those with non-DR (43.4%), suggesting that CA19-9 was a promising indicator for predicting response to chemotherapy ($P < 0.05$). A study by Märkl *et al*[32] illustrated that lymph node staging played a significant role in prognosis evaluation and treatment stratification for CRC. In the current study, we confirmed that clinical N staging had a correlation to chemotherapeutic response. Taken together, the proposed radiomics-clinical nomogram is beneficial in estimating the chemotherapeutic response and in selecting appropriate patients to receive chemotherapy.

Our study had several limitations. First, we only took PP of CE for analysis since the lesions in AP and EP of CE sequence were not visible enough for VOI segmentation. An automatic segmentation method to deal with the AP/EP images remains to be developed. Second, this is a single center study, and the prediction models should be further verified in other centers and in a larger cohort. Third, the inevitable flaw may occur in this retrospective study since the histopathological grade and clinical characteristics of selected patients may be unbalanced. Fourth, as for the criteria for evaluating the response of chemotherapy, we chose the Response Evaluation Criteria in Solid Tumors criterion instead of considering histopathological evidence, which may be complementary to the results of the radiomics. Therefore, our results should be further validated in future multiangle and multiclassification sample studies.

CONCLUSION

In conclusion, our study indicated that the MRI-radiomics logistic model was a helpful and non-invasive predictor for differentiating patients with non-DR from DR. Ra-DWI was more efficient in distinguishing patients with non-DR from DR than that of Ra-T2WI and Ra-CE_{PP}, and the RLM parameter of Ra-DWI was superior in reflecting the delta-radiomics after chemotherapy. Furthermore, the radiomics-clinical nomogram based on the MRI-radiomics signature and clinical factors of CA19-9 and clinical N staging is conducive to better predict non-DR and DR of SLM patients and provides a theoretical and practical basis for the choice of treatment strategies.

ARTICLE HIGHLIGHTS

Research background

Synchronous liver metastasis (SLM) frequently occurs in colorectal cancer (CRC). Nearly 50% of CRC patients develop hepatic metastasis, with 15%-25% of them presenting with SLM. The evaluation of SLM in CRC is crucial for a precise and personalized treatment.

Research motivation

To construct prediction models based on magnetic resonance imaging (MRI)-radiomics and clinical parameters to evaluate the chemotherapy response in SLM patients in the context of CRC.

Research objectives

A total of 102 patients with 223 SLM lesions were identified and divided into disease response (DR) and disease non-response (non-DR) to chemotherapy.

Research methods

The MRI-radiomics logistic models containing T2WI, DWI, and portal phase of dynamic contrast-enhanced sequences radiomics models (Ra-T2WI, Ra-DWI and Ra-portal phase of dynamic contrast-enhanced sequences) were constructed after methods of feature dimension, and the respective radiomics score was calculated. Then radiomics-clinical nomogram was generated by combining radiomics score, CA19-9, and clinical N staging.

Research results

The AUCs of the training and validation set of Ra-DWI were 0.652 and 0.661, which were higher than those of Ra-T2WI and Ra-portal phase of dynamic contrast-enhanced sequences. After chemotherapy, the top four delta-radiomics features of Ra-DWI in DR group belonged to gray-level run-length matrices parameters. The radiomics-clinical nomogram was built with an AUC of 0.809 and can effectively discriminate the patients with DR from non-DR.

Research conclusions

MRI-radiomics is conducive to predict chemotherapeutic response in SLM patients. The Ra-DWI logistic model behaved the best in differentiating DR and non-DR. Run-length matrices parameters of Ra-DWI were more sensitive to reflect the delta-radiomics after chemotherapy. The radiomics-clinical nomogram is more effective in predicting chemotherapeutic response.

Research perspectives

This study provides new insights into the potential ability of MRI-radiomics in evaluating chemotherapeutic response in SLM patents. The MRI-radiomics features combined with clinical characteristics is more effective in evaluation.

Abstract

BACKGROUND

Traditional methods of developing predictive models in inflammatory bowel diseases (IBD) rely on using statistical regression approaches to deriving clinical scores such as the Crohn's disease (CD) activity index. However, traditional approaches are unable to take advantage of more complex data structures such as repeated measurements. Deep learning methods have the potential ability to automatically find and learn complex, hidden relationships between predictive markers and outcomes, but their application to clinical prediction in CD and IBD has not been explored previously.

AIM

To determine and compare the utility of deep learning with conventional algorithms in predicting response to anti-tumor necrosis factor (anti-TNF) therapy in CD.

METHODS

This was a retrospective single-center cohort study of all CD patients who commenced anti-TNF therapy (either adalimumab or infliximab) from January 1, 2010 to December 31, 2015. Remission was defined as a C-reactive protein (CRP) < 5 mg/L at 12 mo after anti-TNF commencement. Three supervised learning algorithms were compared: (1) A conventional statistical learning algorithm using multivariable logistic regression on baseline data only; (2) A deep learning algorithm using a feed-forward artificial neural network on baseline data only; and (3) A deep learning algorithm using a recurrent neural network on repeated data. Predictive performance was assessed using area under the receiver operator characteristic curve (AUC) after 10× repeated 5-fold cross-validation.

Peer-review started: March 5, 2021
First decision: April 17, 2021
Revised: April 26, 2021
Accepted: September 6, 2021

RESULTS

A total of 146 patients were included (median age 36 years, 48% male). Concomitant therapy at anti-TNF commencement included thiopurines (68%), methotrexate (18%), corticosteroids (44%) and aminosalicylates (33%). After 12 mo, 64% had CRP < 5 mg/L. The conventional learning algorithm selected the following baseline variables for the predictive model: Complex disease behavior, albumin, monocytes, lymphocytes, mean corpuscular hemoglobin concentration and gamma-glutamyl transferase, and had a cross-validated AUC of 0.659, 95% confidence interval (CI): 0.562-0.756. A feed-forward artificial neural network using only baseline data demonstrated an AUC of 0.710 (95%CI: 0.622-0.799; P = 0.25 *vs* conventional). A recurrent neural network using repeated biomarker measurements demonstrated significantly higher AUC compared to the conventional algorithm (0.754, 95%CI: 0.674-0.834; P = 0.036).

CONCLUSION

Deep learning methods are feasible and have the potential for stronger predictive performance compared to conventional model building methods when applied to predicting remission after anti-TNF therapy in CD.

Core Tip: Deep learning has vast potential, but its clinical utility in predicting outcomes in Crohn's disease (CD) has not been explored. This study showed that deep learning algorithms (a recurrent neural network) using a more complex information structure including repeated biomarker measurements had a better predictive performance compared to a conventional statistical algorithm using only baseline data. This proof-of-concept study therefore paves the way for further research in the use of deep learning methods in clinical prediction in CD.

INTRODUCTION

Crohn's disease (CD) is a heterogeneous chronic inflammatory bowel disease (IBD) that is characterized by intermittent flares, medication changes, the potential need for surgery and substantial psychological morbidity[1,2]. As with many chronic conditions, predicting disease trajectory, outcomes and response to therapies in CD are key components of clinical practice where management is tailored to the individual [3]. Precision medicine has been in part driven by the vast expansion of available electronic health data, genomic data and novel disease biomarkers[3]. However, deciphering the complex relationships between large amounts of information and multiple data types presents new analytical challenges.

Traditional approaches to constructing prediction models rely on multivariable regression approaches, typically logistic regression for classification or proportional hazards regression for longitudinal prediction[4]. The resulting predictive models are thus typically only linear combinations of the included predictors and may have limited ability to learn more complex relationships within the data. The advantage of machine learning and artificial intelligence over traditional predictive tools is the potential ability for computational algorithms to automatically find and learn complex, hidden relationships between predictive markers and outcomes[5,6]. This is especially true for deep learning or artificial neural network (ANN) methods, although their 'black box' approach has been criticized for an inability to produce a causal

explanation between predictors and outcomes[6].

Despite some limitations, there is much interest in developing and testing machine learning and deep learning tools to aid decision making[5,7]. In luminal gastroenterology, machine learning is gaining traction but its use has been relatively limited to automatic image recognition in endoscopy[8-11] as well as feature selection in genomic and microbiomics data[12,13]. Although there has been great interest in predicting clinical outcomes in CD such as response to therapeutics including biologics[14-18] and immunomodulators[19,20], studies investigating the utility of machine learning models for such predictive tasks have been more limited[21-23]. In particular, the utility of deep learning or ANNs specifically in clinical prediction of CD remains unknown[7].

We aimed to evaluate the utility of deep learning algorithms compared with conventional statistical learning algorithms for clinical prediction in this proof-of-concept study. In particular, we aimed to compare these algorithms as methods of learning and prediction in a general sense, rather than to develop any specific predictive model or score.

MATERIALS AND METHODS

Study design

This proof-of-concept study utilized a retrospective longitudinal cohort at a tertiary health network comprising three acute hospitals in Melbourne, Australia. The focus of the study was to compare the ability of two supervised learning algorithms (conventional statistical learning *vs* deep learning) to predict remission after 12 mo of treatment using clinical variables and biomarkers available at baseline. The performance of each algorithm was evaluated using cross-validation. The emphasis of the study was to compare the predictive performance of the two methods of learning rather than any specific model itself. This study was approved by the Eastern Health Office of Research & Ethics (approval number: LR 61/2015).

Study cohort

All adult patients > 18 years with confirmed CD according to standard criteria[24] were included if they were commenced on treatment with an anti-tumor necrosis factor (anti-TNF) agent (adalimumab or infliximab) for luminal CD and received at least one dose of the drug between January 2010 and December 2015. Patients receiving anti-TNF for perianal disease without luminal disease were excluded. Patients were followed up for 12 mo to determine rates of biochemical remission.

Outcomes

Response to anti-TNF was defined as having achieved biochemical remission as per serum C-reactive protein (CRP) < 5 mg/L at 12 mo. This endpoint was chosen because CRP is an accepted biomarker to reflect disease activity and predict outcomes in CD [25,26]. Additionally, normalization of CRP predicts better outcomes in CD patients in remission[27,28]. The first CRP measurement after 12 mo and before 18 mo was used. Patients who did not have a CRP measurement in this time period were excluded.

Data collection and pre-processing

Baseline characteristics were collected *via* hospital and clinic records, including Montreal classification, concomitant baseline therapies, prior anti-TNF exposure and prior surgeries. Biomarker data were collected at two time points: (1) A baseline measurement defined as the most proximate measurement prior to commencing anti-TNF, up to 3 mo before commencement; and (2) A prior measurement defined as the second most proximate measurement, up to 12 mo before commencement. Only patients with complete baseline data were included, while missing prior values were imputed with the respective baseline value. The following variables were log-transformed to correct skewness: serum bilirubin, alanine aminotransferase, alkaline phosphatase and gamma-glutamyl transferase (GGT). The data underlying this article cannot be shared publicly due to privacy and ethical concerns. The data will be shared upon reasonable request to the corresponding author.

Statistical learning algorithm (conventional approach)

The conventional approach to developing a predictive clinical model is to run univariable and multivariable regression analysis to find useful and preferably

independent predictors of the outcome of interest (see Figure 1). Criteria for variable selection usually involves significance testing (*P* values) or likelihood-based information criterion (such as the Akaike information criterion). In this study, logistic regression was used given the dichotomous nature of the outcome (CRP < 5 mg/L *vs* CRP ≥ 5 mg/L). The conventional approach typically only uses data from a single time-point, therefore we used baseline data only (the most proximate measurement for all biomarkers). For this conventional approach, we employed the following modelling algorithm: (1) Perform univariable logistic regression on each variable and retain all variables with $P < 0.5$; (2) Run backwards stepwise selection on all retained variables with removal criterion $P > 0.2$; and (3) Use the regression coefficients in the remaining multivariable model to derive the predictive score.

Deep learning algorithms (experimental approach)

A basic deep learning algorithm is a feed-forward ANN[6]. An ANN is composed of layers: an input layer (consisting of all the input predictor variables), an output layer (the prediction), and a number of 'hidden' layers (see Figure 1). Nodes within a hidden layer are called 'neurons'. The hidden layers allow an ANN to learn complex, non-linear relationships between input variables and the outcome of interest. The influence of nodes in a layer on other nodes in subsequent layers is 'trained' or fitted using a mathematical function and ultimately determines how information is propagated through the ANN — this is analogous to fitting a regression line on data in conventional statistics. An ANN with only an input and output layer, without hidden layers, can be analogous to simple logistic regression, although they are not equivalent.

However, like the conventional statistical algorithm, a basic feed-forward ANN is still only able to model relationships between predictors at a single time-point. A recurrent neural network (RNN) is a more advanced deep learning algorithm that is able to model repeated measurements over time. Like a feed-forward ANN, information is propagated from the input layer to the output layer. However, instead of only allowing the information to pass through once, information is fed to the RNN sequentially, or 'recurrently' — that is, each set of repeated measurements is inputted once at a time allowing the RNN to update its knowledge of the relationship between the predictors and the outcome. Therefore, the algorithm is additionally able to learn and utilize the dynamics of biomarkers over time, in a way that cannot be achieved by conventional statistical learning methods.

We tested the feed-forward ANN and the RNN in three separate experiments: (1) Using all baseline clinical data in a feed-forward ANN; (2) Using only baseline biomarker data in a feed-forward ANN; and (3) Using repeated biomarker data in an RNN. In this study after hyper-parameter tuning, we used a feed-forward ANN architecture of 3 hidden layers, each with 64 neurons, and an RNN architecture of 1 hidden layer with 64 neurons.

Comparison of algorithms

The predictive performances of the conventional statistical algorithm and the experimental deep learning algorithm (ANN) was defined as their ability to correctly classify 12-mo CRP < 5 mg/L measured using the area under the receiver operator characteristic curve (AUC). Because the learning ability of an ANN can be arbitrarily increased, an overly powerful ANN that is trained such that it has near-perfect prediction on the original training cohort, would suffer from poor predictive ability in an external cohort (this is called 'over-fitting', a well-known phenomenon). Similarly, the same conventional statistical learning algorithm might result in models with different variables when applied to different cohorts. Therefore, it is important to evaluate the ability of a learning algorithm to predict outcomes in patients that are not included in the original training cohort (external validity).

In the absence of external testing cohorts to assess external validity, cross-validation is an internal validation procedure that is suited to this purpose[4]. During cross-validation, the cohort is randomly divided into *k* equally sized sub-cohorts, known as 'folds' (where *k* is often 5 or 10 by convention). Then, one fold is set aside to be used to test the algorithm, after the algorithm is first trained on the remaining *k*-1 folds (see Figure 2). This allows the algorithms to be tested on patients that were not used during training. The process is then repeated for each fold (where each fold takes turns in being the test fold). The average AUC after repeating *k* times gives the cross-validated AUC. However, this procedure is not free from error, because the partitioning process may have randomly resulted in a better (or worse) than usual performance. Thus it is important to repeat the whole process a number of times, to reduce this error[29].

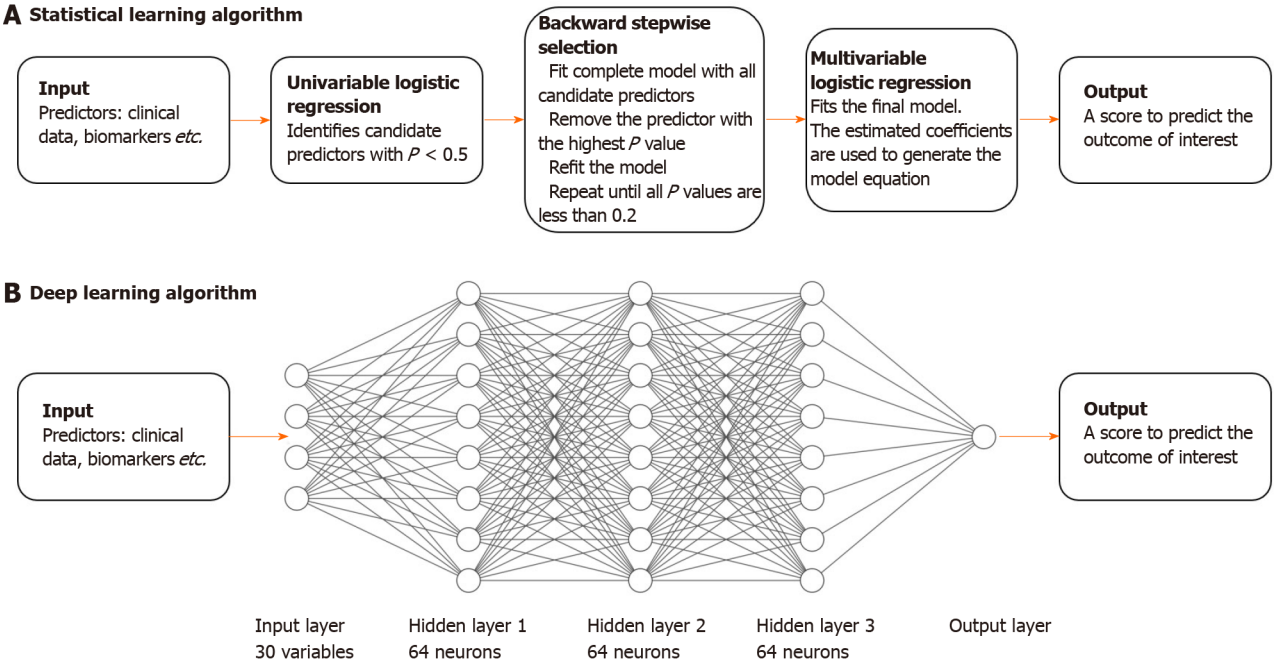

Figure 1 Comparison of the predictive modelling process using two supervised learning algorithms. A: Conventional statistical learning; B: Deep learning.

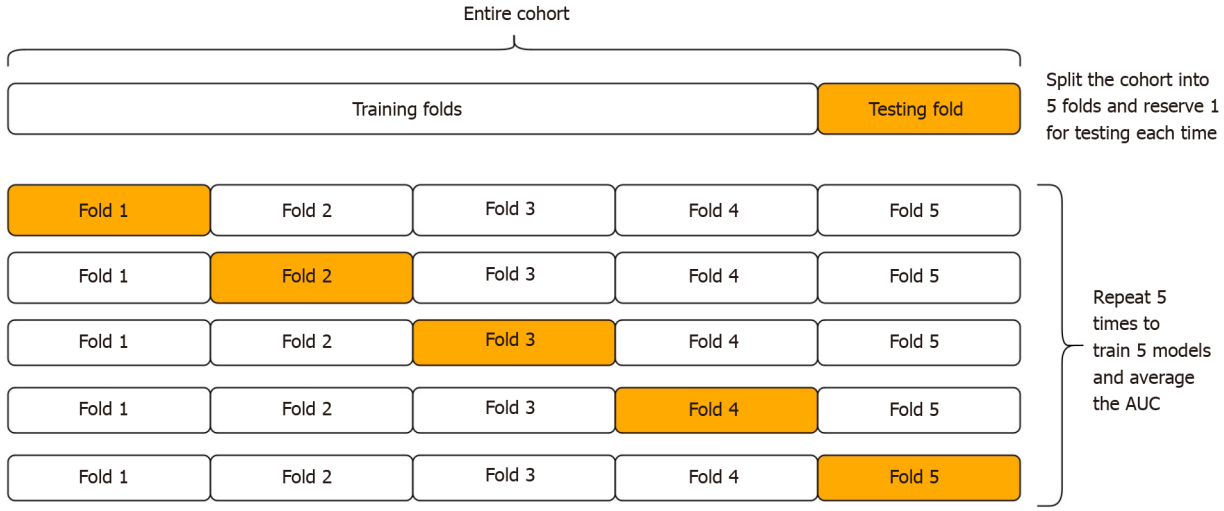

Figure 2 Schematic diagram of *k*-fold cross validation procedure for *k* = 5. This method is considered more reliable than a random train-test split, which would be analogous to training only one model, instead of the average of *k* models. AUC: Area under the receiver operator characteristic curve.

For this study, we used 5-fold cross-validation repeated 10 times to estimate the generalizability of each algorithm on unseen data. Statistical comparison of the cross-validated AUCs of each learning algorithm was made using the variance-corrected repeated *k*-fold *t* test instead of a conventional paired *t* test because of the independency violation from repeated partitioning of the same dataset[29]. For comparison, the naïve or apparent AUC of each model after training and testing on the same entire cohort was given, however this is non-informative. Sample size calculations were conducted only as a guide given the exploratory nature of the study and without prior similar studies on which to base AUC assumptions. The target sample size to detect a 10% difference in AUC with 80% power and 95% significance assuming an AUC variance of 10% was n = 157[30]. To instead detect a 15% difference in AUC under the same conditions, a sample size of n = 70 was required. The Python 3.8.4 programming language with the open-source module PyTorch was used to create the deep learning algorithm. Stata/IC 16 (Texas, United States, 2020) was used to create the statistical learning algorithm.

RESULTS

Baseline characteristics

A total of 146 CD patients were included (see Table 1). Their median age was 36 years [inter-quartile range (IQR) 25-50], 48% were male and median disease duration since diagnosis was 5 years (IQR 1-12). The anti-TNF commenced was infliximab in 58% and adalimumab in 42%. Concomitant therapy at anti-TNF commencement included thiopurines (68%), methotrexate (18%), corticosteroids (44%) and aminosalicylates (33%). Over a quarter of patients (28%) had prior intestinal surgery, while 15% had prior exposure to anti-TNF. After 12 mo, 94 (64%) patients were in biochemical remission (CRP < 5 mg/L).

Statistical learning algorithm

Univariable analysis: Baseline factors associated with biochemical remission at 12 mo on univariable testing included non-complex disease behavior (B1), higher albumin and mean corpuscular hemoglobin concentration (MCHC), and lower platelets, lymphocytes and monocytes (each $P < 0.05$; see Table 2), while lower neutrophil count was nearly significant ($P = 0.06$). There was no significant association with age, sex, disease location or baseline medical therapies (see Table 2).

Multivariable analysis: After backward stepwise selection, the following variables remained in the final multivariable model: Complex disease, baseline albumin, monocytes, lymphocytes, MCHC and GGT (see Table 2). The resulting prediction model was given by the following equation (coefficients correct to two significant figures): Score = 0.079 × (albumin, g/L) + 0.050 × (MCHC, mg/L) - 1.1 × (monocytes, 10^9/L) - 0.43 × (lymphocytes, 10^9/L) - 1.0 × (complex disease, y=1 | n=0) - 0.69 × $\log_e$ (GGT, IU/L).

Outcome prediction: After 10× 5-fold cross validation, the average AUC of the statistical learning algorithm was 0.659 [95% confidence interval (CI): 0.562-0.756]. This suggests the statistical learning algorithm is expected to accurately classify 65.9% of patients in external cohorts who have similar characteristics to the study cohort (see Table 3). The algorithm performed better than chance (AUC > 0.5) 94% of the time and had an AUC > 0.7 in 38% of occasions (see Figure 3). The apparent naïve AUC (when trained and tested on the same data) of the model was 0.771.

Deep learning algorithms

Feed-forward ANN with complete baseline data: The feed-forward ANN with complete baseline data had a cross-validated AUC of 0.710 (95%CI: 0.622-0.799) (see Figure 3 and Table 3). This difference was not statistically significant using the variance corrected t test ($P = 0.25$). The algorithm performed better than chance 100% of the time and had good performance (AUC > 0.7) 54% of the time (see Figure 3). For comparison, the naïve AUC of the model was 0.857.

Feed-forward ANN with baseline biomarker data only: The same feed-forward ANN using only baseline biomarker data had a similar cross-validated AUC of 0.706 (95%CI: 0.621-0.791), which was again not significantly different compared to the conventional algorithm ($P = 0.33$) (see Table 3). The algorithm performed better than chance 100% of the time and had good performance (AUC > 0.7) 58% of the time (see Figure 3). The naïve AUC of the model was 0.776.

RNN with repeated biomarker data: The same feed-forward ANN using only baseline biomarker data had a similar cross-validated AUC of 0.754 (95%CI: 0.674-0.834), which was significantly higher than the AUC of the conventional algorithm ($P = 0.036$) (see Table 3). This suggests the RNN is expected to accurately classify 75.4% of patients in external cohorts who have similar characteristics to the study cohort. The RNN algorithm performed better than chance 100% of the time and had good performance (AUC > 0.7) 72% of the time (see Figure 3). For comparison, the naïve AUC of the model was 0.892.

DISCUSSION

The rapid expansion of available health data has motivated the development of machine learning and deep learning tools to predict useful outcomes in clinical medicine[5,6]. The advent of machine learning and data science techniques is

especially applicable to IBD due to the heterogeneity and chronic nature of such conditions and the repeated measures of disease activity over time which provides data that may be more suitable for complex modelling techniques. For instance, those with CD typically present with a wide array of disparate disease phenotypes and underlying pathogeneses, and their response to treatment and the trajectory of their disease course varies substantially and changes based on their response[31]. This study has exhibited the potential of deep learning algorithms in predicting response to anti-TNF therapy in patients with CD. The ability to predict the likelihood of response to a given treatment is crucial for risk-benefit assessment, which in turn is crucial to facilitate shared decision making between clinicians and patients[32]. Further, although biologic therapies have revolutionized management in IBD[31], medical therapy is now the principal driver of healthcare costs[33,34] and health economic considerations will inevitably affect treatment choice. Ideally, patients should receive therapies that are both likely to work and cost-effective. Therefore, there can be no 'one-size-fits-all' strategy to management, and precision and personalized medicine are key objectives.

Table 2 Estimated odds ratios with 95% confidence intervals on univariable and multivariable logistic regression analysis

Predictor	Univariable		Multivariable	
	OR (95%CI)	*P* value	Adj. OR (95%CI)	*P* value

Variables excluded after univariable regression are in grey; variables excluded after stepwise selection are marked with a dash. CI: Confidence interval; OR: Odds ratio; CD: Crohn's disease; TNF: tumor necrosis factor; HCT: Hematocrit; RCC: Red cell count; MCV: Mean corpuscular volume; MCH: Mean corpuscular hemoglobin; MCHC: Mean corpuscular hemoglobin concentration; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyl transferase.

Table 3 Comparison of learning algorithms during cross-validation experiments

Algorithm	Dataset[1]	AUC (%)		*P* value[2]
		Mean	SD	
Conventional statistics	Baseline clinical + biomarker data	65.9	9.5	-
Feed-forward ANN	Baseline clinical + biomarker data	71.0	8.7	0.25
Feed-forward ANN	Baseline biomarker data only	70.6	8.3	0.33
Recurrent neural network	Baseline and prior biomarker data	75.4	7.8	0.036

[1]Clinical data refers to non-biochemical data such as age, sex, disease characteristics and concurrent treatments. Biomarker data refers to complete blood count, liver function tests and albumin.
[2]*P* value for comparison against conventional statistical algorithm, using the variance-corrected repeated *k*-fold *t* test. AUC: Area under the receiver operator characteristic curve; ANN: Artificial neural network.

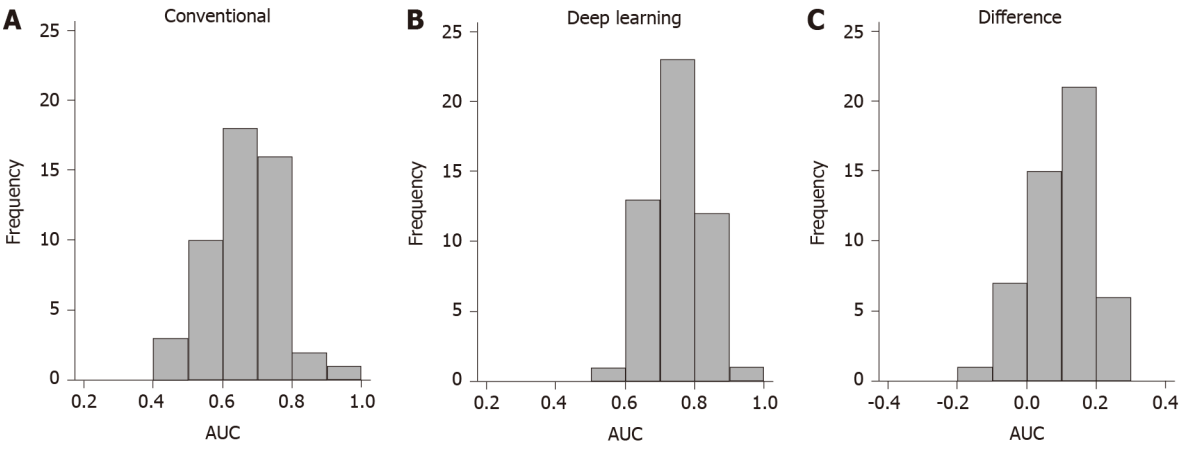

Figure 3 Distribution of area under the receiver operator characteristic curve after 10 × 5 fold cross validation. A: Conventional statistical learning algorithm (mean 0.659, SD 0.095); B: Recurrent neural network (mean 0.754, SD 0.078); C: Head-to-head comparison, matched at each fold and repetition (mean difference, + 0.095, *P* = 0.036). AUC: Area under the receiver operator characteristic curve.

Conventional statistical learning algorithms have generated many useful clinical scores, including the CD activity index[35], the simple endoscopic score for CD[36], scores to predict response to biologic therapies[16], and scores to differentiate CD from intestinal tuberculosis[37]. The advantage of conventional scores is often their simplicity and interpretability. A simple score can be memorized and calculated at the bed side and are intuitive as they utilize important risk factors of the outcome of interest. Yet clinical scores can only apply to a rather generic subgroup of patients and are never specific to any individual, as they utilize relatively few variables. Further, conventional methods are not readily able to model more complex, non-linear or time-dependent health states. With new genomic and microbiomic profiling, as well as the rapid uptake of comprehensive electronic medical records with mass data linkage, the ability of conventional learning algorithms to select useful predictive factors may become redundant[38].

Although the advantages of deep learning for the analysis of non-numerical data types is obvious, such as image data in endoscopy[39-41] and text or speech data in natural language processing[42], the utility of deep learning for the analysis of numerical data is less clear but remains promising. A recent study has demonstrated the utility of machine learning in predicting anti-TNF response in rheumatoid arthritis, but relied on genetic markers in addition to clinical data[43]. Another recent study

used machine learning to predict whether patients with ankylosing spondylitis required anti-TNF therapy, but did not evaluate whether response to therapy could be predicted[44]. It is anticipated that new data science and machine learning techniques are required to handle large amounts of data for use in clinical practice, although the optimal algorithms for this task remain unknown. Nevertheless, with the provision of comprehensive training data, machine learning tools have the potential to aid in individualized risk prediction, although no such model exists in IBD currently. In our cohort, the RNN deep learning algorithm was able to outperform the conventional algorithm after incorporating repeated biomarker measurements and thus additionally learn the non-linear temporal dynamics of the respective biomarkers — a feat that is not possible with conventional prediction models. It is expected that with enough training data, deep learning methods such as the RNN will be able to incorporate the time series data from multiple repeated health states of an individual patient over time. The clear trade-off with deep learning methods is the need for more data coordination and software to execute. However, the continued uptake of automated medical records in routine clinical practice may mitigate this limitation in future. Further, with the ever increasing breadth and volume of information from sources including comprehensive previous medical history, serum and fecal biomarkers, imaging and endoscopic data as well as genetics, the role of machine learning in prediction in chronic diseases including IBD is likely to expand.

This study has also demonstrated the importance of applying model validation techniques during model development[29]. ANNs and other powerful algorithms have the ability to learn intricate differences in data, yet poorly specified models that focus only on learning power have the propensity to learn the random variations or artefacts in the data, which are present only due to chance. This is evidenced by the RNN in this study achieving excellent AUC during training, but a reduced AUC when tested on unseen data (naïve AUC 0.892; cross-validated AUC 0.754). The same phenomenon occurred with the statistical learning algorithm but to a somewhat lesser extent (naïve AUC 0.771; cross-validated AUC 0.659). Therefore, studies developing predictive models should take care to avoid naïvely assessing predictive performance and ensure that effective cross-validation or bootstrapping methods are used for appropriate interval validation[4]. If available, external validation of predictive models in entirely new and different cohorts is the gold standard for model validation[4].

The dataset used in this study was retrospective and from a single center which subjects the results to information bias and limits their external validity. The outcome used was biochemical remission as this is a readily available as a repeated measure which allowed demonstration of more conventional and machine learning models, however it is acknowledged that clinical symptoms and/or mucosal healing are more clinically relevant end-points. Nevertheless, the goal of this study was to demonstrate the feasibility of deep learning methods in clinical prediction in this proof-of-concept study, rather than to develop a specific predictive model. Further, in practice, much larger cohorts will be required to properly train and calibrate deep learning models to maximize their utility in the real world. In future, all studies investigating specific predictive models should be subject to prospective controlled validation prior their application in clinical practice, specifically having shown that outcomes are improved after using predictive models to guide management.

CONCLUSION

In conclusion, we have demonstrated the feasibility of deep learning algorithms for clinical prediction in CD, which demonstrated an improved predictive performance compared to conventional methods. However, conventional statistical methods retain the advantage of simplicity and intuitiveness, allowing their use at the bedside. Yet with the rapid expansion of available health data, machine learning models have the potential to supersede currently conventional methods and greatly improve the development of tools for the clinical prediction of patient outcomes.

ARTICLE HIGHLIGHTS

Research background

Machine learning and artificial intelligence have the potential to revolutionize precision care in inflammatory bowel diseases. The greatest area of interest has been

the application of deep learning methods in automatic tumor detection during endoscopy, yet the application of such techniques in clinical outcome prediction has been lacking.

Research motivation

Traditional approaches to clinical prediction rely on conventional statistical algorithms such as regression, which are not suitable for more complex data such as repeated biomarker measurements.

Research objectives

To determine and compare the utility of deep learning with conventional algorithms in predicting response to anti-tumor necrosis factor (anti-TNF) therapy in Crohn's disease (CD).

Research methods

A retrospective cohort of CD patients commenced on anti-TNF therapy was used to experimentally develop and cross-validate three supervised learning algorithms: (1) Statistical learning algorithm; (2) Feed-forward artificial neural network; and (3) Recurrent neural network with repeated data. Predictive utility was quantified using the area under the receiver operator characteristic curve (AUC).

Research results

Within our cohort of 146 patients, the conventional statistical learning algorithm had the weakest performance [AUC 0.659, 95% confidence interval (CI): 0.562-0.756], compared to the feed-forward artificial neural network (AUC 0.710, 95%CI: 0.622-0.799; P = 0.25 *vs* conventional) and the recurrent neural network using repeated biomarker measurements (AUC 0.754, 95%CI: 0.674-0.834; P = 0.036 *vs* conventional).

Research conclusions

Deep learning methods are feasible and have the potential for stronger predictive performance compared to conventional model building methods when applied to predicting remission after anti-TNF therapy in CD.

Research perspectives

This has been the first study to investigate the utility of deep neural networks in predicting clinical outcomes using repeated clinical data in inflammatory bowel disease. Future studies should incorporate additional data types such as genetic, imaging and endoscopic factors.

Abstract

BACKGROUND

Acute pancreatitis (AP) is an inflammatory disease in which the regulatory pathway is complex and not well understood. Soluble suppression of tumorigenicity 2 (sST2) protein receptor functions as a decoy receptor for interleukin (IL)-33 to prevent IL-33/suppression of tumorigenicity 2L (ST2L)-pathway-mediated T helper (Th)2 immune responses.

AIM

To investigate the role of sST2 in AP.

METHODS

We assessed the association between sST2 and severity of AP in 123 patients enrolled in this study. The serum levels of sST2, C-reactive protein (CRP) and Th1- and Th2-related cytokines, including interferon (IFN)-γ, tumor necrosis factor (TNF)-α, IL-2, IL-4, IL-5 and IL-13, were measured by highly sensitive ELISA, and the severity of AP in patients was evaluated by the 2012 Atlanta Classification Criteria.

RESULTS

Serum sST2 levels were significantly increased in AP patients, and further, these levels were significantly elevated in severe AP (SAP) patients compared to moderately severe AP (MSAP) and mild AP (MAP) patients. Logistic regression showed sST2 was a predictor of SAP [odds ratio (OR): 1.003 (1.001–1.006), P = 0.000]. sST2 cutoff point was 1190 pg/mL, and sST2 above this cutoff was associated with SAP. sST2 was also a predictor of any organ failure and mortality during AP [OR: 1.006 (1.003–1.009), P = 0.000, OR: 1.002 (1.001–1.004), P = 0.012,

respectively]. Additionally, the Th1-related cytokines IFN-γ and TNF-α in the SAP group were higher and the Th2-related cytokine IL-4 in the SAP group was significantly lower than those in MSAP and MAP groups.

CONCLUSION

sST2 may be used as a novel inflammatory marker in predicting AP severity and may regulate the function and differentiation of IL-33/ST2-mediated Th1 and Th2 Lymphocytes in AP homeostasis.

Key Words: Acute pancreatitis; Soluble suppression of tumorigenicity 2; T-helper 1 cells; T-helper 2 cells; Interleukin-33; Biomarker

Core Tip: Acute pancreatitis (AP) is an inflammatory disease in which the regulatory pathway is complex and not well understood. The interleukin (IL)-33/ suppression of tumorigenicity 2L (ST2L) functional pathway is involved in the pathological process of AP. Soluble suppression of tumorigenicity 2 protein (sST2) is a soluble receptor, which is released in the circulation acts as a decoy receptor by binding IL-33. However, sST2 as one of the most promising disease biomarker, has not been studied in the development of AP. In this study we studied the role of sST2 as an inflammatory marker for predicting the severity of acute pancreatitis.

INTRODUCTION

Acute pancreatitis (AP) is caused by activation of pancreatic enzymes induced by a variety of etiologies, resulting in autodigestion, hemorrhage, edema, and even necrosis of pancreatic tissue, with or without other organ function changes. The clinical severity of AP is related to its prognosis. Severe AP (SAP) has a poor prognosis, and can cause severe disorders of multiple organ functions, and the mortality can reach 30%[1]. Excessive activation of inflammatory cells and their cytokines is one of the main mechanisms of pathogenesis of AP. The development and outcome of AP are closely related to immune function[2]. Research on changes in inflammatory mediators in patients with different clinical severity of AP is important clinically. A better understanding of the regulatory inflammatory pathways in AP is beneficial for discovery of new therapeutic targets.

Suppression of tumorigenicity 2 protein (ST2) is a member of the interleukin (IL)-1 receptor family with transmembrane (ST2L) and soluble (sST2) isoforms. The ligand of ST2 is IL-33, which can produce nuclear signal transduction and immunomodulatory functions in various cells when combined with ST2L. IL-33 is mainly produced by epithelial and endothelial cells. After exposure to pathogens, stress or necrosis caused by injury, IL-33 can signal the presence of tissue damage to local immune cells, thereby acting as a danger signal or alarm protein[3]. ST2L can form a heterodimer with IL-1R-related protein, which is widely present in the membranes of mast cells, T helper (Th)2 cells, dendritic cells, basophils, and macrophages[4,5]. The importance and role of the IL-33/ST2L axis have been evaluated and confirmed in several inflammatory and cardiac diseases and cancer. sST2, as a soluble receptor that is released in the circulation, acts as a decoy receptor by binding IL-33, and, thus, sST2 is involved as the counterbalance/response on IL-33/ST2L axis activation by inhibiting its signal transduction through ST2L.

The IL-33/ST2L functional pathway is involved in coxsackievirus B5 (CVB5)-induced pancreatitis[6]. Mice deficient in ST2L develop significantly more severe pancreatitis. Conversely, wild-type mice treated with recombinant IL-33 develop

study participants, or their legal guardian, provided informed written consent prior to study enrollment.

significantly lower viral titers, and pancreatitis is attenuated, indicating that IL-33/ST2L is involved in the pathological process of AP. SAP can cause severe disorders of multiple organ, including AP-related myocardial, kidney, or lung injury. In clinical studies, sST2 is recognized as an important marker for monitoring treatment in heart failure patients and higher sST2 is associated with worse right ventricular dysfunction and higher mean pulmonary and right atrial pressures[7-9]. sST2 is also recognized as an important prognostic marker in patients with kidney injury, where specific characteristics of sST2 enable better assessment of the risk of end-stage renal disease patients on dialysis[10]. It has been also found to be relevant in pulmonary diseases, sepsis, trauma, and gastrointestinal diseases[11-14]. sST2 can be used as a biomarker in heart, lung and kidney injury, and may also be served as biomarker in the severity of AP. However, sST2, as one of the most promising disease biomarkers, has not been studied in the development of AP.

The IL-33/ST2L pathway promotes $CD4^+$ T-cell differentiation to an atypical Th2 phenotype[15]. $CD4^+$ T cells play a major role in the pathogenesis of pancreatitis[16]. In this study, we investigated whether and how the IL-33/ST2L pathway was involved in AP in patients with different clinical severity of AP.

MATERIALS AND METHODS

Patients

A total of 123 hospitalized AP patients were recruited between January 2018 and August 2020 in the Emergency Surgery Department, Emergency Internal Medicine Department, and Comprehensive Intensive Care Unit (ICU) in the First Affiliated Hospital of Zhengzhou University. Inclusion criteria for subject enrollment included: (1) age 18–90 years; (2) clinically and radiographically confirmed AP; and (3) syndrome onset < 24 h prior to study enrollment. Exclusion criteria were: (1) Pregnancy or patients with immunodeficiency, acute and chronic hepatitis, end-stage liver and kidney disease, malignant tumors, or trauma; (2) Patients who have used hormones or immunosuppressive agents within the past 3 mo; and (3) Patients with chronic pancreatitis. This study complied with medical ethics standards and was approved by the hospital Ethics Committee. All participants provided written informed consent.

Demographic and clinical data

Demographic and clinical data were collected, including age, sex, ethnicity, body mass index (BMI), etiology, and comorbidities. According to the 2012 Atlanta Classification Criteria, patients were divided into: (1) Mild AP (MAP): No organ failure and local and systemic complications; (2) Moderately severe AP (MSAP): Local and/or systemic complications and/or transient organ failure (< 48 h); and (3) SAP: Persistent organ failure (> 48 h), with or without local complications.

Measurement of serum sST2, interferon-γ, tumor necrosis factor-α, IL-2, IL-4, IL-5, IL-13 and C-reactive protein

For serum preparation, peripheral venous blood samples (4 mL) were collected from each patient within 24 h after symptom onset and allowed to clot for 2 h at room temperature prior to centrifugation at 1500 rpm for 20 min. Serum was aliquoted and stored at -80 °C until further testing. The laboratory technicians were blinded to the baseline data and AP severity of the patients. Serum sST2 Levels were measured using a human sST2 ELISA kit (Elabscience, Wuhan, China). Serum C-reactive protein (CRP) and levels of Th1-cell-related inflammatory factors interferon (IFN)-γ, tumor necrosis factor (TNF)-α and IL-2 and Th2-cell-related inflammatory factors IL-4, IL-5 and IL-13 were measured in duplicate using an ELISA kit from Elabscience.

Statistical analysis

The Shapiro–Wilk test was used to test the normality of the data, and the Levene test was used to analyze the homogeneity of the data. Normally distributed measurement data are expressed as mean ± SE, and data were compared between groups by Student's *t* test and analysis of variance. Non-normally distributed measurement data are represented by median and interquartile range [M (IQR)], and comparison of data between groups used the Kruskal–Wallis test, and the nonparametric Mann–Whitney *U* test was used for comparison between the two groups. The *Z* value was used for the statistic. Categorical variables were described as frequencies with percentages, and

chi-square test was used to examine significant differences between categorical variables. The influence of serum sST2 levels on severity was assessed using univariate and multivariate binary logistic regression analysis, with significant confounding factors tested in the adjusted univariate analysis. Results were expressed as adjusted odds ratios (ORs) with the corresponding 95% confidence intervals (CIs). Optimal sST2 cutoff points were obtained using receiver operating characteristic (ROC) curve analysis. Additionally, IFN-γ, TNF-α, IL-2, IL-4, IL-5, and IL-13 data were logarithmically transformed for analysis. The relationships between sST2, IFN-γ, TNF-α, IL-2, IL-4, IL-5, and IL-13 and total length of hospital stay and ICU hospital stay were analyzed using Spearman's rank correlation. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using SPSS version 21.0.

RESULTS

Patient characteristics

We enrolled 123 patients: 55 (45%) with MAP, 37 (30%) with MSAP, and 31 (25%) with SAP. The etiology of AP was biliary stones (74.8%), alcohol (8.9%), laparoscopic retrograde cholangiopancreatography (1.6%), alcohol and biliary stones (8.1%) and metabolic factors (2.5%), drug-induced (0.8%), and idiopathic pancreatitis (3.3%). The etiology did not differ significantly among the groups. The incidence of acute pancreatitis with acute cholecystitis is 4.8%. Three patients had accompanying cholecystitis in the MAP group, one patient had cholecystitis in MSAP group, and two patients in the SAP group. There was no significant difference between the groups for cholecystitis.

The BMI of the healthy control group was lower than that of the MAP, MSAP, and SAP groups, and the difference was significant ($Z = -3.15$, $P = 0.002$, $Z = -3.16$, $P = 0.002$, $Z = -5.046$, $P = 0.000$). There was no significant difference in BMI between the MAP and MSAP groups ($Z = -2.27$, $P = 0.820$). The BMI of the MAP and MSAP groups was lower than that of the SAP group ($Z = -2.767$, $P = 0.006$, $Z = -2.452$, $P = 0.014$, respectively).

In the MAP group, three patients had accompanying hypertension, three were complicated by diabetes, and three were complicated by coronary heart disease. In the MSAP group, two patients had hypertension, three were complicated by diabetes, and one was complicated by coronary heart disease. Two patients in the SAP group had hypertension, five were complicated with diabetes, and one with coronary heart disease. There was no significant difference between the groups for co-morbidity, hypertension, diabetes, and coronary heart disease. None of the 123 patients were taking immunosuppressive agents. After statistical analysis, there was no significant difference in age, gender, or ethnicity between the AP groups. Patients in the AP groups had no significant difference in age, gender, or ethnicity compared with the healthy control group (Table 1).

sST2 Levels elevated in SAP patients

To identify the involvement of the IL-33/ST2L pathway in AP, we examined expression of IL-33 and sST2 in the serum after AP. The level of IL-33 was extremely low in the blood of all AP patients. Almost all samples were under the detection limit of the IL-33 ELISA, and only seven patients showed higher values. In addition, the low, almost undetectable levels of IL-33 were unlikely to be associated with worsening clinical outcomes. Nevertheless, we tested the levels of sST2 at the same time.

The sST2 content of the AP group and the healthy control group conformed to a normal distribution and uniformity of variance. We observed increased levels of sST2 in AP patients compared to healthy controls (1115.4 *vs* 211.1 pg/mL, $t = 9.355$, $P = 0.000$) (Figure 1). The sST2 value of the three AP groups did not conform to a normal distribution, and the nonparametric Kruskal–Wallis *H* test was used for comparison among multiple groups. The level of sST2 was significantly higher in the SAP group compared with MSAP and MAP groups ($Z = -3.510$, $P = 0.000$, $Z = -7.305$, $P = 0.000$, respectively). The level of sST2 in the MSAP group was significantly higher than in the MAP group ($Z = -6.489$, $P = 0.000$). The data are shown in Figure 2 and Table 2. The level of CRP in the SAP group was significantly higher than in the MSAP and MAP groups ($Z = -5.634$, $P = 0.000$, $Z = -7.150$, $P = 0.000$, respectively). The level of CRP in the MSAP group was higher than in the MAP group ($Z = -2.891$, $P = 0.000$) (Figure 3). This suggested that sST2 expression was increased in the SAP group, and that IL-33 signaling played a role in regulating the inflammatory response during AP.

Table 1 Demographic and clinical data of acute pancreatitis patients and health controls

sST2 has predictive value for severity of AP

We conducted a multivariate analysis to evaluate whether the relationship of sST2 with SAP was really independent. Logistic regression showed that sST2 levels at admission [OR: 1.003 (1.001–1.006), $P = 0.000$] was a predictor of SAP. With the ROC curve, the optimal cut-off value of serum sST2 levels as an indicator for prediction of SAP was projected to be 1190 pg/mL, which yielded a sensitivity of 90.3% and specificity of 76.1%, with the area under the curve 0.889 (95%CI: 0.829–0.949; $P = 0.000$) (Figure 4).

sST2 was also a predictor of any organ failure and mortality during AP [OR: 1.006 (1.003–1.009), $P = 0.000$, OR: 1.002 (1.000–1.004), $P = 0.012$, respectively]. BMI and CRP

were also predictors of SAP at admission [OR: 2.629 (1.075–6.429), P = 0.034, OR: 1.066 (1.031–1.101), P =0.002, respectively]. However, there was no value of BMI and CRP for predicting organ failure and mortality. sST2, CRP, age, BMI, and gender were not predictive of necrosis. The data are shown in Table 3. Furthermore, there was a significant correlation between the level of sST2 and total hospital stay and length of stay in ICU (r = 0.463, P = 0.000, r = 0.673, P = 0.000) (Table 4).

Relationship between levels of serum inflammatory factors of Th1 and Th2 cells and severity of AP

To further explore the biological mechanism of AP, we examined the production of Th1-related cytokines IFN-γ, TNF-α and IL-2 and Th2-related cytokines IL-4, IL-5 and IL-13 in the serum to clarify the role of the inflammatory process in the pathogenesis of AP. The concentration of inflammatory factors measured after logarithmic conversion was in accordance with the normal distribution. Statistical analysis showed that the serum levels of IFN-γ and TNF-α in the SAP and MSAP groups were higher than those in the MAP group, and the difference was significant. There was no significant difference in IFN-γ and TNF-α between the SAP and MSAP groups. IL-4 expression in the SAP group was significantly lower than that in the MAP and MSAP groups, but there was no significant difference between the MAP and MSAP groups. There was no significant difference in the expression of IL-2, IL-5 and IL-13 between the MAP, MSAP and SAP groups (Table 5).

Expression of Th1-cell-associated inflammatory factor IFN-γ and TNF-α was positively correlated with the length of total hospital stay and total ICU stay, while

expression of Th2-cell-associated inflammatory factor IL-4 was negatively correlated with the length of total hospital stay and total ICU stay (Table 4).

DISCUSSION

The results of our study showed that the levels of sST2 were significantly increased in SAP patients, and there were significant increases in Th1-related cytokines IFN-γ and TNF-α, and a decrease in Th2-related cytokine IL-4. This suggested an insufficient IL-33-driven Th2-type inflammatory response was involved in the pathophysiological process of AP. sST2 is a secreted form of the ST2 receptor and acts as a decoy receptor for IL-33, thus inactivating the functions of IL-33. sST2 expression increases in response to proinflammatory cytokines[17]. Our data were in line with a previous study showing elevated levels of sST2 in AP[18]. Importantly, in our study the levels of sST2 predicted the total hospital stay and length of stay in the ICU, as well as predicted organ failure and mortality during AP. These data support the findings of our study showing that SAP patients more frequently had higher serum levels of sST2 compared with MAP and MSAP patients, and that the early elevated levels of sST2

correlated with worsened outcome of AP. Thus, the normal function of IL-33 may be inhibited in AP.

SAP can cause severe systemic inflammation and multiple organ dysfunction. It is reported that endogenous danger signals, such as tissue damage or necrosis, and exogenous danger signals, such as microbial pathogens and endotoxins, can enhance the production of sST2 and stimulate the secretion of inflammatory cytokines, thereby weakening the immune response of organs exposed to the danger signals and leading to adverse outcomes[19]. It has been suggested that serum levels of sST2 are significantly increased in inflammatory diseases and serve as a prognostic biomarker of multiple organ dysfunction syndrome (MODS), cardiovascular events, heart failure, acute hypoxemic respiratory failure, and progression of kidney failure. A study based on cardiopulmonary resuscitation showed that plasma levels of sST2 were associated with higher risk of MODS and early death[20]. A role of sST2 in acute hypoxemic respiratory failure indicates that using sST2 concentrations to guide ventilator management may more accurately reflect underlying lung injury and outperform traditional measures of readiness for ventilator liberation[21]. Higher sST2 Levels predict mortality in severe sepsis[12]. These findings agree with our results showing that sST2 was a predictor of any organ failure and mortality during AP.

The IL-33/ST2L pathway has been shown to mediate the modulation of inflammation in different diseases by promoting Th2 response and inhibiting Th1 response [22,23]. Mice that lack IL-33 signaling develop significantly more severe pancreatitis [6]. Based on the regulatory effect of the IL-33/ST2 signaling pathway on Th1 and Th2 cells, we further measured the function of Th1 and Th2 cells in patients with AP. An important finding in our study was the relationship between Th1- and Th2-related cytokines and the severity of AP. Cytokine levels in Th1 cells in patients with SAP were significantly higher than those in patients with MAP and MSAP, and cytokines in

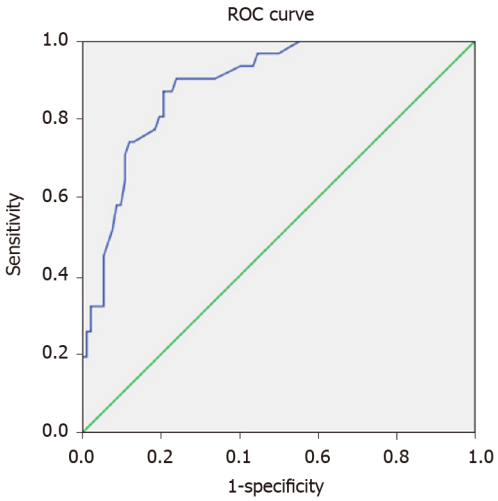

Figure 4 Receiver operating characteristic curve demonstrating sensitivity as a function of 1 – specificity for predicting severe acute pancreatitis based on serum soluble suppression of tumorigenicity 2 levels. ROC: Receiver operating characteristic.

Th2 cells in patients with MAP and MSAP were significantly increased compared with patients with SAP. In our study, we observed that both sST2 and the Th1 cytokines IFN-γ and TNF-α were increased and the Th2 cytokine IL-4 was decreased in SAP. We speculate that increased sST2 in SAP might cause increases in IFN-γ and TNF-α, and decreases in IL-4 by antagonizing the IL-33/ST2 signaling pathway, whereas this inference still needs to be verified by further animal research in the future.

The serum levels of Th1-related cytokines IFN-γ and TNF-α in the SAP group were higher than those in the MAP and MSAP groups, and expression of Th2-related cytokine IL-4 in the SAP group was significantly lower than in the MAP and MSAP groups. The expression of Th1-related inflammatory factors IFN-γ and TNF-α was positively correlated with the length of total hospital stay and total ICU stay, and Th2-cell-associated inflammatory factor IL-4 expression was negatively correlated with the length of hospital and ICU stays. The results suggested that Th1-cell-related immune response was an important factor that aggravated the development of AP, and Th2 cells might have a protective role in the development of AP. Our findings indicate that Th1 and Th2 cells were involved in cytokine-dependent pathways in severity of AP. The results proved that a change in immune response played an important role in the pathogenesis of AP.

In this study, we found an immune imbalance in patients with SAP. Th1-cell-related cytokines IFN-γ and TNF-α in the serum of patients with SAP were higher than those in patients with MSAP. We also found that the expression levels of Th1-cell-associated inflammatory factors IFN-γ and TNF-α were positively correlated with the length of total hospital stay and total ICU stay. This finding is consistent with the latest research showing that inflammatory factors play a consistent role in the pathogenesis of AP[24-26]. IFN-γ and TNF-α could stimulate B cells to produce antibodies, activate macrophages and $CD8^+$ T cells, promote cell-mediated immunity and cytotoxic T cell responses[27], and could induce Th1 cell differentiation and inhibit Th2 cell proliferation. Previous research findings and the present study suggest that Th1 cells are involved in the pathogenesis of AP, especially in the development of SAP. Th1 cells exacerbate the pathophysiological process of AP by releasing Th1-related inflammatory factors.

In humans, serum concentrations of sST2 are increased in several diseases, such as heart disease, pulmonary disease, burn injury, and graft-versus-host disease[28-33]. Few studies have reported the influence of the IL-33/ST2 signaling pathway on the development of AP[6,34-36] and less attention has been paid to Th1 and Th2 cells in the pathogenesis of AP[24]. In this study, we found that the expression of the Th2-related cytokine IL-4 in SAP was significantly lower than that in MAP and MSAP. Expression of the Th2-related inflammatory factor IL-4 was negatively correlated with the length of hospital and ICU hospital stays, suggesting that Th2 cells are involved in the pathogenesis of AP with the tendency to improve symptoms of acute pancreatitis. Collectively, Th2 cells might have a protective effect in the development of AP, tending to delay its development.

Our research had some limitations. Firstly, the main limitation was the small sample size, which may have reduced the statistical power, the accuracy, and effectiveness of identifying true positive results. In future, the results need to be confirmed with larger sample sizes. Secondly, this study was a single-center study, which might have resulted in selection bias. Thirdly, in cases of pancreatitis combined with cholecystitis, cholecystitis might affect the results of the study. Fourthly, we did not examine the numbers of Th1 and Th2 cells. Finally, establishing the initial relationship between AP and elevated sST2 concentrations in our study is novel and useful, but it is necessary to determine the long-term predictive value of sST2 for the prognosis of AP in subsequent longitudinal studies.

CONCLUSION

In conclusion, sST2 may be used as a novel inflammatory marker in predicting AP severity and may regulate the function and differentiation of IL-33/ST2-mediated Th1 and Th2 Lymphocytes in AP homeostasis.

ARTICLE HIGHLIGHTS

Research background

The clinical severity of acute pancreatitis (AP) is related to its prognosis. Excessive activation of inflammatory cells and their cytokines is one of the main mechanisms of pathogenesis of AP. Research on changes in inflammatory mediators in patients with different clinical severity of AP is important clinically. The interleukin (IL)-33/ST2L functional pathway is involved in the pathological process of AP. Soluble suppression of tumorigenicity 2 (sST2) is a secreted form of the ST2 receptor and acts as a decoy receptor for IL-33. In this study, we investigated whether the sST2 could serve as a novel inflammatory marker predicting the severity of acute pancreatitis.

Research motivation

In this study, the authors focused on the function of sST2 in predicting the severity of AP. The key issue to be solved is the association between IL-33/ST2L pathway and AP. The significance of solving these problems may constitute a new therapeutic target for regulating immune activation during the AP inflammatory storm.

Research objectives

The objective of this study was to investigate the role of sST2 in AP.

Research methods

The authors assessed the association between sST2 and severity of AP in 123 patients enrolled in this study. The serum levels of sST2, C-reactive protein (CRP) and Th1- and Th2-related cytokines interferon (IFN)-γ, tumor necrosis factor (TNF)-α ,IL-2, IL-4, IL-5 and IL-13 were measured by highly sensitive ELISA and the severity of AP patients was evaluated by the 2012 Atlanta Classification Criteria.

Research results

The serum sST2 Level was significantly increased in AP patients and significantly elevated in severe acute pancreatitis (SAP) patients compared to moderate severe acute pancreatitis and mild acute pancreatitis patients. The cutoff point of sST2 at 1190pg/mL was associated with SAP.

Research conclusions

This study suggests that sST2 may be used as a novel inflammatory marker in predicting the severity of acute pancreatitis and that sST2 might regulate the function and differentiation of IL-33/ST2L mediated Th1 and Th2 lymphocytes in the homeostasis of acute pancreatitis.

Research perspectives

It is necessary to determine the long-term predictive value of sST2 for the prognosis of AP in subsequent longitudinal studies. Additionally, the role of IL-33/ST2L in acute pancreatitis needs to be further verified in both *in vivo* and *in vitro* experiments.

ACKNOWLEDGEMENTS

We thank the study participants and the clinical staff for their contribution to this study.

Abstract

BACKGROUND

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is a rare primary intestinal T-cell lymphoma, previously known as enteropathy-associated T-cell lymphoma type II. MEITL is an aggressive T-cell lymphoma with a poor prognosis and high mortality rate. The known major complications of MEITL are intestinal perforation and obstruction. Here, we present a case of MEITL that was diagnosed following upper gastrointestinal bleeding from an ulcerative duodenal lesion, with recurrence-free survival for 5 years.

CASE SUMMARY

A 68-year-old female was admitted to our hospital with melena and mild anemia. An urgent esophagogastroduodenoscopy (EGD) revealed bleeding from an ulcerative lesion in the transverse part of the duodenum, for which hemostatic treatment was performed. MEITL was diagnosed following repeated biopsies of the lesion, and cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy was administered. She achieved complete remission after eight full cycles of CHOP therapy. At the last follow-up examination, EGD revealed a scarred ulcer and ^{18}Fluorodeoxyglucose (^{18}FDG) positron emission tomography/computed tomography showed no abnormal FDG accumulation. The patient has been in complete remission for 68 mo after initial diagnosis.

CONCLUSION
To rule out MEITL, it is important to carefully perform histological examination when bleeding from a duodenal ulcer is observed.

Core Tip: Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is a primary intestinal T-cell lymphoma with the known major complications of intestinal perforation and obstruction. We experienced a case of MEITL that was diagnosed after gastrointestinal bleeding from an ulcerative duodenal lesion, who survived for a long time after treatment. MEITL can present as gastrointestinal bleeding. In addition, although MEITL has a poor prognosis, patients with MEITL might survive for a long time if effective treatment is administered at an early stage. Therefore, it is important to perform thorough histological examination for the early diagnosis of MEITL in cases with bleeding duodenal ulcers.

INTRODUCTION

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is a rare primary intestinal T-cell lymphoma newly defined by the 2016 revision of the World Health Organization, that was previously known as enteropathy-associated T-cell lymphoma (EATL) type II[1]. It arises from intestinal intraepithelial T lymphocytes and tends to behave aggressively[2]. EATL was originally categorized into two major groups, EATL type I and EATL type II. EATL type I is now simply classified as EATL, and it is strongly associated with celiac disease and occurs in Western countries. In this type, tumor cells are positive for CD3 and CD30 on immunohistochemistry staining, but negative for CD8 and CD56. On the other hand, EATL type II has been renamed MEITL, shows no definite association with celiac disease, and occurs in an Asian population. In this type of malignancy, tumor cells are positive for CD3, CD8 and CD56, but negative for CD30[3,4]. MEITL is most frequently found in the jejunum and ileum[5,6], and often presents with gastrointestinal perforation or obstruction[2]. MEITL is known to have a very poor prognosis due to treatment resistance and perforation or obstruction of the bowel at diagnosis or during the course of treatment [7]. Herein, we present a case of MEITL that was diagnosed following upper gastrointestinal bleeding from an ulcerative duodenal lesion, and who enjoyed recurrence-free survival for 5 years following treatment.

CASE PRESENTATION

Chief complaints

A 68-year-old female presented to the emergency department with melena.

History of present illness

The melena started a day before she consulted us. She had no past history of chronic abdominal symptoms suggesting the presence of celiac disease.

History of past illness
The patient had a history of hypertension and hyperlipidemia.

Personal and family history
She had no significant personal and family history.

Physical examination
Her body temperature was 36.4 °C, blood pressure was 128/85 mmHg, and heart rate was 98 bpm with sinus rhythm. She had mild abdominal tenderness, but there was no obvious hepatosplenomegaly or lymphadenopathy. Digital rectal examination revealed melena.

Laboratory examinations
Laboratory tests indicated a hemoglobin level of 11.3 g/dL, blood urea nitrogen level of 26.0 mg/dL, and creatinine level of 1.64 mg/dL. Her serum lactate dehydrogenase level was 232 U/L (106- 211 U/L) and soluble interleukin-2 receptor level was 213 U/mL (145- 519 U/mL) (Table 1).

Imaging examinations
Urgent esophagogastroduodenoscopy (EGD) showed an ulcerative lesion with fresh blood clots in the transverse part of the duodenum (Figure 1A). Based on the location and shape of the lesion, we suspected not only a peptic ulcer, but also an ulcer caused by vascular malformation or malignancy. Therefore, we decided to interrupt the endoscopy and perform contrast-enhanced computed tomography (CT) scan, which showed slight localized contrast enhancement on the wall of the transverse part of the duodenum in the early phase of contrast injection (Figure 1B). No vascular lesions were observed, and there was no extravasation of contrast agent in the delayed phase. EGD was immediately resumed again for further observation of the lesion. When we removed the blood clots, a protruding vessel was seen at the base of the ulcer, which was coagulated using hemostatic forceps (Coagrasper; Olympus Corp., Tokyo, Japan) (Figure 1C).

Further diagnostic work-up
Following this hemostatic treatment, the patient was discharged from the hospital without re-bleeding. The lesion that caused the bleeding was suspected to be a malignant tumor of the duodenum based on its location. EGDs, including forceps biopsies from the ulcerative lesion, were performed three times after the initial hemostatic treatment. While the first and second biopsies revealed no malignancy, the third biopsy showed findings suggestive of malignant lymphoma. On pathological evaluation, diffuse proliferation of atypical medium-sized lymphoid cells was seen in the entire mucosa, along with a few intraepithelial lesions (Figure 2A and B). No necrosis was observed. Immunohistochemical analysis revealed that the cells were positive for CD3 and CD56, and negative for CD4, CD5, CD8, CD20 and EBER (Figure 2C-E).

At this point, MEITL was suspected, and examinations for systemic lesions were subsequently performed. No abnormal lymphocytes were found on iliac bone marrow examination. ^{18}Fluorodeoxyglucose (^{18}FDG) positron emission tomography/CT (^{18}FDG-PET/CT) showed nodular FDG accumulation in the wall of the transverse part of the duodenum, consistent with the findings of contrast-enhanced CT (Figure 3). There was no abnormal FDG accumulation in the systemic lymph nodes or other parts of the gastrointestinal tract. The results of total colonoscopy and random biopsies of the gastrointestinal tract were unremarkable.

MULTIDISCIPLINARY EXPERT CONSULTATION

Ayako Gamachi, MD, PhD, Chief of the Department of Diagnostic Pathology, Almeida Memorial Hospital; and Tsutomu Daa, MD, PhD, Professor, Department of Diagnostic Pathology, Oita University
Pathological evaluations of the duodenal biopsy samples were performed by expert pathologists. The results of immunostaining of the duodenal biopsy specimen were consistent with MEITL.

FINAL DIAGNOSIS

Based on the clinical course, features of the tumor and imaging evaluations, we diagnosed MEITL (previously EATL type II) confined to the duodenum.

TREATMENT

Cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy was administered without a dosage reduction.

OUTCOME AND FOLLOW-UP

EGD performed after three cycles of CHOP therapy clearly showed that the ulcerative lesion in the duodenum had reduced in size (Figure 4A), and no atypical lymphoid cells were detected in biopsy specimens taken from the lesion. The patient tolerated the chemotherapy well and received eight full cycles of CHOP chemotherapy. ^{18}FDG-PET/CT after the final cycle revealed no abnormal FDG accumulation in the transverse part of the duodenum. Therefore, we concluded that the patient had achieved complete remission (CR). EGD at the last follow-up examination revealed a scarred ulcer (Figure 4B), and ^{18}FDG-PET/CT showed no abnormal FDG accumulation (Figure 5). The patient has been in CR for 68 mo after the initial diagnosis.

DISCUSSION

Our experience in this case highlights two important clinical points. First, MEITL can present as gastrointestinal bleeding, and not just as intestinal perforation and obstruction. Second, patients with MEITL can survive for a long time if effective treatment is administered early.

MEITL is a primary intestinal T-cell lymphoma previously known as EATL type II [1]. It is a rare intestinal tumor, accounting for 1.7% of all malignant lymphomas[8] and less than 10%-16% of gastrointestinal lymphomas[9]. MEITL differs from EATL (previously EATL type I) in that it predominantly affects Asian populations and is not associated with celiac disease[10]. Histologically, it consists of monomorphic small- to

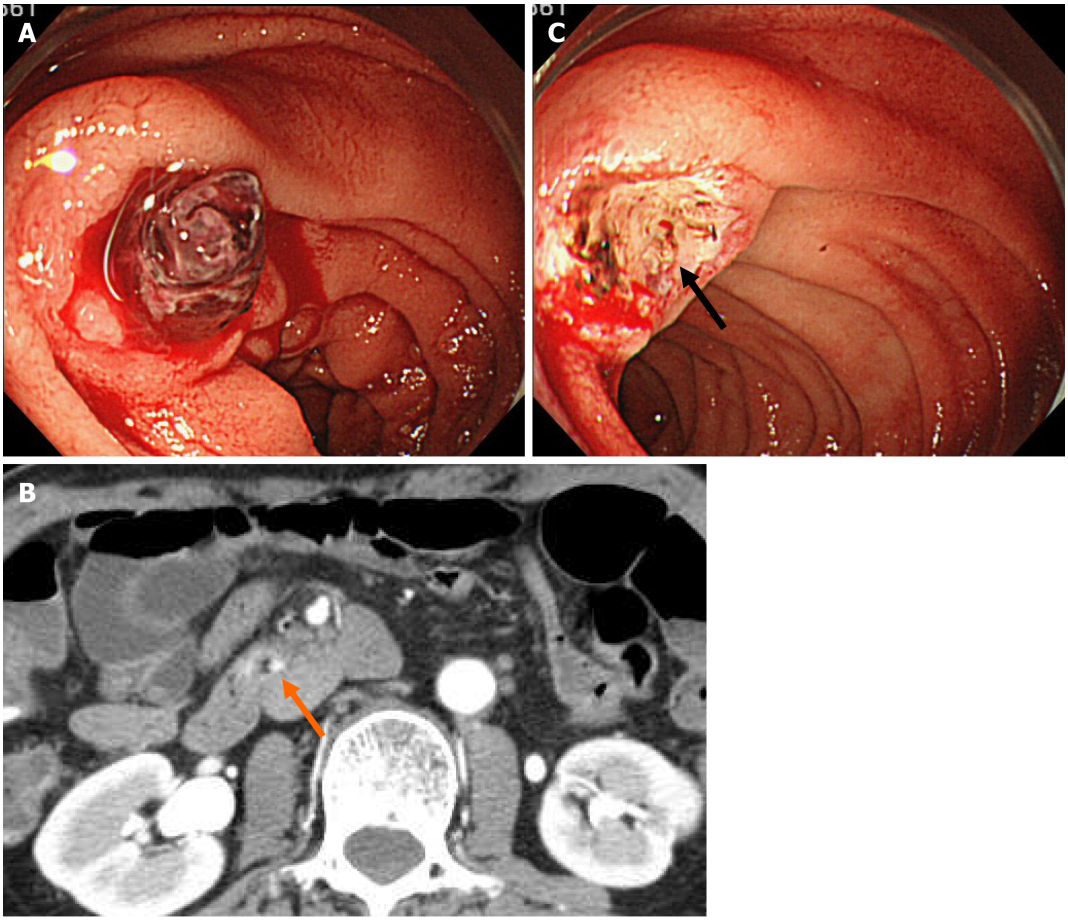

Figure 1 Endoscopic images and abdominal contrast-enhanced computed tomography scan images on initial examination. medium-sized cells that usually express CD3, CD8 and CD56, but not CD30[3,4]. Positive rates for CD8 and CD56 were reported to be 63-79% and 73-95%, respectively [8,11]. The present case had no past history of chronic abdominal symptoms suggestive of the presence of celiac disease. Histopathological examination revealed an infiltration of atypical medium-sized lymphoid cells in the entire mucosa, along with intraepithelial lesions, and immunostaining was positive for CD3 and CD56 and negative for CD5 and CD8, leading to the diagnosis of MEITL.

Our MEITL patient presented with gastrointestinal bleeding and not intestinal perforation or obstruction. More than 50% of MEITL cases are diagnosed as a result of intestinal perforation or obstruction, and emergency surgery is required in about 40% of them[9,12]. In contrast, MEITL is less frequently detected as a result of gastrointestinal bleeding. A search of the PubMed database found four case reports of MEITL or EATL that presented with gastrointestinal bleeding at the first diagnosis[13-16] (Table 2). There was a male preponderance (80%) among the five cases, and all the patients were aged above 60 years including our patient. Two cases had lesions in the jejunum, two in the stomach, and only our case had a lesion in the duodenum. Most of them showed ulcerative lesions. Only one case had a perforated lesion. Four of the five patients were diagnosed with MEITL and one with EATL. Chemotherapy was administered in four cases, and surgery was performed in two cases. To the best of our knowledge, this is the first case of MEITL that was treated with an endoscopic procedure for upper gastrointestinal bleeding. In terms of the outcomes, two cases, including our case, survived for more than 24 mo, and the two cases with gastric involvement died at 13 mo. Although it was previously reported that the median overall survival of all types of MEITL is 7 mo[11,17], the cases diagnosed after gastrointestinal bleeding had a relatively good prognosis.

In a histopathological study of a case of MEITL with perforation, tumor cells positive for TIA-1 or Granzyme B, a cytotoxic molecule, were reported to have markedly infiltrated all layers of the intestinal wall[18,19]. This suggests that MEITL

NA: Not available; MEITL: Monomorphic epitheliotropic intestinal T-cell lymphoma; EATL: Enteropathy-associated T-cell lymphoma.

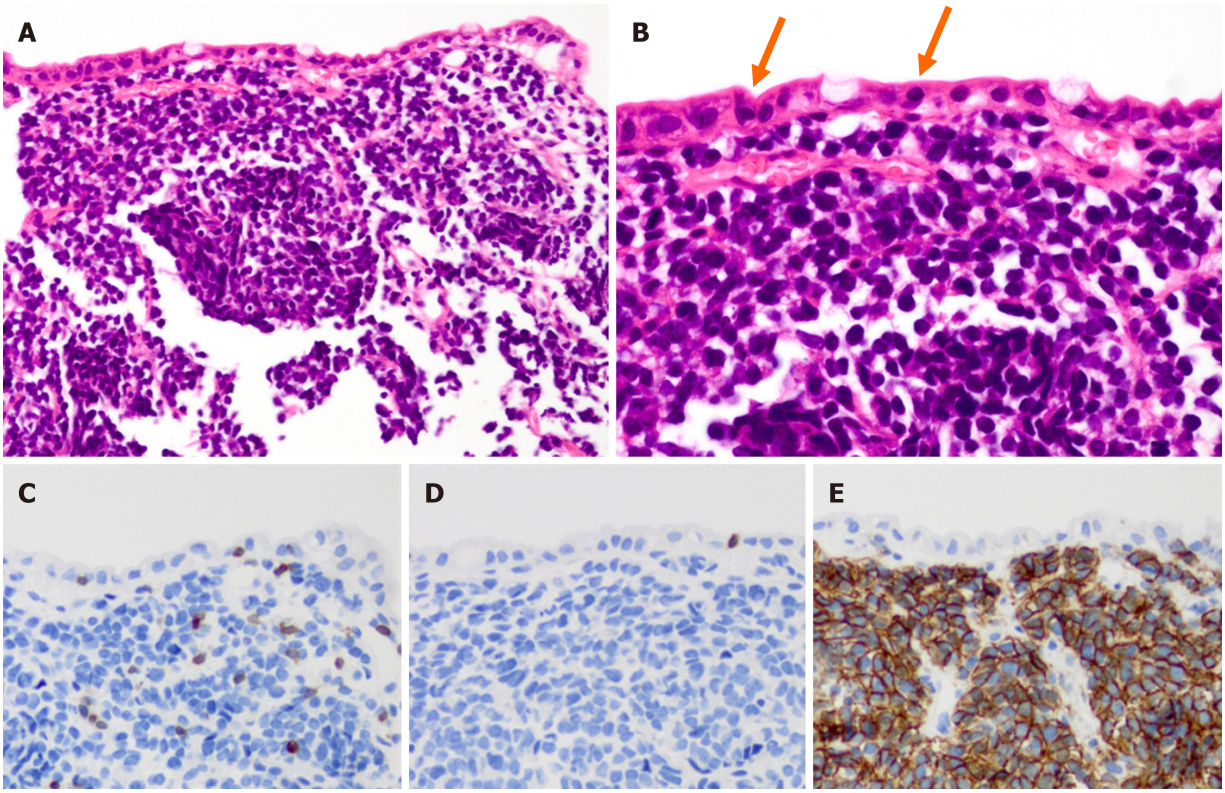

Figure 2 Histological and immunohistochemical analyses. A: Hematoxylin-eosin staining showed infiltration of medium-size atypical lymphoid cells in the mucosa; B: Lymphoid cell infiltration was also observed in the epithelium (arrow); C: Lymphoid cells expressed CD3; D: The lymphoid cells were CD8 negative; E: Lymphoid cells were CD56 positive. Magnification 200× (A, C-E) and 400× (B).

easily penetrates the gastrointestinal tract by growing destructively through all its layers, resulting in a relatively lower incidence of gastrointestinal bleeding.

Our case suggests that patients with MEITL might survive for a long time if effective treatment is administered at an early stage. MEITL is an aggressive T-cell lymphoma with a very poor prognosis and high mortality rate[20]. The median overall survival was previously reported as 7 mo[11,17], and the 5-year survival rate was reported as 20%, with a 5-year failure-free survival rate of 4%[8]. Surgery, chemotherapy and radiotherapy are all used to treat MEITL, although these treatments have shown poor overall outcomes[21]. Although several studies have demonstrated the benefit of autologous stem cell transplantation[22-25], there is no standardized treatment strategy. Moreover, MEITL often requires emergency surgery due to

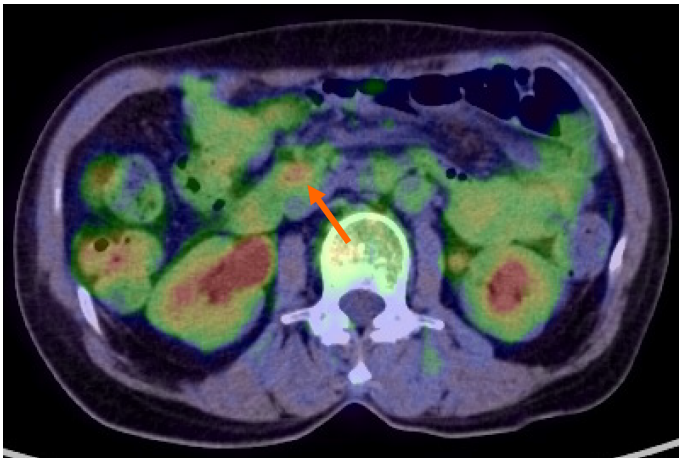

Figure 3 Pre-treatment ^{18}Fluorodeoxyglucose positron emission tomography/computed tomography images. ^{18}Fluorodeoxyglucose positron emission tomography/computed tomography showed abnormal nodular accumulation in the wall of the transverse part of the duodenum (arrow).

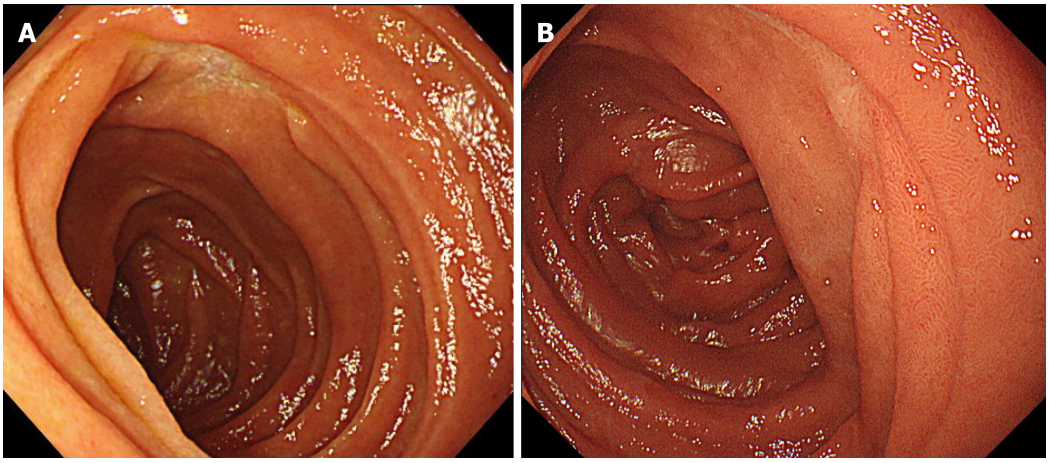

Figure 4 Follow-up endoscopic examinations. A: Esophagogastroduodenoscopy (EGD) after three cycles of cyclophosphamide, doxorubicin, vincristine, and prednisone therapy revealed that the ulcerative lesion had clearly reduced in size; B: EGD performed 60 mo after complete remission showed a scarred ulcer.

intestinal perforation or obstruction, and the lesion has usually spread before it is diagnosed[26]. Unfortunately, most patients are unable to receive effective chemotherapy due to their poor performance status and severe malnutrition at the time of diagnosis[27]. On the other hand, in a study of 26 patients with MEITL, the prognosis of non-perforated cases was significantly better than that of perforated cases, suggesting that early treatment before perforation might improve the prognosis of MEITL[28]. The present case has shown the most favorable prognosis to date, because we were able to diagnose MEITL at an early stage due to her presentation with upper gastrointestinal bleeding, and hence performed chemotherapy while the patient was in good general condition. In the previously reported cases shown in Table 2, as well, the prognosis tended to be relatively good in cases that were diagnosed after hemorrhage. This is probably because the lesion was perforated in only one case and the other cases were able to start chemotherapy before perforation. This suggests that gastrointestinal bleeding is an important sign that can lead to early diagnosis and treatment of MEITL.

So far, only one other case of MEITL with a failure-free survival for more than 5 years has been reported[29]. This case was diagnosed early by the finding of only chorionic changes (white villi) without a mass or ulcer, and CHOP therapy was started before perforation. Ishibashi *et al*[30] reported that edematous and granular mucosae with or without villous atrophy are characteristic findings of prodromal lesions of MEITL in the small intestine or duodenum. Even in the absence of obvious masses or ulcers, it is important not to overlook such micro-changes in the gastrointestinal mucosa to facilitate the early diagnosis of MEITL.

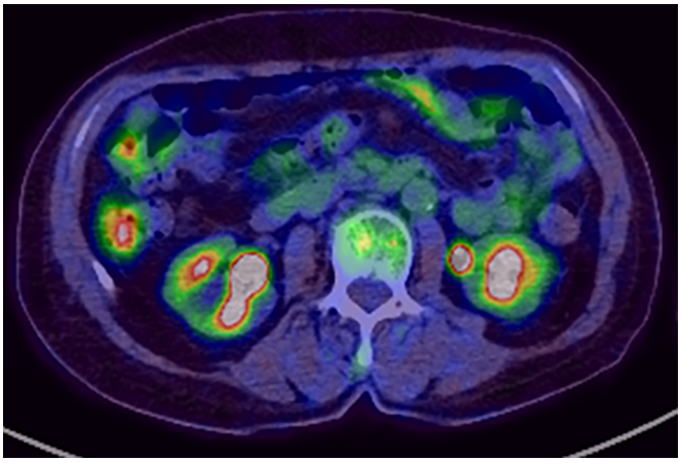

Figure 5 Follow-up ^{18}Fluorodeoxyglucose positron emission tomography/computed tomography at 60 mo after complete remission. ^{8}Fluorodeoxyglucose positron emission tomography/computed tomography showed no abnormal fluorodeoxyglucose accumulation.

Another point to note is that the diagnostic ratio of intestinal T-cell lymphoma (ITCL) by endoscopy, including tissue biopsy, is low. Sun *et al*[31] reported that out of 34 ITCL patients who underwent endoscopy, eight patients (23.5%) were definitively diagnosed with ITCL by histology. Daum *et al*[32] also reported that only 21% of intestinal non-Hodgkin lymphomas were diagnosed endoscopically. In the present case as well, a total of three tissue biopsies were required before the final diagnosis of MEITL. The following are some of the reasons for this: (1) Tissue specimens from endoscopic biopsy are usually not sufficiently large to allow correct diagnosis; (2) ITCL is known to be primarily located in the submucosa and smooth muscle, and it is difficult to detect the lesion from biopsy specimens through the mucosal layer; and (3) The disease is easy to overlook because of its rarity. Hence, a tissue biopsy of ulcerative gastrointestinal lesions should be performed carefully from the base of the ulcer, while considering the possibility of malignant lymphoma.

CONCLUSION

We report a case of MEITL diagnosed after upper gastrointestinal bleeding from an ulcerative duodenal lesion, with recurrence-free survival for 5 years after chemotherapy. MEITL can present as gastrointestinal bleeding, and not only as intestinal perforation and obstruction. In addition, although MEITL is an aggressive T-cell lymphoma with a poor prognosis, patients with MEITL can survive for a long time if effective treatment is administered early. Therefore, it is important to carefully perform histological examination to rule out MEITL when bleeding from a duodenal ulcer is observed.

ACKNOWLEDGEMENTS

We thank Dr. Ayako Gamachi (Chief of the Department of Diagnostic Pathology, Almeida Memorial Hospital) for providing histopathological images of the duodenal biopsy.

Abstract

We corrected the wrong name of the primers used in this study. The correct name should be Bakt_341F (5′-CGCTCTTCCGATCTCTGCCTACGGGNGGCWGCAG-3′) and Bakt_805R (5′-TGCTCTTCCGATCTGACGACTACHVGGGTATCT-AATCC-3′).

Key Words: Correction; Primers; Wrong name; Error; Suggestions

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This revision includes correction of the name of primer used in the study and added content based on reviewer suggestion, such as title revision, commentary on female group's weight loss, and explanations regarding the reduced average daily energy intake in the last month of ingestion period.

TO THE EDITOR

Correction to: Rahayu ES, Mariyatun M, Putri Manurung NE, Hasan PN, Therdtatha P, Mishima R, Komalasari H, Mahfuzah NA, Pamungkaningtyas FH, Yoga WK, Nurfiana DA, Liwan SY, Juffrie M, Nugroho AE, Utami T. "Effect of probiotic Lactobacillus plantarum Dad-13 powder consumption on the gut microbiota and intestinal health of overweight adults". *World J Gastroenterol* 2021; 27(1): 107-128 [PMID: 33505154 DOI: 10.3748/wjg.v27.i1.107].

The name of the primers used in this study[1], Bakt_341F (5′-CGCTCTTCCGATCTCTGCCTACGGGGGGGCWGCAG-355) GGCTATICCCACCATTCCCCATTCCACCACCACCACCACCACCACCACCACCAUTAA was spelled incorrectly. The correct name should be Bakt_341F (5′-CGCTCTTCCGATCTCTGCCTACGGGNGGCWGCAG-3′) and Bakt_805R (5′-TGCTCTTCCGATCTGACGACTACHVGGGTATCTAATCC-3′). We apologize for this error.

The title of this article[1] was "Effect of probiotic Lactobacillus plantarum Dad-13 powder consumption on the gut microbiota and intestinal health of overweight adults". As the focus of the manuscript was on Lombok, Indonesia, the title should be "Effect of probiotic Lactobacillus plantarum Dad-13 powder consumption on the gut microbiota and intestinal health of Indonesian overweight adults".

Regarding the weight loss in females, it may be caused by probiotics influence. This finding also found in the study conducted by Sanchez *et al*[2] that the *Lactobacillus rhamnosus* CGMCC1.3724 (LPR) supplementation was significantly reduce weight on female subjects and had no effect on male subjects.

About the reduced average daily energy intake in the last month of ingestion period, we did not know the exact cause of this case. When the study was carried out, we let the subjects ate as their usual diet. There was no emphasis on reducing the daily intake from us.

We express our gratitude toward reviewer for these suggestions.

Abstract

Few patients with slow-transit constipation refractory to conservative treatment can benefit with a subtotal colectomy with ileorectal anastomosis with the preservation of the superior rectal artery. In this letter to the editor some important issues were discussed. First, the study did not include a comparison group. Second, they did not present the functional results in the short or long term related to the bowel function of these patients after surgery. Finally, the authors showed that this surgical procedure was safe, and no cases of leakage were found.

Key Words: Laparoscopy; Colorectal surgery; Constipation; Colectomy

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Subtotal colectomy remains a treatment option for few patients with slow-transit constipation (STC) refractory to conservative treatment. A careful patient selection is important to improve benefits and reduce risk of adverse outcomes. Laparoscopically assisted subtotal colectomy with ileorectal anastomosis and preservation of the superior rectal artery may be effective for STC and can be the best surgical option in these situation.

TO THE EDITOR

Wu *et al*[1] recently published an observational study on the largest patient sample with vascular preservation with slow transit constipation (STC) who were submitted to laparoscopically assisted subtotal colectomy with ileorectal anastomosis and preservation of the superior rectal artery (SRA). The authors concluded that this surgical approach could significantly improve bowel function with careful patient selection and that sparing the SRA may protect against anastomosis leakage. Despite the relevant information described in the study, some important issues need to be discussed.

First, the study did not include a comparison group, *e.g.*, patients undergoing the same surgical laparoscopic procedure without SRA preservation, to find out whether one procedure is advantageous over the other. Would the SRA preservation status affect the length of hospital stay, first time to flatus, leakage volume, or postoperative complication rate? Second, based on the results, the authors cannot state that the surgery "can significantly improve bowel function with careful patient selection". The authors did not present the functional results in the short or long term related to the bowel function of these patients after surgery, as other authors have[2]. Third, they cannot state that sparing the SRA may protect against anastomosis leakage. What the authors showed is that this surgery was safe, and no cases of leakage were found. Finally, why did the surgeons make a 4-5 cm Pfannenstiel incision and bring out the mobilized bowel segment? The key limitation of the work was the absence of a control group, which would enrich the important and relevant findings of their study. In our clinical practice, we try to preserve the SRA in nononcological procedures, such as for endometriosis, diverticular disease and STC, as described by other authors[3]. However, we remove the surgical specimen using a trocar in the lower right abdominal quadrant. In the other aspects of the manuscript, we agree with the authors and believe that the best surgical option in STC could be laparoscopic subtotal colectomy with ileorectal anastomosis with preservation of the SRA.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, José B Cotter, MD, PhD, Chief Doctor, Professor, Department of Gastroenterology, Hospital da Senhora da Oliveira, Rua dos Cutileiros, Creixomil, Guimarães 4835-044, Portugal. jcotter@hospitaldeguimaraes.min-saude.pt

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

In this editorial, we comment on pancreatic cancer (PC), one of the most aggressive and lethal cancers. Only minimal improvements in survival rates have been achieved over recent years. Available chemotherapeutic regimens have little impact, and surgical resection remains the only reliable curative approach. We address current treatment options for these patients, focusing on the usefulness of *breast cancer (BRCA)* gene mutation as a prognostic biomarker and predictor of response to chemotherapy. Superior survival outcomes have been reported in patients with PC and mutant *BRCA* gene treated with first-line platinum-based chemotherapy. Therefore, it appears appropriate to include *BRCA* gene status among clinical criteria used to select the chemotherapy regimen. In addition, maintenance treatment with poly(ADP-ribose) polymerase inhibitors has been found to improve progression-free survival in patients with PC and mutated *BRCA* whose disease does not progress after first-line platinum-based chemotherapy. This combination has therefore been proposed as the optimal treatment regimen for these patients.

Key Words: Pancreatic cancer; Treatment; *BRCA*; Mutation; Poly(ADP-ribose) polymerase inhibitor; Maintenance

INTRODUCTION

Pancreatic cancer (PC) continues to be one of the most lethal malignant neoplasms, with a 5-year survival rate of only 5%[1]. It currently represents the third cause of cancer-related mortality and is expected to be the second by 2030[2]. Surgery is considered the sole potentially curative treatment; however, only 20% of patients diagnosed with PC are candidates for surgery at the time of diagnosis, and surgical resection is frequently followed by recurrence and therapeutic resistance[3].

There have been only limited advances in PC treatment over the past few decades. However, progress in basic research has recently generated increased molecular information on PC, improving knowledge of its biology and helping to explain the poor effectiveness of current therapies and the therapeutic resistance observed[4]. For instance, *KRAS*[5], *breast cancer* (*BRCA)*[6], and *ataxia-telangiectasia mutated*[7] genes play a major role in the prognosis and response to treatment of patients with advanced PC. Hence, the identification of patients with mutations in these genes can support the design of individualized therapies that may improve survival outcomes.

In this article, we evaluate the usefulness of *BRCA* gene mutation as a prognostic and predictive biomarker of the response to chemotherapy in PC patients, beyond their maintenance treatment.

CURRENT ADVANCED PC TREATMENT

Two first-line chemotherapy options are currently available for advanced PC, FOLFIRINOX and gemcitabine+nab-paclitaxel (GEM+Nab-P)[8]. These have both demonstrated superior overall survival (OS), progression-free survival (PFS), and response rates (RRs) compared to patients receiving monotherapy with gemcitabine. Specifically, the PRODIGE4/ACCORD11 study reported improved OS (11.1 *vs* 6.8 mo, respectively), PFS (6.4 *vs* 3.3 mo), and RR (31.6% *vs* 9.4%) in the FOLFIRINOX *vs* gemcitabine arm[9]. The MPACT study also reported improved OS (8.7 *vs* 6.6 mo), PFS (5.5 *vs* 3.7 mo), and RR (23% *vs* 7%) with GEM+Nab-P *vs* gemcitabine alone[10]. The higher percentage improvements obtained in the PRODIGE4/ACCORD11 study may be explained by the more favorable prognosis of the participants, who were less representative of the real-life clinical setting compared to those in the MPACT study. Specifically, the functional Eastern Cooperative Oncology Group score was 0 in 37% of PRODIGE4/ACCORD11 study participants *vs* 16% of MPACT study participants, the pancreatic head was tumor site in < 40% of the former *vs* 44% of the latter (60%-65% in clinical practice), the mean number of metastatic sites was two in the former *vs* three in the latter, the carbohydrate antigen 19-9 marker was elevated in 42% of the former *vs* 52% of the latter, and no patient over the age of 76 years participated in the former study. It should be noted that the higher survival and RRs in the PRODIGE4/ACCORD11 study were accompanied by a significant increase in hematologic and non-hematologic toxicity. This explains why FOLFIRINOX is frequently administered at a reduced dose or in modified form in the clinical setting. Finally, no randomized trials have been undertaken to compare these options, hampering evaluation of the optimal first-line treatment of PC. The only published studies have a retrospective or non-randomized prospective design, and the results have been contradictory[11-13]. Consequently, the choice of chemotherapy regimen largely depends on clinical variables, such as the performance status and previous comorbidities of patients[14,

15].

There are currently no recommendations for genetic studies to support the selection of PC treatments. One promising approach is the identification of mutations in genes involved in response mechanisms to DNA damage, such as *BRCA*, whose mutation has been associated with superior OS outcomes in PC patients treated with platinum-based chemotherapy[16]. This evidence is based on multiple *in vitro* studies and is supported by the longer OS observed in patients with advanced PC treated with platinum-based regimens who were *BRCA* mutation carriers than in those who were not (14 mo *vs* 5 mo; hazard ratio [HR] = 0.58; P = 0.08); however, this clinical trial was retrospective and only included 12 patients[17].

ROLE OF POLY(ADP-RIBOSE) POLYMERASE AND ITS IMPORTANCE IN MUTATED *BRCA*

Mutations in the genetic code must be detected and repaired to preserve genome integrity, avoiding the uncontrolled proliferation of healthy cells and possible development of cancer[18]. One DNA repair pathway detects single-strand DNA breaks. If defective, another pathway is involved in the detection of double-strand DNA breaks followed by their homologous recombination repair (HRR), using sister chromatids to restore the original DNA sequence in a high-fidelity mechanism[19]. Nuclear enzyme poly(ADP-ribose) polymerase (PARP) is responsible for detecting DNA damage and facilitating its repair. Specifically, PARP1, the main member of the PARP family, binds to and repairs both single- and double-strand DNA breaks[20]. Conversely, PARP1 inhibition results in persistent single-strand DNA breaks that lead to replication bifurcations and double-strand DNA breaks[21].

About 7% of PC patients possess *BRCA* mutations[22]. In these patients, the inhibition of PARP and resulting loss by the tumor of functional DNA repair pathways can synergically interact and produce the specific death of tumor cells. Studies in patients with ovarian, prostate, or breast cancer found that PARP inhibition enhances the activity of cytotoxic DNA agents including alkylating agents, topoisomerase inhibitors, and radiotherapeutic agents[23]. Hence, it appears plausible to assume distinct biological behaviors and responses to therapy in patients with advanced PC who have *BRCA* mutations, especially germline mutations. This has implications for the treatment selection and suggests that *BRCA* mutations may be a useful biomarker to predict the response to first-line treatment with platinum.

PLATINUM-BASED CHEMOTHERAPY IN PATIENTS WITH PC AND MUTATED *BRCA* GENE

Tumors with *BRCA* mutations are phenotypically characterized by their susceptibility to platinum-based chemotherapy, as noted above. *BRCA*-deficient cells accumulate double-strand DNA breaks, generating genomic instability and a greater predisposition to malignant transformation and progression. This is because the loss of HRR and PARP1 pathways leads to so-called synthetic lethality during DNA replication [24].

Patients with ovarian cancer who had mutated *BRCA*, either of somatic or germline origin, respond better to platinum-based chemotherapy regimens, with a superior prognosis and survival rate compared to those without this mutation[25]. In a study of 549 patients with metastatic PC, 78% of whom had at least one family member with a history of cancer, a median OS (mOS) of 8.1 mo (95% confidence interval [CI]: 7.5-9.0) was achieved by platinum-based chemotherapy, and 31% remained alive at 1 year. The mOS was higher in the patients with a family history of breast or ovarian cancer (8.5 mo; HR = 0.76; P = 0.042) and even higher in those with a family history of pancreatic and breast or ovarian cancer (14.8 mo; HR = 0. 43; P = 0.0003)[17]. According to these findings, a substantial subpopulation of patients with PC could benefit from platinum-based regimens. However, the underlying molecular mechanisms have not yet been elucidated, and further research is warranted in patients with *BRCA* mutant/deficient profiles. Other studies of PC patients receiving platinum-based chemotherapy have described a longer OS in those with a family history of breast, ovarian, or PC than in those with no family history of these cancers [26].

Cells with mutated *BRCA* are more susceptible to platinum and anthracyclines, which are selectively lethal in cells with HRR defects[27]. In a retrospective study of 36 PC patients treated with FOLFIRINOX, multivariate analyses confirmed a significantly longer mOS in patients with *vs* without homologous repair gene mutations (odds ratio [OR] = 1.47; 95%CI: 1.04-2.06; P = 0.04)[17]. In a study by Lowery *et al*[28] of 15 patients with advanced PC and germline *BRCA* mutation (*BRCA1* in 4 [27%] and *BRCA2* in 11 [73%]), 6 received platinum chemotherapy as first-line treatment, and 5 of these had a radiological partial response according to RECIST criteria, while the remaining patient had a complete response to the infusion of 5-fluorouracil, leucovorin, oxaliplatin, and irinotecan[28]. A study by Golan *et al*[26] of 71 patients with PC and a mutation in *BRCA1* (n = 21), *BRCA2* (n = 49), or both (n = 1) reported a longer mOS in patients treated with platinum than in those receiving other agents (22 *vs* 4.4 mo, respectively); the authors concluded that outcomes are more favorable in patients with PC who have *BRCA1* or *BRCA2* mutations than in those who do not[26].

USEFULNESS OF IPARP IN PC WITH MUTATED *BRCA*

In the highly influential POLO study[29], 154 patients with PC and germline *BRCA* mutation who showed no disease progression after at least 16 wk with FOLFIRINOX were randomly assigned to a group receiving maintenance therapy with olaparib, a PARP inhibitor (iPARP), or to a group receiving no maintenance treatment. Patients in the olaparib group showed a statistically significant improvement in PFS (7.4 mo *vs* 3.8 mo; HR = 0.53; 95%CI: 0.35-0.82), and 22% of them remained progression-free at 2 years compared to 9.6% in the untreated group, although there was no between-group difference in OS (18.9 *vs* 18.1 mo, respectively). Accordingly, the United States Food and Drug Administration approved olaparib as maintenance therapy for patients with advanced PC and germline *BRCA* mutation who show no disease progression after at least 16 wk of first-line treatment with platinum-based chemotherapy. In this regard, it has been reported that the iPARP-associated response does not depend on the germline or somatic origin of the *BRCA* mutation. Thus, one meta-analysis[22] describes eight studies that reported a response to PARPi in 24/43 (55.8%) patients with somatic *BRCA* mutation *vs* 69/157 (43.9%) patients with germline *BCRA* mutation, a non-significant difference (P = 0.399). In addition, five studies in the meta-analysis found no difference in PFS between patients with somatic *vs* germline *BCRA* mutations. The authors concluded that the response to iPARP therapy is similar between these types of patient.

Platinum-based chemotherapy has been combined with the administration of iPARP. An open-label, randomized, multicenter phase II trial was conducted on the efficacy of cisplatin plus gemcitabine with *vs* without veliparib in 50 patients with PC and germline-mutated *BRCA*. The RR was 74.1% for cisplatin plus gemcitabine with veliparib *vs* 65.2% for cisplatin plus gemcitabine alone (P = 0.55), obtaining a disease control rate of 100% with the former regimen *vs* 78.3% with the latter (P = 0.02). According to the authors, cisplatin plus gemcitabine is effective in advanced germline-mutated *BRCA* PC, and the addition of veliparib offers no improvement in therapeutic response[30-32]. These results support the selection of platinum-based chemotherapy as first-line treatment for patients with PC and germline *BRCA* mutation.

Various clinical trials are currently exploring the combination of iPARP with different chemotherapy and immunotherapy regimens (Table 1). It has been proposed that PARP inhibition induces tumor immunogenicity by increasing the tumor antigen load and the expression of programmed death-ligand 1 in tumor tissue, thereby increasing the susceptibility of patients with *BRCA* mutations to immunotherapy, as already demonstrated in breast cancer[33], small cell lung cancer[34], and ovarian cancer[35].

In summary, current studies suggest that *BRCA* mutation status may be a useful prognostic and predictive biomarker of the response to platinum in patients with PC, identifying those who may benefit from platinum-based chemotherapy as standard first-line treatment.

CLINICAL IMPLICATIONS

PC is associated with a poor prognosis and high resistance to chemotherapy. Few cytotoxic agents have demonstrated activity against this tumor, including platinum-based (FOLFIRINOX) and gemcitabine-based (GEM+Nab-P) regimens, and they

iPARP: Poly(ADP-ribose) polymerase inhibitor.

deliver very modest benefits to the patient. There has been no comparative study of these agents to determine which is more appropriate as a first-line treatment, and this decision relies on the clinical characteristics and comorbidities of the patients. Two important issues must still be resolved: the best regimen for the personalization and optimization of first-line chemotherapy in patients with PC; and the ideal sequencing of chemotherapy lines, taking into account the accumulated toxicity and the molecular profile of the cancer.

As noted above, the *BRCA* gene encodes proteins essential for repairing double-strand DNA damage *via* the HRR pathway, and its mutation has been found to predict the response to first-line chemotherapy with platinum plus iPARP in patients with PC [26]. Thus, patients with advanced PC and germline *BRCA* mutation lived significantly longer when treated with platinum *vs* other cytotoxic agents[17]. In addition, maintenance treatment with iPARP has been found to improve the PFS of patients with PC and mutated *BRCA* whose disease does not progress after first-line platinum-based chemotherapy. Taken together, these findings support the selection of platinum-based regimens as first-line treatment of patients with PC and germline *BRCA* mutation[30-32].

Given the lack of evidence on the optimal treatment of patients with PC, it appears appropriate to consider the presence/absence of *BRCA* mutation among clinical criteria for the selection of first-line chemotherapy regimen.

CONCLUSION

An appreciable number of patients with PC have a mutated *BRCA* gene, and the ongoing development of drugs that target DNA repair pathways may offer relevant therapeutic benefits to this little-studied but clinically important sub-population. This defect in DNA repair pathways has the potential to improve outcomes in patients undergoing platinum-based chemotherapy, assisting individualized selection of the optimal first-line regimen.

Abstract

De novo lipogenesis (DNL) plays an important role in the pathogenesis of hepatic steatosis and also appears to be implicated in hepatic inflammation and fibrosis. Accordingly, the inhibition of acetyl-CoA carboxylase, which catalyzes the rate-limiting step of DNL, might represent a useful approach in the management of patients with nonalcoholic fatty liver disease (NAFLD). Animal studies and preliminary data in patients with NAFLD consistently showed an improvement in steatosis with the use of these agents. However, effects on fibrosis were variable and an increase in plasma triglyceride levels was observed. Therefore, more long-term studies are needed to clarify the role of these agents in NAFLD and to determine their risk/benefit profile.

Key Words: Acetyl-CoA carboxylase inhibitors; Non-alcoholic steatohepatitis; Fibrosis; Steatosis; Firsocostat

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Acetyl-CoA carboxylase inhibitors suppress de novo lipogenesis resulting in improvement in hepatic steatosis in both animal models and in patients with nonalcoholic fatty liver disease. However, the effects of these agents on hepatic fibrosis are inconsistent and they increase plasma triglyceride levels, casting doubt on their risk/benefit profile.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is the commonest chronic liver disease in high-income countries, affecting 17%-46% of the general population[1]. NAFLD includes non-alcoholic fatty liver, characterized by isolated hepatic steatosis, and non-alcoholic steatohepatitis (NASH), where variable degrees of hepatic inflammation and fibrosis coexist with steatosis[2]. NASH is associated with increased risk for cirrhosis, hepatocellular cancer (HCC) and cardiovascular disease[3,4]. Diet and exercise, aiming at weight loss, is the cornerstone of management of NAFLD, but only a minority of patients achieves and maintains weight loss > 5%, which is essential for improvement in liver histology[2,5]. Several pharmacological agents have been evaluated in patients with NAFLD but none is currently licensed for use in this disease[2]. Therefore, there is an unmet need for safe and effective treatments in patients with NASH.

NON-ALCOHOLIC FATTY LIVER DISEASE

The pathogenesis of NASH is complex and multiple pathways, including insulin resistance, inflammation, oxidative stress and apoptosis are implicated[6]. De novo lipogenesis (DNL), defined as the synthesis of fatty acids from non-lipid sources, is pivotal in the development and progression of NASH. DNL is increased in patients with NAFLD and appears to be responsible for up to 38% of intrahepatic triglyceride content in this population[7]. In addition to its contribution to the development of hepatic steatosis, DNL also promotes fibrosis by activating hepatic stellate cells (HSC), which are the principal contributors to liver fibrosis[8,9]. Acetyl-CoA carboxylase (ACC) catalyzes the ATP-dependent carboxylation of acetyl-coenzyme A (CoA) to form malonyl-CoA, which is the rate-limiting and key regulatory step in DNL[10]. ACC exists as two isoenzymes that are encoded by two different genes; ACC1 is cytosolic whereas ACC2 is located at the mitochondrial membrane[10].

Given the central role of ACC in DNL and the implication of the latter in the pathogenesis of NAFLD, ACC might represent an attractive therapeutic target in this disease. Indeed, early studies showed that liver-specific, genetic inactivation of ACC protects against the development of hepatic steatosis[11,12]. More recently, several orally available, liver-specific, dual ACC1/ACC2 inhibitors have been developed and are being evaluated in the management of NAFLD (Table 1). Perhaps the most promising is firsocostat, formerly known as GS-0976. In mice with NASH, this agent improved hepatic steatosis and also reduced hepatic inflammation[13,14]. However, an increase in serum triglyceride, glucose and insulin levels as well in total body fat mass was observed[13,14]. In another study, a structural analog of GS-0976 reduced hepatic steatosis and hepatic insulin resistance in high-fructose-fed rats[15]. However, a 30%-130% increase in plasma triglyceride levels was again observed, which was attributed to an increase in very low density lipoprotein production and a decrease in triglyceride clearance by lipoprotein lipase[15]. Other ACC inhibitors also showed promise in ameliorating hepatic steatosis in rodent models of NASH. ND-630 reduced hepatic steatosis in Zucker diabetic fatty rats[16]. In addition, PF-05221304 not only improved liver steatosis in a rat model of NASH but also reduced hepatic inflammation[17].

In addition to the reduction in hepatic steatosis, ACC inhibition also appears to ameliorate hepatic fibrosis (Table 1), which is the strongest predictor of mortality in NASH[18-20]. In recent studies, firsocostat and a structural analog of this agent inhibited the activation of HSCs and reduced hepatic fibrosis both *in vitro* and in animal models of NASH[9,13,14]. PF-05221304 also prevented the activation of primary HSCs to myofibroblasts *in vitro* and reduced fibrosis in choline-deficient, high-fat-fed rats[17]. In contrast, MK-4074 did not affect fibrosis in a rat model of NASH, suggesting that the effect of ACC inhibition on fibrosis might be agent-specific [21]. On the other hand, another liver-specific, dual ACC1/ACC2 inhibitor, ND-654,

Table 1 Major findings of preclinical and clinical studies that evaluated the effects of acetyl-CoA carboxylase inhibitors in non-alcoholic steatohepatitis

Population	ACC inhibitor	Major findings	Ref.
Mice with NASH	Firsocostat (GS-0976)	↓ Hepatic steatosis, inflammation and fibrosis	[13, 14]
High-fructose-fed rats	A structural analog of firsocostat	↓ Hepatic steatosis; ↓ hepatic insulin resistance	[15]
Zucker diabetic fatty rats	ND-630	↓ Hepatic steatosis	[16]
Rat model of NASH	PF-05221304	↓ Hepatic steatosis, inflammation and fibrosis	[17]
Rat model of NASH	MK-4074	No effect on hepatic fibrosis	[21]
Rat model of NASH	ND-654	↓ Hepatic steatosis; Delayed progression of hepatocellular cancer	[22]
10 patients with NASH	Firsocostat	↓ Hepatic steatosis and fibrosis	[23]
126 patients with NASH	Firsocostat	↓ Hepatic steatosis and tissue inhibitor of metalloproteinase-1 levels	[24]
392 patients with NASH and bridging fibrosis or compensated cirrhosis (F3-F4)	Firsocostat	↓ Hepatic steatosis and stiffness	[25]
Healthy subjects	PF-05221304	Dose-dependent suppression of de novo lipogenesis	[26]
Overweight and/or obese adult males	ND-630	Suppression of de novo lipogenesis	[27]
30 patients with non-alcoholic fatty liver	MK-4074	↓ Hepatic steatosis	[28]

not only reduced hepatic steatosis but also delayed the progression of HCC in a rat model[22].

Preliminary studies suggest that ACC inhibition might also be effective in patients with NAFLD (Table 1). In a pilot, open-label, prospective study in 10 patients with NASH, administration of firsocostat for 12 wk reduced hepatic steatosis, assessed with magnetic resonance imaging (MRI), and fibrosis, assessed with both magnetic resonance elastography (MRE) and serum levels of tissue inhibitor of metalloproteinase 1 (TIMP-1)[23]. However, serum alanine aminotransferase levels did not change[23]. In a phase 2, randomized study in 126 patients with NASH, treatment with GS-0976 for 12 wk reduced hepatic steatosis, assessed with MRI, and TIMP-1 Levels more than placebo[24]. However, changes in MRE-measured liver stiffness did not differ among groups and an 11%-13% increase in serum triglyceride levels was observed in patients treated with GS-0976[24]. In a larger, phase 2b, randomized trial in 392 patients with NASH and bridging fibrosis or compensated cirrhosis (F3-F4), the incidence of the primary endpoint (a ≥ 1-stage improvement in fibrosis without worsening of NASH) did not differ between firsocostat and placebo[25]. However, firsocostat improved steatosis, increased the proportion of patients with ≥ 1-grade improvement in liver histology and improved liver stiffness evaluated by transient elastography and the Enhanced Liver Fibrosis Test compared with placebo[25]. Notably, serum glucose and insulin levels as well as body weight did not change in patients treated with firsocostat [25]. On the other hand, a mean increase in serum triglyceride levels by 42 mg/dL was observed in the firsocostat group[25].

Other ACC inhibitors also showed promising results in pilot clinical studies (Table 1). In healthy subjects, PF-05221304 dose-dependently suppressed DNL and was well-tolerated[26]. With doses yielding ≥ 90% DNL inhibition, asymptomatic increases in serum triglyceride levels and declines in platelet count occurred but these were not observed at ≤ 80% DNL inhibition[26]. A single dose of ND-630 was also shown to suppress DNL in overweight and/or obese but otherwise healthy adult males and was well tolerated[27]. Finally, in a randomized study in 30 patients with NAFL, treatment with MK-4074 for 4 wk decreased hepatic fat more than pioglitazone and placebo[28]. However, a 2-fold increase in plasma triglyceride levels was observed in patients treated with MK-4074 and not in the other groups[28]. It was shown that inhibition of ACC results in reduced intrahepatic content of polyunsaturated fatty acids, which in turn activates sterol regulatory element-binding protein-1c that increases hepatic production of very low density lipoprotein and therefore plasma triglyceride levels[28].

CONCLUSION

In conclusion, ACC inhibitors appear to represent a promising tool for ameliorating hepatic steatosis. The effect of these agents on hepatic fibrosis is less consistent and more studies are needed to assess their impact on NASH. In addition, given the high cardiovascular risk of patients with NASH, the increase in triglyceride levels during treatment with ACC inhibitors is a cause of concern and should be also be factored in the decision to administer them in this population.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is the third leading cause of cancer-related deaths in the United States. Although chemotherapeutic regimens such as gemcitabine+ nab-paclitaxel and FOLFIRINOX (FOLinic acid, 5-Fluroruracil, IRINotecan, and Oxaliplatin) significantly improve patient survival, the prevalence of therapy resistance remains a major roadblock in the success of these agents. This review discusses the molecular mechanisms that play a crucial role in PDAC therapy resistance and how a better understanding of these mechanisms has shaped clinical trials for pancreatic cancer chemotherapy. Specifically, we have discussed the metabolic alterations and DNA repair mechanisms observed in PDAC and current approaches in targeting these mechanisms. Our discussion also includes the lessons learned following the failure of immunotherapy in PDAC and current approaches underway to improve tumor's immunological response.

Key Words: Pancreatic cancer; Metabolism; DNA repair; Therapy-resistance; Immunotherapy

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is a highly aggressive tumor, with a 5-year overall survival of 10%. As the cause of approximately 47000 deaths annually, it is the third leading cause of cancer-related mortality in the United States and is expected to be the second primary cause of cancer-related deaths by 2030[1,2]. Surgical resection of the tumor remains the only curative option for patients with PDAC. However, due to late diagnosis, only a limited number of patients qualify for it. Relapse is common and often observed as early as two months post-surgery. Therefore, adjuvant chemotherapy is often prescribed to improve patient outcomes. For over a decade, gemcitabine was the mainstay for chemotherapy for resectable PDACs. The drug advanced the patient survival to 5.65 mo compared with 4.41 mo with 5-fluorouracil[3]. Recently, a combination therapy FOLFIRINOX (FOLinic acid, 5-Fluroruracil, IRINotecan, and Oxaliplatin) displayed better patient outcomes than gemcitabine[4]. The four-drug cocktail, although toxic, significantly improved survival in PDAC patients and is currently approved for both resectable and metastatic PDAC[5-9] (Table 1).

The complex pancreatic cancer biology is often attributed as the underlying cause of the poor chemotherapeutic response. This review will highlight the current knowledge of the therapeutic resistance mechanisms prevalent in PDAC and the opportunities PDAC tumor biology provides for its efficient targeting.

CURRENT THERAPIES IN PDAC

Gemcitabine

Gemcitabine has been a mainstay for PDAC treatment since 1997, when it was found to improve median and overall survival compared to 5-fluorouracil[3]. Gemcitabine (2′, 2′- difluorodeoxycytidine) is a difluoro analog of deoxycytidine which inhibits DNA synthesis through (1) inhibition of ribonucleotide reductase (RR), (2) inhibition of DNA polymerase (*via* diphosphate analog), or (3) mis-incorporation into the DNA, thus preventing chain elongation (*via* triphosphate analog)[10,11]. The inhibition of RR by the diphosphate analog depletes the deoxy-ribonucleotide pool essential for DNA synthesis.

Numerous mechanisms for gemcitabine inactivity have been demonstrated. Although resistance can be divided into innate and acquired forms, we will present evidence referring to both as "resistance" for this review.

The first interaction of gemcitabine with the cells occurs at the nucleotide transporter level. These transporters-concentrative nucleoside transporters (hCNTs) and equilibrative nucleoside transporters (hENTs) allow the transport of gemcitabine into the cells[12]. Evidence of the importance of nucleotide transporters for gemcitabine activity includes the observation that, in the absence of hENT1, PDAC patients treated with gemcitabine have reduced survival[13]. The enzyme deoxycytidine kinase (dCK) is the rate-limiting enzyme that converts gemcitabine into di-fluoro deoxycytidine mono-phosphate and is essential for gemcitabine-induced cytotoxicity[14]. Acquired resistant models demonstrate reduced expression of dCK in cells that do not respond to gemcitabine[14,15]. However, a recent analysis of the patient-derived xenograft PDAC model found no change in dCK levels in the gemcitabine-resistant tumors[16], indicating that mechanisms independent of dCK contribute to poor response to gemcitabine.

Table 1 Landmark trials for approved pancreatic ductal adenocarcinoma therapies

Treatment	Tumor characteristic	Primary endpoint	Ref.
Gemcitabine	Advanced PDAC	Median survival, 5.65 mo	Burris *et al*[3]
Gemcitabine + Erlotinib *vs* Gemcitabine	Locally Advanced or metastatic PDAC	Overall survival (OS), 6.24 mo *vs* 5.91 mo	Hoffmann *et al*[59]
FOLFIRINOX *vs* Gemcitabine	Metastatic PDAC	OS, 11.1 mo *vs* 6.8 mo	Conroy *et al*[4]
Gemcitabine + nab-paclitaxel *vs* Gemcitabine	Metastatic PDAC	OS, 8.5 mo *vs* 6.7 mo	Couvelard *et al*[60]
Gemcitabine + Capacitabine *vs* Gemcitabine	Resectable PDAC	OS, 28 mo *vs* 25.5 mo	Neoptolemos *et al*[8]

PDAC: Pancreatic ductal adenocarcinoma.

As mentioned earlier, when gemcitabine inhibits RR, the deoxy-ribonucleotide pool of the cells becomes depleted, leading to cell death. Overexpression of M1 and M2 isoforms, namely RRM1 and RRM2, is associated with reduced cellular response to gemcitabine[16-18]. Micro RNAs such as miR20a-5 and miR211 have been shown to downregulate RR, enhancing pancreatic cancer's sensitivity to gemcitabine and inhibiting cellular invasion[19,20]. Similarly, natural product, small molecule, and miRNA-based inhibition of RR sensitizes PDAC cells to gemcitabine[19-21-24]. Although strong *in vitro* data indicate RRM1/RRM2 play a key role in gemcitabine sensitivity, conflicting clinical outcomes have limited the utility of these enzymes for PDAC prognosis[25-28].

Other cellular processes such as epithelial-mesenchymal transition (EMT), mitogenic signaling, and tumor-stroma interaction also contribute to gemcitabine resistance [29]. Analysis of PDAC lines revealed that the EMT gene expression profile differs considerably between drug-sensitive and -resistant cells[30]. The drug-resistant cells showed reduced response to gemcitabine, 5-fluorouracil, and cisplatin, and expressed elevated levels of EMT marker Zeb1[30]. In addition, suppression of EMT enhanced the sensitivity of PDAC to gemcitabine by regulating the expression of nucleoside transporters[31].

5-Fluorouracil

Similar to gemcitabine, 5-fluorouracil belongs to the antimetabolite class of anti-cancer agents. 5-Fluorouracil inhibits the enzyme thymidylate synthetase (TS), which is responsible for methylation of deoxyuridine mono-phosphate to deoxythymidine mono-phosphate, a precursor for DNA synthesis. 5-Fluorouracil was the first drug to be approved as PDAC adjuvant therapy[32,33]. Although no longer used as monotherapy, 5-fluorouracil forms a part of the PDAC chemotherapeutic regimen FOLFIRINOX. Compared to gemcitabine therapy, combination therapy with FOLFIRINOX improved the overall survival and median progression-free survival of patients with metastatic PDAC[4]. Although any improvement in PDAC patient outcomes should be observed as a positive sign, the high toxicity of the drug regimen, limited patient eligibility for FOLFIRINOX, and prevalence of 5-fluorouracil resistant mechanisms may further limit the use this combination therapy in PDAC[34-38]. Multiple mechanisms have demonstrated to contribute to 5-fluorouracil resistance, such as alteration in (1) 5-fluorouracil metabolizing enzymes, (2) membrane transporters, and (3) pro-survival/ pro-apoptotic pathways. High TS expression is associated with poor survival in PDAC patients, however, the difference in survival is more significant in patients that received 5-fluorouracil based therapy[39,40]. The enzyme dihydropyrimidine dehydrogenase (DPD) catabolizes the 5-fluorouracil in the liver. In colorectal cancer patients receiving 5-fluorouracil based therapy, high DPD levels was associated with significantly shorter disease-free survival and overall survival[41]. In vitro analysis of PDAC cells lines and 5-fluorouracil-resistant sub-lines revealed that high expression of TS and DPDY is associated with poor 5-fluorouracil response[42].

Targeted therapies in PDAC

Comprehensive genetic analysis has revealed that pancreatic cancers are a host of numerous genetic mutations[43]. Mutation of *K-ras* is the most frequent genetic alteration observed in more than 90% of pancreatic cancer cases[44]. K-ras protein is a downstream signaling molecule activated by various transmembrane receptor tyrosine kinases, such as the epidermal growth factor receptor (EGFR), insulin-like growth factor receptor, and c-met. EGFR, overexpressed in more than 40% of pancreatic

cancers, is associated with poor disease prognosis, invasion, and aggressive clinical behavior[45,46]. Given its importance, therapies targeting EGFR have been tested to determine their ability to improve the outcomes of PDAC patients. In one phase III trial, the addition of erlotinib (EGFR tyrosine kinase inhibitor) to gemcitabine-based therapy significantly improved the overall survival of PDAC patients[47]. A recent clinical trial compared the efficacy of gemcitabine + erlotinib in rash-positive pancreatic cancer patients and found similar one-year survival and better quality of life compared to patients on FOLFIRINOX[48]. Some trials however, have failed to show the clinical benefit of adding EGFR targeting drugs to PDAC chemotherapy[49-52]. Therapies targeting other molecular mechanisms active in pancreatic cancer have not shown beneficial effects, and EGFR targeting may have a place in PDAC therapy as precision medicine[53-57].

FUTURE OPPORTUNITIES TO TARGET PDAC

Pancreatic tumor metabolism

Pancreatic cancer is characterized by a dense stroma surrounding the tumor. This dense stromal region limits vascularization, creating an environment limiting oxygen and nutrient supply[58,59]. Limited oxygen gives rise to hypoxia that is associated with poor patient prognosis[59-61]. In an abundance of oxygen, the non-malignant cells produce most of their energy from mitochondrial oxidative phosphorylation (OXPHOS) while cancer cells exhibit an altered metabolism, first observed in the 1920s by Warburg[62], in which they produce most of their energy from glycolysis. Further, Warburg[62] observed that the majority of the glucose taken up by the cancer cells is converted to lactate rather than CO_2, an observation that has since been witnessed and verified by various researchers in various tumors, including PDAC[63-70]. Pancreatic cancer shows upregulation in glycolysis, pentose phosphate pathway (PPP), fatty acid synthesis, and purine/pyrimidine synthesis, and downregulation of enzymes involved in Kreb's cycle and the OXPHOS.

Analysis of the pancreatic cancer progression model revealed that the metabolic alterations precede tumor formation[71]. Metabolic rewiring in the early stages involves upregulated glycolytic and PPP. The altered metabolic profile allows quick ATP production and provides nucleotides and other metabolic intermediates required for proliferating cancer cells[72]. However, the suppression of OXPHOS can lead to excessive acid build-up within the cancer cells in the form of lactate. To circumvent this, pancreatic cancers express monocarboxylate transporters (MCT1 and MCT4) to efflux out lactate[73,74]. These metabolic adaptations, aided by the upregulation of glucose transporters GLUT1, allow the cancer cells to utilize glucose for their energy and biosynthetic needs. In addition, the molecular biology of pancreatic cancers, such as mutation of KRAS and P53, contribute to the so-called "glycolytic switch" in the PDACs by regulating genes like hexokinase-2, glucose transporters GLUT-1, and PKM2, and by promoting anabolic processes[75-78].

Altered tumor metabolism is also associated with poor therapy response in pancreatic tumors. Acquired gemcitabine-resistant models of pancreatic cancer show a marked increase in aerobic glycolysis that maintains the EMT phenotype and reduced responsiveness to the therapeutic agent[79]. The resistant cells exhibit elevated glycolytic enzymes HK2, LDHA and PKM2, and glucose transporter GLUT1. Below we discuss the central carbon metabolic pathways — namely, glycolysis, tricarboxylic acid (TCA) cycle, and the PPP — as therapeutic targets in pancreatic cancer.

Glycolysis as therapeutic target: Analysis of pancreatic tumors reveals that HK2 expression is upregulated in localized tumors as well as metastatic tumors compared to non-malignant tissues[80]. Since HK2 plays a crucial role in pancreatic tumors, efforts have been made to evaluate HK2 as a therapeutic target for pancreatic cancers. We were among the first to show that inhibition of glycolytic enzymes HK2 inhibits the growth and pro-survival signaling in pancreatic cancers[81]. In addition, inhibition of HK2 in pancreatic cancer cells suppresses their anchorage-independent growth and invasion[80]. The role of HK2 has also been implicated in gemcitabine resistance, as HK2 dimerization is enhanced in cells that do not respond to gemcitabine[82]. *In vitro* and *in vivo* analysis revealed that inhibition of HK2 enhanced the sensitivity of PDAC to gemcitabine. Similarly, in another study, inhibition of HK2 using chemical inhibitor 2-deoxyglucose enhanced resistant cells' sensitivity to gemcitabine[79].

PKM2: Pyruvate kinase (PK) is a glycolytic enzyme that catalyzes the conversion of phosphoenol pyruvate and ADP into pyruvate and ATP. Four isoforms of the enzyme

exist in vertebrates: PKR in erythrocytes; PKL in liver and kidney; PKM1 in adult muscle, brain, and heart; and PKM2 in most adult tissues and fetal tissues[83]. Phosphorylation of PKM2 at tyrosine residue 105 (Y105) is associated with reduced PKM2 activity and enhanced tumor growth[84,85]. Analyses of PKM isoform show abundance of isoform M2 in tumor cells compared to high levels of M1 in normal tissues[52,53]. In cancer cell lines, high PKM2 Levels are associated with proliferation, metastasis, and angiogenesis[54-56]. The role of PKM2 in pancreatic tumors is, however, controversial. Using the mice model of PDAC, a recent report demonstrated that although PKM2 expression is elevated in PDAC, the loss of PKM2 does not significantly affect the size of tumors or the survival of mice bearing PDAC[86]. Surgical specimens from 115 PDAC patients show that PKM2 expression is associated with better overall survival[87]. However, others have shown that high PKM2 expression correlates with poor patient outcomes[88,89]. Considering several observations demonstrating a vital role of PKM2 in pancreatic cancer survival, invasion, angiogenesis, metastasis, and drug resistance, we believe the PKM2 serves as an attractive target for the treatment of PDAC, even though its role in pancreatic cancer tumorigenesis is still unproven[90-95].

Lactate dehydrogenase (LDH): LDH is an enzyme that exists as a tetramer and catalyzes the conversion of pyruvate to lactate and *vice versa*. LDHA (LDH gene product) regulates pyruvate's conversion to lactate, thus preventing the entry of pyruvate into the TCA cycle. Deregulated expression of LDHA is observed in various tumors, including pancreatic, gastric, bladder, cholangiocarcinoma, lung, and endometrial cancers[96-102]. Numerous oncogenic signaling molecules, namely, HIF1 alpha, myc, FOXM1, and tyrosine kinase receptors, can regulate the level or the activity of LDH[96,103-106]. Elevated levels of LDH are associated with unfavorable prognoses for PDAC patient survival, chemotherapy response, and recurrence[107-112]. Preclinical studies have revealed that inhibition of LDH reduces the survival of PDAC cells[113,114].

PPP as therapeutic target: The PPP branches from glycolysis and contributes to the cancer phenotype through (1) synthesis of NADPH (oxidative PPP), which is important for redox regulation and fatty acid synthesis, and (2) supplying the proliferating cells with pentose sugar (non-oxidative PPP) for nucleic acid biosynthesis [115]. Accumulating evidence indicates that PPP plays a vital role in pancreatic tumor survival, metastasis, and therapy resistance. Our lab and others have shown that MYC regulates the activity of both oxidative and non-oxidative PPP through the regulation of G6PD and the RPIA (non-oxidative PPP) gene[78,116,117]. The regulation of RPIA *via* MYC appears to be under the directive of KRAS. The MAPK-MYC-RPIA-nucleotide biosynthesis pathway is shown to be important for KRAS-mediated maintenance of PDAC[78,116]. Considering that most PDAC patients (90%) express mutant KRAS, inhibition of PPP is an attractive strategy for developing more efficient pancreatic cancer therapies that would target KRAS-induced metabolic abnormalities. Our recent results found that pancreatic cancer cells resistant to erlotinib express elevated levels of G6PD. The upregulated G6PD prevents the induction of ROS in response to erlotinib, thus protecting the cells from drug-induced cytotoxicity[117]. The non-oxidative PPP has also been implicated in PDAC therapy resistance. Shukla *et al*[118] found that gemcitabine-resistant cells express enhanced carbon flux into the non-oxidative PPP, aided by elevated non-oxidative PPP enzyme levels. This alteration in metabolic flux allows elevated pyrimidine synthesis that contributes to gemcitabine resistance[118].

TCA cycle and OXPHOS as therapeutic target: Although cancer cells exhibit an elevated flux of glycolytic intermediate into branched pathways, the TCA cycle is still functional. The TCA cycle continues to provide proliferating cancer cells with energy, macromolecules and maintain the cellular redox balance. Recent reports have demonstrated the importance of the TCA cycle and OXPHOS in pancreatic cancer survival[119-123]. Due to their critical roles, the TCA cycle and OXPHOS have been tested as a therapeutic target for PDAC therapy. Three major approaches have been sought to this end: (1) Targeting TCA cycle enzyme/intermediates; (2) Targeting glutamine-dependent anaplerosis; and (3) Targeting the OXPHOS.

Glutamine, a non-essential amino acid, is considered an important energy source for PDAC along with glucose[124,125]. Accumulating evidence demonstrates that glutamine plays a vital role in PDAC proliferation, invasion, maintenance of redox balance, chemotherapy, and radiotherapy resistance, underlining glutamine metabolism as a potential therapeutic target[126-132]. However, conflicting results show that the presence of glutamine suppresses PDAC growth and invasion, dampening

enthusiasm for targeting glutamine metabolism[133-135]. A current clinical trial (NCT04634539) is analyzing whether adding glutamine improves efficacy and reduces the toxicity of PDAC chemotherapy. The results from this trial will shed light on the effect of glutamine on PDAC chemotherapy.

Two additional approaches, targeting the OXPHOS and the TCA cycle, have shown promise in preclinical evaluations, and agents targeting them are currently in clinical trials (Table 2). IACS-010759 inhibits mitochondrial complex one and has recently completed a phase I study in different tumor types, including advanced pancreatic cancers (Table 2). Although the preclinical data regarding the effect of IACS-010759 on pancreatic tumors is lacking, inhibition of OXPHOS complex one appears to be a promising strategy for overcoming drug resistance[136-139]. The anti-diabetic drug metformin has been tested and continues to be tested for its efficacy in PDAC (NCT01210911, NCT02336087, and NCT01666730). Although the experience with metformin in clinical settings has not resulted in improved patient outcomes, a recent meta-analysis indicated survival benefits in patients with PDAC and concurrent diabetes mellitus, highlighting a need for a personalized therapeutic approach for the success of this therapy[140-142].

CPI-613 or Demivistat (Table 2) is a TCA cycle targeting agent that inhibits the activity of pyruvate dehydrogenase and α- ketoglutarate dehydrogenase. In a phase 1 trial, 61% of patients achieved an objective response, and 3 (17%) patients achieved a complete response after receiving CPI-613[143].

Targeting PDAC DNA repair

Activating KRAS mutations are major drivers of malignant growth in PDAC and have remained undruggable until recent promising developments. Oncogenic KRAS-induced DNA replication stress drives genomic instability and tumorigenesis in PDAC. Genomic analysis have also revealed that modifications in "DNA damage control" is a prominent genetic alteration observed in PDAC[43]. Recently, genetic alterations in PDAC have been classified into four sub-types by Waddell *et al*[144]: (1) Stable; (2) Locally rearranged; (3) Scattered; and (4) Unstable. The "unstable" phenotype harbors mutations in the DNA damage repair (DDR), such as BRCA1, BRCA2, PALB2, and ATM. Mutations in ATM account for the most frequently occurring somatic mutations in approximately 4% of PDAC cases, followed by BRCA2, STK11, and BRCA1[144-147]. Given the important role these DDR genes play in a significant proportion of human PDACs, patients are likely to benefit from tailored, targeted therapies, including platinums, directed against specific DDR (Table 3). The following paragraphs will discuss these therapies.

Platinums: Platinum agents (cisplatin, oxaliplatin) cause DNA damage by forming platinum adducts on the DNA and causing DNA interstrand crosslinks[148]. Oxaliplatin is a component of the standard of care FOLFIRINOX, and platinum compounds alone are well suited in cancers that have a deficiency in the homologous repair (HR) pathway. Many studies have highlighted the advantageous use of platinum compounds for HR-deficient PDAC. Golan *et al*[149] showed a survival benefit (22 mo *vs* 9 mo) in platinum-treated *vs* platinum-naïve BRCA1/2 mutated advanced PDAC. Similarly, platinum improved overall survival in patients with HR-deficient PDACs and in patients with germline BRCA1, BRCA2, and PALB2 mutations[150,151]. Hence careful patient selection depending on the genetic make-up of the tumor would be essential for platinums to succeed.

Poly (ADP-ribose) glycohydrolase: Poly (ADP-ribose) glycohydrolase (PARG) is a macrodomain protein with exo- and endo-glycohydrolase activity[152,153]. It critically regulates DNA damage responses by removing poly (ADP-ribose) molecules (PARylation) on modified proteins during the DNA repair process. It is the primary PAR degrading enzyme and reverses poly (ADP ribose) polymerase (PARP) functions by hydrolyzing the ribose-ribose bonds present in PAR molecules. By preventing cytoplasmic PAR accumulation, PARG prevents PAR-mediated apoptosis, termed as parthanatos[154]. Inhibiting PARG causes DNA replication fork collapse, which leads to irreparable DNA damage and cell death. Recent studies have highlighted the benefits of selectively targeting PARG as an anti-cancer therapeutic strategy alone or in combination with other genotoxic therapies[155-157]. Targeting PARG was shown to enhance chemotherapeutic effects of DNA damaging agents, like oxaliplatin and 5-fluorouracil in PDAC, and was also synergistic with mitotic kinase, Wee-1 inhibition. In a siRNA screen with DNA replication factors, PARG inhibition was shown to be synergistic with TIMELESS, HUS1, MCM2, CHK1, and RFC2 proteins in an ovarian cancer model, indicating that combinations of PARGi and DNA replication stress

Table 2 Pancreatic ductal adenocarcinoma trials involving agents that target tumor metabolism

Drug	Target	Trial description	NCI trial number
IACS-010759	OXPHOS inhibitor	Phase I, in advanced cancers	NCT03291938
CPI-613	PDH/alpha KDH inhibitor	Phase I, combination with Gem + nab-paclitaxel	NCT03435289
CPI-613	PDH/alpha KDH inhibitor	Phase II, combination with FOLFIRINOX	NCT03699319
CPI-613	PDH/alpha KDH inhibitor	Phase III, combination with modified FOLFIRINOX	NCT03504423
Metformin and atorvastatin	Metabolic inhibitors	Metformin + Atorvastatin + Doxycycline + Mebendazole in cancers	NCT02201381
L-glutamine	Glutamine analog	Phase I, combination with Gem + nab-paclitaxel	NCT04634539

OXPHOS: Oxidative phosphorylation; PDH: Pyruvate dehydrogenase; KDH: Ketoglutarate dehydrogenase.

Table 3 Pancreatic ductal adenocarcinoma trials involving agents that target DNA repair

Drug	Target	Trial description	NCI trial number
M6620 (VX-970)	ATR	Phase I, M6620 and irinotecan hydrochloride in treating patients with solid tumors that are metastatic or cannot be removed by surgery	NCT02595931
AZD6738/olaparib	ATR/PARP	Phase II, Phase II trial of AZD6738 alone and in combination with olaparib	NCT03682289
BAY1895344	ATR	Phase I, testing the addition of an anti-cancer drug, BAY 1895344 ATR inhibitor, to the chemotherapy treatment (Gemcitabine) for advanced solid tumors, pancreatic cancer, and ovarian cancer	NCT04616534
Olaparib	PARP	Phase II, a study of pembrolizumab and olaparib for people with metastatic pancreatic ductal adenocarcinoma and homologous recombination deficiency or exceptional treatment response to platinum-based therapy	NCT04666740
Olaparib	PARP	Phase I, targeted PARP or MEK/ERK inhibition in patients with pancreatic cancer	NCT04005690
Olaparib	PARP	Phase II, a phase 2 study of cediranib in combination with olaparib in advanced solid tumors	NCT02498613
Olaparib	PARP	Phase II, olaparib in treating patients with stage IV pancreatic cancer	NCT02677038
Talazoparib	PARP	Phase II, measuring the effects of talazoparib in patients with advanced cancer and DNA repair variations	NCT04550494
Talazoparib	PARP	Phase I/II, a study of avelumab, binimetinib and talazoparib in patients with locally advanced or metastatic RAS-mutant solid tumors	NCT03637491
Niraparib	PARP	Phase II, niraparib in metastatic pancreatic cancer after previous chemotherapy (NIRA-PANC): A phase 2 trial	NCT03553004
Niraparib	PARP	Phase II, niraparib in patients with pancreatic cancer	NCT03601923
Rucaparib	PARP	Phase II, maintenance rucaparib in BRCA1, BRCA2 or PALB2 mutated pancreatic cancer that has not progressed on platinum-based therapy	NCT03140670
MK1775	WEE1	Phase I/II, a phase i and randomized phase II study of nab-paclitaxel/gemcitabine with or without AZD1775 for treatment of metastatic adenocarcinoma of the pancreas	NCT02194829

PARP: Poly (ADP ribose) polymerase.

inducers should be evaluated as potential therapeutic strategies for PDAC treatment [158]. A synthetic lethal relationship with PARG inhibition and DDR proteins like BRCA1, BRCA2, ABRAXAS, BARD1, and PALB2 was reported in an MCF7 breast cancer model[159]. Since genomic screens in PDAC have revealed alterations/mutations in similar DDR proteins, it is valuable to target PARG in such DDR-deficient PDAC tumors.

Wee-1: WEE1 kinase is an important cell cycle regulator of the G2-M checkpoint and is overexpressed in various cancers, including glioblastoma, breast cancer, osteosarcoma, and hepatocellular carcinoma[160-163]. It phosphorylates and inactivates CDK1 to allow for the repair of damaged DNA before entering mitosis. Wee-1 has regulatory roles in DNA replication stress and HR mechanisms[164-166]. In PDAC, Wee-1 expression is upregulated by a post-transcriptional mechanism regulated by RNA

binding protein, HuR[167], and its inhibition has been found to be effective in DNA repair-deficient PDAC cells[168]. In one study, Wee-1 inhibition was found to sensitize PDAC cells to gemcitabine chemo-radiation therapy[165]. Another study showed Wee-1 inhibition was synergistic with gemcitabine in p53-deficient PDAC xenografts[169]. Co-targeting WEE1 and ATM was shown to synergistically reduce cell proliferation and migration *via* downregulation of PDL-1 expression in pancreatic cancers[170]. Recently, it was also published that a combination of Wee-1 with another DNA repair target, PARG, enhances DNA damage and decreases cell survival in PDAC cells[171].

PARP: PARP is a DNA repair enzyme that plays a role in inflammation, regulation of cell death, transcription, and modulation of post-transcriptional gene expression. In response to DNA damage, PARP-1 could either promote cell survival and DNA repair or cause cell death when the damage is high[172]. PARP covalently adds Poly (ADP ribose) (PAR) chains onto its target proteins by consuming beta nicotinamide adenine dinucleotide (β NAD+). PAR further recruits other DNA repair proteins in the process of damage repair. Chemical competitive inhibitors of PARP enzymatic activity have gained interest as treatment options for many cancers, like ovarian, breast, uterine, and prostate[173], specifically for patients with tumors harboring somatic or germline defects/mutations in HR genes like *BRCA1/2*. Recent whole-genome sequencing studies done in patients with familial pancreatic cancer show that mutations in *BRCA2* gene accounts for 5%-10% of familial pancreatic cancers. In the Ashkenazi Jewish population with PDAC, this percentage increases to 13.7% and represents a major subgroup of PDAC cases that could benefit from PARP inhibitor (PARPi) therapy. In the context of synthetic lethality, impairment of two DNA repair pathways induces cell death and thus targeting HR deficient cells (*BRCA1/2* mutants or others) with PARP inhibitors was found to be lethal[174,175]. Following the success of POLO trial (Pancreas Cancer Olaparib Ongoing), in 2019 FDA approved olaparib (PARPi) as a maintenance therapy in patients with a germline BRCA mutated metastatic PDAC that had not progressed on first-line platinum therapy[174]. An increasing amount of ongoing preclinical and clinical studies suggest that PARPi in combination with either conventional chemotherapeutics (gemcitabine/nab-paclitaxel) or radiation therapy could benefit patients in the long run[176]. However, recent research suggests that although these respond greatly to PARP inhibitors, there is still 40%-70% of BRCA1/2-mutated cancers that fail to respond to PARPi therapy and in those settings PARPi cannot be used. Novel efforts to create a 'BRCAness-tumors harboring mutations in HR beyond BRCA1/2' phenotype in the cells by use of other small molecule inhibitors and their combination with PARPi is now being exploited. Bagnolini *et al*[174] discovered a small molecule disruptor of RAD51-BRCA2 interaction synergizes with olaparib in pancreatic cancer cells. Another study showed synthetic lethaility with PARPi therapy and FGFR1 blockade in pancreatic cancer[177]. Failure of PARPi therapy can also be attributed to acquired resistance mechanisms[178]. A study in pancreatic cancer showed a secondary mutation in BRCA2 emerged after the patient's exceptional response to platinum and PARPi therapy, which likely restored BRCA2 function in PARP inhibitor-resistant tumor cells[179]. Thus, careful evaluation and design of PARPi therapy should be pursued, and novel targets for PARPi beyond BRCA1/2 should be explored.

Other inhibitors of DDR pathway: Ataxia telangiectasia mutated (ATM) and RAD-3 related (ATR) are serine/threonine protein kinases that are involved in double/single-strand break repair and modulate DNA replication stress and DDR signaling[180-182]. ATM is one of the most commonly mutated DDR genes, and many whole genomic sequencing studies in PDAC have reported both somatic or germline ATM loss-of-function mutations. ATM loss drives pancreatic cancer progression, angiogenesis, epithelial-to-mesenchymal transition, and stemness[183]. Radiosensitization of cells with ATM loss/inhibition has been well documented in many tumor types, including pancreatic cancers[184-186]. ATM loss can also synergize with platinums and PARP inhibitor therapies, emphasizing its role in DNA repair. Specific to PDAC, two studies have shown that patients with ATM/ATR mutated tumors respond well to oxaliplatin-based chemotherapy, experiencing either improved progression-free survival or a stable disease[187,188]. Based on these data, multiple ongoing clinical trials (Phase I/II) involving ATM-deficient solid tumors have been initiated with DNA damage agents like PARP inhibitor therapies (olaparib, talazoparib, and niraparib), some of which accept pancreatic cancer patients. Chemical inhibition of ATM *via* small molecule inhibitors (AZD0156, AZD1390) is also being tested in combination with other agents in early stage clinical trials in patients with advanced solid tumors and brain tumors (NCT02588105, NCT03423628). Lack of ATM function may lead to

increased dependence on ATR for DDR, and thus ATR inhibition may be particularly potent in PDACs with somatic mutations in ATM. A recent study employing a multi-DDR interference strategy that included an ATR inhibitor and PARP and DNA-PKC inhibitor was shown to inhibit FOLFIRINOX-induced invasive clones in ATM-deficient PDAC tumors[189]. In 2012, a study tested VX-970, an ATR inhibitor, and found it sensitizes PDAC cells to radiation therapy *in vivo* and *in vitro*[190]. Another study found that a combination treatment of AZD6738 (ATR inhibitor) and gemcitabine induces PDAC regression by preventing checkpoint activation by gemcitabine[191]. The ATR inhibitors (VX-970, AZD6738, BAY18953[43]) are currently in the early stages of clinical development, like ATM inhibitors in patients with advanced solid tumors and lymphomas (NCT03188965, NCT03682289, NCT02595931, and NCT03718091), with or without other chemotherapeutic agents. Although these appear to be promising therapies, their clinical activity in PDAC patients is yet to be shown[183].

Immunotherapy

Immunotherapy has achieved promising outcomes in certain cancers, however is yet to be realized in PDAC[192-194]. Tumors with high tumor mutation burden (TMB, approximate mutations per megabase), such as melanomas and NSCLC, have shown to respond better to immunotherapy[195-197]. These TMBs are generally associated with mismatch repair (MMR) deficiency. PDACs intrinsically have low MMR deficiencies, which may explain the lower response to immunotherapy approaches such as immune checkpoint inhibitors (ICI)[198]. The immunosuppressive nature and "*T cell exhaustion*" further contributes to the poor response of PDAC to immunotherapy.

The PDAC is characterized by the presence of dense stroma in the tumor microenvironment. The stromal components include T cells (cytotoxic and regulatory) and myeloid cells such as tumor-associated macrophages (TAM). Infiltration with macrophages is observed in early PDAC tumor development stages and is associated with poor prognosis in PDAC patients[199-201]. These macrophages secrete immunosuppressive factors such as arginase and TGFβ, and thereby regulate T-cell mediated cytotoxicity and surveillance[200]. The myeloid-derived suppressor cells are immature myeloid cells that suppress T cell proliferation and promote ROS-induced T cell apoptosis[202,203]. The term "T cell exhaustion" is used for T cells' differentiation state in chronic antigen exposure. The exhaustion stage is driven by persistent T cell receptor signaling leading to ineffective T cell functioning[204-206]. Recent evidence has shown that the T cells present in the PDAC tumor microenvironment are defective in the production of interferon and tumor necrosis factors following peptide recognition[207,208]. However, the T cells with identical peptide specificity in the spleen retain functionality in tumor-bearing animals[209].

Some approaches that are currently under investigation for improving the immunological response of PDAC include as follow.

Cancer vaccines and immune checkpoint blockade: Monotherapies targeting programmed cell death 1 (PD-1) and programmed cell death ligand 1 (PD-L1) have not shown promising responses in PDAC. However, the therapy showed tumor regression and disease stabilization in other advanced cancers such as NSCLC, melanoma, and renal cancers[193]. Similarly, inhibition of PD-1 or PD-L1 failed to demonstrate a positive response in PDAC animal models[207,210-212]. Similar to ICI inhibitors, vaccine trials using vaccine-GVAX pancreas (granulocyte-macrophage colony-stimulating factor-secreting allogeneic pancreatic tumor cells) failed to improve overall survival in PDAC patients compared to single-agent chemotherapy[213]. Since the vaccines were able to recruit T cells, one approach to improve their efficacy would be to promote the activation of T cells, which may be achieved through the combination of vaccines with ICI[214]. Currently, clinical trials are underway for establishing the safety and efficacy of these GVAX with ICIs (NCT03153410, NCT02451982, and NCT02648282).

Targeting tumor associated macrophages: Another way to improve the efficacy of immunotherapies is to inhibit the immunosuppressive signaling that originates from the tumor microenvironment. For this, one strategy being tested is to inhibit myeloid cells. Researchers found that CD11b agonist reduces the total number of myeloid cells and improves survival in PDAC mice. In addition, when CD11b was combined with anti-PD-1, anti-CLTA-4, and gemcitabine, enhanced infiltration of tumor with CD8 T cells was observed[212]. Similarly, other studies have confirmed that targeting TAMs improves therapeutic and T-cell checkpoint immunotherapy response in PDAC models[215-217]. Blockade of Csf1/Csf1R (macrophage colony-stimulating factor

1/receptor) reduces collagen deposits and enhances CD8 T cell infiltration in the PDAC mice model[218]. Currently, a phase II trial is underway to determine the efficacy of cabralizumab (CSF1R inhibitor) in combination with nivolumab and chemotherapy in PDAC (NCT03336216).

Adoptive T cell therapy

Adoptive T cell therapy involves isolating T cells from tumors and then engineering, expanding, and infusing them back into the patients[219]. The chimeric antigen receptor (CAR) T cell therapy is an example of adoptive T cell therapy wherein the T cells are manipulated to express CAR to assist tumor recognition[220]. Antigen targets that are being tested for PDAC include mesothelin, prostate stem cell antigen, CEA, MUC1, and HER2[221]. However, the immunosuppressive microenvironment remains a hindrance in CAR-T cell therapy's success in PDAC[222,223]. Other barrier to the success of adoptive T cell therapy in PDAC include antigen selection and toxicities [224-226]. Still, a few promising outcomes have sustained hope for the use of this approach in PDAC. A phase 1 trial found that treatment of PDAC patients with mesothelin-targeting-CART-T cells stabilized disease in 2 out of 6 patients[227]. Similarly, analysis of efficacy and safety of MUC1-targeting CART-T cells found the therapy to be safe and successfully elevated the levels of CD4+ and CD8+ T cells at the tumor[228]. Currently, clinical trials are underway to determine MUC-1-targeted CAR-T cell therapy's efficacy and safety in patients with solid tumors, including PDAC (NCT02587689 and NCT02617134).

CONCLUSION

The PDAC remains an intractable disease that is slated to be the second leading cause of cancer-related deaths by 2030. Although surgical resection remains the only curative treatment option, late diagnosis, in addition to the patient's performance status, limits the scope of surgical intervention. Chemotherapeutic regimens such as gemcitabine+nab-paclitaxel and FOLFIRINOX has shown promise in improving patient survival; however, drug resistance remains a continuing challenge that has limited their efficacy. Two approaches that may improve PDAC patient outcomes include inhibiting the mechanism(s) that promote therapy resistance and targeting the key pathways essential for PDAC survival. The altered metabolism provides the PDAC cells with energy (ATP) and macromolecules essential for tumor growth. Additionally, studies have shown that metabolism plays a key role in PDAC therapy resistance. Similarly, PARP targeting therapies' success has once again brought the importance of DNA repair mechanisms in PDAC into the center. The limited success of immunotherapy has dampened the enthusiasm for targeting PDAC using this approach. However, the uncovering of mechanisms contributing to poor PDAC's response to immunotherapy has provided opportunities to test newer approaches. Even though the strategies mentioned above have shown promising pre-clinical results individually, a regimen targeting multiple aspects of PDAC will likely deliver a better clinical outcome in this deadly disease.

Abstract

Information about the coronavirus disease 2019 (COVID-19) pandemic is still evolving since its appearance in December 2019 and has affected the whole world. Particularly, a search for an effective and safe treatment for COVID-19 continues. Botanical mixtures contain secondary metabolites (such as flavonoids, phenolics, alkaloids, essential oils *etc.*) with many therapeutic effects. In this study, the use of herbal treatments against COVID-19 was evaluated. Medical synthetic drugs focus mainly on respiratory symptoms, however herbal therapy with plant extracts may be useful to relieve overall symptoms of COVID-19 due to the variety of bioactive ingredients. Since COVID-19 is a virus that affects the respiratory tract, the antiviral effects of botanicals/plants against respiratory viruses have been examined through clinical studies. Data about COVID-19 patients revealed that the virus not only affects the respiratory system but different organs including the gastrointestinal (GI) system. As GI symptoms seriously affect quality of life, herbal options that might eliminate these problems were also evaluated. Finally, computer modeling studies of plants and their active compounds on COVID-19 were included. In summary, herbal therapies were identified as potential options for both antiviral effects and control of COVID-19 symptoms. Further data will be needed to enlighten all aspects of COVID-19 pathogenesis, before determining the effects of plants on severe acute respiratory syndrome coronavirus 2.

Key Words: COVID-19; Herbal therapies; Plant; SARS-CoV-2; Antiviral; Symptom

INTRODUCTION

New coronavirus disease 2019 (COVID-19), which emerged in Wuhan in December 2019, spread rapidly and affected the whole world. The emergence, epidemiology, origin and evolution of COVID-19 has been extensively studied by Sun *et al*[1].

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has been shown to carry out viral replication in the human host mainly through three main proteins and enzymes: 3-chymotrypsin-like protease (3CLpro), angiotensin-converting enzyme-2 (ACE2) and spike protein (TMPRSS2)[2,3]. ACE2 receptors are found in the body not only in the lungs but also in tissues such as the endothelium, heart, kidney and intestine[2]. This distribution makes many organs a target of COVID-19. The significance of ACE2, which is found in intestinal tissues, especially for amino acid uptake from foods, has been emphasized and it has been suggested that the intestine may be an important entry site for SARS-CoV-2[2-4] Azithromycin, chloroquine, lopinavir, remdesivir, ritonavir are options used in treatment and whose effects are evaluated[5]. Effective and safe drugs and vaccines are sought all over the world to prevent novel coronavirus. Minerals, herbs, herbal products, probiotics and vitamins are the main natural resources, whose effectiveness and also the usability of herbal medicines in COVID-19 were investigated and benefit, risk assessments were evaluated[6-8]. Truly, since the beginning of the COVID-19, herbal medicines have been used in China. A study has shown that 90% of the 214 patients were treated with the traditional herbal medicine, moreover, it is reported that some of them prevented COVID-19 infection in healthy individuals and enhanced the health state of patients with mild or severe symptoms[9,10]. Health scientists from the Zhongnan Hospital of Wuhan University included the use of traditional medicines in the guidelines for the treatment and prevention of COVID-19. The experts recommended using medicinal plants for the prevention of COVID-19, additionally, the use of different herbal mixtures were recommended according to the disease-stage[11].

Herbs and herbal products provide generous sources of primary and mostly secondary metabolites, which are valuable compounds (phenolics, flavonoids, tannins, alkaloids, essential oils, *etc.*) for prophylactic and chronical therapeutic purposes. Some of these metabolites in herbs and herbal mixtures have high chemical variety than the synthetics in stopping viral proliferations, and having antiviral activities[12]. Thus, botanicals can both show antiviral effects and relieve the symptoms of COVID-19 thanks to the different substance groups, which demonstrate different biological effects that will not be possible to achieve with a single synthetic drug. Based on this understanding, in this review, we offer all the potential interventions for COVID-19 infection according to previous and recently found antiviral effects of herbals. Considering the major transmission routes of COVID-19, where mostly ACE2 receptors found and the symptoms, the plants have been handled especially with their effects on the mostly respiratory and also gastrointestinal (GI) systems. Although ACE2, is typically expressed in epithelial cells of the airways, various GI symptoms in COVID-19 might be explained by the high expression of ACE2 in the digestive tract. Additionally, liver tests abnormalities, active viral replication in GI tract and patients' manifestations with GI symptoms (abdominal pain, diarrhea, nausea, vomiting) and possible fecal-oral transmission reveal the GI involvement in COVID-19[13].

Recent findings demonstrated that early blocking of COVID-19 with ACE2 inhibitors was one of the mechanisms used by novel drugs[14], on the other hand diabetes mellitus and hypertension enhanced the risk of COVID-19 infection, in spite of using ACE2 inhibitors[15-17]. Furthermore, unpredicted ACE2 upregulation by

ACE2 inhibitors, ibuprofen and angiotensin II type-I receptor blockers lead to need of identifying/using alternative ACE2 blockers[18]. Consequently, botanicals or natural products might be alternatively and selectively might block the ACE2 receptors without inhibiting the enzyme activity in order to treat and/or prevent COVID-19 spread in humans without increasing ACE2 expression in patients and therefore increased risk for COVID-19[19].

Clinical human studies showing the effect of plants on respiratory infections are presented as a table. Based on the pharmacological properties of plants, their practicality on COVID-19 symptoms have been evaluated. In the last part of the article, plants that inhibit ACE receptors, the research studies and their active compounds on COVID-19 also included and it is aimed to examine the plants from a broad perspective.

ANTIVIRAL EFFECTS OF HERBAL THERAPIES

Most of the respiratory diseases (approximately 80%) are caused by viral agents[20]. Viral respiratory diseases are responsible for high mortality and morbidity, especially in disadvantaged and sensitive elderlies and immunocompromised individuals[21, 22]. The main respiratory viruses are adenovirus, coronavirus, influenza virus, respiratory syncytial virus and rhinovirus[20]. Plants with antiviral effects and studies showing the effects of these on respiratory viruses are given in Table 1. Human clinical studies showing the effects of plants on respiratory tract infections are presented in Table 2.

EFFECTS OF HERBAL TREATMENT ON COVID-19 SYMPTOMS

Cough and fever are common symptoms in patients with COVID-19, including fatigue, shortness of breath, headache, muscle pain, sore throat, sputum, hemoptysis, diarrhea, dyspnea, rhinorrhea, chest pain, nausea, and vomiting[23]. COVID-19 symptoms in children are similar to those in adults and are relatively mild[24].

Although, the current synthetic drugs focus on mainly respiratory symptoms, herbal therapy can be used to relieve overall symptoms of COVID-19 with their bioactive ingredients[25]. The meta-analysis study, which included randomized controlled trial studies, found significant effects of the combination of western medicine and herbal therapies. Combined treatment has been effective in cough, fever, dry and sore throat, fatigue and overall GI symptoms. The combined therapy significantly improved the disappearance rate of cough and sputum production[26]. In another meta-analysis, it was found that the addition of Chinese herbal medicine for standard care improved the symptoms and signs of COVID-19 as well as decreased levels of C-reactive protein[27]. The effects of plants that can alleviate the symptoms of COVID-19 are summarized in Table 3. In addition, plants regarded as ACE inhibitors are shown in Table 4.

THE EFFECTS OF HERBS AND THEIR ACTIVE COMPOUNDS ON COVID-19

In recent years, artificial intelligence has often been used to discover natural products as medicine[28,29]. After the outbreak of COVID-19, computer models were used to investigate the effect of many plants and their components on SARS-CoV-2. Khaerunnisa *et al*[30], determined the COVID-19 Main Protease (Mpro) inhibitor effects of medicinal plant components in a molecular docking study. They suggested apigenin-7-glucoside, curcumin, catechin, demethoxycurcumin, epicatechin-gallate, luteolin-7-glucoside, and oleuropein, as potential inhibitors of COVID-19 Mpro. In a similar molecular docking study using sixty-seven molecules of natural origin, crocin, digitoxigenin and b-eudesmol were proposed as inhibitors against coronavirus[31]. Another study was carried out using one hundred seventy-one essential oil components. The study determined the best docking ligands for the SARS-CoV target proteins were (E)--farnesene, (E,E)--farnesene and (E,E)-farnesol, thereby suggesting essential oil components may act synergistically with other antiviral agents, or they may provide some relief of COVID-19 symptoms[32]. Computer modeling studies and clinical studies against SARS-CoV-2 in some prominent plants/products and their

Table 1 Antiviral effects of plants on respiratory viruses

Plant name	Preparation	Susceptible viruses	Ref.
Allium sativum (Garlic)	Aqueous extracts	Influenza A (H9N2)	Rasool *et al*[53], 2017
	Extract	Infectious bronchitis virus	Mohajer Shojai *et al*[54], 2016
	Ethanolic extract	Influenza A (H1N1)	Chavan *et al*[55], 2016
	Garlic oil	Influenza A (H1N1)	Choi[56], 2018
	Fresh extract	Influenza A (H1N1)	Mehrbod *et al*[57], 2013
	Aqueous extract	Adenovirus (ADV3 and ADV41)	Chen *et al*[58], 2011
Aloe vera (Aloe)	Aloe anthraquinones and several derivatives (3-O-tetraacetoglupiranosil)	Influenza A	Borges-Argáez *et al*[59], 2019
	Aloe-emodin	Influenza A	Li *et al*[60], 2014
Astragalus mongholicus (Astragalus)	*Astragalus* polysaccharides	Avian infectious bronchitis virus	Zhang *et al*[61], 2018
	Astragalus polysaccharide	Influenza A (H9N2)	Kallon *et al*[62], 2013
Camellia sinensis (Green tea)	Catechins -EGCG	Adenovirus	Weber *et al*[63], 2003
	Catechin	Influenza A	Kuzuhara *et al*[64], 2009
	Catechins	Influenza A (H5N1)	Liu *et al*[65], 2012
	Polyphenols	Influenza A; Influenza B	Yang *et al*[66], 2014
Curcuma longa (Turmeric)	Curcumin	Influenza A virus	Chen *et al*[67], 2013
			Dai *et al*[68], 2018
	Curcumin	Influenza A (H1N1, H6N1)	Chen *et al*[69], 2010
	Curcumin	RSV	Obata *et al*[70], 2013
Echinacea purpurea (Purple coneflower)	*E. purpurea* fresh herb and root tinctures	Influenza	Vimalanathan *et al*[71], 2013
	Standardized *E. purpurea* extract	Influenza A (H5N1, H7N7, H1N1)	Pleschka *et al*[72], 2009
	Standardized *E. purpurea* extract	Rhinoviruses, RSV	Hudson *et al*[73], 2011
Eucalyptus globulus (Eucalyptus)	Essential oil- vapor phase	Influenza	Vimalanathan *et al*[74], 2014
Ginkgo biloba (Ginkgo)	Leaf extract	Influenza A (H1N1, H3N2)	Haruyama *et al*[75], 2013
Glycyrrhiza sp. (Licorice)	Water extract of licorice (*Glycyrrhiza uralensis*)	RSV	Feng Yeh *et al*[76], 2013
	Glycyrrhizic acid derivatives	SARS-CoV	Hoever *et al*[77], 2005
	Extract of *Glycyrrhiza inflata*	Influenza A (H1N1)	Dao *et al*[78], 2011
	Glycyrrhizin	Influenza A	Wolkerstorfer *et al*[79], 2009
	Glycyrrhizin	Influenza A (H5N1)	Michaelis *et al*[80], 2010
Lepidium meyenii (Maca)	Extracted with methanol	Influenza A; Influenza B	Del Valle Mendoza *et al* [81], 2014
Melaleuca alternifolia (Tea tree)	Tea tree oil	Influenza A (H1N1)	Garozzo *et al*[82], 2011
	Aerosol and vapor of tea tree oil	Influenza A (H11N9)	Usachev *et al*[83], 2013
	Tea tree oil	Influenza A (H11N9)	Pyankov *et al*[84], 2012
Melissa officinalis (Lemon balm)	Essential oil	Influenza A (H9N2)	Pourghanbari *et al*[85], 2016
	Extract	Avian infectious bronchitis	Lelešius *et al*[86], 2019
Mentha piperita (Peppermint)	Ethanol extract	RSV	Li *et al*[87], 2017
	Extract	Avian infectious bronchitis	Lelešius *et al*[86], 2019

Nigella sativa (Black cumin)	Ethanol extracts of	Influenza A (H5N1)	Dorra *et al*[88], 2019
	Ethanol extracts of	Influenza A (H9N2)	Umar *et al*[89], 2016
	Extract	Coronavirus	Ulasli *et al*[90], 2014
Panax ginseng (Ginseng)	Root of plant *Panax ginseng*	RSV	Lee *et al*[91], 2014
	Panax Korean red ginseng extract	RSV	Lee *et al*[92], 2014
	Red ginseng extract and polysaccharide and saponin fractions	Influenza A (H1N1)	Yin *et al*[93], 2013
	Korean red ginseng extract	Influenza A (H1N1, H3N2)	Yoo *et al*[94], 2012
Pelargonium sidoides (Pelargonium)	*Pelargonium sidoides* radix extract EPs® 7630	Rhinovirus	Roth *et al*[95], 2019
	EPs® 7630	Respiratory viruses	Michaelis *et al*[96], 2011
	EPs® 7630	Influenza A (H1N1, H3N2)	Theisen *et al*[97], 2012
Sambucus nigra (Black elder)	Extract	Infectious bronchitis virus	Chen *et al*[98], 2014
	Standardized elderberry liquid extract	Influenza A; Influenza B	Krawitz *et al*[99], 2011
	Concentrated juice of elderberry	Influenza A	Kinoshita *et al*[100], 2012
	Elderberry flavonoids	Influenza A (H1N1)	Roschek *et al*[101], 2009
Scutellaria baicalensis (Chinese skullcap)	Chemical constituents	Influenza A (H1N1)	Ji *et al*[102], 2015
	Baicalin	SARS-CoV	Chen *et al*[103], 2004
Torreya nucifera (Japanese nutmeg yew)	Ethanol extract	SARS-CoV	Ryu *et al*[104], 2010
Thymus vulgaris (Thyme)	Essential oil- liquid phase	Influenza	Vimalanathan *et al*[74], 2014
	Extract	Avian infectious bronchitis	Lelešius *et al*[86], 2019
Withania somnifera (Ashwagandha)	Withaferin A	Influenza A (H1N1)	Cai *et al*[105], 2015
Zingiber officinalis (Ginger)	Aqueous extracts	Influenza A (H9N2)	Rasool *et al*[53], 2017
	Ethanol extracts	Influenza A- (H5N1)	Dorra *et al*[88], 2019
	Fresh ginger	RSV	Chang *et al*[106], 2013

Influenza A strains: H1N1, H3N2, H5N1, H6N1, H7N7, H9N2, H11N9; RSV: Respiratory syncytial virus; H1N1: Influenza A; SARS-CoV: Severe acute respiratory syndrome coronavirus.

metabolites are given below.

Curcuma longa

Utomo and Meiyanto[33] revealed the potential of several compounds of *Curcuma longa* against SARS-CoV-2 by binding to three protein receptors (*RBD-S*, *PD-ACE2*, *SARS-CoV-2 protease*). They showed that *Curcuma* sp. compounds can bind to target receptors, thus, have potential inhibitory effects on SARS-CoV-2 infectivity. Rajagopal *et al*[34] showed in their *in silico* docking study that *Curcuma longa* components could be effective against COVID-19 by inhibiting the SARS-CoV-2 Mpro enzyme. Morever, cyclocurcumin and curcumin possess significant binding at the active site of SARS-CoV-2 Mpro when compared to hydroxychloroquine and nelfinavir. When compared to remdesivir, cyclocurcumin is significantly more active [Glide score: Cyclocurcumin (−6.77); remdesivir (−6.38); curcumin (−6.13); nelfinavir (−5.93); hydroxychloroquine (− 5.47)]. In a similar study, diacetylcurcuminin was more effective on COVID-19 (Mpro) than nelfinavir[35]. Another study suggested the use of curcumin with hydroxychloroquine to destabilize the SARS-CoV2 receptor proteins[36]. Gonzalez-Paz *et al*[37] showed that curcumin strongly binds to 3CL-protease of COVID-19 Curcumin caused enzyme folding and structural changes in viral protease. Moreover, curcumin bound more strongly to the enzyme than chloroquine.

Eucalyptus globulus

Sharma[38] suggested that eucalyptus essential oil active compounds are potential inhibitors of COVID-19 Mpro. They conducted a molecular docking study to evaluate

Table 2 Human clinical studies showing the effect of plants on respiratory infections

Plant	Disease state	Participant	Dosage	Study design	Results
Aged garlic extract[107]	Cold andflu illness	120 healthy subjects, 2 groups (21-50 yr)	4 capsules/d (2.56 g); 90 d	Double-blind, randomized, placebo-controlled parallel intervention	Increase in γδ-T cell and NK cell. Reduction in cold and flu severity; decrease in symptom days
E. purpurea and *E. angustifolia* root[108]	New-onset common cold	719 patients, 4 parallel groups (12-80 yr)	First 24 h: Equivalent of 10.2 g of root. Next 4 d: 5.1 g	Randomized, controlled trial	Disease duration and severity are not statistically significantly changed
Echinacea purpurea alcohol extract (Echinaforce®) [109]	Common cold	755 healthy subjects, 2 groups (≥ 18 yr)	Illness prevention: 3 × 0.9 mL. Acute stages of colds: 5 × 0.9 mL	Randomized, double-blind, placebo-controlled trial	Reduction of the total number of cold episodes, cumulated episode days, and pain-killer medicated episodes. Inhibited virally confirmed colds and especially prevented enveloped virus infections. Maximal effects on recurrent infections. Prophylactic intake of *E. purpurea* over a period of 4 mo to provide a positive risk/benefit ratio
Echinacea root extract[110]	Respiratory symptoms	175 adults, 2 groups (18–65 yr)	Tablets: 112.5 mg *E. purpurea* 6:1 extract (equivalent to 675 mg dry root) and 150 mg *E. angustifolia* 4:1 extract (equivalent to 600 mg dry root) 3 × 1 tablet, if required: 3 × 2 tablets	Randomized, double blind, placebo-controlled trial	Lower respiratory symptom scores. Preventive effect against the development of respiratory symptoms during travel, including long-haul flights
Green tea catechins and theanine[111]	Influenza	200 healthcare workers, 2 groups	Capsules: Green tea catechins (378 mg/d) and theanine (210 mg/d). 5 m	Randomized, double-blind, placebo-controlled trial	Lower incidence of influenza infection in the catechin/theanine group
Ivy leaf extract[112]	Acute or chronic bronchial inflammatory disease	9657 patients (5181 children)	Ivy leaves extract [drug-to-extract ratio: 5-7.5:1; extraction solvent: ethanol 30% (w/w)]. 0–5 yr: 3 × 2.5 mL; 6–12 yr: 3 × 5 mL; 12 yr and adults: 3 × 5–7.5 mL. 7 d	Prospective, open, multicenter post marketing study	Healing or improvement in 95% of symptoms. Effective and well tolerated
Ivy extract (Hedelix®) [113]	Acute respiratory catarrh and/or chronic recidivating inflammatory bronchial disease	268 children, 2 groups (syrup and drops groups) (0-12 yr)	0-1 yr: 1 × 2.5 mL syrup or 3 × 5 drops, 1-4 yr: 3 × 2.5 mL syrup or 3 × 16 drops, 4-10 yr: 4 × 2.5 mL syrup or 3 × 21 drops, 10-12 yr: 3 × 5 mL syrup or 3 × 31 drops. 14 d	Independent open, non-interventional studies	Effective and safe treatment of cough. Reduction in symptoms (especially rhinitis, cough and viscous mucus)
Ivy leaves dry extract (Prospan ®) [114]	Bronchial asthma	30 children (suffering from partial or uncontrolled mild persistent allergic asthma despite long-term treatment with 400 μg budesonide equivalent), 2 groups (6–11 yr)	2 × 5 mL (corresponding to 70 mg extract) 28–30 d	Randomized, double blind, placebo-controlled, cross-over study	Improvement of MEF75-25, MEF25 and VC
Korean red ginseng extract[115]	Influenza-like illness	100 healthy adults, 2 groups (30-70 yr)	9 capsules/d. 3 m	Placebo-controlled trial	Reduced the incidence of influenza-like illness
Modified ginseng extracts (GS-3K8 and GINST)[116]	Acute respiratory illness	45 healthy applicants, 3 groups (39-65 yr)	Capsules: 500 mg; 6 capsules/d; 8 wk	Randomized, double-blind, placebo-controlled pilot study	Reduction in acute respiratory illness development and symptom duration
Panax quinquefolius extract CVT-E002[117]	Acute respiratory illness and Chronic Lymphocytic Leukemia	293 patients, 2 groups (≥ 18 yr)	2 × 200 mg extract. 3 m	Randomized, double-blind, placebo-controlled study	Reduction intense acute respiratory illness and moderately-severe sore throat. Increased antibody responses.

Panax ginseng [118]	Chronic obstructive pulmonary disease	14 participants, 2 groups (57–73 yr)	2 × 200 mg 4 wk	Clinical trial protocol and pilot study	One participant in *P. ginseng* group reported events of sore throat, cough and fever
Panax ginseng root extract [119]	Chronic obstructive pulmonary disease	168 participants, 2 groups	2 × 100 mg capsules. 24 wk	Randomized, multi-center, double-blind, placebo controlled	Reduction in symptoms
Pelargonium sidoides extract EPs® 7630 [120]	Chronic obstructive pulmonary disease	199 adults, 2 groups (18 yr and older)	30 drops. 24 wk	Randomized, double-blind, placebo-controlled, parallel group trial	Improvement in HRQoL (health-related quality-of-life) and PRO (Patient-reported outcomes)
Pelargonium sidoides extract EPs® 7630 [121]	Acute bronchitis	220 patients (1-18 yr)	1-6 yr: 3 × 10 drops; 6–12 yr: 3 × 20 drops; 12-18 yr: 3 × 30 drops; 7 d	Randomized, double-blind, placebo-controlled clinical trial	Reduction in the total score of bronchitis-specific symptoms (especially cough and rales at auscultation)
Pelargonium sidoides extract EPs® 7630 [122]	Upper respiratory tract infections	28 children with a diagnosed transient hypogammaglobulinemia of infancy (1-5 yr)	3 × 10 drops; 7 d	Randomized, placebo controlled, prospective, monocentric pilot study	Increased appetite. Reduction of nasal congestion
Pelargonium sidoides root extract EPs® 7630[123]	Upper respiratory tract- asthma attacks	61 children (1–14 yr)	1–5 yr: 3 × 10 drops; 6–12 yr: 3 × 20 drops; 12 yr and above: 3 × 30 drops; 5 d	Randomized, placebo controlled	Reduction the severity of symptoms (especially cough and nasal congestion). Shortening of the duration of upper respiratory viral infections. Reduction asthma attack frequency
Pelargonium sidoides preparation EPs® 7630 [124]	Acute non-streptococcal tonsillopharyngitis	126 children, 2 groups (6–10 yr)	3 × 20 drops. 6 d	Double-blind, placebo-controlled clinical trial	Decrease in tonsillitis severity score compared to placebo in the EPs® 7630 group after 4 d of treatment
Pelargonium sidoides extract EPs® 7630 [125]	Common cold	207 adults (18-55 yr)	SD: 3 × 30 drops; HD: 3 × 60 drops; 10 d	Prospective, double-blind, parallel-group, placebo-controlled, phase 3, 2 parts, 2-arm, clinical trial	After 10 d, clinical treatment in 90.4% of the active drug group. Reduction the severity of symptoms and short the duration of the disease. Higher full recovery rates or greater recovery for HD treatment on day 5
Sambucus nigra extract [126]	Influenza	64 patients (16-60 yr)	Lozenge: 175 mg extract; 4 lozenges/d; 2 d	Randomized, double-blind, placebo-controlled, pilot clinical trials	Significant improvement in most symptoms within 24 h (fever, headache, muscle aches and nasal congestion). Significant improvement in all investigated symptoms within 48 h (cough and mucus discharge)
Sambucus nigra extract [127]	Respiratory health	312 adults, 2 groups	Capsules: 300 mg. Before travel: 2 capsules/d. During travel and after arrival: 3 capsules/d. 14 d	Randomized, double-blind placebo-controlled clinical trial	Reduction of cold duration and severity in air travelers. Low symptom score

SD: Standard dose; HD: High dose.

the effect of eucalyptol (1.8 cineol), which is a component of eucalyptus essential oil, on Mpro. They showed that eucalyptol/Mpro complexes produce hydrophobic interactions, strong ionic interactions, hydrogen bond interactions, and eucalyptol may be a potential inhibitor of COVID-19 Mpro. Similarly, M pro/3CL pro/eucalyptol complexes have been shown to form hydrophobic interactions[39]. In another study, Sharma and Kaur[40] suggested jensenone, the component of eucalyptus essential oil, as a potential COVID-19 Mpro inhibitor. In a molecular docking study of 12 active ingredients of eucalyptus essential oil, all of these ingredients were found to bind effectively to the COVID-19 S-protein. Especially the toruatone component was effectively bound and the Spike (S) protein/Toruatone complexes formed hydrogen and hydrophobic interactions[41]. Muhammad *et al*[42], in a study of the molecular

insertion of eucalyptus active ingredients into Mpro, showed that the α-gurjune of eucalyptus, aromadene and allo-aromadene components have strong binding energy.

Glycyrrhiza glabra

Sinha *et al*[43] conducted molecular docking simulation studies of two antiviral drugs (lopinavir and ribavirin) and 20 compounds of *Glycyrrhiza glabra*. Two protein targets from COVID-19 have been identified: Non-structural protein-15 endoribonuclease and spike glycoprotein. Glycyrrhizic acid prevented the virus from entering the host cell, due to its bulky structure. Gliasperin A showed high affinity to Nsp15 endoribonuclease and inhibited its activity. The authors suggested that glycyrrhizic acid disrupts the connection of the virus with the ACE2 receptor at the input level, and Gliasperin A inhibits the replication process of the virus after it enters the host cell. Another study showed that glycyrrhizin can be highly bound to Mpro[44].

Scutellaria baicalensis

Liu *et al*[45] investigated the *in vitro* effect of *Scutellaria baicalensis* and its components on COVID-19. Baicalein (its main ingredient) and the ethanol extract of the plant inhibited the 3CLpro activity and replication of COVID-19. The ethanol extract also inhibited viral entry. Udrea *et al*[46] suggested the benefit *Scutellaria baicalensis* flavones (especially baicalein) against respiratory damage caused by COVID-19. Flavones bound to 3CLpro. strongly bound to wogonin flavone, nitric oxide synthase and cyclooxygenase 2. In addition, norwogonin and baicalein arachidonate modulated 15-lipoxygenase and lysine-specific demethylase 4D analogue.

Thymus vulgaris

In a randomized clinical study conducted on patients suffering from COVID-19, it was found that *Thymus vulgaris* strengthens the immune system and can be used to reduce COVID-19 symptoms. In the study, 83 COVID-19 patients were randomly divided into the control group and the group receiving thyme (TRG). TRG was given as thyme essential oil three times a day for seven days. A questionnaire asking about symptoms such as fever, cough, fatigue, and loss of appetite was completed before and at the end of treatment to determine the effect of thyme on symptoms. Thyme essential oil significantly reduced the severity of symptoms such as fever, cough, shortness of breath, dizziness, muscle pain, anorexia, weakness and lethargy and fatigue. Additionally, thyme increased lymphocyte count and calcium while decreasing blood urea nitrogen and neutrophil count[47]. Carvacrol, a component of thyme, has been

Table 4 Angiotensin-converting enzyme inhibitor plant

Plants	The compound under study	Results	Ref.
Ammoides verticillata essential oil	Isothymol	SARS-CoV-2/ACE2 inhibition	Abdelli *et al*[183], 2021
Allium sativum essential oil	Organosulfur compounds (99.4% of its essential oil)	SARS-CoV-2/ACE2 inhibition. Garlic essential oil can prevent protein maturation of the virus and the spread of infection	Thuy *et al*[184], 2020
Apium graveolens	Apigenin	Kidneys of spontaneous hypertensive rats/Regulation in ACE2 expression	Sui *et al*[185], 2010
Camellia sinensis	Black tea; Dark tea; Green tea; Oolong tea; White tea	ACE inhibition: Green < oolong < white < black < dark teas	Dong *et al*[186], 2011
Citrus aurantium *Erigeron breviscapus* *Glycine max* *Glycyrrhiza radix* *Scutellaria baicalensis*	Hesperetin. Scutellarin. Nicotianamine. Glycyrrhizin. Baicalin	SARS-CoV-2/Connecting to ACE2 and blocking the SARS-CoV-2 input	Chen and Du[187], 2020
Geranium and lemon essential oils	Citronellol and limonene	SARS-CoV-2/ACE2 inhibition	Senthil Kumar *et al*[188], 2020
Ginseng *Glycyrrhiza uralensis*	Ginsenoside Rg6; Ginsenoside F1; Monoammonium glycyrrhizinate; Glycyrrhizic acid methyl ester	SARS-CoV-2/ACE2 kinase inhibition	Zi *et al*[189], 2020
Glycine max (soybean)	Nicotianamine	ACE2 inhibition	Takahashi *et al*[190], 2015
Glycyrrhiza glabra	Glycyrrhizic acid	SARS-CoV-2/Glycyrrhizic acid disrupts the connection of the virus with the ACE2 receptor at the entry level	Sinha *et al*[43], 2021
Hibiscus sabdariffa anthocyanins	Delphinidin- and cyanidin-3-O-sambubiosides	ACE inhibition	Ojeda *et al*[191], 2010
Linum usitatissimum (Flaxseed)	Secoisolariciresinol diglucoside	ACE inhibition	Prasad *et al*[192], 2013
Melaleuca cajuputi essential oil	Components (70.9% of the oil)	SARS-CoV-2/ACE2 and PDB6LU7 proteins inhibition	My *et al*[193], 2020
Nicotiana benthamiana	Recombinant ACE2-Fc fusion protein produced from *N. benthamiana*	SARS-CoV-2/Strong binding to the RBD of SARS-CoV-2 and inhibition	Siriwattananon *et al*[194], 2020
Withania somnifera	Withanone	SARS-CoV-2/Docking to the connector interface of the AEC2-RBD complex	Balkrishna *et al*[51], 2020

ACE: Angiotensin-converting enzyme; RBD: Receptor binding domain; SARS-CoV-2: Severe acute respiratory syndrome coronavirus 2; ACE2: Angiotensin-converting enzyme-2.

shown to inhibit Mpro by *in silico* study. It can be a potential inhibitor of controlling viral replication[48].

Withania somnifera

W. somnifera components withanolides have potential antiviral properties on COVID-19[49]. Patel *et al*[50] demonstrated that *W. somnifera*'s Withanoside VI components have positive interactions at the binding site of protein targets of SARS-CoV-2. Withanone reduced the electrostatic interaction between ACE2 and receptor binding domain[51]. Withaferin A, which is found in the *W. somnifera* plant, has been shown to interact with Mpro and Glucose regulated protein 78 (GRP78) receptor[52].

CONCLUSION

In this study, the concept of "being effective against COVID-19" for herbal treatments was discussed from the angles of antiviral effect and control of symptoms, specifically related to GI system.

Antiviral effects on COVID-19

Since COVID-19 is a virus that mainly affects the respiratory tract, the antiviral effects of medicinal plants against respiratory viruses have been examined firstly. The structure similarities of SARS-CoV-2 have been found with SARS-CoV and Middle East respiratory syndrome coronavirus. Therefore, it can be suggested that plants and their compounds affecting these viruses may also be potential treatment options for COVID-19. Here firstly, clinical studies supporting antiviral effects of 22 plant on respiratory viruses has been reviewed which determined that glycyrrhizic acid derivatives obtained from *Glycyrrhiza* sp, *Nigella sativa*, *Scutellaria baicalensis* and *Torreya nucifera* have anti-COVID-19 effects. Plants such as *Allium sativum*, *Glycyrrhiza glabra*, *Melaleuca* sp, *Withania somnifera* have been shown to bind to ACE2 receptors that are imperative for COVID-19 replication. Focusing on these plants might be a logical way to go for herbal treatment against COVID-19.

This review also showed the antiviral effects of essential oils obtained from plants have the potential to affect COVID-19. The treatment involves using inhaled steam supplemented by essential oils possessing natural antimicrobial properties, oropharyngeal sanitization, as well as they are remedies for symptomatic relief. Inhalation of antimicrobial essential oils may help attenuate the virus in the nasal cavity, nasopharynx, oropharynx, and laryngopharynx. Antiseptic mouthwashes and gargles can also help to sanitize the oral cavity and oropharynx, whereas antiseptic lozenges can help to sanitize the oro- and laryngopharynx as well. The steam will carry the tiny particles of the antimicrobial constituents from these essential oils into the respiratory tract and is likely to improve the efficacy of the steam treatment. The steam supplemented by antimicrobial volatile oils may help to provide a local antimicrobial effect within the airways.

There are computer model studies showing that some botanicals and active ingredients are effective in COVID-19. *Allium sativum*, *Curcuma longa*, *Eucalyptus globulus*, *Glycyrrhiza glabra*, *Melaleuca* sp, *Thymus vulgaris*, *Withania somnifera* is among these plants. These studies with commonly found plants will guide future studies to develop effective supplements or drugs for COVID-19.

Symptomatic treatment of COVID-19

Since the symptoms of COVID-19 seriously affect the quality of life, herbal options to eliminate them were also evaluated in this review. Previously, herbs such as garlic, echinacea and ginseng were found to reduce the symptoms of cold in healthy individuals. Plants with their pharmacological effects are natural options for eliminating the symptoms of COVID-19. Based on the effects described in Table 3, *Allium sativum*, *Curcuma longa*, *Scutellaria baicalensis* and *Zingiber officinale* are easily found as prominent plants to eliminate the GI symptoms of COVID-19. For example, ginger can eliminate the negative effects of COVID-19 on the GI system with its antiemetic and hepatic protective properties. A clinical study was conducted with thyme essential oil on COVID-19. Thyme essential oil was found to significantly reduce COVID-19 symptoms. This revealed an option that thyme and essential oil have potential effects for consideration in treatment of COVID-19. Studies on more essential oils of eucalyptus reveal more effects of eucalyptus on respiratory system symptoms. *Eucalyptus globulus*, *Hedera helix*, *Pelargonium sidoides*, *Sambucus nigra*, *Thymus vulgaris* can be recommended for relief of respiratory symptoms. ACE2 receptors are found in tissues other than the lung, such as the intestine. Based on this fact, we concluded that the use of herbs binding to ACE2 receptors can eliminate the side effects that may occur in variety of organs including GI tract. As shown in Table 4 these plants are *Ammoides verticillate*, *Allium sativum*, *Apium graveolens*, *Camellia sinensis*, *Citrus aurantium*, *Erigeron breviscapus*, *Glycine max*, *Glycyrrhiza glabra*, *Hibiscus sabdariffa*, *Linum usitatissimum*, *Melaleuca* sp., *Nicotiana benthamiana*, *Withania somnifera*.

Based on these studies, herbal treatments offer several potential treatments of COVID-19. Plants may be an option for the treatment of COVID-19 and its symptoms, as well as protection from COVID-19. Even though these data point to good outcomes there is always the possibility of interaction between drugs used and these herbs. For instance, herbs such as ginger with antithrombotic effects can be beneficial on COVID-19 symptoms, but one might be cautious about escalated risk of bleeding when it is used together with antithrombotic or anticoagulant drugs. Therefore, it is extremely important to avoid the indiscriminate use of plants.

For a plant to be used as a medicine, its effect must be supported by clinical studies. COVID-19 is just emerging, and more research are needed for its treatment. Yet, herbal therapies are potential options for both antiviral effects and the control of COVID-19 symptoms. Since plants with multiple pharmacological effects can affect many systems

(respiratory, GI, and nervous), herbs might be more effective against COVID-19 than synthetic drugs. But first, all aspects of SARS-CoV-2 need to be examined. Then, the effects of plants on this virus should be determined by further studies.

The strengths and weaknesses of this review

Unlike other studies, in this report, the effect of plants on COVID-19 was evaluated in several ways. Preclinical studies, clinical studies and silico studies are included in this review. Moreover, the efficacy on COVID-19 symptoms has been addressed by including different systems. On the other hand, the focus is on the respiratory and GI systems. The effects, not only of botanicals but also active metabolites of have been studied.

The biggest limitation of this study is the lack of sufficient studies on the efficacy of botanicals. Since botanical studies are generally preclinical studies, results may vary due to conducting and including clinical studies. In clinical studies showing the effects of the plants in Table 2 on respiratory tract infections, the results were generally obtained with questionnaire studies. Placebo effects and breadth of study may be effective in positive results.

Abstract

Pancreatic carcinoma (PC) is one of the leading causes of cancer-related deaths worldwide. Despite early detection and advances in therapeutics, the prognosis remains dismal. The outcome and therapeutic approach are dependent on the stage of PC at the time of diagnosis. The standard of care is surgery, followed by adjuvant chemotherapy. The advent of newer drugs has changed the landscape of adjuvant therapy. Moreover, recent trials have highlighted the role of neoadjuvant therapy and chemoradiotherapy for resectable and borderline resectable PC. As we progress towards a better understanding of tumor biology, genetics, and microenvironment, novel therapeutic strategies and targeted agents are now on the horizon. We have described the current and emerging therapeutic strategies in PC.

Key Words: Resectable pancreatic carcinoma; Borderline resectable pancreatic carcinoma; Locally advanced pancreatic carcinoma; Adjuvant therapy; Neoadjuvant therapy; Newer advances in pancreatic carcinoma

INTRODUCTION

World over, new cases of pancreatic carcinoma (PC) add up close to three lakh each year[1,2]. There hasn't been a significant increase in the long-term survival rates, with the 5-year survival rates increasing to 5%-6% over the last 30 years, despite early detection and advances in therapeutics for pancreatic cancer[3,4]. The estimates of leading causes of cancer deaths suggest that PC may become the second, next only to lung cancer in the United States over the next decade[1].

Pancreatic ductal adenocarcinoma (PDAC) is exemplified by abundant genetic mutations, germline or acquired. Among the common ones are *CDK2NA* and *KRAS* seen in nearly 90%, *TP53* in 75%-90%, and *SMAD4/DPC4* in about 50%[5,6]. Additionally, genomic and epigenetic alterations are present, which have ignited research for targeted therapy. The desmoplastic stroma and the tumor microenvironment have been the focus of clinical explorations.

The outcomes of PC depend on the stage at diagnosis. Nearly half the cases are diagnosed as metastatic, wherein the survival ranges from 7-11 mo, at best[7,8]. In cases where the disease is non-metastatic but unresectable, there is a modest increase of survival, of nearly 6 months over the metastatic disease. The peculiarity of resectable PC lies in the poor overall survival, of approximately 2 years with adjuvant therapy. This is in stark contrast to most of the other resectable cancers.

The standard of care of resectable PC is surgery followed by adjuvant chemotherapy (CT). The benefit for this approach was established by the European Study Group for Pancreatic Cancer 1 (ESPAC-1) and the CONKO-001 trials, using 5-fluorouracil (5-FU)/leucovorin and gemcitabine respectively[7-9]. The phase III randomized PRODIGE 24 trial using 5-FU/leucovorin with irinotecan and oxaliplatin (FOLFIRINOX) and APACT trial with nab-paclitaxel with gemcitabine changed the landscape of adjuvant therapy following their success noticed in the metastatic setting [10,11]. The role of chemoradiotherapy (CRT) in the adjuvant setting is yet to see the final statement based on the existing literature. Following the lack of survival benefit with CRT in the ESPAC-1 and European Organization for Research and Treatment of Cancer (EORTC) trials and contrasting results with two registry data showing survival benefit of CRT compared to CT, one large series compared the three modalities of systemic CT, CRT or CRT followed by CT. There was a significant survival benefit with CT and CRT followed by CT than in the CRT in patients with stage III disease. This benefit was however not seen in patients with stage I/II disease[12-16].

The management of borderline resectable pancreatic adenocarcinomas (BRPCs) has seen the emergence of adjuvant regimes in the 'neoadjuvant' or 'induction therapy' role with FOLFIRINOX and nab-paclitaxel with gemcitabine[17,18]. There is no robust data to suggest the survival benefit of these protocols so far; however, there has been demonstrable tolerability and increased resection rates. A clinical challenge has been to offer adjuvant therapy to patients receiving induction therapy. The results of phase II ESPAC-5F trial, presented at the 2020 virtual ASCO meeting, comparing four arms-frontline surgery, induction therapy with gemcitabine and capecitabine, or modified FOLFIRINOX and CRT. The study revealed similar outcomes between the frontline and induction treatment[19].

The metastatic setting is seeing numerous trials with conventional CT as well as targeted agents as the biology and tumor microenvironment, genetics, and molecular concepts are being better understood. This has led to a search for novel therapeutic strategies for managing PC. This review attempts to address the challenge faced by the practicing clinician in optimal sequencing of the available modalities in the various stages of the illness.

MANAGEMENT OF RESECTABLE PANCREATIC CANCER

A resectable adenocarcinoma does not have metastases to a distant organ or distant lymph nodes; there is no vascular involvement [characterized by absence of superior mesenteric vein (SMV) or portal vein (PV) involvement], tumor thrombosis, or venous encasement > 180°. Also, the fat planes around the celiac axis (CA), hepatic artery (HA), and superior mesenteric artery (SMA) ought to be clear[20].

Surgery

Surgery is the only treatment option that offers a cure for PDAC. Surgery aims to completely resect the tumor and achieve a microscopically negative tumor margin (R0). R0 dissection is defined as clearance of > 1 mm *i.e.*, the margin of healthy tissue around the removed tumor should be > 1 mm. The various surgical options include pancreaticoduodenectomy (Whipple's procedure) and distal pancreatectomy. Pancreaticoduodenectomy with SMA first approach is the standard of care for adenocarcinoma localized to the head of the pancreas (HOP). The surgery should involve dissection of greater than 15 lymph nodes and skeletonization of SMA down to adventitia of anterior, left lateral and posterior borders[21,22]. A sampling of paraaortic lymph nodes with an examination of the frozen section is an additional option. For PDAC involving the body and tail of the pancreas, distal pancreatectomy along with splenectomy is the treatment option. This involves dissection of greater than 15 lymph nodes[23,24].

Minimally invasive techniques for pancreatic resection beginning with laparoscopic distal pancreatectomy have been attempted. They offer advantages in the form of reduced blood loss and decreased hospital stay. However, the rate of achieving positive resection margin, morbidity, and mortality of the procedure remains the same as that of an open procedure. The use of robotic techniques in Whipple's procedure has shown reduced rates of post-procedure complications[25]. Traditionally preoperative biliary drainage has been advised for patients who present with obstructive jaundice. Recent evidence, however, points towards a higher rate of perioperative complications among those undergoing pre-operative drainage *vs* those undergoing upfront surgery[26].

The risk of developing tumor recurrence among those patients who undergo curative resection for PC varies from 69%-75% at 2 years to 80%-90% at 5 years post-surgery[27]. Tumor recurrence occurs secondary to locoregional occurrence in a majority of cases. This led to the hypothesis that the use of adjuvant therapy may reduce locoregional tumor recurrence.

Post-operative complications may reduce a patients' access to adjuvant CT and overall survival. Hence, it becomes imperative to screen patients who are at high risk of post-operative complications, like elderly patients, patients with poor performance status, or higher comorbidity profiles. Preoperative pancreatic resection score (PREPARE) and Surgical results analysis and search (SOAR) are validated and useful scoring systems for assessing the risk of developing complications post-operatively[28,29].

Adjuvant CT

The gold standard treatment for resectable PC is surgery followed by adjuvant CT. The era of adjuvant CT gained prominence when the results of the European Group for Pancreatic Cancer (ESPAC-1) trial showed significant improved median survival and 5-year survival in patients who received adjuvant CT of fluorouracil and folinic acid *vs* those who underwent surgery alone (20.1 mo *vs* 15.5 mo, respectively; $P = 0.009$). This was followed by the CONKO-001 (Charité Onkologietrial) trial, using adjuvant gemcitabine, which showed a median disease-free survival of 13.4 mo and 5-year survival of 20.7% *vs* 10.4% *vs* 6.9 mo respectively in the surgery alone group. The efficacy of these two treatment regimens was compared in the ESPAC-3 trial. Results of this study showed no survival benefit of one treatment regimen over the other, however, the treatment-related adverse effects were higher in the fluorouracil and folinic acid group.

To further improve the therapeutic outcome with adjuvant CT, a concept of combination systemic therapy has evolved. Several agents have been studied in various trials (Table 1). Among those of note are the ESPAC-4, PRODIGE and APACT studies. The ESPAC-4 trial carried out a comparison of gemcitabine *vs* a combination of gemcitabine plus capecitabine, which showed favorable overall survival benefit while using combination therapy [hazard ratio (HR): 0.82, 95% confidence interval (CI): 0.68-0.98; $P = 0.032$]. However, no significant recurrence-free survival benefit was seen in 2 years of follow-up of these patients (HR: 0.86, 95%CI: 0.73-1.02; $P = 0.082$).

Table 1 Landmark trials on adjuvant treatment in pancreatic adenocarcinoma

Study	No. of patients	Treatment arms	Median DFS in mo	Median OS in mo
GITSG[33]	43	Observation	NR	20.0
		Radiotherapy + 5-FU f/b adjuvant 5-FU	NR	10.9
ESPAC-1[34]	289	Observation	NR	15.5
		Chemoradiotherapy	NR	13.9
		5-FU/folinic acid	NR	20.1
		Chemoradiotherapy + 5-FU/folinic acid	NR	19.9
CONKO-001[9]	354	Observation	6.7	20.2
		Gemcitabine	13.4	22.8
ESPAC-3[35]	1088	5-FU/folinic acid	14.1	23.0
		Gemcitabine	14.3	23.6
ESPAC-4[36]	730	Gemcitabine	13.1	25.5
		Gemcitabine + Capecitabine	13.9	28.0
CONKO-005[30]	436	Gemcitabine	11.4	26.5
		Gemcitabine + Erlotinib	11.4	24.6
PRODIGE 24-PA6[37]	493	Gemcitabine	12.8	35.0
		FOLFIRINOX	21.6	54.4
APACT[11]	866	Gemcitabine	18.8	36.2
		Gemcitabine + nab-paclitaxel	19.4	40.5

5-FU: 5-Fluorouracil; CONKO: Charité Onkologie; DFS: Disease-free survival; ESPAC: European Group for Pancreatic Cancer; GITSG: Gastrointestinal Tumor Study Group; NR: Not reported; OS: Overall survival; PRODIGE: Partenariat de Recherche en Oncologie DIGEstive.

The Partenariat de Recherche en Oncologie Digestive (PRODIGE 24-PA6) trial highlighted the successful use of FOLFIRINOX (oxaliplatin + irinotecan + leucovorin) *vs* gemcitabine in patients with good performance status (Eastern Cooperative Oncology Group, ECOG: 0-1). The median disease-free survival in patients with combination therapy was 21.6 mo *vs* 12.8 mo in the gemcitabine group. The latest in series is the Nab-paclitaxel and Gemcitabine *vs* Gemcitabine Alone as Adjuvant Therapy for Patients with Resected Pancreatic Cancer (APACT) study, which has shown encouraging results of using combination therapy of gemcitabine plus nanoparticle albumin-bound paclitaxel (nab-paclitaxel). Median disease-free survival was not statistically significant in the two arms (19.4 mo in combination arm *vs* 18.8 mo in gemcitabine only arm). Overall survival favored the combination CT group (HR: 0.82, 95%CI: 0.68-0.996; $P = 0.045$)[27].

Another concept is the use of targeted agents (erlotinib or sorafenib) or immunotherapy (algenpantucel-L) in combination with gemcitabine. However, to date, none of these agents have shown any favorable survival outcome *vs* the use of gemcitabine alone[30-32].

Adjuvant CRT

Adjuvant CRT aims to prevent locoregional tumor recurrence. Amongst the first trials to assess the efficacy of CRT in PC was the EORTC trial, which showed no significant survival benefit amongst patients of PDAC who received CRT (40 Gy + continuous infusion of fluorouracil)[13]. This was followed by the ESPAC-1 trial, which employed the following three different adjuvant therapy designs: CRT, CT alone, and CRT followed by adjuvant CT. Patients undergoing adjuvant CT were found to have poor survival benefits after a median follow-up of 47 mo (HR: 1.28, 95%CI: 0.99-1.66; $P = 0.05$)[34]. The RTOG 9704 trial was carried out to assess the benefit of adding gemcitabine to postoperative radiation + fluorouracil *vs* adjuvant therapy with fluorouracil. The trial showed no survival benefit in either of the two treatment groups [38].

Although these trials failed to prove any survival benefit, they nevertheless provided useful information on the feasibility and tolerability of these treatment options. Analysis of the US National Cancer Database which included patients of pancreatic adenocarcinoma who underwent curative resection followed by adjuvant CT showed survival benefit (median overall survival with CT + radiation: 22.3 mo and adjuvant CT alone: 20.0 mo; $P = 0.001$)[14].

Timing of adjuvant CT

There are definite gaps in our knowledge regarding the optimal timing of initiating CT following surgery and follow-up of patients undergoing adjuvant therapy for curable PC. Delay in initiating as well as non-initiation of adjuvant treatment is not uncommon. Post-operative morbidity adversely impacts the initiation of adjuvant treatment. It has been estimated that approximately 20% of patients become ineligible for adjuvant CT. The ESPAC-3 trial aimed to analyze the outcome among those who were initiated on CT within 8 wk of surgery and those who were initiated on CT after 8 wk of surgery. There was no survival benefit in either of the two arms, while successful completion of six cycles of CT was found to be an independent predictor of survival[39]. Similar results have been put forward by analyzing multi-institutional retrospective data of patients who had undergone curative resection for PDAC. Thus, the evidence so far suggests that patients who receive adjuvant therapy more than 12 wk following surgery are still good candidates for adjuvant CT[40].

Therefore, in summary, the standard of care in resectable pancreatic adenocarcinoma is surgical resection followed by adjuvant CT. Single-agent (5-FU) is preferred for periampullary tumors of pancreatic origin. Patients with adenocarcinoma in the head, body, or tail of the pancreas may be treated with FOLFIRINOX (patients with good post-operative performance status, ECOG: 0-1) and combination therapy of gemcitabine+ capecitabine in those with poor performance status postoperatively (Figure 1).

Neoadjuvant therapy

Conceptually, the use of neoadjuvant therapy in resectable PC gained prominence when this approach was shown to have improved survival benefit in other gastrointestinal malignancies[41]. It offers the following theoretical advantages: reduction of circulating tumor cells and micrometastasis before surgery, and avoiding surgery in those who experience disease progression while on neoadjuvant therapy, thus, reducing surgical mortality and morbidity. Of particular interest is the ability of neoadjuvant treatment to achieve tumor downsizing or downstaging (lower T and N stages, reducing the rates of vascular, lymphatic, and perineural invasion, and the ability to achieve better R0 resection post-surgery). Moreover, individuals who receive neoadjuvant CT are more likely to be able to access the entire therapeutic sequence[42, 43].

The preoperative or postoperative CT for resectable pancreatic adenocarcinoma (PACT-15) trial has shown the efficacy of neoadjuvant CT in patients with resectable PDAC[44]. One of the first published phase III trials assessing the role of neoadjuvant gemcitabine followed by gemcitabine and radiation before surgery is the PREOPANC trial. Although it has not shown statistically significant survival benefit in patients using neoadjuvant CT + CRT (overall survival of 16 mo for neoadjuvant therapy *vs* 14.3 mo for initial surgery), better R0 resection rates, locoregional disease-free survival, and lower rates of vascular and perineural invasion favor neoadjuvant CT[45]. Analyses of 'US National Cancer Database data have shown a favorable survival using perioperative CT in patients with early PC as compared with upfront surgery. Another similar cohort study by Mokdad and colleagues[46] demonstrated statistically significant median overall survival in the neoadjuvant group *vis a vis* upfront surgery group (26 mo *vs* 23 mo respectively; $P = 0.01$). Many other phase III trials are being conducted to have a better understanding of this therapeutic aspect[27] (Table 2). Neoadjuvant treatment is well tolerated. The risk of postoperative pancreatic fistula formation (3%-11%), risk of postoperative infections (3%-7%) and mortality (0%-4%) compared to those who have undergone surgery alone[47].

MANAGEMENT OF BRPC

The National Comprehensive Cancer Network has defined BRPC based on the following radiological criteria: Contrast-enhanced computerized tomographic (CECT) scan using the pancreatic protocol, the relationship of tumor with the surrounding

Table 2 Landmark trails on use of neoadjuvant chemotherapy

Study	No. of patients	Treatment arms	Resection rate, %	R0	Median DFS in mo	Median OS in mo
PACT-15[44]	93 Resectable	Surgery + gemcitabine	85	27	4.7	20.4
		Surgery + 6 PEXG	90	37	12.4	26.4
		3PEXG + surgery + 3 PEXG	84	63	16.9	16.9
PREOPANC-01[48]	248 Resectable + BRPC	26Gy/15fr + gemcitabine	60	63	9.9	17.1
		Surgery	72	31	7.9	13.7

BRPC: Borderline resectable pancreatic cancer; DFS: Disease-free survival; OS: Overall survival; PEXG: Cisplatin, epirubicin, gemcitabine, and capecitabine.

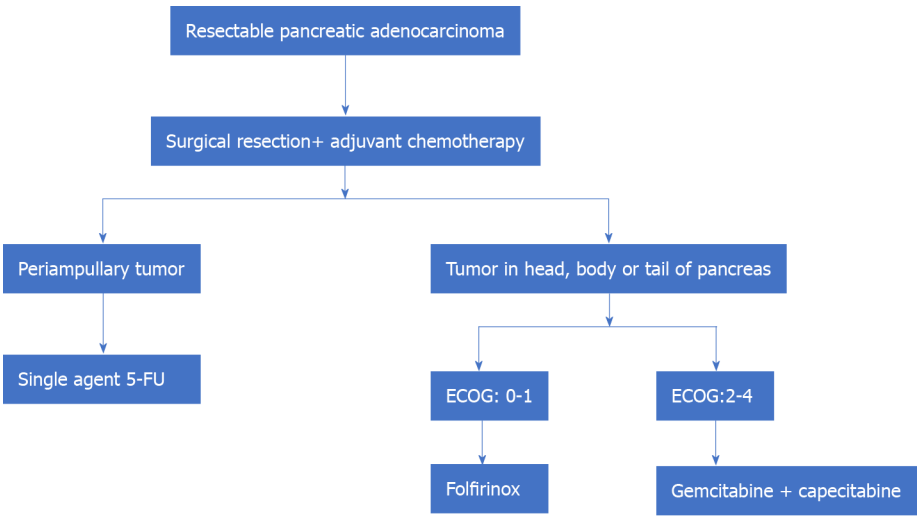

Figure 1 Management of resectable pancreatic adenocarcinoma. 5-FU: 5-Fluorouracil; ECOG: Eastern Cooperative Oncology Group.

vasculature, and the absence/presence of metastasis.

Thus, a BRPC localized to the HOP is one where the tumor is in contact with the common HA but without extension to the CA or artery bifurcation and variant arterial anatomy, contact with the SMA < 180°, contact with the SMV or PV < 180° without venous contour irregularity or thrombosis, which allows for safe and complete arterial and venous resection and reconstruction[20].

Borderline resectable PDAC in the pancreatic body or tail is 'the solid tumor in contact with the CA of < 180° or contact with the CA > 180° without the involvement of the aorta and gastroduodenal artery to allow a 'modified Appleby surgery'[20]. Another definition, the Anderson classification for BRPC, classifies it into the following three different groups: Group A includes patients with a tumor that abuts visceral arteries or causes short-segment occlusion of SMV; group B, have findings suggestive of metastasis; and group C patients are those who have marginal performance status[49].

Historically, therapeutic options for BRPC consist of upfront surgery, surgery followed by adjuvant CT/CRT, and neoadjuvant CT. The standard surgical options remain Whipple procedure, total pancreatectomy, or distal pancreatectomy, based on the tumor localization. An approach favoring upfront surgery carries with itself the risk of early failure, which has often been attributed to the poor pre-operative staging of tumor radiologically, inability to carry out a radical surgery, and the aggressive tumor behavior owing to variations in tumor biology. This has brought about an interest in considering neoadjuvant CT for patients with BRPC.

A meta-analysis carried out by the Dutch Pancreatic Cancer Group has shown a median survival of 19.2 mo in patients undergoing neoadjuvant CT *vs* 12.8 mo in those undergoing upfront surgery[50]. A peculiar problem in comparing different groups arises when different CT/CRT regimens are being compared. A recent patient-level meta-analysis has analyzed the efficacy of neoadjuvant FOLFIRINOX in BRPC, finding a favorable trend using FOLFIRINOX (median overall survival of 22 mo and median disease progression-free survival of 18.0 mo)[18].

A recent randomized control trial has assessed the use of CRT as neoadjuvant therapy for BRPC. The investigators combined 54 Gy in 30 fractions + weekly gemcitabine followed by adjuvant gemcitabine. Results have shown a better resection rate in the neoadjuvant group *vs* the surgery only group (51.8% *vs* 26.1% respectively) as well as a statistically significant 2-year survival (40.7% *vs* 26%; $P = 0.028$)[51]. The preoperative CRT *vs* immediate surgery for resectable and borderline resectable pancreatic cancer (PREOPANC-1) trial has used intention-to-treat analysis to study the efficacy of neoadjuvant CRT (gemcitabine-based) *vs* upfront surgery in BRPC. Patients in the neoadjuvant CRT group had a lower resection rate (60%) *vs* those in the upfront surgery group (72%; $P = 0.065$). R0 resection rate was statistically higher in the neoadjuvant group *vs* the upfront surgery group (61% *vs* 31%; $P < 0.001$). To add to the benefits, patients receiving neoadjuvant CRT had a longer median time till recurrence *vs* the surgery only group (9.9 mo *vs* 7.9 mo; $P = 0.023$)[48].

Results of these trials have shown the efficacy of both neoadjuvant CT as well as for CRT in BRPC. Several ongoing trials are being carried out to study the efficacy of induction therapy in improving overall survival in BRPC and which of the two therapeutic strategies (CT/CRT) is better suited for the same.

MANAGEMENT OF LOCALLY ADVANCED PC

The concept of locally advanced PC (LAPC) has evolved based on the development of radiological criteria of resectability and the availability of neoadjuvant therapy. Practically, the pancreatic tumors which are not metastatic and are unresectable due to 'irreversible' vascular invasion (encasement of aorta, invasion of PV or SMV, involvement of the SMA or celiac trunk by > 180°) are considered as LAPC[52,53]. The median survival has been variably reported from 10 mo to 30 mo.

The standard treatment for LAPC is gemcitabine-based CT. For patients with good performance status (ECOG0-1), the FOLFIRINOX-based regimen and for those with ECOG0-2, the nab-paclitaxel-gemcitabine-based regimen may be considered[53]. Some observational studies and pooled analyses of different approaches have advocated induction treatment with either FOLFIRINOX or nab-paclitaxel–gemcitabine followed by CRT. Using this approach median survival of 24.2 mo and disease progression-free survival of 15 mo has been reported[54]. However, the use of either upfront radiation therapy or following induction treatment with gemcitabine is not beneficial for patients with LAPC. Recently published meta-analysis has reported similar overall survival and drug-related side effects of CRT and CT in the setting of LAPC[55]. CRT using capecitabine as a radiosensitizer, however, has been tried for improvement of local control of disease in a subset of patients with LAPC. Since this is not a standard treatment approach, it has been proposed that this may be offered to only a select group of individuals[56].

Ongoing trials in LAPC are trying to assess the efficacy of FOLFIRINOC *vs* gemcitabine as induction therapy (NEOPAN; NCT02539537), use of nab-paclitaxel-gemcitabine for induction regimen + radiation therapy *vs* continuous CT, and use of activation of the *DPC4* gene (RTOG 1201; NCT01921751).

An interesting recent concept that has emerged in the management of LAPC is the role of surgery. This was proposed by researchers from the Medical College of Wisconsin based on the observation that those with an initially unresectable disease as per radiological criteria may convert to the resectable tumor after induction CT ± CRT. They have proposed the classification of patients with LAPC into the following two distinct categories: Type A, tumors that may be considered for resection following induction CT; and type B: Definitively unresectable tumors (> 270° encasement of the SMA, > 180° encasement of the CA, encasement of the aorta, and > 180° encasement of the HA with extension beyond the bifurcation of the proper HA into right and left HA)[52]. Thus, patients with LAPC type A, who have completed induction CT should be considered for surgical exploration. This is especially pertinent as the specificity of a CECT scan to determine tumor staging, operability, and R0 resectability for HOP carcinoma decrease following induction therapy. In such a setting, surgical exploration is the ideal modality to prove/ rule out vascular involvement[57]. Resected patients who have received CT preoperatively can also be considered for an additional course of CT following surgery[58] (Figure 2).

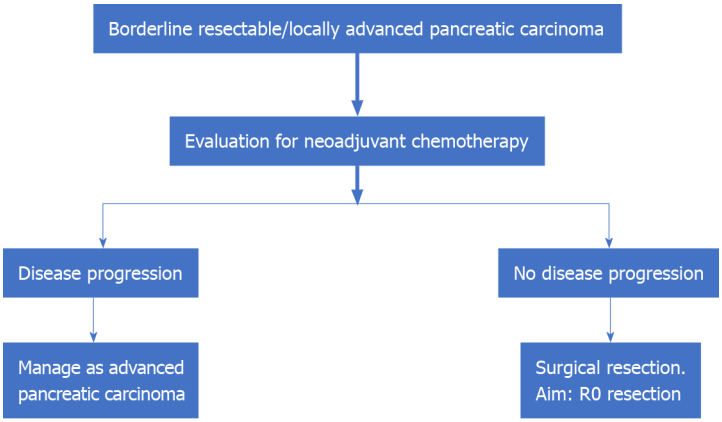

Figure 2 Management of borderline resectable/locally advance pancreatic carcinoma.

MANAGEMENT OF ADVANCED METASTATIC PC

CT forms the backbone of therapeutic regimens for the management of metastatic PC. Till the advent of gemcitabine, fluorouracil was the only approved drug in the management of APC. The use of gemcitabine has brought about benefits of disease progression-free survival, and overall survival (from 4.4 mo to 5.7 mo, $P = 0.0025$) with similar drug-related side effects as compared to fluorouracil[59]. This was followed by trials that analyzed the survival benefit of adding another cytotoxic drug or targeted therapy to gemcitabine. Use of erlotinib to gemcitabine-based regimen has shown median overall survival benefit (5.91 mo to 6.24 mo, $P = 0.038$) and 1-year survival benefit (17% to 23%, $P = 0.023$)[60]. A combination regimen consisting of cisplatin, epirubicin, fluorouracil, and gemcitabine (PEFG) *vs* gemcitabine has shown 'four-month progression-free survival' of 60% *vs* 28% in gemcitabine alone arm, $P = 0.001$ with no difference in overall survival[44]. A combination of gemcitabine + nab-paclitaxel in patients with ECOG0-2 has shown an improvement of 'median overall survival' *vs* gemcitabine alone (8.5 mo *vs* 6.7 mo, $P < 0.001$). The PRODIGE 4-ACCORD11 trial is a landmark trial that has shown the overall survival benefit of using FOLFIRINOX (median survival: 11.1 mo) in patients with APC *vs* gemcitabine (6.8 mo, $P < 0.001$)[10]. FOLFIRINOX has not been compared to nab-paclitaxel + gemcitabine in any prospective trial to date. Thus, the FOLFIRINOX regimen is now the standard of care for patients of APC with ECOG: 0-1, normal serum bilirubin, and no underlying cardiac pathology. The limiting step in the FOLFIRINOX regimen happens to be the performance status of the individual and comorbidity profile with the elderly or low-profile patients likely to have a poorer outcome. Other prognostic factors are the number of metastases, and liver metastases, presence of genetic mutations such as *DNA damage response* (*DDR*) gene mutations and *BRCA* tumor suppressor gene mutations[61-63]. Modified FOLFIRINOX has been tried with similar efficacy and better tolerance profile as compared to the standard FOLFIRINOX regimen. This regimen includes fluorouracil bolus suppression or a dose reduction of irinotecan (or both)[64].

Progress of disease in patients with first-line CT regimens presents a particular challenge with around 50% of patients being eligible for second-line CT[65]. Combination regimens like gemcitabine-platinum and fluoropyrimidine-platinum have shown disease progression-free survival of 2.5 mo *vs* 1.9 mo for single agents ($P = 0.169$) but no improvement in overall survival (5.1 mo *vs* 4.3 mo, $P = 0.169$)[66]. The various combination regimens that have been tried on the failure of first- and second-line regimens are oxaliplatin, folinic acid, and 5-FU (OFF regimen), and nanoliposomal irinotecan (MM-398), 5-FU, and folinic acid regimen. The CONKO-003 trial has shown overall survival benefit of using the OFF regimen over the 5-FU–folinic acid (FF regimen); the median survival was 5.9 mo *vs* 3.3 mo respectively ($P = 0.01$)[67]. The disease progression-free survival with use of nanoliposomal irinotecan (MM-398), 5-FU, and folinic acid regimen after failure of the FOLFIRINOX regimen has been reported to be 5.1 mo with overall survival of 8.8 mo[68]. The results of using targeted agents, namely the Jak1 and Jak2 tyrosine kinase inhibitor ruxolitinib and glufosfamide, have been rather disappointing. However, patients with metastatic solid tumors (including 8 patients with pancreatic tumors), with deficient mismatch repair and failed first-line therapy have shown response to the PD-1 immune checkpoint

inhibitor (ICI) pembrolizumab (disease control rate: 77%, objective response: 53% and complete radiological recovery: 21%)[69]. Mutation in the *BRCA* gene has been reported in around 5% of patients with APC. Targeted therapy in patients with *BRCA* gene mutation using 'poly ADP-ribose polymerase (PARP) inhibitors' is being actively investigated[70] (Figure 3).

Palliative treatment

Palliative treatment aims to allay patients' symptoms and improve their quality of life. Pain management, symptomatic relief, and psychological support are the pillars of this strategy.

Gastric outlet obstruction (GOO), extrahepatic biliary obstruction (EHBO), and abdominal pain are the three most common disabling symptoms in APC which adversely affect an individual's quality of life besides being a major source of 'caregiver fatigue'. GOO, presenting as nausea, vomiting, dehydration, and weight loss, is seen in 10%-25% of all APC cases. Palliative surgery with open gastrojejunostomy (GJ) is the traditional approach to managing a malignant GOO. Placement of endoscopic duodenal stents and laparoscopic GJ has been tried, with varying degrees of success. Surgical procedures offer good functional outcomes at the cost of increased mortality[71]. EHBO can present with obstructive jaundice. Endoscopic retrograde cholangiopancreatography (ERCP)-guided biliary stent placement is the accepted gold standard approach for the management of malignant EHBO. Both plastic and self-expanding metal stents (SEMSs) have been used, with literature favoring the use of covered SEMSs. Failure of ERCP-guided biliary drainage may warrant drainage through the percutaneous route or an endoscopic ultrasonography-guided biliary drainage (EUS BD)[72]. Hepaticojejunostomy with a Roux-en-Y reconstruction and cholecystectomy is the favored palliative surgical procedure for palliation of EHBO secondary to PC. Laparoscopic biliary bypass and robot-assisted laparoscopic hepaticojejunostomy have been technically successful with satisfactory surgical outcomes[73,74]. Thus, patients with good performance status may benefit from a palliative surgical procedure while those with poor performance status warrant endoscopic biliary drainage.

Malignant infiltration of celiac or mesenteric nerve plexus in patients of APC may cause abdominal and back pain. This may adversely affect an individual's quality of life. Multimodal drug therapy encompassing the use of non-steroidal anti-inflammatory drugs and or opioid analgesics in various combinations form the bedrock of pain management. Intraoperative celiac block using ethanol or a local anesthetic using either laparoscopic or open approach and EUS-guided neurolysis of celiac plexus, have all been tried[71] (Figure 4).

NEWER MODALITIES FOR PANCREATIC CANCER

Immunotherapy for pancreatic cancer

The tumor microenvironment of PC is responsible for aggressiveness as well as chemoresistance. This makes the case for utilizing immunotherapy in the advanced and metastatic settings. However, the approval for ICI is currently for patients with mismatch repair-deficient cases[69]. The updated results of the Keynote-158, using pembrolizumab in patients with advanced PDAC revealed an overall response rate (ORR) of 18.2%, median progression-free survival of 2.1 mo, and median overall survival of 4.0 mo[75]. The results are not very encouraging despite this, due to fewer driver mutations, variable expression of PD-1/PD-L1 and neoantigen burden in the tumor tissue, and absence of DDR, which are hallmarks of this malignancy[76].

Targeted therapy

The highly actionable mutations detected in molecular profiling of the Know Your Tumor initiative were 27%, of which the common ones involved the *KRAS, TP53, MLL3, CDKN2A, SMAD4, TGFBR2, ARID1A,* and *SF3B1* genes. These mutations, however, do not have any therapeutic modality to target[77,78]. *Neurotrophic receptor tyrosine kinase* (*NTRK*) gene fusions have been detected in about 6% of pancreatic adenocarcinomas. Larotrectinib and entrectinib are two newer agents receiving accelerated approval for use in metastatic tumors with *NTRK* gene biomarker with tissue agnostic indication[79,80]. Three single-arm trials, namely LOXO-TRK-14001, SCOUT and NAVIGATE, had a total of 55 patients with *NTRK* fusions and had an ORR of 55% with Larotrectinib[81]. The median progression-free survival was not achieved after a median duration of 9.9 mo. Similarly, in three other single-arm trials,

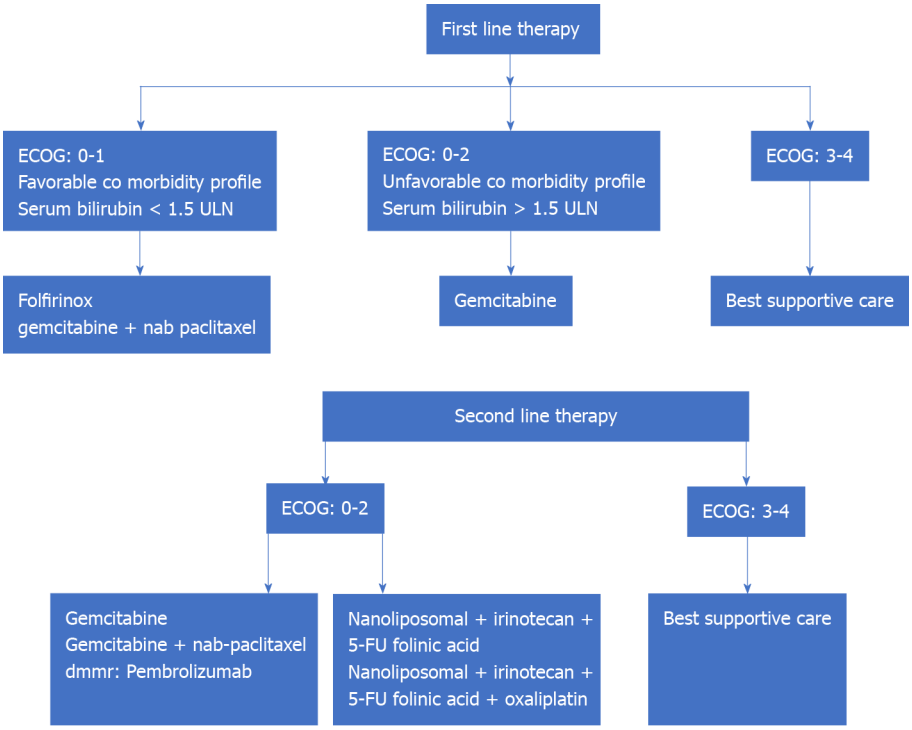

Figure 3 Management of advanced metastatic pancreatic carcinoma. ECOG: Eastern Cooperative Oncology Group; ULN: Upper limit of normal.

including ALKA-372-001, STARTRK-1 and STARTRK-2, with 60 patients in total, the patients with *NTRK* fusion had an ORR of 100%[82].

Germline *BRCA1/2* mutations and homologous recombination deficiency enable the utility of platinum agents as well as poly (adenosine diphosphate-ribose) polymerase (PARP) inhibition as a novel therapeutic modality. Olaparib, a PARP inhibitor was approved by the United States' Food and Drug Administration in December 2019 for patients with advanced metastatic malignancy having germline *BRCA1/2* mutation. The phase III POLO trial utilizing olaparib in PAC, progressing after platinum-based therapy revealed median progression-free survival of 7.4 mo *vs* 3.8 in the control arm (HR: 0.53, 95%CI: 0.35-0.82; P = 0.004). This did not translate into an overall survival benefit[83].

Macrophage-targeted therapy

Macrophages residing in the tumor environment are labeled as tumor-associated macrophages. CD 51 is a marker of macrophages that promotes the stemness of PDAC cells by regulating the TGF-β1/smad2/3 pathway. As a result, CD 51- targeted therapy is evolving as a newer therapeutic modality. Similarly, CD 40 activation, which promotes anti-tumor T-cell responses has been targeted by using anti-CD 40 antibody, CP-870893 along with gemcitabine, providing initial results of response[84].

Cancer vaccines

The ability of cancer vaccines to stimulate dendritic cell responses and activate the adaptive immune responses has been harnessed for many cancers, including PC. The expression of murine enzyme alpha-1,3-galactosyltransferase (alpha-GT) by genetic engineering on PC cell lines HAPa1 and HAPa2 lead to anti-alpha-Gal antibody responses in humans[85]. Algenpanteucel-L was used in a phase II study and phase III (IMPRESS Trial). When algenpanteucel-L was given after gemcitabine and 5-FU based CRT, 81%-86% 1-year disease-free survival and 96% 1-year overall survival were observed[86,87].

GVAX, a line of engineered pancreatic tumor cells secreting GM-CSF has been tested in phase I study along with cyclophosphamide (Cy) with early results of tolerability and survival. In a phase II study, GVAX/Cy was tested against a GVAX/Cy followed by CRS 207 (a live-attenuated *Listeria* strain that induces tumor-associated antigens) and resulted in better overall survival in the latter arm (6.1 mo *vs* 3.9 mo, P = 0.02)[88].

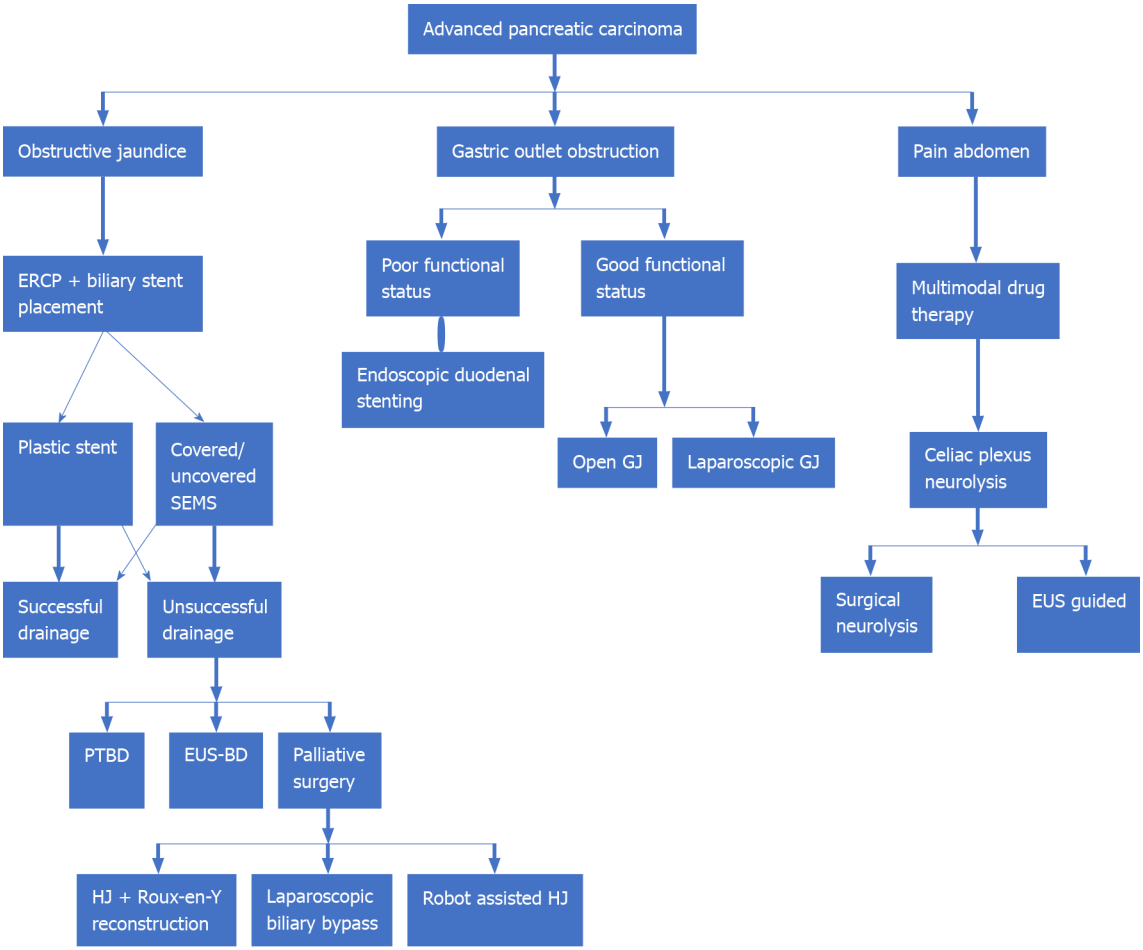

Figure 4 Palliative management in metastatic pancreatic carcinoma. ERCP: Endoscopic retrograde cholangiopancreatography; EUS: Endoscopic ultrasound; EUS-BD: Endoscopic ultrasound guided biliary drainage; GJ: Gastrojejunostomy; HJ: Hepaticojejunostomy; PTBD: Percutaneous transhepatic biliary drainage; SEMS: Self-expanding metal stent.

Other membranous and intracytoplasmic targets

There have been numerous trials using targets like vascular endothelial growth factor (VEGF) and VEGF-receptor, RAS-RAF-MEK-ERK pathway, *etc.* but none have shown robust survival data[89,90]. The rapamycin-insensitive companion of mTOR (RICTOR) expression was found to have a survival benefit in resected PAC patients, with those having a lower expression doubling the survival as compared to the high expressers [91].

CONCLUSION

We have attempted to provide an inclusive version of the management of PC, with special emphasis on current strategies and the road ahead with emerging modalities of therapy. Of course, there are certain gaps in the understanding of this disease and the evolution of treatment options is always challenging. For times to come, newer modalities appear promising; however, there is no substitute for early diagnosis and management for disease-free survival.

Abstract

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) seems to employ two routes of entrance to the host cell; *via* membrane fusion (with the cells expressing both angiotensin converting enzyme 2 (ACE2) and transmembrane peptidase/serine subfamily member 2/4 (TMPRSS2/4)) or *via* receptor-mediated endocytosis (to the target cells expressing only ACE2). The second mode is associated with cysteine cathepsins (probably cathepsin L) involvement in the virus spike protein (S protein) proteolytic activation. Also furin might activate the virus S protein enabling it to enter cells. Gastrointestinal tract (GIT) involvement in SARS-CoV-2 infection is evident in a subset of coronavirus disease 2019 (COVID-19) patients exhibiting GIT symptoms, such as diarrhea, and presenting viral-shedding in feces. Considering the abundance and co-localization of ACE2 and TMPRSS2 in the lower GIT (especially brush-border enterocytes), these two receptors seem to be mainly involved in SARS-CoV-2 invasion of the digestive tract. Additionally, *in vitro* studies have demonstrated the virions capability of infection and replication in the human epithelial cells lining GIT. However, also furin and cysteine cathepsins (cathepsin L) might participate in the activation of SARS-CoV-2 spike protein contributing to the virus invasiveness within GIT. Moreover, cathepsin L (due to its involvement in extracellular matrix components degradation and remodeling, the processes enhanced during SARS-CoV-2-induced inflammation) might be responsible for the dysregulation of absorption/digestion functions of GIT, thus adding to the observed in some COVID-19 patients symptoms such as diarrhea.

Key Words: COVID-19; SARS-CoV-2; Angiotensin converting enzyme 2; Transmembrane peptidase/serine subfamily member 2/4; Cathepsin L; Gastrointestinal tract

Core Tip: Gastrointestinal tract (GIT) is believed to participate in severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) dissemination. The current research shows the abundance and co-localization of angiotensin converting enzyme 2 (ACE2) and transmembrane peptidase/serine subfamily member 2 receptors in the lower GIT. Furthermore, about half of coronavirus disease 2019 patients present with GIT symptoms, such as diarrhea, and exhibit viral-shedding in feces. Additionally, *in vitro* studies have demonstrated the virions capability of infection and replication in the human epithelial cells lining GIT. This paper reviews the possible routes of the virus infection with respect to the host-enzymatic systems responsible for the proteolytic priming of SARS-CoV-2.

INTRODUCTION

Coronaviruses may employ several host proteases for their invasion into target cells. The enzymes participating in the viruses activation include: proprotein convertases (PCs) (mainly furin), transmembrane serine proteases, especially transmembrane peptidase/serine subfamily member 2 (TMPRSS2), the lysosomal cathepsins (mainly cathepsin L), elastase, and coagulation factor Xa[1].

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) virus responsible for coronavirus disease 2019 (COVID-19) pandemic exhibits many similarities when compared to SARS-CoV. It employs a similar mechanism of host cells invasion; recognizes and binds the same type of angiotensin converting enzyme 2 (ACE2) receptors to enter host cells (but with higher affinity[2]), and comparable processing of spike protein (S protein) seems to be necessary for the virion fusion with the host cell membrane[3-7] (Figure 1).

Two proteolytic events need to be conducted for SARS-CoV-2 activation; initially spike protein is cut in the specific cleavage site between S1 and S2 domain, then the second cleavage within S2 domain (S2′ site) allows for the exposition of the fusion peptide, which enables membrane fusion. The first proteolytic step can happen in the producer cell, in the extracellular space, or within the host cell's endosome. This cleavage site in SARS-CoV-2 spike protein is recognized by various proteases, including furin (unlike in SARS-CoV lacking furin-cleavage site between S1 and S2)[6, 8] and TMPRSS2[3]. The second cleavage can be either performed by TMPRSS2 on the surface of the host cell, or in the endolysosomes by lysosomal proteases, most probably cathepsin L[9].

Therefore, as proposed by Pislar *et al*[10], two routes of SARS-CoV-2 entry to the host cell are likely; *via* membrane fusion with the host cells which expose both ACE2 and TMPRSS2 (and/or other transmembrane serine proteases such as TMPRSS4[11]) proteins, or *via* receptor-mediated endocytosis (RME) to the target cells expressing only ACE2 receptors. In the first case, both processing steps performed by TMPRSS2 before the virus entry enable membrane fusion, whereas in the second mechanism, the virion binding with ACE2 receptors induces endocytosis followed by spike protein activation by cathepsin L (and/or other cysteine cathepsins)[4,10]. As a result of either of these pathways, viral RNA is released in the host cell and undergoes the processes of replication (Figure 2).

TYPES OF HOST PROTEASES IN SARS-CoV-2 INVASION

The findings of several studies support the notion that, apart from ACE2 receptors, the main host peptidases involved in SARS-CoV-2 spike protein processing include: TMPRSS2 (and/or TMPRSS4), lysosomal cysteine cathepsins (mainly cathepsin L), as well as furin-like PCs. They may participate in SARS-CoV-2 activation independently,

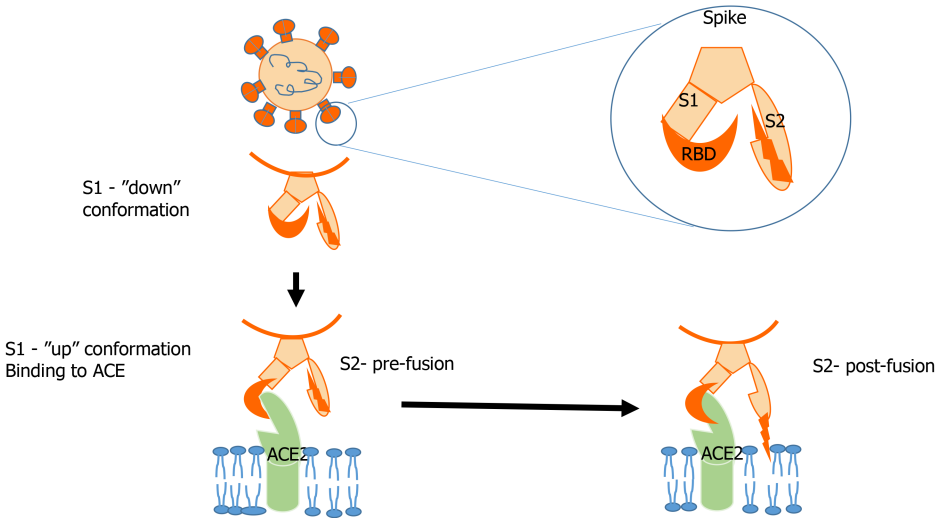

Figure 1 Alternations in spike proteins conformation upon binding to ACE 2. Spike S1 subunit contains receptor binding domain, that has to change from "down-conformation" state to "up-conformation" state to be accessible for ACE2. Changes in S1 subunit trigger conformational changes in S2 subunit, causing exposition of hydrophobic domain, changing it from "pre-fusion" to "post-fusion" state. This enables fusion of the virus with host membrane (after Zhu *et al*[7]).

or their actions may overlap or complete one another, depending on the pattern of the virion-recognized proteins exposed on the host cells (*e.g.* expressing or not TMPRSS2).

Cysteine cathepsins (CCs) in pathology

Cysteine cathepsins belonging to the papain-like family of cysteine proteases (containing cysteine in their catalytic center) comprise 11 cathepsins (B, C, F, H, K, L, O, S, V, X and W) in the human organism[12,13]. They belong to lysosomal proteases involved mainly in intracellular protein breakdown, antigen processing, MHC-II mediated immune response, and apoptosis. However, their functions go far beyond this; they participate in various physio-pathological processes not only intracellularly, but also in the extracellular matrix (ECM), because, except for their endolysosomal sequestration, they have been observed in the nucleus, cytosol, mitochondria, at the plasma membranes and in the extracellular milieu[13,14]. Their secretion is observed in physiological conditions (*e.g.* in bone remodeling – conducted by osteoclasts-secreted cathepsin K, in wound healing performed by keratinocytes-secreted cathepsin B, in prohormone processing – thyroid hormones released from thyroglobulin by cathepsins B, L and K secreted from the thyroid epithelial cells). However, an excessive secretion of cysteine cathepsins is mostly observed in pathological states associated with inflammatory processes, such as cancer diseases (cathepsins B, C, K, L, S, H, X), cardiovascular diseases (cathepsins C, K, L, S, V), joint and bone diseases (cathepsins K, B, L, S, H), inflammatory bowel disease (cathepsin L), and many other disorders (summarized in[12-15]). In these pathological states CCs typically act extracellularly, where they participate in collagen, elastin, and other ECM components degradation directly or indirectly (activating other proteases) after being secreted from recruited immune cells (mostly), as well as from inflamed tissue cells (to the lesser extent). Macrophages and other immune cells infiltrating tissues seem to be the main extracellular source of CCs whose secretion is stimulated by inflammatory factors like cytokines. However, also other cell types secrete excessive amounts of CCs, including osteoclasts or chondrocytes (oversecreting cathepsin K and/or S in arthritis and osteoporosis), or cancer cells and tumor-associated fibroblasts (oversecreting cathepsin S, L and/or B in cancer invasion)[14]. Apart from degradation of main components of ECM, also more refined processing of ECM (undergoing both intra-, and extracellularly) is ascribed to CCs. This comprises modifying and shedding cell adhesion molecules and cell membrane receptors, which affects signal transduction pathways, as well as processing cytokines and chemokines, which upregulates immune response [14]. The resulting augmentation of inflammatory processes further induces the secretion of CCs, enhancing the destruction of ECM, which eventually leads to the acceleration of the processes observed in the aforementioned disorders.

Due to their roles in multiple inflammatory-based disorders, CCs have been considered for a long time as a target for medicinal drugs design. However, because of ubiquitous expression of most CCs, their constitutive, overlapping functions, broad substrate specificities, most of the studied so far medicines have exhibited unfavorable

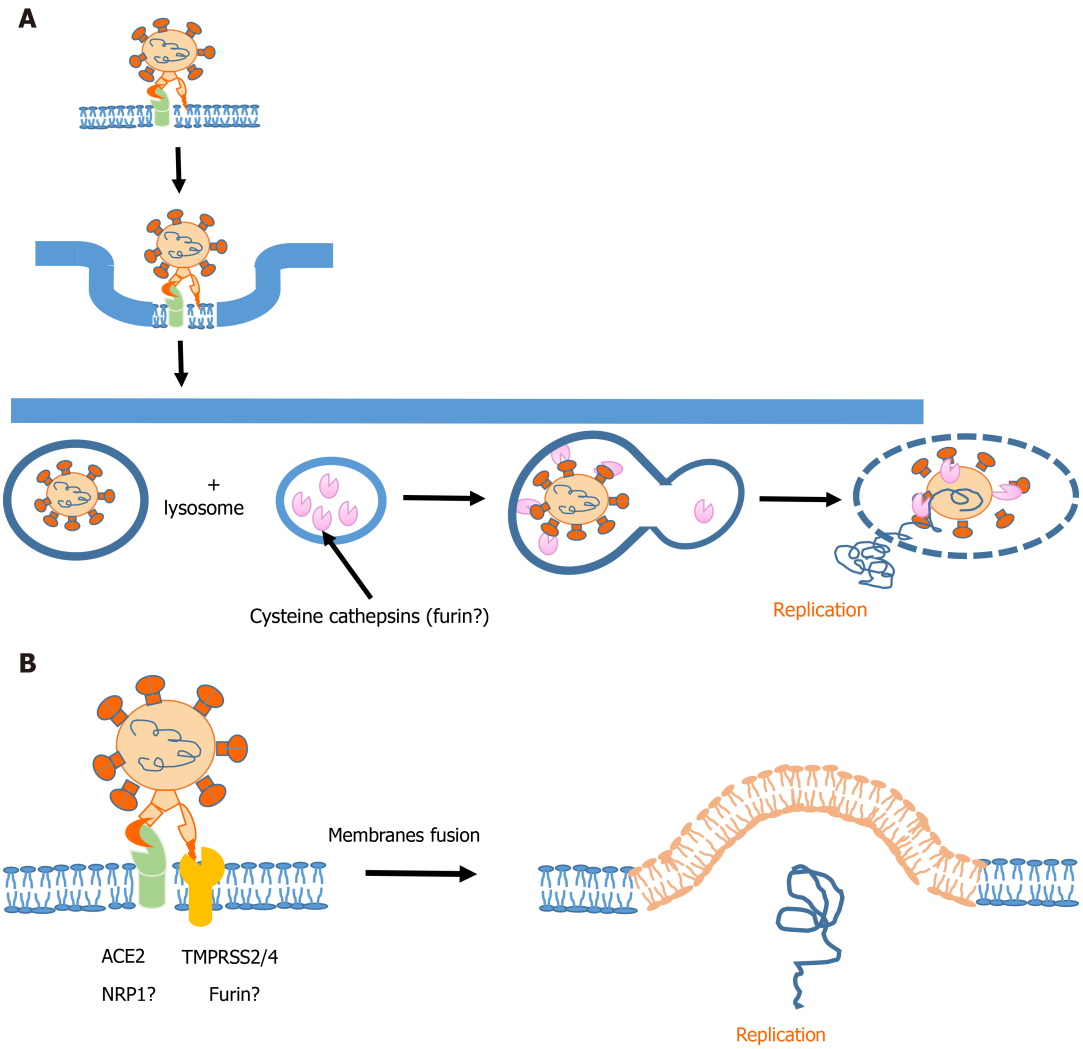

Figure 2 Two modes of virus entry. A: Receptor-mediated endocytosis of severe acute respiratory syndrome coronavirus-2. After binding to ACE2 and formation of endosome, lysosomal cathepsins activate spike protein, which leads to the release of the viral RNA into host cell. B: Membrane fusion mechanism - priming of the spike proteins is mediated by transmembrane peptidase/serine subfamily member 2/4, which leads to fusion of viral and host membranes and release of the viral RNA into host cell.

side effects, thus not surviving clinical trials. However, the attempts to construct CCs-aimed drugs, taking advantage of the newest technology, are underway. The most clinical trials have been conducted on cathepsins K and S inhibitors, also cathepsin C seems to be a promising target, whereas the remaining cathepsins inhibitors have either got stuck in the initial stages of clinical trials or their trials have been discontinued (reviewed in[14]).

Cathepsin L in inflammatory processes

Similarly to other cysteine cathepsins, cathepsin L exhibits pleiotropic activities in the human organism. One of the most evident actions of this enzyme is (beside cathepsins S, K and V) its participation in inflammatory processes associated with various pathological conditions[14-16]. For example Menzel *et al*[17] have demonstrated the up to 10-fold induction of cathepsin L expression (mRNA) in intestinal macrophages derived from inflammatory bowel disease (IBD) patients, and the clear improvement of the disorder symptoms in DSS (dextran-sulphate-sodium)-induced colitis mice mode, when a simultaneous application of cathepsins L and B inhibitors was investigated. Xu *et al*[18] have exhibited the stimulatory function of cathepsin L in microglia-mediated neuroinflammation, which accompanies many neurological disorders including Parkinson's disease. Cao *et al*[19] have shown the correlation between serum cathepsin L activity and the markers of inflammation (such as neutrophile counts and hs-CRP) in the patients with chronic kidney disease.

Cysteine cathepsins and TMPRSS2 in SARS-CoV-2 invasion

Cell line experimental systems creating the environment aimed at the inhibition of CCs have substantiated the function of these enzymes in the processes of SARS-CoV-2 activation. Raising pH in the endolysosomal compartments (with ammonium chloride and/or bafilomycin A), which inactivates lysosomal proteases working in acidic environment, or application of cysteine proteases inhibitors (such as E-64d inhibitor - inactivating cysteine cathepsins L, B, H, as well as cytosolic calpain) have significantly limited entry of SARS-CoV-2 into chosen cell lines[4]. Ou *et al*[20] (applying lentiviral pseudotype system) have demonstrated that the treatment of HEK-293/hACE2 cells with E-64d inhibitor reduced entry of SARS-CoV-2 S pseudovirions by over 90%. Further, the Authors compared the effect of two specific inhibitors of cathepsin L (SID 26681509), and cathepsin B (CA-074). Whereas the first inhibitor limited the pseudovirions entry by over 76%, the second one did not exhibit any significant effect, which suggests a prevalent function of cathepsin L in the receptor-mediated endocytosis mechanism of the virus invasion. RME mechanism in HEK- 293/hACE2 cells has been confirmed by the Authors in the experiments showing the inhibition of the SARS-CoV-2 S protein entry by blocking the factors inevitable in the process of endolysosomal trafficking (PI(3)P 5-kinase (PIKfyve) and two-pore channel subtype 2 (TPC2)[20]. The involvement of CCs has been also observed by Hoffmann *et al*[3] who demonstrated that the increase in pH (with ammonium chloride) almost completely inhibited SARS-2-S-driven entry into 293T cells expressing ACE2 but devoid of TMPRSS2. This observation is in agreement with Ou *et al*[20] findings confirming that the virus entry into these cells undergoes *via* RME with the involvement of cathepsin L in spike protein activation. In their experiments on the human colon cell line - Caco-2 cells overexpressing TMPRSS2, Hoffmann *et al*[3] exhibited the participation of both TMPRSS2 and CCs in the mechanism of the virus entry into these cells. Alkalization of the environment caused around 90% reduction in SARS-2-S-driven entry, whereas incubation with E-64d inhibited the virus entry by around 40%. On the other hand, the application of camostat mesylate (inhibitor of TMPRSS2 and other serine proteases) reduced the virus entry by about 90%, and when the Authors used both inhibitors simultaneously, they achieved nearly complete virus-entry inhibition to Caco-2 TMPRSS2 (+) cells. They also found that E-64 inhibitor significantly reduced the virus entry into Vero and 293T cells not expressing TMPRSS2, which indicates the endolysosomal pathway. However, the transduction of these cell lines with TMPRSS2 markedly reversed the effect of CCs inhibition, emphasizing the function of TMPRSS2 in the S protein priming, agreeably with Ou *et al*[20] findings that the expression of TMPRSS 2, 4, 11 A, 11D, and 11E on 293/hACE2 cells enhanced SARS-CoV-2 S protein-mediated cell–cell fusion. Moreover, the Authors noted that, however the addition of trypsin (like TMPRSS belonging to serine proteases) stimulated the formation of syncytia in 293/hACE2 cells (indicative of activated by trypsin SARS-2-S protein-stimulated cell-cell fusion), this process was also noticed in the experiments without trypsin. These findings indicate that binding with ACE2 receptors may be a sufficient event inducing cell-cell fusion (without the proteolytic priming with the extracellular protease). Nevertheless, it is possible that other host extracellular peptidases are involved in spike protein activation. The findings derived from Hoffmann *et al*[3] and Ou *et al*[20] experiments are depicted in Table 1.

Furin in SARS-CoV-2 invasion

As determined by Shang *et al*[8], another enzyme involved in SARS-CoV-2 spike protein priming is furin belonging to proprotein convertases (PCs). PCs are eukaryotic serine proteases, and ubiquitously expressed furin belongs to the PCs subfamily present in the organelles of the constitutive protein secretion pathway. These enzymes participate in the proteolytic post-translational modification of a variety of functionally important peptides and proteins, such as growth factors and hormones, both intra- and extracellularly (in the trans-Golgi network, endosomes, and pericellular environment). The amino acid sequence specifically recognized and cleaved by PCs including furin, is found in many viral surface proteins, so different viruses (like MERS-CoV) are activated by these enzymes[1]. Unlike SARS-CoV (exhibiting PC cleavage site motif only in the S2' site) [1], SARS-CoV-2 spike protein includes PCs specific motif at the S1/S2 boundary[8]. Shang *et al*[8] have performed experiments to examine whether this sequence is cut by furin. They demonstrated that PCs inhibitors reduced SARS-CoV-2 pseudovirus entry into three cell lines expressing hACE2 receptors; HeLa cells (human cervical cells), Calu-3 cells (human lung epithelial cells), and MRC-5 cells (human lung fibroblast cells). Moreover, the mutation of the PCs specific motif significantly reduced the pseudovirions entry to the studied cells. The

Table 1 Receptors/proteases involved in Severe acute respiratory syndrome coronavirus-2 invasion of human cells

Receptor/protease	Experimental model	Observation	Ref.
ACE2 and TMPRSS2/4	Human small intestinal enteroids; HEK-293T cell line transfected with ACE2, TMPRSS2, or TMPRSS4	Productive infection of SARS-CoV-2 in ACE2 (+) mature enterocytes; Correlation of ACE2, TMPRSS2 and 4 with SARS-CoV-2 invasiveness	Zang *et al*[11]
ACE2 and TMPRSS2	ACE2 and TMPRSS2 expressing C2BBe1, Caco-2, and Calu-3 cell lines	Persistent invasion and replication of SARS-CoV-2 in the cells; Correlation of TMPRSS2 (but not ACE2) with SARS-CoV-2 RNA	Lee *et al*[33]
ACE2, TMPRSS2, and CCs	HEK-293T cell line transfected with ACE2; Caco-2 cells overexpressing TMPRSS2	Inhibition of SARS-CoV-2 pseudovirus entry into HEK-293T ACE2(+)/TMPRSS2(-) by pH increase and E-64 inhibitor; Inhibition of SARS-CoV-2 pseudovirus entry into Caco-2 TMPRSS2(+) by pH increase, CCs inhibitor (E-64d), and TMPRSS2 inhibitor (camostat mesylate)	Hoffmann *et al*[3]
ACE2, TMPRSS 2, 4, 11A, 11D, 11E, and CCs (cathepsin L)	HEK-293T cell line transfected with ACE2	Inhibition of SARS-CoV-2 pseudovirus entry into the cells with CCs inhibitor (E-64d) and cathepsin L inhibitor (but not cathepsin B inhibitor); Intensification of SARS-CoV-2 S protein-mediated cell–cell fusion, caused by expression of TMPRSS 2, 4, 11A, 11D, and 11E on 293/hACE2 cells	Ou *et al*[20]
ACE2 and TMPRSS2	ACE2 and TMPRSS2 expressing Caco-2 and T84 cell lines	Persistent invasion and replication of SARS-CoV-2 in the cells	Stanifer *et al*[35]
ACE2, furin, TMPRSS2, and CCs	ACE2-expressing HeLa, Calu-3, and MRC-5 cell lines	Reduction of SARS-CoV-2 pseudovirus entry into cells by inhibitors of PCs, CCs and TMPRSS2	Shang *et al*[8]
NRP1, ACE2, and TMPRSS2	HEK-293T cell line transfected with ACE2, TMPRSS2, or NRP1	Augmentation of SARS-CoV-2 infectivity when NRP1 was coexpressed with ACE2 and TMPRSS2	Cantuti-Castelvetri *et al*[21]

ACE2: Angiotensin converting enzyme 2; NRP1: Neuropilin 1 (receptor which binds furin-cleaved substrates); TMPRSS2/4: Transmembrane peptidase/serine subfamily member 2/4; CCs: Cysteine cathepsins; HEK-293T: Human embryonic kidney 293T cells; Caco-2: Human colorectal adenocarcinoma cell line; C2BBe1: A subclone of Caco-2; T84: Human colon carcinoma cell line; HeLa: Human cervical cell line; Calu-3: Human lung epithelial cell line; MRC-5: Human lung fibroblast cell line; PCs: Proprotein convertases.

Authors detected no cleavage within the spike protein, when they packaged the pseudoviruses to HEK293T cells pretreated with furin-targeting siRNA. Additionally, they excluded the participation of matrix metalloproteinases (MMPs) in the experiment with the application of MMP inhibitor. Therefore, they confirmed the involvement of furin in SARS-CoV-2 entry into chosen cells. Additionally, furin priming of SARS-CoV-2 spike protein has been associated with the virions recognition and binding by neuropilin 1 (NRP1 - receptor which binds furin-cleaved substrates). Cantuti-Castelvetri *et al*[21] have shown that, except for ACE2, also NRP1 receptors are involved in SARS-CoV-2 invasion. Although the exact mechanism of NRP1 participation in this process is not elucidated, the Authors found the receptors to markedly enhance the virus infectivity. Apart from furin involvement, Shang *et al*[8] also observed the association of other aforementioned peptidases with SARS-CoV-2 invasion. They noticed the reduction in the pseudovirus entry to the three studied cell lines, caused by the application of both serine proteases (camostat) and cysteine cathepsins (E64) inhibitors. Furthermore, the pseudovirus entry to HeLa cells was more markedly reduced when either camostat or E64d was applied in the cells pretreated with proprotein convertases inhibitor[8]. Therefore, it might be concluded that depending on the type of target cells, TMPRSS2, lysosomal cathepsins, and furin might be involved in the activation of SARS-CoV-2 entry exhibiting cumulative/overlapping final effect (Figure 2). The observations of Shang *et al*[8] and Cantuti-Castelvetri *et al*[21] are collected in Table 1.

Cysteine cathepsins as a target in search for COVID-19 therapy

Focusing on cathepsin L expression as a target in search for an anti-Covid-19 drug, Smieszek *et al*[22] have tested an array of medications applied in clinical practice. They found amantadine (a drug used previously to treat influenza A, and now applied in neurological diseases including Parkinson's disease) to be a promising compound. Being able to accumulate in lysosomes and alkalize them, amantadine belongs to lysosomotropic agents. Such compounds inactivate lysosomal enzymes including CCs whose optimal pH lies below 5. The Authors demonstrated a significant reduction in cathepsin L gene expression using amantadine, however also other cysteine cathepsin

genes expression was inhibited, including cathepsins B and K, with the most pronounced effect observed for cathepsin H. Therefore, it might be hypothesized that this is also cathepsin H which plays an important role in the processing of the SARS-2-S spike protein. The activity of cathepsin H would have been inhibited similarly to other lysosomal cathepsins in the aforementioned experiments (raising pH and/or using E64 inhibitor), which demonstrated a significant reduction of SARS-2-S-mediated entry to the studied cells. However, in comparison with thoroughly studied cathepsins B, L, S, and K, there is much less scientific data referring to cathepsin H.

Amantadine efficiency in COVID-19 treatment has been suggested by Rejdak *et al* [23] who documented no clinical manifestations of COVID-19 infection in 22 patients in spite of the confirmation of SARS-CoV-2 presence with rRT-PCR testing in all of these individuals. The patients had been treated with either amantadine or memantine, for at least 3 months prior to the infection exposure, due to their conditions (multiple sclerosis, Parkinson's disease or cognitive impairment). Therefore, amantadine seems to be a promising treatment for COVID-19 patients. The effect of amantadine may be associated with the down-regulation of cysteine cathepsins (L and/or H) in the endolysosomal compartment and/or the disturbance of viroporin protein channel probably involved in the viral RNA release, as suggested for SARS-CoV[24].

As discussed before, the generation of anti-CCs medicinal drugs is a problematic issue (associated with the observation of unfavorable side effects). Hence, the attitude aimed at screening the already existing therapeutics, which would lower the activity of proteases involved in SARS-CoV-2 activation, seems a rational approach.

EFFECT OF SARS-CoV-2 ON GASTROINTESTINAL TRACT

Gastrointestinal symptoms and fecal virus shedding in COVID-19 patients

A significant amount of scientific evidence accumulated so far points to gastrointestinal tract (GIT), especially its lower part, as a target organ affected by SARS-CoV-2, beside the respiratory system[25]. Apart from the typical pulmonary symptoms (cough, fever, shortness of breath), some of the patients (around 4%-50% individuals) present with digestive symptoms like diarrhea, nausea, vomiting and abdominal pain[26]. Moreover, the virus mRNA presence in stool samples has been observed in some patients, often persisting long after its disappearance from the respiratory tract. Wu *et al*[27] have documented SARS-CoV-2 mRNA presence in the feces of more than half of the studied patients, with duration for up to 5 wk after its vanishing from the respiratory tract specimens. It might suggest active proliferation of the virus in the gastrointestinal tract of some patients. Similarly, Xiao *et al*[28] have observed fecal virus shedding in more than 50% of the studied patients, and in over 20% of them the duration of positive results in stool exceeded the virus presence in the respiratory samples. Additionally, the Authors detected the protein parts of the virus (as well as the presence of ACE2 receptors) in gastrointestinal epithelial cells. The virus replication in rectal tissue derived from a COVID-19 patient has been noted by Qian *et al*[29] who detected SARS-CoV-2 components in the intestinal epithelial cells (but mainly in intestinal lymphocytes and macrophages). The Authors hypothesize that, like in the case of influenza virus, it is possible for SARS-CoV-2 virions to be transported from the respiratory tract to the GIT *via* the immune cells. In the meta-analysis of 60 studies comprising over 4000 COVID-19 patients, performed by Cheung *et al*[30], 17.6% of the patients exhibited gastrointestinal symptoms, and in almost 50% (30%-70%) the virus mRNA was detected in the feces. Most of these positive stool samples (above 70%) were collected after the loss of the virus from the respiratory specimens.

However, it is still not clear, whether the virus is transmittable *via* fecal-oral route. Whereas Wang *et al*[31] detected live virus in the fecal samples, Zang *et al*[11] demonstrated the inactivation of the virions released into the intestinal lumen in the environment simulating human colonic fluid. Moreover, the Authors did not manage to recover infectious virus from the stool specimens.

Ability of SARS-CoV-2 to productively infect human GIT cells via ACE2 and TMPRSS

Several studies have demonstrated the invasion and replication of SARS-CoV-2 in the human GIT cells. Chu *et al*[32] in their ex-vivo experiments on human intestinal tissues have evidenced the ability of SARS-CoV-2 to infect, proliferate and release infectious virus particles from intestinal cells. In comparison with SARS-CoV, SARS-CoV-2 replicated less efficiently and brought about less damages in the human intestinal

epithelium, but evoked greater response of innate immune system (inducing the expression of proinflammatory mediators such as interferons and interleukins). Hence, the Authors suggested that the gastrointestinal tract might serve as an alternative route of virus dissemination. The vulnerability of the human GIT epithelial cells to SARS-CoV-2 invasion *via* ACE2 and TMPRSS-2 receptors has been confirmed in other studies with the application of intestinal cell lines models, as well as human small intestinal organoids – hSIOs[11,33-35]. Lee *et al*[33] investigated the growth of SARS-CoV-2 in a human GIT cell line model; C2BBe1 (a subclone of human epithelial colorectal adenocarcinoma cells: Caco-2). C2BBe1 (genetically and structurally resembling the brush border epithelial cells in the human GIT[36,37], and expressing moderate level of ACE2 and high level of TMPRSS2[33]) exhibited the greatest susceptibility to the virus. SARS-CoV-2 virions invaded and replicated in these cells, as well as in Caco-2[33,35] and T84 (human colon carcinoma) cells[35]. Furthermore, Stanifer *et al*[35] demonstrated SARS-CoV-2 infection of human colon organoids followed by active virions replication. These observations are in agreement with other studies on hSIOs[11,34]. Zang *et al*[11] reported productive infection of SARS-CoV-2 in $ACE2^{(+)}$ mature enterocytes, dependent on TMPRSS2 and TMPRSS4 receptors in human small intestinal enteroids. The Authors noted the role of an additional serine protease: TMPRSS4 which heightened the effect of TMPRSS2. Also, the two serine proteases enhanced SARS-CoV-2 spike protein-induced cell-cell fusion observed by the Authors.

ACE2 receptors (except for the respiratory system) are present in a variety of other organs including the gastrointestinal tract, where a great number of these proteins has been detected in the lower part of GIT[38]. Unlike in the upper segment (oral cavity, esophagus, stomach), high expression of ACE2 (both mRNA and protein) is observed in the small intestine (the greatest level), colon and rectum, as well as in the gall bladder[38,39]. Actually, ACE2 expression in the small intestine is much higher in comparison with all other organs in the human organism including the respiratory tract[11]. Specifically, ACE2 is present in the enterocyte cytoplasm and in the apical brush border, as well as in the glandular cells (in the lining epithelium of the lower GIT)[37]. The expression of ACE2 receptors has been exhibited to increase upon enterocytes differentiation. Lee *et al*[33] observed that (unlike constitutively expressed TMPRSS2), the expression of ACE2 receptors was significantly stimulated in the experiment inducing C2BBe1 enterocytes differentiation, associated with the generation of more pronounced features typical for brush border cells. Similarly, Zang *et al*[11] detected the greatest expression of ACE2 in mature brush border enterocytes, and Lamers *et al*[34] noticed around 1000-fold increase in ACE2 mRNA expression upon enterocytes differentiation. Zang *et al*[11] observed all studied receptors (ACE2, as well as TMPRSS2 and TMPRSS4) to be correlated with the virus invasiveness, similarly as Lee *et al*[33] noted a strong correlation between TMPRSS2 (although not ACE2) and viral RNA levels in the studied human epithelial cell lines (including Caco-2 and C2BBe1). Lee *et al*[33] found that the ectopic coexpression of ACE2 and TMPRSS2 in RPMI 2650 cells enhanced viral dissemination by 56.7 times (over 10-fold more in comparison with the sole ACE2 effect – 4.9 times, whereas TMPRSS2 transfection alone did not enhance the level of infectivity). It might be supposed that an effective level of ACE2 receptors is a prerequisite for the virions invasion of epithelial cells, but abundant expression of TMPRSS2 (and possibly TMPRSS4) greatly facilitates ACE2-mediated SARS-CoV-2 dissemination in the human GIT.

The involvement of both ACE2 and TMPRSS2 in SARS-CoV-2 invasion of GIT epithelial cells is in accordance with the reported co-localization of the two receptors in the lower GIT[38-40]. The most abundant expression of both proteins has been detected in the small intestine epithelial cells[38]; especially in the brush border cells [33]. Lee *et al*[39] evaluated single-cell RNA-sequencing datasets from the GIT in search for these two genes co-expression, and found the small intestine enterocytes as well as colonocytes to display the highest proportions of cells co-expressing ACE2 and TMPRSS2. Additionally, the Authors checked for the co-expression of ACE2, TMPRSS2 and TMPRSS4, and demonstrated the highest proportions of the three genes co-expression in the progenitor and stem-like epithelial cells in the small intestine. TMPRSS4 is an extra serine protease involved in SARS-CoV-2 activation and invasion, enhancing TMPRSS2 priming effect[11]. Therefore, both ACE2 and TMPRSS2 seem to be the main receptors responsible for SARS-CoV-2 invasion of GIT. The experimental data coming from Lee *et al*[33], Zang *et al*[11], and Stanifer *et al*[35] investigations are displayed in Table 1.

Putative association between SARS-CoV-2-mediated ACE2 disturbance and gastrointestinal symptoms development in COVID-19 patients

The known function of angiotensin converting enzyme 2 (ACE2) is the regulation of systemic arterial blood pressure (renin-angiotensin system). ACE2 catalyzes the conversion of Ang I to angiotensin (1–9) and angiotensin II (Ang II) to angiotensin (1–7), what counteracts the effects of Ang II, leading to decrease in blood pressure and inflammatory processes attenuation (reviewed in[41]). However, the role of ACE2 in GIT (where it is abundantly expressed) seems to be rather associated with the processes occurring in this organ. The analysis of the digestive system specific functional enrichment map for ACE2 gene suggests the involvement of ACE2 in digestion (with reference to its proteolytic activity) and transport of metabolites (the regulation of amino acid transport)[38]. In fact, ACE-2 proteins have been demonstrated to be coupled with sodium-dependent amino acids and glucose transporters. ACE2 is a chaperone for the sodium-dependent amino acid transporter B0AT1 which is involved in transport of neutral amino acids[42]. Moreover, ACE2 participates in the regulation of gut microbiota homeostasis[43,44].

Therefore, as proposed by Kumar *et al*[38], it might be hypothesized that SARS-CoV-2-associated dysregulation of ACE2 receptors in the human GIT may be involved in the mechanism of GIT symptoms development in COVID-19 patients.

CONCLUSION

In light of the presented studies, the impact of SARS-CoV-2 virus on GIT is evident, with the most substantiated involvement of ACE2 and TMPRSS2. However, except for these two receptors (and probably TMPRSS4), also other proteases might be implicated in SARS-CoV-2 invasion of GIT, as well as the development of the observed symptoms. Ubiquitously expressed furin and cathepsin L may be involved in spike protein processing, contributing to the virus invasiveness. Cathepsin L (and other CCs) might participate in the endolysosomal processing of the spike protein following ACE2-mediated endocytosis of the virion particles. Additionally, SARS-CoV-2 – induced inflammatory cytokines could stimulate the secretion of cathepsin L. Therefore, extracellular cathepsin L may contribute both to the spike protein processing, as well as degradation/remodeling of the ECM components and membrane-bound receptors including TMPRSS2/4 and ACE2. The resulting events might accelerate the inflammatory processes disturbing the digestion/absorption of nutrients yielding the observed symptoms such as diarrhea. However, more research is required, since the participation of furin and lysosomal cathepsins in SARS-CoV-2 GIT-invasion is more speculative.

Abstract

Gastroesophageal reflux disease has an increasing incidence and prevalence worldwide. A significant proportion of patients have a suboptimal response to proton pump inhibitors or are unwilling to take lifelong medication due to concerns about long-term adverse effects. Endoscopic anti-reflux therapies offer a minimally invasive option for patients unwilling to undergo surgical treatment or take lifelong medication. The best candidates are those with a good response to proton pump inhibitors and without a significant sliding hiatal hernia. Transoral incisionless fundoplication and nonablative radiofrequency are the techniques with the largest body of evidence and that have been tested in several randomized clinical trials. Band-assisted ligation techniques, anti-reflux mucosectomy, anti-reflux mucosal ablation, and new plication devices have yielded promising results in recent noncontrolled studies. Nonetheless, the role of endoscopic procedures remains controversial due to limited long-term and comparative data, and no consensus exists in current clinical guidelines. This review provides an updated summary focused on the patient selection, technical details, clinical success, and safety of current and future endoscopic anti-reflux techniques.

Key Words: Treatment; Gastroesophageal reflux; Transoral incisionless fundoplication; Anti-reflux mucosectomy; Anti-reflux mucosal ablation; Stretta

Core Tip: Gastroesophageal reflux disease is a common disorder that impacts quality of life. Endoscopic anti-reflux therapies are intended to offer an alternative for patients unwilling to undergo surgical treatment or take lifelong medication. Several techniques, such as transoral incisionless fundoplication, nonablative radiofrequency, plication methods, and anti-reflux mucosectomy, have shown encouraging results, but their role in the management of gastroesophageal reflux disease remains controversial. Careful patient selection and awareness of the advantages and disadvantages of each technique are essential to optimize outcomes. We herein provide an updated review of the technical aspects, clinical success, and safety of the principle endoscopic anti-reflux procedures.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a condition that develops when reflux of stomach contents causes troublesome symptoms or complications in the esophagus or beyond[1,2]. GERD is very frequent worldwide, with a prevalence ranging from 7.4% in Southern Asia to 19.6% in Central America, and it affects both sexes similarly[3]. The increment in aging and obesity, both predisposing factors for GERD, may increase its impact in the near future even further[4]. Many other factors also favor GERD exacerbation, including tobacco and certain drugs, such as calcium blockers and tricyclic antidepressants[5,6]. GERD negatively affects quality of life and imposes economic and productivity loss burdens[7].

Although the cause of GERD is still incompletely understood, several underlying predisposing pathophysiological mechanisms have been described. While low esophageal sphincter (LES) basal pressure may facilitate reflux after abdominal strain or during swallowing, a more pertinent mechanism is transient LES relaxation (TLESR), which can be associated with esophageal shortening[8,9]. Gastroesophageal junction (GEJ) disruption due to a hiatal hernia (HH) constitutes an additional factor because it contributes to LES incompetence and also displaces the acid pocket closer to the esophageal mucosa[10,11]. Altered visceral sensitivity has a bidirectional effect in GERD, magnifying symptoms in patients without mucosal injury and reducing symptom awareness in Barrett's esophagus patients[12]. Esophageal hypomotility, low saliva production, and other mechanisms such as certain breathing patterns may also contribute to GERD[13].

The management of GERD is multimodal. Lifestyle modifications such as weight loss, tobacco cessation, and, in selected cases, postural advice[14] have proven efficacy and may be sufficient in mild cases. Drug therapy occupies the next level, with proton pump inhibitors (PPIs) having a huge impact on GERD treatment due to high esophagitis healing rates, surpassing the performance of histamine receptor antagonists and exhibiting high cost-efficacy[15,16]. They are the cornerstone of medical GERD treatment. Anti-reflux surgery (ARS), namely laparoscopic fundoplication, is the last step in GERD management. Its objectives are as follows: (1) LES fixation to the hiatus and intraabdominal segment length augmentation; (2) LES basal pressure increase; and (3) hiatal repair. The latter aspect appears crucial because hiatal repair itself impacts the length and pressure of the LES more than fundoplication[17]. Randomized controlled trials (RCTs) have failed to demonstrate a clear long-term superiority of ARS over PPIs[18]. Consequently, ARS is reserved for patients who do not respond to PPIs, do not tolerate them due to adverse effects, or are unwilling to maintain them in the long term.

PPI refractoriness probably constitutes the most frequent indication for surgery, although it is a confusing term and thus deserves further consideration. The same concept frequently encompasses vastly different realities. Refractoriness can be partial or complete, a distinction that is clinically relevant. Recent and major trials have defined the grade of refractoriness needed to meet inclusion criteria[19]. Subsequently,

symptoms can persist for very different reasons, such as poor adherence to medical therapies, absence of a relationship with reflux (*e.g.*, functional heartburn), or objectively proven reflux persistence despite proper medical treatment. Therefore, guidelines advise a full diagnostic workup before surgery to demonstrate as consistently as possible that the symptoms, whether refractory or not, are objectively secondary to GERD[2,20-27].

In the last 30 years, effort has been made to design endoscopic anti-reflux therapies that serve as a valuable option for GERD management, either as an alternative to ARS or as bridge therapy between pharmacological treatment and surgery. They do not thus far allow hiatal repair and constrain candidate selection to individuals without a HH. In 1979, Angelchik[28] used a silicon prosthesis as the first endoscopic treatment for GERD. Since then, numerous other treatments have emerged, with many, such as GEJ injections of bulking agents and several plication techniques, disappearing because of low efficacy or unacceptable adverse effects[29-31]. Here, we present a comprehensive review of the endoscopic approaches for the treatment of GERD that have survived the test of time or have recently been designed (Table 1).

INDICATIONS FOR ENDOSCOPIC ANTI-REFLUX THERAPY

Endoscopic therapies should be considered at least in the same scenarios as surgery and should offer some advantages over ARS. Specifically, endoscopic anti-reflux therapy should be considered in PPI nonresponders, in patients who have a contraindication to PPIs or have concerns regarding their long-term adverse effects, and in those who either do not qualify for ARS or refuse it. Ideally, endoscopic techniques should demonstrate noninferior efficacy, alongside a shorter operation time, lower complication rate, and lower secondary long-term morbidity. Finally, they should not preclude a future fundoplication in case of failure.

Laparoscopic fundoplication performed by skilled surgeons has a low short-term morbidity and mortality but can cause significant adverse effects in the medium term, such as dysphagia (in up to 24% of patients), gas-bloat syndrome, and incisional hernia, and revision surgeries are not infrequent[22]. It fails in 10%-15% of patients in the short term, and long-term studies have shown that more than 30% of patients are still on PPIs years after surgery[22,32]. This constitutes the scenario against which endoscopic therapies should be compared.

The guidelines of the main medical and surgical societies and expert consensus documents published in the last 10 years have addressed the endoscopic alternatives as well as the surgical option. Their recommendations and the level of evidence or consensus that they are based upon are summarized in Table 2[2,20-26,33-35]. Transoral incisionless fundoplication (TIF) and nonablative radiofrequency are considered appropriate in well-selected patients and situations according to recent guidelines.

CURRENT ENDOSCOPIC THERAPIES

Transoral incisionless fundoplication

The aim of TIF is to perform an endoscopic fundoplication by reestablishing the flap valve mechanism with a 3-cm high-pressure zone at the distal esophagus to durably restore LES function[36]. This procedure mirrors ARS by using an endoscopic suturing device with T-fasteners, the EsophyXâ device (EndoGastric Solutions, Inc., Redmond, WA, United States)[37]. These devices have evolved from a longitudinally oriented gastrogastric plication to one with a greater degree of rotational movement, 200° to 300° in circumference and a 2-3-cm length wrap over the distal esophagus below the diaphragm to create full-thickness serosa-to-serosa esophagogastric plications. This easier to use and more automated device can deploy about 20 fasteners without the need for visualization of the stylet/fastener deployment. The objective of the technique is to restore the integrity of the angle of His by firing stabilizing T-fasteners, deployed 2 to 3 cm above the GEJ, with a 270° esophagogastric wrap, to mimic a Toupet surgical fundoplication. The EsophyXâ device was approved in 2007 by the United States Food and Drug Administration as a single-use, two-operator device comprising a tip (tissue retractor, tissue mold and chassis, fasteners over a stylet, and the invaginator) and body (H-fasteners, helix retractor lock, vacuum connection, fastener pusher, helix retractor control, tissue mold knob, gastroscope point of insertion).

Optimal candidates for TIF are patients who demonstrate LES incompetence (Hill grade II) without a concomitant HH. TIF 1.0 has been discontinued because TIF 2.0 achieves much better results[36]. The improved procedure has been evaluated in nine noncomparative studies[38-46] and in five RCTs[47-51] comprising 886 patients with moderate GERD without a large HH, Los Angeles grade C or D esophagitis, or Barrett´s esophagus (Table 3). Clinical success rates ranged from a modest 50% at 12 mo to as high as 92% at 10 years. Severe adverse events (SAEs) have been reported in 2.4% of patients[52]. A recent network meta-analysis suggested that the TIF 2.0 procedure manages symptoms and allows PPI discontinuation at rates similar to those of ARS with an improved safety profile and fewer long-term adverse events[53]. A clinical response, defined by an improvement of at least 50% in GERD health-related quality of life (GERD-HRQL) score or remission of heartburn and regurgitation, was observed in 66% of patients treated with TIF. Moreover, TIF had the highest probability of improving GERD-HRQL (0.96), followed by ARS (0.66) and PPIs (0.042). In contrast, ARS had the highest probability of increasing the percent time at pH < 4 (0.99), followed by PPIs (0.64) and TIF (0.32)[53]. A review of the published evidence supports the belief that most selected patients undergoing TIF 2.0 experience a long-term elimination of GERD symptoms with no SAEs and that this procedure is a cost-effective alternative to ARS.

Medigus ultrasonic surgical endostapler

The Medigus ultrasonic surgical endostapler (MUSE), or MUSE™ system (Medigus, Omer, Israel), combines microvisual, ultrasonic, and surgical stapling capabilities into one device, which enables a single endoscopist to perform a transoral anterior fundoplication. This flexible surgical endostapler resembles an endoscope with a rigid section holding a cartridge with five standard 4.8-mm titanium surgical staples. The distal tip contains an anvil for bending the staples, two small 21-gauge screws, and an ultrasonic transducer to measure the distance to the cartridge. This method is a three-step procedure: (1) The stapler is advanced into the stomach through an overtube and retroflex; (2) The system is retracted to 3 cm proximal to the GEJ for clamping when the tissue thickness is 1.4-1.6 mm, and the stapler is then fired; and (3) The procedure is repeated to add quintuplets of staples to create an anti-reflux barrier.

This endoscopic stapling system has been evaluated in four noncomparative studies [46,54-56] and in one two-arm case series study[57] including 209 patients with GERD without a HH larger than 3 cm (Table 3). Clinical success rates ranged from 69% to 92% with follow-up durations from 6 mo to 5 years. The risk of SAEs (empyema, hemorrhage, esophageal perforation) was 3.5%. Overall, data on the efficacy and safety of MUSE are scarce and evidence from RCTs is lacking.

Nonablative radiofrequency treatment (Stretta®)

This endoscopic-guided method involves the application of radiofrequency energy to the muscle fibers of the LES and the gastric cardia, through the Stretta® system (Restech, Houston, TX, United States). The Stretta® catheter is introduced over the guidewire and positioned sequentially at three levels: 0.5 cm proximal to the GEJ, at the GEJ, and 0.5 cm below the GEJ. At each level, the balloon basket assembly is

Table 2 Summary of guidelines and consensus recommendations and invasive gastroesophageal reflux disease therapies

ACG: American College of Gastroenterology; EAES: European Association of Endoscopic Surgery; SAGES: Society of the Americans Gastrointestinal and Endoscopic Surgeons; GERD: Gastroesophageal reflux disease; ESGE: European Society of Gastrointestinal Endoscopy; ESNM: European Society of Neurogastroenterology and Motility; ASNM: American Society of Neurogastroenterology and Motility; PPIs: Proton pump inhibitors; NERD: Nonerosive reflux disease.

inflated and then four nitinol needle electrodes (22-gauge, 5.5-mm) are extended into the muscular layer to deliver a radiofrequency current and induce a thermal reaction. Next, to deliver radiofrequency energy to four additional points, the catheter is rotated 45º clockwise[58]. The pathophysiological mechanism is not fully understood, but the thermal injury is thought to promote submucosal fibrosis and muscularis propria hypertrophy, which would decrease the frequency of TLESR and GEJ compliance while increasing LES and gastric yield pressures[58].

The Stretta® procedure has been evaluated in numerous cohort studies and in five RCTs, three with sham therapy and two with PPI use[59] (Tables 1 and 3). The RCT results did not show significant changes in esophageal acid exposure at 6 mo following Stretta®, compared with the PPI group[60]. Likewise, patients treated with Stretta® presented significant improvements in heartburn symptoms and quality of life in only the short term, compared with a sham procedure, with no long-term data[61-63]. A meta-analysis including 159 patients, limited to four RCTs, confirmed the absence of significant changes in patients with GERD[64]. More recently, a second meta-analysis that included both RCTs and 24 other cohort studies with 2468 evaluated patients[65] showed a significant postprocedural improvement in quality of life and in heartburn score but no improvement in basal LES pressure. The procedure is safe and well-tolerated, and SAEs are very rare. RCTs and cohort studies reported erosions, mucosal lacerations, gastroparesis, mediastinal inflammation, pneumonia,

Table 3 Clinical success and safety of endoscopic therapies

Technique	Study design and population	Clinical success, range	Major adverse events, range
Transoral incisionless fundoplication	No. of RCTs: 5; *n* = 343 No. of nonrandomized case series: 9; *n* = 543	50%–92%	0%–4.4%

[1]Clinical success not defined in the randomized controlled trial. There was a significant reduction in gastroesophageal reflux disease health-related quality of life score and 24-h pH-metry outcomes. RCT: Randomized controlled trial; PPIs: Proton pump inhibitors.

and pleural effusion[66].

Endoscopic plication device (GERDx™)

The GERDx™ device (G-SURG GmbH, Seeon-Seebruck, Germany) uses hydraulic elements for control and requires a slim gastroscope that works as a light source. It is the advanced single-use product of the company that has acquired the Plicator technology after withdrawal of the Plicator device (Ethicon Endo-Surgery, Sommerville, NJ) from the market. The experience with GERDx™ is still minimal, with only two publications in this regard, one of which is an interim analysis by the same authors (Tables 1 and 3).

In a single-center, single-arm trial, Weitzendorfer *et al*[67,68] prospectively assessed the outcomes of 40 patients with refractory GERD treated with the GERDx™ device. Of the 40 patients, 7 underwent LARS before the 3-mo follow-up. The mean DeMeester score was reduced from 46.48 to 20.03 in the 30 patients who completed the follow-up. Of these 30 patients, 18 (60.0%) achieved normal DeMeester score levels. In addition, 3 (10.0%) stated that they were on daily PPI medication after the plication, with 8 (26.7%) taking on-demand medication and 19 (63.3%) off medication. Moderate SAEs were reported by 10% of the patients (a hematoma at the GEJ, a case of pneumonia, a suture passing through the left hepatic lobe, pleural empyema, a severe Mallory-Weiss tear). The single-study evidence, lack of a comparator arm, and the very short follow-up make this endoscopic treatment experimental at this time, necessitating new RCTs to corroborate improvements in quality of life and acid exposure and confirm procedural safety.

Anti-reflux mucosectomy and anti-reflux mucosal ablation

Anti-reflux mucosectomy (ARMS) was first devised in a patient with a Barrett's esophagus-related lesion treated by endoscopic submucosal dissection. The resulting scar improved GERD symptoms and normalized the DeMeester score[69]. This observation led to the first case series, published by Inoue *et al*[69] in 2014. In ARMS, endoscopic resection of the gastric cardiac mucosa is performed to reduce the opening

of the GEJ. Initial ARMS cases were performed by endoscopic submucosal dissection, but subsequent reports indicated that cap- or band-assisted mucosal resection is faster, easier to perform, and equally effective[70-72]. ARMS has been suggested to suppress the backflow of gastric content and enhance the GEJ flap valve mechanism, but the underlying anti-reflux mechanism is poorly understood[72]. A RCT conducted in animals found that ARMS increased the pressure and volume required to induce fluid passage from the gastric cavity to the esophagus[73]. One clinical study revealed that ARMS increased the integrated relaxation pressure and LES resting pressure but decreased GEJ distensibility, which could hypothetically reduce the frequency of TLESR[72,74].

In 2020, Inoue *et al*[75] and Hernández Mondragón *et al*[76] proposed that ablation of the gastric cardiac mucosa by argon plasma coagulation (forced mode 100 W) or a coagulation current applied by an endoknive (spray coagulation 50 W, effect 2) can also induce scar formation and yield similar clinical outcomes. This approach, named anti-reflux mucosal ablation (ARMA), is intended to simplify the procedure, reduce the risk of perforation, and facilitate the retreatment of patients who have failed ARMS.

In addition to their technical simplicity, ARMS and ARMA do not require costly add-on devices and can be performed in a standard endoscopy room[72,76]. Key points during ARMS and ARMA are adequate submucosal injection to prevent perforation and the sparing of a rim of healthy mucosa to minimize the risk of GEJ stenosis**.** The procedure is not standardized, but most authors spare the esophageal mucosa and perform a gastric cardia 270°-320° treatment or mimic a "butterfly" shape by sparing 1 cm of normal mucosa along the greater and lesser curvature[72,75-77].

In total, 15 nonrandomized studies (12 on ARMS[69-72,74,77-83] and three on ARMA[75,76,84]) comprising 461 patients have evaluated the safety and effectiveness of these techniques (Tables 1 and 3). Follow-up ranged from 2 mo to a maximum of 3 years (in two studies[72,76]). Clinical success ranged from 58% to 100% at 2-6 mo[81, 83] and from 72% to 76% at 3 years[72,76]. Dysphagia was the most common adverse event, occurring in about 5% to 10% of the patients. In contrast to what occurs with dysphagia associated with ARS[85], ARMS- and ARMA-associated dysphagia can be easily treated by small-caliber balloon dilation and does not necessarily compromise clinical success[72,76]. Gastrointestinal perforation is the most feared complication and has been reported in four patients treated with ARMS[72,77,78] and in none treated with ARMA. Given the lack of RCT and long-term data, these techniques should be viewed as experimental and reserved for patients included in research protocols.

Band ligation techniques

Three studies have assessed the outcomes of rubber band placement at the GEJ to reduce the width of the opening of the gastric cardia. Seleem *et al*[86] performed a RCT that included 150 patients with refractory GERD. The number of bands applied and the frequency of endoscopic sessions were determined according to the narrowing of the GEJ during banding. A maximum of four bands per session were allowed. Follow-up at 1 year showed a significant improvement in GERD-HRQL score and the number of reflux episodes. Mild dysphagia (25.3%) and epigastric pain (40%) were the most common adverse events, but no SAEs were recorded[86]. Hu *et al*[87] also reported favorable subjective and 24-h pH-metry outcomes in a case series of 13 patients and named the procedure "peroral endoscopic cardial constriction". The authors placed two single-band ligation devices (Fujinon, Tokyo, Japan) at the greater and lesser curvatures, close to the Z line. The first band was placed approximately 1.0 cm above the cardia along the lesser curvature, whereas the second band was delivered 1.0 cm above the greater curvature[87]. Finally, a clip was placed at the base of the bands to minimize the risk of band slippage. In 2020, another Chinese group reported favorable results with this technique in a nonrandomized study of 60 patients, with the approach now named "clip band ligation anti-reflux therapy (C-BLART)"[88] (Tables 1 and 3).

Because the above-mentioned RCT does not adhere to the Consolidated Standards of Reporting Trials quality requirements and the two case series were noncontrolled and included a limited number of patients, the technique should currently be viewed as experimental.

FUTURE DIRECTIONS

The history of endoscopic therapies for GERD is replete with encouraging preclinical studies and case series that fail to clear the hurdle of long-term and well-designed

RCTs. The main underlying reasons are the complex and multifactorial pathophysiology of GERD and the often short-lived anatomical changes induced by endoscopic therapies. Moreover, many endoscopic techniques require expensive add-on devices and cumbersome technical steps that have limited their popularization. To complicate further this issue, patient selection has been heterogeneous, and we lack consensus regarding the definition of clinical success or the admissible thresholds of cost and adverse events. Future endoscopic therapies and GERD research should bear all of this in mind.

The first consideration is that only a subset of well-selected GERD patients are good candidates for endoscopic therapies because current techniques remain unable to fix the hiatus, enhance esophageal motility, or normalize LES competence. Artificial intelligence through knowledge-based clinical decision support systems could be of help in the future for improving patient selection. Combined approaches that consider more than one GERD mechanism have been proposed to address this issue, such as a combination of ARMS with a plication method[89] or of TIF with laparoscopic HH repair[90]. Second, technical feasibility is critical for introducing a procedure into clinical practice. The learning curve of anti-reflux endoscopic therapies has not been well-described, and scientific societies have not published curricula documents to guide training. Band ligation, ARMS, and, more recently, ARMA are at very early stages but represent an attractive option from this perspective. Our group is currently performing a double-blind RCT to assess the clinical success and safety of ARMA[91]. Third, patient-reported outcomes are increasingly being recognized by clinicians, regulatory agencies, and patients as highly valuable tools to assess the impact of new interventions. Thus, we believe that studies should place symptoms and GERD-related quality of life as primary endpoints. A "black or white" perspective for clinical success does not reflect the complexity of GERD patients, and partial but significant improvements should also be taken into account. This makes anti-reflux endoscopy not only an alternative to PPIs, but also a complementary tool that can reduce their consumption and partially improve quality of life. A > 50% drop in the GERD-HRQL score or in other validated clinical questionnaires has been used in recent RCTs and appears to be a reasonable approach[52,53]. In addition, more objective GERD parameters (24-h pH-impedance testing, endoscopic esophagitis) and sham/placebo arms are needed to support subjective improvements. Outcome definitions should be in line with recent international consensus[26,27,92,93]. RCTs should include long-term follow-up as part of the trial or as a post-RCT prospective observational phase to assess durability. Finally, endoscopic therapies seem cost-effective, but we need more comparative data with PPI and surgery[94].

CONCLUSION

Endoscopic therapy for GERD aims to offer an alternative to PPIs and ARS in patients without significant diaphragmatic crura impairment. TIF, the technique with the largest body of evidence, has been proven to improve GERD symptoms and acid exposure time and reduce PPI consumption. Nonablative radiofrequency (Stretta®) is the method with the lowest rate of SAEs, but its efficacy has been called into question in recent meta-analyses. Band ligation techniques, ARMS, ARMA, and new plication devices have shown promising results in initial reports and RCTs are eagerly awaited. Careful patient selection, ongoing technical refinements, and RCTs with long-term data are the roadmap to unveil the potential of minimally invasive anti-reflux endoscopic techniques.

Abstract

BACKGROUND

Extracellular matrix (ECM) remodeling and stiffening, which are correlated with tumor malignancy, drives tumor development. However, the relationship between ECM remodeling and rat experimental model of 1,2-dimethylhyrazine (DMH)-induced colorectal cancer (CRC) imposed by cold and capsaicin exposure remains unclear.

AIM

To explore the effects of cold exposure and capsaicin on ECM remodeling and ECM enzymes in DMH-induced CRC.

METHODS

For histopathological analysis, the sections of colon tissues were stained with hematoxylin and eosin, Masson's trichrome, Picrosirius red, and Weigert's Resorcin-Fuchsin to observe the remodeling of collagen and elastin. Additionally, the protein expression level of type I collagen (COL I), type 3 collagen (COL III0, elastin, matrix metalloproteinase (MMP) 1, MMP2, MMP9, and tissue-specific

matrix metalloproteinase 1 (TIMP1) was assessed by immunohistochemistry. The messenger RNA (mRNA) levels of COL I, COL III, elastin, and lysyl oxidase-like-2 (LOXL2) in the colon tissues of rats was measured by reverse-transcriptase quantitative polymerase chain reaction.

RESULTS

Although no differences were observed in the proportion of adenomas, a trend towards the increase of invasive tumors was observed in the cold and capsaicin group. The cold exposure group had a metastasis rate compared with the other groups. Additionally, abnormal accumulation of both collagen and elastin was observed in the cold exposure and capsaicin group. Specifically, collagen quantitative analysis showed increased length, width, angle, and straightness compared with the DMH group. Collagen deposition and straightness were significantly increased in the cold exposure group compared with the capsaicin group. Cold exposure and capsaicin significantly increased the protein levels of COL I, elastin, and LOXL2 along with increases in their mRNA levels in the colon tissues compared with the DMH group, while COL III did not show a significant difference. Furthermore, in immunohistochemical evaluations, MMP1, MMP2, MMP9, and TIMP1 staining increased in the cold exposure and capsaicin group compared with the DMH group.

CONCLUSION

These results suggest that chronic cold and capsaicin exposure further increased the deposition of collagen and elastin in the colonic tissue. Increased COL I and elastin mRNA and protein levels expression may account for the enhanced ECM remodel and stiffness variations of colon tissue. The upregulated expression of the LOXL2 and physiological imbalance between MMP/TIMP activation and deactivation could contribute to the progression of the CRC resulting from cold and capsaicin exposure.

Key Words: Colon cancer; Cold exposure; Capsaicin; Extracellular matrix remodeling; Extracellular matrix enzymes

Core Tip: In this study, we discovered that remodeling of extracellular matrix (ECM) plays an important role in the progression of colorectal cancer (CRC). These results suggest that increased stiffness of colonic tissue and the remodeling of ECM mediated by ECM enzymes resulting from cold and capsaicin exposure predisposes an environment suitable for CRC development and progression. To target ECM in CRC tumor tissue could represent a novel potential therapeutic strategy.

INTRODUCTION

Colorectal cancer (CRC), a common cause of cancer deaths in the world, is a multifactorial disease driven by genetic predisposition, epigenetic alterations, and environmental factors[1]. Only a minority of CRC is caused by the accumulation of genetic epigenetic alterations, while the majority is linked to environmental factors such as dietary intake, alcohol consumption, and ambient environment[2,3]. Increasing epidemiological data have indicated that cold weather might be associated with an increased occurrence of cancer[4]. Additionally, the consumption of chili-pepper and cancer incidence have a positive correlation[5,6]. However, the mechanisms under-

lying the effects of cold exposure and capsaicin in 1,2-dimethylhyrazine (DMH)-induced CRC tumorigenesis and progression remain poorly understood. Extracellular matrix (ECM) is a non-cellular structure that is essential for the maintenance of normal tissue and organ function and disease pathophysiology[7]. Collagen is a major component of the ECM. It provides cellular components with physical support and is an important contributor to tumor growth and progression[8]. Tumor progression is accompanied by the dysregulation of collagen structure and deposition. Tumor associated-collagen is usually compacted to thick collagen bundles and the anisotropic arrangement of relatively straight in the matrix of malignancies compared with healthy tissues[9,10]. In clinical samples of breast tumors, collagen deposition increased, and linearization and thickening of collagen occurred; these processes can be linked to poor prognosis and high risk of mortality[11,12].

Elastin is another important fibrous ECM protein that provides elastic recoil to tissue. Importantly, excessive accumulation of ECM, particularly collagen and elastin, gradually leads to progressive organ fibrosis[13]. The fibrosis results in tissue stiffness and can predispose tissue to malignancy. Several human studies indicated that patients with liver fibrosis and stiffness are positively correlated with the risk hepatocellular carcinoma[14]. ECM remodeling is mainly orchestrated by ECM modifying enzymes such as lysyl oxidase-like-2 (LOXL2), matrix metalloproteinases (MMP), and tissue-specific matrix metalloproteinase inhibitors (TIMPs)[15]. LOXL2 is a key factor in ECM remodeling and is a copper-dependent amine oxidase that catalyzes the cross-linking of collagen or elastin in the ECM and thus regulates the tensile strength of tissues. LOXL2 causes disorganization and composition of ECM, resulting in many pathological conditions, including fibrosis and cancer[16]. Active LOXL2 is involved in stiffness-associated cancer progression, whereas inhibition of LOXL2 result in less collagen cross-linking and impeded cancer progression[17]. Moreover, LOXL2 expression is overexpressed in many types of tumors and is associated with poor prognosis[18-20].

MMP has been implicated in cancer development, progression, invasiveness, and dissemination by promoting a protumorigenic microenvironment and modulating the ECM and intercellular junctions[21]. MMPs and TIMPs are the main enzymes involved in the regulation of ECM remodeling and collagen degradation process[22]. Their expression and activity are upregulated in almost all human cancers with disparate changes, and this phenomenon is associated with advanced tumor stage, poor prognosis, and decreased overall survival rate[23,24]. Increased MMP expression/activity or decreased TIMPs could lead to MMP/TIMP imbalance, resulting in various pathological conditions including fibrosis and cancers[25].

Limited information, however, is available about ECM remolding and ECM enzyme activity in the progression of experimental colorectal malignancy. We have previously shown that cold exposure and long-term administration of capsaicin at a low dose further promote the development and progression of CRC[26]. However, the specific mechanisms underlying cold and capsaicin exposure tumor promotion remained unknown. This study aimed to investigate the effects of cold exposure and capsaicin on ECM remodeling and ECM enzymes in DMH-induced CRC. Moreover, we determined whether excessive ECM deposition, particular whether collagen and elastin and dysregulation of ECM enzymes expression and/or secretion in rat treatment with cold exposure, could further stiffen the colon tissues and disrupt the intestinal morphogenesis to exacerbate the experimental colorectal malignancy.

MATERIALS AND METHODS

Experimental design in adult male rats

Wistar rats weighing 200-250 g (6-wk-old) were obtained from Experimental Animal Center in Guangzhou University of Chinese Medicine. Animals were housed in plastic cages under a controlled environment (24 ± 2 °C, 50% ± 5% humidity, 12 h/12 h light-dark cycle) with *ad libitum* food and water access. All the experimental protocols were approved by the Institutional Animal Ethics Committee of the Guangzhou University of Chinese Medicine (No. 20130001). Briefly, after 3 d of acclimation, the animals were randomly assigned into four groups (n = 10). Rats in group A received no treatment and served as control. Five weeks later, rats in groups B-D received subcutaneous injection of DMH (25 mg/kg) once a week for 12 wk. In addition to DMH, Group C rats received cold distilled water (10 mg/kg) until the end of 38 wk. Group D rats were given capsaicin (0.9 mg/mL) every day throughout the experiment. By the end of the week, 10 rats from each group were sacrificed. For macroscopic evaluation of the

incidence of polyps at the end of the experimental period, rats were sacrificed and colons were incised and washed with physiological saline. Then cleaned colons were cut opened longitudinally and the total number of polyps/tumors was carefully counted and later verified with histopathological examination. The counting and histopathological analysis of gross macroscopic neoplastic lesions was carried out by two investigators from this study. If the histopathological types of these two investigators were different, then tumor histology was classified as adenomas and adenocarcinomas by one pathologist under blinded conditions from the Pathology Department in Guangzhou University of Chinese Medicine. Microscope findings were classified as adenomas and adenocarcinomas according to previous criteria described by Jikihara *et al*[27]. Tumor incidence is the percentage of rat bearing the indicated type of tumor.

Histopathological staining

All specimens were fixed in 4% paraformaldehyde solution for 24 h and embedded in paraffin and processed by standard histological processing techniques. Serial issue sections (8-μm thick) were obtained from each sample with the microtome and then were stained with hematoxylin and eosin (HE), picrosirius red, Masson's trichrome (MT), and Weigert's Resorcin-Fuschin (WRF). For Picrosirius red staining, sections were stained in picrosirius red solution 0.1) (Sirius red F3B; Sigma-Aldrich Co., St Louis, MO, United States) in a saturated aqueous solution of picric acid for 1 h at room temperature for collagen bundle staining. Images were subsequently analyzed using ImageJ to calculate the fiber density, which was measured as image % area coverage. MT was performed according to the manufacture's protocol including Weigert's Iron Hematoxylin Solution, Ponceau acid fuchsin, and Aniline Blue as reagents. The collagen volume fraction was measured by ImageJ software and calculated as the proportion of blue positive areas in the total section areas. The process of WRF used reagents and kits from Solarbio (Beijing, China). Sections were then mounted for observation under polarized light microscopy (NIKON Eclipse Ci, Tokyo, Japan) and light microscopy, respectively. Three microphotographs of the reticular dermis were taken with a 400 × magnification with light microscopy and polarized microscopy, respectively. Digitized images of histological sections obtained under final magnification of × 400 were analyzed using the Image-Pro Plus 4.5 software.

Collagen fiber analysis

CT-FIRE, an open-resource software (http://Loci.wisc.edu/software/cifire), was used as previously described to quantify automatically collagen fibers[28]. The quantitative parameters included alignment of collagen fibers as well as individual length, straightness, and width. These features of collagen fibers are widely used to investigate collagen organization in a various of cancer[29]. All the picrosirius red images were converted to 8-bit images and threshold values between 10-255 to eliminate background noise using FIJI ImageJ[30]. These images were uploaded to CT-FIRE; collagen fiber extraction parameters were set to default parameters.

Real-time quantitative reverse-transcriptase polymerase chain reaction

Total RNA extracts of colon tissues were prepared using TRIZOL reagent (TaKaRa, Kusatsu, Japan). RNA (1 μg) was reverse transcribed in a 20 μL reaction mixture using Prime Script RT Master Mix (TaKaRa). The purity of total RNA was evaluated by measuring the concentration and $OD_{260:280}$ values with a Nanodrop 2000 spectrophotometer (Thermo Fisher Scientific, Waltham, MA, United States). The mRNA levels of collagen type 1, alpha1 (COL1A1), collagen type 3, alpha1 (COL3A1), LOXL2, and elastin in colon mucosa were assessed using a Step One Plus real-time polymerase chain reaction system (CFX384TM Real-time System; Thermo Fisher Scientific). The relative levels of gene expression were enumerated using the comparative formula 2-ΔΔCt. The primer sequences used in this polymerase chain reaction amplification were as follows: 5′-AGCCATGTACGTAGCCATCC-3′/3′-ACCCTCATAGATGGGCACAG-5′ for β-actin; 5′-AGGCATAAAGGGTCATCGTGGCTT-3′/3′-AGTCCATCTTTGC-CAGGAGAACCA-5′ for COL1a1; 5′-GGTTTGGAGAATCTATGAATGGTGG-3′/3′-GCTGGAAAGAAGTCTGAGGAAGG-5′ for Col3a1; 5′-AGCCTATAAGCCG-GAGCAAC-3′/3′-GTCCCACTTGTCATCGCAGA-5 'for LOXL2; 5′-CGCCTGTAAT-GCCTCCAATC-3′/3′-AGCAGCTAAAGCAGCGAAGT-5′ for elastin.

Immunohistochemistry

Colonic tissue sections were deparaffinized and rehydrated through a series of xylene and ethanol/water. The sections were placed in a 95 °C antigen retrieval solution (citrate buffer; PH 6.0) for 15 min. After cooling in retrieval solutions for 20 min at

Table 1 Incidence of various tumors induced in different treatment groups

Group	Total number of tumors	Adenoma incidence, %			Adenocarcinoma incidence, %				With lymphytic metastasis (%)

1,2-dimethylhyrazine compared with cold exposure and capsaicin-treated group. DMH: 1,2-Dimethylhyrazine.

room temperature, the slides were treated with hydrogen peroxide for 10 min to block endogenous peroxidase activity. Primary rabbit anti-histone polyclonal antibodies were applied for 14 h at 4 °C overnight at the following dilutions: Type I collagen (COL I) (1:500; ab34710; Abcam, Cambridge, United Kingdom), type III collagen (COL III) (1:200, ab7778; Abcam), LOXL2 (1:400), elastin (1:600; ab217356; Abcam), MMP1 (1:500; 10371-2-AP; Proteintech, Rosemont, IL, United States), MMP2 (1:200; ab86607; Abcam), MMP9 (1:800; ab38898; Abcam), and TIMP1 (1:600, ab61224; Abcam). The next day, biotin-conjugated secondary antibody and streptavidin-biotin peroxidase were applied each for 20 min. 3,3'-Diaminobenzidine tetrahydrochloride (0.05%) was used as the substrate, and nuclear contrast was performed using hematoxylin counter-staining. Each section was analyzed in three different fields using Image Pro Plus software. The density of yellow reflects the expression levels of target proteins. Integral optical density sum / area SUM was applied to quantify the relative expression of COL I, COL III, LOXL2, elastin, MMP1, MMP2, MMP9, and TIMP1.

Statistical analysis

All the data are summarized as mean ± SD, and data were analyzed using SPSS 23.0 statistical software. We performed the data with a one-way analysis of variance with the post-hoc comparison by the L.S.D. method and Fisher's exact test was employed to compare tumor incidence. Differences with values of $P < 0.05$ were considered statistically significant.

RESULTS

Macroscopic and pathological observation study of colon tumor

No visible colon tumor was found in the normal control. We observed findings such as colonic mucosal thickening, stiffness, and not tiled completely on filter paper in the majority of rats of the cold exposure group (Figure 1C). As shown in Figure 1B, the length of colon in the DMH and normal group was not significantly different. However, the length of the colon in the cold exposure and capsaicin group was shorter than that of DMH group. The pathological classification of colonic tumors in each group is shown in Table 1. No difference was observed in the proportion of adenomas among groups. In the DMH-induced group of animals, most tumors had well-differentiated tubular adenocarcinomas. Invasive tumors increased in the cold and capsaicin group. Histopathological analysis showed in the cold exposure group that an evident malignant transformation occurred in the colon with the features of poor-differentiated mucinous adenocarcinomas, and some of the glands were filled with mucinous material (Figure 2C). In addition, the mesenteric lymph nodes of rats in each group were stained with hematoxylin and eosin, and the lymphatic metastasis was observed under light microscope (Figure 2B). No lymphatic metastasis was observed in the DMH and capsaicin group, while a mesocolic lymph node was totally replaced by

metastatic cancer tissue in the cold exposure group; the lymph node metastasis rate was 20.0% (Table 1, Figures 1 and 2).

Alterations in collagens after cold exposure and capsaicin

Colon tissue sections were stained by MT and picrosirius red to identify the total collagen in the colon mucosa. As shown in Figure 3A, there were few collagen fibers in normal colonic mucosa. After DMH treatment, wave shape collagens stained blue were markedly increased around the glands, and this was increased further in the cold exposure and capsaicin treatment group. The collagen density was quantified using ImageJ, and it was significantly increased in the colonic tissue of cold exposure and capsaicin group. This excessive collagen deposition was further confirmed by picrosirius red staining. As shown in Figure 3B, picrosirius red staining revealed in normal tissue the collagen fibers with sparse deposition composed of thin collagen fibers. The collagen fibers in the DMH group were denser than that in normal collagen

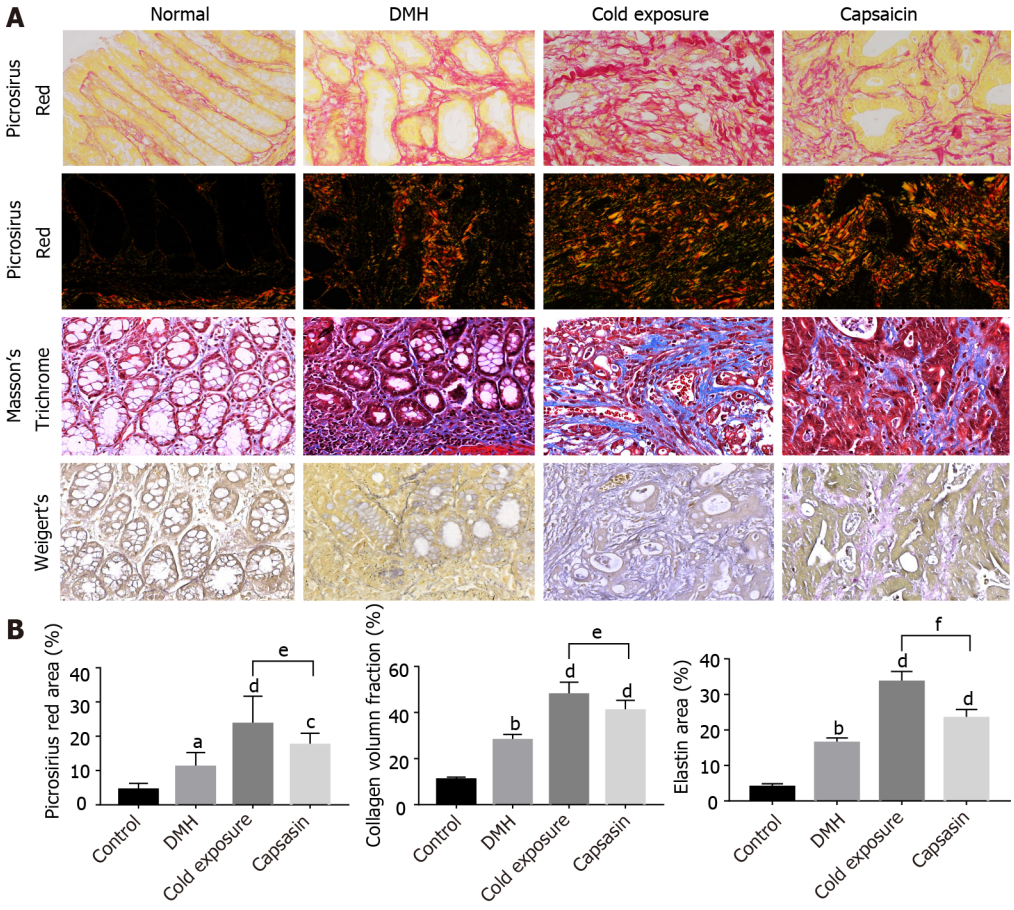

Figure 3 Changes in extracellular matrix components (collagen fibers and elastin) in colonic mucosa of different treatment groups. A: Representative photographs of colonic tissues in rats of normal, 1,2-dimethylhyrazine (DMH), cold exposure and capsaicin groups using Masson's trichrome: collagen (blue), nuclei and cytoplasm (red); picrosirius red in bright-field: collagen (red); polarized light: collagen (yellow-orange to green birefringence) and Weigert's Resorcin-Fuschin: elastin (blue-black), myofibers (yellow). fibers. In the capsaicin treatment group, collagen fibers showed an evident increase and were crosslinked into bundles. On the other hand, the cold exposure group apparently displayed an increased amount of collagen fibers with heterogeneous thickness and alignment. The collagen in the cold exposure and capsaicin group exhibited a predominant reddish or yellow-orange. The structure and organization of collagen fibers were evaluated in colon tissue sections by quantifying the polarization microscopy images. As shown in Figure 4A, visualized collagen fibers were extracted and analyzed for fiber width, angle, length, and straightness using CT-FIRE software. As shown in Figure 4B, compared with the DMH group, collagen fibers in the cold exposure and capsaicin group showed a significant increase in angle, length, width, and straightness. These results revealed that cold exposure and capsaicin induced a progressive increase in the content and orientation of collagen fibers in CRC as a function of malignancy.

Alterations in elastin after cold exposure and capsaicin

Treatment WRF was used to identify the elastin fibers, which were stained black. As shown in Figure 3A, elastin was hardly expressed in the colonic mucosa of the normal rats. After treatment with DMH, the elastin fibers aligned surrounding the epithelium and stroma. After cold exposure and capsaicin treatment, the amount of elastin fibers increased, and thick elastic fibers was found highly disorganized between the gland compared with their respective control and DMH groups. Alterations in the mRNA levels of COL I, COL III, LOXL2, and elastin. The expression levels of COL I, COL III, LOXL2, and elastin mRNAs in colonic tissue are shown in Figure 5. The COL I, LOXL2, and elastin mRNA levels were higher in the DMH-induced cancer group than in the control group. In comparison with the DMH group, a significant increase was detected both in the cold exposure and capsaicin treatment group, but the mRNA levels of COL III were not significantly different between DMH and capsaicin ex-

posure group.

Alterations in the protein levels of COL I, COL III, LOXL2, and elastin

The expression levels of COL I, COL III, LOXL2, and elastin in colonic tissue are shown in Figure 6A and B. The protein expression levels of collagen type I, III, LOXL2, and elastin were significantly elevated in colonic tissue from DMH-treated rats in comparison to the control group. The expression level of proteins in the cold exposure and capsaicin treatment group increased. COL I and LOXL2 levels were significantly higher in the cold exposure group, but no statistical difference was observed in the change of COL III and elastin between cold exposure and capsaicin group.

Alterations in the protein levels of MMP1, MMP2, MMP9, and TIMP1

The expression levels of MMP1, MMP2, MMP9, and TIMP1 in colonic tissue are shown in Figure 7. Significantly elevated MMP1, MMP2, MMP9, and TIMP1 immunoreactivity was observed in DMH-treated rats compared with the control group. The expression levels of proteins in the cold and capsaicin group increased compared with the DMH group. In comparison with the capsaicin group, the expression of MMP2, MMP9, and TIMP1 increased in the cold exposure group.

DISCUSSION

ECM has been increasingly considered as an important regulator at diverse aspects of tumor initiation, promotion, neoplastic transformation, invasion, and metastasis[31].

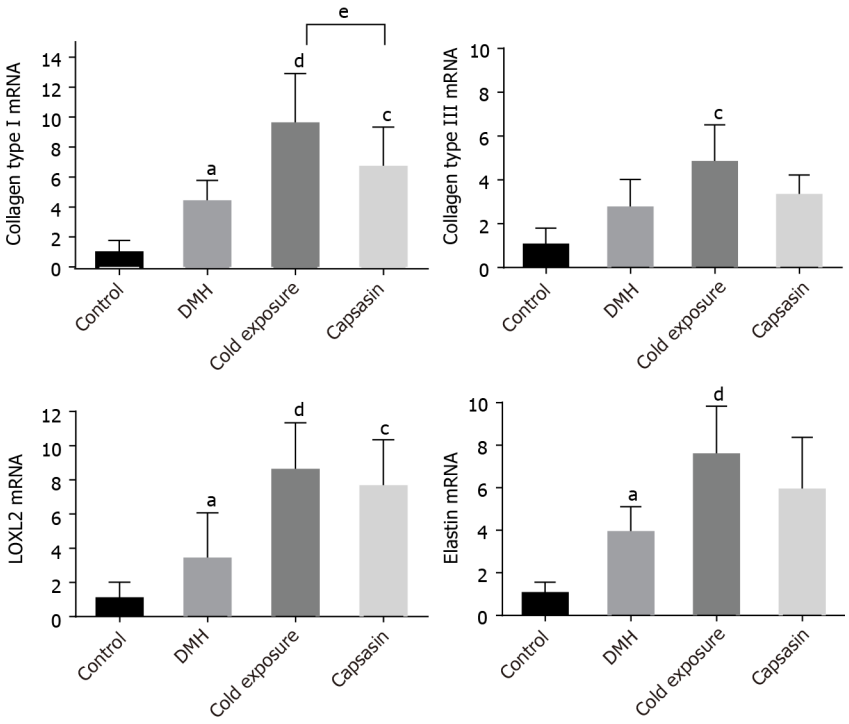

Figure 5 The mRNA expression levels of collagen type I, III, elastin and lysyl oxidase-like-2 in the colon tissues of rats in different groups. Data were presented as the mean ± SD form six independent experiments. [a]*P* < 0.05, control compared with 1,2-dimethylhyrazine (DMH); [c]*P* < 0.05, [d]*P* < 0.01, DMH compared with cold exposure and capsaicin-treated group; [e]*P* < 0.05, cold exposure compared with capsaicin-treated group. LOXL2: Lysyl oxidase-like-2.

Furthermore, ECM remodeling is a consequence of or increases risk for malignant transformation of colonic, hepatic, pulmonary, and pancreatic cells[32,33]. Collagen and elastin are the major components of ECM, and their excessive deposition has been implicated in a number of diseases, particularly fibrosis and cancer. However, the morphology and structure of collagen and elastin fibers in the animal models of CRC remains unclear. In the present study, we analyzed the morphology and structure of collagen and elastin fibers in rat experimental model of DMH-induced CRC imposed by cold and capsaicin exposure. Results showed an association between collagen expression or ECM modifying enzymes and CRC development, thus supporting ECM remodeling is highly relevant to CRC cancer progression. Tumor tissue often exhibits fibrosis, and this fibrotic state is characterized by the excessive deposition of collagen and elastin[34].

Fibrosis can develop in nearly any organ, and it is an important driver of tissue stiffness and increases the risk of malignancy[35]. In fibrotic kidney biopsy specimens or multiple experimental kidney fibrosis rodent models, the accumulation of elastin can be observed in renal tissue[36]. In human fibrosis of the liver, kidney, and pancreas, the ECM on average becomes stiffer than normal. Our previous study indicated in human CRC that the collagen development features numerous changes in composition and organization compared with normal colonic tissues[37]. In the present study, we found that collagen components were quantitatively and qualitatively changed in the rat experimental model of CRC. By using picrosirius red, MT, and WRF staining, we revealed a marked increase in collagen and elastin deposition in rats exposed to cold and capsaicin treatment. Furthermore, they were more orderly organized based on the collagen fibers being more aligned with each other, longer, wider, and slightly straighter.

The structure, orientation, and physical properties of collagen regulate the aggressive behavior of cancer. For example, in glioblastoma, Pointer *et al*[38] showed that patients with more organized glioblastoma multiforme collagen survive longer than patients with less organized glioblastoma multiforme collagen. Zhou *et al*[39] also demonstrated that the increased density, length, or width of collagen negatively affects patients with gastric cancer prognosis. The stromal tissue in CRC has also shown that an increase in the collagen content of the ECM increases mechanical stiffness, which predisposes to aggressive CRC[40]. In human breast cancer, linear organization and relatively straight collagen that facilitates migration of tumor cells indicate poor cancer outcome[41]. Similarly, our data indicated that cold and capsaicin exposure increased

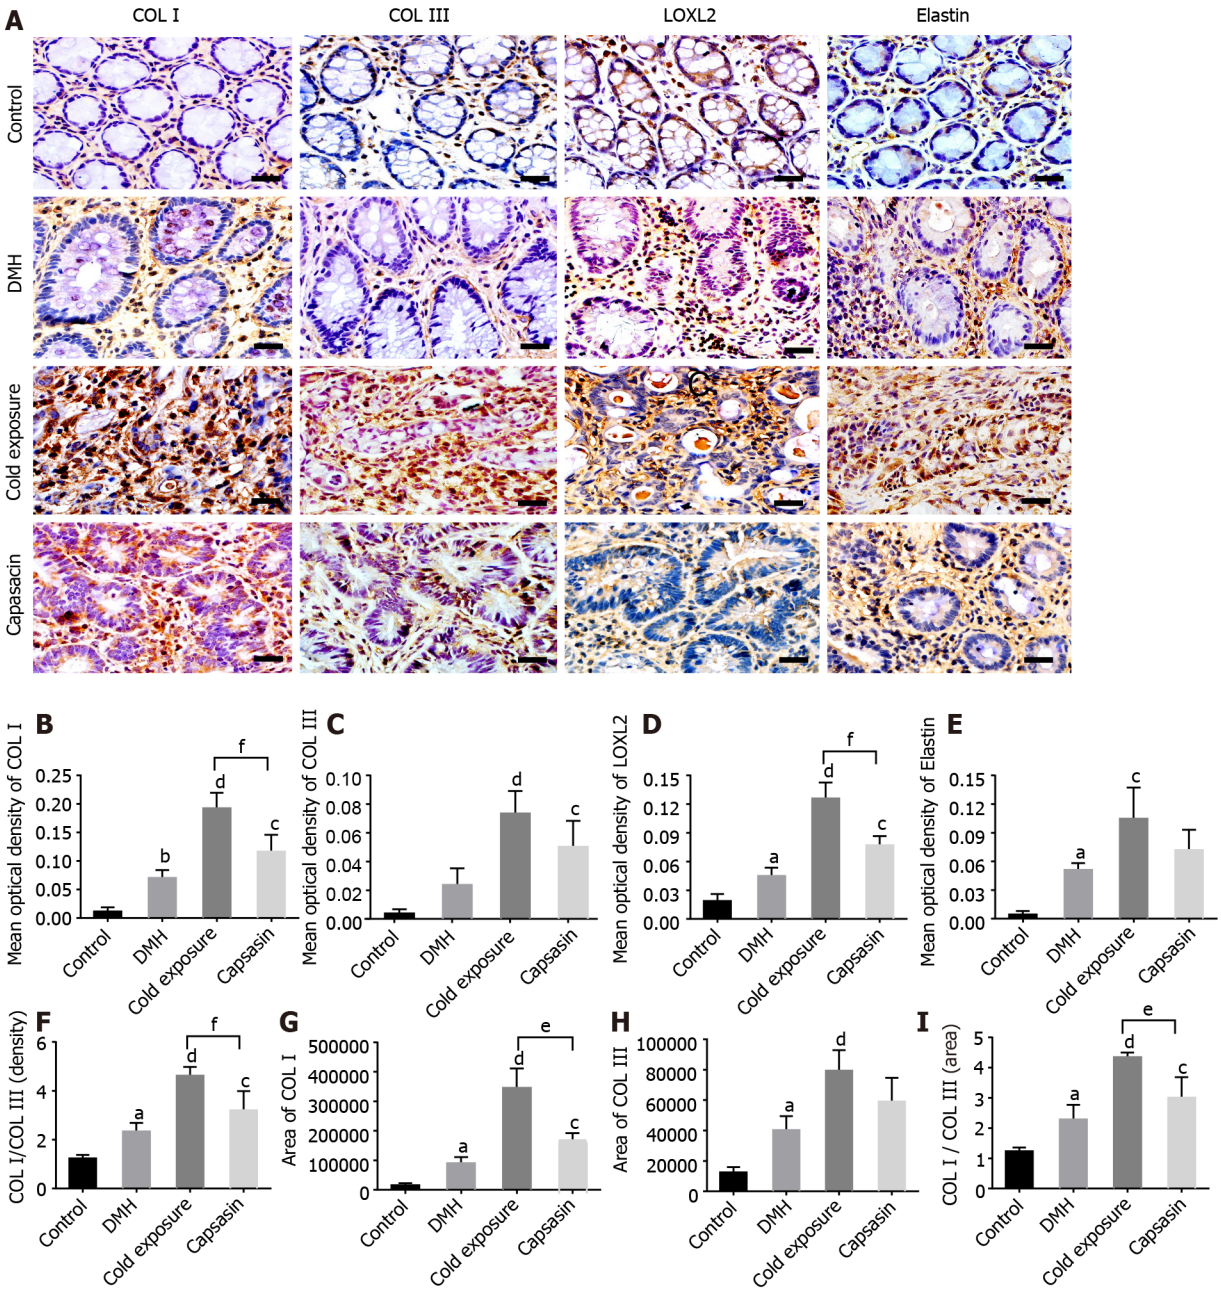

Figure 6 Changes in collagen, elastin and lysyl oxidase-like-2 proteins in the colonic tissues of different treatment groups. Magnification, × 400, scalar bar 20 μm; B-I: Densitometric analysis of COL I (B), COL III (C), LOXL2 (D), elastin(E), COL I/COL III (F), COL I area (G), COL III area (H), and COL I area/COL III area (I) during immunohistochemical staining. $^{a}P < 0.05$, $^{b}P < 0.01$, control compared with 1,2-dimethylhyrazine (DMH); $^{c}P < 0.05$, $^{d}P < 0.01$, DMH compared with cold exposure and capsaicin-treated group; $^{e}P < 0.05$, $^{f}P < 0.01$, cold exposure compared with capsaicin-treated group.

collagen and elastin deposition, thus triggering alterations in the ECM architecture and organization in the DMH-induced CRC for further tumor development and progression. Furthermore, all parameters of collagen fibers (*e.g.*, density, angle, length, width, and straightness) significantly increased in the cold exposure group and could accurately explain the cold-induced CRC more seriously.

Recently, the relationship between ECM remodeling and malignant transformation of cancer has attracted much attention[42]. COL I is the most abundant protein present in the body. COL I, a major component of collagen, was significantly up-regulated in CRC tissues and showed enhanced CRC migratory capabilities through the overexpression of WNT/planar cell polarity signaling pathway[43]. Moreover, the elevated expression of type I collagen in CRC tissues is correlated to patients with high metastasis that was due to activation of phosphatidylinositol-3-kinase/AKT signaling [44]. Bode *et al*[45] also showed that the expression of COL was increased in malignant colon tissue compared with COL III. Moreover, the elevated expression of COL I has

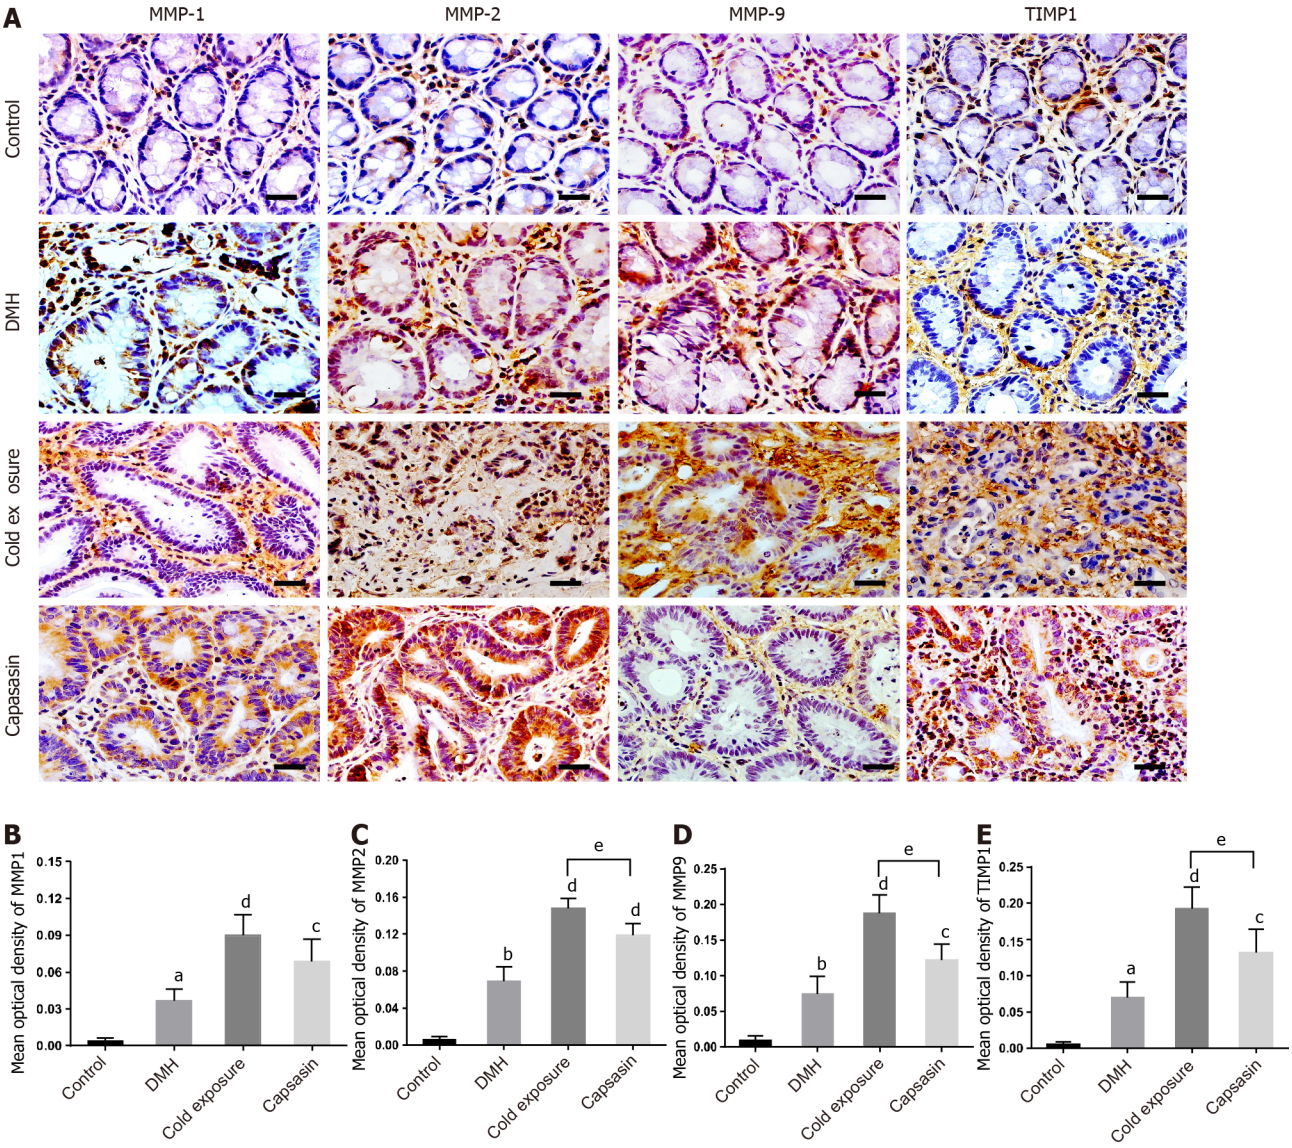

Figure 7 Changes in matrix metalloproteinase 1, matrix metalloproteinase 2, matrix metalloproteinase 9, and tissue-specific matrix metalloproteinase 1 proteins in the colonic tissues of different treatment groups. A: Protein expressions of matrix metalloproteinase (MMP) 1, MMP2, MMP9 and tissue-specific matrix metalloproteinase 1 (TIMP1) in the colonic tissues *via* immunohistochemical staining. Magnification, × 400, scalar bar 20 μm; B-E: Densitometric analysis of MMP1 (B), MMP2 (C), MMP9 (D) and TIMP1 (E) during immunohistochemical staining. $^{a}P < 0.05$, $^{b}P < 0.01$, control compared with 1,2-dimethylhyrazine (DMH); $^{c}P < 0.05$, $^{d}P < 0.01$, DMH compared with cold exposure and capsaicin-treated group; $^{e}P < 0.05$, cold exposure compared with capsaicin-treated group.

been linked to the invasive and aggressive behavior of CRC[46]. In the present study, we also evaluated the expression of COL I in cold exposure and capsaicin treatment CRC colonic tissue. The increase in expression levels of COL I in our study is consistent with other reports in CRC. However, the mRNA level of COL III was not significantly different between the DMH and capsaicin group. In addition, compared with other groups, the COL I/ COL III in cold exposure group was significantly increased. With the increase in collagen expression, distribution area, and collagen ratio, the degree of fibrosis in ECM pathological characteristics was aggravated[47,48]. Therefore, the colonic tissue stiffness was significantly higher than that of the other groups, and the degree of ECM fibrosis in CRC with cold exposure was more serious than that in other groups. ECM remodeling is regulated by ECM enzymes such as LOXL2, MMPs, and TIMPs. ECM-crosslinking enzyme LOXL2 has been implicated in stiffness-associated tumor progression[49]. The LOXL2-mediated collagen cross-linking, both *in vitro* and *in vivo* models of CRC, results in increased tissue stiffness and activation of the focal adhesion kinase/SRC signaling[50].

MMP1, MMP-2, and MMP-9 play a fundamental role in many pathophysiological processes such as cell migration, angiogenesis, and the invasion and metastasis of malignant tumors[51]. TIMPs are the most important physiological inhibitors of MMP,

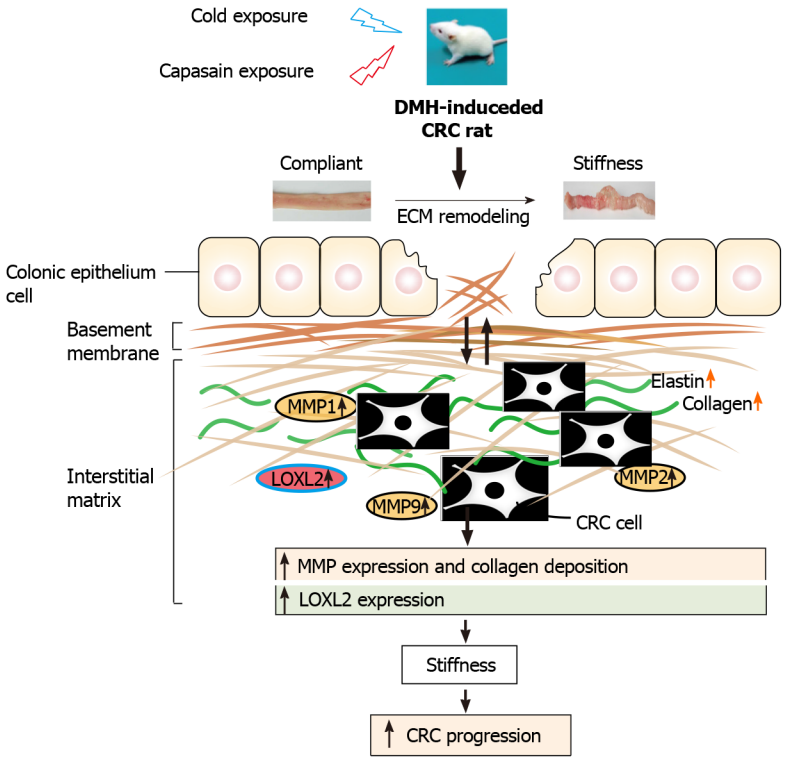

Figure 8 Schematic diagram depicting the role of extracellular matrix and extracellular matrix enzymes in promoting colorectal cancer pathogenesis. Comparison with the normal rats, rats exposed to cold and capsaicin with profound remodeling of extracellular matrix (ECM) in the colonic tissue, which was mediated by ECM enzymes. These results implicate a crucial role of ECM remodeling on cold and capsaicin exposure colorectal cancer development and progression. CRC: Colorectal cancer; DMH: 1,2-Dimethylhyrazine; MMP: Matrix metalloproteinase.

and they are also commonly expressed in tumor sites[52]. The expression of both MMP-2 MMP9 and TIMP-2 is higher in invasive tumors and is strongly associated with angiogenesis in DMH-induced CRC[24]. A previous study indicated that the cross-linking of collagen is known to activate enzymes involved in matrix remodeling, such as LOXL2, MMPs, and TIMPs[53,54]. MMPs are responsible for the degradation of ECM; LOXL2 mediate ECM cross-linking and stiffening[55]. However, recent studies indicated that LOXL2 activity promotes breast cancer metastasis by regulating the expression of MMPs and TIMPs involved in matrix remodeling[56]. LOXL2, TIMP1, and MMP9 are co-expressed during mammary metastasis, suggesting that they function together in glandular remodeling. Our previous study also found that expression levels of LOXL2, MMP1, MMP2, and MMP9 are positively correlated in CRC tissues, and they play synergistic roles in ECM remodeling of human CRC[37].

In the present study, the LOXL2, MMP1, MMP2, MMP9, and TIMP parameters were analyzed, and the results indicated a significant increase in the expression of these proteins in the cold exposure and capsaicin group accompanied by the enhancement of collagen and elastin deposition. Therefore, they may act together in regulating ECM remodeling. Growing insights from experimental studies on the roles of the ECM in CRC suggest that the quantitative and qualitative changes in ECM mediated by specific enzymes promote numerous cellular functions that steer cancer progression and metastasis[57,58]. In the present study, the ECM remodeling in the colonic tissue under cold and capsaicin exposure was more serious, thus increasing the exacerbation severity of CRC. Therefore, environmental factors, such as diet, will affect the internal and external constitutions of organism, causing different manifestations and disease progression in the organism. In the cold exposure and capsaicin treatment group, remodeling of the ECM and stromal stiffness is associated with increased propensity for progression to invasive CRC. Therefore, the levels of ECM remodeling can distinguish different organism characteristics and evaluate the CRC progression successfully, thus providing a novel pathological direction of analysis for clinicians. Furthermore, nanoscale mechanical imaging can be used to observe patients with heterogenous features of ECM, who would benefit most from ECM target therapies.

CONCLUSION

In summary, as shown in Figure 8, the present study revealed profound remodeling of the ECM in cold exposure and long-term administration of capsaicin at a low dose in rats. Collagen signatures including angle, length, width, and straightness have a great impact on CRC progression. Additionally, our results show that higher colonic tissue stiffness might result from ECM enzymes-mediated ECM crosslinking and excessive deposition of collagen and elastin, and such changes are strongly associated with the tumor progression of cold and capsaicin exposure CRC. A better understanding of the role of ECM remodeling and ECM enzymes on the pathogenic mechanisms of colon cancer may help in determining the molecular mechanism of CRC progression and could afford a novel therapeutic intervention in the treatment of this disease.

ARTICLE HIGHLIGHTS

Research background

Colorectal cancer (CRC) is a cancer with high prevalence and mortality in the world. Extracellular matrix (ECM) is a dynamic compartment that regulates tissue development and homeostasis, and its remodeling contributes to neoplastic progression. The cancerous ECM can change cell phenotype and has profound influence on the colonization of metastatic cancer cells. However, the relationship between ECM remodeling and progression and aggression CRC from imposed by cold and capsaicin exposure remains unclear.

Research motivation

To identify the effect of cold exposure and capsaicin on ECM remodeling, ECM enzymes, and the underlying mechanism.

Research objectives

To explore the role of ECM remodeling and ECM enzymes in the 1,2-dimethylhydrazine (DMH)-induced CRC progression and the underlying mechanism.

Research methods

The CRC rat model was conducted by adding DMH and examining the role of ECM remodeling and ECM enzymes on DMH-induced CRC in the model. We investigated the morphology and structure of collagen and elastin using Masson's trichrome, Picrosirius red, and Weigert's Resorcin-Fuchsin stains. Additionally, we evaluated the protein expression level of type I collagen (COL I), type III collagen (COL III), elastin, lysyl oxidase-like 2 (LOXL2), matrix metalloproteinase (MMP) 1, MMP2, MMP9, and tissue-specific matrix metalloproteinase 1 by immunohistochemistry and observed the expression of COL I, COL III, elastin, and LOXL2 in the colon tissues of rats by reverse-transcriptase quantitative polymerase chain reaction.

Research results

We found that although there were no differences in the proportion of adenomas, a trend towards the increase of invasive tumors was observed in the cold and capsaicin group. Cold exposure group had a metastasis rate comparative with the other groups. Additionally, abnormal accumulation of both collagen and elastin was observed in the cold exposure and capsaicin group. Specifically, collagen quantitative analysis showed increased length, width, angle, and straightness compared with the DMH group. Collagen deposition and straightness were significantly increased in the cold exposure group compared with the capsaicin group. Cold exposure and capsaicin significantly increased the protein levels of COL I, elastin, and LOXL2 along with increases in their messenger RNA levels in the colon tissues compared with the DMH group, while COL III did not show a significant difference. Furthermore, in immunohistochemical evaluations, MMP1, MMP2, MMP9, and tissue-specific matrix metalloproteinase 1 staining increased in the cold exposure and capsaicin group compared with the DMH group.

Research conclusions

Increased stiffness of colonic tissue and the remodeling of ECM mediated by ECM enzymes resulted from cold and capsaicin exposure, predisposing an environment suitable for CRC development and progression.

Research perspectives

To target ECM in CRC tumor tissue could represent a novel potential therapeutic strategy.

Abstract

BACKGROUND

Different types of pathogenic mutations may produce different clinical phenotypes, but a correlation between Peutz-Jeghers syndrome (PJS) genotype and clinical phenotype has not been found. Not all patients with PJS have detectable mutations of the *STK11/LKB1* gene, what is the genetic basis of clinical phenotypic heterogeneity of PJS? Do PJS cases without *STK11/LKB1* mutations have other pathogenic genes? Those are clinical problems that perplex doctors.

AIM

The aim was to investigate the specific gene mutation of PJS, and the correlation between the genotype and clinical phenotype of PJS.

METHODS

A total of 24 patients with PJS admitted to the Air Force Medical Center, PLA (formerly the Air Force General Hospital, PLA) from November 1994 to January 2020 were randomly selected for inclusion in the study. One hundred thirty-nine common hereditary tumor-related genes including *STK11/LKB1* were screened and analyzed for pathogenic germline mutations by high-throughput next-generation sequencing (NGS). The mutation status of the genes and their relationship with clinical phenotypes of PJS were explored.

RESULTS

Twenty of the 24 PJS patients in this group (83.3%) had *STK11/LKB1* gene mutations, 90% of which were pathogenic mutations, and ten had new mutation sites. Pathogenic mutations in exon 7 of *STK11/LKB1* gene were significantly lower than in other exons. Truncation mutations are more common in exons 1 and 4 of *STK11/LKB1*, and their pathogenicity was significantly higher than that of missense mutations. We also found *SLX4* gene mutations in PJS patients.

CONCLUSION

PJS has a relatively complicated genetic background. Changes in the sites responsible for coding functional proteins in exon 1 and exon 4 of *STK11/LKB1* may be one of the main causes of PJS. Mutation of the *SLX4* gene may be a cause of genetic heterogeneity in PJS.

Key Words: Peutz-Jeghers syndrome; Genotype; Phenotype; STK11; Mutation

©The Author(s) 2021. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: It is currently believed that Peutz-Jeghers syndrome (PJS) is an autosomal dominant genetic disease predominantly caused by germline mutations in the *STK11/LKB1* gene. No correlation of the PJS genotype and clinical phenotype has been found so far. The correlation of genotype and clinical phenotype and exploration of the internal molecular mechanism of different clinical phenotypes were studied in 24 treated PJS patients with different clinical phenotypes. Peripheral venous blood or normal tissue adjacent to polyps were collected for high-throughput next-generation sequencing (NGS) of 139 hereditary colorectal tumor-related genes including *STK11/LKB1*. A newly discovered likely pathogenic gene (*SLX4*) provided new data explaining the genetic heterogeneity of PJS.

INTRODUCTION

It is currently believed that Peutz-Jeghers syndrome (PJS) is an autosomal dominant genetic disease predominantly caused by germline mutations in the *STK11/LKB1* gene. PJS is characterized by multiple hamartoma polyps in the gastrointestinal tract, pigmentation at specific sites, and hereditary tumors[1-4]. Pathogenic mutations of *STK11/LKB1* lead to inactivation of its expression product and loss of inhibition of mammalian target of rapamycin (mTOR) activity, which leads to abnormal activation of the LKB1/mTOR signal pathway and the occurrence of black spots on the skin and gastrointestinal hamartoma polyps[5]. More than 400 different pathogenic *STK11/LKB1* gene mutations are included in the Human Gene Mutation Database (HGMD), most of which are microminiature. Different types of pathogenic mutations may produce different clinical phenotypes, but no correlations of PJS genotype and clinical phenotype has been found so far[6], Not all patients with PJS have detectable mutations in the *STK11/LKB1* gene. What is the genetic basis of clinical phenotypic heterogeneity in PJS? Do PJS patients without *STK11/LKB1* mutations have other pathogenic genes? These are clinical problems that perplex doctors[7,8]. We enrolled 24 patients treated for PJS. Peripheral venous blood and normal tissue adjacent to polyps were collected for high-throughput next-generation sequencing (NGS) of 139 hereditary colorectal tumor-related genes including *STK11/LKB1* to study the correlation between genotype and clinical phenotype of PJS and explore the internal molecular mechanism of the clinical phenotypes.

patients (legal guardians of minors) understood the process and purpose of this study and signed an informed consent form. In the process of sample collection, follow the principles of informed consent in the Declaration of Helsinki, the Universal Declaration of Human Genome and Human Rights, and the Declaration of the Human Genome Ethics Committee on DNA Sampling, Control, and Acquisition. No additional data are available.

MATERIALS AND METHODS

Study participants

Patients with PJS, from 18-70 years of age, met the clinical diagnostic criteria of PJs, had complete clinicopathological data, well preserved specimens, were eligible for inclusion. All participants gave their signed informed consent. Patients who could not provide experimental specimens or did not agree to participate in the study were excluded. Twenty-four PJS patients admitted to the Air Force Medical Center (formerly the Air Force General Hospital) from November 1994 to January 2020 met the above criteria and were enrolled. Their clinical information is shown in Table 1. Twenty-three were inpatients, one was an outpatient, 11 had family histories, and 12 had early onset pigment spots that had appeared when they were younger than 3 years of age. All patients met the PJS diagnostic criteria recommended by the National Comprehensive Cancer Network (NCCN)[9]. The experimental samples included 5 mL peripheral venous blood samples collected from 19 patients into tubes containing EDTA-2Na, and paraffin-embedded normal tissue surgically removed from areas adjacent to polyps in five patients. The study was reviewed and approved by the Ethics Committee of the Air Force Medical Center and the Second Affiliated Hospital of Zhejiang University School of Medicine. All patients or the legal guardians of minors, understood the process and purpose of this study and signed an informed consent form. Sample collection followed the ethical principles of the Declaration of Helsinki, the Universal Declaration of Human Genome and Human Rights, and the Declaration of the Human Genome Ethics Committee on DNA Sampling, Control, and Acquisition.

Methods

DNA was extracted from peripheral venous blood samples with TGuide Blood Genomic DNA Kits (CHI-TIANGEN) following the manufacturer's instructions. DNA was extracted from paraffin-embedded tissue specimens with QIAamp DNA FFPE micro sample tissue kits (GER-QIAGEN). Nucleic acids were broken into small, random 150-200 bp fragments by ultrasonic fragmentation (Covaris S220) and separated and evaluated with a Tapestation 2200 electrophoresis working platform (Agilent) to check whether the fragments met the requirements for library construction. A standard gene library was constructed using KAPA HyperPlus Kit (Illumina). A panel of 139 common tumor genetic susceptibility genes including colorectal cancer (Table 2) was selected and provided by Genetron Health Co.(Beijing). The specific gene capture probe was hybridized with the library in the environment of a hybridization buffer, and purified by the magnetic bead method. High-throughput NGS was performed with a Novaseq 6000 sequencer (Illumina, United States). Trimmomatic (version 0.33) was used to crop and filter the original data, which was stored in FastQ format, after sequencing. The reads at the end of each pair were aligned with the human reference sequence GRCh37 (hg19) using the BWA-MEM algorithm (BWA version 0.7.10-r789) and the default parameters. The Picard tool (version 1.103 http://broadinstitute.github.io/picard/) was used to delete duplicate readings, and GATK (version 3.1-0-g72492bb) was used to realign the sequences around the known insertion loss at the single sample level and to recalibrate the base quality. Integrative Genomics Viewer version 2.3.34 (https://software.broadinstitute.org/software/igv/) was used to check the mutations in the coding region.

The Chinese (1000 CN), general population (1000 MAF). and dbSNP (https://www.ncbi.nlm.nih.gov/) at 1000 Genome Project (http://ftp.ncbi.nih.gov/) Snip/), ESP6500 AA/EA (NHLBI GO Exome Sequencing Project https://evs gs.washington.edu/EVS/), ExAC MAF (The Exome Aggregation Consortium) and other population databases were searched for the mutation frequency of this gene. The location of genes with a mutation frequency < 0.01 in the HGMD database (HGMD-PUBLIC version 20152) were used for pathogenicity analysis.

The diseases that the variant gene was related to were searched in the OMIM disease database (https://omim.org/) by ClinVar (https://www.ncbi.nlm.nih.gov/clinvar/). HGMD https://www.hgmd.cf.ac.uk) retrieved the description of the mutation. SIFT[10] (http://sift.jcvi.org), PolyPhen2[11] (http://genetics.bwh.harvard.edu/pph2), and Mutation Assessor (http://mutationassessor.org) make conservative predictions of amino acid sequences. The results were used to evaluate the pathogenicity of the mutations[12,13].

SPSS 24.0 was used for statistical analysis of the acquired data. Qualitative results were reported as numbers and percentages. The chi-square test or Fisher's exact probability method was used for between-group comparisons. $P < 0.05$ was considered

RESULTS

STK11/LKB1 gene detection results and pathogenicity analysis

Twenty of the 24 PJS patients (83.3%) in this group had *STK11/LKB1* gene mutations (Table 3). All were heterozygous and ten were newly discovered mutation sites not included in the dbSNP database. There were eight frameshift mutations, five splice-site mutations, four missense mutations and three nonsense mutations. The mutations occurred in eight of the ten exons in the *STK11/LKB1* gene, mutations in exons 1 and 4 and 4 each in exon 7, two in each exons 5 and 8, and one in exons 2, 3, and 6. Frameshift mutations, splice-site mutations, and nonsense mutations were all related to pathogenicity. Frameshift mutations accounted for 62.5% (5/8) that were clearly pathogenic, and 37.5% (3/8) that might cause disease. Splice-site mutations accounted for 40% (2/5) that are clearly pathogenic, and 60% (3/5) that might cause disease. All three nonsense mutations were clearly pathogenic, and the missense mutations were related to and might cause disease. Sites of unclear clinical significance accounted for 50% (2/4); of the 11 truncated mutations, eight cases were clearly pathogenic and three were likely to cause disease. The pathogenicity of STK11 gene mutations in exon 7 was significantly lower than that of other exons (P = 0.000). Truncation mutations were significantly more pathogenic than missense mutations (P = 0.012). The prediction results of bioinformatics tools for missense mutations are shown in Table 4, and the relevant database records and the pathogenicity judgment of all mutations are shown in Table 5.

Considering that the type of specimen may impact on the detection rate of *STK11/LKB1* gene mutations, we analyzed the paraffin-embedded tissue and blood samples separately. The detection rate of *STK11/LKB1* mutations in 60 patients with paraffin samples was 60% (3/5), slightly less than the 89.4% (17/19) of the blood samples from 19 patients. The difference in mutation detection rate of this gene in the two types of sample was not statistically different (P = 0.116).

SLX4 gene detection results and pathogenicity analysis

SLX4 gene mutation (Table 6) was detected in 5 PJS patient samples in this group, with a total detection rate of 20.83% (5/24), all of which were heterozygous mutations. The mutation occurred in 4 of 15 exons of *SLX4* gene. Mutation types include: 3 missense mutations, one splice-site mutation, and one non-frameshift mutation. No truncation mutation was found. The *SLX4* gene is a tumor suppressor gene, and there are three newly discovered mutation sites. The prediction results of three cases of missense mutations by bioinformatics tools (Table 7), the collection of relevant databases and the judgment of the pathogenicity of all mutations (Table 8) are as follows.

Other gene detection results and pathogenicity analysis

A total of 55 mutations of 46 genes other than *STK11/LKB1* and *SLX4* were detected in 21 cases (Table 9), f a detection rate of 87.5% (21/24). Twenty-three of the genes were related to cancer suppression and had 32 different mutation sites. Two mismatch repair *MMR* genes were detected, *MSH2*, *MSH6*. Except for a frameshift mutation (frameshift deletion) in the *BRIP1* gene detected in one patient (No. 18), the rest were missense mutations (Table 10).

STK11/LKB1 genotype-phenotype correlation analysis

Investigation of the relationship between genotype and family history found that the proportion of patients with truncated mutations was slightly higher in those with a family history than in those without a history (60% *vs* 50%). The proportion of splice-site mutations was lower in those with a family history (20% *vs* 30%), and the proportion of nonsense mutations was higher in patients with a family history (20.0% *vs* 11.1%). The proportions of missense mutations were the same (20% *vs* 20%), and the proportion of frameshift mutations were also equal (40% *vs* 10%). There were no significant difference between-group differences in $P_{truncation\ mutation} = 0.653$, $P_{splice\ site\ mutation} = 0.606$, $P_{nonsense\ mutation} = 0.371$, $P_{missense\ mutation} = 1.000$, and $P_{frameshift\ mutation} = 1.000$.

Evaluation of the relationship between genotype and early onset/late onset found that the proportion of truncated mutations in patients with early onset was higher than that in patients with late onset (72.7% *vs* 33.3%). In patients with early onset, the

suppressor gene[14] and is widely expressed in human tissues. Pathogenic mutation of *STK11* can inactivate its expressed product, which results in the loss of its inhibitory effect on the activity of mammalian target of rapamycin (mTOR), leading to the occurrence of skin and mucous membrane black spots and gastrointestinal polyps[5]. Methylation of the *STK11/LKB1* gene promoter has an important role in the process of malignant transformation of gastrointestinal polyps[15]. At present, the comprehensive mutation rate of *STK11/LKB1* gene in PJS patients detected by multiple sequencing methods is about 80%-94%[8,15,16]. The detection rate of *STK11/LKB1* gene mutation in PJS patients in this study was 83.3% (20/24), 90% of which are related to pathogenicity. Analysis of the pathogenicity of all the detected mutation sites included in the Mendelian Inheritance in Man (OMIM) database found that about 90% of the *STK11/LKB1* mutations were related to PJS. Except for the *STK11/LKB1* gene and one case of *SLX4* gene mutation, no other gene mutations related to the disease or the possibility of disease were found.

Research on whether there is a correlation between the PJS genotype and clinical phenotype is ongoing. Although the correlation is currently unclear[6,17], some studies have reported positive results. For example, Forcet *et al*[18] reported that patients often present with only black spots and without gastrointestinal polyps when heterozygous mutations occur in exon 8 of the *STK11* gene. Amos *et al*[19] found that PJS patients with missense mutations had a first episode of polypectomy and appearance of other symptoms significantly later than those with truncated mutations or no detectable mutations. In a study including 116 PJS patients in 52 families, Wang *et al*[20] found that nearly 30% of the mutations occurred in exon 7, and some of those mutations affected the protein Kinase domain XI region, which is associated with 90% of cases with gastrointestinal polyp dysplasia. An analysis of the start region of the *STK11/LKB1* coding sequence by Hearle *et al*[21] found that a change in promoter sequence was unlikely to be the cause of PJS. In this study the time that dark spots first appeared, which is a relatively objective indicator, was the basis of clinical classification, and was used to determine whether there was a correlation between the appearance of the spots and any of the genotypes. Spots that appear in early childhood will be noticed. On the other hand, unless there are obvious clinical symptoms, it is extremely difficult to know about gastrointestinal polyps that appear in early childhood. Also, PJS is an autosomal dominant genetic disease and does not completely follow Mendelian inheritance[6]. In clinical practice, it is often found that neither parent has a family history but their child has the disease. This is difficult to fully explain if the disease is caused by a single gene. Therefore, whether the patient has a family history was also included in the basis of clinical classification.

This study did not found that patients with different clinical phenotypes (early onset/late onset and with or without a family history) had statistically significant differences in their *STK11/LKB1* gene mutations and loci. However, we found that the

HGMD: Human Gene Mutation Database; OMIM: Online Mendelian Inheritance in Man; TSG: Tumor suppressor gene.

most truncation mutations of the *STK11/LKB1* gene mostly occurred in exons 1 and 4, most missense mutations occurred in exon 7, and that truncation mutations were significantly more pathogenic than missense mutations. The results indicate that changes in the sites encoding functional proteins in exon regions 1 and 4 may be among the main causes of PJS. Also, the percentage of *STK11/LKB1* truncation mutations in patients with early onset PJS was higher than that in patients with late onset PJS, and the between-group difference in the percentage of missense mutations was not significant. Because the evidence of a correlation with missense mutations was not strong, it suggests that early onset PJS is more likely to be caused by pathogenic mutations in *STK11/LKB1*, while late onset disease is likely to be clinically heterogeneous. The study results also suggest that analysis of the age of appearance of dark spots in a large sample of PJS patients would yield some interesting findings.

For the first time, we detected more concentrated mutations in the *SLX4* gene in PJS patients. The *SLX4* (*FANCP*) gene is a tumor suppressor gene located on chromosome 16p13.3[21]. It serves as a key scaffold element for the assembly of multiprotein complexes containing enzymes involved in DNA maintenance and repair[22] and has low to moderate expression in all adult and fetal tissues and specific adult brain regions[23]. It has been reported that[24] truncated mutations in the *SLX4* gene were detected in families with Fanconi anemia, and it was determined that *SLX4* mutations are clearly related to one of the subtypes of the disease. Fanconi anemia is a rare autosomal recessive genetic disease[25]. In addition to blood system-related manifestations, the clinical manifestations of FA include multiple congenital malformations, brown pigmentation of the skin, and tumor susceptibility[26]. There are many similarities with PJS, mutations in the *SLX4* gene have been detected in patients with PJS in previous studies, the first of which was found in this group. *SLX4* is considered

Table 10 Prediction of protein function changes caused by other gene mutations

to be an important regulator of DNA repair. Studies have shown that repairing specific types of DNA damage requires *SLX4* and other endonucleases to participate together [22]. At present, it is believed that[27-29] the loss of DNA MMR genes causes the accumulation of mismatches in the process of DNA replication, resulting in the occurrence of microsatellite instability and partial junctions. Colorectal cancer has obvious genetic characteristics. We also detected mutations in some MMR genes (*MSH2* and *MSH6*) in PJS, and the role of *SLX4* gene is highly similar to that. Perhaps the mutation of the *SLX4* gene may explain the genetic heterogeneity of PJS to some extent.

CONCLUSION

In conclusion, we discovered a series of new gene mutation sites, analyzed their pathogenicity, and enriched the mutation spectrum of PJS pathogenic genes. And through the summary of the clinical phenotypes with different *STK11* genotypes, to explore whether they are related, and get some tendentious research results. The detection of *SLX4* gene mutations in patients with PJS was reported for the first time. The relationship between *SLX4* gene mutations and the occurrence of PJS is still unclear, but may help to explain the genetic heterogeneity of PJS.

ARTICLE HIGHLIGHTS

Research background

Different types of pathogenic mutations may produce different clinical phenotypes, but no exact correlation between Peutz-Jeghers syndrome (PJS) genotype and clinical phenotype has been found so far. So it is necessary to study the correlation between genotype and clinical phenotype of PJS, and explore the internal molecular mechanism of different clinical phenotypes.

Research motivation

The authors included 24 cases of treated PJS cases as study participants, collected peripheral venous blood or normal tissue adjacent to polyps for high-throughput next-generation sequencing (NGS) of 139 hereditary colorectal tumor-related genes including *STK11/LKB1* to study the correlation between genotype and clinical phenotype of PJS.

Research objectives

To investigate the correlation between the genotype and clinical phenotype of PJS.

Research methods

Twenty-four patients with PJS were randomly selected for study inclusion. A total of 139 common hereditary tumor-related genes including *STK11/LKB1* were screened and analyzed for pathogenic germline mutations by high-throughput next-generation sequencing (NGS), and the pathogenicity of these mutations was evaluated.

Research results

STK11/LKB1 gene mutations were identified in 20 PJS patients, 90% of which were pathogenic mutations. 10 cases had new mutation sites. Pathogenic mutations were significantly less frequent in exon 7 of the *STK11/LKB1* gene than in other exons. Truncation mutations were more common in exons 1 and 4, and their pathogenicity was significantly higher than that of missense mutations. We also identified *SLX4* gene mutations in PJS patients.

Research conclusions

PJS has a relatively complicated genetic background. Changes in the sites responsible for coding functional proteins in exon 1 and exon 4 of *STK11/LKB1* may be one of the main causes of PJS. Mutation of the *SLX4* gene may help to explain the genetic heterogeneity of PJS.

Research perspectives

Exploration of the relationships of clinical phenotypes with different *STK11* genotypes, may help to interpret some controversial research results. The detection of *SLX4* gene mutations in patients with PJS was reported for the first time.

Abstract

BACKGROUND

Stigmatization is the separation of an individual from a group due to aspects that make them different. Resilience may in turn influence the perception of stigma. Patients with inflammatory bowel disease (IBD) are susceptible to stigma, although data are very limited.

AIM

To validate an Italian translation of the IBD perceived stigma scale (PSS) in relation to patients' resilience.

METHODS

Consecutive IBD outpatients were prospectively enrolled (December 2018-September 2019) in an Italian, tertiary referral, IBD center. Clinical and demographic data were collected. Stigma and resilience were evaluated through the IBD-PSS and the 25-item Connor-Davidson Resilience Scale, respectively. The International Quality of Life Assessment Project approach was followed to translate the IBD-PSS into Italian and to establish data quality. Higher scores represent greater perceived stigma and resilience. Multivariable analysis for factors associated with greater stigma was computed.

RESULTS

statement: The study was approved by the local Ethics Committee (Protocol Number 20190003611). The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a priori approval by the institution's human research committee.

Informed consent statement: All participants gave their informed written consent to take part to the study and for the anonymized publication of data.

Conflict-of-interest statement: The authors of this manuscript having no conflicts of interest to disclose.

Data sharing statement: There is no additional data available.

Overall, 126 IBD patients (mean age 46.1 ± 16.9) were enrolled. The International Quality of Life Assessment criteria for acceptable psychometric properties of the scale were satisfied, with optimal data completeness. There was no ceiling effect, whilst floor effect was present (7.1%). The discriminant validity and the internal consistency reliability were good (Cronbach alpha = 0.87). The overall internal consistency was 95%, and the test-retest reliability was excellent 0.996. The median PSS score was 0.45 (0.20-0.85). Resilience negatively correlated with perceived stigma (Spearman's correlation = -0.18, 95% confidence intervals: -0.42-0.08, P = 0.03).

CONCLUSION
We herein validated the Italian translation of the PSS scale, also demonstrating that resilience negatively impacts perceived stigma.

Key Words: Crohn's disease; Quality of life; Stress; Ulcerative colitis

Core Tip: We have here validated an Italian version of the Perceived Stigma Scale for patients with inflammatory bowel disease. We have also found that resilience levels negatively correlated with perceived stigma. This is the first study assessing this issue in patients with inflammatory bowel disease.

INTRODUCTION

Stigmatization is defined as the societal identification of an individual as abnormal and worthy of separation from the group, leading to discrimination and loss of their social status[1]. It has been reported that inflammatory bowel disease (IBD) is susceptible to stigmatization, not only because of the *taboo* around its symptoms, but also due to the assumption of being a psychosomatic condition affecting people because of their "obsessive behavior"[2] and because it affects sexual life[3]. Stigmatization in IBD patients was reported to be as high as 84%, regardless of disease activity [4].

An important aim of taking care of chronic patients should be the improvement of their quality of life (QoL), taking into account the social context and their needs[5]. Nonetheless, it emerged from a recent review that the burden of stigmatization in IBD, and the ability to positively cope with the disease (*i.e.* resilience), are not adequately addressed by clinicians[6]. In IBD patients, resilience has been found to be influenced by individual characteristics, including age, sex, and employment status and to influence positively the disease prognosis[7-9]. Stigma can be evaluated through the use of different scales, including the IBD perceived stigma scale (PSS)[10], which has been adapted and used in IBD patients[11]. Similarly, resilience can be measured through the Connor-Davidson resilience scale (CD-RISC), a 25-item self-administrated scale exploring different aspects related to the individual ability to cope with adversity and stress[12]. The CD-RISC was initially designed for psychiatric American patients, and it has now been translated into more than 70 languages, being the most widely used resilience scale in a variety of conditions[13].

The first study looking into perceived stigma in IBD showed that functional impairment was mainly due to IBD patients' psychological dimension rather than to their physical one. They also reported that patients with Crohn's disease (CD) had a higher degree of perceived stigma than patients with ulcerative colitis (UC)[14]. While perceived stigma is difficult to address and modify, resilience is responsive to

behavioral intervention and is independently associated with better QoL and lower disease activity in IBD[9].

There are very limited data regarding perceived stigma in IBD, and no validated translation of the PSS into Italian is available. As a consequence, perceived stigma in Italian IBD patients has never been assessed. Therefore, we aimed to validate the Italian version of the PSS in IBD patients in order to obtain a meaningful instrument for assessing stigmatization and compare with international studies. We also assessed resilience and its relation with stigmatization.

MATERIALS AND METHODS

Study population

All IBD patients followed-up at the IBD Clinical & Research Centre of the San Matteo Hospital Foundation were consecutively enrolled between December 2018 and September 2019. IBD diagnosis was established according to internationally agreed criteria[15]. Patients were eligible for inclusion if they had at least a 3-mo history of IBD, were aged ≥ 18, were able to complete a questionnaire, and were willing to give written informed consent. Patients with an inconclusive or uncertain diagnosis of IBD or those diagnosed less than 3 mo before or unwilling to provide informed consent were excluded. Demographic and clinical characteristics were gathered, including IBD type, disease activity and duration, comorbidities, and previous IBD-related surgery. Clinical activity was assessed using the Harvey-Bradshaw index (HBI)[16,17] for CD and the partial Mayo score (pMayo)[18] for UC. For CD patients, HBI < 5 was defined as clinical remission, HBI 5-7 as mild disease, HBI 8-16 as moderate disease, and HBI > 16 as severe disease[16,17]. For UC patients, pMayo < 2 was defined as remission, pMayo 2-4 was defined as mild activity, pMayo 5-7 was defined as moderate activity, and pMayo > 7 was defined as severe activity[18]. The study was approved by the local Ethics Committee (Protocol Number 20190003611), and all participants gave their informed written consent to take part to the study and for the anonymized publication of data. The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a priori approval by the institution's human research committee.

Assessment of the PSS

The PSS was initially designed to assess stigma in irritable bowel syndrome (IBS) patients and was validated in IBD in 2009 in a cohort of patients from the United States [4]. The PSS is a self-administered questionnaire designed to measure perceived stigma through 10 items on a five-point Likert scale (ranging from 0 = never to 4 = always), with a higher score reflecting a greater level of perceived stigma. Each item is assessed on two different domains: Significant others (SO) and healthcare professionals (HP), leading to a total of 20 items. The two-domain PSS version has already been used for different gastrointestinal disease and was found to have an excellent internal consistency and split-half reliability (≥ 0.89)[19].

The score indicating the perceived stigma ranges from 0 to 4 and is obtained by calculating the mean of all the values and the values within each domain.

Translation and cultural validation

We aimed to create a version that was easy to understand and complete by Italian IBD patients, without losing the original English version's equivalence and psychometric validity. The translation and adaptation were made in accordance with the International QoL Assessment (IQOLA) Project approach, which consists of three steps: A forward translation, a backward translation, and a cognitive testing[20,21].

Step 1—Forward translation: Two bilingual physicians (Lenti MV and Cococcia S) blindly translated the questionnaire from English into Italian. The two versions were compared, and discrepancies reconciled. Difficulty and degree of agreement of the translation were rated on a 1 to 100 scale (lowest–highest). For each item, the agreed forward translation was accepted if the scores were ≥ 75, otherwise retranslation was independently performed and scoring repeated.

Step 2—Backward translation: The Italian translation was blindly translated back into British English by two mother-tongue English people with a high educational level (graduated). The same reconciliation process reported for the forward translation was applied. The equivalence of the agreed backward translation to the original version

was rated and expected to be ≥ 75. If that threshold was not reached, the four translators had to agree on a new forward translation.

Step 3—Cognitive testing: Cognitive testing of the agreed Italian version was performed on 10 individuals with different age, sex, and educational background to verify that the translation was clear and understandable by a range of different people. Finally, a panel discussion was held to approve the final version (see Supplementary data).

Resilience assessment

Resilience was assessed through the Italian validated translation of the CD-RISC scale, a self-administered questionnaire assessing resilience through 25 items on a five-point Likert scale (ranging from 0 = totally disagree to 4 = totally agree)[12]. The score is calculated by summing the score of each item (ranging from 0 to 100) with higher scores meaning higher resilience.

Statistical analysis and psychometric evaluation

The sample size was computed based on the primary endpoint. A sample of 100 subjects responding to 20 items would achieve 80% power to detect the difference between the coefficient alpha under the null hypothesis of 0.70 and the coefficient alpha under the alternative hypothesis of 0.81, using a two-sided *F*-test with a significance level of 0.05. Twenty-six extra patients were enrolled to account for possible dropouts.

The PSS scoring was performed according to the scoring manuals, meaning that higher scores represent a higher level of perceived stigma. The psychometric evaluation of the Italian version of the PSS questionnaire included evaluation of data quality, including completeness (Table 1). Results were described as mean and standard deviation, and ceiling and floor effect were evaluated. Reliability was assessed and expressed by means of Cronbach's alpha for internal consistency, alpha = k × r/[1+(k-1) × r]; with k = number of items and r = mean correlation. Item internal consistency (correlation of item and corresponding scale, corrected for overlap), equality of item-scale correlations, and item discriminant validity (correlation of item with the corresponding scale *vs* correlation of item with other scales) were evaluated through the multi-trait/multi-item correlation matrix. Means of Pearson's correlation coefficient and intraclass correlation coefficient were used to evaluate the test-retest correlation for temporal stability (within 1 mo), with 95% confidence intervals (95%CI). External validity was assessed through the comparison of PSS scores in patients with different characteristics by means of the Kruskall Wallis test, the test for trend; the correlation with continuous variables was assessed with the Spearman R. Stata 16 (StataCorp, College Station, TX, United States) was used for all computations. All tests were two-sided, and a P value < 0.05 was considered statistically significant. In the presence of missing data, missing items were replaced by the median of the corresponding scale, unless more than 50% of the items were missing, in which instance the questionnaire was dropped.

RESULTS

Demographic and clinical characteristics

Overall, 146 IBD patients were screened for inclusion in the study. Of these, 20 patients did not participate because denied consent (15 patients) or because were due to be followed up in another hospital. Hence, 126 IBD patients (mean age 46.1 ± 16.9, male 56.4%), 57 with CD and 69 with UC, were consecutively enrolled in the study. The demographic and clinical characteristics of the enrolled patients are reported in Table 2. CD patients were significantly younger than UC patients (42.3 ± 15.7 *vs* 49.3 ± 17.4; P = 0.03). Psychiatric disorders, including anxiety and depression, were the most common concomitant diseases (25.4%), followed by hypertension (22.2%) and cardiomyopathy (11.9%), which was significantly more common among UC patients (17.4% *vs* 5.26%; P = 0.05). Overall, the median disease duration was 8 years [interquartile range (IQR) 3-16]. The majority of the CD patients had a disease with an inflammatory behavior (56.1%), 43.9% had a structuring behavior, and 28.1% had a penetrating disease. Almost half of the CD patients (49.1%) had ileo-colonic involvement, and 33.3% had perianal disease. Among UC patients, half (52.2%) had an extensive disease, 37.7% had a left UC, 10.1% had an ulcerative proctitis, and 4.4% had

Table 1 Thresholds defining acceptable psychometric properties according to the International Quality of Life Assessment project

	Definition	Threshold
Data quality		
Missing items	Unanswered items	< 5%-10%
	Incomplete scales (< 50% of items answered)	< 5%-10%
Floor and ceiling effect	Extreme scores (either on the lower- or higher-end)	< 10%
Scaling assumption		
Internal consistency		
Item	Correlation among items of the same scale (Pearson correlation ≥ 0.4)	> 90%
Reliability	Overall consistency of the scale (Cronbach's alpha coefficient)	> 0.7
Discriminant validity	Items whose Pearson correlation with other scales is higher than with their scale	0%
Test-retest evaluation	Correlation between the results scales filled in twice by the same patients at defined time points (Pearson correlation)	> 0.7

a pouch. The proportion of patients with severe disease activity was higher among UC patients (10.1% *vs* 0%), while two-thirds were in remission in both groups. A quarter of the enrolled patients had an extraintestinal manifestation (28.6%), including anemia, arthritis, uveitis, and dermatological manifestations. When available, calprotectin and C-reactive protein (CRP) were used as inflammatory markers. Overall, 34.1% of the patients had a calprotectin < 50 mg/kg, 16.2% between 51-250 mg/kg, and 12.7% > 250 mg/kg with no difference according to the disease (P = 0.54). Similarly, 61.1% of the patients had a normal CRP, whilst roughly a third had raised levels of CRP (31.0%), with no difference between UC and CD patients (P = 1.00).

Translation and cultural validation

The PSS was translated according to the IQOLA project guidelines[20,21]. For the forward translation, the median difficulty was rated as 10 (range: 10-60) and the agreement was found to be 95 (range: 70-100). Items 1, 5, and 10 were adjusted after discussion. The backward translation equivalence was rated at 95 (range: 80-100). Minor changes were made to item 2 and 4 of the Italian translation to improve the original version's equivalence. A cognitive testing of the agreed Italian version was performed on 10 individuals with different ages (median 48-years-old, range: 29-88), sex (5 female), and educational background (5 graduated), which did not lead to any adjustment of the scale. Supplementary data show the validated Italian version of the PSS-IBD, while the questions of the original English version have already been published elsewhere[4].

Psychometric evaluation

The majority of the IQOLA criteria for acceptable psychometric properties of the scale were satisfied in our cohort as reported in Table 3. We reached an optimal data completeness, and we did not have any ceiling effect, whilst a floor effect was present in 7.1% of the cases (overall domain). The floor effect was greater for the HP domain when compared to the SO domain (42.1% *vs* 8.7%). When looking at scaling assumption, the internal consistency reliability of the Italian version of the PSS was good, with an overall Cronbach alpha coefficient of 0.87 (0.83 for SO and 0.81 for HP). Although an excellent item, internal consistency was found in each domain, with a Pearson correlation ranging from 0.4 to 0.6, and one item (item 8, SO domain) did not reach the predetermined threshold of 0.4, determining an overall item internal consistency of 95% (still indicative of an excellent item internal consistency). The discriminant validity of the scale was good for items 1 to 7 in both domains, whereas items 8 to 10 had exactly the same Pearson correlation with their domain and the other one for both SO and HP.

The test-retest reliability was excellent, being 0.999 (0.997-1.000) overall, 0.99 (0.997-1.000) in the SO domain and 0.994 (0.979-0.998) in the HP domain. The median PSS score was 0.45 (0.20-0.85) with a significantly higher score for the SO domain (0.70 IQR 0.40-1.40 *vs* 0.10 IQR 0.00-0.40, P < 0.001), whilst the median resilience score was 64 (IQR 53-78). The level of perceived stigma did not differ according to sex (P = 0.51), IBD type (P = 0.33), disease activity, age (P = 0.11), or disease duration (P = 0.49) (See

Table 4). On the contrary, disease activity was found to significantly reduce resilience (Spearman's correlation -0.18, 95%CI: -0.42-0.08, P = 0.03) in CD patients, whilst no significant difference was found in UC patients according to the disease activity (P = 0.23). When exploring the relations between perceived stigma and resilience, a significant negative Spearman's correlation was found (-0.20, 95%CI: -0.36 to -0.02; P = 0.03).

DISCUSSION

Stigmatization is an important, though often unattended, issue in clinical medicine. Whilst for other conditions (*e.g.*, human immunodeficiency virus, mental illness, and lung cancer) stigmatization has been widely studied[22-25], IBD data are scant and fragmentary. This might be partly due to the lack of a validated tool to be used for this purpose. We herein validated an Italian version of the PSS questionnaire that performs well, has good psychometric properties, and is easily understandable. The psychometric evaluation of the Italian PSS version showed an excellent Cronbach alpha coefficient, item internal consistency, and test-retest reliability. Our results are in line

Table 4 Correlation between inflammatory bowel disease perceived stigma scale scores and demographic or clinical characteristics

	PSS	*P*	Spearman's correlation (95%CI)	PSS SO	*P*	Spearman's correlation (95%CI)	PSS HP	*P*	Spearman's correlation (95%CI)

with previous literature validating stigma scales in different settings[4,10,26,27], showing that our translation is reliable and offers a tool to assess stigma in Italian IBD patients. In our cohort, the main concern is the high floor effect recorded, especially in the HP domain. However, this result was partially expected since all the included patients were followed-up at a tertiary IBD center. These patients likely experience lower levels of perceived stigma since they are looked after by IBD dedicated HP, whereas a different result might be obtained if the questionnaire would be administered in different settings, such as community centers or private practices. Even considering the setting bias, the level of perceived stigma was found to be lower than expected (median 0.45, IQR 0.20-0.85), when compared to previous literature showing a low-to-moderate level of perceived stigma among IBD patients, using the PSS[4]. This might be explained by the fact that the PSS has been originally designed to address perceived stigma in patients affected by a functional disorder rather than by an organic disease, such as IBD. In the PSS questionnaire, there are no questions addressing some of IBD patients' main concerns, including the fear of relapsing or of incontinence. Therefore, even if this scale offers a useful tool to assess stigma in IBD, it is our opinion that some adjustments are needed.

Additionally, levels of perceived stigma in IBD patients tend to decrease in long-standing disease, in contrast with what happens for IBS[11]. Since IBD is an organic disease not associated with unhealthy or socially unacceptable vices, it is therefore

more likely to be recognized and accepted as a "real" organic disease over time, especially when compared to IBS[11]. Most of the included patients have a longstanding history, which could have led to lower levels of perceived stigma in our sample.

Stigmatization is multifactorial and is influenced by both patient-dependent and environment-dependent factors[28-30]. Among these factors, we have previously speculated that a relation between stigma and resilience may exist[6]. In line with previous literature, we found a moderate level of resilience in our cohort[9]. We have here shown for the first time that, in IBD patients, higher levels of resilience correlate with lower levels of perceived stigma (overall and for SO) and, conceivably, to better QoL. Such correlation was not found for the HP domain, which might be due to the high floor effect reported in this domain. In case of adversity, resilience can modulate catecholamine and cortisol production reducing long-term effects on the body[31] and leading to better outcome also in IBD, which requires continuous adaptation to the unpredictable course of the disease. This hypothesis is supported by a recent study in which higher levels of resilience are associated with lower disease activity, although it is unclear if this result was due to reverse causation[9]. Our findings suggest that downstream public health intervention that focus on patients' resilience may reduce the level of perceived stigma and consequently may improve the patients' QoL. Follow-up data are being gathered to support this hypothesis, since resilience is easily influenced by other events and a single assessment might be misleading. In addition to intervention focused on building individual resilience, upstream public health interventions are needed to reduce stigma around IBD improving the awareness on the disease.

This study has some limitations. Firstly, the sample size was calculated to validate the Italian translation of the PSS and was not adequate to draw firm conclusions about the level of perceived stigma among IBD patients. Larger prospective studies are needed to explore this aspect. Secondly, the majority of the included patients had a low disease activity and that could represent a bias in interpreting the results. Stigma is internalized over time and, since IBD is a chronic disease, the level of perceived stigma is influenced mostly by the social environment rather than by acute events. On the contrary, resilience is strongly influenced by contextual events and can be improved through behavioral intervention, and this is why the ongoing follow-up of these patients will be useful to better assess the relation between stigma and resilience in IBD. Additionally, the level of resilience of the sampled patients ranged from average to good, and this might have played a role in lowering the stigma scores.

CONCLUSION

To conclude, we have herein developed a validated Italian version of the PSS. Also, we have assessed for the first-time stigmatization and its relation with resilience in a cohort of IBD patients. Interventions aimed at building a stronger resilience may reduce perceived stigma. The follow-up data on the variation of stigma and resilience levels over time are being collected.

ARTICLE HIGHLIGHTS

Research background

Patients living with inflammatory bowel disease (IBD) often experience a poor quality of life due to stigmatization that can be assessed through the IBD perceived stigma scale (PSS). Resilience is the ability to cope positively with a specific disease or situation.

Research motivation

Stigmatization in IBD patients, especially in relation to one's own resilience, has been poorly characterized. A validated Italian version of the IBD-PSS is not available.

Research objectives

To validate an Italian version of the PSS in IBD patients and to assess patients' resilience and its relation with stigmatization.

Research methods

We enrolled 126 consecutive IBD patients (mean age 46.1 ± 16.9, male 56.4%), 57 with CD and 69 with UC, in an Italian, tertiary referral, IBD center. Clinical and demographic data were collected, and stigma and resilience were evaluated through the IBD-PSS and the 25-item Connor-Davidson Resilience Scale, respectively. Psychometric validity of the IBD-PSS was assessed, and a multivariable analysis for factors associated with greater stigma was computed.

Research results

We found that the Italian version of the IBD-PSS had an acceptable reliability, having a Cronbach alpha of 0.87, with an excellent test-retest score. The median PSS score was 0.45 (0.20-0.85), and resilience negatively correlated with perceived stigma (Spearman's correlation -0.18, 95%CI: -0.42-0.08, $P = 0.03$).

Research conclusions

We have developed a reliable tool to be used in clinical practice for assessing stigmatization in Italian IBD patients. Also, we found that resilience may have an influence on stigmatization, possibly improving patients' illness perception.

Research perspectives

The Italian IBD-PSS should be used extensively in order to assess this important endpoint in the care of IBD patients. More prospective, long-term studies looking at more detailed factors influencing stigmatization and resilience are urgently needed.

ACKNOWLEDGEMENTS

Dr. Marco Vincenzo Lenti is grateful to the University of Pavia for supporting his research projects. Mr. Tim Brown and Mrs. Joan Brown kindly provided backward translation for free. We also thank Prof. Tiffany Taft for providing the English version of the PSS-IBD. Dr. Marco Vincenzo Lenti has been awarded for presenting the abstract of this research project to the Italian Group for the study of Inflammatory Bowel Disease National Congress (2019; Best Clinical Communication).

Abstract

BACKGROUND

Gastric cancer is the third leading cause of cancer-related death worldwide and surgical resection remains the sole curative treatment for gastric cancer. Minimally invasive gastrectomy including laparoscopic and robotic approaches has been increasingly used in a few decades. Thus far, only a few reports have investigated the oncological outcomes following minimally invasive gastrectomy.

AIM

To determine the 5-year survival following minimally invasive gastrectomy for gastric cancer and identify prognostic predictors.

METHODS

This retrospective cohort study identified 939 patients who underwent gastrectomy for gastric cancer during the study period. After excluding 125 patients with non-curative surgery (n = 77), other synchronous cancer (n = 2), remnant gastric cancer (n = 25), insufficient physical function (n = 13), and open gastrectomy (n = 8), a total of 814 consecutive patients with primary gastric cancer who underwent minimally invasive R0 gastrectomy at our institution between 2009 and 2014 were retrospectively examined. Accordingly, 5-year overall and recurrence-free survival were analyzed using the Kaplan–Meier method with the log-rank test and Cox regression analyses, while factors associated with survival were determined using multivariate analysis.

RESULTS

Our analysis showed that age > 65 years, American Society of Anesthesiologists

(ASA) physical status 3, total or proximal gastrectomy, and pathological T4 and N positive status were independent predictors of both 5-year overall and recurrence-free survival. Accordingly, the included patients had a 5-year overall and recurrence-free survival of 80.3% and 78.2%, respectively. Among the 814 patients, 157 (19.3%) underwent robotic gastrectomy, while 308 (37.2%) were diagnosed with pathological stage II or III disease. Notably, our findings showed that robotic gastrectomy was an independent positive predictor for recurrence-free survival in patients with pathological stage II/III [hazard ratio: 0.56 (0.33-0.96), P = 0.035]. Comparison of recurrence-free survival between the robotic and laparoscopic approach using propensity score matching analysis verified that the robotic group had less morbidity (P = 0.005).

CONCLUSION

Age, ASA status, gastrectomy type, and pathological T and N status were prognostic factors of minimally invasive gastrectomy, with the robot approach possibly improving long-term outcomes of advanced gastric cancer.

Core Tip: This retrospective cohort study on 814 patients undergoing minimally invasive surgery for primary gastric cancer revealed a 5-year overall and recurrence-free survival of 80.3% and 78.2%, respectively. Moreover, our analysis identified age, American Society of Anesthesiologists status, type of gastrectomy, and pathological T and N status as prognostic predictors for overall and recurrence-free survival. The robotic approach was also identified as an independent positive predictor for recurrence-free survival in patients with pathological stage II/III disease, confirmed by the lesser morbidity in the robotic group following propensity score analysis.

INTRODUCTION

Gastric cancer is the fifth most common malignancy and the third leading cause of cancer-related death worldwide[1]. Surgical resection remains the sole curative treatment for gastric cancer, with regional lymphadenectomy being recommended as a component of radical gastrectomy[2]. Laparoscopic gastrectomy has been increasingly used, considering its better short-term effects and comparable long-term outcomes compared to open gastrectomy[2].

The da Vinci surgical system (DVSS; Intuitive Surgical, Sunnyvale, CA, United States) had been developed to overcome several disadvantages identified for standard minimally invasive laparoscopic surgery[2]. Most laparoscopic surgeons expect that utilizing the DVSS for gastric surgery would allow them to overcome the technical difficulties of laparoscopic gastrectomy, thereby improving its safety, reproducibility, teachability, and long-term outcomes. However, only one large, nonrandomized prospective study (NCT01309256) has compared DVSS with laparoscopic gastrectomy. Accordingly, the study results mentioned above demonstrated that DVSS had higher operative time and cost than laparoscopic gastrectomy with no difference in morbidity, suggesting that DVSS might reduce cost-effectiveness[3]. Concurrently, robotic gastrectomy, which has been actively used for operable patients with resectable gastric cancer at the patient's own expense[2], was introduced at our institution in 2009. Analysis of patient outcomes following robotic gastrectomy had demonstrated that its morbidity was approximately one-fifth of that observed with

laparoscopic gastrectomy, with such a reduction in morbidity, including decreased incidences of postoperative pancreatic fistula, certainly improving the short-term postoperative course[2]. Moreover, our previous study had compared the oncological outcomes, particularly 3-year survival rates, between robotic gastrectomy and laparoscopic gastrectomy[2]. Thus far, only a few reports have investigated the oncological outcomes following robotic gastrectomy, considering that DVSS remains a relatively new technology. Therefore, the current study aimed to determine the prognostic factors of minimally invasive gastrectomy, including laparoscopic and robotic procedures.

MATERIALS AND METHODS

Patients

This single-center retrospective cohort study included patients who underwent curative gastrectomy for gastric cancer at our institution between January 2009 and September 2014. The inclusion criteria were patients with primary gastric adenocarcinoma who underwent curative resection using minimally invasive surgery (MIS). The exclusion criteria were patients with other synchronous cancer and those whose resection was limited due to poor physical functioning. Among the 939 patients who underwent gastrectomy for gastric cancer during the study period, 125 were excluded due to non-curative surgery (n = 77), other synchronous cancer (n = 2), remnant gastric cancer (n = 25), insufficient physical function (n = 13), and open gastrectomy (n = 8). Thus, the 814 patients who satisfied the study criteria were ultimately analyzed. The clinicopathological variables collected included age, sex, body mass index (BMI), American Society of Anesthesiologists (ASA) physical status classification, date of surgery, type of approach, histologic type, lymphovascular invasion status, TNM staging (Japanese Gastric Cancer Association classification, 14th edition), number of harvested lymph nodes, postoperative complications determined by Clavien–Dindo (C-D) classification[4], date of the first recurrence, and date and status of the last follow-up. The extent of gastrectomy and lymphadenectomy was defined based on Japanese gastric cancer treatment guidelines[5]. Overall survival (OS) was calculated from the date of resection to the date of the last follow-up or death of any cause. Recurrence-free survival (RFS) was calculated from the date of resection to the date of first recurrence, last follow-up, or death of any cause, whichever occurred first. Details regarding indications for radical gastrectomy, including the selection of laparoscopic or robotic approach, surgical procedures, perioperative management, adjuvant chemotherapy, and oncologic follow-up, have been previously reported[2]. Neoadjuvant chemotherapy (NAC) (S-1 80 mg/m^2 days 1-21 + CDDP 60 mg/m^2 day 8 or S-1 80 mg/m^2 days 1-28) was offered to patients with clinical T ≥ 2, tumor size ≥ 5 cm, and/or swollen locoregional lymph nodes ≥ 1.5 cm[2]. All patients were uniformly offered robotic surgery without considering their backgrounds, including physical and oncological status. Patients who agreed to the uninsured use of the surgical robot underwent robotic gastrectomy, whereas those who wished for insured treatment underwent laparoscopic gastrectomy[2]. All patients were completely involved in the decision-making process and provided informed consent prior to participation. All surgical procedures were performed or guided by surgeons qualified by the Japanese Society for Endoscopic Surgical Skill Qualification System, initiated in 2004 by the Japanese Society for Endoscopic Surgery to develop a tool for the reliable and reproducible evaluation of trainees' surgical techniques[6]. All procedures were supervised by an expert gastric surgeon (I.U.) who had performed more than 1500 Laparoscopic gastrectomies and 400 robotic gastrectomies. This study was approved by the institutional review board of Fujita Health University.

Statistical analysis

All statistical analyses were conducted using IBM SPSS Statistics 25 (IBM Corporation, Armonk, NY, United States). Long-term outcomes were analyzed using the Kaplan–Meier method with the log-rank test and Cox regression analyses. Considering our relatively small sample size, multivariate analysis was conducted using all variables determined to be significant (P < 0.1) during univariate analysis as independent variables. Data were expressed as median, interquartile range, or hazard ratio (HR) with the 95% confidence interval (CI) unless otherwise stated. A P value of < 0.05 (two-tailed) was considered statistically significant. Propensity score matching analysis was used to reduce selection bias with regard to potential confounding factors when establishing the laparoscopic and robotic groups. Possible confounders were

selected based on their potential association with the outcome of interest according to clinical knowledge. Therefore, clinicopathological characteristics (age, BMI, sex, ASA status, pathological T and N factor, type of surgery, tumor size, and NAC) were used to adjust differences between the laparoscopic and robotic groups through one-to-one pair matching using optimal match without replacement. Propensity scores were matched using a caliper width 1/5 Logit of the standard deviation. The absolute standardized difference was used to measure covariate balance, in which an absolute standardized mean difference above represented a meaningful imbalance[7]. Independent continuous variables were compared using the Mann–Whitney *U* test or Kruskal-Wallis test. Categorical variables were compared using the χ^2 test or Fisher's exact test.

RESULTS

Patient characteristics

Table 1 summarizes the characteristics of all patients included herein. Accordingly, the included patients had a median age of 68 years, among whom 31.4% (n = 256) were diagnosed with clinical stage II or more disease, while 14.6% (n = 119) underwent NAC. Laparoscopic and robotic gastrectomy was performed in 657 (80.7%) and 157 (19.3%) patients, respectively. None of the patients required intraoperative conversion to open procedure from MIS. Pathological stage II and III disease was diagnosed in 160 (19.7%) and 148 (18.2%) patients, respectively. Morbidity of C-D grade ≥ III was observed in 72 patients (8.8%).

Survival outcomes

The median follow-up period was 59.5 mo, while the 5-year OS and RFS were 80.3% and 78.2%, respectively (Figure 1A and B). Patients with pStage I, II, and III had a 5-year OS of 91.9%, 76.3%, and 43.7%, and a 5-year RFS of 91.6%, 74.7%, and 36.0%, respectively.

Factors related to survival

Univariate analysis identified age > 65 years, ASA status 3, total or proximal gastrectomy, D2 lymphadenectomy, tumor size > 30 mm, lymphovascular invasion, C–D grade ≥ III morbidity, NAC administration, adjuvant chemotherapy administration, and higher pT and pN status as factors significantly associated with OS (Table 2). However, multivariate analysis revealed that only age > 65 years [HR: 1.62 (1.09-2.40), P = 0.017], ASA status 3 [HR: 1.91 (1.18-3.10), P = 0.009], total or proximal gastrectomy [HR: 1.45 (1.03-2.05), P = 0.036], pT4 [HR: 4.31 (2.37–7.82), P < 0.001], and pN positive status were significantly and independently associated with OS (Table 2). Similarly, multivariate analysis identified age > 65 years [HR: 1.48 (1.02-2.14), P = 0.038], ASA status 3 [HR: 1.62 (1.02-2.60), P = 0.043], total or proximal gastrectomy [HR: 1.55 (1.12–2.15), P = 0.009], pT4 [HR: 4.20 (2.38–7.41), P < 0.001], and pN positive status as factors significantly and independently associated with RFS (Table 3). Moreover, multivariate analysis showed that robotic approach could likely be a positive predictor for RFS, although no significant association was observed [HR 0.68 (0.44-1.06), P = 0.088] (Table 3).

Survival outcomes following the laparoscopic and robotic approach

The laparoscopic and robotic approach had a 5-year OS of 79.4% and 83.4% (P = 0.243) and a 5-year RFS of 76.9% and 84.2% (P = 0.085), respectively. No significant difference in the 5-year OS and RFS was noted between both groups for patients with pStage I (91.6% *vs* 93.4%, P = 0.471 and 91.4% *vs* 92.7%, P = 0.634) (Figure 2A and B). Notably, among patients with pStage II/III, those in the robotic group had significantly better RFS compared to those in the laparoscopic group (74.1% *vs* 51.7%, P = 0.006) (Figure 2D), although no significant difference in the 5-year OS was observed (P = 0.071) (Figure 2C).

Factors associated with survival in pStage II/III diseases

Our analysis showed that pT4 [HR: 4.02 (1.21-13.42), P = 0.024] and pN positive status were significantly and independently associated with OS. Notably, univariate analysis showed that robotic gastrectomy (P = 0.007), total or proximal gastrectomy (P = 0.004), tumor size > 30 mm (P = 0.014), pT4 (P = 0.007), and pN positive status were significantly associated with RFS. Meanwhile, multivariate analysis found that robotic

gastrectomy was independently and positively associated with RFS [HR: 0.56 (0.33–0.96), P = 0.035]. Apart from robotic gastrectomy, only pT4 and pN positive status were identified as factors independently associated with RFS (Table 4).

Comparison between robotic and laparoscopic gastrectomy in pStage II/III diseases

To account for confounding factors between both groups, propensity score matching was performed (Table 5). In the prematched cohort of 308 patients with pStage II/III disease, 67 and 241 patients belonged to the robotic and laparoscopic groups, respectively. After matching, each group comprised 61 patients. The matched cohort had a considerably better balance of covariates, with < 0.245 of the cutoff value of an absolute standardized difference. In the postmatched cohort, no differences in clinicopathological variables were observed between the laparoscopic and robotic groups, although the robotic group had lower morbidity (4.9% *vs* 16.4%, P = 0.04) (Table 5). Furthermore, the robotic group had significantly better 5-year OS (70.4% *vs* 50.2%, P = 0.039) and RFS (74.1% *vs* 44.5%, P = 0.005) than the laparoscopic group in the postmatched cohort (Figure 3A and B).

DISCUSSION

The current study clearly identified factors related to survival in patients with gastric cancer who underwent MIS, subsequently presenting three significant findings.

First, the present study highlighted the feasibility and safety of MIS for gastric cancer as determined by the 5-year outcomes. While the long-term outcomes of laparoscopic surgery have been increasingly reported in recent years, only a few studies have investigated the long-term outcomes of the robotic approach[2,8,9]. Consistent with previous studies, including those from our group, the current study demonstrated no significant difference in OS and RFS between the laparoscopic and robotic approaches [2,8,9]. However, among patients with pStage II/III, those in the robotic group demonstrated significantly better RFS than those in the laparoscopic group (P = 0.006).

Second, our results showed that pT and pN status was independently associated with both OS and RFS. Currently, multidisciplinary treatment for gastric cancer utilizing various chemotherapeutic options has been developed worldwide. In Western countries, neoadjuvant and adjuvant chemotherapy combined with curative resection has been the standard treatment for advanced gastric cancer[10,11], whereas adjuvant chemotherapy following curative resection remains the standard approach in Japan[5]. Regardless of treatment options, however, evidence has shown that the pN factor is consistently strongly associated with survival following gastric cancer treatment[12-14]. The results of the current study are consistent with those presented

in previous studies.

Third, the use of the surgical robot was significantly associated with improved RFS among propensity score-matched patients with pStage II/III disease. This could have been attributed to lower morbidity in the robotic gastrectomy group, a causal relationship between morbidity and survival, and higher morbidity in patients undergoing surgery for advanced disease. First, a few studies have shown that robotic gastrectomy was technically safe and feasible but did not have superior morbidity compared to the laparoscopic approach[3]. However, Wang *et al*[15] who compared morbidity between robotic and laparoscopic gastrectomy using propensity score-

matched analysis, reported that the robotic group exhibited significantly lower morbidity, particularly with regard to infectious complications (*e.g.*, anastomotic leakage and intra-abdominal abscess)[15]. Furthermore, a multicenter, prospective, single-arm study by our group recently reported that robotic gastrectomy promoted lesser morbidity than laparoscopic gastrectomy among historical controls[2]. Similarly, the present study showed that the robotic group had significantly lesser morbidity compared to the laparoscopic in the postmatched cohort. Second, several studies have demonstrated that morbidity was associated with worse survival in gastric cancer[16-19]. In fact, Jin *et al*[16] reported that patients with and without postoperative complic-

ations had RFS rates of 23% and 40%, respectively ($P < 0.001$). Third, advanced gastric cancer requires complicated procedures, which can cause more complications. Notably, studies have reported that patient with advanced disease had morbidity rates of 8.3%-15.2% following minimally invasive gastrectomy, respectively[20,21]. The aforementioned findings therefore indicate that utilizing surgical robots, which cause less morbidity, might at least partly contribute to the better RFS in patients with advanced gastric cancer, suggesting that surgical robots may be more beneficial for patients with advanced disease. However, although univariate analysis found morbidity to be significantly associated with RFS, multivariate analysis did not identify the same as a significant independent factor associated with RFS in the entire cohort. As such, further investigations are warranted to confirm such findings.

The current study has several limitations worth noting. First, this study was retrospective in nature and involved only a single institution. Moreover, the sample

size, particularly that of the robotic group, was relatively small. Therefore, given that biases may exist in our data, the overall results should be interpreted with caution. As described in our previous reports[2,6], patients were selected according to whether the they agreed to the uninsured use of robot-assisted surgery, which may have caused

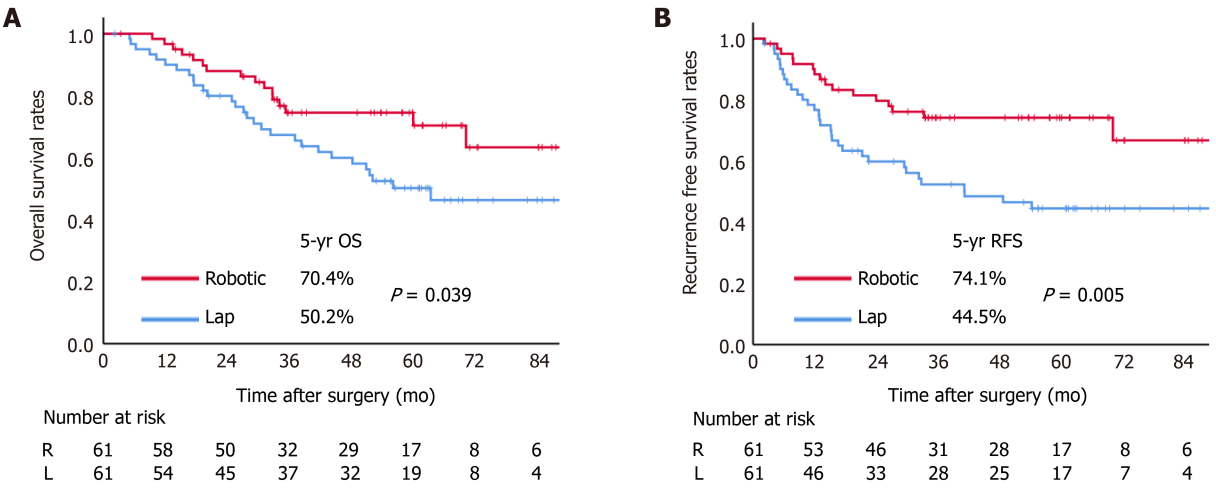

Figure 3 Kaplan-Meier curves. Kaplan-Meier estimates in the postmatched cohort. A: Overall survival probability; B: Recurrence-free survival probability. OS: Overall survival; RFS: Recurrence-free survival.

selection bias due to a possible preference for robotic gastrectomy in patients of higher economic status. However, this was an inherent limitation at the time of study enrollment considering that the DVSS was not covered by the medical insurance in Japan at the time the enrolled patients underwent gastrectomy, whereas conventional laparoscopic gastrectomy was covered. Second, propensity score matching between the laparoscopic and robotic group did not account for adjuvant chemotherapy administration given that, similarly to postoperative complications, adjuvant chemotherapy was determined after robotic or laparoscopic gastrectomy was conducted. Considering that both adjuvant chemotherapy and postoperative complications may affect prognosis[2,6,21], well-designed prospective trials are needed to determine a cause-effect relationship between robotic or laparoscopic gastrectomy and postoperative complications, as well as adjuvant chemotherapy administration.

CONCLUSION

In conclusion, the current study identified age, ASA status, type of gastrectomy, and pathological T and N status are prognostic factors of minimally invasive gastrectomy for gastric cancer. Moreover, the use of robotic assistance was associated with reduced early morbidity, as well as potentially better oncological outcomes in advanced gastric cancer.

ARTICLE HIGHLIGHTS

Research background

Minimally invasive surgery (MIS) including laparoscopic and robotic approaches for gastric cancer has been increasingly used because of its beneficial short-term effects over the open approach. However, oncological outcomes are not established.

Research motivation

There have been few reports on the oncological outcomes of MIS for gastric cancer patients, especially for the robotic approach, because a surgical robot remains a relatively new technology. Therefore, this study aimed to determine the prognostic factors of minimally invasive gastrectomy, including laparoscopic and robotic approaches.

Research objectives

This study aimed to determine the prognostic factors of minimally invasive gastrectomy, including laparoscopic and robotic approaches.

Research methods

This single-institutional retrospective cohort study included 814 consecutive patients with primary gastric cancer who underwent minimally invasive R0 gastrectomy between 2009 and 2014. We retrospectively examined 5-year overall survival and recurrence-free survival and investigated factors related to survival.

Research results

Age > 65 years, American Society of Anesthesiologists (ASA) physical status 3, total or proximal gastrectomy, and pathological T4 and N positive status were independent predictors of overall survival and recurrence-free survival. The five-year overall survival and recurrence-free survival were 80.3% and 78.2%, respectively. Of all 814 patients, 157 patients (19.3%) underwent robotic gastrectomy and 308 (37.2%) were diagnosed with pathological stage II or III disease. Robotic gastrectomy was an independent positive predictor for recurrence-free survival in pathological stage II/III patients (hazard ratio: 0.56 [0.33-0.96], P = 0.035). Comparison of recurrence-free survival between robotic and laparoscopic approach using propensity score matching analysis verified that with less morbidity in the robotic group (P = 0.005).

Research conclusions

Age, ASA status, type of gastrectomy, and pathological T and N status were prognostic factors of minimally invasive gastrectomy for gastric cancer, and the use of a surgical robot may improve its long-term outcomes for advanced gastric cancer.

Research perspectives

Future studies to better prove the efficacy of robotic gastrectomy for advanced gastric cancer patients are warranted.

Abstract

BACKGROUND

Uncontrolled growth and loss of control over basic metabolic functions, leading to invasive proliferation and metastases, are the salient traits of malignant tumors in general and colorectal cancer in particular. Invasion and metastases hinder effective tumor treatment. While surgical techniques and radiotherapy can be used to remove tumor focus, only chemotherapy can eliminate dispersed neoplastic cells. However, the efficacy of the latter method is limited in the advanced stages of the disease. Therefore, recognition of the mechanisms involved in neoplastic cell spreading is indispensable for developing effective therapies.

AIM

To use a number of biomarkers involved in cancer progression and identify a panel that could be used for effective early diagnosis.

METHODS

We recruited 185 patients with colorectal adenocarcinoma (98 men, 87 women with median age 63). Thirty-five healthy controls were sex and age-matched. Dukes' staging was as follows: A = 22, B = 52, C = 72, D = 39. We analyzed patients' blood serum before surgery. We determined: (1) Cathepsin B (CB) with Barrett's method (fluorogenic substrate); (2) Leukocytic elastase (LE) in a complex

with alpha 1 trypsin inhibitor (AAT) using the immunoenzymatic MERCK test; (3) Total sialic acid (TSA) with the colorimetric periodate-resorcinol method; (4) Lipid-bound sialic acid (LASA) with the colorimetric Taut's method; and (5) The antitrypsin activity (ATA) employing the colorimetric test.

RESULTS

In patients, the values of the five biochemical parameters were as follows: CB = 16.1 ± 8.8 mU/L, LE = 875 ± 598 μg/L, TSA = 99 ± 31 mg%, LASA = 0.68 ± 0.33 mg%, and ATA = 3211 ± 1504 U/mL. Except for LASA, they were significantly greater than those of controls: CB = 11.4 ± 6.5 mU/L, LE = 379 ± 187 μg/L, TSA = 71.4 ± 15.1 mg%, LASA = 0.69 ± 0.28 mg%, and ATA = 2016 ± 690 U/mL. For CB and LASA, the differences between the four Dukes' stages and controls were not statistically significant. The inter-stage differences for CB and LASA were also absent. The receiver operating characteristic (ROC) analysis revealed the potential diagnostic value of CB, TSA, and ATA. The area under ROC, sensitivity, and specificity for these three parameters were: 0.85, 72%, 90%; 0.75, 66%, 77%; and 0.77, 63%, 84%, respectively. The sensitivity and specificity for the three-parameter panel CB-TSA-ATA were equal to 88.2% and 100%, respectively.

CONCLUSION

The increased value of CB, TSA, and ATA parameters are associated with tumor biology, invasion, and metastasis of colorectal cancer. The presented evidence suggests the potential value of the CB-TSA-ATA biochemical marker panel in early diagnostics.

Core Tip: We searched for biomarkers applicable to the early detection of colorectal adenocarcinoma. Five parameters were determined in sera of patients and healthy individuals: Cathepsin B activity, total sialic acids concentration, lipid-associated sialic acids concentration, elastase concentration, and alpha 1 antitrypsin activity. We performed receiver operating characteristic analysis for single and multiple parameters. While the sensitivity and specificity were not very high for single parameters, the combined analysis of cathepsin B, alpha 1 antitrypsin, and total sialic acids concentration yielded 88% sensitivity and 100% specificity. We believe that this set of markers can be useful in clinical practice.

INTRODUCTION

The process of neoplastic invasion consists of two main stages: Penetration of tissues surrounding cancer and creation of metastases in places distant from the original location. During migration, cancer-transformed cells encounter anatomical barriers: The basement membrane and connective tissue. Cathepsins play an important role in the process of overcoming them.

Under normal conditions, cathepsins do not occur extracellularly or appear outside the cell only in small quantities. Their main function is to participate in processes related to the "turn-over" of endogenous proteins and degradation of exogenous proteins absorbed in the process of endocytosis[1-4]. In smaller concentrations, *e.g.*, in extralysosomal spaces, the enzymes can catalyze — by means of limited proteolysis — posttranslational processes of conversion of many peptides and proteins, including

growth factors and hormones such as albumins, insulins, endorphins, and enkephalins [5,6]. The release of cathepsins from cancer cells and their expression in the plasma membrane of cancer cells facilitates the dissolution of the basement membrane and participation in the proteolytic metastatic cascade. In clinical practice, a significant increase in the activity of cathepsin B (CB) is observed in the serum of patients with malignant tumors. This phenomenon occurs regardless of the location of the tumor and is closely related to the severity of ovarian, cervical, breast, laryngeal and colorectal cancer. It was also found that the activation of CB, which takes place with the participation of elastase coming from the neutrophil intumescence and tumor tissue, has an impact on its invasiveness and metastatic capacity. Studies have also confirmed that an increase in cathepsin expression in colorectal tumor tissue homogenates may be a sensitive marker for cancer progression[7-16].

Leukocytic elastase (LE) belongs to the group of serine proteases. It is located mainly in the azurophilic granules of neutrophils, where it is an active component of the phagocytic system along with other hydrolyses and reactive oxygen species. The enzyme is also cytochemically detected in the nuclear membrane, the Golgi complex, endoplasmic reticulum, and mitochondria[17,18]. It also participates in remodeling and tissue repair processes and modulates the activity of cytokines and their receptors (*e.g.*, mitogen-activated protein kinase 3). It can degrade elements of connective tissue by hydrolysis of elastin, various types of collagen, and other extracellular matrix proteins such as fibronectin, laminin, or proteoglycans. The physiological regulation of the activity and prevention of potentially destructive effects of elastase in pathological states is caused by protein inhibitors present in the blood serum. They include alfa 1 trypsin inhibitor (AAT), alpha 2-macroglobulin (alpha-2-MG), a secretory leukocytic protease inhibitor (SLPI), and elaphin[19-21]. In a healthy organism, LE remains in balance with them, and after the secretion from the cells, it is directly bound by inhibitors. The inhibitor molecules are thermally very stable and do not undergo proteolysis. Increased levels of LE in blood plasma, most often determined as LE-AAT complexes, have been found in many associated inflammatory conditions and are therefore considered acute-phase factors. Many authors regard the concentration of the above complexes to be a measure of the activity of the inflammatory process itself and be a marker of stimulation of neutrophils in the inflammatory focus. Lowering the level of AAT, caused by genetic or environmental factors, enables uncontrolled elastase activity and leads to many serious pathological conditions. This is caused by the enzyme-inhibitor imbalance and overexpression of the enzyme or a decrease in inhibitor concentration.

Sialic acid (N-acetyloneuraminic acid, NANA) is an organic compound from the sugar group, a derivative of neuraminic acid. It is a sugar component of glycoproteins and glycolipids. It occupies a terminal position in carbohydrate glycoprotein residues and has an important function in cell physiology as well as in the metabolism and maintenance of the proper concentration of glycoproteins in serum. It is also part of the ligand for the selectin and lectin receptors on leukocytes, T lymphocytes, platelets, and endothelium. It plays a key role in the immune response and hemostasis[22].

In the blood of patients suffering from metabolic disorders (*e.g.*, diabetes mellitus, atherosclerosis), a clear increase in the glycoprotein fraction is observed, while the sialic acid content remains low. In the case of cancer, the level of glycoproteins that contain normal or increased amounts of sialic acid increases in the blood. Increased sialisation is associated with the development of a neoplastic tumor and malignant cell metastasis. An increase in sialic acid concentration is observed in the case of malignant melanoma, lung, larynx, breast, ovary, prostate, liver, or colorectal cancer. It has been shown that the sialyltransferase activity in blood serum taken from people with cancer is increased and reaches its highest concentration at advanced stages of cancer development. The main areas of protein glycosylation include the endoplasmic reticulum and Golgi apparatus[23]. During the transformation of normal cells into cancer cells, there are significant differences in the biosynthesis of the sugar parts of proteins and membrane lipids. These changes are primarily of a qualitative nature. The external part of the plasma membrane of cancer cells has an increased number of sialic acid molecules compared to normal cells. Glycoproteins rich in sialic acids are more frequently found in case of metastatic cancer. The increased level of sialoglycoproteins and sialoglycolipids in neoplasms is mainly due to increased disintegration of cancer cells, increased synthesis and secretion of glycoconjugates (glycoproteins and glycolipids) containing sialic acid[24-32].

Recently, many works have been published on the activity of proteolytic enzymes and their inhibitors in blood serum. However, they do not solve all the problems related to the diagnostic and prognostic usefulness of these parameters in neoplastic diseases.

In this study, a statistically consistent group of colorectal cancer patients was collected: Women and men. The division of colorectal cancer into the colon and rectal cancer, histopathological criteria (adenocarcinoma), a clinical division system based on Dukes' cancer staging were considered.

The study presented below has both basic and diagnostic-clinical nature. The results of the study may be used in the future in the complementary diagnosis of colorectal adenocarcinoma to determine the severity of the disease and in further monitoring of patients under outpatient control and prognosis.

MATERIALS AND METHODS

Patients

One hundred and eighty-five patients were recruited from the Lower Silesian Oncology Center and the Provincial Specialist Hospital in Wroclaw. The study material presented in this paper was blood serum from patients with colorectal adenocarcinoma. The patients' blood serum was examined before surgery.

The examined patients were evaluated in terms of their age, sex, location of neoplastic lesions (colon, sigmoid colon, rectum), histopathological differentiation of neoplastic cells (G), and their clinical stages were based on the Dukes' classification. The characteristics of the examined patients are summarized in Table 1.

Biochemical measurements

The following tests were performed in blood serum according to the methods given below: (1) CB was determined with the use of fluorogenic substrate using the Barrett method[33]; (2) LE in a complex with AAT was determined immunoenzymatically using the MERCK test; (3) Total sialic acid (TSA) was determined colorimetrically using the periodate-resorcinol method, according to Jourdian *et al*[34]; (4) Lipid-bound sialic acid (LASA) was determined colorimetrically using Tautu *et al*[35]; and (5) The antitrypsin activity (ATA) in blood plasma (in the study referred to as antitrypsin capacity — ATA) was determined colorimetrically against trypsin using the method proposed by Warwas *et al*[36] and Dietz *et al*[37].

Statistical analysis

The examined continuous features were characterized by the distribution parameters of these features, *i.e.*, mean value (M), standard deviation (SD), and the number of patients (*n*). For the analysis of the statistical material, the following were used: For continuous features — single-factor analysis of variance (ANOVA), using Tukey's *post hoc* tests and multi-factor analysis of variance (MANOVA). The t-Student's *t*-test was also used for dependent samples. For features deviating from the normal distribution, which were also characterized by a median value, non-parametric tests were used: For independent samples — the Mann-Whitney *U* test, and for dependent samples — the Wilcoxon test. For categorized or dichotomous features, the χ^2 test and the non-parametric Kruskal-Wallis test were used. The relationship between these features was also studied by determining the Spearman correlation coefficient. The receiver operating characteristic (ROC) curve method was used to determine the threshold values of clinical markers (continuous variables) with optimal precision. The significance threshold *P* for all statistical tests was set to 0.05. The statistical analysis was conducted using Statistica v. 10.

RESULTS

Table 2 presents the results of biochemical parameters examined, their M, SD, *n*, including the group of colorectal cancer patients and the control group of healthy individuals.

In the group of patients with colorectal cancer, differences were observed in the values of examined biochemical parameters in blood serum compared to the control group. Despite clear changes in the levels and activity of the studied factors, not in all groups, these differences were statistically significant. Relevance was observed between patient groups suffering from colorectal cancers and the control group for CB, LE, TSA, and ATA.

Table 3 presents statistically significant differences between the examined groups of patients according to Dukes' classification and the control group. There were no

significant differences for CB and LASA ($P > 0.05$), while the differences for other parameters were: LE ($P < 0.001$), TSA ($P < 0.001$), ATA ($P < 0.01$).

Table 4 presents a comparison of statistically significant differences between individual parameters in the patient groups (A, B, C, D, according to Dukes' classification) and control group. There were statistically significant differences for all groups except for group A. Statistically significant differences between patient groups were also being observed. For LE, the most statistically significant difference was observed between groups C and D ($P < 0.002$). For TSA, the difference was most strongly pronounced for A and D ($P < 0.05$). There were no stage differences for ATA.

In Table 5 the correlations between in main parameters are summarized. The values of all the above-mentioned correlation coefficients were positive except for CB and ATA and LASA and ATA. The highest correlations were observed between CB and ATA; LE and TSA; TSA and ATA ($P < 0.001$).

No statistically significant differences in the examined parameters in respect to histopathological differentiation of tumor cells (G1, G2, G3) were observed (data not shown).

The examined biochemical factors in the blood serum were also examined using ROC analysis. The analyses are summarized in Figure 1. The highest diagnostic value was observed for a single value for CB in blood serum, with a threshold value of 11.22 mU/L. The sensitivity of the method was 72%, and its specificity was 90%. Then, respectively: for TSA, with a threshold value of 75.34 mg% — 66% and 77%; for LASA with a threshold value of 0.562mg% — 80% and 41%; for LE with a threshold value of 543 μg/L — 49% and 89% and ATA in blood serum with a threshold value of 2400 U/mL — 63% and 84%.

The analysis of the ROC curves of the two associated parameters has shown that the connection between CB and TSA gives a sensitivity of 73% and a specificity of 100%, with a value under the curve reaching 95%.

Table 2 Characteristics of the tested biochemical parameters in blood serum in all patients and in the control group

No.	Biochemical parameters tested	Groups	ABCD	K	Significance level *P* value
1	CB, mU/L	M	16.1	11.4	< 0.050
		n	185	35	
		SD	8.8	6.5	
2	LE, μg/L	M	875.1	379.1	< 0.001
		n	51	30	
		SD	597.9	187.3	
3	TSA, mg%	M	98.9	71.4	< 0.001
		n	71	31	
		SD	30.8	15.1

		n	68	35	
		SD	0.33	0.28	
5	ATA, U/mL	M	3211.4	2015.9	< 0.001
		n	74	29	
		SD	1504.1	689.6	

ABCD: All patients with colorectal adenocarcinoma; ATA: Antitrypsin activity; CB: Cathepsin B; K: Control group; LASA: Lipid-bound sialic acid; LE: Leukocytic elastase; M: Mean value; NS: Not significant; TSA: Total sialic acid.

Combining three parameters for the ROC curve: CB, TSA, and ATA, in blood serum, gives a sensitivity of 88% and a specificity of 100%, respectively, with a value of area under the curve of 95%.

In conclusion, ROC analysis has a high diagnostic value and can be helpful, especially in the combined analysis (biomarker panel determination).

DISCUSSION

The ability of the tumor to invade and metastasize is associated, among other pathogenic issues, with an increase in the expression of cysteine peptides. The source of these enzymes may be, in addition to the neoplastic tissue, neutrophils infiltrating the tumor. It is believed that CB determination may be helpful in the diagnosis and monitoring of colon and rectal cancer therapy[38-40].

In our study, the average CB activity determined in the blood serum of patients with colorectal cancers using a synthetic Z-Arg-Arg-N-MC substrate was about 1.5 times higher than that of healthy individuals ($P < 0.05$). Statistically significant results were obtained in the group of patients with different degrees of clinical advancement (ABCD: $P < 0.05$) (Table 2 and Figure 1A). On the other hand, CB did not statistically significantly differentiate patients according to Dukes' staging of colorectal cancer (A, B, C, D), although the average values in patients exceeded the average values in the control group (Table 3). Among other parameters, CB correlated only with ATA ($P < 0.001$) (Table 5).

The activity of CB in serums of patients with colon and rectal cancers was also studied by other authors. Dufek *et al*[41] observed a fivefold increase in this parameter. It was found that the CB activity in patients with colon and rectal cancers was significantly higher than in patients with polyps and in healthy individuals. This difference may be due to the use of the other substrate (Z-Ala-Arg-Arg-N-MC), which may also have been hydrolyzed by other proteases. These studies have also shown a high level of alkali-stable form of CB. In people with mild lesions (polyps) and in healthy people, the level of this form did not reach the threshold of determination. After the effective treatment, CB levels decreased significantly and increased again in case of metastases or resistant chemotherapy.

Table 3 Characteristics of biochemical parameters in patients' blood serum in relation to the severity according to the Dukes' classification

Dukes' classification system for colorectal cancer: A, B, C, D: All patients with colorectal adenocarcinoma; ATA: Antitrypsin activity; CB: Cathepsin B; K: Control group; LASA: Lipid-bound sialic acid; LE: Leukocytic elastase; M: Mean value; NS: Not significant; TSA: Total sialic acid.

Kos *et al*[40] also observed the fivefold increase in CB concentration using immune-enzymatic method. The CB level correlated well with stage C and D of Dukes' staging system. As in our research, no correlation between CB and age or gender was observed. However, it should be stressed that the antibodies used in this method detected both the active and non-active precursor form of this enzyme and their complexes with inhibitors, such as cystatins.

Similar studies on the proteolytic activity of blood serum with colon and rectal cancer were performed by Amiguet *et al*[42]. Similar to our research, the proteolytic activities of CB and elastase, were determined. Patients in Dukes' B and D stages were examined. The activities of the examined proteases were increased in relation to the control group of healthy individuals. In Dukes' stage D, the increase in CB levels was directly proportional to the weight of the tumor. In metastatic carcinomas, the increase in CB was accompanied by an increase in AAT concentration.

Padilla *et al*[43] showed, with the use of the immunoreactive method, that CB levels in colorectal cancer patients were different from the control group.

Clinical and pathological evaluation of patients with the use of serum CB and cathepsin D, based on the TNM system before and after the operation, was performed by Skrzydlewska *et al*[44]. The CB activity before the cancer tumor resection was significantly higher. However, in relation to the control group, both before and after the procedure, the CB activity was approximately 8.4 times lower. The authors concluded that the postoperative level of CB was associated with the involvement of the surrounding lymph nodes and higher when not accompanied by lymph node involvement. However, a relatively non-specific Z-Arg-pNA substrate was used to test the CB activity, and thus the observations might have been biased by the activity of other proteases.

Zore *et al*[45] examined CB levels in the complex with cystatin C using the ELISA method. Their observations show that CB in the Dukes' CD stage was significantly lower than in the AB stage (P = 0.02). Our study did not observe any significant differences between these groups (the results are not presented). The inhibitory capacity of cystatin C does not compensate for the increase in CB levels in patients suffering from colorectal cancers. This supports the hypothesis that inhibitory capacity might have been impaired during colorectal cancer progression.

Values of linear correlation coefficients between concentrations or activities of the studied biochemical parameters (number of the examined). Description of other parts as in Table 2. ATA: Antitrypsin activity; CB: Cathepsin B; LASA: Lipid-bound sialic acid; LE: Leukocytic elastase; TSA: Total sialic acid.

Cysteine proteases — CB and cathepsin L levels in blood serum in patients with colorectal cancer were studied by Herszényi *et al*[46], who used the ELISA method for this purpose. CB correlated with the progressive Dukes' scale, reaching a 2.3 times higher level in patients compared to the control group. Analysis of the ROC curve confirmed the diagnostic importance of the examined factors, including CB. The sensitivity and specificity in the ROC analysis of CB were similar to the results obtained in our study (72 and 89% respectively *vs* 82 and 88%, and the areas under the ROC curve 0.85 *vs* 0.87), thus confirming the high diagnostic value of the studied parameter. Comparing CB with other biochemical parameters such as TSA and ATA in the ROC analysis results in an even higher level of sensitivity and specificity. Also, other researchers noticed that proteolytic enzymes are excellent indicators for colorectal cancers, often better than the commonly used tumor markers[47].

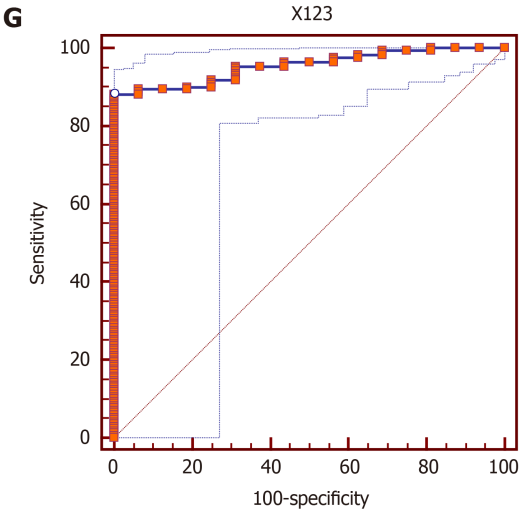

Figure 1 Diagram of receiver operating characteristic curve. A: For cathepsin B (CB). Threshold value of > 11.22 mU/L yielded sensitivity of 72.3% and specificity of 90%. Area under the receiver operating characteristic curve = 0.85; B: For total sialic acid (TSA). Threshold value > 75.34 mg% yielded sensitivity of 65.8% and specificity of 76.9%. Area under the receiver operating characteristic curve = 0.75; C: For lipid-bound sialic acid (LASA). Threshold value > 0.739 mg% yielded sensitivity of 79.7% and specificity of 40.6%. Area under the receiver operating characteristic curve = 0.56; D: For leukocytic elastase (LE). Threshold value > 543 μg/L yielded sensitivity of 49.2% and specificity of 88.5%. Area under the receiver operating characteristic curve = 0.56; E: For antitrypsin activity (ATA). Threshold value > 2400 U/mL yielded sensitivity of 63.2% and specificity of 84.0%. Area under the receiver operating characteristic curve = 0.77; F: For the combined two biochemical parameters. Threshold value > 0.4757 yielded sensitivity of 73.4% and specificity of 100%. Area under the receiver operating characteristic curve = 0.91; G: The three parameters combined (X123): CB, TSA, and ATA. Threshold value > 1.3457 yielded sensitivity of 88.2% and specificity of 100%. Area under the receiver operating characteristic curve = 0.95.

The imbalance of protease/inhibitors ratio is particularly relevant for LE and AAT involvement in the pathogenesis of cancer. The level of AAT, an acute-phase protein, increases in cancer patients in response to the increased levels of proteolytic enzymes released from leukocytes into circulation. In patients, despite an increase in their levels, the functional activity of the inhibitor decreases, thus disturbing the LE/AAT balance. This imbalance is further exacerbated by the fact that membrane forms of proteases, such as CB or elastase are more resistant to these inhibitors. Moreover, LE has itself ability to degrade those inhibitors[48]. A disturbed balance between LE and AAT may be associated with an increased risk of liver, cholecystitis, bladder, lymphoma, or lung cancer[49-55]. Apart from AAT, other protein inhibitors present in the blood serum are also responsible for the physiological regulation of LE: α2MG, SLPI, or elaphin. SLPI, as it is clear from the work by Sugino *et al*[54], performed in various types of cancer, including colorectal cancer, has a dual effect. On the one hand, it suppresses the invasion of neoplastic cells, and on the other hand, it promotes metastasis that transmits through blood circulation.

The inclusion of serum ATA and LE, as indicated by the results of our research, may be a factor informing about the balance of serine proteases.

LE in all listed patient groups according to the Dukes' classification: Combined ABCD stages and A, B, C, D stages separately (Table 2 and Figure 1D), shows a clear statistically significant difference when compared to the control group. Its activity reached the highest values in groups B and D. It is possible that it is associated with subsequent stages of cancer spread and the presence of metastatic foci rich in granulocytic intumescence, increased elastase-induced adhesion of cancer cells to the endothelium of vessels, or through mitogenic activity[56,57].

The different activity of serum elastase, in successive stages of the disease according to the Dukes' classification eliminates the possibility of using this parameter for early diagnosis in colorectal cancers. In addition, serum elastase is characterized by relatively low sensitivity in the ROC analysis (49%) (Figure 1D). On the other hand, some authors have found it as a putative diagnostic biomarker and also a potential therapeutic target[58].

AAT is a blood plasma protein belonging to α_1-globulin fraction, one of the strongest inhibitors of circulating serine proteases (serpins). It is also an acute-phase protein, synthesized mainly in the liver but also by macrophages. AAT has the ability to inactivate many proteolytic enzymes, but its most important effect is the inactivation of LE released by neutrophils as a result of an inflammatory reaction.

In our study, statistically significant ($P < 0.001$) elevated ATA levels were observed in the cumulative group of patients, regardless of the Dukes' classification stage (ABCD) in relation to the control group. In the B, C, and D stages, in relation to the control, these levels were highly statistically significant ($P < 0.001$; $P < 0.004$; $P < 0.001$). Also, ATA differentiated very well patients with Dukes' stages B against C and C against D ($P < 0.05$ and $P < 0.002$, respectively). In our ROC analysis, with the cut-off value > 2400 U/mL, the ATA value reached the sensitivity of 63% and specificity of 84%, respectively. The listed sensitivity and specificity parameters are lower than in the ROC analysis for CB (72% and 90%, respectively).

There is little clinical work on the contribution of AAT to the diagnosis or monitoring of the treatment of colorectal cancer[59-64]. Yüceyar *et al*[65] and Gallardo-Valverde *et al*[66] did not find relationship between the AAT and the severity of colorectal cancer and showed a statistically significant correlation between AAT and other biochemical factors such as acute-phase protein, carcinoembryonic antigen (CEA), or tumor-associated trypsin inhibitor (TATI).

Bernacka *et al*[67] studied plasma levels of AAT in patients with gastrointestinal cancers: Stomach and colorectal cancers of adenocarcinoma type. This marker did not differentiate colorectal cancer patients in terms of local and metastatic lesions. However, it had the highest level in stage C and differentiated patients in terms of the histological degree of tumor stage (G). The author postulates that AAT levels are associated with increased production by liver cells in response to the increased release of lysosomal proteases of tumor cells or from mononuclear inflammatory tumor-infiltrating cells. It seems that tumor cells may be the third source of antiproteases.

Ward *et al*[68], using proteomic profiling, identified AAT as having the potential to classify the colorectal patients with 95% sensitivity and 91% specificity.

Interesting conclusions were drawn from the work of Bujanda *et al*[64], who studied a group of 42 colorectal cancer patients using combined AAT, matrix metalloproteinase 7 (MMP-7), urokinase-type plasmin activator receptor (uPAR), and cyclooxygenase-2 (COX-2). Compared to the control group, AAT levels were about 1.4 times higher at stages B and C, and the AAT level was high and reached its value under the ROC curve (0.88). The above results are similar to those obtained in our study. The level under the ROC curve was 0.77. In patients in stages B and C, ATA levels were 1.5 and 1.6 times higher, respectively, than in the control group. AAT has a promising diagnostic profile and, most importantly, at the early stages of colorectal cancer.

The neoplastic process is associated not only with the activation of the cascade system of proteolytic enzymes, the activation of which mainly takes place with the participation of CB and LE, but also induces the activation of acute-phase proteins.

The interest in the sialic acids (TSA, LASA) as markers useful in diagnosing and monitoring the course of many diseases, including colorectal cancer, is reflected in the publications briefly reviewed in[69-72]. Increased levels of sialic acid expression are associated with changes in biosynthesis and posttranslational processes of acute-phase proteins glycosylation in the liver. This phenomenon is associated with increased expression of sialyltransferases by cancer cells[73]. The mechanism of increased TSA levels in serum takes the following into account: (1) Spontaneous release of the compounds from the surface of cancer cells; (2) Increase in concentration and/or glycosylation of serum glycoproteins; and (3) Secondary inflammatory reaction associated with the increase in acute-phase proteins[32,74]. Increased sialyltransferases activities, observed in cancer cells, results in increased glycoprotein secretion as well as the secretion of cell membrane components into the culture medium. The cancer cell hypoxia may also contribute to the above[75]. Increased sialisation of glycosphingolipids leads to abnormal adhesion and a disturbed premembranous signal exchange [75]. Determination of sialic acids is a laboratory marker of many pathological lesions. A significant increase in serum levels of sialic acids was observed in many malignant diseases[76]. Elevated levels of TSA or LASA were observed in malignant melanoma, lung, breast, ovary, and laryngeal cancers[28,32,77], as well as in colorectal cancer[26,31,70,78-82].

In our study, TSA in blood serum was elevated and statistically significantly different from the control group. The above observation concerns the cumulative group of patients (ABCD: $P < 0.001$) as well as individual groups (B, C, D in relation to the control: $P < 0.001$; $P < 0.003$; $P < 0.001$ respectively). The lowest level among patients was found in group A, and the highest in group D. The above clearly shows differences between particular patient groups. TSA was only less effective than ATA. The TSA level moderately but statistically significantly correlates with LE and ATA. The results of the ROC analysis are interesting. With a cut-off value for TSA > 75.34 mg%, the sensitivity of the method was 66%, and its specificity was 77%. In ROC analysis TSA clearly benefits when combined CB with the same cut-off values)

sensitivity 74% and specificity 100%were obtained. The sensitivity further increases if we also take the ATA into account, which is also studied by the authors and reflects the AAT level. In the TSA test, the main component determined is the sialic acid associated with proteins. The level of sialic acids increases in the sera of cancer patients as a result of increased concentration of acute-phase proteins rather than gangliosides from decaying cancer cells[65,74,75,83].

CONCLUSION

We have found a statistically significant increase in the CB activity in the blood serum of the examined individuals suffering from colorectal cancers. The highest CB level was observed in Dukes' stage A patients, and in stages B, C and D, it was lower and comparable to each other.

Concordantly, the following increased concentrations in blood serum of investigated markers were observed: LE, TSA, and ATA. According to Dukes' classification, these values were statistically significantly increased with respect to the control group, gradually rising from the A to D stage.

The ROC analysis showed the high diagnostic value of CB, TSA, ATA determinations in blood serum, both in the single and combined analysis (biomarker panels) with two biochemical parameters: CB and TSA, and with three parameters: CB, TSA, and ATA. The above results suggest high diagnostic usefulness in determining these 2 or 3 combined parameters in relation to single determinations, obtaining sensitivity and specificity of 88.2% and 100% for three parameters.

ARTICLE HIGHLIGHTS

Research background

Recognition of the mechanisms involved in neoplastic cell spreading is indispensable for the early diagnosis and detection of colorectal cancer.

Research motivation

Colorectal cancer is the third most common type of cancer, making up about 10% of all cases. In 2018, there were 1.09 million new cases and 551000 deaths from the disease. Consequently, early diagnosis of colorectal cancer remains a significant medical and economic problem.

Research objectives

Using several biomarkers involved in cancer progression, we have tried to identify a panel that could be used for effective early diagnosis.

Research methods

Before surgery, we analyzed the blood serum of 185 patients with colorectal cancer and determined: Cathepsin B (CB), leukocytic elastase (LE), total sialic acid (TSA), lipid-bound sialic acid (LASA), and antitrypsin activity (ATA).

Research results

The receiver operating characteristic analysis revealed the potential diagnostic value of CB, TSA, and ATA. The sensitivity and specificity for the three-parameter panel CB-TSA-ATA were equal to 88.2% and 100%, respectively.

Research conclusions

The increased value of CB, TSA, and ATA parameters are associated with tumor biology, invasion, and metastasis of colorectal cancer.

Research perspectives

The presented evidence suggests the potential diagnostic and prognostic value of the CB-TSA-ATA biochemical marker panel.

ACKNOWLEDGEMENTS

We thank Dr. Filipowski H, PhD, for help with the statistical analysis.

Abstract

BACKGROUND

The implementation of a colorectal cancer (CRC) screening programme may increase the awareness of Primary Care Physicians, reduce the diagnostic delay in CRC detected outside the scope of the screening programme and thus improve prognosis.

AIM

To determine the effect of implementation of a CRC screening programme on diagnostic delays and prognosis of CRC detected outside the scope of a screening programme.

METHODS

We performed a retrospective intervention study with a pre-post design. We identified 322 patients with incident and confirmed CRC in the pre-implantation cohort (June 2014 – May 2015) and 285 in the post-implantation cohort (June 2017 - May 2018) in the Cancer Registry detected outside the scope of a CRC screening programme. In each patient we calculated the different healthcare diagnostics delays: global, primary and secondary healthcare, referral and colonoscopy-related delays. In addition, we collected the initial healthcare that evaluated the patient, the home location (urban/rural), and the CRC stage at diagnosis. We

determined the two-year survival and we performed a multivariate proportional hazard regression analysis to determine the variables associated with survival.

RESULTS

We did not detect any differences in the patient or CRC baseline-related variables. A total of 20.1% of patients was detected with metastatic disease. There was a significant increase in direct referral to colonoscopy from primary healthcare (25.5%, 35.8%; P = 0.04) in the post-implantation cohort. Diagnostic delay was reduced by 24 d (106.64 ± 148.84 days, 82.84 ± 109.31 d; P = 0.02) due to the reduction in secondary healthcare delay (46.01 ± 111.65 d; 29.20 ± 60.83 d; P = 0.02). However, we did not find any differences in CRC stage at diagnosis or in two-year survival (70.3%; P = 0.9). Variables independently associated with two-year risk of death were age (Hazard Ratio-HR: 1.06, 95%CI: 1.04-1.07), CRC stage (II HR: 2.17, 95%CI: 1.07-4.40; III HR: 3.07, 95%CI: 1.56-6.08; IV HR: 19.22, 95%CI: 9.86-37.44; unknown HR: 9.24, 95%CI: 4.27-19.99), initial healthcare consultation (secondary HR: 2.93, 95%CI: 1.01-8.55; emergency department HR: 2.06, 95%CI: 0.67-6.34), hospitalization during the diagnostic process (HR: 1.67, 95%CI: 1.17-2.38) and urban residence (HR: 1.44, 95%CI: 1.06-1.98).

CONCLUSION

Although implementation of a CRC screening programme can reduce diagnostic delays for CRC detected in symptomatic patients, this has no effect on CRC stage or survival.

Core Tip: We have designed a retrospective intervention study with a pre-post design to confirm the hypothesis that the implementation of a colorectal cancer (CRC) screening program may increase the awareness of primary care physicians and, thus, reduce the diagnostic delays in CRC detected outside the screening program and improve prognosis. Our results confirm that the implementation of the CRC screening program reduced the diagnostic delays due to an increase in the direct referrals to colonoscopy from primary healthcare. However, this reduction in the delays had no effect on the stage at diagnosis or in the two year survival. These later results were confirmed in a multivariable Cox regression analysis.

INTRODUCTION

Colorectal cancer (CRC) is one of the most important health problems in the Western world. In 2018, almost half a million new cases were diagnosed in Europe and 250,000 patients died due to CRC[1]. In order to reduce the disease burden, population-based CRC screening programmes have been established in the Western world. This strategy has demonstrated its efficacy to reduce CRC mortality and incidence in randomized controlled trials. Furthermore, we have real data showing that implementation of CRC screening programmes has achieved its expected efficiency in reducing both CRC mortality and incidence[2,3].

In spite of the implementation of CRC screening programmes, most CRC are detected among symptomatic patients outside the scope of CRC screening mainly due to the limited participation and the detection in age cohorts that are not candidates for CRC screening[4,5]. However, as in breast cancer screening, the implementation of

conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethics Committee of Galicia, Spain (code 2016/274). As long as the study was based on database use, no informed consent was required. The information was accessed according to prevailing European and Spanish legislation.

Informed consent statement: All study participants, or their legal guardian, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: There are no conflicts of interest to report.

Data sharing statement: We will share the data base on demand and according to European legislation.

STROBE statement: The authors have read the STROBE Statement—checklist of items, and the manuscript was prepared and revised according to the STROBE Statement—checklist of items.

CRC screening may have an additional positive effect on these patients due to increased awareness and creation of multidisciplinary teams[6]. In this sense, CRC screening may increase the CRC awareness of patients and primary care physicians (PCPs) and promote use of faecal immunochemical test (FIT) as a triage test to refer patients to colonoscopy[7].

The delay to diagnosis in cancer is due to factors related to the patient and health system. The period from initial symptoms until final diagnosis is made can be highly variable. Although the common belief is that a longer delay can lead to an advanced stage at diagnosis and worse prognosis, evidence on CRC is controversial[8]. Patients seeking assistance with more severe symptoms are diagnosed in a shorter period and have more advanced disease[9]. In contrast, there is no evidence that a health system delay lower than six months worsens prognosis in the context of an outpatient diagnosis[10].

Based on the hypothesis that implementation of a mass CRC screening programme could raise awareness of patients and PCPs, we decided to design a retrospective intervention study to determine whether implementation of a CRC screening programme could reduce health system delays and, secondarily, improve CRC staging at diagnosis and long term survival.

MATERIALS AND METHODS

Study design

We designed a retrospective intervention study with a pre-post design without a control group.

Description of the intervention

The intervention was the first round of the Galician CRC screening programme that took place between 1 July 2015 and 30 June 2017 in Ourense, Spain. Galician CRC mass screening is based on biennial FIT with a 20 μg haemoglobin/g of faeces threshold. FIT is offered to subjects aged 50 to 69 years. It is coordinated by the Public Health Department of the Galician Regional Health Department. They are in charge of the identification of subjects, invitation to participate, reception of FIT results, citation of patients with a positive result to perform a colonoscopy and final evaluation of the endoscopic and histological results. Primary healthcare clinics are in charge of promoting participation in the screening programme, collecting FIT kits and evaluation of subjects with a positive FIT prior to colonoscopy. The hospitals in each health area are responsible for FIT analysis, colonoscopies, histological analysis and evaluation and treatment of patients with a CRC. Finally, personnel at the Coordination Unit key in data into the screening programme's information system regarding CRC stage according to the AJCC classification,[11]. the final classification of patients with a positive result[12]. as well as several quality endoscopist indicators according to the Spanish guideline on quality in screening colonoscopy[13]. During the implantation of the CRC screening program no change was performed in the diagnostic pathways for CRC diagnosis in symptomatic patients.

Inclusion criteria and definition of the cohorts

Pre cohort: We included all invasive incident CRC histologically confirmed detected in the natural year before implementation of the CRC screening programme (1 July 2014 – 30 June 2015) in Ourense.

Post cohort: We included all invasive incident CRC histologically confirmed and detected outside the scope of the CRC screening programme in the natural year after the first round: (1 July 2017- 30 June 2018).

Identification of the incident CRC

We identified the incident using the case identification structure developed and validated by the project for implementation of the Galician Tumour Registry (Project REGAT). REGAT uses the topographic codes ICD-O-3.1 C18-C19-C20 to identify the CRC[14]. Codes C18.1 (appendix), C21 (anus and anal canal) were excluded. REGAT data were crosslinked with the Galician CRC screening information system to exclude those patients with a CRC diagnosed within the screening programme.

Variables analyzed

We collected information regarding: (1) Demographics (age and sex); and (2) Tumour

location in relation to the splenic flexure: proximal (caecum, ascending colon, hepatic flexure and transverse colon) and distal (rectum, sigma, descending colon and splenic flexure).

Cancer stage at diagnosis according to the TNM classification (AJCC 7th edition) [11]. We used the following data to determine the stage at diagnosis: clinical or anatomo-pathological stage for metastatic disease, imaging tests for the local rectal cancer stage (T and N), anatomo-pathological evaluation for the remaining situations (colon cancer T and N).

We searched in IANUS, the unified clinical record database of the Galician Health Department, for information regarding the contacts and referrals in the healthcare system. IANUS includes all information regarding attendance in primary and secondary healthcare as well as emergency departments and hospitalization. We determined the first contact in the health system (primary, secondary, emergency), whether the patient required hospitalization during the diagnostic process and the diagnostic delays. We defined five diagnostic delays (Figure 1): (1) Global diagnostic delay: Overall delay from the first consultation to definitive diagnosis; (2) Primary healthcare delay: Delay from the initial evaluation in primary healthcare until the decision to refer to secondary healthcare. In the event of colonoscopy being directly requested from primary healthcare, this date was considered as the referral date; (3) Referral delay: Delay from the primary healthcare referral to the first attendance in secondary healthcare (either clinical consultation or performing of colonoscopy); (4) Secondary healthcare delay: Delay from the first attendance in secondary healthcare to final diagnosis; and (5) Colonoscopy delay: Delay from the colonoscopy request to the performing of colonoscopy.

Statistical analysis

First, we performed a descriptive analysis of the variables included: number and frequencies in the qualitative variables and mean and standard deviation in the quantitative variables. We determined whether there were differences between both cohorts in the diagnostic pathways (hospitalization, direct referral to colonoscopy from primary healthcare) using the Chi-square test. In order to detect whether there were differences in the referral delays between both cohorts we used the Student *t* test. We analyzed whether there were differences in two-year survival between both cohorts in the Kaplan-Meier analysis using the log-rank test. Finally, to control confounding variables we performed a Cox multivariate regression analysis and we determined which variables were independently associated with survival after diagnosis. The study was statistically reviewed by a biomedical statistician.

Ethics aspects

The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethics Committee of Galicia, Spain (code 2016/274). As long as the study was based on database use, no informed consent was required. The information was accessed according to prevailing European and Spanish legislation.

RESULTS

Description of the sample

We identified records from 757 patients in the two periods analyzed in the cancer registry. We excluded 92 patients that did not meet the inclusion criteria and 58 patients with CRC detected within the CRC screening programme in the post-implantation cohort. Finally, the pre-implantation and post-implantation cohort consisted of 322 and 285 patients, respectively (Figure 2).

As we show in Table 1, we did not detect baseline differences between both cohorts. CRC was detected more commonly in males (59.6%) with a mean age of 74.5 ± 11.5 years and more than two thirds were distal to the splenic flexure. There were no differences with respect to the place of residence either. Most patients were initially evaluated in primary healthcare but up to 41.0% required hospitalization before reaching final diagnosis. Diagnosis was made through colonoscopy in 89.8% of detected CRC. In this sense, we detected a significant increase in the colonoscopy directly requested from primary healthcare in the post-implantation cohort (P = 0.04). When we limited the analysis to those patients initially seen in primary healthcare (522), the results were similar. In this sense, we only found differences in the rate of colonoscopy directly referred from primary healthcare (29.2%, 42.3%; P = 0.005).

Table 1 Characteristics of the patients included

	Pre-implantation cohort (*n* = 322)	Post-implantation cohort (*n* = 285)	*P* value[1]
Sex			0.1

[1]Statistical significance in the univariate analysis using the Chi-square test for qualitative variables and the Student *t* test for quantitative variables.

Delay to diagnosis

The delay to diagnosis was reduced in 24 d after implantation of the CRC screening programme (P = 0.02). We did not detect any differences in the primary healthcare, referral or colonoscopy delay. The reduction was due to a secondary healthcare delay in relation to an increased rate of direct referral to colonoscopy from primary healthcare, as we show in Table 2 and Figure 3.

The global delay was also reduced by 27 d in patients evaluated initially in primary healthcare (117.66 ± 154.08 days, 90.06 ± 111.31 days; P = 0.02) also due to a reduction in secondary healthcare delay (48.17 ± 116.42 d, 26.89 ± 54.50 d; P = 0.02). There were no differences in primary healthcare, referral or colonoscopy delay.

Factors associated with survival

The incidence of metastatic CRC remained stable (20.1%) in both cohorts and overall survival after one and two years was 71.3% and 70.3% without differences in the log-

Table 2 Delay to colorectal cancer diagnosis in the pre and post-implantation cohorts

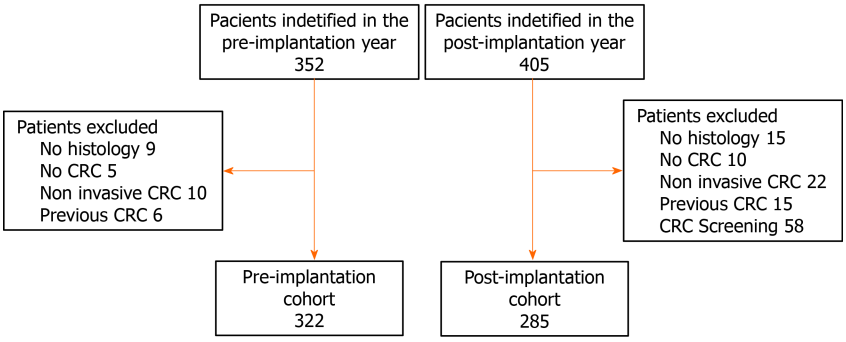

Figure 2 Flowchart of the patients included in the analysis.

rank test (P = 0.9) as we show in Figure 4. These results were confirmed in the Cox multivariate regression analysis and there were no differences in the survival between both cohorts (post-implantation cohort HR: 1.12, 95%CI: 0.83-1.51). As we show in Table 3, only age, CRC staging according to TNM classification, initial healthcare consultation, hospitalization during the diagnostic process and residence were independently associated with death after CRC diagnosis.

DISCUSSION

Our study shows that implementation of the CRC screening programme reduced healthcare referral delays due to the direct request of colonoscopy from primary healthcare. Unfortunately, this reduction in referral delay had no effect on CRC staging at diagnosis nor on the two-year survival. Finally, although we detected several variables associated with overall survival, multivariate logistic analysis confirms that neither implantation of the CRC screening nor diagnostic delay were related to the prognosis of CRC detected outside the scope of CRC screening.

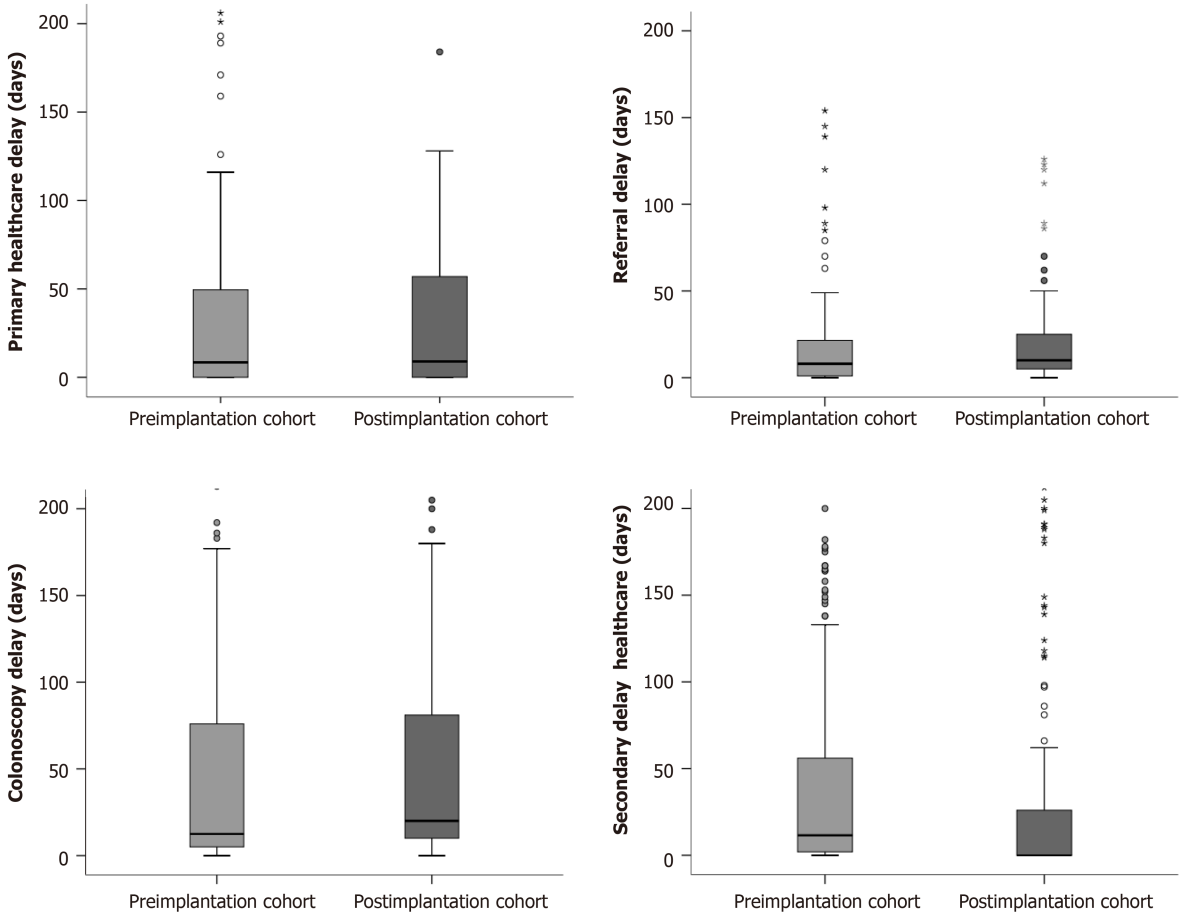

Figure 3 Healthcare diagnostic delays. We show the distribution of the primary and secondary healthcare, referral and colonoscopy delays expressed in days.

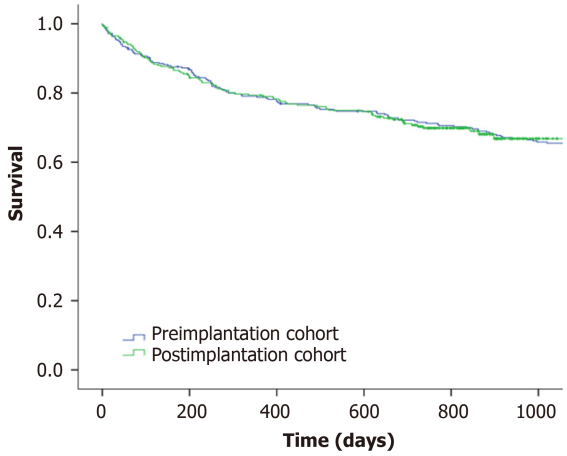

Figure 4 Survival curves of the pre and post-implantation cohorts. Survival curves were calculated using the Kaplan-Meier method.

PCPs play an important role in CRC care, from encouraging screening and accurate diagnosis to providing care during and after treatment for cancer and any comorbid complications. The implication of PCPs on CRC screening is variable according to the screening programme. Participation rates are increased when PCPs are involved in the invitation process. However, in the European population-based programmes in Europe PCPs play a rather supportive, informative or facilitating role[15]. In our case, PCPs receive full information on the screening programme organization and they are in charge of promoting participation as well as resolving any doubts. Within the training, PCPs are reminded which symptoms may lead to suspicion of CRC as well as the established referral pathways, including direct referral criteria for colonoscopy evaluation from primary healthcare[8,16].

We designed this analysis under the hypothesis that increased awareness on CRC and training in the diagnosis of CRC and the established protocols could reduce delays attributed to the health system. In this sense, our results confirm that implementation of the screening programme enabled a reduction in the diagnostic delay due to an increase in direct referrals to colonoscopy from primary healthcare. PCPs, as demonstrated in our study, are the main gateway and responsible for a significant part of the delay[17-19]. The role of PCPs in CRC diagnosis is complex since gastrointestinal symptoms that may suggest CRC are very common, the CRC prevalence low and the diagnostic performance of available symptom-based tools is very limited[20]. Recently, implementation of the faecal immunochemical test to triage patients with gastrointestinal symptoms in primary healthcare has improved diagnostic referral pathways[20,21]. In the health area of Ourense, faecal immunochemical test was implemented as a triage test seven years ago, so we cannot attribute the decreases in delay to this modification[16].

However, it is relevant that, despite the reduction in delay, we have not detected any changes in the stage at diagnosis or in the prognosis of CRC. These data are in accordance with results previously published by our group[8]. and with the data in the available meta-analysis on the effect of diagnostic delays in CRC prognosis[9]. In this sense, the prognosis of patients with shorter diagnostic delay is worse due to presentation with urgent symptoms that require hospitalization or more serious systemic symptoms[19]. In fact, in our study, hospitalization during admission was associated with a higher risk of mortality after diagnosis. In our research, although initial urgent presentation was rare, up to 40% of patients required hospitalization during the diagnostic process, similar to the information available on literature[22-24]. This lack of relationship between delay and prognosis may be related to different forms of presentation. In this sense, a prospective study on patients that met the National Institute for Health and Care Excellence referral criteria demonstrated that a delay of more than six months was associated with a worse prognosis compared to patients with the same symptoms diagnosed in an interval of less than one month[10].

Our study has two main strengths. We had the opportunity to evaluate the effect of the CRC screening programme on the diagnostic delays of CRC detected in symptomatic patients. This is the first study that evaluates additional impacts of the implementation of CRC screening on CRC diagnosis. No study has evaluated whether a CRC screening programme can increase the awareness of patients and PCPs, reduce delays and improve prognosis. However, we could identify all the CRC through the Galician cancer registry, confirm the diagnosis in IANUS, the centralized clinical record and determine when the patient was evaluated in the health system and thus calculate all the referral delays[25].

There are several limitations. Due to the design of the study, we could not evaluate the effect of CRC screening on the patient delays to seek assistance. Patient delay accounts for a relevant proportion of the delay between the onset of symptoms and the final diagnosis[26]. Moreover, we did not collect the initial symptoms as long as they were not collected uniformly in the clinical records.

CONCLUSION

To conclude, the implementation of a CRC screening programme enabled reduction of health system diagnostic delay by means of increased patients referred directly by PCPs to colonoscopy. However, this reduction in referral delay did not modify either CRC stage at diagnosis or two-year survival.

ARTICLE HIGHLIGHTS

Research background

In spite of the implementation of colorectal cancer (CRC) screening programmes, most CRC are detected among symptomatic patients outside the scope of CRC screening. However, they may increase the CRC awareness of patients and primary care physicians (PCP).

Research motivation

The implementation of a mass CRC screening programme could raise awareness of patients and PCPs, we decided to design a retrospective intervention study to

determine whether implementation of a CRC screening programme could reduce health system delays and, secondarily, improve CRC staging at diagnosis and long term survival.

Research objectives

To determine the effect of implementation of a CRC screening programme on diagnostic delays and prognosis of CRC detected outside the scope of a screening programme.

Research methods

We designed a retrospective intervention study with a pre-post design without a control group. We compared diagnostic delays, CRC stage and two year survival of a yearly CRC diagnosed before the implementation of a CRC screening programa with a CRC cohort diagnosed the year after the first round.

Research results

There was a significant increase in direct referral to colonoscopy from primary healthcare (25.5%, 35.8%; $P = 0.04$) in the post-implantation cohort. Diagnostic delay was reduced by 24 d (106.64 ± 148.84 d, 82.84 ± 109.31 d; $P = 0.02$) due to the reduction in secondary healthcare delay (46.01 ± 111.65 d; 29.20 ± 60.83 d; $P = 0.02$). However, we did not find any differences in CRC stage at diagnosis or in two-year survival (70.3%; $P = 0.9$).

Research conclusions

Although implementation of a CRC screening programme can reduce diagnostic delays for CRC detected in symptomatic patients, this has no effect on CRC stage or survival.

Research perspectives

We need more research on the motivations and perspectives of patients seeking help in primary healthcare.

Abstract

BACKGROUND

Standard liver weight (SLW) is frequently used in deceased donor liver transplantation to avoid size mismatches with the recipient. However, some deceased donors (DDs) have fatty liver (FL). A few studies have reported that FL could impact liver size. To the best of our knowledge, there are no relevant SLW models for predicting liver size.

AIM

To demonstrate the relationship between FL and total liver weight (TLW) in detail

involved with drafting of the manuscript; all authors have read and approve the final manuscript.

Supported by New Clinical Technology Project, West China Hospital, Sichuan University, No. 20HXJS012; and National Natural Science Foundation of China, No. 81770653 and No. 82070674.

Institutional review board statement: This study was reviewed and approved by the West China Hospital of Sichuan University Institutional Review Board.

Clinical trial registration statement: This study was registered at http://www.chictr.org.cn. The registration identification number is ChiCTR2000041406.

Informed consent statement: All study participants, or their legal guardians, provided informed written consent prior to study enrollment.

Conflict-of-interest statement: The authors of this manuscript have no conflicts of interest to disclose.

Data sharing statement: No additional data are available.

CONSORT 2010 statement: The authors have read the CONSORT 2010 Statement, and the manuscript was prepared and revised according to the CONSORT 2010 Statement.

and present a related SLW formula.

METHODS

We prospectively enrolled 212 adult DDs from West China Hospital of Sichuan University from June 2019 to February 2021, recorded their basic information, such as sex, age, body height (BH) and body weight (BW), and performed abdominal ultrasound (US) and pathological biopsy (PB). The chi-square test and kappa consistency score were used to assess the consistency in terms of FL diagnosed by US relative to PB. Simple linear regression analysis was used to explore the variables related to TLW. Multiple linear regression analysis was used to formulate SLW models, and the root mean standard error and interclass correlation coefficient were used to test the fitting efficiency and accuracy of the model, respectively. Furthermore, the optimal formula was compared with previous formulas.

RESULTS

Approximately 28.8% of DDs had FL. US had a high diagnostic ability (sensitivity and specificity were 86.2% and 92.9%, respectively; kappa value was 0.70, $P < 0.001$) for livers with more than a 5% fatty change. Simple linear regression analysis showed that sex (R^2, 0.226; $P < 0.001$), BH (R^2, 0.241; $P < 0.001$), BW (R^2, 0.441; $P < 0.001$), BMI (R^2, 0.224; $P < 0.001$), BSA (R^2, 0.454; $P < 0.001$) and FL (R^2, 0.130; $P < 0.001$) significantly impacted TLW. In addition, multiple linear regression analysis showed that there was no significant difference in liver weight between the DDs with no steatosis and those with steatosis within 5%. Furthermore, in the context of hepatic steatosis, TLW increased positively (non-linear); compared with the TLW of the non-FL group, the TLW of the groups with hepatic steatosis within 5%, between 5% and 20% and more than 20% increased by 0 g, 90 g, and 340 g, respectively. A novel formula, namely, -348.6 + (110.7 x Sex [0 = Female, 1 = Male]) + 958.0 x BSA + (179.8 x FL_{US} [0 = No, 1 = Yes]), where FL was diagnosed by US, was more convenient and accurate than any other formula for predicting SLW.

CONCLUSION

FL is positively correlated with TLW. The novel formula deduced using sex, BSA and FL_{US} is the optimal formula for predicting SLW in adult DDs.

Key Words: Standard liver weight; Body surface area; Fatty liver; Sex; Deceased donors

Core Tip: This study was the first to explore the relationship between fatty liver (FL) and total liver weight (TLW) in detail using pathological biopsy based on adult deceased donors (DDs) and developed a new standard liver weight (SLW) formula. Moreover, to conveniently apply the SLW formula to the clinic, we introduced ultrasound (US). Notably, we found that FL was positively correlated with TLW and that US had a high diagnostic ability for mild to severe FL, which could increase liver weight significantly. The formula deduced using sex, BSA and FL_{US} is the optimal formula for predicting SLW in adult DDs.

INTRODUCTION

Standard liver weight (SLW) is a key parameter in liver surgery. Its accurate evaluation is the basis for patient safety in both hepatectomy and liver transplantation

(LT). In hepatectomy, the underestimation of SLW may lead to residual liver failure[1,2], and in living donor liver transplantation (LDLT)/split liver transplantation (SLT), the underestimation of SLW can lead to small-for-size syndrome (SFSS)[3-5]. Since the establishment of Urata's standard liver volume (SLV) model[6], approximately 14 SLV models have been published worldwide, most of which are based on healthy people, living donors and autopsy donors from various medical centres. Deceased donor liver transplantation (DDLT) is a crucial donor liver source for alleviating the shortage of donor livers. Subsequently, SLT was established and further expanded the donor liver pool. Previous studies[7-10] have reported that SLT is not inferior to whole liver transplantation in terms of patient prognosis, which has encouraged the extensive use of SLT and necessitated an urgent demand for an SLW formula for DDLT to avoid severe mismatches, large-for-size syndrome[11,12] or SFSS. Moreover, deceased donors (DDs) and living donors (LDs) are from the general population and may have hepatic steatosis, which has a reported global incidence of 15%-30%[13,14]. To our knowledge, fatty liver (FL) may be associated with marginal grafts, as severe steatosis is a risk factor related to graft survival[15] and may affect liver size[16,17]. However, these associations have not been quantified conclusively. To the best of our knowledge, only one model[18] has been published for DDs, and it was based on a Western population and did not address FL. Therefore, this study prospectively collected adult DDs' clinical data combined with FL parameters to develop an SLW model.

MATERIALS AND METHODS

The present study prospectively enrolled consecutive deceased liver donors from West China Hospital of Sichuan University from June 2019 to February 2021 and recorded basic patient information, such as sex, age, body height (BH) and body weight (BW). This study was reviewed and approved by the West China Hospital of Sichuan University Institutional Review Board and registered at http://www.chictr.org.cn. The registration identification number is ChiCTR2000041406. All the study participants, or their legal guardians, provided informed written consent prior to study enrollment, and the study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a priori approval by the ethics committee. No executed prisoners were included in the study. A total of 212 DDs were enrolled, and brain death was confirmed in all of them before organ procurement. Advanced life support was maintained in an intensive care unit (ICU); moreover, abdominal ultrasound (US) examinations, liver function tests and kidney function tests were completed for each donor. Pathological biopsy (PB) was performed for all enrolled donor livers after they were obtained.

US examination

A US examination was carried out for all DDs before organ procurement. Scanning and diagnosis were conducted by 2 experienced (> 5 years) US doctors who were blinded to the final PB diagnosis. The examinations were performed by using a MultiWave ultrasound system (Aixplorer, France) equipped with an SC6–1 (1–6 MHz) transducer. FL was identified as a diffuse increase in fine echoes in the liver parenchyma. Representative images[19] are presented in Figure 1.

Donor liver weight measurement, tissue sampling and histological assessment

Donor livers were procured and trimmed in the operating room and were then weighed with a precision electronic balance (unit: kg, accurate to 0.001 kg, Figure 2) on a back table.

A single tissue wedge of approximately 1.0 cm × 1.0 cm × 1.0 cm was excised from the left lateral lobe surface of the donor liver, fixed in formalin and embedded in paraffin. Each donor liver was stained with haematoxylin and eosin (HE) and Masson's trichrome. The histological degree of liver pathology, including hepatic steatosis, ballooning of hepatocytes, lobular inflammation, necrosis, and fibrosis, was evaluated by two expert liver pathologists blinded to any other clinical information and laboratory data. The extent of hepatic steatosis was assessed by the percentage of hepatocytes containing large- and medium-sized intracytoplasmic lipid droplets (but not foamy microvesicles). The definition of ballooning of hepatocytes and lobular inflammation was as described by Kleiner *et al*[20] and Bedossa *et al*[21]. The definition of necrosis is described in Table 1. Fibrosis was scored according to the standard grading (inflammation) and staging (fibrosis) method based on the modified Scheuer

system[22].

Estimating SLW using previous formulas

According to previous studies at our centre[23] and other centres[24-26], the density of the liver was determined to be 1 g/cm^3; that is, the weight and volume of the donor liver were equal. For comparison, we calculated the estimated SLW according to

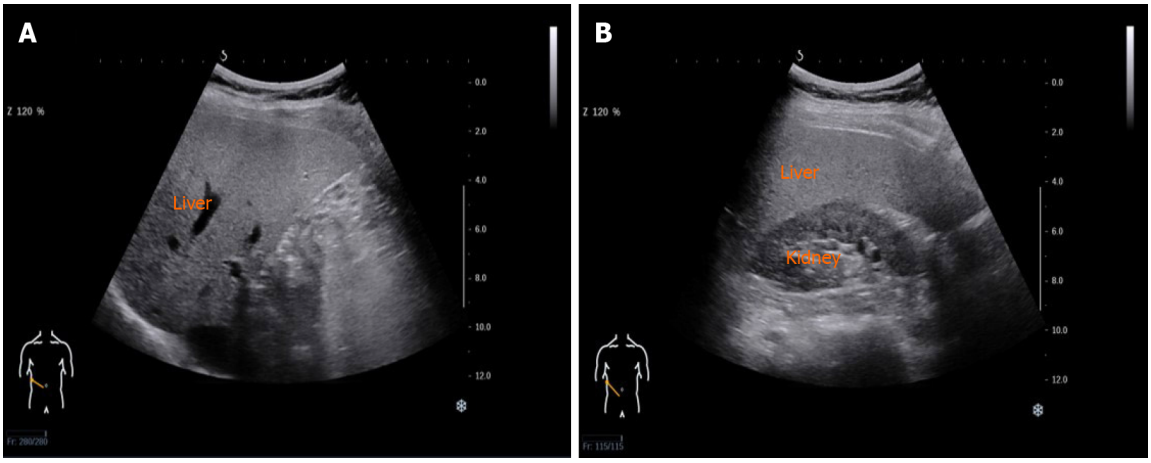

Figure 1 Diagram of fatty liver diagnosed by ultrasound from the view of the liver and kidney. A: Diffuse increase in fine echoes in liver parenchyma with normal visualization of intrahepatic vessel borders; B: Diffuse increase in fine echoes in liver parenchyma. There was an increase in echogenicity of the liver compared with the echogenicity of the renal cortex.

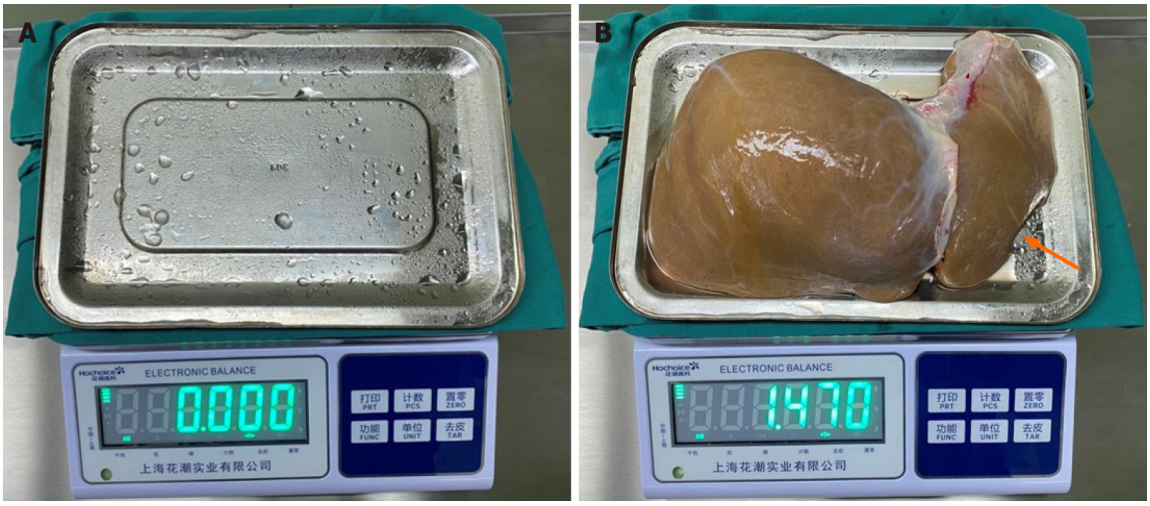

Figure 2 Actual liver weight measurement by electronic balance. A: Zero correction of electronic balance; B: Donor liver weighing. The arrow indicates that a single tissue wedge of approximately 1.0 cm × 1.0 cm × 1.0 cm was excised from the left lateral lobe surface of the donor liver.

previous formulas for adults[6-19]. Body mass index (BMI) = BW/BH^2 and body surface area (BSA) = $BW^{0.425}$ x $BH^{0.725}$ x 0.007184 using the Dubois formula[27] were also calculated.

Statistical analysis

In this study, simple linear regression analysis was used to explore the variables related to TLW. Multiple linear regression analysis was used to formulate the SLW. As BH, BW, BMI and BSA are collinear variables, each was applied in a different prediction model. The root mean standard error (RMSE) and interclass correlation coefficient (ICC) were used to test the fitting efficiency and accuracy of the model, respectively. The chi-square test and kappa consistency score were used to assess the consistency in terms of FL diagnosed by US relative to PB. Continuous variables were analysed by a paired-samples *t* test. Two-tailed statistical analysis was used, and *P* values less than 0.05 were considered to be statistically significant. SPSS, version 25.0 (IBM, Armonk, NY, United States) was used for all statistical analyses. GraphPad Prism 7.0 (GraphPad Software, Inc.) was used for drawing.

RESULTS

Baseline data

This study included 167 males (78.8%). The median age was 49 years, ranging from 18 to 68 years. The median BH, BW, BMI, BSA and TLW were 1.68 m, 65 kg, 23.35 kg/m^2, 1.73 m^2 and 1400 g, respectively. The main causes of death of the DDs were trauma (50%), cerebrovasculature (45.8%), and other (4.2%), which included brain tumours and hypoxic-ischaemic encephalopathy. There were 151 DDs (71.2%) with no steatosis, 32 (15.1%) with steatosis within 5%, 22 (10.4%) with steatosis between 5% and 33%, and 7 (3.3%) with steatosis greater than 33%. Moreover, hepatocyte ballooning was observed in 88.9% of DDs. Lobular inflammation was observed in approximately 69.1% of DDs. Necrosis (focal or unicellular necrosis, in 3.7% of DDs samples, and more extensive necrosis, in 1.9% of DDs samples) was observed in only a few DDs liver tissue samples. Stage 0–2 Liver fibrosis was observed in approximately 97.5% of DDs (Table 1).

Impact factors related to the TLW of deceased donors

Simple linear regression analysis showed that sex, BH, BW, BMI, BSA and FL significantly impacted TLW ($P < 0.001$) (Table 2). BSA was the most influential factor related to liver size [R^2, 0.454; 95% confidence interval (CI): 1024.56–1383.79]. Multiple linear regression analysis showed that there was no significant difference in TLW between no steatosis and steatosis within 5% ($P = 0.147$, Figure 3A). Furthermore, in the context of hepatic steatosis, TLW increased positively (non-linear); compared with the TLW of the non-FL group, the TLW of the groups with hepatic steatosis within 5%, between 5% and 20% and more than 20% increased by 0 g, 90 g, and 340 g, respectively (Figure 3B).

Consistency test for FL diagnosis between US and PB

This study investigated 61 hepatic steatosis cases, which accounted for 28.8% of all cases, and moderate and severe steatosis cases, which accounted for 3.3%. The cases of hepatic steatosis and non-hepatic steatosis diagnosed by US were 38 and 174, respectively. The sensitivity and specificity of US were 55.7% and 97.4%, respectively, and the kappa value was 0.598 ($P < 0.001$). That is, its diagnostic consistency was good (Supplementary Table 1). Furthermore, when setting 5% as the cut-off value for diagnosing FL by PB, there were 174 cases within a 5% fatty change and 38 cases with more than a 5% fatty change diagnosed by US, with a sensitivity and specificity of 86.2% and 92.9%, respectively, and a kappa value of 0.70 ($P < 0.001$). Therefore, the diagnostic consistency between US and PB was high (Table 3).

Current formulas for estimating SLW

The SLW models were separately formulated based on four collinear variables, namely, BH, BW, BMI and BSA. Subsequently, three prediction model groups were established, two of which were used to assess the presence of FL based on US or PB; the third group did not include FL as an indicator. The present study showed that the SLW models based on BSA, FL and sex had the best fitness, and the adjusted R^2 and RMSE for PB and US were 0.546 and 169.985 and 0.546 and 169.913, respectively. The fitting efficiency of these two models was almost equal and better than that of the traditional method (adjusted R^2, 0.485; RMSE, 181.095) (Table 4).

Comparison between the current formula and previous formulas

Previously reported formulas were used to assess our DDs cohort, and the results showed that the fitting efficiency and accuracy of the SLW model introducing FL diagnosed by US were 168.3 (RMSE) and 0.71 (ICC), with a non-significant difference ($P = 1.00$) between the SLW and TLW of 1.5 g. The RMSE and ICC of Yu *et al*[25]'s and Lin *et al*[28]'s models were 187.5 and 0.61 and 188.0 and 0.63, respectively. There were no significant differences between the SLW and actual TLW for these two formulas, but those of the remaining formulas were significantly different (Table 5)[6,18,25-37].

DISCUSSION

The shortage of donor livers is a problem worldwide and has become a major obstacle hindering the development of LT. To date, experts in the LT field have explored expanding the donor liver pool, including *via* SLT, marginal donor LT, domino LT and

Table 2 Factors related to the total liver weight of the deceased donors

Factor	R^2	*P* value	95%CI
Sex	0.226	< 0.001	220.89–369.68
BH	0.241	< 0.001	13.92–22.78
BW	0.441	< 0.001	15.25–20.77
BSA	0.454	< 0.001	1024.56–1383.79
BMI	0.224	< 0.001	32.28–54.18
Degree of fatty change (< 5%, 5%–20%, > 20%)	0.130	< 0.001	116.89–244.17
Hepatic steatosis[1]	0.125	< 0.001	149.67–318.33

[1]Diagnosed by ultrasound. BH: Body height; BW: Body weight; BSA: Body surface area; BMI: Body mass index.

Table 3 Results for livers with more than 5% fatty change diagnosed by ultrasound and pathological biopsy in the deceased donors

Ultrasound	Pathological biopsy		Total
	+	-	
+	25	13	38
-	4	170	174
Total	29	183	212

According to the table above, livers with a fatty change of more than 5% were diagnosed by ultrasound, and the sensitivity and specificity were 86.2% and 92.9%, respectively. The chi-square test showed that the kappa value was 0.70, $P < 0.001$.

so on. These schemes have successfully and significantly expanded the donor liver pool, and SLT has become one of the most valuable means of promotion. Graft weight (GW) plays a key role in recipients, especially in DDLT and LDLT. Therefore, it is necessary to evaluate the donor liver size in LT.

DDs are patients with brain death caused by non-liver diseases. This study illustrated that 95.8% of DDs died from trauma or cardiovascular and cerebrovascular accidents. Biopsies showed that many donor livers had hepatocyte oedema and lobular inflammation, which can be explained by the cause of death. Trauma and cardiovascular and cerebrovascular accidents can cause instability of the circulatory system, leading to long-term ICU stays and the requirement for resuscitative therapy, which may cause unstable organ perfusion (hypoperfusion or hyperperfusion) and reperfusion injury. In addition, the use of a large number of vasoactive drugs may aggravate organ microcirculation disorder. Thus, the graft may have acute injury, such as lobular inflammation, hepatocyte oedema and even necrosis. The present study found that 28.8% of DDs had hepatic steatosis and that 2.5% had stage 3–4 Liver fibrosis. Unlike DDs, LDs screened from healthy populations rarely have FL or other acute liver injuries. In addition, it was unclear whether there was a difference in the SLW between DDs and LDs. To the best of our knowledge, there have been few relevant reports. Therefore, we explored the SLW model based on DDs data derived from West China Hospital.

Simple linear regression analysis showed that liver size was correlated with sex. The liver size of males was larger than that of females, which was in line with previous studies[30,33]. We speculated that this might be related to the fact that the body size of men is generally larger than that of women and that men have a larger skeletal muscle system and higher daily consumption and metabolic requirements. Therefore, a larger liver mass is needed to meet physiological needs[38,39]. In addition, the present study found that BH, BW, BMI and BSA were closely related to liver size, which was similar to previous studies[6,25,31,40]. Indeed, multiple linear regression analysis revealed that the above four variables were collinear. From the perspective of morphology, liver size and physical indicators are supposed to be positively correlated. Moreover, in terms of energy requirements, to meet metabolic needs, a larger body size needs more organ support. Furthermore, the current study found that BSA was the most influential factor impacting TLW, which was consistent with previous studies[6,29,

Table 4 Results of multiple linear regression analysis performed to predict the total liver weight using each of the body anthropometric measures divided into groups of the traditional method and two new methods, which introduce the parameter of fatty liver diagnosed by ultrasound and pathological biopsy

Groups	Formulas	Adjusted R^2	RMSE
Traditional method			
BH	- 809.4 + 167.3 x Sex + 12.6 x BH	0.29	212.0
BW	322.1 + 147.0 x Sex + 15.2 x BW	0.49	181.1
BSA	- 466.9 + 99.0 x Sex + 1051.0 x BSA	0.48	182.8
BMI	329.2 + 264.5 x Sex + 37.8 x BMI	0.39	196.5
Ultrasound method			
BH	- 1011.9 + 149.7 x Sex + 13.6 x BH + 240.7 x FL_{US}	0.43	191.1
BW	392.7 + 158.3 x Sex + 13.5 x BW + 158.6 x FL_{US}	0.54	171.4
BSA	- 348.6 + 110.7 x Sex + 958.0 x BSA + 179.8 x FL_{US}	0.55	169.9
BMI	453.7 + 264.5 x Sex + 31.2 x BMI + 162.9 x FL_{US}	0.45	187.5
Pathological biopsy method (< 5%, 5%–20%, > 20%)			
BH	- 803.7 + 178.5 x sex + 12.3 x BH + FL_{PB} (0 = 0, 1 = 163.5, 2 = 393.0)	0.43	190.0
BW	414.5 + 172.6 x sex + 13.1 x BW + FL_{PB} (0 = 0, 1 = 79.8, 2 = 280.7)	0.54	170.8
BSA	- 288.8 + 129.5 x sex + 919.6 x BSA + FL_{PB} (0 = 0, 1 = 93.9, 2 = 304.5)	0.55	170.0
BMI	478.1 + 276.5 x Sex + 30.0 x BMI + FL_{PB} (0 = 0, 1 = 105.3, 2 = 299.1)	0.46	185.4

Sex and FL_{US} are binary variables; FL_{PB} is a dummy variable. Sex: 0 = Female, 1 = Male; FL_{US}: 0 = No, 1 = Yes; FL_{PB}: 0 < 5%, 1 = 5%–20%, 2 > 20%. BH: Body height; BW: Body weight; BSA: Body surface area; BMI: Body mass index; FL_{US}: Fatty liver diagnosed by ultrasound; FL_{PB}: Fatty liver diagnosed by pathological biopsy; RMSE: Root mean standard error.

31]. BSA is a widely used parameter in physiology and clinical medicine for normalizing biological function with respect to variations in body size and conformation. Thus, we believe that the liver size required to meet the metabolic demands of the individual may correlate more closely with BSA than with any other parameter. Additionally, previous studies[30,34] reported that age was associated with TLW; however, similar to Poovathumkadavil's study[35], we failed to identify an association between age and TLW. Several previous studies[31,40] reported that the partial regression coefficient of age was very small, and the authors considered the effect of this variable in adults to be negligible. Therefore, our negative result may be explained by the age distribution of patients in our study and the sample size, and further studies with larger sample sizes are needed to confirm the relation between age and TLW.

Interestingly, this study found that more than a quarter of DDs from the general population had hepatic steatosis, which was similar to Zhou *et al*[41]'s report (29.2%). To our knowledge, an increasing number of individuals, especially those who are obese, suffer from FL worldwide[42,43]. Furthermore, the present study also found that 10.4% and 3.3% of livers had mild and moderate steatosis, respectively, while no liver was detected to have severe steatosis. Several studies have confirmed that mild steatosis grafts (< 33%) can be used safely in LT. However, the eligibility of livers with moderate steatosis is controversial, while livers with severe steatosis are generally discarded because of the increased probability of primary non-function[15,44,45]. Importantly, in the current study, simple linear regression analysis demonstrated that FL was correlated with TLW. Moreover, multivariate analysis showed that steatosis significantly affected TLW, and the degree of steatosis was positively correlated with liver size, which was consistent with previous studies[16,46,47]. Multiple linear regression analysis showed that compared with non-FLs, the presence of hepatic steatosis within 5%, 5%–20% and over 20% resulted in an increase in liver weight by 0 g, 93.9 g, and 304.5 g, respectively. In LT, we generally evaluate the feasibility of SLT

Table 5 Differences between the estimated and actual liver weights calculated using previous formulas in our deceased donor cohort.

based on the criteria of GW/SLW (30%–40%) or GW/BW (0.8%)[11]. Thus, for FL, the GW required for recipients would be underestimated if calculated according to the traditional SLV method, leading to an increased risk of SFSS. Therefore, the current study introduced the FL variable for the first time to develop an SLW model. To diagnose FL before organ procurement, US was performed for all DDs. Notably, for a diagnosis of mild steatosis and greater (≥ 5%), the sensitivity and specificity of US were 86.2% and 92.9%, respectively, and the ICC was 0.70 ($P < 0.001$). That is, US had a higher diagnostic consistency with PB. In addition, this study revealed that the size of livers with a fatty change less than 5% was not different from that of livers without fatty change but was different from that of livers with a fatty change of 5% or greater. The gap of liver size between these two hepatic steatosis categories was significant (180 g, $P < 0.001$), which laid a solid theoretical foundation to apply US in the diagnosis of FL and develop the SLW model, highlighting its clinical practical value.

In this study, the deduced best fit formula based on US had equivalence with that based on PB and was better than the best fit traditional model. Furthermore, the present study showed that the formulas of Deland *et al*[29], Heinemann *et al*[26], and Choukèr *et al*[30] overestimated liver size, while the formulas of Urata *et al*[6], Vauthey *et al*[31], Yoshizumi *et al*[18], Hashimoto *et al*[32], Chan *et al*[33], Yuan *et al*[34], Fu Gui *et al*[23], Poovathumkadavil *et al*[35], and Um *et al*[36] underestimated liver size. On the other hand, there was no significant difference between the actual liver weight and the predicted liver weight calculated by Yu *et al*[25]'s and Lin *et al*[28]'s formulas. This was speculated to be related to the characteristics of the study samples. Deland *et al*[29]'s, Heinemann *et al*[26]'s and Choukèr *et al*[30]'s cohorts were autopsy samples. To

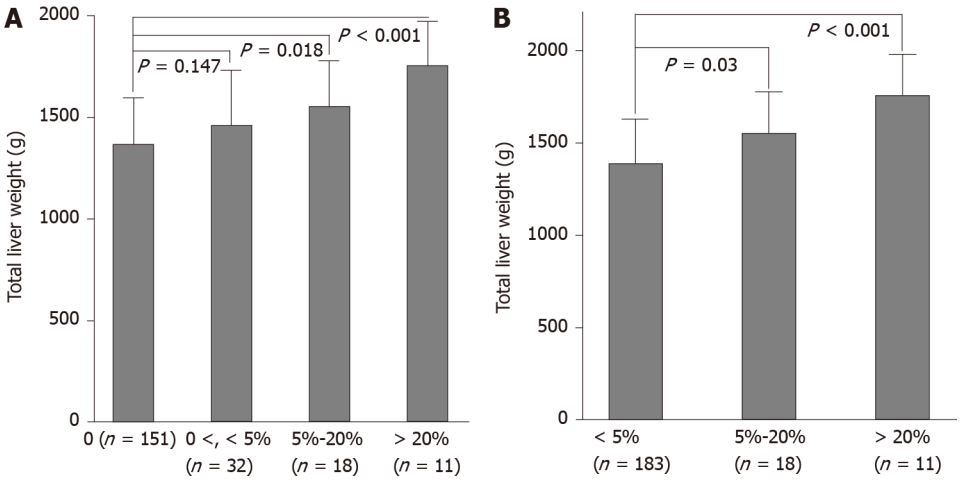

Figure 3 Total liver weight comparison of different groups according to the degree of fatty change of donor livers. A: Groups according to the degree of fatty change of 0, (0 <, < 5%), (5%–20%) and > 20%; B: Groups according to the degree of fatty change of < 5%, (5%–20%) and > 20%. Multiple linear regression analysis including parameters of sex, BSA, and FL_{PB}, which were dummy variables divided into groups according to the degree of fatty change in donor livers, was used. FL_{PB}, fatty liver diagnosed by pathological biopsy.

our knowledge, data from autopsy studies[29] includes the weight of the gallbladder, the attached ligaments, and the hepatic vena cava. In addition, various causes of death, *i.e.*, cardiac failure and traffic accidents, might increase liver weight through mechanisms associated with shock-related hepatic congestion. On the other hand, due to long-term immersion in the fixed solution, the weight of the specimen may exceed the actual size *in vivo*. However, the autopsy study of Yu *et al*[25] was not consistent with the other three autopsy studies but was similar to our study, which may be explained by racial differences. Additionally, the cohorts of Vauthey *et al*[31], Hashimoto *et al*[32], Chan *et al*[33], Yuan *et al*[34], Fu Gui *et al*[23], Poovathumkadavil *et al*[35], and Um *et al*[36] were based on healthy populations without liver disease. However, Lin *et al*[28]'s study cohort comprised 44 (57.1%) patients with chronic liver disease (alcoholic hepatitis, 9; hepatitis B, 24; and hepatitis C, 11), which may explain the difference from other studies based on the general population. Notably, the difference was significant between actual liver weight and estimated liver weight using the formula of Yoshizumi *et al*[18], which was the only previous study based on a cadaveric population. Their study included DDs of several races, most of which were Western, and subjects under 18 years were enrolled. These confounding factors may explain the difference. Therefore, for different study populations, the model for predicting liver size is supposed to be different, which highlights the need for this study for adult DDs. In addition, this study shows the practicability and rationality of the current SLW model in DDLT. Theoretically, it suggests that the current formula is the most suitable for recipients assigned with FL in SLT, and use of this formula is anticipated to reduce the risk of SFSS.

However, the sample size of this study was relatively small, especially in regard to cases of moderate to severe hepatic steatosis. Therefore, studies with larger sample sizes are warranted to optimize the SLW model. Additionally, the extrapolation and clinical practicability of the current SLW model need to be further verified.

CONCLUSION

In conclusion, this study was the first to demonstrate the positive correlation between the degree of hepatic steatosis and liver size based on pathological findings. Furthermore, this study creatively proposed and verified the equivalent value of FL diagnosed by US instead of that diagnosed by PB in terms of the FL variable in the SLW model as follows: SLW (g)= -348.6 + [110.7 x Sex (0 = Female, 1 = Male)] + 958.0 x BSA + [179.8 x FL_{US} (0 = No, 1 = Yes)]. This formula can be used to estimate the liver weight before liver procurement. Additionally, our formula lays a theoretical and practical basis for the further application of donor livers with fatty changes in SLT.

ARTICLE HIGHLIGHTS

Research background

Standard liver weight (SLW) is frequently used in liver transplantation, especially for living donor liver transplantation/split liver transplantation (SLT). However, some deceased donors (DDs) have fatty liver (FL). There have been a few studies to report that FL could impact liver size. This study was to develop a new formula including FL to predict liver size.

Research motivation

To explore SLW model in adult DDs with FL and help transplant doctors make allocation decisions, especially for recipients assigned with FL in SLT to reduce the risk of small-for-size syndrome.

Research objectives

To explore the liver pathology of DDs, such as hepatic steatosis, and diagnostic ability of ultrasound for FL, as well as the relationship between FL and total liver weight. Furthermore, to develop an SLW formula, combined with FL parameter, used to predict graft weight required for recipients in SLT.

Research methods

This study prospectively enrolled consecutive DDs from West China Hospital of Sichuan University from June 2019 to February 2021 and recorded basic patient information, and abdominal ultrasound (US) examination and pathological biopsy (PB) were performed for them. Furthermore, the chi-square test and kappa consistency score were used to assess the consistency in terms of FL diagnosed by US relative to PB. Simple linear regression analysis was used to explore the variables related to TLW. Multiple linear regression analysis was used to formulate SLW models.

Research results

More than a quarter of DDs had hepatic steatosis, and US had a high diagnostic ability for mild to severe FL. Furthermore, this study found that FL was positively correlated with liver size and deduced an optimal SLW formula in adult DDs with FL. However, the extrapolation and clinical practicability of the current SLW model need to be further verified in the future.

Research conclusions

FL is positively correlated with liver size. Our novel formula deduced using sex, BSA and FL_{US} is the optimal formula for predicting SLW in adult DDs with FL.

Research perspectives

To verify the extrapolation of the current SLW model using multicentre data and its clinical practicability in SLT.

ACKNOWLEDGEMENTS

We gratefully acknowledge Dr. Qi-Qi Zhou (Institute of Clinical Pathology, West China Hospital of Sichuan University, Chengdu 610041, Sichuan Province, China) for helping us scan pathological sections and process data. We gratefully acknowledge Dr. Min Jiang (Department of Epidemiology and Health Statistics, West China School of Public Health and West China Fourth Hospital, Sichuan University, Chengdu 610041, Sichuan Province, China) for reviewing the statistical methods of this study.

Abstract

BACKGROUND

Dementia is a chronic progressive neurological disease affecting millions of people worldwide, and represents a relevant economic burden for healthcare systems. Although its pathogenesis is still unknown, recent findings have reported that a dysregulated gut-brain axis communication, a fundamental relationship mediated by several host and microbial molecules, is associated with cognitive disorders. In addition, gut microbiota manipulation reduces neuroinflammation, improving cognitive function by restoring the functional gut-brain axis.

AIM

To better define the effects of probiotics, prebiotics, synbiotics, and fecal microbiota transplant (FMT) on cognitive function.

METHODS

We performed a literature search of human randomized clinical trials to examine the effects of the administration of probiotics, prebiotics, synbiotics, or FMT on cognition outcomes in healthy or sick people of every age, sex, and nationality. We systematically searched Embase, Medline/PubMed, Cochrane Library, central and clinicaltrials.gov databases with a combination of comprehensive terms related to cognition and gut microbiota manipulation. Then we carefully reviewed and synthesized the data by type of study design and setting, characteristics of the studied population, kind of intervention (strain type or mixture type, dosage, and frequency of administration), control treatment, inclusion and exclusion criteria, follow-up duration, and cognitive or memory outcomes.

RESULTS

After examining the titles and abstracts, the initial literature screening identified

995 articles, but we added 23 papers in our systematic review. The analyses of these selected studies highlighted that both probiotic supplementation and FMT improved cognitive function regardless of the type and posology of administration and the adopted cognitive tests and questionnaires. We found that most of the studies conducted in healthy people showed a significant positive effect of the intervention on at least one of the performed cognitive tests. Regarding unhealthy subjects, while FMT and especially probiotic administration had multiple beneficial effects on different cognitive functions, supplementation with prebiotics did not provide any cognitive improvement.

CONCLUSION
Probiotic supplementation and FMT may represent a promising strategy to restore gut eubiosis and enhance the cognitive functions of healthy people and patients with neurological disorders.

Key Words: Dementia; Cognitive disorders; Gut microbiota; Probiotics; Prebiotics; Fecal microbiota transplant

Core Tip: Dementia and cognitive impairment are age-related conditions that are on the rise worldwide. Recent studies have demonstrated the existence of a gut-brain axis and that the manipulation of gut microbiota composition can exert positive effects on cognition. The administration of probiotics, prebiotics, and fecal microbiota transplant may represent a good strategy to counteract gut dysbiosis and ameliorate cognitive dysfunction by reducing neuroinflammation and brain damage.

INTRODUCTION

Global population ageing, defined as the increasing proportion of older people around the globe, represents a deep shift in society and a considerable challenge for the sustainability of healthcare systems due to the rise of geriatric illnesses[1,2]. Currently, the prevalence of cognition impairment, particularly dementia, is estimated worldwide in 50 million people with an economic burden of 818 billion dollars in 2016 and a forecast of about 115 million people by 2050[3,4].

Dementia is an acquired, gradual, and progressive disorder involving multiple adverse neurocognitive changes that can affect learning processes, memory, executive function, language, complex attention, mood, perceptual-motor function or social cognition. Moreover, although its detailed pathological mechanism is still not well understood, dementia often occurs in association with advanced age or the presence of contributing causes, usually Alzheimer's disease (AD), Parkinson's disease (PD), or cerebrovascular pathology[5-7]. Unfortunately, current therapies are only symptomatic, and notably, no treatment stops the disease progression[8].

Recent studies have shown that that the gut microbiota, with more than 100 trillion microorganisms carrying three times of human genes, plays a pivotal role in human health; manipulation of the intestinal microbiota can modify the release of neuroactive metabolites, which affect brain health[9,10]. This role can be further explained by the documented existence of the gut-brain axis, a complex bidirectional system in which communication occurs through three parallel and interplaying pathways that involve nervous, endocrine, and immune signals[11]. Therefore, different preclinical and observational studies have demonstrated that the gut dysbiosis is responsible for increased intestinal permeability, which correlates with both neuroinflammation and a decline of cognitive abilities[12-15].

Dietary interventions (in nutritional supplements or specific diets) have often been applied in clinical practice to restore intestinal eubiosis and prevent and treat cognitive disorders. For example, a Mediterranean diet and/or a healthy diet based on fruits, vegetables, and fish seems to stabilize or slow cognitive decline[16].

Nevertheless, the most promising strategy to counteract gut dysbiosis and to maintain cognitive function seems represented by the administration of probiotics, prebiotics, and fecal microbiota transplant (FMT).

Interestingly, administration in animal models of an adequate posology of multistrain probiotics reduces both Firmicutes/Bacteroidetes ratio and intestinal permeability, slowing cognitive decline and reducing neuroinflammation[17,18]. Moreover, using specific prebiotics seems to ameliorate cognitive performance with a direct effect on gut microbiota[19].

Moreover, even FMT has demonstrated remarkable efficacy in healthy subjects and people affected by various diseases caused by gut microbiota perturbation, particularly *Clostridium difficile* infection. It could represent a promising therapy for cognitive impairment improvement because of its capability to re-establish a healthy gut microbial community[20,21].

Therefore, since the evidence derived from human randomized clinical trials (RCTs) is currently limited, this systematic review identified the available RCTs and better defined the effects of probiotics, prebiotics, synbiotics, and FMT on cognitive functions.

MATERIALS AND METHODS

Literature search

Our study followed the PRISMA statement guidelines. A computerized search of the articles published until 24 October 2019 was conducted in Embase, Medline/PubMed, Cochrane Library, central and clinicaltrials.gov databases and other individual journal sources, using the following search string: (memory OR cognition OR dementia) AND (lactobacillus OR bifidobacteria OR streptococcus OR enterococcus OR probiotic OR prebiotic OR symbiotic OR fecal, transplantation). In the PubMed database, we activated the filter "Humans"; in Embase, we selected the filter "Research articles"; in Cochrane Library, we activated the filter "Trials"; and in clinicaltrials.gov, we selected the filter "recruitment: terminated or completed." The search did not apply filters for language, country, duration of follow-up, and participants' characteristics (age and sex).

Study selection

Two authors independently reviewed the titles and abstracts of the collected articles, applying predefined inclusion/exclusion criteria. The inclusion criteria were as follows: RCTs; availability of full text; patients regardless of age, nationality, sex, and health status; comparison between oral intake of probiotics, prebiotics, or symbiotic and control treatment or placebo; and outcome as cognitive or memory evaluation. The adopted exclusion criteria were as follows: Studies with fewer than 10 participants; reviews, articles, and case reports; or studies with incomplete outcomes.

Data extraction

The same two authors performed analyses of the full text and data extraction with the intervention of a third author in case of poor agreement or discrepancies. Each reviewer independently recorded the data in a predefined data extraction form. The following data, if reported, were obtained from each selected trial: First author name, year of publication, study design, setting (institution, city, and country), characteristics of the studied population (mainly age and health status), number of total participants and their gender, number of subjects in both treatment and control groups, characteristics of the intervention (strain type or mixture type, dosage and frequency of administration), control treatment, inclusion and exclusion criteria, follow-up duration, cognitive or memory outcomes and compliance data.

Outcome assessment

For each selected study, cognitive functions were assessed through specific tests which evaluated the eight main cognitive skills: sustained attention, speed of information processing, cognitive flexibility and control, multiple simultaneous attention, working memory (short-term memory), category formation, pattern recognition, and response

inhibition[22]. A detailed description of all cognitive tests performed in the selected papers for this systematic review is annexed in Supplementary material.

RESULTS

Study selection

The initial literature screening identified 995 papers. Eight studies were excluded for duplication and another 964 papers were removed after the title and abstract screening because they did not respect inclusion criteria. The selection process, in accordance with the PRISMA statement 2009, is illustrated in Figure 1.

Characteristics of the included studies

An overview of the 23 studies included in this systematic review is reported in Table 1. All 23 included papers were RCTs published from 2007 to 2019[23-45]. The total number of participants was 1285 (491 males and 650 females); unfortunately, both articles published by Tamtaji *et al*[44,45] did not report the gender of the participants. Regarding the age of the enrolled subjects, one study was conducted in healthy scholars (7-9 years)[31], four studies enrolled young adults (19-30 years)[25,36,40,43], and most of the studies involved adults or older people (48-95 years)[23,24,26-30,32-35,37-39,40,42,44,45]. Most studies (four) were performed in Iran[22,24,44,45]; three in the United States[26-28] and Japan[34,37,39]; two in the United Kingdom[29,31], South Korea[33,35], and Spain[30,41]; and one in Austria[25], Italy[32], Ireland[36], Malaysia [38], Poland[42], Wales[43] and the Netherlands[40].

Concerning the patients' health state, most studies enrolled healthy people[25,29,31,33-36,40,43], whereas three studies involved patients with AD[23,24,44] or cirrhotic subjects with recurrent encephalopathy[26-28]. The other studies were focused on stressed adults[38], patients with PD[45], human immunodeficiency virus (HIV)-1-infected individuals[32], subjects affected by fibromyalgia syndrome[41], people with major depression[42], elderly with frailty syndrome[30], and adults with forgetfulness [39] and mild cognitive impairment[37].

In the trials, subjects were administered probiotics[22-25,26,29,32-42,44,45], prebiotics[30,31,43], or FMT[27,28] and its duration lasted a maximum of 24 wk[32] and a minimum of 4 h[43]; however, the trials continued for 12 wk for most of the studies[23,24,31,33-35,37,38,44,45]. No studies have reported the administration of synbiotics. In the studies examining the effects of probiotics, a total of 21 different bacterial species were administered (alone or in combination) in a dosage ranging from 1×10^9 CFU/mL to 2.5×10^{10} CFU/mL; the most represented species were *Lactobacillus plantarum*, *L. acidophilus*, and *Bifidobacterium bifidum*. On the other side, the administered prebiotics was composed of inulin or galacto-oligosaccharides (GOS), in a dosage that ranged from 5 g/d to 7.5 g/d. In FMT studies, subjects were administered a capsule containing 550 μL stool and buffer solution or enema infusion of 90 mL FMT solution. Lastly, only five studies reported their compliance[31,33-35,44,45], and it was generally considered high because it ranged from 82.69% to 100%.

Effects of probiotics and prebiotics on the cognitive functions of healthy people

Regarding the healthy subjects, three studies showed no significant difference between probiotic and placebo groups[29,31,36]. In comparison, five studies showed a significant positive effect of the intervention on at least one of the performed cognitive tests[25,33,35,40,43].

In Benton *et al*[29], the healthy enrolled subjects ingested fermented milk containing *L. casei* Shirota daily for 3 wk. However, no significant differences between the probiotic and placebo groups were reported regarding episodic and long-term memory, assessed with the Wechsler Memory Scale test and the ability to remember the capitals of 30 countries. Moreover, the healthy people treated with *L. rhamnosus* supplement in Kelly *et al*[36] did not report any cognitive improvement, as assessed with the Paired Associates Learning, Attention Switching Task, Rapid Visual Information-Processing task (RVIP), Emotion Recognition Task and electroencephalography tests.

Considering the five studies reporting a significant cognitive improvement, Bagga *et al*[25] found that 4 wk administration of a multistrain probiotic increased Positive and Negative Affect Schedule (PANAS) score (paired with the response accuracy to unpleasant stimuli test) and showed the activation of the cingulum, pre-cuneum and cerebellum areas, involved in decision making and memory process.

Table 1 Summarizing of all selected studies

Ref.	Study design	Setting	Characteristics of the studied population	Number of participants (M/F)	Intervention	Comparison	Duration of intervention	Outcomes	Compliance
Agahi *et al*[23], 2018	RCT	Cities: Emam Ali, Golabchi, Miad, Barekat; Country: Iran	Patients with Alzheimer disease; Age: 65-90 yr; Control group: 80.57 ± 1.79 yr; Intervention group: 79.70 ± 1.72 yr	Total: 48; Control group = 23 (10/13); Intervention group = 25 (7/18)	1 capsule with *L. fermentum, L. plantarum, B. lactis* and 1 capsule with *L. acidophilus, B. bifidum, and B. longum* (3×10^9 CFU)	Placebo	12 wk	TYM	-
Akbari *et al* [24], 2016	RCT	Cities: Golabchi, Sadeghyeh; Country: Iran	Patients with Alzheimer disease; Age: 60-95 yr; Control group: 82.00 ± 1.69 yr; Intervention group: 77.67 ± 2.62 yr	Total: 60; Control group = 30 (24/6); Intervention group = 30 (24/6)	200 mL/d probiotic milk containing *L. acidophilus*, *L. casei*, *B. bifidum*, and *L. fermentum* (2×10^9 CFU each)	Placebo	12 wk	MMSE	-
Bagga *et al*[25], 2018	RCT	City: Graz Country: Austria	Healthy volunteers; Age: 20-40 yr; Control group (placebo): 27.25 ± 5.78 yr; No intervention group: 23.87 ± 4.97 yr; Intervention group: 28.27 ± 4.2 yr	Total: 45; Control group = 15 (9/6); No intervention group = 15 (7/8); Intervention group = 15 (7/8)	1 sachet/d with 3 g freeze-dried powder containing *L. casei* W56, *L. acidophilus* W22, *L. paracasei* W20, *B. lactis* W51, *L. salivarius* W24, *L. lactis* W19, *B. lactis* W52, *L. plantarum* W62 and *B. bifidum* W23(7.5×10^6 CFU/g)	Placebo or no intervention	4 wk	PANAS, SCL-90, ADS, LEIDS, RM task, ED task	-
Bajaj *et al*[26], 2014	RCT	City: Richmond, Virginia Country: United States	Patients with hepatic encephalopathy; Age: 18-65 yr; Control group: 58.5 ± 4.5 yr; Intervention group: 58.4 ± 3.8 yr	Total: 30; Control group = 16 (12/4); Intervention group = 14 (10/4)	*L. rhamnosus* GG (ATCC 53103)(> 50 billion CFU/gm)	Placebo	8 wk	NCT-A, NCT-B, DS, BDT	-
Bajaj *et al*[27], 2017	RCT	City: Richmond, Virginia Country: United States	Patients with hepatic encephalopathy; Mean age: 62 yr; Control group: 62.9 ± 9.8 yr; Intervention group: 64.5 ± 5.1 yr	Total: 20; Control group = 10 (10/0); Intervention group = 10 (10/0)	FMT units (90 mL total) instilled by enema and retained for 30 min	Standard of care	20 wk	EncephalApp-Stroop, PHES	-
Bajaj *et al*[28], 2019	RCT	City: Richmond, Virginia Country: United States	Patients with hepatic encephalopathy; Control group: 64.2 ± 6.2 yr; Intervention group: 63.3 ± 4.2 yr	Total: 20; Control group = 10 (8/2); Intervention group = 10 (8/2)	FMT capsules (550 µL of stool and buffer solution)	Placebo	20 wk	EncephalApp-Stroop, PHES	-
Benton *et al* [29], 2007	RCT	City: Swansea Country: Wales	Healthy volunteers; Age: 48-79 yr; Average age 61.8 ±7.3 yr	Total: 126 (51/75)	65 mL of milk drink containing *L. casei* Shirota (10^8/mL)	Placebo	3 wk	POMS, WMS, VFT, NART, Ability to recall the capital cities of countries	-
Buigues *et al* [30], 2016	RCT	City: Valencia Country: Spain	People with frailty syndrome; Age: 66-90 yr; Control group: 73.4 ± 1.8 yr; Intervention group: 74.2 ± 1.6 yr	Total: 50; Control group = 22 (6 /16); Intervention group = 28 (9/19)	7.5 g/d of Darmocare Pre® (Inulin 3375 mg, FOS 3488)	Placebo	13 wk	MMSE	-

Capitão *et al* [31], 2020	RCT	Cities: Swindon, Milton Keynes, London Country: United Kingdom	Healthy scholars; Age: 7-9 yr; Control group: 9.12 ± 1.02 yr; Intervention group: 8.54 ± 0.79 yr	Total: 35; Control group = 18 (12/6); Intervention group = 17 (12/5)	5.5 g/d of Bimuno (B-GOS, Lactose, Glucose, Galactose)	Placebo	12 wk	BAS-III, CogTrackTM battery, STAIC, MFQ	High (> 80%)
Ceccarelli *et al* [32], 2017	RCT	City: Rome Country: Italy	HIV-1 infected individuals; Median age: 48 (IQR: 38-54) yr; Intervention group: 45 (35-52.5) yr; Control group: 43 (38.2-53) yr	Total: 35; Control group = 26 (24/2); Intervention group = 9 (9/0)	Sachet containing *L. plantarum* DSM 24730 *S. thermophilus* DSM 24731, *B. breve* DSM 24732, *L. paracasei* DSM 24733, *L. delbrueckii subsp. bulgaricus* DSM 24734, *L. acidophilus* DSM 24735 *B. longum* DSM 24736, and *B. infantis* DSM 24737(450×10^9 bacteria)	Control group	24 wk	ROCF, RAVLT, STEP, VST, PVF, SVF, SPM, DS, CBTT, AAT, TMT A, TMT B	-
Chung *et al* [33], 2014	RCT	City: Jeonju Country: Korea	Healthy volunteers; Age: 60-75 yr; Control group: 64.50 ± 4.84 yr; Intervention group (500 mg): 64.50 ± 2.17 yr; Intervention group (1000 mg): 64.43 ± 4.47 yr; Intervention group (2000 mg): 66.56 ± 4.98 yr	Total: 36; Control group = 10 (4/6); Intervention group (500 mg) = 10 (9/1); Intervention group (1000 mg) = 7 (2/5); Intervention group (2000 mg) = 9 (5/4)	Daily doses of 500, 1000, or 2000 mg. of tablet containing *L. helveticus* IDCC3801	Placebo	12 wk	DS, SRT, VLT, RVIP, SCWT	> 70%
Inoue *et al*[34], 2018	RCT	City; Hyogo prefecture, Country: Japan	Healthy volunteers; Average age: 70.3 ± 3.1 yr; Control group: 70.9 ± 3.2 yr; Intervention group: 69.9 ± 3.0 yr	Total: 38; Control group = 18 (7/11); Intervention group = 20 (7/13)	Sachet containing lyophilised powder of *B. longum* BB536, *B. infantis* M-63, *B. breve* M-16V and *B.breve* B-3 (1.25×10^{10} CFU each)	Placebo	12 wk	MoCA, Modified flanker task, PHQ-9, GAD-7	> 99%
Hwang *et al* [35], 2019	RCT	City: Jeonju Country: South Korea	People with mild cognitive impairment; Age: 55-85 yr; Control group: 69.2 ± 7.00 yr; Intervention group: 68.0 ± 5.12 yr	Total: 100; Control group = 50 (14/36); Intervention group = 50 (20/30)	Mixture of fermented soybean powder and *L. plantarum* C29 (1.25×10^{10} CFU/g)	Placebo	12 wk	VLT, DS, ACPT	> 90%
Kelly *et al*[36], 2017	RCT	City: Cork Country: Ireland	Healthy volunteers; Age: 20-33 yr; Placebo/Probiotic group: 23.6 ± 0.97 yr; Probiotic/Placebo group: 25.64 ± 1.14 yr	Total: 29; Placebo/Probiotic group = 15 (15/0); Probiotic/Placebo group = 14 (14/0)	Active capsules contained corn starch, magnesium stearate, silicon dioxide and *L. Rhamnosus*(1×10^9 CFU)	Placebo	8 wk	MOT, PAL, AST, RVIP, ERT, Emotional Stroop	-
Kobayashi *et al* [37], 2019	RCT	City: Tokyo Country: Japan	People with memory complaints; Age: 50-80 yr; Control group: 61.6 ± 6.37 yr; Intervention group: 61.5 ± 6.83 yr	Total: 117; Control group = 58 (29/29); Intervention group = 59 (29/30)	1 capsule per day with *B. breve* A1 ($> 2 \times 10^{10}$ CFU)	Placebo	12 wk	RBANS, MMSE	-
Lew *et al*[38], 2019	RCT	Cities: Penang, Kubang Kerian Country: Malaysia	Stressed adults; Age: 18-60 yr; Control group: 32.1 ± 11.4 yr; Intervention group: 31.3 ± 10.8 yr	Total: 103; Control group = 51 (12/39); Probiotic group = 52 (12/40)	*L. plantarum* P8 (10^{10} CFU/sachet per day)	Placebo	12 wk	PSS-10, DASS-42, CBB	-
Ohsawa *et al* [39], 2018	RCT	Country: Japan	People with forgetfulness; 50-70 yr; Control group: 57.8	Total: 60; Control group = 29 (13/16); Intervention	One bottle per day (190 g per bottle) of a *L. helveticus*-fermented	Placebo	8 wk	RBANS, POMS	-

			± 5.9 yr; Intervention group: 58.5 ± 6.5 yr	group = 31 (13/18)	milk contained 2.4 mg of lactononadecapeptide				
Papalini *et al* [40], 2019	RCT	City: Nijmegen Country: The Netherlands	Healthy volunteers; Age:18-40 yr; Control group: 22 yr (SE = 0.5); Intervention group: 21 yr (SE = 0.4)	Total: 58; Control group = 29 (0/29); Intervention group = 29 (0/29)	2 g/d of powder diluted in water or milk containing *B. bifidum* W23, *B. lactis* W51, *B. lactis* W52, *L. acidophilus* W37, *L. brevis* W63, *L. casei* W56, *L. salivarius* W24, *L. lactis* W19 *L. lactis* W58(5×10^9 CFU)	Placebo	4 wk	BDI, LEIDS-r, Emotional face-word Stroop task, Emotional face-matching paradigm, SCWT, DS, SECPT	-
Roman *et al* [41], 2018	RCT	City: Almeria Country: Spain	Fibromyalgia patients; Control group: 50.27 ± 2.03 yr; Intervention group: 55.00 ± 2.09 yr	Total: 31; Control group = 15 (2/13); Intervention group = 16 (1/15)	4 pills/d containing *L. Rhamnosus* GG®, *L. casei*, *L. acidophilus*, and *B. Bifidus* (6×10^6 bacteria per capsule)	Placebo	8 wk	MMSE, BDI, IGT, Two-choice Task	-
Rudzki *et al* [42], 2019	RCT	City: Bialystok Country: Poland	People with major depression; Control group: 38.90 (12) yr (SD); Intervention group: 39.13 (9.96) yr	Total: 60; Control group = 30 (10/20); Intervention group = 30 (7/23)	2 capsules/d containing *L. plantarum* 299v (10×10^9 CFU per capsule)	Placebo	8 wk	HAM-D 17, SCL-90, PSS-10, APT, RFFT, TMT A, TMT B, CVLT Stroop Test parts A and B	-
Smith *et al*[43], 2015	RCT	City: Cardiff Country: Galles	Healthy volunteers; Age: 19-30 yr; Mean age 23.0 yr	Total: 47 (19/28)	One sachet of Inulin per day (5 mg)	Placebo	4 h	Mood, Performance Tasks, Memory Tasks, Psychomotor Tasks, Selective Attention Tasks, Sustained Attention Task	-
Tamtaji *et al* [44], 2019	RCT	City: Kashan, Shahrekord Country: Iran	Patients with Alzheimer disease; Age: 55-100 yr; Control group: 78.5 ± 8.0 yr; Intervention group (Selenium): 78.8 ± 10.2 yr; Intervention group (Selenium + probiotic): 76.2 ± 8.1 yr	Total: 79; Control group = 26; Intervention group (Selenium) = 26; Intervention group (Selenium + probiotic) = 27	Selenium (200 μg/d) and probiotic containing *L. acidophilus*, *B. bifidum*, and *B. longum* (2×10^9 CFU/d each)	Placebo or only selenium (200 μg/d)	12 wk	MMSE	100%
Tamtaji *et al* [45], 2019	RCT	City: Kashan Country: Iran	Patients with Parkinson disease; Age: 50-90 yr; Control group: 67.7 ± 10.2 yr; Intervention group: 68.2 ± 7.8 yr	Total: 60; Control group = 30; Intervention group = 30	Probiotic containing *L. acidophilus*, *B. bifidum*, *L. reuteri*, and *L. fermentum* (each 2×10^9 CFU/g)	Placebo	12 wk	MDS-UPDRS	90%

Papalini *et al*[40] tested a probiotic multistrain mixture in women who underwent a stressful condition for 4 wk. The results showed that the trial reduced the unfavorable stress effect on working memory performance measured by the DS backward test. In addition, Chung *et al*[33] demonstrated a significant improvement in Verbal Learning Test, Story Recall Test, RVIP and Stroop Color and Word Test after 12 wk administration of *L. helveticus* in healthy subjects compared to placebo. Finally, Inoue *et al*[34] demonstrated that intervention with *Bifidobacterium spp.* for 12 wk, added to resistance training, significantly improved response accuracy and reaction time tests in healthy elderly subjects. Regarding the cognitive effects of prebiotic administration, the study conducted in healthy children by Capitão *et al*[31] reported that 12 wk GOS supplement only improved memory retrieval speed assessed with the CogTrackTM test battery. By contrast, Smith *et al*[43] investigated the acute effects of inulin intake on healthy volunteers and reported improving memory tasks, especially immediate free and delayed recall. No FMT intervention has been carried out in healthy subjects. Hence, although three of eight studies conducted in healthy subjects showed no significant difference between intervention and placebo groups, probiotics resulted were more effective in improving cognitive function than prebiotics.

Patients with different pathologies and the impact of probiotics/prebiotics/FMT on cognitive functions

The effects of probiotics, prebiotics, and FMT on cognitive functions were also assessed in different diseases, of which the most represented were hepatic encephalopathy (HE) and AD. Bajaj *et al*[26] conducted three studies on HE. In particular, the authors first investigated the effect of *Lactobacillus GG* administration on HE but did not report changes in cognition. However, they also treated HE patients with FMT *via* enema and reported a significant improvement in PHES and EncephalApp Stroop tests[27]. Moreover, Bajaj *et al*[28] evaluated the treatment with FMT capsules effects on HE patients, and they reported only a significant improvement in the EncephalApp Stroop test.

Regarding AD, Agahi *et al*[23] administered two different multistrain probiotic capsules to patients affected by severe disease for 12 wk, but no effect on TYM cognitive tests were reported. By contrast, Akbari *et al*[24] found that daily administration of probiotic milk enriched with *Lactobacillus spp.* led to a decline in Mini Mental State Evaluation (MMSE) score in AD patients compared to placebo. Moreover, Tamtaji *et al*[44] found that a probiotic and selenium co-supplement in AD patients was responsible for a significant increase in MMSE score. In addition, Hwang *et al*[35] found that people with mild cognitive impairment showed an improvement in a

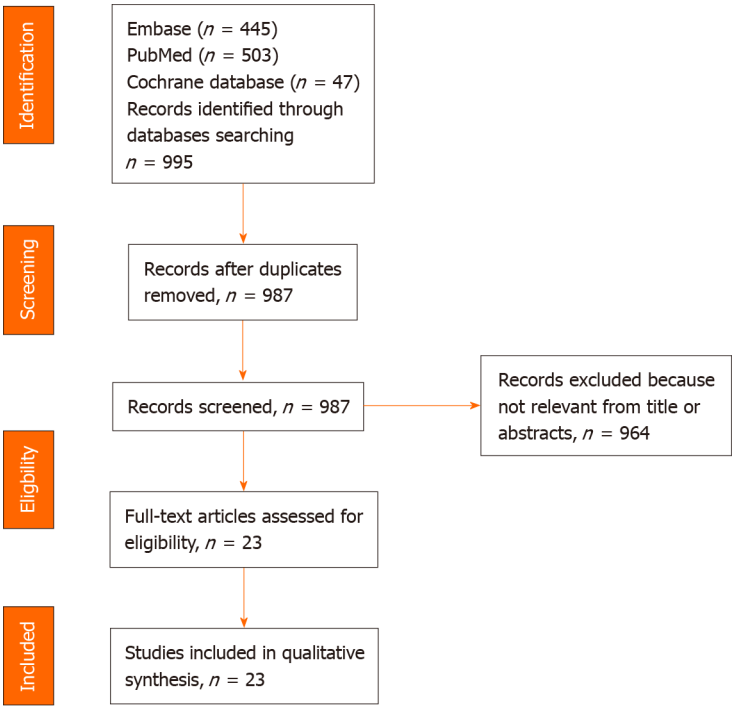

Figure 1 PRISMA flow diagram.

battery of tests related to verbal memory and attention domains after ingesting a mixture of *L. plantarum* C29 and fermented soybean powder. Finally, Lew *et al*[38] reported that daily administration of *L. plantarum* P8 for 12 wk in stressed adults led to a reduction of stress score and enhanced cognition and verbal learning memory, assessed through the CBB. Another study, conducted by Roman *et al*[41], explored the effect of a multispecies probiotic on fibromyalgia patients and found a significantly reduced number of impulsive choices. Moreover, Kobayashi *et al*[37] carried out a 12-wk treatment with *Bifidobacterium breve* A1 in elderly subjects with memory complaints, documenting a significant decline of total scores of both Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) and MMSE tests. Regarding patients affected by PD, Tamtaji *et al*[45] highlighted a favorable reduction of the Movement Disorders Society-Unified PD Rating Scale (MDS-UPDRS) after ingesting a probiotic mixture for 12 wk. In addition, Ohsawa *et al*[39] reported improved attention, coding, and delayed memory scores (assessed with RBANS) in people with forgetfulness after 8 wk intake of a *L. helveticus* fermented milk drink. Also, Rudzki *et al*[42] reported a significant improvement in CVLT and APT in people with major depression treated with *L. plantarum 299v*. Moreover, Ceccarelli *et al*[32] demonstrated a significant improvement in several cognitive functions in HIV-1 infected patients ingesting a multistrain probiotic for 24 wk (primarily in the following neurocognitive tests: Rey-Osterrieth Complex Figure, Rey Auditory Verbal Learning Test, Test of Time and Weights Estimation, Phonological Verbal Fluency Test, Corsi Block Tapping Test and Trail Making Test A). Finally, the only study which assessed the effectiveness of a prebiotic intake (inulin and fructooligosaccharides), conducted by Buigues *et al*[30] on elderly affected by frailty syndrome, the MMSE did not report significant cognitive improvement. As a result, while the FMT and especially probiotics played multiple beneficial effects on different cognitive functions of unhealthy subjects, the prebiotics' supplementation did not provide any cognitive improvement, maybe because of their short-term administration.

DISCUSSION

Dementia is a chronic, gradual, and progressive neurological disease that affects millions of people in both industrialized and rural countries. Cognitive decline and daily activities impairment limits patients' self-care and causes a severe burden to parents, friends, caregivers, and especially to the healthcare systems[46,47]. Increasing evidence suggests that the prevalence of dementia rises with age and is strongly

associated with other comorbidities, including AD and cardiovascular risk factors such as hypertension and hypercholesterolaemia[48].

Although the specific dementia pathogenesis is not yet understood and current therapies only attempt to counterbalance the disturbance, several studies recently highlighted the central role of the gut microbiota in brain health and the onset and persistence of neurodegenerative diseases[49,50]. Nevertheless, our systematic review of human RCTs reported contradictory results due to the diverse type, posology, and duration of interventions and the different responses of healthy or diseased people to the treatment.

In general, supplementation with probiotics and prebiotics determined the positive effects on healthy subjects. Five (63%) out[25,33,34,40,43] of the eight studies conducted in volunteers reported beneficial effects on the cognitive functions, while the other three[29,31,36] studies did not find any difference between the intervention and control groups.

Regarding the different evaluated patients, only 3 (20%)[23,26,30] of the 15 studies did not report an amelioration of cognitive functions for other possible reasons. For example, the probiotics' administration performed by Bajaj *et al*[26] probably did not last for a sufficient time to obtain cognitive improvement in patients with HE. In contrast, with 13 wk of prebiotics' supplementation, Buigues *et al*[30] did not observe effects on cognitive behaviour because MMSE does not represent a sensitive tool to detect the small changes in cognition that may occur after inulin and FOS supplementation. In addition, in the study conducted by Agahi *et al*[23], the 12 wk probiotic administration did not lead to cognitive amelioration in patients with AD; a probable explanation could be the enrollment of only patients with advanced disease.

Probiotic supplementation improves cognitive functions in many different diseases such as HIV[32], PD[45], fibromyalgia, major depression[42], AD[24,44], and other mild cognitive deficits[35,37-39]. Furthermore, studies evaluating the effects of FMT on patients with HE highlighted a significant amelioration in cognitive functionality[27,28]. It is well established that a balanced gut microbiota composition (eubiosis condition) plays a crucial role in our health; a dysbiotic status (meaning a reduced gut microbiota diversity) is related to many human gastrointestinal, immunological, and neurodegenerative diseases[51]. Concerning neurological impairments, recent findings elucidated the importance of the gut microbiota in the bidirectional communication between the central and enteric nervous systems, called the gut-brain axis[52]. Hence, the main factors responsible for intestinal dysbiosis such as stress, unbalanced diet, and drug abuse also determine an alteration of the gut-brain axis by causing a loss of epithelial integrity. The loss of this barrier functionality allows microbial-derived molecules to enter the systemic circulation, promoting endotoxemia, oxidative stress and low-grade inflammation responsible for the blood-brain barrier disruption[53,54] (Figure 2); these factors represent a signature for neurodegenerative disorders, especially AD. Consequently, given the importance of the intestinal barrier integrity for the prevention of neuroinflammation and brain damage, gut microbiota modulation by psychobiotics, namely beneficial bacteria (probiotics) or support for such bacteria (prebiotics) and FMT, represent an excellent strategy to restore the intestinal permeability and prevent the consequences of a leaky gut[55-57].

However, although several studies have highlighted the local beneficial effects of probiotics, prebiotics and FMT (*e.g.*, modification of the gut microbiota composition, strengthening of the gut epithelial barrier and modulation of the local (mucosal) immune system), they also exerted systemic effects, in particular on the central nervous system[58,60]. More specifically, recent studies have reported that the intestinal microbiota affects neurodevelopment and diverse brain functions by regulating the gut-brain axis, for example, by acting on the electrophysiological thresholds of the enteric nervous system neurons, which interact *via* neurotransmitters (adrenaline, noradrenaline, and acetylcholine) with the central nervous system[61].

Another important neuronal pathway in gut-brain communication involves the vagus nerve, and many effects of probiotics strains influence its activity[62]. Furthermore, since the gut houses the most extensive collection of lymphoid tissues in the human body and various intestinal immune cells can cross the blood-brain barrier, gut microbiota manipulation represents a key indirect route for communication between the gut microbiota and the central nervous system[63]. Intriguingly, specific probiotic formulations have also been shown an ability to stimulate the production of neurotransmitters (*e.g.*, GABA, serotonin, and dopamine) or are even microbially neuroactive. These microbial metabolites can trigger epigenetic signals on human brain genes involved in various complex networks or act as a ligand for specific human receptors[64].

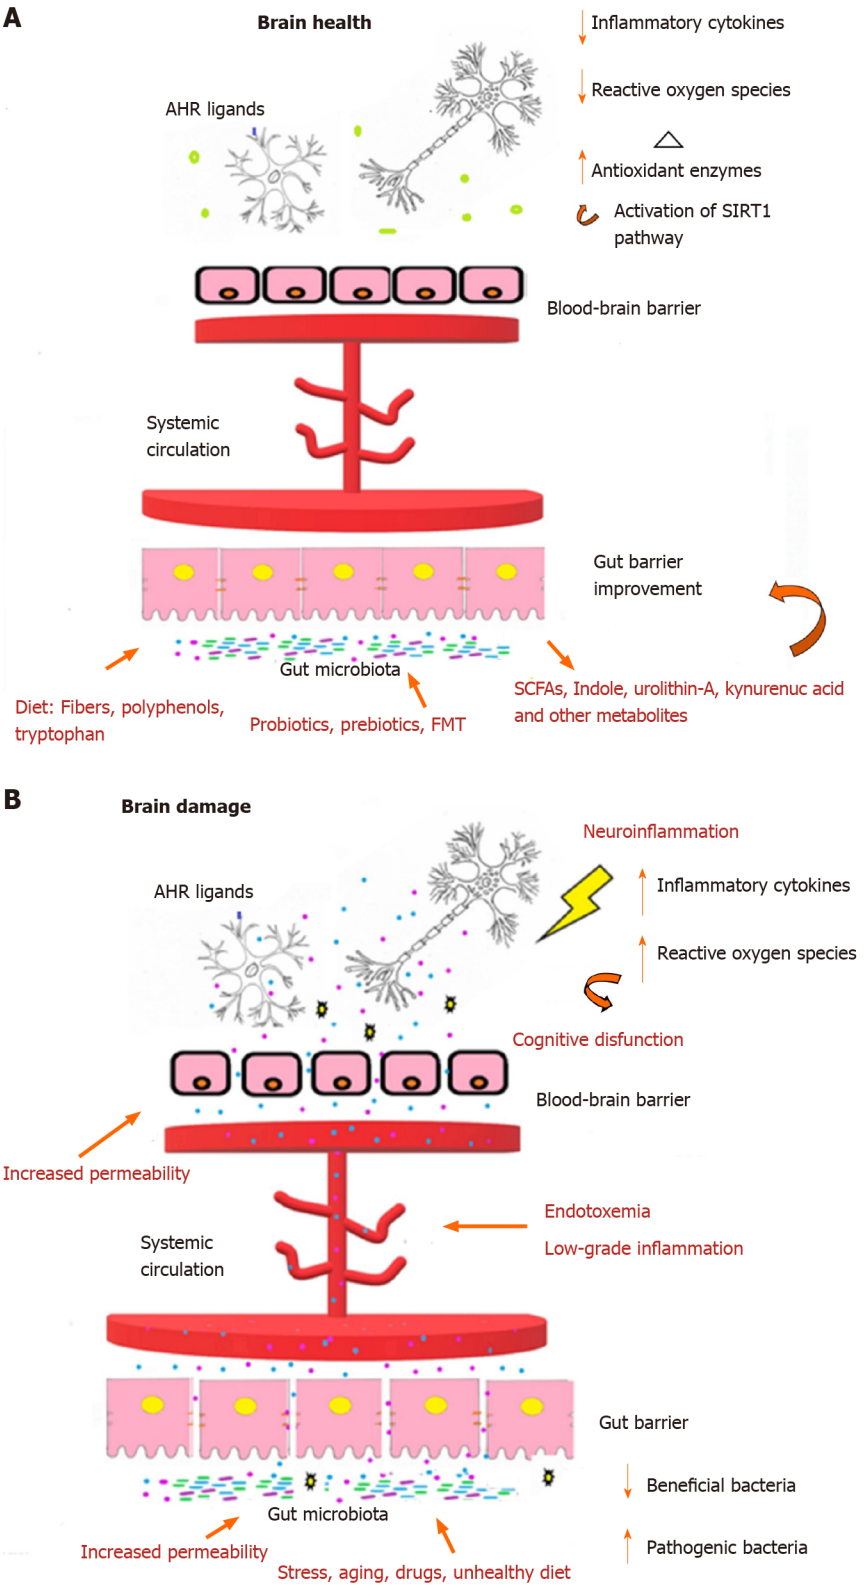

Figure 2 Gut-brain axis in eubiosis and dysbiosis condition. A: Eubiosis; B: Dysbiosis condition. AHR: Aryl hydrocarbon receptor; FMT: Fecal microbiota transplant; SCFA: Short-chain fatty acid; SIRT1: Sirtuin 1.

For instance, the probiotic activated Sirtuin 1 pathway, which regulates the brain antioxidant enzymes such as superoxide dismutase and glutathione peroxidase, could favor cognitive improvements by preventing oxidative stress and deposition of beta-amyloid in the brain[65]. Even the modulation of kynurenine metabolism, the primary route for tryptophan catabolism, which is closely related to the structural and functional dynamics of the gut microbiota, could positively affect brain health[66]. Indeed, *in vivo L. plantarum* administration demonstrated a beneficial reduction of

kynurenines as most act as neurotoxic compounds[42,67,68]. Notably, although *L. plantarum* was administered to healthy or ill people in most of our selected RCTs, its positive effects have been probably underestimated because of the unknown impact of the other components of the probiotic formula that include it.

By contrast, indole-3-lactic acid (ILA) is an interesting neuroprotective tryptophan metabolite mainly produced by *Bifidobacterium spp*. acting as an aryl hydrocarbon receptor (AhR) agonist, expressed by intestinal and neuronal cells[69,70]. In detail, microbial agonists produced by *L. bulgaricus* and *L. reuteri* could activate microglia and astrocytes AhRs, suppressing pro-inflammatory signals and preventing neuronal damage[71-73]. Furthermore, the administration of some probiotics (especially *L. helveticus*, *L. casei* and *L. rhamnosus*) and prebiotics could also improve cognitive functions by stimulating the production of short-chain fatty acids as they enhance the transcription of the brain-derived neurotrophic factor that stimulates neuronal plasticity, protecting against neuroinflammation and neuronal apoptosis[74-78]. Moreover, the FMT represents a very promising strategy to re-establish gut eubiosis and improve cognitive functions. For instance, in transgenic mice, FMT significantly improved cognitive deficits, beta-amyloid accumulation, and neuroinflammation while reducing UPDRS score and tremor in people with Parkinson disease[79].

Finally, our recent study demonstrated that age-associated shifts of the microbiota have a detrimental impact on the central nervous system's protein expression and critical functions. Still, FMT represents an excellent strategy to restore a young-like microbiota and improve cognitive functions[80]. Therefore, although the modulation of intestinal microbiota represents a new precious therapeutic opportunity, it also shows some restrictions and risks. In particular, even if probiotics are generally considered safe and have many advantages such as a tolerated mode of administration (orally) and the possibility to integrate them with other pharmacological/non-pharmacological approaches, they displayed some limitations mainly due to potential side effects, especially in some patients (including immunocompromised people), or to their long-term safety[81]. Besides, even if probiotics can promote the production of several compounds such as lactic acid, bioamines, bile salts and other molecules that could play detrimental effects on the host, most of them are sold as dietetic supplements, and the regulatory agencies do not require safety studies in humans before their commercialization[82,83].

Although reported to be fairly safe in most clinical trials, FMT can be responsible for acute or prolonged adverse effects such as diarrhea, abdominal pain, nausea, headaches, and fatigue[84]. In particular, immunological concerns have been raised regarding safety assessments for both probiotics and the FMT because either indigenous or transient microorganisms could impact the immune system's functionality. Hence, the FMT application or the administration of probiotics to specific vulnerable populations and stressed or aged people, immunocompromised patients, newborns or pregnant women must be well evaluated to prevent microbial translocation and sepsis[85-87]. Moreover, the current literature lacks information about the long-term administration of probiotics; therefore, the possible horizontal transfer of antibiotic resistance genes favored by their supplementation cannot be excluded. Likewise, because stool contains thousands of microorganisms and a vast number of metabolites, FMT represents a constant risk of pathogens or commensals transfer to donors that may harmfully affect them[88].

CONCLUSION

As a final note, the different defects found in the evaluated studies highlighted some methodical limitations such as small sample sizes, the limited sampling time and the wide range of other cognitive tests. Supplementation of probiotics and FMT could represent a non-invasive successful strategy to restore gut eubiosis and enhance cognitive functions in healthy people and patients with different neurological/neurodegenerative diseases. Of course, further specific and clinical studies with numerous patients are needed to confirm this encouraging hypothesis.

ARTICLE HIGHLIGHTS

Research background

Due to the global population aging, cognitive impairments will affect approximately

115 million people by 2050. Since current therapies only attempt to counterbalance cognitive disorders, many recent studies recently highlighted the central role of the gut microbiota in brain health.

Research motivation

The pathogenesis of several cognitive disorders is still not fully understood; however, it has been recently established that a dysregulated gut-brain axis communication is associated with the onset and persistence of neurodegenerative diseases. Thus, gut microbiota manipulation could restore a functional gut-brain axis improving cognitive functions.

Research objectives

Since the evidence derived from human randomized clinical trials (RCTs) is currently limited, the main purpose of this systematic review was to detect the currently available RCTs, to define better the effects of probiotics, prebiotics, and fecal microbiota transplant (FMT) on cognitive functions.

Research methods

We systematically searched Embase, Medline/PubMed, Cochrane Library, central and clinicaltrials.gov databases with a combination of comprehensive terms related to cognition and gut microbiota manipulation. Then, we carefully reviewed and synthesized the data by types of study design and setting, characteristics of the studied population, kind of the intervention (strain type or mixture type, dosage and frequency of administration), control treatment, inclusion and exclusion criteria, follow-up duration, and cognitive or memory outcomes.

Research results

The analysis of the 23 included in our systematic review highlighted that, although the different type and posology of administration and the various cognitive tests and questionnaires adopted, both probiotics supplementation and FMT improved the cognitive functions in most of healthy people and patients affected by different neurological pathologies.

Research conclusions

The gut microbiota manipulation could represent a good strategy to counteract gut dysbiosis and so ameliorate cognitive dysfunction.

Research perspectives

The supplementation of probiotics and FMT could represent a non-invasive successful strategy to restore gut eubiosis and enhance cognitive functions in healthy people and patients with different neurological/neurodegenerative diseases.

Abstract

We have read with interest the Letter to the Editor by Drs. Zhuang and Zhong, who presented the clinical data of 68 patients with Wilson's disease (WD) who were admitted to the hospital before and during the coronavirus disease 2019 (COVID-19) pandemic, and appreciated their findings on hepatic and some extrahepatic manifestations. Nevertheless, given the strong impact of the pandemic on patients with neurological and psychiatric disorders, we would have expected a worsening of the psychiatric and/or neurological impairments in these patients. In contrast, according to the authors, these manifestations remained, somewhat unexpectedly, unchanged. This finding is in contrast with most of the current literature that highlights not only an increased incidence of mental health disorders in the general population but also an exacerbation of neurological and psychiatric symptoms in patients with chronic diseases, especially in those with pre-existing neuropsychiatric disorders, such as WD. Although the study was mainly focused on the hepatic features of WD patients taking anti-copper treatment, a generic and cumulative definition of neurological and psychiatric manifestations, as in this study, does not allow for further considerations. Future studies during and after the pandemic are necessary to clarify the real impact, either direct or indirect, of the COVID-19 pandemic on the neurological and psychiatric symptoms of WD patients.

Core Tip: In the interesting letter by Drs. Zhuang and Zhong, the psychiatric and neurological manifestations of 68 patients with Wilson's disease who were treated with anti-copper therapy unexpectedly remained unchanged after the pandemic. Given the impact of the pandemic on patients with neurological and psychiatric disorders, a worsening in the severity or frequency of these manifestations could have been expected. The possible reasons underlying this finding, including the relatively small sample size, the effect of therapy, and the patients' resilience, are discussed.

TO THE EDITOR

We have read with interest the Letter to the Editor by Zhuang and Zhong[1], who presented the clinical data of 68 patients with Wilson's disease (WD) who were admitted to the hospital before and during the coronavirus disease 2019 (COVID-19) pandemic in Guangzhou (China). Of note, none of the patients had COVID-19. As WD is a rare chronic systemic disease, the impact of the pandemic on the multiorgan clinical status of these patients is still unclear and, therefore, certainly worth investigating. Indeed, we have appreciated the findings that showed a marked shortage of medical resources for the clinical management of patients with WD during the pandemic, as well as the findings that patients who consistently took anti-copper medications showed no significant difference in hepatic and some extrahepatic features, although the incidence of their complications (especially those related to infections) significantly increased. For these reasons, we fully support the authors' recommendations to strictly adhere to the anti-copper therapy and closely monitor these patients to prevent complications[1].

However, given the strong psychological and socio-behavioral impacts of the pandemic on the clinical symptoms of different neuropsychiatric disorders[2,3], a worsening, or at least an increase in the frequency or severity, of psychiatric and/or neurological manifestations in WD patients could have been expected. Conversely, according to the authors, before the COVID-19 pandemic, 50 out of the 68 patients had neurological involvement, and three had psychiatric manifestations, which remained, somewhat unexpectedly, unchanged after the pandemic (49 and 4 out of the 68 patients, respectively)[1]. Although this study was mainly focused on the hepatic features of WD, only a generic and cumulative definition of neurological and psychiatric manifestations was adopted without additional specifications (*e.g.*, type, onset, severity, and duration), which did not allow for any further considerations; indeed, these apparently negative results were not discussed. Moreover, it was not specified how neurological and psychiatric manifestations were evaluated (*e.g.*, were specific scales used?), both at the study entry and at the end of the study. A more detailed stratification, for instance, by type of manifestation (such as cognitive or motor deficits, among the neurological aspects, and anxiety or mood disorders, among the psychiatric conditions), would have likely disclosed additional findings.

In this context, COVID-19, being the major infectious outbreak in the 21st century, has led to an unprecedented global hazard to mental health. A recent systematic review[4] on the impact of the pandemic on mental health in the general population found significantly higher rates of symptoms of anxiety (6.3%-50.9%), depression (14.6%-48.3%), post-traumatic stress disorder (7.0%-53.8%), psychological distress (34.4%-38.0%), and stress in general (8.1%-81.9%) in several countries worldwide, including China. Although a certain degree of heterogeneity was noted across the studies, the risk factors associated with these manifestations included, among others, a

younger age (≤ 40 years) and comorbid chronic or neuropsychiatric illnesses[4], such as WD.

On the other hand, the negative effect of the COVID-19 outbreak on mental health and health care services has been and will likely continue to be significant because of the unpredictability and uncertainty of the pandemic, the associated lockdowns, physical distancing, and other containment strategies, and the resulting economic breakdown[5]. Reasonably, as also observed in the Letter discussed here[1], the impact of the COVID-19 pandemic on the utilization of health care services, in terms of outpatient visits, hospital admissions, diagnostic exams, and therapeutic interventions, decreased by approximately one-third during the pandemic, with considerable variations and greater reductions among people with less severe illness[6]. Throughout the pandemic and even still, there has also been evidence of increased levels of relapse, in people with pre-existing mental health conditions and even in people with no previous history of a mental health disorder[7]. In particular, patients with pre-existing anxiety, depression, panic, delirium, psychosis, and suicidality appear to be extremely vulnerable[8].

Nevertheless, the matter is still debated, since it has also been observed that some individuals with severe mental illnesses, such as schizophrenia and affective disorders, may not report a worsening of symptoms, thus appearing to be resilient to the negative effects of the pandemic[9]. However, frequent assessments and periodic follow-up are needed to determine whether this resilience will persist as the pandemic progresses or after its end. In this context, in addition to the relatively small sample size, the potential effect of anti-copper therapy in this cohort, and the fact that none of the patients were affected by COVID-19, the patients' resilience might also represent a possible reason that supports the findings reported by Zhuang and Zhong[1]. However, their patients did not seem to be affected by severe psychopathologies, thus making this possibility less likely to justify the authors' conclusions. Moreover, although WD is a rare pathology, it is worth mentioning some methodological issues in the study[1] that may be appropriate and relevant for discussion. In particular, the relatively small sample size, the fact that not all patients were admitted to the hospital during the pandemic, and the possibility of the patients' resilience raise crucial questions that need to be addressed in the near future. Further multicenter prospective cohort studies, retrospective studies, and case-control studies on inpatients and outpatients with WD, both before and after anti-copper treatment, should be performed.

Less is known about the effects of the COVID-19 pandemic on neurological disorders, although a recent systematic review concluded that patients with pre-existing conditions (including those characterized by cognitive impairments or parkinsonism, which may be part of the clinical spectrum of WD) can develop exacerbation of their neurological symptoms, thus encouraging clinicians to be aware of this risk and to focus on its prevention and early management[10]. In this context, it is known that concomitant infections, especially infections of the respiratory and urinary tracts (such as those reported in the letter[1]), frequently worsen the symptoms and the course of several neurological diseases, including parkinsonism and dementia[11,12]. Therefore, the fact that the increased infection incidence detected in the study[1] did not induce an even transient worsening of the patients' clinical status remains to be explained or at least briefly commented on.

In conclusion, the study by Zhuang and Zhong[1] provides a valid clinical basis for the proper management of WD patients during the pandemic, thus representing an advance in this field of clinical and research interest. However, further independent multicenter studies during and after the pandemic are necessary to clarify the real impact, either direct (*i.e.*, infected patients) or indirect (*i.e.*, psychological and sociobehavioral consequences), of the COVID-19 pandemic on the neurological and psychiatric symptoms of WD.

ABOUT COVER

Editorial Board Member of *World Journal of Gastroenterology*, Pietro Fusaroli, MD, Associate Professor, Chief, Gastrointestinal Unit, University of Bologna at the Hospital of Imola, Via Montericco 4, Imola 40026, Italy. pietro.fusaroli@unibo.it

AIMS AND SCOPE

The primary aim of *World Journal of Gastroenterology* (*WJG*, *World J Gastroenterol*) is to provide scholars and readers from various fields of gastroenterology and hepatology with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJG* mainly publishes articles reporting research results and findings obtained in the field of gastroenterology and hepatology and covering a wide range of topics including gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, gastrointestinal oncology, and pediatric gastroenterology.

INDEXING/ABSTRACTING

The *WJG* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, and Scopus. The 2021 edition of Journal Citation Report® cites the 2020 impact factor (IF) for *WJG* as 5.742; Journal Citation Indicator: 0.79; IF without journal self cites: 5.590; 5-year IF: 5.044; Ranking: 28 among 92 journals in gastroenterology and hepatology; and Quartile category: Q2. The *WJG*'s CiteScore for 2020 is 6.9 and Scopus CiteScore rank 2020: Gastroenterology is 19/136.

Abstract

Hepatitis C virus (HCV) chronic infection is associated with fibrosis progression, end-stage liver complications and HCC. Not surprisingly, HCV infection is a leading cause of liver-related morbidity and mortality worldwide. After sustained virological response (SVR), the risk of developing hepatocellular carcinoma is not completely eliminated in patients with established cirrhosis or with advanced fibrosis. Therefore, lifelong surveillance is currently recommended. This strategy is likely not universally cost-effective and harmless, considering that not all patients with advanced fibrosis have the same risk of developing HCC. Factors related to the severity of liver disease and its potential to improve after SVR, the molecular and epigenetic changes that occur during infection and other associated comorbidities might account for different risk levels and are likely essential for identifying patients who would benefit from screening programs after SVR. Efforts to develop predictive models and risk calculators, biomarkers and genetic panels and even deep learning models to estimate the individual risk of HCC have been made in the direct-acting antiviral agents era, when thousands of patients with advanced fibrosis and cirrhosis have reached SVR. These tools could help to identify patients with very low HCC risk in whom surveillance might not be justified. In this review, factors affecting the probability of HCC development after SVR, the benefits and risks of surveillance, suggested strategies to estimate individualized HCC risk and the current evidence to recommend lifelong surveillance are discussed.

Core Tip: Hepatocellular carcinoma (HCC) risk is reduced after sustained viral response, but a substantial threat persists over time. Understanding the natural history of hepatitis C virus infection and the variable influence of viral eradication in the molecular and epigenetic changes that occur during infection are essential to explain the different risk of developing HCC in patients with advanced fibrosis. The definition of the appropriate tools to estimate the individual risk of HCC after antiviral treatment providing reliable recommendations about HCC surveillance is probably the most important challenge to be clarified in this field.

INTRODUCTION

Hepatitis C virus (HCV) chronic infection is a major cause of liver-related morbidity and mortality worldwide. Direct-acting antiviral agents (DAAs) have definitely changed the natural history of the disease by reducing liver-related complications in patients with advanced liver fibrosis (including those with cirrhosis) and improving the survival rate. Nonetheless, the risk of developing hepatocellular carcinoma is not completely eliminated with viral clearance. Not surprisingly, clinical guidelines still recommend life-long ultrasound surveillance in all patients with advanced fibrosis (F3) and cirrhosis (F4)[1,2].

However, the risk of HCC occurrence is not homogenous within the spectrum of compensated advanced chronic liver disease (c-ACLD). Therefore, surveillance strategies might not be cost-effective or harmless in all patients. Thus, the identification of patients who truly benefit from screening programs and for how long is a matter of debate.

HCC risk factors are associated with the severity of liver disease and the degree of improvement after sustained virological response but also with the presence of other comorbidities and preneoplastic changes induced by HCV. All of them are discussed in this review, as well as their predictive capacity to estimate individualized HCC risk. We also discuss the current evidence to recommend surveillance.

FACTORS AFFECTING HCC OCCURRENCE IN HCV PATIENTS

A combination of different factors, occurring either before or after SVR, is involved in the risk of HCC associated with HCV chronic infection (Figure 1).

Development of fibrosis during HCV infection

Chronic HCV infection typically causes damage and inflammation in the liver parenchyma, which can be followed by fibrosis deposition of different severities. Fibrogenesis is a dynamic process characterized by the synthesis of extracellular matrix (ECM), composed of a mixed complex of glycoproteins (collagen, elastin, fibronectin, laminin) and proteoglycans organized in a three-dimensional network[3]. Therefore, fibrosis is a physiological mechanism that can become pathological when viral infection and chronic hepatocellular injury persist[4].

In chronic hepatitis, including hepatitis C, active fibrosis begins around the portal areas (periportal or zone 1 fibrosis) and gradually extends out into the lobules toward the central veins (zone 3), with septum formation and then bridging fibrosis[5]. The

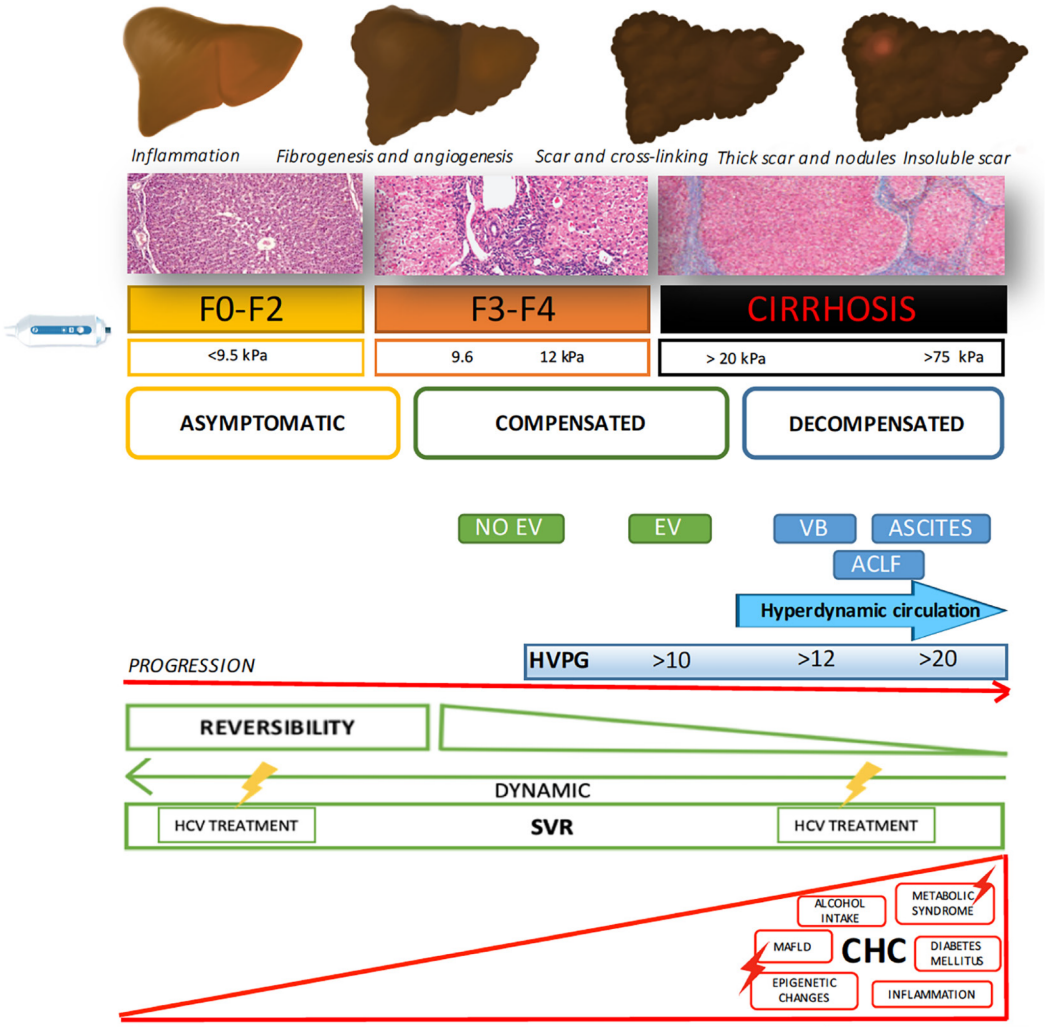

Figure 1 Factors involved in increasing or decreasing hepatocellular carcinoma risk, either before or after sustained virologic response. EV: Esophageal varices; VB: Variceal bleeding; ACLF: Acute on chronic liver failure; PH: Portal hypertension; SVR: Sustained virologic response; HCC: Hepatocellular carcinoma; MAFLD: Metabolic associated fatty liver disease.

final stage of this process constitutes cirrhosis, in which extensive fibrosis linking portal and central areas and nodular regeneration of the liver parenchyma appear. Collagen and matrix proteins are largely produced by activated hepatic stellate cells (HSCs). In contrast, activated liver sinusoidal endothelial cells (LSECs) contribute to ECM production, including the synthesis of basement membrane components, leading to perisinusoidal fibrosis. They also produce cytokines that activate HSCs and secrete factors that contribute to intrahepatic vasoconstriction and to portal hypertension in cirrhosis[6]. It has been widely demonstrated that the severity of liver fibrosis and the development of cirrhosis are the most important risk factors for HCC[7-9]. Therefore, the earlier that this process is discontinued by means of SVR, the lower that the likelihood is of HCC occurrence.

Epigenetic changes involved in hepatitis C infection

Cirrhosis of all causes can be complicated by the appearance of liver tumors, but the risk is higher in patients with chronic liver disease of a viral etiology[7]. In 2018, a large cohort study aimed to compare HCC risk according to the etiology of liver disease and showed that patients with HCV-related cirrhosis had a 3-fold increased HCC risk compared to ALD or NAFLD-related cirrhosis, suggesting that hepatitis C virus itself might have a direct carcinogenic effect[10].

HCV is an RNA virus with limited potential for integration into the host genome and therefore requires continuous replication to maintain chronic infection. HCV directly contributes to hepatocarcinogenesis, interrupting the signal transduction pathways that affect cell survival, proliferation, and transformation *via* HCV protein or RNA and indirectly by inducing chronic inflammation[8,11].

Epigenetic regulation is an indispensable process for the normal development and preservation of tissue-specific gene expression profiles. Thus, any perturbation of the epigenetic landscape can lead to shifted gene function and malignant cellular transformation. The changed epigenome of HCC is characterized by gene-specific hypermethylation or hypomethylation, global genomic hypomethylation, abnormal expression of DNA methyltransferases and histone modifying enzymes, altered histone modification patterns, and aberrant expression of microRNAs, which can affect the expression of oncogenes, tumor suppressor genes and other tumor-related genes altering the cancer development pathways over time[12]. In fact, a recent study showed a clear, positive correlation between epigenetic changes and fibrosis stages in HCV chronic infection[13], which persist after SVR.

Reversibility of liver fibrosis

Effective antiviral treatment has proved to change the natural history of HCV-related liver disease, reducing the risk of liver events and HCC, even in patients with advanced liver disease and cirrhosis. A recent meta-analysis[14] showed a significant absolute risk reduction in HCC after SVR, which was even greater in patients with cirrhosis (22%; 95%CI: 13-31) than in patients with any stage of fibrosis (6.7%; 95%CI: 5-8). It has been suggested that regression of fibrosis is one of the key mechanisms. In contrast to what was previously believed, there is currently substantial evidence indicating that the removal of fibrosis, hepatocyte repopulation and microvasculature remodeling occur after SVR following several cellular processes[15,16]. Mechanisms of the resolution of liver fibrosis involve senescence and apoptosis of activated HSCs/myofibroblasts caused by deprivation of fibrogenic cytokines. Reversal of these cells to an inactive phenotype during liver fibrosis regression[6,15] has also been described. However, regression of liver disease depends on the severity of fibrosis before antiviral therapy, with total regression being more likely in patients with mild/moderate fibrosis than in those with established cirrhosis due to the presence of a stronger cross-linking matrix, which is more difficult to remove by methaloproteases. Furthermore, the presence of architectural distortion with vascular shunts also contributes to the persistence of architectural changes[17-21]. However, the "point of no return" is controversial. A Canadian study[16] examined explants of patients with cirrhosis or precirrhosis who underwent transplantation, in which the causative agent of the liver disease was controlled or had been removed. The authors found that regression involves two main processes: removal of fibrosis and repopulation of scarred regions with hepatocytes, concluding that reversibility is possible in all stages of fibrosis, including precirrhotic stages and even macronodular cirrhosis. Interestingly, "sinusoidal capillarization" was considered the "point of no return". Moreover, advanced stages of cirrhosis with thicker septa and smaller micronodules are associated with the presence of clinically significant portal hypertension and therefore with a lower likelihood of reversibility[20].

An Italian study including patients with cirrhosis with paired biopsies after achieving SVR with PEGINF/RBV showed that, in more than half of the patients, regression of cirrhosis was observed during follow-up. Patients who did not change their METAVIR scores after SVR also presented a decrease in the amount of collagen fibers, coinciding with the transformation of micronodular cirrhosis into a macronodular form or incomplete septal cirrhosis[21]. Finally, a Spanish study published in 2018 evaluated the regression of fibrosis using paired biopsies in 112 patients with posttransplant recurrence of HCV infection after treatment with DAAs [22]. Fibrosis regression occurred in 72-85% of the patients without liver cirrhosis (F1-F3) and in 43% of the patients with cirrhosis. Interestingly, in this study, more than 50% of the cirrhotic patients had a history of decompensation, suggesting that patients with liver cirrhosis without clinically significant portal hypertension are more likely to have improved liver injury, likely decreasing the risk of developing HCC after SVR.

Therefore, among patients with advanced fibrosis and cirrhosis, the risk of HCC seems to be lower in patients with less severe disease, who are in fact those who benefit the most after SVR.

One important issue is how to assess fibrosis regression since liver biopsy is an invasive procedure, does not distinguish early from advanced stages of cirrhosis and cannot be performed repeatedly after SVR. Not surprisingly, noninvasive elastographic and direct or indirect serological markers have been widely used to assess fibrosis regression[23]. However, in regressed cirrhosis, macronodules and aberrant vasculature with capillarization of the sinusoids can persist despite a decrease in liver stiffness assessed by TE. The study from D' Ambrosio *et al*[24] revealed that, after 61 mo of follow-up, 38% of patients with biopsy-proven F4 had liver stiffness < 12 kPa, resulting in low predictive power of TE to diagnose cirrhosis after viral

eradication. Thus, a combination of TE and serological noninvasive markers might improve the capacity to assess fibrosis regression.

Inflammation and liver cancer

Another factor specifically affecting HCC risk during HCV chronic infection is the presence of inflammation. Various types of cancer arise in the setting of chronic inflammation, indicating a strong link between inflammation and cancer. It has been estimated that approximately 15% of all human cancers are associated with inflammation and chronic infections[25]. During chronic viral hepatitis, host immune responses to HBV or HCV are often not sufficiently strong to completely eradicate the infection, inducing persistent stimulation of antigen-specific immune responses. Host immune cells are known to destroy virus-infected liver cells, resulting in the production of different cytokines and growth factors, consequently inducing compensatory regeneration of hepatocytes. The persistent cycle of hepatocyte necroinflammation and regeneration has a synergistic effect with the severity of liver fibrosis and cirrhosis, promoting architectural distortion and portal hypertension with reduced sinusoidal perfusion favoring hypoxia, which is the substrate for the formation of hypervascular tumors. These factors increase the risk of genetic changes in hepatocytes, promoting the survival and expansion of the initiated cells and leading to dysregulated hepatocyte proliferation, which contributes to the development and progression of liver cancer. Furthermore, oxidative stress accelerates hepatocarcinogenesis through several mechanisms, including transcription and activation of cytokines and growth factors, oxidative DNA damage, DNA methylation, and hepatocyte injury[26-30]. Therefore, HCC risk is expected to decrease after eradicating infection and the subsequent decrease in inflammation mechanisms.

HCC RISK CAN PERSIST AFTER SUSTAINED VIROLOGICAL RESPONSE

Although SVR is associated with a reduction in some of the HCC pathogenetic factors mentioned above, there are many other contributors to HCC occurrence that can persist after viral eradication, related either to the stage of liver disease (*e.g.*, Child B, portal hypertension, low platelet count) or to the presence of comorbidities, such as diabetes, alcohol consumption, smoking and older age[31-34].

A recent publication suggested that regression of liver damage after SVR can last for years, with HCC risk persisting during this period; in other patients, liver injury is not reversed due to advanced cirrhosis stage, or it progresses because of the coexistence of other factors, such as obesity, diabetes, and alcohol intake[35]. In addition, older age contributes, even years after SVR, to the progression of liver fibrosis and to an increased risk of HCC.

Epigenetic memory is another of the possible mechanisms involved in HCC risk persistence after SVR. As mentioned above, HCV infection induces epigenetic alterations. DAA treatment eliminates the virus inside cells, but it is not able to restore the concomitant epigenetic signatures already produced and associated with the risk of HCC. Available data suggest that, when infection has already induced epigenetic changes, gene expression is conserved in cells; therefore, the presence of the virus is no longer necessary to exert oncogenic effects on host cells, producing what is known as epigenetic memory or persistent epigenetic changes[13,36].

HCC SURVEILLANCE AFTER SVR: CURRENT RECOMMENDATIONS

Current guidelines from EASL[1] and AASLD[37] agree regarding the recommendation of hepatocellular carcinoma surveillance after SVR in all patients with cirrhosis. However, EASL recommends indefinite HCC screening in patients with advanced fibrosis (F3) by ultrasound every six months, whereas AASLD does not. These differences are likely related to controversy regarding the risk of developing HCC in F3 patients due to the heterogeneity of this population, which could include misclassified patients (over- or underestimating the severity of fibrosis).

ACCURACY IN THE DIAGNOSIS OF ADVANCED FIBROSIS AND CIRRHOSIS

Considering that advanced fibrosis and especially cirrhosis are the main factors contributing to HCC risk, an accurate diagnosis prior to antiviral therapy is mandatory to predict individual risk after SVR. Liver biopsy remains the gold standard for the assessment of hepatic fibrosis, although noninvasive methods for estimating liver fibrosis are increasingly used. However, the accuracy of fibrosis staging in the noninvasive assessment era is imperfect -- even more so after sustained virological response. This fact is especially important in patients with advanced fibrosis but without cirrhosis, in which liver stiffness measurements (LSMs) can occasionally overestimate fibrosis, especially when marked inflammation is present[38]. Another problem is the definition of F3 stage by LSM, with cutoffs varying from 9.5 kPa to 14.5 kPa according to Castera's[39] study or up to 12.5 kPa as Ziol *et al*[40] suggested. Therefore, a substantial proportion of patients might be misclassified, overestimating or underestimating fibrosis and leading to an indefinite link to medical care or, alternatively, mistaken discharge. Thus, other clinical or serological markers should be available to accurately define the severity of compensated advanced liver disease and the remaining HCC risk after SVR.

COST-EFFECTIVENESS, BENEFITS AND RISKS OF HCC SURVEILLANCE

HCC surveillance aims to prolong patient survival and quality of life by improving early diagnosis and curative therapy. Based on estimated tumor doubling times, current guidelines recommend ultrasound every six months, and they establish an incidence of at least 1.5% per year to justify HCC surveillance. Although this threshold is likely too high due to the clinical benefits induced by DAA after SVR and the improvement in HCC therapies, it is not clear whether HCC surveillance remains cost effective in all patients with advanced fibrosis after SVR. Regarding this point, a study suggested that HCC surveillance is unlikely to be cost effective in patients with F3 fibrosis, whereas both annual and biannual modalities are likely to be cost effective for patients with cirrhosis compared with no surveillance[41]. The study suggested that an annual HCC incidence greater than 0.5% might be currently cost-effective, and it proved that both an APRI greater than 2 or an FIB-4 greater than 3.25 allow for the identification of patients for whom HCC surveillance becomes cost effective, suggesting that patients with values less than these thresholds should be discharged from follow-up evaluation. Another study evaluated the cost-effectiveness of risk-stratified HCC screening in cirrhosis based on a combination of biomarkers and clinical variables, including epidermal growth factor single-nucleotide polymorphism, age, sex, smoking status, alkaline phosphatase level, and platelet count. The study showed that HCC surveillance strategies targeting high- and intermediate-risk patients with cirrhosis are cost-effective. Finally, the authors suggested that omitting screening in the lowest-risk subjects was cost-effective compared with biannual screening, without sacrificing net survival benefit[42].

Moreover, in a recent opinion article, Jepsen *et al*[43] argued that randomized trials of HCC surveillance *vs* no surveillance are necessary to make formal recommendations involving thousands of patients. The authors made their arguments indicating that universal surveillance could negatively impact patients' quality of life by generating anxiety about the possibility of a cancer diagnosis. Furthermore, the problems associated with false positives in screening procedures and the need to be connected for life to hospital care in patients with negligible HCC risk are also matters of concern. Therefore, accurate models including predictive factors to identify different risk levels are likely the key to adequate follow-up of patients after SVR.

PREDICTIVE FACTORS OF HCC RISK

Multiple models including clinical, serological, molecular and elastographic variables have attempted to stratify HCC risk in patients with advanced fibrosis. Importantly, there are controversies about the markers that should be used and when they should be measured, considering the dynamic changes that occur after SVR. Table 1 summarizes some studies that have assessed the risk of HCC according to both baseline and dynamic risk factors.

Table 1 Studies assessing the risk of hepatocellular carcinoma according to baseline and dynamic risk factors

Ref.	Country	*n*	Population at risk	Diagnosis of cirrhosis	Treatment regimens	Baseline risk factors	Dynamic risk factors
Lleo *et al*[33], 2019	Italy	1766	All cirrhosis 11.4% Child B/C	1 or more of the following: Stage 4 fibrosis by METAVIR score, esophageal and/or gastric varices at endoscopy, LSM > 12.5 kPa	All were treated with DAA	Age > 50 years old and presence of esophageal varices, platelets < 110000/L and LSM > 25 kPa	Lack of SVR
Ioannou *et al* [44], 2018	United States	45810	23% cirrhosis	Clinical, based on ICD-9 or 10 codes for cirrhosis or its complications	Either IFN or DAA	Cirrhosis, SVR, ALT, AST, platelets, albumin, age	
Ioannou *et al* [45], 2019	United States	48135	9784 with pretreatment cirrhosis	Clinical, based on ICD-9 or 10 codes for cirrhosis or its complications	Either IFN or DAA	Cirrhosis and FIB-4 ≥ 3.25 before treatment	FIB-4 ≥ 3.25 post-SVR
Ravaioli *et al* [47], 2018	Italy	139	All cirrhosis; Included previous HCC 11.5% Child B		All were treated with DAA	History of previous HCC	Child B and LSM reduction after DAA treatment < 30%
Pons *et al*[48], 2019	Spain	572	All LSM ≥ 10 kPa; All compensated	cACLD defined by LSM ≥ 10 kPa	All were treated with DAA	High risk: baseline albumin < 4 g/dL; Low risk: Baseline albumin ≥ 4 g/dL	High risk: LSM ≥ 20 kPa or LSM 10-20 kPa and albumin < 4.4 g/dL; Low risk: LSM < 10 kPa or LSM 10-20 kPa and albumin ≥ 4.4 g/dL
Fan *et al*[50], 2020	China	3566	75.3% cirrhosis compensated and decompensated	Histological and/or radiological	Either IFN or DAA	aMAP score; Low risk: 0-50; Intermediate risk: 50-60; High risk: 60-100	
Alonso *et al* [49], 2020	Spain	993	Advanced fibrosis or compensated cirrhosis	Clinical or histological; advanced fibrosis defined by a LSM by TE > 9.5 Kpa	All were treated with DAA	Albumin < 4.2 g/dL; LSM > 17,3 kPaFIB-4 > 3.7	Delta LSM < 25.5%; FIB-4 > 3.3; GGT > 42 IU
Ioannou *et al* [62], 2020	United States	48151	All cirrhosis compensated and decompensated	Clinical, based on ICD-9 or 10 codes for cirrhosis or its complications	Either IFN or DAA	Deep learning RNN model Cirrhosis diagnosis, sex, race and HCV genotype 3	Development of cirrhosis, SVR, BMI, AST, ALT, bilirubin, FIB-4, APRI, platelets

LSM: Liver stiffness measurement; TE: Transient elastography; INF: Interferon, DAA: Direct-acting antiviral agent; HCV: Hepatitis C virus; SVR: Sustained virologic response; FIB-4: Fibrosis 4; HCC: Hepatocellular carcinoma; c-ACLD: Compensated advanced chronic liver disease; CP: Child-Pugh; FU: Follow-up; amap: age, male, ALBI and platelets; GGT: Gamma-glutamyltransferase; RNN: Recurrent neural networks; APRI: AST to platelet ratio index; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; BMI: Body mass index.

The study by Ioannou *et al*[44] introduced the need for risk modeling, suggesting that screening strategies based on HCC risk models were superior to "screen-all" or "screen-none" strategies. The proposed HCC risk model, which included the presence of cirrhosis, SVR, baseline ALT, AST, platelets, albumin and age, allowed us to calculate the individual risk of HCC. However, the definition of cirrhosis was made based on the presence of portal hypertension signs and/or clinical complications, suggesting that perhaps patients with advanced fibrosis or with early stages of cirrhosis could be misclassified as not having cirrhosis.

In a further study, the authors used a different evaluation of liver disease severity, introducing not only baseline data but also changes in FIB-4 over time, to assess

different HCC risk levels. In this second study, the authors showed that patients in whom FIB-4 was less than 3.25 before treatment and after SVR had a lower risk of HCC[45].

Other predictive models have included different combinations of laboratory and elastographic parameters. A study from Italy[33] aimed to evaluate the risk of HCC occurrence and recurrence in cirrhotic patients after DAA therapy. The authors identified a subgroup of patients with SVR and the "Extended Baveno Criteria"[46] (> 110000 platelets and LSM < 25 kPa), with an HCC incidence of 0.5%/per year, suggesting that the Baveno Criteria could be an appropriate tool for stratification, advising less frequent follow-up in this population.

Models that include dynamic changes after SVR could be especially relevant since they can identify patients with less severe disease more likely to regress or improve after SVR. The dynamic change in LSM as an HCC risk factor was previously described in a study showing that a reduction in liver stiffness > 30% at the end of treatment was associated with a significantly lower risk of HCC at one year after EOT [47]. In this study, TE was likely performed too early to detect regression or improvement, although it could identify those patients with overestimated fibrosis at baseline, in whom the resolution of inflammatory activity accounts for the rapid decrease in liver stiffness.

A Spanish study developed a model to estimate HCC risk in patients with c-ACLD after SVR. This study revealed that the combination of follow-up LSM and serum albumin levels at one year after SVR was able to identify different HCC risk groups. The authors observed that patients with LSM < 10 kPa or with LSM between 10-20 kPa and high albumin levels at follow-up had an incidence rate of HCC of less than 1/100 patients per year; thus, the authors considered them a low-risk group[48].

Furthermore, a recent large, multicenter cohort study performed in our unit[49] confirmed the impact of both baseline and dynamic changes in noninvasive markers on the risk of HCC development. We constructed two simple models: the first one included baseline albumin (g/dL) and LSM (Kpa) and the percentage of LSM variation one year after EOT. Patients with baseline albumin > 4.2 g/dL, baseline LSM ≤ 17.3 kPa, and 1-year DeltaLSM > 25.5% had the lowest HCC risk (cumulative incidence of HCC at 3 years of 0%). Considering that LSM might not be universally available, we also built a second model that exclusively included noninvasive serological markers. Similarly, the FIB-4-based model identified patients with baseline albumin > 4.2 g/dL, baseline FIB-4 ≤ 3.7, 1-year FIB-4 score ≤ 3.3, and 1-year GGT ≤ 42 IU/mL as the group with the lowest HCC risk (cumulative incidence of 0.4% at 3 years). Notably, our results suggested that baseline and dynamic LSM (or FIB-4, when TE is not available) could identify patients with a lower incidence of HCC after SVR that does not justify continuous HCC screening. Approximately 20% of the patients were considered to have low or very low HCC risk, and according to our findings, they could be safely discharged from surveillance.

Another recently validated predictive model is the aMAP score[50], which includes laboratory and clinical parameters such as the albumin-bilirubin score (ALBI score) platelets, age and sex. The score identifies two different risk groups, suggesting that only patients belonging to the high-risk group (aMAP score > 60) should undergo intensive surveillance to detect early HCC. This prognostic tool was externally validated in patients with different cirrhosis etiologies from 11 global prospective studies; interestingly, the score properly discriminated 5-year HCC irrespective of etiology of liver disease and ethnicity.

Thus, predictive models and risk scores, preferably based on baseline data and dynamic changes, are likely the best approach for determining the individual risk of HCC after SVR.

LONG-TERM RISK OF HCC: DOES IT DECREASE OVER TIME?

Different long-term studies in HCV patients treated with IFN-based regimens have documented a reduction in the incidence of HCC by 75% in patients with SVR[51-53]. Currently, there is growing evidence that the same occurs after DAA therapy. Several data have shown that SVR after DAAs does not have a significant impact on the development of HCC in the short or medium term since many of the patients were treated with a more advanced disease, it but reduces the risk of HCC in the medium and long term, like what occurs in patients treated with IFN-based regimens[9].

Conversely, it has been suggested that HCC risk persists for up to 10 years after HCV eradication in patients with baseline cirrhosis or high FIB-4 scores[45]. In this

study, HCC incidence remained > 2% per year even 10 years after antiviral treatment in patients with a high baseline FIB-4 ≥ 3.25, especially if it remained ≥ 3.25 after SVR. Conversely, patients with baseline FIB-4 < 3.25 had an HCC incidence < 1%.

Moreover, aging and comorbidities that can occur or progress over time could have an additive effect on HCC risk. Consequently, there is no strong evidence to support a dynamic assessment of HCC risk over time, and the best strategy is likely to continue screening patients with intermediate and high HCC risk until they reach an age when it is no longer cost effective.

HCC SCREENING: WHO DOES BENEFIT AND FOR HOW LONG?

It seems clear that the current recommendations regarding HCC screening after SVR in HCV patients with advanced fibrosis at baseline should be modified in the future. While changes become formal, we provide below a proposal based on the current data (Figure 2).

Cirrhotic patients with baseline decompensated or compensated advanced liver disease with significant portal hypertension. HCC risk in this population remains greater than the accepted threshold for surveillance; therefore, biannual US screening is recommended.

Patients with findings of advanced chronic liver disease without clear evidence of baseline portal hypertension. In our opinion, these patients should be screened for HCC at least 1 year after EOT to evaluate early dynamic changes and make more accurate estimations of the individual HCC risk.

FUTURE STRATEGIES IN SURVEILLANCE

As previously stated, several questions remain concerning surveillance strategies. Most likely, the most important concern is that we do not have accurate information about whether HCC risk persists constantly over the long term and therefore for how long patients with medium or high risk should continue HCC surveillance.

It is possible that, in the near future, patients will benefit from a more specific biomarker panel, genetic and molecular profiles and even deep learning models to predict the risk of developing HCC.

Circulating biomarkers are promising tools for better stratification of patients[54-56]. Biomarker panels, such as the GALAD score, are excellent tools for the detection of early-stage HCC, including tumors with negative AFP (AUC of 0.96 for detection of early-stage HCC)[57,58]. As previously exposed, HCV induces epigenetic alterations persisting after DAA cure[13], so the opportunity to detect epigenetic changes of histones bound to circulating DNA in plasma represents a new opportunity to uncover biomarkers of HCC risk. These approaches could represent personalized, noninvasive and cost-effective alternatives based on clinical and biological findings for HCC screening.

The use of deep learning models, which have also been successfully applied in other settings to predict clinical events[59], could also be relevant. Various types of model architectures, such as recurrent neural networks, have been used to capture temporal dynamics and long-term information over time[60]. Recently, it was suggested that some machine-learning algorithms accurately stratify the risk of HCC in patients with cirrhosis, identifying those at high risk for developing HCC[61]. Additionally, it has been shown that, in terms of cost-effectiveness, deep learning and recurrent neural network models were able to improve HCC surveillance strategies in HCV patients, thereby identifying high-risk cases[62].

CONCLUSION

In conclusion, HCC surveillance in HCV patients should likely be based on an evaluation of individualized risk rather than exclusively based on baseline fibrosis stage. Currently available risk scores should be improved and validated, likely by including novel approaches, such as personalized biomarkers and deep learning methods.

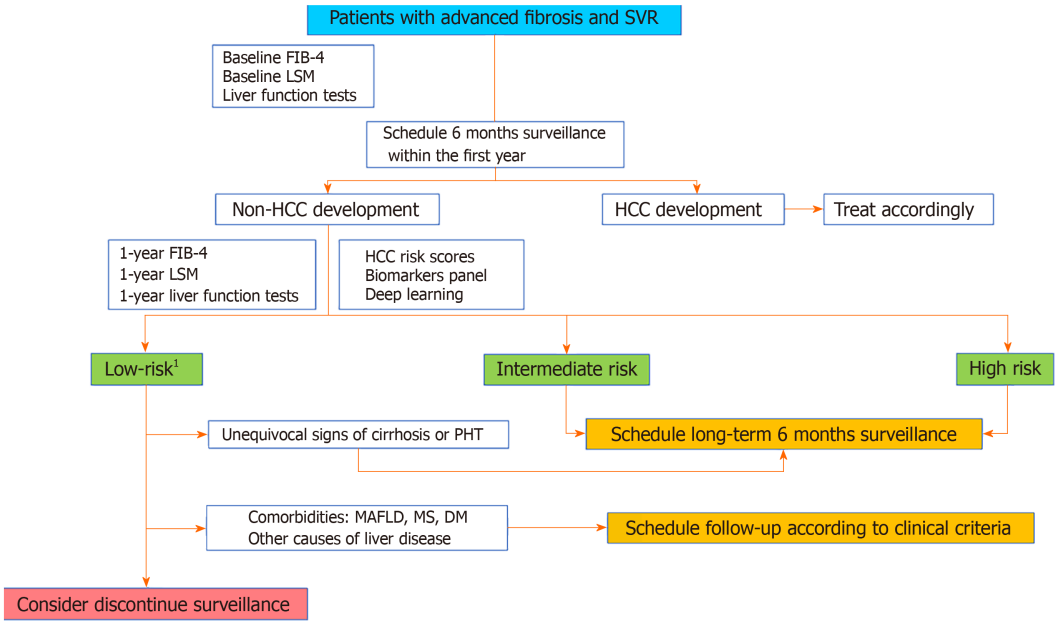

Figure 2 Surveillance hepatocellular carcinoma algorithm proposed. [1]Most likely, annual incidence < 0.5% per year. FIB-4: Fibrosis 4; LSM: Liver stiffness measurement; TE: Transient elastography; PHT: Portal hypertension; DM: Diabetes mellitus; MS: Metabolic syndrome; MAFLD: Metabolic associated fatty liver disease.

Abstract

The significance of plasma ascorbic acid (AA) is underscored by its enzymatic and antioxidant properties as well as involvement in many aspects of health including the synthesis of biomolecules during acute illness, trauma and chronic health conditions. Dietary intake supports maintenance of optimal levels with supplementation at higher doses more likely pursued. Transient increased intestinal paracellular permeability following high dose AA may be utilised to enhance delivery of other micronutrients across the intestinal lumen. The potential mechanism following dietary intake however needs further study but may provide an avenue to increase small intestinal nutrient co transport and absorption, including in acute and chronic illness.

Key Words: Aspirin; Ascorbic acid; Paracellular permeability; Antioxidant; Lactulose mannitol test

INTRODUCTION

Ascorbic acid (AA) or Vitamin C is an essential micronutrient in the human diet, due to the non-functional gene encoding L-glucono lactone oxidase that is involved in the catalysis of the last biosynthetic step in the pathway. The physiology and pathophysiology of AA has been extensively studied and the estimated plasma half-life reported to be between 7-14 d on the basis of depletion-repletion studies, conducted in healthy male subjects. Ergo, providing an approximation of the plasma half-life in those individuals that may have acute illness, trauma or chronic health conditions. The importance of maintaining optimal AA levels is underscored by both its antioxidant and non-antioxidant, *i.e.*, enzymatic roles and involvement in many aspects of health which include being an essential factor in the synthesis of collagen, carnitine and norepinephrine. Reduced dietary consumption, due to lower intake of fresh fruit and vegetables, or increased utilization *via* intracellular uptake are important aspects in the maintenance of plasma AA levels. Increased cellular distribution of AA has been shown to be associated with high leukocyte turnover and oxidative stress, whereby the redox potential of AA mitigates the production of reactive oxygen species (ROS). Dehydroascorbic acid (DHA), formed by the loss of electron by the ascorbic radical, has the same biological activity as the reduced form. The subsequent hydrolysis of DHA, if not reduced back to AA, to 2,3-diketogulonic acid is an irreversible step that results in the loss of antioxidant properties and its degradation.

Exogenous AA uptake is provided by, but not limited to, dietary intake. Due to AAs proposed antioxidant as well as enzymatic health benefits it is a widely sought-after dietary supplement that is available for consumption alone or as a multivitamin. Notably, AA has been co-formulated not only with other vitamins but also with anti-inflammatory pharmacological agents[1-3], in particular with aspirin. Monotherapy with aspirin has been shown to decrease the concentration of AA not only within the intestinal enterocytes[4] but also in gastric juice[5] potentiating negative impacts by reducing the ability of intestinal mucosal cells to manage oxidative stress[4]. Therefore, the co-formulation of AA with aspirin is considered to mitigate and ameliorate ROS induced gastrointestinal damage that has been implicated with the etiology of aspirin monotherapy[6].

Of interest is, a body of work conducted by our group that demonstrated that a single dose of aspirin has the potential to cause transient increases in small intestinal permeability over a 6 h period in healthy individuals. More importantly that rather than mitigating the aspirin induced increase in intestinal permeability[7], assessed by the lactulose mannitol test[8], the administration of 500 mg AA augmented absorption of lactulose either when given alone or in combination with the single 500 mg dose of aspirin (Table 1).

Therefore, it appears that while simultaneous dosage of AA with aspirin may potentially have longer term beneficial effects, related to the antioxidant properties of AA, in the short term however it may not mitigate the aspirin-induced increase in intestinal permeability. It is notable that, in the investigation, participants received an aspirin drink thirty minutes prior to the AA drink[7] in contrast to other studies where AA and aspirin were administered together as a single solution or in the form of a tablet[1-3,5,9]. Hence, it may be considered that the extent of ionization of each of these weak organic acids could have differed in the intestinal lumen consequentially affecting their ability to access transporters in the gut wall. The proportion of unionized AA increases to 99% and 15% in the stomach (pH 1) and small intestine (pH 5) respectively, and under these conditions passive diffusion is thought to play a significant role in AA uptake[10]. Indeed, it has been previously shown that co-administration of aspirin with AA decreased the rate at which AA was absorbed *in vivo*[11] and could have resulted from interference with sodium dependent secondary active transport *via* sodium-dependent vitamin C transporters (SVCT1 and SVCT2)[12]. These transporters are differentially expressed along the length of the gastrointestinal tract, with the pattern of expression mediated in part by transcriptional and epigenetic mechanisms[13].

Table 1 Variation in the cumulative excretion of lactulose in bulked urine samples collected over two time periods (first three hours and the second three hours) during a six hours collection period in 28 healthy female participants

Treatment	Lactulose excretion (% recovery of ingested dose)	
	First 3 h	Second 3 h
Aspirin	0.37 ± 0.05[a,b]	0.46 ± 0.05[d]
Ascorbic acid	0.47 ± 0.05[a,c]	0.53 ± 0.04
Combined dosage	0.68 ± 0.09[b,c]	0.77 ± 0.14[d]

[a]Statistically significant ($P < 0.05$) differences between treatments during the first 3 h, results expressed as mean ± SEM.
[b]Statistically significant ($P < 0.05$) differences between treatments during the first 3 h, results expressed as mean ± SEM.
[c]Statistically significant ($P < 0.05$) differences between treatments during the first 3 h, results expressed as mean ± SEM.
[d]Statistically significant ($P < 0.05$) differences between treatments during the second 3 h during the lactulose mannitol test, results expressed as mean ± SEM.

Pertinent however is that increased small intestinal mucosal permeability, even if transient, following dosage with AA raises questions as to whether similar changes may occur following dietary ingestion of foods that are rich in AA. It is noteworthy that the dose of 500 mg AA administered in our study[7] is higher than the recommended daily allowance (RDA 60-120 mg)[14], guidelines for which are variable. An increase in the RDA to 200 mg has been proposed[15] to maximize the attributed health benefits, with evidence suggesting that regular supplement users consume more than 1 g AA per day[16]. Whether the increase in intestinal permeability detected in our study was dose dependent is not known and a comparison with other publications is not possible as the effect of AA on intestinal permeability has not been previously studied. We hypothesize that the dose of AA induced increase in intestinal permeability could be due to its action on apical transporters. Glucose has been shown to modulate vitamin C transport at the small intestinal brush border membrane with similar rates of uptake of DHA and AA reported in the absence of glucose[17]. The reduced form, AA, is absorbed *via* SVCT1 and SVCT2[18]. Given that the stoichiometry of the SVCTs are similar to those of the sodium dependent glucose transporter (SGLT1)[19,20] it is possible that absorption of AA may bring about intracellular changes that modulate, *i.e.*, relax, tight junctions in a manner similar to that of glucose transport *via* SGLT1[21]. Additionally, the oxidised form DHA has been shown to compete with glucose for transport *via* glucose transporters[22] in particular GLUT2 and GLUT8[23], which have been suggested along with SGLT1 to cause cytoskeletal contraction[24]. The modulation of the tight junctions in this manner has been shown to increase mucosal permeability[25], allowing greater quantities of larger molecules to be absorbed *via* the paracellular pathway[26].

Relating and extending the results of our study to AA levels from dietary intake maybe difficult and may necessitate human intervention studies using whole foods or extracts at comparable doses. However, an extrapolation of the effect of foods/extract would require careful study design as the amount of available AA in different foods may vary widely[27]. Particularly in fruits and vegetables where the quantity of AA is determined by a variety of factors which include cultivars, environmental conditions including regional and seasonal conditions as well as maturation[28]. Additionally, depending on the levels of hydration it is very likely that there may be inherent variability in the proportion of reduced and oxidized AA within fruits and vegetables, much like AA in solutions which have a greater susceptibility to oxidation. At pH < 4 [29] the concentration of AA deteriorates, with greater losses shown to occur in frozen products that are processed/canned [mean: 26 % (0% - 78 %)] than from frozen fresh products [mean: 18 % (0% - 50 %)][30]. Furthermore, supplementation of products with synthetic AA has been shown to facilitate oxidation within products[31].

The degradation of AA not only occurs during processing and storage of the food/extract but also once it is consumed and introduced into the gastrointestinal lumen. Being an antioxidant, AA gets oxidized in the gastrointestinal tract to maintain the reduced state of other nutrients, *e.g.*, iron or form metal-oxygen-ascorbate complexes[32]. However, the acidic conditions of the gastrointestinal tract protect AA against chemical and enzymatic oxidation[32] with 93% of AA from bioactive broccoli inflorescence[33] and 71% from pomegranate juice[34] shown to be stable following *in vitro* gastric digestion. Conversely, in the small intestinal environment greater amounts

of AA was oxidized, with 39% of AA recovered[35] in this segment of the gut following *in vitro* small intestinal digestion of blended fruit juice. While this information is pertinent to our understanding, the bioavailability of luminal AA also requires consideration of the interaction with other contained dietary constituents *e.g.*, fiber and other bioflavanoids. Micronutrients within fruit juice have been shown to inhibit the absorption of AA[36] at doses between 50-500 mg. One mechanism for the inhibition is thought to occur *via* competition with transporters which has been particularly attributed to flavanoids such as quercetin and myricetin that are shown to decrease ascorbate as well as DHA absorption in *in vitro* models[37,38]. Vinson *et al*[39] further demonstrated in guinea pigs that dosage with a citrus fruit extract, containing 18% bioflavonoids, 15% proteins and 30% carbohydrates, resulted in a significantly slower rise in plasma ascorbate concentrations in comparison to a simple ascorbate solution. In alignment with these findings, a similar effect was also reported in human participants following the intake of citrus fruit extract[40].

Contrary to these findings it has also been shown that flavonoids, following consumption of half a golden kiwi fruit a day (50 g) over six weeks, did not alter the bioavailability of contained AA when compared to 50 g of synthetic AA[41]. This inferred effect appeared consistent as the administration of AA with blackcurrant juice [42] or orange juice[43] containing flavonoids did not impede absorption. Therefore, it seems likely that these differences in the manner in which AA is absorbed when co-administered could have arisen due to the differential gastric transit times[44]. Gastric emptying of liquid meals or beverages is dependent on the pressure gradient across the gastroduodenal junction and in part by the composition of the duodenal content, and hence it is conceivable that the nutrient content and composition of these different solutions or fruit slowed down gastric emptying[44]. Alternatively, these incongruent results may in part have been due to the different forms and dosages at which AA was administered, *i.e.*, as solutions or gels. Ergo resulting in potentially variable gastrointestinal residence and emptying times to influence absorption and the subsequent appearance of AA in sampled biological fluids *i.e.*, plasma, urine *etc.*

Given these inconsistencies in evidence regarding the bioavailability when co-administered with other substances, it remains unclear as to whether the effects of AA on intestinal permeability can be extended to situations when it is delivered in foods. This in particular considering the dose and quantity of the foods/extract that would have to be consumed to show comparable effects. All the same, the ability of a pharmaceutical dose of 500 mg AA to augment absorption of larger inert sugars such as lactulose does raise the possibility that AA could be a putative agent that could be co-administered with poorly absorbed drugs, nutrients or food substances of similar or larger molecular weight to enhance their absorption[45,46].

Increased paracellular permeability, *via* the modulation of tight junctions, has been reported after consumption of a meal especially in the presence of glucose[47] and alanine[48]. Using Caco 2 models, food components such as plant extracts[49-51] and isolated food components[52-54] have been shown to increase paracellular permeability with a the resultant flux in macromolecules, such as mannitol[51,55,56]. These authors, including Kosińska *et al*[57], postulated that food components could be safe alternatives to reversibly 'open' tight junctions in order to enhance the absorption of molecules of interest. Conversely, glutamine, polyunsaturated fatty acids and polyphenols have been shown to 'tighten' tight junctions through increased expression of tight junction associated proteins[58].

CONCLUSION

Whilst the molecular mechanism by which AA increases paracellular permeability remains to be elucidated, a dose of 500 mg, which is higher than the current RDA, has been shown to increase small intestinal permeability in healthy individuals. Whether this effect is dose dependent requires further exploration however together with its antioxidant properties, the alteration of intestinal permeability by AA can be potentially explored as a safe and novel application for the delivery of molecules *via* the paracellular pathway. Indeed it is also conceivable the co-administration of AA, as a supplement or through consumption of a rich food source, with aspirin may potentiate its serum levels and analgesic effects.

ACKNOWLEDGEMENTS

The studies were conducted at the Human Nutrition Unit at Massey University, Palmerston North under the supervision of Prof Roger G Lentle, Prof Marlena C Kruger and Dr Roger D Hurst.

Abstract

The risk of thromboembolism (TE) is increased in patients with inflammatory bowel disease (IBD), mainly due to an increased risk of venous TE (VTE). The risk of arterial TE (ATE) is less pronounced, but an increased risk of cardiovascular diseases needs to be addressed in IBD patients. IBD predisposes to arterial and venous thrombosis through similar prothrombotic mechanisms, including triggering activation of coagulation, in part mediated by impairment of the intestinal barrier and released bacterial components. VTE in IBD has clinical specificities, *i.e.*, an earlier first episode in life, high rates during both active and remission stages, higher recurrence rates, and poor prognosis. The increased likelihood of VTE in IBD patients may be related to surgery, the use of medications such as corticosteroids or tofacitinib, whereas infliximab is antithrombotic. Long-term complications of VTE can include post-thrombotic syndrome and high recurrence rate during post-hospital discharge. A global clot lysis assay may be useful in identifying patients with IBD who are at risk for TE. Many VTEs occur in IBD outpatients; therefore, outpatient prophylaxis in high-risk patients is recommended. It is crucial to continue focusing on prevention and adequate treatment of VTE in patients with IBD.

risk for venous thromboembolism (VTE) than patients with other inflammatory and immune-mediated diseases. The prevalence of arterial vascular disease is also higher in IBD. Inflammatory and molecular aspects of coagulation cascades are strictly linked and share several common mediators, including bacterial components as a possible link between intestinal microbiota and coagulation. We explored risk factors of thrombosis in IBD including clinical specificity, fibrin clot phenotype, *Clostridium difficile* infection, medication and surgery. We also present long-lasting thromboembolic complications and consider the advantage of post-discharge VTE prophylaxis.

INTRODUCTION

Inflammatory bowel disease (IBD) includes ulcerative colitis (UC) that primarily involves the large intestine, and Crohn's disease (CD) that may affect any part of the gastrointestinal tract, from the oral cavity to the rectum. However, about 20%–30% of IBD cases are associated with manifestations in other organs[1]. Venous thromboembolism (VTE) is a common extraintestinal complication in CD and UC, which is related to significant morbidity and mortality[2,3].

The number of hospitalizations of adults with VTE in the USA was estimated at more than 500 000 individuals each year, and 100 000 deaths are attributed to VTE annually, as indicated by data from the National Hospital Discharge Survey[4]. VTE is the third most common cause of vascular death after myocardial infarction and stroke. In recent years, there have been a growing number of reports on the VTE mechanism, risk factors, including medication and surgery, and the management of IBD patients. In light of the recent evidence, this review is focused on prothrombotic factors of VTE and arterial thromboembolism (ATE) and clinical complications of thrombotic events in patients with IBD, and summarizes the approach to the prevention during hospitalization and in the post-discharge period, and treatment of VTE in IBD.

EPIDEMIOLOGY AND LOCATION OF VTE

Population–based cohort studies have shown that patients with IBD seem to have an approximately threefold increased risk for developing VTE compared to the general population, and this relative risk is significantly higher during active IBD[2,3,5-7]. In their cohort study, Bernstein *et al*[5] found that the incidence rate of deep venous thrombosis (DVT) was 31.4/10000 person-years and the incidence rate of pulmonary embolism (PE) was 10.3/10000 person-years in CD, while the incidence rates were 30.0/10000 person-years for DVT and 19.8/10000 person-years for PE in UC. In an Austrian multicenter study, the incidence rate of all VTE was 6.3 per 1000 person-years, which was similar to the rate reported in the earlier study[7]. The incidence of VTE increases with age. However, no significant sex-related differences have been found[7,8]. The mortality associated with IBD-related VTE ranges from 8% to 22%[9,10]. Nguyen and Sam showed a significant, 2.5-fold-increased odds [odds ratio (OR): 1.83–3.43] of mortality associated with VTE-related hospitalization in patients with IBD compared to patients without VTE[2] .

In terms of VTE location, DVT of the lower extremity and PE are the most common VTE complications in IBD. However, VTE may occur in the abdominal (portal, mesenteric and splenic) veins[11]. VTE is also reported in the arm vein, and unusual sites such as the retinal vein, and cerebral sinus veins[7,12]. In an Austrian multicenter study among patients with IBD with a history of VTE, 90.4% of patients presented with DVT and/or PE, whereas 9.6% had portal, mesenteric, cerebral or internal jugular vein thrombosis[7]. The most commonly applied procedures for diagnosis of DVT include ultrasound and venography[13,14].Ventilation-perfusion scan and multidetector helical computer axial tomography are tools for the diagnosis of PE[14].

ATE COMPLICATIONS

ATE occur less frequently than VTE in IBD, including the limb arteries, and even central vessels including the aorta[15-17]. In the past few years, studies have suggested that patients with IBD might also be at an increased risk of coronary heart disease and stroke[16,18]. In a recent meta-analysis, IBD was associated with a modest increase in the risk of cerebrovascular disease incidence [hazard ratio (HR: 1.29)], in both CD (HR: 1.32) and UC (HR: 1.18)[18]. In another meta-analysis, patients with IBD were associated with a modest increase in the risk of coronary artery disease (OR: 1.19) in patients with CD and UC[19]. After adjusting for potential confounders, the meta-analysis of five studies revealed an 18% higher risk of cerebrovascular events in both CD and UC, with no significant differences between the two forms, but a higher risk for women compared to men [OR: 1.28 adjusted, 95% confidence interval (CI): 1.17–1.41]. No increased risk of ATE was found in a French study, including 33 studies with a large cohort of hospitalized IBD patients and controls. However, an increased risk of coronary heart disease and mesenteric ischemia was found[20]. An increased risk for potentially life-threatening arterial vascular diseases in patients with IBD also requires assessment of conventional risk factors such as hypertension, obesity, diabetes and dyslipidemia. However, typical cardiovascular risk factors other than hypertension have not been confirmed in IBD[21].

ETIOPATHOGENESIS OF VTE AND ATE IN IBD

Impairment of hemostasis in patients with IBD

Unregulated activation of the coagulation system may cause thrombosis or embolism. Local hemostasis is initiated when chronic inflammation, surgery or trauma disrupts the vascular endothelial lining, and blood is exposed to subendothelial connective tissue. In primary hemostasis, a platelet plug is formed, and then plasma coagulation proteins are activated to initiate secondary hemostasis. The complex of tissue factor (TF) and active factor VII is the most important initiator of coagulation. Activation of coagulation results in thrombin generation, and in turn may generate fibrin formation as well as platelet activation *via* the cleavage of and binding to thrombin receptors (Figure 1)[22]. Several authors have indicated systemic evidence for impairment of fibrinolysis and intravascular thrombin generation in patients with IBD to measure prothrombin fragments (formed during the conversion of prothrombin to thrombin, F1+2) and thrombin–antithrombin complexes[23,24]. The plasma level of protein C, a natural coagulation inhibitor, has been shown to be unchanged or decreased in IBD[25,26], while its decreased cofactor, the protein S plasma level, was demonstrated in most studies[27]. Importantly, in some studies, thrombin-activatable fibrinolysis inhibitor (TAFI) which provides a link between coagulation and fibrinolysis, has been found to be increased in patients with IBD[28,29]. Activated by thrombin, TAFI removes lysine residues from fibrin, which is essential for plasmin formation in the fibrin network, and in turn inhibits fibrinolysis, which contributes to the prothrombotic state. Elevated D-dimer levels were found mainly in active IBD patients, which provides evidence of fibrin formation and reactive fibrinolysis (Figure 1)[24,25].

The increased platelet count correlates with IBD activity, and higher platelet count is even proposed to distinguish IBD from infectious diarrhea. Abnormal platelet aggregation *in vitro*, and activation *in vivo* are found in both active and inactive IBD[24,25,30]. Thus, platelet activation is a feature of IBD, and along with thrombocytosis, it may have a role in the development of thrombosis. Systemic endothelial cell dysfunction has been reported in UC and CD. Serum concentration of von Willebrand factor and thrombomodulin level, which are the markers of vascular injury, are also increased in the serum of IBD patients in relation to the disease activity[31,32]. In their large epidemiological study, Thompson *et al*[33] indicated an opposite approach showing that IBD occurred less frequently as expected in large cohort patients with the main inherited coagulation deficiency disorders, including hemophilia or von Willebrand disease.

Mutual activation of coagulation and inflammation in IBD

Activation of coagulation is a significant constituent of the inflammatory response and probably is involved in the pathogenesis of IBD[34,35]. Proinflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), which are elevated in circulation and intestinal lesions in IBD, may initiate coagulation by induction of the TFs in monocytes/macrophages, endothelial cells and platelets. IL-1 and TNF–α are

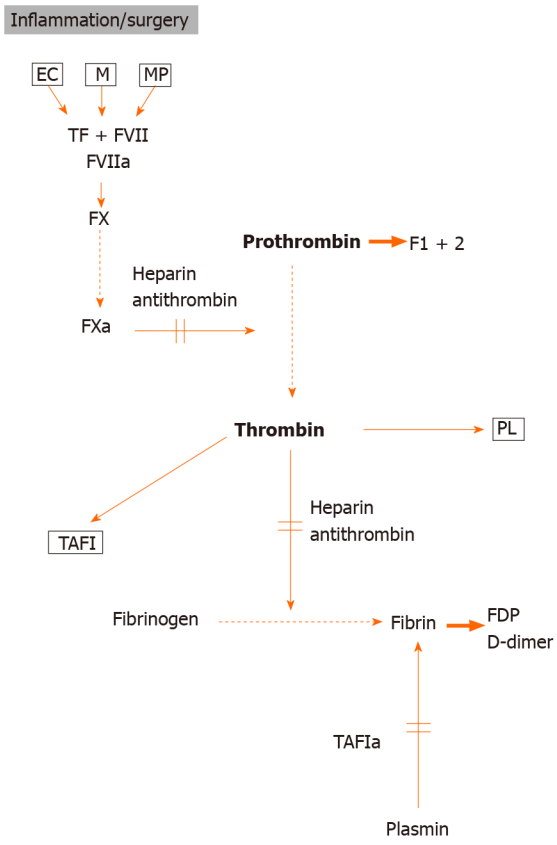

Figure 1 Diagram of the main pathways of the hemostatic process. Solid arrows designate activation, dashed arrows conversion, open arrow indicates release, and interrupted lines indicate inhibition. EC: Endothelial cell; M: Monocyte; MP: Microparticle; PL: Platelet; TF: Tissue factor; TAFI: Thrombin activatable fibrinolysis inhibitor; FDP: Fibrin degradation product.

capable of inducing procoagulant activity and suppressing the anticoagulant activity of thrombomodulin, in part due to a downregulation of endothelial protein C receptor, which is expressed normally by endothelial cells[36]. In addition, the cell components, known as microparticles, are found in plasma of adult and pediatric IBD patients[37-39]. There are vesicles of cell membranes mainly from activated platelets with the expression of TFs on their surface, suggesting their role in the activation of coagulation. Importantly, platelets may mediate leukocyte recruitment to the inflamed colon *via* surface CD40 ligand (CD40L). Danese *et al*[40] found an increased platelet expression of CD40L, and an increased plasma level of platelet soluble CD40L in both UC and CD compared to normal controls. Taken together, it seems that platelets are involved in hemostasis and thrombosis. They also act as inflammatory cells in IBD.

Evidence suggests that thrombin may, in turn, mediate and amplify inflammatory cascades in IBD *via* activating protease activated receptors (PARs), which have been identified as mediators of cellular responses, especially in the context of a link between coagulation and inflammation. Thrombin is an essential mediator of PAR activation as this enzyme can activate PAR1, 3 and 4, and in turn mediate detrimental cellular effects, especially barrier disruption in endothelial cells[41]. In addition, recent studies have shown that the protein C pathway is expressed not only in endothelial cells of the mucosal microvasculature, but also in intestinal epithelial cells and plays a unique role in controlling the integrity of tight junctions[42]. Expression of epithelial protein C pathway is altered in patients with CD and UC, which may enhance intestinal permeability[43].

Due to the overlapping risk factors, patients with VTE are at increased risk for arterial thrombotic events, including coronary heart disease and stroke. Endotheliopathy and abnormalities in the coagulation cascade and their cellular components play a role for the development of VTE and ATE. A growing number of studies have indicated that patients with IBD are at an increased risk of developing cardiovascular disease (CVD). Both diseases are chronic inflammatory conditions and share certain pathophysiological mechanisms that may influence each other. High levels of cytokines, C-reactive protein, and homocysteine in IBD patients may lead to endothelial dysfunction, which is an early sign of atherosclerosis. Platelet–leukocyte

interaction and an increased CD40/CD40L system may be important links in the generation of atherosclerosis and IBD[40]. Higher levels of coagulation factors and an increased number of activated circulating platelets frequently occur in IBD, which may predispose to ATE events[32].

Bacterial components and gut microbiota

Endotoxins (lipopolysaccharide; LPS) are glycolipids found on the outer membrane of Gram-negative bacteria, which originate from the intestine and may activate receptors in monocytes, endothelial cells and platelets directly or *via* augmentation of cytokines, promoting a procoagulant state. The epithelium of the intestine creates a barrier to potentially immunogenic and noxious factors, including microorganisms and dietary components within the intestinal lumen. Luminal proteases include the host's digestive enzymes and the proteases released by the microbiota. PAR1 and PAR2 are expressed throughout the gastrointestinal (GI) tract[41]. Although PARs are traditionally known to affect several vascular responses, recent studies have indicated the functional role of PAR signaling in the GI tract. Proteases A, either from the gut lumen or from the mucosa, are capable of activating PARs, thus influencing gut permeability regulation[44].

Both endothelial cells and platelets possess innate immunity receptors, such as Toll-like receptors (TLRs). After being activated by bacterial components, TLR2 and TLR4 promote cell activation and the subsequent release of different procoagulant molecules [45,46]. The role of the impairment of the intestinal barrier has been recently indicated by Pastorelli *et al*[47] who showed that LPS level increased in systemic circulation of IBD patients and correlated with TLR4 concentrations in both active and remission phases of IBD. Simultaneously, serum LPS level correlated with both D-dimer and F1+2 levels, which supports the role of the impairment of the intestinal barrier in triggering the activation of the coagulation cascade in IBD. In fact, LPS might act as the link between the microbiome and hypercoagulability.

Gut microbiome and TE

Recent reports have suggested that alterations in gut microbiome due to a decrease in commensal anaerobic bacteria and an increase in the abundance of the Gram-negative Enterobacteriaceae family may increase the risk of TE[48]. It was found that dietary nutrients, such as choline, carnitine and butyrobetaine, common in a western diet, can be used by gut microbes to produce trimethylamine (TMA), which is converted into TMA N-oxide (TMAO)[49]. Clinical studies have revealed that TMAO level is associated with thrombotic risk of CVD[49-51]. The mechanisms in which TMAO may enhance CVD risk include endothelial cell activation and vascular inflammation, as well as alterations in tissue sterol metabolism[50]. A recent study has revealed that gut microbes directly contribute to platelet hyper-reactivity through generation of TMAO and increased plasma TMAO levels independently predicted the event of thrombosis [51]. Patients with IBD show microbial imbalance, and a less diverse gut microbiome compared to healthy individuals[52]. Currently, there are no data showing metabolic pathways by specific gut microbiota in IBD that might cause the risk of thrombosis.

RISK FACTORS OF THROMBOEMBOLIC COMPLICATIONS IN IBD

Disease activity and hospitalization

Several IBD-specific risk factors are responsible for the increased risk of VTE, especially in hospitalized IBD patients, which in part may reflect periods of increased inflammation[2,3,53]. The disease phenotype, *e.g.*, pancolitis in patients with UC, extensive colonic involvement and active fistulizing CD are significantly associated with VTE in IBD patients[2,3,10]. Similar data reported by a recent large cohort Swiss study and a recent cohort multinational study in East Asia demonstrated that VTEs were prevalent in CD patients with ileocolonic involvement, and in UC patients with pancolitis[54,55]. During hospitalization, VTE events are also related to immobility, the use of a venous catheter for parenteral nutrition, and fluid depletion due to diarrhea.

Clinical and biochemical specificities

VTEs in IBD patients are characterized by unusual clinical and biochemical specificities (an earlier first episode in life, high rates of remission, and high recurrence rates). The incidence of VTE increases with age. However, it occurs more frequently in younger patients with IBD than in those without this condition[2,3,53,56]. A large

population-based study from Denmark showed that the risk of VTE was particularly high (sixfold higher HR) in young patients with IBD as compared to age and sex-matched patients without IBD[53]. VTE events are more frequent in active IBD. However, in one-third of the patients with IBD, VTE was observed during clinical remission[7,56,57]. Although the epidemiological data demonstrate a relative prevalence of VTE in some immune-mediated disorders[58], especially among many inflammatory and/or immune-mediated conditions, IBD is related to a significantly more prominent risk of VTE[56]. Therefore, IBD is itself prothrombotic.

Polish studies have shown that plasma fibrin clot permeability is reduced and fibrin network is mostly resistant to lysis in patients with IBD, which may represent a mechanism for increasing the thrombotic risk in IBD[59]. Recently, the investigators at the University of Leuven, Belgium indicated that clot lysis parameters (area under the curve, 50% clot lysis time, and amplitude) were significantly higher in IBD compared to controls and in IBD with thrombotic events and a history of thrombosis compared to IBD without thrombosis[60]. Taken together, fibrin clot phenotype in IBD may be considered a potential novel risk factor for TE.

Recurrence of VTE

IBD represents an independent risk factor for the recurrence of VTE. Novacek *et al*[61] showed that patients with IBD who experienced their first episode of unprovoked VTE had 33% likelihood of the second episode of VTE within 5 years compared to 21% in non-IBD patients (HR: 2.5). Recently, Bollen *et al*[62] presented a monocentric cohort of IBD patients with a history of VTE and ATE and focused on the recurrence rate. These authors confirmed the high recurrence rate of thrombotic events in patients with IBD. They found that 30% of patients were identified to have recurrent TE events. In this group, 83% developed VTE, with DVT as the major manifestation (40%), followed by PE (23%). However, a relatively high number of thrombotic events (*i.e.* 17%) became recurrent in arterial circulation. De Fonseka *et al*[63] found that a history of TE was the most significant predictor of VTE in IBD. Similarly, Faye *et al*[64] showed that in patients with IBD, prior VTE was associated with readmission for VTE within 2 mo.

Post-thrombotic syndrome

Post-thrombotic syndrome (PTS) may increase the likelihood of VTE recurrence among IBD patients. It is the most frequent complication of VTE located in the lower limbs, which develops in 20%–50% of cases after proximal DVT and is severe in 5%–10% of cases[65]. Reported risk factors of PTS include extensive proximal character of DVT, involving the popliteal vein or above. Other reported risk factors include pre-existing chronic venous insufficiency (especially with mild or severe contralateral leg venous ectasia), older age and high body mass index[65]. The risk of PTS is substantial but significantly lower after an isolated distal infrapopliteal DVT. Since signs and symptoms of DVT and PTS may be similar, diagnosis of PTS should be delayed for 3–6 mo after DVT diagnosis. Compression ultrasonography, which is based on leg vein compression using the ultrasound probe, should be performed to evaluate the degree of obstruction by clots, the location of these clots, and the detection of venous insufficiency[13].

Clostridium difficile infection

IBD has been shown to be a specific risk factor for the development of *C. difficile* infection, which may lead to higher morbidity and mortality[66]. A large cohort retrospective study assessing the Nationwide Inpatient Sample in the USA found that the rate of VTE was twofold higher in hospitalized patients with IBD and *C. difficile* infection than in those without *C. difficile* infection (adjusted OR: 1.7)[67]. In their most recent study, Faye *et al*[64] found that *C. difficile* infection was an independent risk factor of readmission for VTE in patients with IBD during a 2-month time period. Therefore, clinicians need to be vigilant to assess *C. difficile* infections in patients with IBD with a flare of diarrhea to counteract *C. difficile* and minimize the risk of VTE.

Nonspecific risk factors

IBD-associated comorbidity is prothrombotic in itself and is an independent predictor of VTE; *e.g.*, congestive heart failure, chronic obstructive pulmonary disease, obesity, Behcet's disease, myeloproliferative diseases (polycythemia vera, paroxysmal nocturnal hemoglobinuria, paraproteinemia), liver cirrhosis, or diabetes mellitus[68].

Low serum albumin is a well-recognized risk factor for VTE in nephrotic syndrome [69]. In patients with IBD, low albumin levels may reflect excess loss of intestinal protein, and particularly circulating antithrombotic proteins, especially antithrombin.

Serum level of antithrombin may be a marker of underlying inflammation as a negative acute phase reactant.

An increased level of lipoprotein(a), an independent risk factor for TE, has been shown to account for a tendency toward TE in some CD patients[70]. Autoimmune abnormalities and increased production of various antibodies are often associated with IBD. Serum cardiolipin autoantibodies involved in higher risk of arterial and venous thrombosis are increased in patients with IBD. However, their elevated titer is not associated with higher VTE rates[71]. Similarly, in a recent IBD cohort study, a higher prevalence of various types of antiphospholipid antibodies was documented in patients with CD. However, this status was not associated with more TE events[72].

Provoked VTE and ATE may occur in hyperhomocysteinemia due to deficiency of vitamins B12, B6 or folate, or hereditary genetic abnormalities such as gene mutation of methylenetetrahydrofolate reductase (MTHFR)[73]. In a meta-analysis, the mean plasma homocysteine level was significantly higher in IBD patients compared to controls. However, in this study the risk of hyperhomocysteinemia was not higher among IBD patients who presented with TE complications[74].

In CD patients, oral contraceptive drugs are well-known risk factors for TE[75]. In spite of this, Cotton *et al*[76] in a large internet-based cohort of patients with IBD found that use of hormonal contraceptives in women with multiple risk factors for TE was similar to that in women without risk factors. Thus, patients with IBD should be asked about risk factors for thromboembolic disease to have an opportunity for alternative contraception. Patients with CD are more likely to be smokers, which increases the risk of vascular disease in this condition. However, UC is generally a disease of non-smokers and exsmokers[77].

Extended traveling with prolonged sitting is known as a risk factor for VTE, although it is currently recognized that reduced movement on long distance flights is more significant than immobilization. As summarized by Byard, long-distance flights of ≥ 8 h are associated with a 2–4-fold increased risk of VTE, but only in those individuals who have underlying risk factors. Importantly, the potential impact of lethal pulmonary VTE exists with increasing numbers of flights of > 16-h duration[78].

IBD medications

Some drugs used in IBD treatment can be considered potential thrombotic factors. Glucocorticosteroids used to maintain remission in IBD by multifactorial anti-inflammatory effects are also known to induce hypercoagulability, increasing plasma fibrinogen level, and decreasing tissue plasminogen activator activity and prostacyclin synthesis[79]. The use of corticosteroids prior to hospitalization is an independent risk for VTE[68]. Nguyen *et al*[80] in their large retrospective cohort study compared the risk of postoperative complications between preoperative steroid users and nonusers. They found that preoperative steroid use was associated with an increased risk of VTE in CD (OR: 1.66) and UC (OR: 2.66).

The role of TNF-α that occupies a central position to generate the inflammatory and coagulation cascade has been well defined in CD and UC. Compounds that contain anti-TNF-α antibody are currently the most recommended for biological treatment of moderate and active CD and UC[81]. Hommes *et al*[82] demonstrated that treatment with infliximab decreased thrombin generation, indicating that coagulation activation is mediated by TNF-α or a subsequent cascade of cytokines. In addition, treatment with infliximab reduces the level of circulating and prothrombotic serum-soluble CD40L in patients with CD[83]. Anti-TNF-α therapy with infliximab also downregulates isoprostane generation and thromboxane synthesis, which may reduce thromboxane-dependent platelet activation in IBD patients[84]. Bollen *et al*[85] in a prospective study investigated the effect of infliximab therapy on the hemostatic profile. They documented normalization of the clot lysis profile in responders to infliximab treatment, suggesting that infliximab is especially advisable for patients with IBD with an activated hemostatic profile. Swiss investigators in their single-center retrospective study found that in patients with IBD, TNF-α inhibitor therapy was associated with a reduced risk of TE (OR: 0.20), whereas corticosteroid use increased (OR: 4.62) TE[63]. A recent meta-analysis conducted by Hungarian investigators showed that systemic corticosteroids were associated with a significantly higher rate of VTE complications in IBD patients as compared to IBD patients without steroid medication (OR: 2.202). In contrast, treatment with anti-TNF-α agents resulted in a fivefold decreased risk of VTE compared to steroid medication (OR: 0.267)[86].

Tofacitinib, a small-molecule Janus kinase inhibitor, has been used for the treatment of moderate and severe UC. Recently, safety data for tofacitinib in rheumatology studies showed that tofacitinib 10 mg twice daily increased the frequency of VTE, although the study comprised patients aged ≥ 50 years who presented with other

cardiovascular risk factors[87]. The US Food and Drug Administration has indicated that tofacitinib 10 mg twice daily may increase the risk of VTE[88]. The most recent preliminary analysis of UC patients treated with tofacitinib 10 mg twice daily demonstrated that five presented with VTE (four PE, and one DVT), as compared to two patients receiving placebo[89]. The analysis was limited by the small group of patients, and hence further studies are warranted. At present, since uncertainty exists, the lower dose of tofacitinib (5 mg twice daily) is indicated.

Surgery

Colorectal surgery is a strong predictor of developing VTE[90]. A combination of pathophysiology of IBD and surgical risk factors increases the risk of postoperative VTE in IBD patients. A recently conducted Canadian meta-analysis showed that IBD patients undergoing colorectal surgery were at a higher risk for postoperative VTE as compared to patients undergoing surgery for colorectal cancer[91]. Patients with UC may be at higher risk for postoperative VTE as compared to those with CD. Wilson *et al*[92] found that during admission and within 30 d of hospital discharge, the incidence of VTE was higher in UC patients (2.74%) than in patients with colorectal cancer (1.74%). However, the lowest incidence was seen in patients with CD (1.2%). Similarly, McCurdy *et al*[93] reported that the cumulative incidence of VTE at 1 mo after discharge was higher in surgical patients with UC (HR: 1.68; 95%CI: 1.16–2.45) but not in surgical patients with CD. In UC patients, the risk of VTE is mostly higher in patients after colectomy[94,95]. McKenna *et al*[95] using the American College of Surgeons-National Surgical Quality Improvement Project database found that surgically urgent UC cases showed a higher rate of VTE than non-IBD patients undergoing colorectal resections (6.9% *vs* 3.1%).

PROPHYLAXIS OF VTE IN IBD

Of note, controlling the disease activity as the primary aim of IBD treatment may partly prevent VTE events and also reduce the risk of recurrent VTE episodes. Correction of vitamin deficiencies (particularly B6, B12 and folic acid) can reduce homocysteine levels[74]. In addition, therapy with sulfasalazine or methotrexate may induce folate deficiency, thus supplementation of folic acid is advocated.

Pharmacological prophylaxis

It has been confirmed that that IBD patients have an elevated risk of VTE compared to the general population. Consequently, GI societies from North America and Europe have advocated the use of pharmacological prophylaxis among hospitalized IBD patients[15,96,97]. Low molecular-weight heparin (LMWH) and unfractionated heparin are recommended for thromboprophylaxis in IBD patients. Primary prophylaxis is advocated for all hospitalized IBD patients, because the higher risk of VTE in hospitalized IBD patients also includes those hospitalized for non-IBD related reasons[96-98]. In the period of active bleeding, mechanical prophylaxis is temporarily advisable. If bleeding is not severe, anticoagulant thromboprophylaxis should be substituted for mechanical thromboprophylaxis. Anticoagulant thromboprophylaxis during hospitalization is recommended for IBD patients who underwent major abdominal-pelvic or general surgery. Similarly, anticoagulant thromboprophylaxis during hospitalization is indicated for pregnant women with IBD who underwent cesarean section. Another recommendation for pharmacological prophylaxis is advocated (related to secondary prophylaxis) during moderate-severe IBD flares in outpatients with a history of VTE. The unresolved question is whether thromboprophylaxis should be extended to all outpatients with the disease flare. Thus, the absolute risk of VTE should be assessed for each ambulatory patient with active IBD, including co-morbidity, previous VTE events, the use of oral contraceptives, smoking, and the presence of venous catheters[68,98]. Moreover, disease features could be useful in assessing the individual prothrombotic risk. Another question arises whether thromboprophylaxis should be extended after hospitalization to IBD patients with a higher risk for VTE. In a recent population-based study, McCurdy *et al*[93] found that surgical IBD patients with UC and non-surgical IBD patients were 1.7-fold more likely to develop post-discharge VTE than non-IBD matched controls. These authors showed that the risk score of post-discharge VTE for IBD patients included age over 45 years and the length of admission (more than 7 d), which would indicate prolonged post-hospitalization VTE prophylaxis. In another recent study evaluating predictors of post-hospitalization VTE in patients with IBD, Faye *et al*[64] showed that risk factors such as

older age, discharge to a nursing facility, and a previous C. *difficile* infection at the time of admission increased this risk. In addition, they found that over 90% of VTE readmissions occurred within 60 d post-discharge, with the majority in the first 20 d. These findings should increase alertness and consideration of thromboprophylaxis in this population.

Finally, it is well known that surgery represents a major risk factor for VTE, particularly in patients with IBD, and thromboprophylaxis is universally performed from the day of surgery to discharge. However, as reported before, in the IBD patient population, colorectal surgery is related to an additional VTE risk, including post-discharge period[93,95]. Recent meta-analyses in the United States indicated that IBD patients undergoing colorectal surgery were at a higher in-hospital and post-discharge risk for postoperative VTE compared to non-IBD patients undergoing surgery for colorectal cancer[91,99]. Current prophylaxis may not be sufficient to prevent VTE, especially for UC patients undergoing emergency colorectal procedures who might benefit from extended TE prophylaxis[92,94]. Kaplan *et al*[94] presented a population-based surveillance of UC hospitalized patients during a flare and compared VTE events between UC patients who responded to medical management and patients who underwent colectomy. These authors showed that VTE was significantly higher among patients who underwent colectomy, and mostly higher in patients after emergency colectomy, although more than 90% of surgical patients were given heparin prophylaxis. Despite a large amount of evidence demonstrating the high VTE risk in IBD, no randomized controlled trials specifically assessed the efficacy of anticoagulation in reducing the rate of VTE in IBD patients or in applying extended-duration prophylaxis after surgery to this population.

Implementation of prophylaxis in IBD

Although the increased risk of VTE among IBD patients has been documented, thromboprophylaxis rates in hospitalized patients with IBD seem to be low[98]. Recent and prior studies showed that patients with IBD admitted to surgical service received anticoagulation prophylaxis more often than those admitted to medical centers. In a multicenter retrospective study from Canada, patients with IBD admitted to the surgical setting were more likely to receive VTE prophylaxis than those admitted to medical service (84% *vs* 74%)[100]. Implementation of an electronic alert system seems to be an effective tool for increasing VTE prophylaxis rates in hospitalized patients with IBD. The introduction of this system was associated with a significant improvement in prophylaxis rates in both medical (26.3% *vs* 62.8%) and surgical (83.7% *vs* 95.5%) services[101]. All providers should be educated on the increased risk of VTE as well as the safety of pharmacologic prophylaxis. Inadequate implementation of VTE prophylaxis in patients with IBD is still mainly due to the concern about the safety of anticoagulation. Although prior data of Ra *et al*[102] indicated that the rate of major and minor bleeding was not significantly higher in the group who received pharmacological VTE prophylaxis compared to those who did not receive it, Faye *et al*[103] showed that IBD patients with minor hematochezia (OR: 0.27) were significantly less likely to receive VTE prophylaxis. In addition, these investigators concluded that VTE prophylaxis was not associated with increased blood transfusion rates or a clinically significant decline in hemoglobin level during hospitalization[]. It should be underlined that most patients with hematochezia will have a disease flare, and they are at a significantly increased risk for VTE during this time.

Mechanical prophylaxis

Mechanical thromboprophylaxis, graduated compression stockings, and/or intermittent pneumatic compression devices are indicated for IBD patients hospitalized with major GI bleeding[96]. Early mobilization in hospitalized surgical and non-surgical IBD patients should be always considered. These methods address the venous stasis portion of the Virchow triad by increasing venous blood flow. There are several proposed mechanism for the efficacy of induced venous stasis, including increased level of tissue factor inhibitor, the resultant factor Xa–related coagulation inhibition, and promotion of fibrinolysis by increased release of t-PA from the endothelium[104]. However, in cases of severe limb ischemia, the use of mechanical prophylaxis could worsen the ischemia and should not be used in these patients.

TEST SCREENING FOR THROMBOSIS RISK

Thrombophilia is related to acquired or inherited susceptibility to thrombosis.

However, thrombophilia testing in IBD patients is not routinely recommended. In general, no interaction between IBD and inherited factors of thrombophilia was found. Study results showed that the prevalence of factor V Leiden (which makes factor V resistant to inactivation by activated protein C) in IBD is not different compared to the general population. Studies failed to demonstrate the prevalence of the genetic variant prothrombin G20210A, and MTHFR, or gene mutation related to hyperhomocysteinemia in IBD patients[105,106]. However, hereditary genetic screening should be performed in IBD when a familial history of thrombosis, myocardial infarction, or stroke before the age of 50 is confirmed in first-degree relatives[107]. In addition, myeloproliferative neoplasms should be considered in patients with splanchnic vein thrombosis, particularly in the absence of an additional provoking factor. In these cases, testing for the JAK2V617F mutation, which is present in most patients with a myeloproliferative neoplasm is useful for identifying this disorder[100].

D-dimer, a fibrin degradation product, is effective for VTE screening, and adequately demonstrates the occurrence of VTE in the general population, although this test is characterized by low specificity[108]. However, high prevalence of elevated D-dimer in active patients with IBD usually rules out its utility in IBD[24,25,109].

Search for a biomarker which could select patients with and increased risk for thrombosis among IBD subjects is a challenging dilemma for clinicians. The endogenous thrombin potential (ETP) test may be considered a new tool for prospective studies on IBD patients to assess the risk of TE[110]. As opposed to coagulation intermediates or fragments which are markers of thrombin already generated, the ETP quantifies thrombin activity that can be generated in plasma. The increased ETP has been demonstrated in adult patients with IBD, and in active and quiescent stages in pediatric IBD patients, which indicates that procoagulant potential is a feature of the disease[38,110]. Probably the prospective studies are needed to evaluate clinical value of ETP, which stratifies the VTE risk, especially in pediatric IBD patients, in whom anticoagulation prophylaxis is not routinely recommended. Recently, investigators at the University of Leuven have determined the clot lysis profiles in patients with IBD before and after developing thrombosis and showed that clot lysis parameters differed significantly between IBD patients with and without a history of TE[62]. Therefore, a functional clot lysis assay could be included in the assessment of TE risk[60]. Nevertheless, it should be noted that both ETP test and clot lysis assay have sophisticated methodology, and hence are not routinely used.

TREATMENT OF VTE IN PATIENTS WITH IBD

The general approach to treatment of VTE in patients with IBD is similar to patients without IBD. If there is no hemodynamically significant bleeding, LMWH is the most appropriate treatment. LMWH is usually switched to an oral vitamin K antagonist (*e.g.* warfarin). In terms of VTE treatment, strong recommendations are made for a period of minimum 3 mo of anticoagulant therapy for adult and pediatric IBD patients with a symptomatic VTE, including symptomatic splanchnic vein thrombosis. In patients with active IBD, in the first event of VTE, anticoagulation therapy should be continued until IBD has been in remission for at least 3 mo. For IBD patients with unprovoked VTE presenting during clinical remission, indefinite anticoagulant therapy is recommended with a periodic analysis of the decision. In similar cases, if there is a reversible risk factor, anticoagulation therapy is recommended for at least three months until a risk factor has resolved. In addition, in those cases it is recommended that therapy should be prolonged for at least 1 mo until the risk factor has resolved. The risk-benefit ratio of long-term therapy should be evaluated on an individual basis. Anticoagulant treatment should aim not only at preventing thrombus extension but also at preventing early and late recurrences[111].

Treatment of PTS

The presence of residual vein thrombosis (partial recanalization) at 3 to 6 mo post-DVT is associated with symptomatic PTS and an increased risk of VTE recurrence in about one third in the post-DVT patients after regular discontinuation of anticoagulant treatment. Patients with PTS with delayed recanalization, and venous reflux confirmed by compression ultrasonography should receive extended anticoagulation treatment [112]. In addition, in patients hospitalized at risk of PTS, recurrence prevention includes immediate mobilization and compression stockings[65]. Vitamin K antagonists (mainly warfarin) are effective in treating VTE, but they require frequent monitoring. Poor quality of anticoagulation control (*e.g.*, too low doses during

treatment) may explain why at least some patients develop PTS[65].

OTHER TREATMENT MODALITIES

New oral anticoagulants

Anticoagulation treatment options have undergone a significant change within the last 10 years due to the development of direct oral anticoagulants (DOACs). Direct factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban), and thrombin inhibitor (dabigatran) are currently available. In patients on DOACs, it is not necessary to monitor the INR ratio or heparin bridging. DOACs may allow stable patients with VTE to be treated at home earlier than in the case of warfarin. In fact, DOACs might be superior to vitamin K antagonists in treatment of VTE and prevention of PTS[113]. VTE is a dynamic process resulting from clot propagation exceeding clot lysis over time[114]. Anticoagulant therapy attenuates thrombin generation and promotes clot lysis by preventing thrombin activation of TAFI, and in turn inhibition of clot lysis. A failure to adequately suppress thrombin generation and/or activity will permit continued feedback activation of thrombin generation, fibrin formation, and inhibition of fibrinolysis by activation of TAFI. Some reports indicated that treatment with DOACs of acute symptomatic VTE was associated with a significantly lower risk of bleeding complications as compared with the vitamin K antagonist[115]. However, in case of overdose, there is no reversing agent for these drugs. In relation to IBD, currently there are no data related to the use of these promising drugs. DOACs, and perhaps low-dose DOACs, could have a particularly important role in the management of outpatients with IBD in remission and in outpatients with IBD-associated PTS. In such cases, controlled trials are warranted.

Acetylsalicylic acid

Acetylsalicylic acid (ASA) is commonly used for preventing arterial thrombosis. Some studies showed that aspirin reduced the relative risk of recurrent VTE by 30% in the high risk population compared to placebo[116]. However, the use of ASA in prevention of VTE is currently not routinely recommended. It should be underlined that if patients are scheduled for anticoagulation therapy, and have been on ASA for another indication, the risk of bleeding might be increased. A new generation of antiplatelet compounds which selectively inhibit platelet activation rather than platelet aggregation merits future studies.

Local thrombolysis

Catheter-directed thrombolysis (CDT) is increasingly used to treat acute TE. Currently used thrombolytic agents include t-PA, urokinase or streptokinase. It is accepted that systemic thrombolytic therapy should be considered in patients with massive PE, defined by hemodynamic compromise[117]. The cases of severe thrombosis causing limb ischemia may also require CDT. The role for thrombolysis, particularly CDT in other patients with DVT is less well established. CDT would be favorable in otherwise healthy patients with significant iliofemoral DVT. The rationale here is that CDT may decrease the incidence and severity of PTS. In IBD, a systematic review of outcomes with anticoagulation *vs* CDT was compared. It was found that CDT was more effective to achieve complete or partial symptomatic and radiologic resolution of thrombus in patients with IBD. Although hemorrhagic complication tended to occur more frequently in patients treated with CDT, no statistically significant differences were found in terms of complications between the two groups[118].

CONCLUSION

VTE events in IBD may increase as the incidence of IBD and life expectancy also increase. The risk of arterial TE is significantly lower than VTE, but an increased risk of cardiovascular diseases need to be monitored in IBD patients. Patients with IBD have a higher baseline risk of VTE, which further increases with surgery and corticosteroid therapy. Long-term complications of VTE can include post-thrombotic syndrome or chronic thromboembolic pulmonary hypertension. Thus focus on prevention and consideration of the utility of post-discharge prophylaxis and effort of implementation of VTE prophylaxis should be continued. The pathogenesis of TE in IBD is multifactorial and incompletely understood. The activation of coagulation is

recognized as an important component of the inflammatory response in IBD, and is also significant in the progression and possible pathogenesis. Whereas intestinal bacterial components may trigger the coagulation cascade in IBD, the gut microbiome could be an innovative approach for decreasing the risk of thrombosis in IBD.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is an aggressive tumor with high lethality. Even with surgery, radiotherapy, chemotherapy, and other locoregional or systemic therapies, the survival rates for PDAC are low and have not significantly changed in the past decades. The special characteristics of the PDAC's microenvironment and its complex immune escape mechanism need to be considered when designing novel therapeutic approaches in this disease. PDAC is characterized by chronic inflammation with a high rate of tumor-associated macrophages and myeloid-derived suppressor cells and a low rate of natural killer and effector T cells. The pancreatic microenvironment is a fibrotic, microvascularized stroma that isolates the tumor from systemic vascularization. Immunotherapy, a novel approach that has demonstrated effectiveness in certain solid tumors, has failed to show any practice-changing results in pancreatic cancer, with the exception of PDACs with mismatch repair deficiency and high tumor mutational burden, which show prolonged survival rates with immunotherapy. Currently, numerous clinical trials are attempting to assess the efficacy of immunotherapeutic strategies in PDAC, including immune checkpoint inhibitors, cancer vaccines, and adoptive cell transfer, alone or in combination with other immunotherapeutic agents, chemoradiotherapy, and other targeted therapies. A deep understanding of the immune response will help in the development of new therapeutic strategies leading to improved clinical outcomes for patients with PDAC.

Core Tip: Immunotherapy has demonstrated effectiveness in treating several solid tumors and has become a major revolution in oncology. In pancreatic ductal adenocarcinoma, however, the outcomes continue to be poor due to its special immune response and microenvironmental characteristics. In this review, we summarize the most important concepts of the immune system and the current landscape of immunotherapy in pancreatic cancer.

INTRODUCTION

Pancreatic ductal adenocarcinoma cancer (PDAC) derives from pancreatic glandular tissue and is considered the fourth most lethal malignant tumor worldwide, with high mortality and poor prognosis[1]. The aggressive nature of PDAC is the result of a multifactorial condition related to its desmoplastic stroma and characteristic tumor microenvironment (TME), the ability to evade the immune response, the low tumor mutational burden (TMB) and the lack of effective treatments[2].

Despite the use of various approaches and therapies such as surgical resection, radiotherapy, systemic chemotherapy and the combination of these therapies[3], 80% of such patients will die within a year of the diagnosis[4]. Even for patients with resectable disease who undergo R0 pancreatic surgery, the 5-year survival rate is less than 20%[5,6], and the 5-year overall survival (OS) is lower than 7% for those with metastatic PDAC[7]. Novel therapeutic strategies such as adjuvant modified FOLFIRINOX (folinic acid, 5-fluorouracil, irinotecan, and oxaliplatin) have improved postoperative survival rates[8]. For advanced and metastatic PDAC, chemotherapy is the only treatment option. Despite the new chemotherapy regimens developed over the past few years (FOLFIRINOX and gemcitabine plus nab-paclitaxel), however, the median OS is still under 12 mo[1,8]. Most of the driver mutations identified in PDAC lack targeted therapies. Nevertheless, patients might benefit from platinum-based chemotherapy and poly (ADP-ribose) polymerase (PARP) inhibitors in the case of BRCA1/2 mutation[9], immune checkpoint inhibitors in microsatellite instability[10] and tyrosine-kinase inhibitors for patients harboring neurotrophic-tropomyosin receptor kinase (NTRK) gene fusions[11], although the improvement in survival is not as successful as in other tumors. Even with all these advances, the OS for PDAC has hardly improved in recent decades.

Immunotherapy is a classic treatment approach and has been recognized since 2017 as the fourth pillar of treatment for many solid tumors[12]. A high number of preclinical and clinical studies are evaluating the efficacy of immunotherapeutic strategies in PDAC, including immune checkpoint inhibitors, cancer vaccines, and adoptive cell transfer, combined with other immunotherapeutic agents, chemoradiotherapy or other molecularly targeted agents. However, this new strategy still fails to meet the clinical needs of patients with PDAC, a consequence of the complex immune escape mechanisms, which need to be understood to improve the efficacy of new therapies.

In this review, we summarize the immune response mechanisms, the current landscape and the limitations of immunotherapy in PDAC.

IMMUNE RESPONSE IN PANCREATIC CANCER

The immune system and inflammatory state involve numerous interactions with premalignant and malignant lesions. While chronic inflammation induced by the immune system is associated with tumor growth[13], tumors cause tissue destruction and trigger inflammatory signals leading to the recruitment of cells of the innate immune system such as natural killer (NK), T cells, macrophages, and dendritic cells

(DCs)[13]. Inflammation is characterized by supporting hallmarks capabilities that contribute to tumor progression by providing cytokines, chemokines, proteases, and growth and proangiogenic factors; encouraging angiogenesis and tissue remodeling, assisting in the invasion and metastasis and ultimately driving local and systemic immune suppression[13].

In an effort to understand the dynamics of the immune response from preinvasive pancreatic intraepithelial neoplasia (PanIN) to invasive and metastatic PDAC, a study with genetically engineered *KRAS* and p53 mutant mice showed that immune system cells with suppressive properties are involved from the earliest stages of tumorigenesis. The *RAS* oncogene induces inflammation and immune suppression in the microenvironment, and both carry immune privilege in the tumor[14]. The predominant cells in the tumor stroma are immunosuppressive leukocytes that weakens the antitumor functions of lymphocytes infiltrating the pancreas and promote disease progression[15]. In contrast, many other solid tumors harbor a larger infiltration of effector T cells, which has been associated with enhanced clinical outcomes [14].

Immune system cells in pancreatic ductal adenocarcinoma

The most common immune cells in the tumor microenvironment (from PanIN to PDAC) include tumor-associated macrophages (TAM), myeloid-derived suppressor cells (MDSC), neutrophils, regulatory T cells (Treg), a smaller number of effector T cells and, rarely, NK cells[13-15].

TAMs and MDSCs are innate immune cells that play a dual role in PDAC and are involved in cancer cell recognition and antitumor response but also lead to chronic inflammation[16,17]. Macrophages are predominant in the initial stages of the disease, but the ratio of TAMs and MDSCs becomes similar as the disease progresses[15]. There are very few lymphocytes in the tumor; CD4+ T cells, along with a high portion of Tregs, are the most frequent. NK and CD8+ T cells are extremely rare at any stage [15].

Tumor-associated macrophages

Two types of TAMs have been identified: M1 and M2 macrophages. M1 macrophages secrete proinflammatory cytokines with antineoplastic effects, while M2 macrophages release cytokines that lead to tumor progression[18,19]. Macrophages are the most common immune cells in the tumor microenvironment at the early stage. Several reports have shown an inverse correlation between the prognosis and M2 TAM infiltration in vairous tumors, including PDAC[20,21].

TAMs produce cytokines, proteases and metabolites, such as indoleamine dioxygenase and reactive oxygen species, which inhibit T-cell activity against tumor and attract Tregs to the tumor site[22]. Moreover, TAMs facilitate tumor angiogenesis by releasing pro-angiogenic factors such as vascular endothelial growth factor (VEGF) and participate in matrix remodeling to facilitate invasion and metastasis[23].

Myeloid derived suppressor cells

MDSCs are a heterogeneous group of immature cells divided into polymorphonuclear (PMN-MDSC) and monocytic (M-MDSC), resembling neutrophils and monocytes, respectively[24,25]. Myeloid cells are more frequent in the advanced stages of PDAC, when the number of these cells is comparable to TAMs'. MDSCs inhibit the innate antitumor immunity[26].

MDSCs have a variety of mechanisms to attenuate immune response. They inhibit the antigen-specific response of CD4+ and CD8+ T cells. Some of these mechanisms occur through direct cell-to-cell contact between MDSCs and lymphocytes with the participation of programmed death-ligand 1 (PD-L1) and programmed death-1 (PD-1). MDSCS therefore induce the suppression of T-cell activation and self-tolerance[26]. In addition, MDSCs suppress the proliferation, cytokine production, and cytotoxic function of T cells[27]; decrease T-cell receptor signaling[28]; and induce apoptosis of intratumor T cells[28]. Furthermore, MDSCs induce Treg expansion through interleukin (IL)-10[29], resulting in additional suppression of T-cell function. As with TAMs, an increase in MDSCs in patients with cancer is related to high levels of VEGF [30].

Natural Killer cells

NK cells are an important immune component in controlling the antitumor immune response. These immune cells can interact with DCs, macrophages, T cells and endothelial cells through cell-to-cell contact and secreting cytokines[31]. A number of studies have found that natural killer (NK) cells are positively correlated with survival

in patients with PDAC[32]. However, PDAC is characterized by a very low count of NK cells in the tumor site (< 0.5%)[33]. Furthermore, the antitumor effect of NK cells decreases by the action of pancreatic stellate cells[34] and the expression of IL-10, transforming growth factor beta (TGF-b), indoleamine 2,3-dioxygenase (IDO), and matrix metalloproteinases (MMPs)[35].

Tumor associated Neutrophils

Tumor associated neutrophils (TANs) are typically localized at the periphery of the tumor site in early stages of the disease and infiltrate the center of the tumor in advanced stages. The neutrophil-to-lymphocyte ratio (NLR) has been studied as a predictor, and high TAN counts are correlated with poor prognoses[36-38]. However, the value of the NLR with regard to prognosis and survival prediction requires further validation.

There are two types of TANs: N1 and N2 which have different functions[39]. N1 TANs are proinflammatory and releases IL-12, tumor necrosis factor (TNF)-a and other immunostimulatory cytokines involved in the migration and activation of CD8+ T cells[40]. N2 TANs are immunosuppressive and promote angiogenesis, invasion and metastases. These tumor-promoting activities are mediated by hepatocyte growth factor (HGF), oncostatin M, reactive oxygen species (ROS), reactive nitrogen species (RNS), matrix metalloproteinase (MMPS), and neutrophil elastase (NE)[39].

T cells

PDAC presents a variable number of T cells, encompassing several T-cell subpopulations. The immunosuppressive microenvironment, compounded by fibroblast and desmoplastic stroma, prevents T-cell infiltration and influences their spatial distribution in the tumor site[41]. CD4+ and CD8+ T cells have specific regulation, produce several cytokines, and have different functions in immunity[42]. Consequently, the effects of T cells in PDAC depend on the subpopulation type, their spatial distribution, and macrophage infiltration. A high infiltration of CD4+ and CD8+ T cells, low infiltration of Treg cells, and high ratio of M1/M2 macrophages are therefore associated with greater survival in PDAC[43,44].

CD4+ lymphocytes are differentiated into T helper (Th) 1, Th2, Th17 and Treg subpopulations. Th1 produces interferon gamma (IFN-γ) and cytotoxic molecules that support cellular type I immunity (priming, activation and recruitment of cytotoxic T lymphocytes, M1 macrophages and NK cells) that attack intracellular pathogens and tumors immunity[45]. Th2 produces IL-4, IL-5 and IL-3, participates in humoral type II immunity (inducing M2 macrophages) and contributes to allergy and asthma[45]. Th2 is predominant in PDAC and is associated with disease progression[46] and shorter OS[47]. Th17 produces IL-17, IL-21 and IL-22 and protects against extracellular bacterial and fungal infections[48]. Oncogenic *KRAS*, expressed in pancreatic cells, induces the recruitment of Th17 cells into the TME[49]. Th17 and IL-17 are involved in PDAC progression[49]. A high proportion of Th17 cells in tumor site is correlated with shorter OS and distant disease.

Regulatory T cells or suppressor T cells are a subpopulation of CD4+ lymphocytes that infiltrate the tumor. The main function of Treg in healthy patients is to maintain tolerance to self-antigen and prevent autoimmune disease[50]. Treg counts increases from PanIN to advanced PDAC[15]. In case of PDAC, Tregs have differing roles depending on the tumor stage. Tregs promote tumorigenesis by suppressing the cytotoxic function of T cells, IFN- γ and IL-2, induced by tumor antigens[15]. In contrast, Tregs can delay tumor progression by assessing the suppressive myeloid cells [51]. Tregs are associated with worse prognosis and decreased survival[52].

CD8+ T cells, also Known as cytotoxic T lymphocytes and effector T lymphocytes, produce IFN-γ, TNF and cytotoxic molecules against tumor cells and protect from cancer recurrence[53]. CD8+ T cells are scarce in PDAC.

T cell evasion

The most well-known mechanism of immune tolerance in cancer is the exhaustion of effector T cells (CD8+ T lymphocytes), produced by the binding of cytotoxic T lymphocyte antigen 4 (CTLA-4) to CD80 and of PD-L1 (CD86) to PD-1. However, effector T lymphocytes are scarce in pancreatic cancer, and the inflammatory immune reaction develops early, suppressing the development of an adaptative immune response.

T cell evasion in PDAC has been describe as a 4-step process[14,15]: 1) Induction: mutations in oncogenes (*i.e.*, *KRAS*) and tumor suppressor genes initiate the process of tumorigenesis from normal pancreatic cells to PDAC. 2) Inflammation: PanIN, a

preinvasive lesion, produces soluble factors inducing local inflammation and recruitment of immune cells in the tumor site. 3) Immunosuppression: chronic inflammatory reaction and enrollment of TAMs, MDSCs and Treg cells produce immunosuppressive cytokines and suppressive response with cell-to-cell contact. Macrophages and suppressive T cells prevent effector T cells from entering the TME[54], while cytokines such as IL-10 and TGF inactivate the few effector T cells present in TME[55]. This condition prevents an efficient adaptive response against the tumor. 4) Immune Privilege: in the advanced stage of the disease, immune evasion persists, and the TME becomes a site of immune privilege for pancreatic tumor cells.

Tumor microenvironment: A barrier for immunotherapy

The PDAC microenvironment is a classical barrier involved in tumor progression[56], and low microvascular density hinders the diffusion of therapeutic agents[57,58]. This fibroinflammatory structure is a mixture of immune cells, malignant cells, and a dense desmoplastic stroma, which includes fibroblasts, blood vessels, and pancreatic stellate cells[59,60]. The stroma is a traditional characteristic of PDAC that participates in tumor growth, vascularization, drug diffusion, resistance to treatment, and metastasis [61]. Tumor cells and stromal cells undergo into a continuous change throughout the transformation process from a healthy pancreatic tissue to an invasive malignance[13]. TME plays a key role in this immunosuppression and presents similar characteristics in both primary and metastatic lesions[62].

Based on the biological, prognostic, and predictive characteristics, it is possible to differentiate two molecular subtypes (classical and basal-like)[63-65] and two stromal subtypes of PDAC (normal and activated)[66]. The basal-like subtype is associated with an activated stroma and poor prognosis[64,65]. Patients with the activated stromal PDAC subtype have a poorer prognosis compared with the normal stromal subtype, presenting a median OS of 15 *vs* 24 mo, respectively[66]. Activated stroma is associated with a greater presence of macrophages and activated fibroblasts, both responsible for poor clinical outcomes[66]. Modulating the TME would possibly redirect the immune system to eliminate the tumor, achieving greater efficiency in antitumor therapies.

Tumor mutational burden and mismatch repair deficiency: Assistance for immunotherapy

TMB is defined as the total number of nonsynonymous mutations per coding area of a tumor gene[67]. A high number of somatic mutations produces and releases neoantigens in the TME which lead to increase in inflammatory cytokines and effector T cells[2,10,68]. A high TMB therefore stimulates the efficacy of immunotherapy[67, 69]. PDAC is characterized by low immunogenicity and low TMB (1 mutation/megabase) compared with other tumors such as melanoma (10 mutations/megabase) [67] and lung or bladder cancer (just under 10 mutations/megabase)[70].

There is a known association between mismatch repair deficiency (dMMR) and high TMB, and PDAC is not an exception[71]. dMMR represents a loss of function of the mismatch repair (MMR) pathway, a DNA repair pathway that plays a key role in maintaining genomic stability. Random mutations occurring in small repetitive elements define microsatellite instability (MSI)[72]. dMMR is defined as the loss of expression of one or more of the MLH1, MSH2, MSH6, and PMS2 proteins. Characteristically, dMMR is correlated with high TMB[72] and increased effector T cells in tumor site[63]. A high MSI status, an emerging predictor of immunotherapy response in PDAC, has a prevalence of 0.3-1.3% in this tumor type[73]. Patients with this condition present prolonged survival rates[71,74]. Neoantigens must be presented by antigen-presenting cells (APCs) to achieve a T-cell response and, in the case of PDAC, DCs (the major APCs), are usually immature or scarce, causing weakened T-cell activation[75].

LANDSCAPE OF IMMUNOTHERAPY IN PANCREATIC DUCTAL ADENOCARCINOMA

Our understanding of the immune response in cancer is still incomplete and continues to be investigated, with the reported relationships between the various cell populations and microenvironment composition[59,60] the basis for the development of immune-based therapies in PDAC. The combination of several immune strategies, such as checkpoints inhibitors, immune checkpoints inhibitors or vaccines plus

chemotherapy, and the use of adoptive cellular therapy are some of these new approaches[76].

Immune checkpoints agents

Whereas immune checkpoint inhibitors have proven their efficacy in many tumors, they have falied to do so in PDAC due to its low immunogenicity and low TMB[67]. These inhibitors help to interrupt the intratumoral T-cell dysfunction and provide the block of the overexpressed receptors involved in its exhaustion such as PD-1 and CTLA-4[77]. The union between PD-L1 or PD-L2 and PD-1 induces the cessation of T-cell effector functions causing a suppression in T-cell motility[78], an antagonization of T cell receptor (TCR) signaling[79] and a suppression in gene transcription[80]. PD-L1 expression is therefore inversely correlated with survival. Thus, anti-PD-L1 and anti-PD-1 therapies have been shown to reduce tumor volume in mice that were subcutaneously injected with a murine PDAC cell line[81].

Antibody anticytotoxic T lymphocyte antigen-4

Several phase II clinical trials in PDAC have been developed using antibodies against CTLA-4, such as Ipilimumab[82] and Tremelimumab[83] as single agents; however, these studies have not achieved an impact in OS[82,83]. Ipilimumab in a phase II trial (NCT00112580) of pretreated patients with locally advanced and metastatic pancreatic cancer showed a median OS of 4.5 mo, with no responders except for one patient who had a delayed objective response. A phase II trial of Tremelimumab (NCT02527434) in metastatic pancreatic cancer had a median OS of 4 mo (95%CI 2.83-5.42), with 18 out 20 patients with progressive disease.

Antibody anti-programmed death-1

The efficacy of pembrolizumab in MSI-H PDAC has been reported in the phase II NTC02628067 study. The OS and progression-free survival (PFS) were 4 mo and 2.1 mo, respectively[76], highly disappointing results compared with those obtained in other tumors such as colorectal cancer in which a PFS of 16.5 mo was reported in the KEYNOTE-177 trial[84]. We do not have results for nivolumab or pembrolizumab as single agents in microsatellite stable tumors.

Antibody anti-programmed death-ligand 1

A phase I/II clinical trial (NCT03829501) assessing the efficacy of atezolizumab in advanced PDAC and other tumors refractory to first-line treatment is currently ongoing.

Combination of immune checkpoints agents

The combination of anti–PD-1/anti–PD-L1 and anti–CTLA-4 might have additive or synergistic activity[85]. In fact, the combination has shown enhanced activity in certain tumor types such as melanoma and non-small cell-lung cancer[85]. Several clinical trials have therefore sought to assess the efficacy of this combination.

Durvalumab alone or in combination with tremelimumab for patients with previously treated metastatic PDAC (NCT 02558894) did not achieved any improvement in OS. The combination achieved a median of 3.1 mo, while durvalumab alone achieved 3.6 mo[85]. However, the evaluation of the combination of other immunotherapy agents such as nivolumab and ipilimumab (NCT01928394) is still ongoing, with no results posted yet[86]. Table 1 Lists other immunotherapy agents that have been employed in treating PDAC.

Combination of immune checkpoints and chemotherapy

It has been suggested that the efficacy of immune checkpoint inhibitors could improve when combined with chemotherapy, the latter acting by activating the intratumoral immune response when inducing immunogenic cell death. This type of cell death is characterized by a necrolytic release of danger signals that can modify the stroma, change cytokine rates, reduce the presence of suppressive cells such as MDSCs and Tregs, promote the expression of molecules of the major histocompatibility complex (MHC) in cancerous cells and stimulate DC maturation[87]. In animal models, a synergetic effect has been observed between the combination of gemcitabine and anti-PDL1[88].

Several clinical trials have investigated the combination of immune checkpoint inhibitors and chemotherapy in PDAC. Table 2 Lists the main clinical trials in this field.

Table 1 Clinical trials on pancreatic ductal adenocarcinoma using immunotherapy

National clinical trial number	Sample	Phase	Settings	Drug	Results
NCT00112580	82	II	Advanced; Metastatic; Any line	Ipilimumab	No improvement in survival rate
NCT02527434	64	II	Advanced; Metastatic; ≥ Second line	Tremelimumab	OS 4 m (95%CI: 2.83-5.42)
NCT02558894	65	II	Metastatic; ≥ Second line	Tremelimumab + Durvalumab *vs* Durvalumab alone	OS 3.1 m (95%CI: 2.2-6.1) Combination therapy; OS 3.6 m (95%CI: 2.7-6.1) Durvalumab alone
NCT00112580	27	II	Advanced; Metastatic; ≥ Second line	Ipilimumab	No improvement in survival rate
NCT03379259	14	I	Advanced (PDAC and other tumors); ≥ Second line	Anti-PD-L1 (BMS-936559)	No improvement in survival rate
NCT01928394	1131	I/II	Advanced (PDAC and other tumors) Any line	Nivolumab ± Ipilimumab	Ongoing
NCT03829501	412	I/II	Advanced (PDAC and other tumors); ≥ Second line	Atezolizumab	Ongoing
NCT03080974	10	I	Advanced (stage III) Any line	Nivolumab +Irreversible electroporation	PFS 6.3 m (95%CI: 3.5-10.0); OS 18 m (95%CI: 9.2-26.8)

OS: Overall survival; PDAC: Pancreatic ductal adenocarcinoma; PFS: Progression-free survival.

A phase I/II clinical trial (NCT02331251) of metastatic PDAC naïve chemotherapy, tested the combination of pembrolizumab (anti-PDL1), nab-pacliatxel and gemcitabine [89], achieving a median PFS and OS of 9,1 and 15.0 mo, respectively[89].

Other combinations such as ipilimumab plus gemcitabine (NCT01473940)[90] or CD40 agonist plus gemcitabine[91] in a phase I clinical trial in first-line treatment have also improved OS in the experimental arm , with an OS of 8.5 mo and 8.4 mo, respectively. CD40 is a member of the tumor necrosis factor receptor superfamily. The binding of CD40 by its ligand or by an agonistic monoclonal antibody activates the receptor and results in APC activation, including DCs, B cells and monocytes. In mouse pancreatic cancer models, the combination of agonistic CD40 monoclonal antibody with gemcitabine plus nab-paclitaxel triggers T-cell-dependent tumor regressions and improves survival benefit, which are further augmented by the addition of an anti-PD-1 monoclonal antibody. The preliminary results from the combination of a CD40 monoclonal antibody agonist combined with gemcitabine plus nab-paclitaxel and PD1 inhibitor have been published, showing a 58% response rate from 24 evaluable patients[92].

The COMBAT/Keynote-2020 clinical trial deserves special mention. This trial is based on CXC chemokine receptor 4 (CXCR4) blockades, that promotes T-cell tumor infiltration and is synergistic with anti-PD-1 therapy in PDAC mouse models. One cohort included 22 patients and combined the CXCR4 antagonist BL-8040 (motixafortide) with pembrolizumab-nanoliposomal irinotecan-fluorouracil-folinic acid in PDAC second-line treatment. The preliminary results showed an objective response rate, disease control rate and median duration of response of 32%, 77% and 7.8 mo, respectively, suggesting that it is indeed a promising strategy in treating PDAC[93].

According to trial results, patients, who received only immunotherapy, experienced 9%-11% of grade ≥ 3 immune related adverse events[76], while patients receiving immunotherapy in combination with chemotherapy presented grade ≥ 3 adverse effects in up to 53%. In these cases the most common toxicities were hematologic[2].

Vaccines treatment as a single agent or in combination

Several types of vaccines have been tested as single agents (Table 3) or in combination with chemotherapy (Table 4) or immunotherapy (Table 5), including whole-cell vaccines, DCs, DNA and peptide vaccines that entail the presentation of immunogenic cancer antigens to the immune system, resulting in the activation of cancer antigen-specific cytotoxic T lymphocytes *in vivo* and the subsequent anticancer immune response[94].

OS: Overall survival; PDAC: Pancreatic ductal adenocarcinoma; PFS: Progression-free survival; OR: Objective response.

GVAX

The mechanism of actions of GVAX vaccines is the stimulation of APC antigen uptake and T-cell priming through PDAC cell modification to express granulocyte-macrophage colony-stimulating factor (GM-CSF)[95].

A number of phase I and II clinical trials have been conducted on localized PDAC. A phase II clinical trial (NCT00084383) with 60 randomized patients evaluated the effectiveness of the GVAX vaccine administrated in two times: 1) after surgery and before 5-fluoracil based chemotherapy and 2) after chemotherapy had finished. The median PFS was 17.3 mo, and the median OS of 24.8 mo[96].

The GVAX vaccine has also been tested in metastatic PDAC. A phase II clinical trial (NCT01417000) in which 93 patients were randomized to the combination of GVAX plus cyclophosphamide with or without CRS-207 reported an OS of 6.1 mo in the experimental arm *vs* 3.9 mo in the control arm[97]. However, a phase IIb clinical trial (NCT02004262) showed no benefit in its primary endpoint of OS[98].

Algenpantucel

Algenpantucel is a whole cell vaccine that works by harnessing a natural robust immune response against pancreatic cancer[99]. The vaccine has been tested in combination with gemcitabine plus 5-Fluoracil chemoraditherapy in patients with resected PDAC, achieving a 12 mo PFS of 65% and a 12 mo OS of 83% (*vs* 45% and 63% in the control arm, respectively)[99]. This trial is still on-going for patients with borderline and locally advanced PDAC[99].

KIF20A-66 and survivin-2B 80-88 peptides

KIF20A and survivin are two up-regulated HLA-A24-restricted peptides that have been employed as epitopes in vaccines development[100,101]. KIF20A-66 was tested in a phase I/II clinical trial for patients with metastatic HLA-2402-positive PDAC who

had progressed to first-line gemcitabine chemotherapy (UMIN000004919). The OS was 4.7 mo in the treated arm *vs* 2.7 mo in the best supportive care arm. The PFS was 1.8 mo in the vaccine arm[100].

Survivine-2B (SVN-2B) is an HLA-A24 restricted peptide that has been investigated since 2003 with inconspicuous results. A clinical trial (UMIN000000905) with 6 HLA-A2402-positive patients was conducted, resulting in a clinical y immunogenic response in 50% of patients[101].

Other vaccines targeting KRAS and MUC-1

These vaccines target distinct tumor antigens based on the identification of mutated oncogenes, such as *KRAS*, altered tumor suppressor genes, such as *TP53*, *CDKN2A*, *DPC4*, *BRCA2*, and *ERBB2*, as well as the overexpression of tumor-associated antigens, such as *CEA* and *MUC-1*, in pancreatic carcinoma cells[102]. A phase I clinical trial was conducted using MUC-1 vaccines in advanced PDAC, the results of which confirmed that a specific T-cell immune response was obtained, achieving a significant improvement in OS (15.3 mo *vs* 3.9 mo)[103].

A phase I/II clinical trial was conducted in the adjuvant setting, the results of which revealed that 4 out of 12 patients survived without disease recurrence[104].

Clinical trials using *KRAS* against vaccines have also been developed. There is a phase I/II study that combines mutant RAS peptides and GM-CSF in patients with resected or locally advanced PDAC, with an OS of 25.6 mo and 10.2 mo, respectively [105].

GV1001 is another tested vaccine. A phase I/II trial combining this vaccine with GM-CSF for unresectable PDAC[106], and observed an immune response in 63% of patients, with an OS of 7.2 mo *vs* 2.9 mo in no-immune responders. After these encouraging results, a phase III study for locally advanced PDAC was conducted [107]. However, the combination of GV1001 plus gemcitabine plus capecitabine did not improve OS compared with chemotherapy alone (6.9 mo *vs* 7.9 mo).

Combination of vaccines treatment with immune checkpoints

Preclinical reports have supported the concept of synergy between cancer vaccines and immune checkpoint blockade in non-immunogenic tumors. Based on these results, several clinical trials have been conducted to assess the efficacy of this combination in

PDAC therapy[108].

In clinical trial NCT00836407, 30 patients with previously treated metastatic PDAC were randomized to a high dose of Ipilimumab (10mg/kg) as the single agent or in combination with the GVAX vaccine. Five patients showed stable disease, and an OS of 5.7 mo was achieved in the experimental arm compared with 3.6 mo in the control arm[108].

Other studies that included patients with metastatic PDAC combined with nivolumab and ipilimumab, with or without GVAX and CRS-207, showed enhanced T-cell responses. Studies are currently evaluating the role of immune checkpoint inhibitors in combination with cyclophosphamide/GVAX and CRS-207 vaccines (NCT02243371, NCT02451982), and the results have yet to be published[99].

Pembrolizumab combined with the modified p53-expressing Ankara virus (p53MVA) vaccine has been studied in patients with several malignancies included PDAC, with clinical responses observed in 3 of 11 patients and disease stabilization for 30, 32 and 49 wk[109].

Vaccines were well tolerated. Most common toxicities were grade 1-2 induration/erythema or pain/soreness at the vaccine sites, pyrexia, chills, fatigue and nausea, with < 5% of patients reporting serious adverse events[96,98-99,106]. There were not reported clinical signs of auto-immune disease, abnormal biochemical or

haematological parameters related with the vaccinations[105]. A grade 5 fatal myocarditis was reported with Pembrolizumab combined with the p53MVA vaccine [109].

Adoptive cell transfer

The most clinically important form of adoptive cell transfer therapy is chimeric antigen receptor (CAR) T-cell therapy (Table 6). CAR-T cells can target any extracellular molecular structure recognizable by an antibody, thereby avoiding the MHC restriction. CAR consists of an extracellular domain of a single-chain variable fragment (scFv) of an antibody that recognizes a specific tumor antigen and an intracellular domain that contains the T cell receptor signal transduction sequence[39]. To generate the appropriate cell therapy product for adaptive transfer, T cells are collected from patients *via* leukapheresis, manipulated to target the specific antigen, expanded, and then reinfused[110].

The ideal target antigen is one that is selectively expressed in tumor cells; however, most targets of CAR-T cells are also expressed in normal tissues such as the mesothelin, CD24, carcinoembryonic antigen (CEA) and human epidermal growth factor receptor 2 (HER2), and have been considered as targets in PDAC[110].

Several clinical trials have followed this approach; however, the use of CAR-T cell therapy in PDAC is scarce, and the clinical results are moderate. For example, a phase I study of Her2-specific CAR-T cells (NCT01935843) showed that 5 out of the 11 treated patients achieved stable disease, while 2 patients achieved partial response with a median PFS of 4.8 mo[111].

However, CAR-T cell therapy might trigger a cytokine release syndrome, a severe complication that consists of the release of cytokines that cause several symptoms including fever and hypotension[110].

The most characteristic toxicity associated with CAR-T therapy is the cytokine release syndrome. If the antigen selected for CAR-T cell therapy is expressed on normal tissues, toxicity and autoimmunity might appear[2].

CONCLUSION

The immune response in cancer is a complex process that involves the balance between tumor-promoting innate immune responses and tumor-suppressing adaptive immune responses. In PDAC, immune evasion is an early event during tumorigenesis and is associated with proinflammatory signals, infiltration of immunosuppressive cells (Tregs and MDSCs), and a sophisticated TME where numerous interactions occur between stromal signals, the immune system and tumor cells. As a consequence, PDAC is characterized by low immunogenicity and antigenicity, a critical concept when developing novel immunotherapeutic approaches for treating PDAC.

The emergence of immunotherapy as a new treatment approach for solid tumors has become a revolution in modern oncology. Immune checkpoint inhibitors improve survival in several tumors, such as melanoma, lung cancer, head and neck, and genitourinary. These tumors, known as “hot tumors”, present numerous mutations

that create a high number of neoantigens recognized by effector T cells that are released to fight the cancerous cells. However, in the case of PDAC, these results have not been as spectacular as other tumors' due to the intrinsic characteristics of PDAC, which enable it to self-isolate through a complex stroma, thereby evading the immune system.

Immune checkpoint inhibitors as single agents do not provide a benefit in PDAC. However, their combination with chemotherapy may transform PDAC into a "hot tumor" that is more susceptible to immunotherapy. The outcomes in phase I/II clinical trials using this approach are encouraging, with a benefit in OS in several combinations. Cancer vaccines employed as single-agent treatments or combined with classical chemotherapy, chemoradiotherapy or immunotherapy have promising results in the early phases of clinical trials. However, these outcomes have not been confirmed in more advanced studies. Lastly, adoptive cell transfer, specifically the CART-T cell approach, is still in very early phase of development.

Despite advances in treating PDAC, this tumor continues to be associated with extremely poor outcomes and high mortality. Systemic therapies and new strategies therefore need to be developed to improve patient prognoses, which will depend on an ever-increasing understanding of basic immunity and its role in PDAC. They keys to achieving significant changes in the treatment of PDAC include research into safe novel inhibitors (such as immunosuppressive factor, TAMs, MDSCs, and Tregs), increasing the prophylactic efforts in the early stages of carcinogenesis, deepening the understanding of molecular subtyping in PDAC and conducting appropriate patient selection.

Abstract

The development of artificial intelligence (AI) has increased dramatically in the last 20 years, with clinical applications progressively being explored for most of the medical specialties. The field of gastroenterology and hepatology, substantially reliant on vast amounts of imaging studies, is not an exception. The clinical applications of AI systems in this field include the identification of premalignant or malignant lesions (*e.g.*, identification of dysplasia or esophageal adenocarcinoma in Barrett's esophagus, pancreatic malignancies), detection of lesions (*e.g.*, polyp identification and classification, small-bowel bleeding lesion on capsule endoscopy, pancreatic cystic lesions), development of objective scoring systems for risk stratification, predicting disease prognosis or treatment response [*e.g.*,

Core Tip: Artificial intelligence (AI) clinical applications in gastroenterology and hepatology, which heavily relies on imaging, have dramatically expanded in the last 20 years. These applications include the detection of lesions, identification of pre-malignant or malignant lesions, development of objective scoring systems for risk stratification, predicting disease prognosis or treatment response, or evaluation of metrics such as bowel preparation score or quality of endoscopic examination. The objective of this review is to pool the available AI-related studies pertaining to the entire gastrointestinal tract, discussing findings and clinical applications, as well as outlining the current limitations and future directions in this field.

INTRODUCTION

As artificial intelligence (AI) continues to rapidly evolve in medicine, the clinical applications of this technology are becoming increasingly evident[1]. Relying heavily on endoscopic and radiologic imaging, gastroenterology has become an attractive field in which to apply AI. Special interest has already been devoted to several areas, including the detection of gastrointestinal neoplastic lesions to assist with rapid diagnosis, reduction of misdiagnosis, improvement in quality of imaging, reduction of interobserver variability in visual classifications, and radiologic and histopathologic interpretation[2-4].

AI is a broad term that encompasses disciplines such as machine learning (ML) and subdisciplines or specific techniques such as deep learning (DL) (Figure 1). The central motivation of ML to use large datasets to recognize patterns of interactions between variables, often ultimately in a way that allows the learned function to be applied to new data[5]. ML is composed of both "supervised" and "unsupervised" learning methods. The goal of supervised learning is to predict a labelled output focusing primarily on classifying data input into specific subgroups, or alternately for prediction of quantitative outcomes[6]. An example of supervised learning is training a system to assist in identifying gastric intestinal metaplasia (GIM) using a large database of lesions that have previously been identified by an operator as corresponding to GIM. In comparison, unsupervised learning does not have an output to predict. It relies on attempting to identify naturally occurring patterns from within the input, often to then group them accordingly (*e.g.*, tissue sample clustering based on similar gene expression values)[6]. DL is a subset of ML, based on artificial neural networks (ANN), which are loosely inspired by the neuronal interplay in the human brain. DL autonomously utilizes the data input to learn, identify, and leverage predictive factors of an outcome, which can use multi-layered systems [*i.e.*, convolutional neural networks (CNN)] to process complex information[3,7]. The realization of

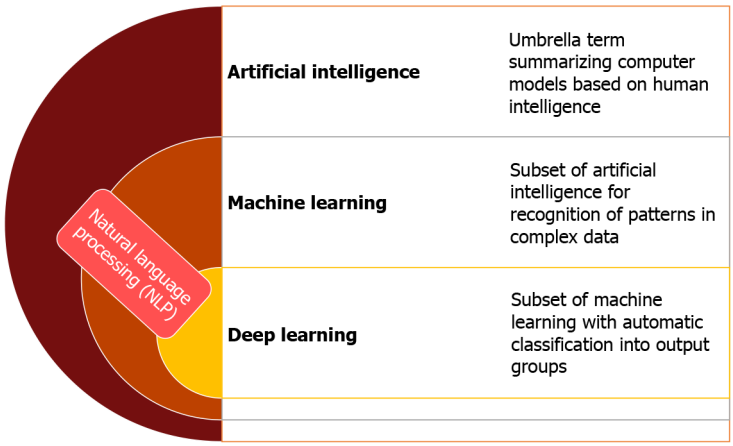

Figure 1 Primary concepts of artificial intelligence.

the concept of DL has recently become possible with rapid advancements in specialized computer hardware, such as increased graphics processing unit power, and accompanying software and algorithmic achievements.

With increased recognition of the importance of AI in gastroenterology, the first global AI in gastroenterology and endoscopy summit was held in Washington D.C. in late 2019, which included multiple experts in the domains of academia, industry and regulatory institutions. The consortium anticipated that in the next 10 years the clinical applications of AI in gastroenterology will positively influence patient care and clinical workflow. The consortium recognized the importance of a close multidisciplinary collaboration between gastroenterologists, industry, and regulatory institutions in the development and application of new technologies in the clinical setting[8]. Therefore, the main objective of this review is to introduce the topic of AI and its clinical applications, outline current limitations and knowledge gaps, and trace the future directions in each field by summarizing the global rapidly expanding pool of ever-changing literature to date (Figures 2 and 3).

UPPER GASTROINTESTINAL TRACT

Detection of premalignant and malignant lesions

The upper gastrointestinal tract has several areas of interest for detection of premalignant and malignant lesions, such as identification of dysplasia and early neoplasia in Barrett's esophagus (BE), esophageal squamous cell carcinoma (SCC), and gastric cancer (GC)[9] (Supplementary Table 1).

Despite the fact that histopathologic analysis is the gold standard to establish the diagnosis of BE and determine the presence of dysplasia, it is of paramount importance for endoscopists to obtain targeted biopsies from specific locations that harbor the actual lesion. By identifying areas that may harbor BE with or without dysplasia, AI can orient the clinician in performing directed biopsies instead of relying on random sampling. Importantly, detection of early esophageal neoplasia with conventional white light imaging (WLI) and digital chromoendoscopy [*i.e.*, narrow band imaging (NBI)] represents a challenge, an issue for which AI has been proposed as a possible solution[10,11].

In total, we included 8 studies that examined BE, all of which addressed the detection of dysplasia or early esophageal adenocarcinoma (EAC) based on endoscopic imaging or laser endomicroscopy[10-17]. The most popular analytic models were CNNs and support vector machines (SVMs), while cross-validation techniques were the primary basis of validation methods. In general, the models were able to discern between normal and dysplastic/neoplastic images with an accuracy of at least 89.9%, performing better than nonexpert endoscopists. De Groof *et al*[12] developed a DL algorithm based on a hybrid ResNet-UNet model using 4-fold per-patient cross-validation to detect early neoplasia in BE. The model was trained in a stepwise fashion, using a database with over 490000 endoscopic still images of the gastrointestinal tract for training, out of which 1247 corresponded to early BE neoplasia. This model achieved higher level of accuracy than non-expert endoscopists and could also detect the optimal biopsy site in up to 97% of patients. Ebigbo *et al*[14] developed a

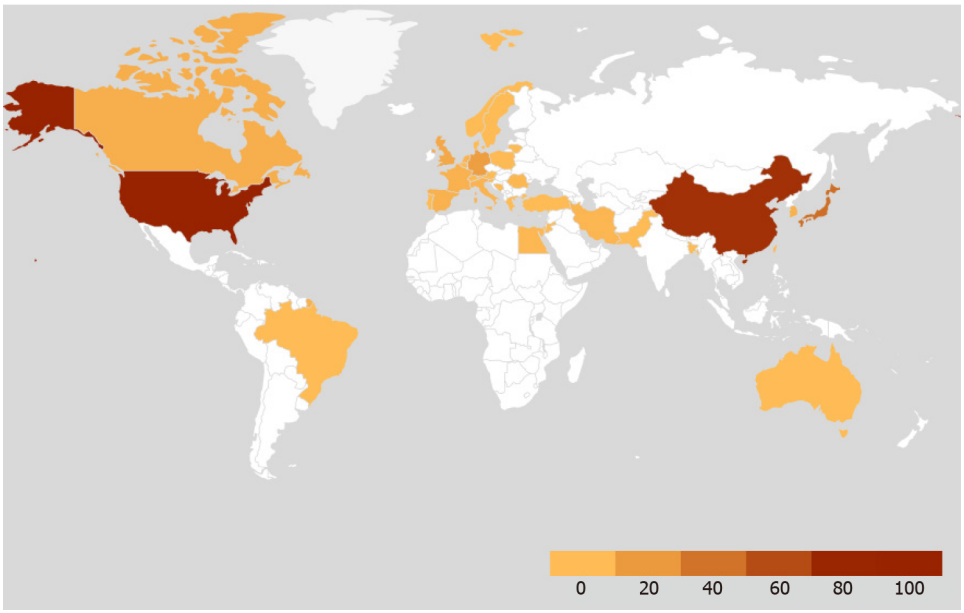

Figure 2 Geographic distribution of country from which the included studies originated.

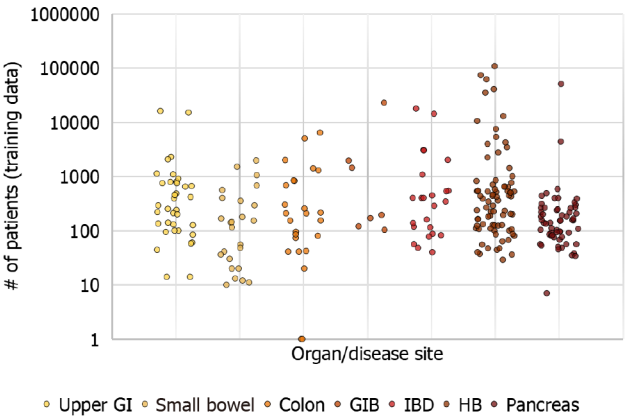

Figure 3 Scatterplot depicting distribution of studies across the organ systems in gastroenterology and hepatology. GI: Gastrointestinal; GIB: Gastrointestinal bleeding; IBD: Inflammatory bowel disease; HB: Hepatobiliary.

computer-aided diagnosis model based on ResNet that differentiated between normal BE and early EAC, with 89.9% accuracy, 83.7 sensitivity and 100% specificity.

Similarly, identification of SCC poses a similar clinical challenge, as traditional diagnostic techniques (*e.g.*, chromoendoscopy with lugol or NBI) have relatively low specificity[18]. As complex novel methods that rely heavily on endoscopic imaging such as endocytoscopy or volumetric laser endomicroscopy have been progressively implemented in clinical practice, the interpretation of large volumes of images has been noted to be a challenging and time-consuming issue[19]. Therefore, AI-assisted image interpretation has also found a use in identifying abnormalities in the image inputs[17].

Thirteen studies examining esophageal cancer were examined, of which 11 specifically studied SCC. Nine of the studies targeted to develop DL models for malignancy detection, while two studies aimed to develop models that predict malignancy depth of invasion with DL models. Most studies (8) were based on CNN models, while others used joint diagonalization principal component analysis (JDPCA), VGG16 Net, or GoogLeNet as classifiers. Although the values of accuracy, sensitivity and specificity in esophageal SCC detection varied between the studies, all models performed at least as good as endoscopists in lesion detection and characterization or substantially improved the endoscopists' lesion detection[20-30]. Fukuda *et al*[21] developed a DL model aimed at detecting suspicious lesions and characterize SCC using more than 28000 NBI-enhanced images in the construction of the model. The model achieved a higher sensitivity for SCC detection and higher accuracy for

SCC characterization from normal tissue than endoscopic experts. Two studies by Nakagawa *et al*[31] and Shimamoto *et al*[32] aimed at developing models that predicted esophageal malignancy depth utilizing a DL model based on a CNN with a belief-propagation decoder using independent validation datasets. These models achieved an accuracy of 89.2% and 91% in predicting invasion depth, with sensitivities of 70.8% and 90.1%, and specificities of 94.4% and 95.8%, respectively.

GC is the fourth most common cause of cancer-related death in the world. Identification of premalignant lesions or early gastric neoplasia is of paramount importance. Unfortunately, as with esophageal diseases, several studies have shown that conventional endoscopic imaging (*e.g.*, WLI or NBI) or other advanced endoscopic modalities (*e.g.*, magnifying endoscopy, blue laser imaging) have relatively low sensitivity and specificity in identifying premalignant or early neoplastic gastric lesions[33-36].

Twenty-four studies examined gastric malignancy or premalignant conditions. Eleven (46%) studies directly addressed early GC (EGC) detection, of which eight models used DL, two used SVM and one used JDPCA. The sample size in the training and validation datasets varied from less than 100 million to 1.03 million. The accuracy in EGC detection of all models ranged from 86.5%-98.7%, with sensitivity of 80.0%-96.7% and specificity of 89.2%-100%[30-37-51]. Specifically, Wu *et al*[52] developed a CNN-based model using over 9000 images to train the algorithm, which not only detected EGC lesions with a 92.5% accuracy, 94.0% sensitivity and 91.0% specificity but also performed significantly better than expert endoscopists at this task. Two studies, one based on faster region-based CNNs and another one based on quantum neural networks, used biomarkers, histology and computed tomography (CT) images to predict metastasis to the liver or lymph nodes. These models predicted metastasis to liver and lymph nodes with sensitivity of 66.7%, specificity 97.1% and an area under the curve (AUC) of 0.95[53,54]. Four studies developed models predicting survival in GC or stratification of risk of developing GC[55,56]. While 1 model based on SVM achieved higher accuracy than the tumor, nodes, metastasis cancer staging (TNM) system to predict overall survival and disease-free survival[57], another model based on a preoperative ANN was not superior in predicting survival compared to TNM [58]. Zhu *et al*[59] developed a ResNet50-based computer-aided detection and diagnosis (CAD) model to predict GC invasion depth, based on endoscopic images. The model achieved an accuracy of 89.16% in identifying GC invasion depth, compared to 71.49% in endoscopists.

Non-malignant conditions

Currently, diagnosis of *Helicobacter pylori (H. pylori)* infection (a known risk factor for the development of peptic ulcer disease and GC) relies on stool or breath testing and histopathology (invasive and expensive). Endoscopic identification of *H. pylori* has been a target for AI-assisted systems[60,61]. For *H. pylori* detection and classification, 4 of 4 studies used a CNN model[62-65]. A study by Martin *et al*[62] using gastric biopsy histopathology images as an input with small number of samples (n = 210 in training dataset and 90-106 in 2 test datasets) had diagnostic accuracy of 98.9%-99.1% for detecting current *H. pylori* infection. This result was higher than the accuracy achieved in 2 studies using esophagogastroduodenoscopy images as an input with higher number of samples (98.9%-99.1% *vs* 77.5%-87.7%). The mean accuracy of endoscopists for detecting currently infected *H. pylori* in 2 studies was around 79.0%-79.4%[62]. A study by Shichijo *et al*[64] found that the average *H. pylori* diagnostic time for the AI model was 194 s, while it was 230 ± 65 min for endoscopists. The AI model also had a significantly higher accuracy than the endoscopists by 5.3%, demonstrating that AI algorithms had significantly better accuracy and faster diagnostic time for *H. pylori* than the endoscopists. More recently, Nakashima *et al*[63] developed a CAD system based on linked color imaging combined with DL, which achieved 82.5% accuracy, demonstrating comparable diagnostic accuracy of *H. pylori* to that of experienced endoscopists.

In the area of gastrointestinal bleeding (GIB), risk stratification is of paramount importance not only to identify high-risk patients and guide clinical decision-making but to also identify areas where relatively scarce resources require allocation. In general, risk-stratification tools examine risk factors that are associated with a condition to predict one or several outcomes (*e.g.*, survival, length of hospitalization, rebleeding rates, need for endoscopic therapy, response to treatment)[66-68]. Regarding upper GIB, studies focused on developing prognostic models that predict rebleeding or the need for endoscopic/surgical therapy[69].

Seven studies examining outcome measures in GIB were included, all of which were developed by reviewing medical record parameters to construct ML algorithms, which were primarily based on ANN[67-73]. Half of the studies had both internal and

external validation cohorts, and patient sample sizes varied from 147 to over 22800. Shung *et al*[69] developed a gradient-boosting ML model that identified patients with upper GIB who met a composite endpoint with superior AUC, sensitivity and specificity to that of the Glasgow-Blatchford (GBS), Rockall and AIMS-65 scores. Seo *et al*[68] developed 4 different ML algorithms in patients with nonvariceal upper GIB that achieved superior AUC for mortality, rebleeding and hypotension than that of the GBS, particularly with the use of the random forest (RF) analytic model. However, for rebleeding prediction, a gradient-boosting model developed by Ayaru *et al*[73] showed a higher accuracy than the VC model in the aforementioned study (88% *vs* 78.5%). Das *et al*[70] developed a predictive ML model in lower GIB and compared it in internal and external validation cohorts to the validated BLEED score. Both internal and external validation cohorts reached accuracies, sensitivities, and specificities that were superior to the BLEED score.

LOWER GASTROINTESTINAL TRACT

Direct endoscopic visualization of the colon continues to be the gold standard for detection and resection of colonic premalignant lesions. In addition, patient- and polyp-specific characteristics have also been identified as predictors of missed colorectal cancer (CRC)[74]. Therefore, quality measures such as cecal intubation time, withdrawal time, bowel preparation quality and adenoma detection rates (ADR) have been instituted to attempt and standardize practice and mitigate the rates of missed CRC[74,75]. Since colonoscopy is an operator-dependent procedure, this may lead to variability in polyp detection rates, polyp characterization and estimation of depth of invasion of malignant lesions between endoscopists. CAD has been studied to address these current shortcomings, as well as to improve ADR and reduce CRC risk and colon cancer-related deaths[76] (Supplementary Table 2).

Detection of premalignant and malignant lesions

Polyp detection during colonoscopy is the cornerstone of CRC prevention. It is estimated that CRC develops in 2%-6% of cases after colonoscopy but before the next scheduled surveillance and, therefore, could represent missed or new postcolonoscopy CRC[74,77]. A large number of research studies have been devoted to identifying factors that play a role in the detection of premalignant lesions during colonoscopy, as well as factors that are associated with missed CRC[77]. An observation that has gained considerable attention is that the presence of experienced endoscopy nurses, fellows or any trained second observer during the procedure itself improves ADR[78,79]. Therefore, and answering the call for improved polyp detection measures during colonoscopy, AI has become a promising technology serving the role of a more standardized "second observer," appropriately termed "computer-aided detection" (CADe).

Eighteen studies that evaluated polyp detection were included in this review, thirteen of which employed DL models, while five used other ML models. Nearly all the studies were limited to having internal validation only. The training datasets in these studies utilized still images from colonoscopy videos ranging from 176 to more than 8600 images. Seven studies calculated the ADR of the developed model and compared it to that of endoscopists, most of which found that the AI had significantly higher ADR than endoscopists, with a decreased reaction time, while the remaining studies showed equivalent ADR[80-87]. Repici *et al*[82] conducted a multicenter study showing that the ADR was 40.4% in the study's participating endoscopists alone, while it was 54.8% in the group using the CADe-based GI-Genius (®Medtronic, Minneapolis, MN) module. Similarly, Wang *et al*[85] conducted a study that evaluated over 520 colonoscopies, also examining the use of a CADe model, and found that the ADR increased from 20.34% in endoscopists alone to 29.12% in the CADe-assisted group. Other studies explored the accuracy, sensitivity and specificity of polyp-detection AI models, displaying accuracies of up to 96.4%, sensitivity of up to 99.7% and specificity of up to 93.7%[88-98]. Kominami *et al*[93] designed an SVM-based model using real-time images with NBI and magnification enhancement to detect colon polyps, achieving an accuracy, sensitivity, and specificity of 93.2%, 93.0%, and 93.3%, respectively. Three studies addressed subjects in the realm of CRC, specifically detecting malignancy on colonoscopy with chromoendoscopy and NBI enhancement, hematoxylin-eosin histopathology slides, or estimating invasion depth on regular WLI colonoscopy images[99-101]. Ito *et al*[100] developed a DL model based on CNN to detect deeply invasive CRC based on WLI colonoscopy, which utilized over 9900

images from 41 patients to train the model. Furthermore, over 5000 images were used in the testing cohort, achieving an accuracy, sensitivity and specificity in differentiating invasion depth of 81.2%, 67.5%, and 89.0%, respectively. Kudo *et al*[101] developed a model based on EndoBRAIN (®Cybernet Systems Co., Tokyo, Japan) using colonoscopy with chromoendoscopy and NBI enhancement to detect malignant lesions in the colon. The training sample used over 69000 images and achieved accuracies of 98.0% and 96.0% for chromoendoscopy and NBI enhancement, respectively. These diagnostic parameters were higher than those of expert and nonexpert endoscopists.

In an attempt to morphologically classify polyps according to their malignant potential, numerous classification systems have been developed. As an example, the Paris classification classifies polyps according to whether they are pedunculated, sessile, slightly raised, or excavated[102]. These visual characteristics are then used to predict whether the polyp has invasive potential or lymph node involvement and potentially contribute to clinical decision-making, such as determining whether the polyp is resectable endoscopically[103]. Unfortunately, research has shown that interobserver variability with this classification is moderately high, suggesting that this visual classification should not be routinely used in research or practice[104]. In addition, considering that most resected polyps during colonoscopy are diminutive and that histopathologic analysis of resected polyps is costly, optical diagnosis has been proposed in this subset of polyps and termed "optical biopsy"[105]. The concept of optical biopsy has been proposed to support cost-effective strategies in CRC screening such as resecting-and-discarding, as well as diagnosing-and-leaving this subset of polyps[106]. However, the concept of optical biopsy has the same limitations as endoscopic polyp characterization does: relatively high interobserver variability. Hence, computer-aided diagnosis has been proposed as a potential solution to standardization of interpretation of endoscopic images.

Nine studies pertaining to colonic polyp classification or differentiation were included in this review[107-115]. While some studies did not report on validation methods, others had cross-validation, internal, and external methods. Most studies relied on ML-based algorithms to assess colonoscopy with enhancement measures (*e.g.*, magnification, NBI, endocytoscopy), while deep CNN models were used in studies evaluating real-time polyp differentiation. Sánchez-Montes *et al*[114] developed an SVM-based model to predict polyp histologic classification using high-definition WLI from 225 colonoscopies, achieving accuracy, sensitivity, and specificity of 91.1%, 92.3%, and 89.2%, respectively. Additionally, Misawa *et al*[111] evaluated the performance of EndoBRAIN (®Cybernet Systems Co., Tokyo) analyzing endocytoscopic images obtained during colonoscopy to characterize polyps as neoplastic *vs* non-neoplastic with an accuracy, sensitivity, and specificity of 96.9%, 97.6%, and 95.8%, respectively. These findings hold promise in determining screening and surveillance schedules, and in instituting cost-effective strategies such as "resect-and-leave".

Knowledge on the depth of invasion of early CRC is critical for determining resection modality. Intramucosal and submucosal cancerous lesions can be resected with endoscopic techniques such as endoscopic mucosal resection or endoscopic submucosal dissection[116]. However, lesions that invade the deeper layers have a higher association with lymph node metastasis and, hence, may require a combined surgical and oncologic approach[116,117]. Several features on direct endoscopic visualization have been associated with deep invasion of a lesion, including lesion depression, fold convergence, and significantly irregular, and heterogeneous surface capillary pattern[118]. As with any image-based field, a significant degree of interobserver variability exists in characterizing lesions and determining their depth or invasion, for which CAD represents an attractive option to standardize the approach of estimating lesion invasion depth.

Finally, 6 studies assessed other subjects within the realm of the lower gastrointestinal tract, including developing models that predict outcomes in patients with CRC, models examining quality of colonoscopy performance, and studies estimating cost reductions of the use of AI[119-122]. Of 4 studies examining prediction of outcomes, 2 were based on DL (*i.e.*, CNN-based) models, using a wide numerical range of histopathologic images: from 300 million to 12 million. Skrede *et al*[123] developed a DL model using over 12 million histopathological images to develop a biomarker for automatic prediction of cancer-specific survival, which outperformed existing markers. The authors conclude this strategy can potentially be utilized in the treatment selection process by identifying high-risk groups. Thakkar *et al*[120] recently developed a DL model aimed at automatically quantifying quality metrics during colonoscopy, providing intra-procedural feedback to the performing endoscopist.

Non-malignant conditions

Video capsule endoscopy: Owing to its ease of use and noninvasiveness, video capsule endoscopy (VCE) is the current diagnostic method of choice to assess the small bowel for conditions such as occult GIB and Crohn's disease (CD). However, since it lacks self-locomotion, it relies on the motility of the bowel to advance within the gastrointestinal tract. Therefore, it requires a very large number of images (up to 60000 per examination) to be automatically obtained, rendering the process of interpretation lengthy and tedious[124]. VCE has been an area of focus for AI since its early stages, seeing the initial AI classifying methods such as SVM and multilayer perceptron network[125-127]. With faster processors, increased computational power by improved graphics processing units and evolving CNNs, DL algorithms have become the modality of choice for image analysis in VCE[128,129]. As in the lower gastrointestinal tract, the same principles of CADe and computer-aided diagnosis could be applied to deep balloon-assisted or motorized enteroscopy systems (Supplementary Table 3).

A total of 31 studies pertaining to VCE were identified. Fifteen studies (48%) developed models to assist in detection of active GIB or angioectasia. Four studies used CNN, five used SVM, and the remaining ones used ML-based analytic models. Five studies reported cross-validation methods. All studies reported accuracy ranging from 94% to 98% in identifying GIB and angioectasias, with sensitivity of 92.0%-100% and specificity of 82.9%-99.9%[130-142]. Specifically, Tsuboi *et al*[140] developed a DL model based on CNN for angioectasia detection, which achieved an AUC of 0.998, with a sensitivity and specificity of 98.8% and 98.4%, respectively.

Six studies assessed for the presence of small-intestinal ulcers, of which five used DL models based on CNN and one used SVM[128,134,143-146]. Aoki *et al*[128,143] conducted 2 studies in testing DL models to detect ulcerations, yielding a sensitivity of 88.2%, a specificity of 90.9%, and an AUC of 0.958, respectively. Two more studies evaluated the detection of small-bowel CD by identifying ulcers on VCE[147,148]. Klang *et al*[147] developed a DL model based on CNN that used over 17000 VCE images to identify CD ulcers, achieving an AUC of 0.99. Two studies examined small intestinal polyp detection using NN-based models, both achieving an accuracy of at least 98%, with sensitivity and specificity of up to 95.5% and 98.5%, respectively[149,150].

Regarding celiac disease (CeD) detection, 4 studies were evaluated, 3 of which used CNN and 1 that used a clinical decision support system[151]. A study by Zhou *et al*[152] reported 100% sensitivity and specificity in detecting CeD using GoogLeNet as classifier. A study by Wimmer *et al*[153] using AlexNet, VGGf net, and VGG-16 net as classifiers obtained an optimal accuracy of 92.5% using VGG-16, although the report did not include sample size. More recently, Wang *et al*[154] developed a DL model using the CNN-based InceptionV3 as well as the SVM-based ResNet50 that was 95.94% accurate, 97.20% sensitive and 95.63% specific in identifying CeD in VCE images.

Hookworm infection represents a significant healthcare issue in the developing world, with an estimated 600 million people harboring this infection[155]. As this helminth typically dwells in the small bowel, it may occasionally be a finding in VCE. Three studies evaluated hookworm detection, of which two used CNN and one used SVM with all using cross-validation[156-158]. Specifically, He *et al*[157] developed a DL model based on deep CNN, which was trained on a large VCE dataset consisting of more than 440000 images. The model outperformed other handcrafted, feature-based methods, reaching an accuracy of 88.5% and a sensitivity of 84.6% in detecting hookworm in the small bowel.

To assess for quality of bowel preparation during VCE Leenhardt *et al*[159] and Noorda *et al*[160] developed a DL models based on CNN. Both models achieved accuracy of over 95%, with sensitivity and specificity of 94.7%-96.18% and 94.0%-94.33%, respectively. Overall, Ding *et al*[131] developed a DL model based on CNN to identify and categorize all small-bowel ulcers, polyps, bleeding, lymphangiectasia, follicular hyperplasia, protruding lesions, diverticula or inflammation using over 100 million VCE images. The model achieved an impressive 99.90% overall sensitivity and 99.88% specificity, whereas gastroenterologists identified lesions with a 74.57% sensitivity in the per-patient analysis and 76.89% sensitivity in the per-lesion analysis. Furthermore, the reading time per patient was 5.9 min by the CNN model, compared to 96.6 min by conventional reading.

Inflammatory bowel disease: The complex interplay of pathophysiological factors in inflammatory bowel disease (IBD) has led to the realization that differences in patients' biology may confer differences in disease activity and response to therapy- an example of "precision medicine"[161]. Integration of AI algorithms into the IBD realm

brings promise not only in diagnosis or reducing interobserver variability in severity grading but also opens up the possibility of analyzing large databases to identify complex or occult patterns of disease[162-167].

A total of 25 studies pertaining to IBD were included in this review, of which 9 dealt with CD, 6 studied ulcerative colitis (UC,) and 10 investigated both. Five studies aimed to detect CD, UC, or IBD in general from VCE images, endoscopic images, histology, magnetic resonance imaging (MRI) images, and genetics. Most of the studies used cross-validated ML methods, of which SVM was the method of choice; while another study used DL-based CNN. These studies displayed high levels of accuracy in detecting IBD, from 83.3%-90.8%[143,168-171]. Aoki *et al*[143] developed a DL model based on CNN that used more than 10000 VCE images in the validation dataset to detect CD ulcers in the small bowel, achieving an accuracy, sensitivity and specificity of 90.8%, 88.2% and 90.9%, respectively.

Nine studies that addressed predicting disease severity were primarily based on endoscopic imaging; although other studies also used laboratory studies, demographics, histopathology and CT enterography[172-179]. Five studies utilized ML-based analytic models, while the remaining four utilized DL-based models, of which CNNs were the preferred ones. Five studies reported internal validation, and two studies had external validation cohorts; while two studies did not report validation. The size of patient cohorts varied greatly, from 87 to over 3000, with studies reporting up to 40000 images in the validation datasets. Yao *et al*[179] designed a DL model based on CNN to grade the severity of UC using colonoscopy images, which was constructed with over 16000 images from 3000 patients. The reported accuracy, sensitivity, and specificity was 87.6%, 90.2%, and 87.0%, respectively. The authors concluded that these results support the use of AI in UC severity grading , which approximates the scoring of experienced human reviewers. Maeda *et al*[172] designed a ML model with CAD to detect histologic inflammation based on colonoscopy images enhanced with endocytoscopy. The model achieved an accuracy, sensitivity and specificity of 90.0%, 74.0%, and 91.0%, respectively, using over 9900 images from 100 patients in the validation cohort.

To predict therapeutic response in patients with IBD treated with thiopurines or biologics seven studies constructed internally validated ML algorithms, based on RF analytic models. All models achieved an accuracy of 80.0%-89.8% or an AUC of 0.73-0.846 in identifying patients who will respond at 6-8 wk to therapeutic regimens[180-186]. Waljee *et al*[186] designed a model using only demographic and laboratory data from 401 patients to predict response at 8 wk in patients receiving ustekinumab with an AUC of 0.78, potentially laying the foundation to avoid costly therapeutic drug monitoring. Waljee *et al*[184] also constructed a model based on laboratory values and demographics with a validation dataset of over 6100 patients to predict IBD-related hospitalization and outpatient steroid use, achieving an AUC of 0.87, suggesting such AI models could be used to identify patients at risk of an IBD flare and enable precision medicine-based therapeutic approaches (Supplementary Table 4).

A further 2 internally validated ML models using SVM and RF were developed to predict the risk of IBD based on a genomic datasets[187,188]. Isakov *et al*[187] developed a gene prioritization model using 4 combined analytic models (RF, SVM GB, and an elastic net regularized generalized linear model) to identify genes related to IBD, achieving an accuracy of 80.8%. An internally validated natural language processing (NLP) model by Hou *et al*[189] used histopathology reports to identify surveillance *vs* nonsurveillance colonoscopy in patients with IBD, with an accuracy of 80.0%. Lastly, Firouzi *et al*[190] developed an internally validated model based on Waikato Environment for Knowledge Analysis that identified, with an accuracy of up to 89.8%, patients with IBD who required a bone mineral density scan, using electronic health record data.

HEPATOBILIARY SYSTEM

Liver diseases are broad and complex, ranging from asymptomatic liver chemistry elevation to life-threatening conditions such as acute liver failure or orthotopic liver transplantation (OLT). Hepatology is can be a fertile ground for applying AI in survival models (*e.g.*, model for end-stage liver disease), disease detection models [*e.g.*, early detection of non-alcoholic fatty liver disease (NAFLD)], disease severity models (*e.g.*, alcoholic hepatitis discriminant function), or disease estimation models (*e.g.*, aspartate aminotransferase-to-platelet ratio index), but also for pattern recognition in radiological images, histopathology and even selection of LT candidates[191,192]. A

total of eighty-five studies pertaining to hepatology were examined, out of which twenty assessed prediction of outcome measures, forty-one examined prediction or detection of steatosis, fibrosis or cirrhosis, nine studies examined differentiation of malignant liver neoplasms, six studies explored predictive models for portal hypertension, and eight studies investigated AI models for other purposes.

Nine studies developed models that assisted with detection or classification of hepatobiliary neoplastic lesion, six of which involved DL-based CNN[193-202]. Schmauch *et al*[197] constructed an internally validated CNN-based DL model using ultrasonographic images of the liver to detect and classify focal liver lesions, achieving an overall AUC of 0.891. Six studies constructed models assisting in predicting the presence of portal hypertension complications in patients with all-cause cirrhosis, based on clinical data or radiological images obtained from modalities such as CT scans[203-208]. Dong *et al*[204] constructed an ML-based model on an RF analytic model that used clinical data and predicted the presence of esophageal varices in patients with cirrhosis with an AUC of 0.82, potentially being useful in performing a better triage of patients who actually require an upper endoscopy for variceal screening. Liu *et al*[206] developed an ML model that had a higher diagnostic performance than conventional noninvasive tools (either conventional image-based or serum-based tools) in identifying clinically significant portal hypertension from contrast-enhanced CT or MRI, with an accuracy of 91.1% and 88.9%, respectively.

Forty-two studies developed models addressing detection of steatosis, fibrosis, or cirrhosis based on clinical data, shear-wave elastography, CT or MRI scans, histopathology, or genetics. Of these, 27 studies developed models to detect, quantify, or predict steatosis, fibrosis, or cirrhosis[202,209-234]. Forlano *et al*[215] developed a ML-based model for quantification of steatosis, inflammation, ballooning, and fibrosis using biopsies from patients with NAFLD. The model identified characteristics of NAFLD with intra- and inter-observer agreement from 0.95-0.99, and has a potential use in objective assessment of treatment response in patients with NAFLD. Yasaka *et al*[202] constructed a DCCN model based on over 144000 MRI images from 534 patients to stage hepatic fibrosis, achieving AUCs of 0.84, 0.84, and 0.85 for F4, F3, and F2 fibrosis, respectively. In assessing fibrosis in patients with hepatitis B virus, Wang *et al*[232] created a DL-based CNN model that used ultrasonographic and elastography data from 132 patients to predict fibrosis, with AUCs of 0.97, 0.98 and 0.82 for F4, F3 and F2 fibrosis, respectively. Eight studies developed AI models to establish the diagnosis of fatty liver disease or distinguish between the causes of liver disease[235-242]. In distinguishing NAFLD from non-alcoholic steatohepatitis (NASH), Fialoke *et al*[237] constructed an ML model testing decision tree, linear regression,, RF, and extreme gradient boosting (XGB) analytic models, of which the XGB achieved the highest accuracy, AUC, sensitivity, and specificity at 79.7%. 0.876, 77.4%, and 80.8%, respectively. Taylor-Weiner *et al*[239] constructed an ML model that enabled quantitative measurement of liver histology and disease monitoring in NASH, characterizing disease severity, heterogeneity and treatment response in NASH.

Of 20 studies examining outcome predictors, 8 evaluated predictor models in OLT involving donor-recipient matching, recipient survival at determined time frame, graft survival at different time frames, survival predictors, and morbidity predictors[243-250]. Bertsimas *et al*[245] constructed an internally-validated decision tree-based ML model using clinical data that predicted 3-mo waitlist mortality or removal with an AUC of 0.895. Five studies designed models for outcome prediction in patients with hepatocellular carcinoma (HCC), including response to trans-arterial chemoembolization (TACE), recurrence or survival after resection, most of which were based on CNN[251-255]. Saillard *et al*[254] designed an externally-validated model based on a pre-trained CNN based on histology slides from 328 patients that independently predicted survival after HCC resection with a c-index of 0.75. Other studies evaluated outcomes in patients with acetaminophen-related ALF, primary sclerosing cholangitis, predicted the presence of choledocholithiasis, predicted hepatotoxicity of stereotactic body radiation, or mortality in patients with cirrhosis[256-263]. Eaton *et al*[256] constructed a ML model with XGB that accurately predicted hepatic decompensation in patients with primary sclerosing cholangitis with a C-statistic of 0.90.

Other studies focused on developing models for miscellaneous topics such as estimating liver stiffness from MRI, assessing pretransplant cognitive impairment, detecting spectral differences between normal and hepatitis B virus serum samples, classifying seroconversion to HBeAg, predicting hepatotoxicity in early stages of drug development, predicting fibrosis in hepatitis C virus, or AI-assisted liver tumor segmentation[264-272]. Williams *et al*[271] developed a ML model based on a Bayesian network using hepatic safety assays to predict drug-induced liver injury in compounds during drug development, achieving an accuracy, sensitivity, and specificity

of 86.0%, 87.0%, and 85.0%, respectively. An externally-validated ML model based on SVM and radiomics by He *et al*[267] used MRI and clinical data to estimate liver stiffness, achieving an AUC of 0.80, with an accuracy, sensitivity, and specificity of 75.0%, 63.6%, and 82.4%, respectively. Lastly, models addressing prediction of NAFLD or NASH based on clinical or genetic data, as well as models analyzing donor liver texture for steatosis, have also been developed[272-278] (Supplementary Table 5).

PANCREATIC DISEASES

Pancreatic diseases contain areas where AI can be effectively applied. Of primary interest is the use of AI in improving existing disease severity scoring systems or prognostic models in complicated acute pancreatitis (AP) or chronic pancreatitis (CP), based on clinical and radiological data, detection and differentiation of pancreas cystic neoplasms (PCN) with prediction of malignant potential, radiologic early detection of pancreatic ductal adenocarcinoma (PDAC), radiologic differentiation between PDAC and benign pancreatic conditions [*e.g.*, autoimmune pancreatitis (AIP)], and histopathologic interpretation of tissue samples[279-282]. A total of 59 studies pertaining to the pancreas were reviewed. Of these, 20 (34%) addressed prediction of outcomes in patients with pancreatic diseases ranging from AP to neoplasia.

Eleven of these studies examined outcome prediction in AP. All of the studies' ANN models outperformed logistic regression models, Glasgow, and APACHE-II scoring systems in predicting AP severity; while requiring less number of parameters[283-293]. Qiu *et al*[292] compared the performance of SVM, logistic regression analysis, and ANN models to predict multiorgan failure in AP. All 3 models predicted multiorgan failure, with AUC of 0.840, 0.832, and 0.834, respectively, with ANN requiring a lesser number of parameters.

Seven (12%) studies used AI algorithms to construct clinical registries, segment the pancreas based on imaging, or differentiate between certain pancreatic diseases based on cross-sectional imaging or endoscopic ultrasound (EUS)[294-300]. Zhang *et al*[298] constructed a DL station classification model and a segmentation model to reduce the difficulty in EUS interpretation for trainees. The trainee station recognition accuracy improved from 67.2% to 78.4% in the crossover study. Interobserver agreement between endoscopists and deep CNN with Cohen's kappa coefficient was substantial, ranging from 0.826-0.879. The authors conclude that this technology may play a key role in shortening the learning curve of EUS among trainees.

Fifteen studies (25%) addressed prediction of malignancy based on imaging findings, or differentiation of benign from malignant pancreatic conditions[280,301-315]. Marya *et al*[280] developed an EUS-based CNN model that distinguished AIP from normal pancreas with 99% sensitivity and 98% specificity, AIP from CP with 94% sensitivity and 71% specificity, and AIP from PDAC with 90% sensitivity and 93% specificity. Chu *et al*[301] conducted a study utilizing CT radiomics features to differentiate PDAC from normal pancreas tissue. The accuracy of the RF binary classification was 99.2%, with an AUC of 99.9%. All cases of PDAC were correctly identified, with a sensitivity of 100% and specificity of 98.5%.

Eleven studies (19%) evaluated differentiation of PCNs by classifying them into their respective subtypes based on their characteristics on imaging[316-326]. Springer *et al*[324] developed a multimodality ML model that integrated clinical, radiological and genetic/biochemical markers data to determine whether patients with pancreas cyst should undergo surgery, monitoring, or no further surveillance. The model correctly identified serous cystic neoplasms in 65% of the cases with 99% specificity, clearly outperforming the current standard of care of clinical identification in only 18% of cases. The authors conclude that these systems may serve an adjunct role in clinical practice, enabling the clinician to take better-informed clinical decisions[324].

Eight studies addressed PDAC, from developing risk scores for development of PDAC based on urinary biomarkers, predicting clinical performance and response to celiac plexus neurolysis, to prediction of survival time. AI models performed at least as well as the logistic regression models in predicting the selected outcome[327-334].

Six studies directly examined early pancreatic cancer detection in PDAC or PCN by examining the imaging characteristics or identifying high-risk patients on electronic health records based on factors such as family history of pancreatic cancer[335-340]. Roch *et al*[339] developed NLP-based algorithms based on common terminology used by physicians in describing pancreatic cysts and applied them to automatically conduct searches in electronic health records. The algorithm tracked patients with cysts with a 99.9% sensitivity and 98.8% specificity, demonstrating its utility in

capturing patients swiftly and with more ease than manual review. Ozkan *et al*[338] developed a CAD image-processing system using EUS images to diagnose PDAC, taking patient age into consideration. The accuracy of the model was 87.5, with sensitivity and specificity of 83.3% and 93.3%, respectively (Supplementary Table 6).

CURRENT LIMITATIONS AND KNOWLEDGE GAPS

Despite the numerous positive advances in AI, there remain several limitations to current studies and obstacles to overcome for future studies. Most current models are based on labeled data and, hence, interpretation is only as good as the observer who labeled the "gold-standard" data. Current algorithms are specifically fitted for a determined dataset. A sizeable proportion of the AI models applied to the clinical setting are only internally validated. Ideally, models should be externally validated on diverse cohorts to ensure that overfitting does not become an issue. Therefore, this issue could be potentially addressed by the creation of a universal, well-annotated, high-quality dataset, and by creating algorithms with more plasticity. However, creating "universal datasets" creates additional challenges, particularly related to data integrity and privacy. A potential solution to this is the decentralized "federated datasets", which involves combining multiple datasets stored on their respective servers, addressing these challenges[341]. Specific protocols are required for choosing an analytic model and selecting or developing validation techniques (*e.g.*, external-, internal-, cross-validation) for data fine-tuning or augmentation. Algorithms that yield the best accuracy should be promoted. Calibration has translated into improvements in probability prediction, for which they should be instituted in all models. Most current studies were cohort studies, whereas well-designed randomized controlled trials would be needed to better support conclusions. Some studies utilized custom-built models, which are not explained in detail. Therefore, custom-built algorithms should have their background and processes thoroughly declared. The studies presented numerous different newly developed models, which would require validation to determine whether these can be applied to other datasets. Several studies examine different techniques during an equivalent endoscopic procedure (*e.g.*, endoscopic image processing in NBI, WLI, or chromoendoscopy), which renders comparisons between techniques cumbersome or not possible. Data matrixes should be completely reported[342]. Significant efforts have been devoted to developing guidelines, such as the CONSORT-AI extension, to standardize reporting in trials evaluating performance of the AI. Adherence to current guidelines and flexibility to revise them as technology continues to advance is of paramount importance. The majority of studies use still images and high-definition images, which is not in line with the "real-world experience" of real-time settings, imaging affected by motion artifact or poor image processing from outdated technical equipment.

APPLICATION IN CLINICAL CARE (ARTICLE HIGHLIGHTS)

ML and DL could assist clinicians in the diagnosis of gastrointestinal and liver neoplasms, bleeding, infection, and inflammatory process, and also predict outcome measures in these conditions.

The initial use of ML or DL models might be used in backing up clinicians in establishing diagnoses or determining a treatment plan.

Given its high predictive value, if AI suggestions match the clinician's reasoning, clinicians could make a decision more confidently. If the answers are discrepant, careful investigation should be undertaken.

In the future, if ML or DL models find a place to be integrated in standard clinical care, to guide in establishing diagnoses, selecting treatment interventions, predicting outcomes, and influencing clinical decision-making. However, future studies are also necessary to explore avenues of how these measures can be better instituted in clinical practice as a whole.

FUTURE DIRECTIONS

As demonstrated by this review, AI applications in clinical gastroenterology and hepatology continue to rapidly expand and evolve at many different levels. For

general clinical care, the recent proliferation in AI applications is likely to enable "precision medicine" on a broader scale. Clinically, it is predicted that invasive diagnostic interventions will generally fall out of favor for some conditions, as better noninvasive ML-based algorithms pave the way for improved clinical prediction models. Some diagnostic interventions, such as VCE interpretation, may see a considerable decrease in human interpretation, minimizing the human role to that of supervision and attestation of findings of the model. AI-assisted technology will prove important in real-time clinical settings (*e.g.*, polyp detection during colonoscopy). Integration of monitoring devices (*e.g.*, smartphones, smart watches) with ML in the management of selected diseases is also predicted to significantly receive more attention the coming years. The creation of a universal, large, high-quality, well-labelled dataset is a necessity, from which algorithms could be developed to better define the epidemiology and risk factors of diseases. Well-harnessed AI assistance should decrease physician workload or at least maximize their productivity by allowing them to shift from menial tasks to faster, more accurate clinical decision-making. ML algorithms based on these datasets can also be used for other quality measures, such as improvement of process efficiency or identifying cost-effective interventions. In terms of data analysis, traditional analytic models (*e.g.*, logistic regression and clinical scoring systems) may be substituted or augmented by ML algorithms to achieve greater capability and accuracy. Developing and maintaining multidisciplinary teams of data scientists, physicians, content subject experts and industry is of paramount importance in the advancement of AI in gastroenterology and hepatology. Finally, educating clinicians and patients in the future paths of AI applications is critical to increase understanding of future value and decrease reluctance in engagement.

CONCLUSION

The latest advances in AI in gastroenterology and hepatology are promising for aspect many fields of clinical care, from detection of neoplastic lesions on endoscopic assessment and improving current survival models to predicting treatment response. The application of AI to large and complex datasets may assist in the identification of new associations between variables, potentially leading to changes in clinical practice. Furthermore, the use of AI-assisted technologies has the potential to dramatically improve the quality of care. Finally, the time for assisted precision medicine is at hand, with the AI being able to tailor a treatment regimen or potentially predict the response to treatment in a specific patient based on extensive amounts of clinical data from large patient datasets. It is important to realize that, while AI currently does not substitute human clinical reasoning, it has a bright future in the betterment of patient care.

ACKNOWLEDGEMENTS

Abstract

Chronic liver diseases (CLDs) are becoming increasingly more prevalent in modern society. The use of imaging techniques for early detection, such as magnetic resonance imaging (MRI), is crucial in reducing the impact of these diseases on healthcare systems. Artificial intelligence (AI) algorithms have been shown over the past decade to excel at image-based analysis tasks such as detection and segmentation. When applied to liver MRI, they have the potential to improve clinical decision making, and increase throughput by automating analyses. With Liver diseases becoming more prevalent in society, the need to implement these techniques to utilize liver MRI to its full potential, is paramount. In this review, we report on the current methods and applications of AI methods in liver MRI, with a focus on machine learning and deep learning methods. We

assess four main themes of segmentation, classification, image synthesis and artefact detection, and their respective potential in liver MRI and the wider clinic. We provide a brief explanation of some of the algorithms used and explore the current challenges affecting the field. Though there are many hurdles to overcome in implementing AI methods in the clinic, we conclude that AI methods have the potential to positively aid healthcare professionals for years to come.

Key Words: Liver diseases; Magnetic resonance imaging; Machine learning; Deep learning; Artificial intelligence; Computer vision

Core Tip: Artificial Intelligence (AI) algorithms are becoming increasingly prevalent in magnetic resonance imaging (MRI) after their proven success in computer vision tasks. With regards to liver MRI, these methods have been shown to be successful in tasks from hepatocellular carcinoma detection, to motion reduction to improve undiagnostic scans. They have also been shown in some cases to outperform radiographer level performance. The widespread use of these techniques could positively aid clinicians for years to come, if implemented properly into clinical workflows.

INTRODUCTION

Since the advent of magnetic resonance imaging (MRI) in the 1970s, its use has grown exponentially worldwide, due to its ability to give high resolution images in the body, allowing the early diagnosis and accurate prognosis of many diseases[1,2]. In contrast to computed tomography (CT), MRI uses no ionising radiation, has superior soft tissue contrast and allows the probing of metabolic processes due to the ubiquitous nature of water in our bodies. With regards to the liver, it has become an essential tool for anatomical assessment. In addition, current cutting edge methods allow for quantification of liver fat, liver iron and staging of fibrosis levels within the liver[3-5]. These methods have the possibility to provide early detection and staging of many chronic liver diseases (CLDs), and are becoming more in demand with the rising prevalence in liver disease in western society. With 1/3 of adults believed to have non-alcoholic fatty liver disease (NAFLD) and 12% the more severe non-alcoholic steatohepatitis (NASH), NAFLD has been defined as a silent pandemic and the most prevalent liver disease in human history[6-9]. As there is currently no medical treatment for NAFLD beyond lifestyle interventions, the need for early detection is paramount, so that the disease progression can be halted and reversed, and MRI can play an important role in this [10].

The need for early detection is not only limited to CLDs but is also important in detection of liver cell cancer (hepatocellular cancer; HCC). With mortality rates from HCC predicted to rise to become the third highest leading cause of cancer-related deaths in the US by 2030, the need for early diagnosis is needed so that treatment can be effective[11]. Currently this requires expert radiologists studying liver MRI scans trying to find a tumour. Though many tumours are identified, some tumours can also be missed, with one study finding that 16% of lesions were missed in multiparametric MR imaging of the prostate, highlighting the need for a method for identifying these missed cases[12].

Early detection can be addressed in many liver diseases using liver MRI. The current gold standard for staging is liver biopsy, however, it is invasive, is localized (sampling error) and has risk of complications[13]. Liver MRI is overtaking this standard, due to being non-invasive and allowing global metrics to be calculated across the whole liver. When diagnosing liver fibrosis stage, an important biomarker

in staging NAFLD, many different sequences have predictive potential, such as MRE, T1 and T2* mapping, diffusion weighted imaging (DWI) and hepatocellular function imaging using contrast agents[14]. When identifying HCC within the liver, hepatocellular function imaging is commonly used, however DWI also has good predictive power[15,16]. These methods all require a level of expert analysis to interpret the images, similarly to biopsies, which means they are prime candidates for automation using AI methods.

Artificial intelligence (AI) techniques, have been shown to perform well when applied to computer vision problems, from classification of objects in a photograph to fast object segmentation of video frames for self-driving cars[17,18]. These techniques have also been applied successfully to many areas of MRI in the body, such as segmentation of brain tissue, ejection fraction prediction and diagnosis of heart conditions[19-21]. An AI approach to report mammograms for the presence of breast cancer has been shown to outperform radiologist reporting[22]. AI techniques in Liver MRI are relatively underdeveloped compared to brain and cardiac MRI, but nevertheless, they provide opportunities to alleviate workload in many settings.

In this review, we assess the current gold standard of AI in liver imaging. Specifically, we review the recent application of AI techniques for segmentation (Table 1), classification (Table 2) and image synthesis for different CLDs and MR imaging techniques. We briefly provide an overview of AI techniques in the field, describe the implementation of AI to achieve these applications and explain how they are quantitatively and qualitatively assessed. We explore the publications that have sought to solve these problems and assess the challenges that still face the field.

AI ALGORITHMS

We broadly focus on two subsets of AI algorithms: traditional machine learning (ML) algorithms and deep learning (DL) algorithms. Traditional machine learning algorithms often rely on the input of handcrafted features, an additional piece of data which has been derived from acquired data. In the case of MR images, these handcrafted features are often statistical measurements such as the mean intensity of the image or a sub region of the image, and are called radiomic features as they are derived from medical images. These radiomic features are then passed to a statistical model, such as a support vector machine (SVM), kMeans Clustering, random forests or a naïve bayes algorithm among many others[23,24]. These models can either be supervised, where you have a desired target outcome, or unsupervised, where no target outcome is enforced. When you have selected the appropriate model for your task, the model is then trained. In the case of supervised models, the model updates its parameters to minimise the error between your desired output and the model output, as new data is sequentially passed to it. An example would be inputting radiomic features extracted from tumours and the model getting better at classifying the tumours into their classes, such as hepatocellular carcinoma (HCC) or intrahepatic cholangiocarcinoma (ICC), as it updates its parameters to minimise the error between its output prediction and the ground truth. In the case of unsupervised models, the model updates its parameters to be able to separate input data into a predefined number of classes, without knowledge of what those classes may be. In the above example, you would input the radiomic features from different tumours and ask the model to output two distinct classes for HCC and ICC, without explicitly giving the model information about which tumour corresponds to which class. During training you monitor the success at a desired task and stop training once the model performance meets some predefined criteria, such as the model no longer improving even when new data is added. If the model is accurate, *i.e.*, it rivals human performance, it can then be used in a research or clinical setting.

LeCun *et al*[25] defines DL methods as ML methods with multiple levels of features, obtained by composing simple but non-linear modules that each transform the feature at one level (starting with the raw input) into a feature at a higher, slightly more abstract level. In essence, this means that DL algorithms calculate successive features based on the features or data that you provide it. The most common way of doing this in MR images is to employ convolutional layers. A convolution, in terms of images, is a filter of a defined size, which when applied to a portion of an MR image of the liver equal to the size of the filter, outputs a singular value, as shown in Figure 1. When applied sequentially to a whole scan, it outputs an image containing these values, known as a feature map. Additional convolutional layers are applied to these feature maps, to produce feature maps with deeper information. When these layers are

stacked together, a convolutional neural network (CNN) is generated. The final convolutional layer generates the desired size of your output, anything from a single value to classify the disease state, or a new image which could be a segmentation map of the liver. Like traditional machine learning, the accuracy of the output compared to a gold standard measurement, is maximised during training.

SEGMENTATION

Segmentation describes the process by which anatomical structures can be selected from a radiological image. Anatomical structures can be organs like the liver, tissues like subcutaneous and visceral fat or malignant deposits. Metrics resulting from the segmentation process and segmentation maps can help with estimation of volumes (*e.g.*, liver volume), important metabolic ratios (ratio of visceral to subcutaneous fat) and provide important anatomical information that can help in the radiotherapy and surgical planning for the treatment of malignant tumours[26,27]. Segmentation can therefore play an important role in many aspects of clinical decision making. Segmentation maps are also often used in quantitative techniques, such as T1 mapping and MRE, to give accurate measurements across the whole liver and not just in a region of interest[26,28].

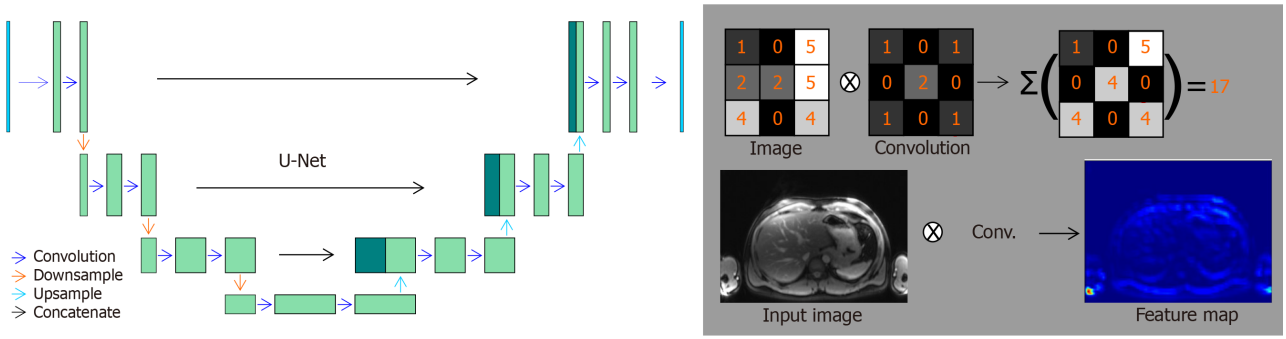

Figure 1 A deep convolutional network. An example deep learning segmentation network, the U-Net. A series of convolutions, combined with downsampling and upsampling to learn feature maps at different scales, are used to output a segmentation map. An example of a convolution, and feature map are shown on the right.

The segmentation processes are usually carried out manually using software tools for this purpose. However, these manual processes can be time consuming and inaccurate, and the introduction of automated AI methods can reliably supersede these methods, improving output and reliability by performing close to the level of expert radiologists in a much shorter time[28]. For example, automatic segmentation to measure liver fat, adipose tissue depots and muscle volume and fat content led to an improved risk stratification for the presence of type 2 diabetes and cardiovascular disease compared to discrete categorisations of body composition in a large population study (n = 10000)[29]. Such a study would not be possible without automatic segmentation to measure the parameters of interest.

When applying AI algorithms to segmentation tasks, the aim is to highlight every voxel in an MR image that applies to a certain class. For example, this could be that the voxel contains the liver, a tumour, or neither. Though different algorithms have different approaches to achieving this goal, they are all evaluated by their ability to

correctly identify which voxel of the MR image corresponds to which class. One common metric for evaluating this is the DICE score, which is defined as follows (Formula 1):

$$DICE = \frac{2TP}{2TP + FP + FN}$$

Where TP is the number of true positives, where the voxel has been correctly classified, FP the false positives, where the voxel has been incorrectly given a class instead of no class, and FN the false negatives, where a voxel which belongs to a desired class has been labelled as belonging to no class. If the DICE score is high, then the segmentation map is accurate. Additional metrics of performance do exist, such as intersect over union (IoU), where the closer to 1 the result is, the better the segmentation.

Though non-deep learning AI segmentation methods do exist, the majority of papers presented here are based on deep learning methods due to the successful application of these methods in natural image space, an example being the U-Net, as shown in Figure 1[30]. Though other methods are used, the U-Net is the most common due to its proven performance in segmentation maps, in part down to its ability to learn features at different scales due to the downsampling, and inclusion of previous feature maps in the concatenation steps.

Segmentation for surgical and radiotherapy planning

Segmentation maps are crucial in surgical planning, especially in giving the clinician information of the size and location of tumours, to allow for safe and successful surgery. They are also useful in radiotherapy planning, allowing the therapy to be performed such that there is minimal risk to organs and maximal damage to tumours.

Chen *et al*[31] and Huang *et al*[32] implemented a 2D U-Net, with densely connected blocks, to segment up to 10 organs at risk in radiotherapy. They achieved a DICE coefficient of 0.963 ± 0.0010 in the liver with high metrics in most of all the other organs studied. Likewise, Valindria *et al*[33] and He *et al*[34] trained a 2D residual network to segment out multiple organs in CT or MR scans which can similarly be used for radiotherapy planning. The use of both modalities increased performance in both their segmentation maps, achieving a DICE score of 0.914 in the liver, when compared to training with just one modality. This is still less than that achieved by Chen *et al*[31], even with the additional information from the CT scans used in the Valindria study. This may be due to the use of T2-weighted MR images being used by Valindria *et al*[33] as opposed to T1 -weighted. Fu *et al*[35] used a trio of CNNs to segment multiple organs in images acquired on a dual radiotherapy MR machine, in order to expediate the MRI guided adaptive radiotherapy. They achieved a DICE score of 0.953 ± 0.007 in the liver. The segmentations took approximately 5 s to produce and as such could not be used yet in a real-time radiotherapy setting, however, the method does still alleviate radiologist workflow, where they only quality control the output which takes a quarter of the time of a full manual segmentation. Bousabarah *et al*[36] automate the segmentation of the liver and classification of tumours within into the Liver Imaging Reporting and Data System (LI-RADS) classes. They used a 2D U-Net to segment contrast enhanced MR images into two segmentation maps, one of the liver and one of any tumours within. The proposed tumour segmentation then undergoes post-processing by using a random forest classifier using radiomic features extracted from the proposed region. The combined model detected 75% of lesions in the test data, when there was a DICE score of 0.2 or greater between the detected and actual tumour. The output could not only be used in surgery and radiotherapy planning, but also be used in conjunction with a radiologist's assessment to improve detection accuracy. They achieved a similar performance as Valindria *et al*[33], but with the harder task of segmenting out bodies within the liver itself, which will likely decrease performance in liver segmentation. Mole *et al*[37] and Owler *et al*[38] used a 3D U-Net to segment out the liver in a pipeline for surgical planning. They segmented the liver in a T1-mapping acquisition with a DICE score of 0.970. The metrics calculated using this segmentation map were used to predict post-operative liver function with a high degree of accuracy. This shows that the method could be used in determining whether a patient should go for surgery or whether other treatments should be considered. Christ *et al*[39] implemented two 2D U-Nets to segment out the liver and metastases within the liver, in both CT and MRI images, which could be used both for radiotherapy planning and measuring response to therapy. The first U-Net segments out the liver region, which is used to process the input MR image. The second U-Net segments out any tumours within this identified region. They achieved a DICE score of 0.87 when applied to diffusion weighted MRI images. Jansen *et al*[40] utilised

information from both dynamic contrast enhanced MRI (DCE-MRI) and DW-MRI to segment out the liver and metastases within, achieving a DICE score of 0.95 in the liver, and an accuracy of 96% in detecting the liver metastases.

Non-CNN based methods have also been used to segment out the liver in multi-phase contrast enhanced MRI[41]. Ivashchenko *et al*[41] used a K-means clustering algorithm on multiple phases of the contrast enhancement to generate 8 initial compartments. They then select a best candidate and apply multiple post-processing non-AI methods to generate a full segmentation of the liver, achieving a DICE score of 0.949 ± 1.2. This method could also be used to segment out the vessels and biliary tree, allowing safer execution of complicated liver resections. Masoumi *et al*[42] also used a non -CNN based method using both traditional non-AI methods, the watershed algorithm, and an artificial neural network (ANN) to automate the traditional algorithm. Six ANNs were trained to estimate 6 chosen features from the image, such as the ratio of the maximum and minimum diameter of the liver. These also extracted from the watershed algorithm and the error between the two feature sets calculated. This error is then iteratively used to update the watershed algorithm parameters until there is no longer a reduction in the error between the two feature sets. They achieved a mean Intersect over Union (IoU) of 0.94.

Segmentation of the liver when applied to surgical planning is, in most studies covered, exceeding a DICE score of 0.9. Variations in this value for the liver will likely be down to imaging protocol used (T1-weighted, T2-weighted, *etc.*), the patient group of interest, and the target outcome, in this case whether you are optimising to segment out the liver or whether it is a subtask among others, *e.g.*, segmenting out metastases or multiple over organs.

Segmentation for liver function assessment

Another application area for AI segmentation methods is liver function assessment. A full liver segmentation provides a more comprehensive estimation of liver function compared to region of interest placement. To get an overview of whole liver quantitative measures, radiologists must take the time to create these segmentations, that can easily be automated. Winther *et al*[27] showed that it is possible to segment out Gd-EOB-DTPA-enhanced liver MR images to calculate liver volumetry to assess hepatic functional reserve. They trained a 3D U-Net using the liver images of 100 patients, achieving a DICE score of 0.967 ± 0.019, when compared to two experts who had a corresponding DICE score of 0.952 ± 0.028. The segmentation time using a 3D U-Net took on average 60 s to generate a 3D segmentation map, compared to 10 min for an expert. Another study seeks to automate quantification of liver iron using a liver segmentation[30]. Liu *et al*[30] used a 2D U-Net to output a segmentation map for a T2* quantitative map, generated using 16 slices from the T2* relaxometry method used to calculate it. They achieved a DICE score of 0.86 ± 0.01 with the manual segmentations and subsequently a strong correlation of the liver iron in mg/g calculated using the automated and manual methods. This lower DICE score in T2*-weighted images correlates with the lower DICE score seen in the Valindria *et al*[33] study above, suggesting that it is harder for these networks to segment the liver in T2* weighted images, or that it is harder for humans to segment out the liver accurately in T2*-weighted images leading to a larger variation in your training dataset. Wang *et al*[43] implemented a 2D U-Net to segment the liver from abdominal MRI and CT scans. They achieved a DICE score of 0.95 in 100 T1-weighted MRI scans, and 0.92 in T2*-weighted MRI scans. They used the segmentations to automate the calculation of liver volumetry and hepatic PDFF, both of which had good agreement with manual segmentation derived values. Liver function assessment can also be performed during scanning. Irving *et al*[44], used a 2D U-Net to segment out the liver with exclusion of internal vasculature, so that quantitative liver T1 scores could be calculated. They achieved a DICE score of 0.95. The above four studies, all showed to have liver function assessment measurements that correlate with the current methods. Though, most of the measurements derived from the automated segmentations are usually derived from manual segmentations and so if the segmentation is accurate, then it should be expected that the output measurement would correlate highly. Yang *et al*[45] also used a 2D U-Net to generate segmentation maps of the liver, however by using a process known as disentangled representation, they were able to transform MR and CT images into a shared image space which contains only shared content. On these images, they achieved a DICE score or 0.891 ± 0.040. This segmentation network could be applied to multiple imaging modalities, which could be useful in clinical uptake as the end user won't have to carefully choose which model they apply. However, if accuracy of segmentation is the most important outcome, then many of the papers

covered here have shown better performance when seeking to maximise the segmentation accuracy in a single use case. Cunha *et al*[46] used AI methods to determine the optimal point for hepatobiliary phase acquisition in contrast enhanced MRI, thus avoiding overwaiting. They used a 2D U-Net to segment out a liver mask, which is applied to the original image. This masked liver is then passed to a classification CNN, which outputs a contrast uptake quality ranging from 0, minimal uptake, to 1, adequate uptake. They achieve an area under the receiver operating characteristic (AUROC) curve of 0.952 in the test set, indicating good classification accuracy. By applying their model in situ, they could reduce examination time in 48% of patients, by detecting when optimal uptake of contrast has occurred.

CLASSIFICATION

Classification or stratification is an important step in any disease treatment in healthcare. Without a proper classification of the disease causing symptoms, it is not possible to implement the correct medical response. Unfortunately, some diseases are hard to differentiate, even by experienced healthcare professionals. Providing additional support in this task could help ensure that patients are stratified correctly and swiftly. AI algorithms have been shown to deal well with image-to-class-based tasks, as demonstrated in applications to the ImageNet dataset[47].

AI classification algorithms are almost identical in their approach as segmentation networks. Whereas segmentation networks classify each voxel in an image, a classification seeks to classify all voxel in an image into a single class. They are evaluated against their ability to do this, by use of metrics such as accuracy, the percentage true positives and true negatives, sensitivity, the rate of true positives, specificity, the true negative rate, and by using receiver operating characteristic (ROC) curves, the true positive rate *vs* the false positive rate (1 – true negative rate/specificity), as shown in Figure 2.

Tumour detection and classification

Tumour classification is a useful tool in staging the severity of the cancer. The ability to differentiate between the various types of liver tumours would give the ability to medical professionals to implement an optimised treatment plan. Wu *et al*[48] used the AlexNet network architecture to classify cropped HCC tumours into either LR-3 (intermediate probability for HCC) or the combined class LR-4/LR-5 (likely/definite HCC respectively)[48,49]. They achieved a 90% accuracy in classification and an AUROC 0.95 with reference to an expert radiologist. Messaoudi *et al*[50] achieved similar accuracy when applying a CNN to classify HCC tumours from liver dynamic contrast enhanced (DCE) MRI sequences with an accuracy of 90% when classifying between HCC and non-HCC. Hamm *et al*[51] also implemented a CNN for the classification of tumours into both the LI-RADS grading system and the lesion class. Their input to the network was the three phases, arterial, venous and equilibrium phases, of the contrast enhanced scans. They achieved an accuracy of 91.9% when classifying into the distinct lesion classes, and an accuracy of 94.3% when classifying into the LI-RADS score. This was both more accurate and faster (1.0ms runtime of the model) than two radiologists on the same dataset. When comparing to the study by Wu *et al*[48], though they both sought to differentiate cases using the LI-RADS system, Hamm *et al*[51] differentiated into more classes (LR-1,LR-4,LR-M) instead of just between LR-3 and LR-4/5. Hamm *et al*[51] outperformed the performance of Wu *et al*[48], however it is likely that it is harder to differentiate between LR-3 and 4/5, so they are not directly comparable. Ideally a neural network would be able to differentiate between all LI-RADS classes. Kim *et al*[52] used a CNN to detect presence of HCC in liver MRI scans. By simplifying the problem into detection without segmentation, they get a high accuracy of 93.7% in detecting liver HCC lesions. This was comparable to the performance of a junior radiologist with an AUROC of 0.9 compared to 0.893, though was outperformed by an expert radiologist who had an AUROC of 0.957. Zhen *et al*[53] used a CNN to classify tumours into multiple classes of benign, primary malignant and metastatic tumours using a combination of MR, clinical data and laboratory results. When using all the data together they achieved their best model performance with AUROCs of 0.951, 0.985 and 0.989 when classifying HCC, metastatic malignancy and primary malignancy (excluding HCC) respectively. Trivizakis *et al*[54] trained both a 2D and 3D CNN to classify liver tumours into primary and metastatic classes. The 2D network took the axial slices as input, whereas the 3D network took the abdominal volume. Unlike the papers above, they then used the features learnt

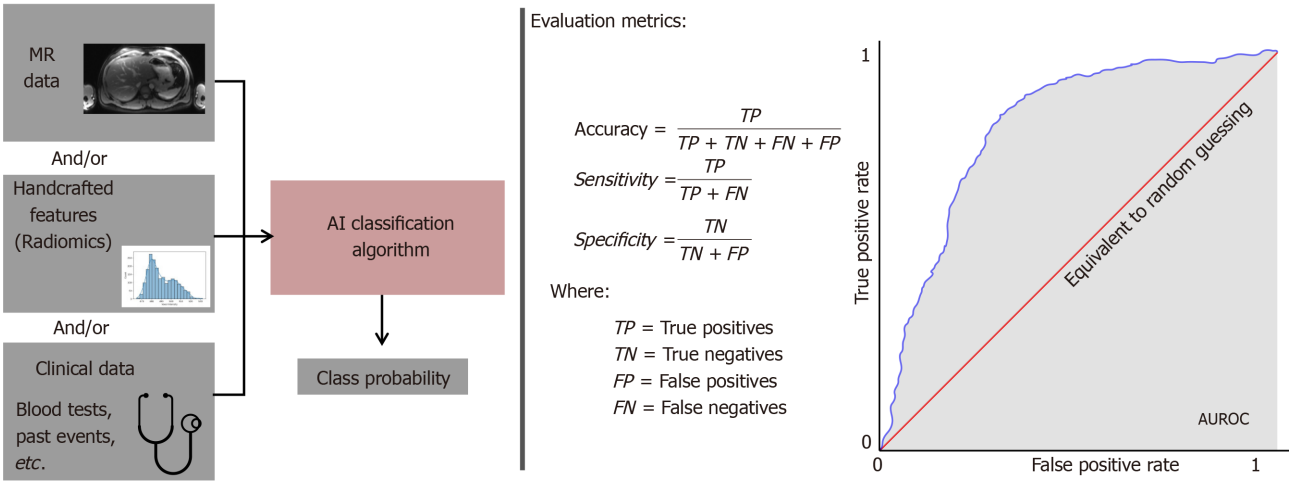

Figure 2 Classification algorithms and their performance metrics. Artificial intelligence classification algorithms use the combination of data provided to them and output a class probability. They are often evaluated according to the metrics on the right. MR: Magnetic resonance; AUROC: Area under the receiver operating characteristic curve.

during the training of these networks to train a support vector machine (SVM), a non-CNN based AI approach. They achieved an accuracy of 83% in the SVM trained on the features from the 3D network, and 67.4% in the SVM trained on the features from the 2D network. When not using the SVM as an additional step, they achieved an accuracy of 85.5% in the 3D network, with unreported accuracy in the 2D network though they conclude that the 3D model outperforms this. It shows that the inclusion of additional data, in this case more slices as a volume, often leads to an increased performance in the network performance. Though that does not always hold true, as in the study by Hamm *et al*[51] where the inclusion of all phases of a gadoxetic acid-enhanced MRI scan produced worse results that selected phases. It is important that the addition of data is performed with care, such that you are not adding more noise to the data.

Radiomic-based approaches have also been shown to be successful in classifying detected tumours into potential classes. Liu *et al*[55] extract radiomic features from tumours manually segmented from Gd-EOB-DTPA-enhanced liver MR images. These features are input into two support vector machines (SVM), with the first classifying into combined hepatocellular cholangiocarcinoma (cHCC-CC) or non-cHCC-CC, and the second classifying into HCC and non-HCC. They achieved a mean AUROC of 0.77 ± 0.19 and 0.81 ± 0.13 for the first and second methods respectively. Conversely, radiologists misdiagnosed cHCC-CC as HCC or CC in 69% of cases. With the model accuracy higher than that of the radiologists, having the model available as an additional tool for radiologists would help improve the diagnostic accuracy. Lewis *et al*[56] used extracted radiomic features from diffusion weighted imaging (DWI) MR, combined with LI-RADS category, to classify whether a tumour is HCC or another primary liver cancer such as intrahepatic cholangiocarcinoma (ICC) and combined HCC-ICC. Using binary logistic regression, they achieved an AUROC of 0.9 and 0.89 when compared to two observers. This is comparable in performance to similar LI-RADS based studies above, but without the expertise an training time needed for a large neural network. Another radiomic based study, by Wu *et al*[57], similarly extracted radiomic features from lesions detected in T2-weighted and DWI images. They achieved a similar AUROC score of 0.89, when compared to Lewis *et al*[56], by also using logistic regression on their extracted features. They additionally showed that their model outperformed a junior radiologist with 2 years' experience and rivalled a senior radiographer with 10 years' experience. Other radiomic based studies have shown similar performance, when applied to tumour classification, when using a variety of MR sequences and often the addition of additional non-MR features such as BMI and medical records[58,59].

Liver disease staging and response

Liver fibrosis staging is used clinically in predicting the prognosis of liver diseases and helps in determining the appropriate action to take in treatment[60]. Several approaches of AI applications on liver MR have been described for the assessment of liver fibrosis. Hectors *et al*[60], used a VGG16 network to predict the fibrosis stage from F1-4 using Gd-EOB-DTPA-enhanced liver MR images. The network, which was

pretrained on image net with only the last few layers being trainable, predicted a class from F1-F4, F2-F4, F3-F4 and F4, achieving an AUROC of 0.77, 0.91, 0.91 and 0.85 respectively, showing good diagnostic ability. This was comparable to the use of MRE with no significant difference between MRE and the use of deep learning methods for fibrosis prediction. The diagnostic performance of combined MRE and AI classification of contrast enhanced MRI was better overall at 0.87, 0.93, 0.95 and 0.87 for F1-F4, F2-F4, F3-F4, and F4 respectively, but was not significantly better than MRE alone. Schawkat *et al*[61] also sought to quantify the liver fibrosis from T1- or T2-weighted MR images. To do this, they did an initial texture analysis, to extract handmade features from the data. These handmade features underwent some pre-processing, then were input into an SVM which was trained to output whether the patient had a high fibrosis score, 3-4 on a standardized scale using multiple different scoring approaches, or low fibrosis score, 0-2. They achieved an AUROC of 0.82 for T1 and an AUROC of 0.57 for T2. However, when applied to MRE they achieved an AUROC of 0.92. This shows that machine learning methods are only as good as the data that is input. In the above two cases, MRE contains the information needed to output an accurate classification. However, MRE is often expensive and limited to highly funded MRI centres, therefore it is still important that techniques that don't use MRE are explored and developed while uptake of MRE is limited. The two studies above have shown in this case that deep learning methods are outperforming more traditional methods, however the use of two different scanning sequences doesn't allow for a direct comparison, as any difference in performance could be down to the data provided. Yasaka *et al*[62] also used a CNN with contrast enhanced MR images and clinical information as input, to stage liver fibrosis. They achieved AUROCs of 0.84, 0.84 and 0.85 for classifying into cirrhosis, advanced fibrosis and substantial fibrosis respectively. They were unable to differentiate fibrosis scores as well as Hectors *et al*[60] with similar methods, likely due to the Hectors study pre-training on Image Net data and so compensating for the small datasets that these study have to train on. Radiomics combined with a logistic regression model has also been used to classify into liver fibrosis scores. Park *et al*[63] extracted radiomic features from Gd-EOB-DTPA-enhanced liver MR images, and used these to classify into F0 to F4 fibrosis stages, achieving an accuracy of 80.3% in classifying F2-F4, 80.3% in F3-F4 and 81.3% in F4. Gallego-Duran *et al*[64] used radiomics approaches, combined with a logistic regression classifier, on non-contrast enhanced MRI scans to define the NASH-MRI and fibro-MRI score that could diagnose non-alcoholic steatohepatitis and advanced fibrosis with an AUROC of 0.83 and 0.85 respectively. He *et al*[65] utilised an SVM to classify patient groups into MR elastography liver stiffness measurement of ≤ 3 kPa and ≥ 3 kPa as surrogates of low and high fibrosis burden respectively, They combine radiomic features derived from T2-weighted images, with clinical data such as blood scores, BMI and their medical history. The SVM achieves an accuracy of 81.8% with an AUROC of 0.84.

Portal hypertension is one of the complications of liver fibrosis and develops in late stage disease. Portal hypertension is usually assessed by the hepatic vein pressure gradient with a gradient of ≥ 10 mmHg signifying "clinically significant portal hypertension (CSPH)" which is associated with a higher risk of adverse outcomes. AI techniques to identify CSPH have been applied to CT and MR images with some promising results. Liu *et al*[66], used a CNN to predict the presence of CSPH in both the liver and the spleen, which were then input into a logistic regression model to output an overall prediction. They achieved an AUROC of 0.940 in their test set when classifying between CSPH and non-CSPH.

Zhao *et al*[67] extracted radiomics from four MRI acquisitions (fat suppressed T2-weighted images, arterial phase, portal venous phase and delayed phase of contrast enhanced imaging) to predict early recurrence of intrahepatic mass-forming cholangiocarcinoma (IMCC). This was combined with biomarkers from histology studies, and input into a logistic regression model, to achieve an AUROC of 0.949 in predicting early recurrence of IMCC. This would assist in personalising a treatment plan for each patient. Reimer *et al*[68] utilised a radiomics approach combined with logistic regression, to predict the response to therapy in patients with liver metastases. They classified patients into two classes of stable disease and progressive disease based on features extracted from dynamic contrast enhanced MR images taken at a mean of 2.2 d after transarterial radioembolization. They achieved an AUROC of 0.73 and 0.76 in the radiomics extracted from the arterial and venous phase respectively. Chen *et al*[69] used a combination of clinical data and radiomics with decision trees to predict the immunoscore of HCC pre-treatment and therefore its response to therapy. Their best model, when using all the clinical and radiomics data, achieved and AUROC of 0.926 when classifying into high (≥ 3) and low (≤ 2) immunoscores. Finally Kim *et al*[70] utilise random forests with radiomics to predict the postoperative reoccurrence time of

single HCC. Additionally, they combine their radiomics model with a clinicopathologic model. When evaluating their model using Harrell c-index, a measure where higher than 0.5 has predictive value, their combined model was 0.716. This was better than the current clinicopathologic model (0.696), however the difference was not significant. As Kim *et al*[70] and Zhao *et al*[67] use different performance metrics, it is hard to compare their ability in tumour reoccurrence, regardless of each study focusing on different tumour types. It is important that these studies, where possible, quote similar metrics so that future researchers can determine which one is best for their task.

IMAGE SYNTHESIS

It is often the case that, when training an AI model, we are limited by the data that we have available. This is also true in healthcare settings when making clinical decisions. The simplest way to rectify this lack of data is to find more, however, this is not always possible due to many reasons both medical and logistical. The field of image synthesis or domain transfer seeks to address this. These algorithms can generate synthetic MR data based on information they are provided with, allowing this data to be either used in a setting where you might not have access to a particular technique, *e.g.*, hospitals without an MR scanner, or used to improve AI algorithms by giving it more data to train on. A common group of networks for image synthesis are conditional generative adversarial networks (cGAN). A cGAN combines a generator network, *e.g.*, a U-Net for generating the new MR image, and a discriminator network, a classification network to distinguish between real ground truth MR image and fake generated image. These networks compete against each other. The generator seeks to create an output that the discriminator believes is anatomically plausible, and the discriminator seeks to detect the output of the generator. This adversarial training often leads to improved results in segmentation or domain transfer tasks.

Liu *et al*[71] developed a cGAN to generate CT images from T1-weighted MR images, also to aid clinicians in radiotherapy treatment planning. They achieved a low mean absolute error of 72.87 HU in their generated CT scans. Jiang *et al*[72] used a cGAN to perform the opposite transformation of synthesising MR images from CT images in order to improve segmentation maps of organs at risk in MR for radiotherapy planning. They achieve a DICE score of 0.91, 0.92 in the liver when applied to real non-synthesised T2-weighted images and T1-weighted images respectively.

GANs were also implemented in Zhao *et al*[73] study to synthesise contrast enhanced MR images from non-contrast enhanced images, in order to improve tumour detection. They combined this with an additional tumour detection CNN which was applied to synthetic images in order to help improve the quality of the synthesised image, and the detection of tumours. The combined synthesis and detection networks achieved a classification accuracy of 91.3% when classifying between healthy and hemangioma present, 88.4% when classifying between healthy and HCC present and 89.2% when classifying between hemangioma and HCC. This combination of networks not only allows for accurate detection of tumours, but also supersedes the need for a contrast enhanced scan, while still giving the radiographer a proposed contrast scan to aid in their diagnosis.

ARTEFACT DETECTION

Motion detection and removal

Artefacts can occur in many forms in MRI scans, from patient induced breathing artefacts to scanner related field susceptibility artefacts. AI based methods, as shown with classification and image synthesis, have the potential to detect these artefacts and generate artefact free images which can then be used in a clinical setting. Motion is the dominating artefact present in many MR techniques. Breath holding is necessary in most scanning protocols to reduce movement artefacts. New scanning sequences are specifically designed to be shorter (*i.e.*, shorter breath-holds) and produce the same output in order to reduce these problems[74,75]. However, motion still occurs even when these steps are implemented. AI offers us the opportunity to detect, so that re-acquisition of the scans can occur; remove, so that a motion degraded scan can be used clinically; and predict, so that free-breathing methods can be used with optimal

acquisition.

Romaguera *et al*[76] have developed a spatial transformer network that takes an image sequence and predicts the next image in the sequence with an error in vessel localisation of 0.45 ± 0.55 mm when 320 ms has passed. This rises to 0.77 ± 1.36 mm at 1.6 s, but still allows the accurate prediction of frames in the future based on what has been acquired so far. This would be useful in predicting when to acquire a scan so that any data is motion free, and can also be useful in the MR-Linac systems so that radiotherapy is only applied to any tumours within the liver, reducing damage to the organs. Esses *et al*[77] used a CNN, similar to those presented in the classification section, to classify artefact degraded images into a quality score of diagnostic to non-diagnostic. They achieve a concordance rate with two trained radiographers of 79% and 73%. Tamada *et al*[78] utilise a CNN to reduce motion artefacts caused by respiratory motion in DCE-MRI. They generated simulated motion data from the ground truth data and then trained a network to predict the residual between that and collected ground truth data. They then tested on non-simulated motion degraded data, with radiographers rating on a scale of no artefact (0) to non-diagnostic (5). The output of the network was better by a mean score of 0.37 and 0.35 when rated by two radiologists. Kromrey *et al*[79] utilised the same CNN to reduce motion artifacts in arterial phase contrast enhanced MRI by 0.56 on average, on a scale of no artifact (0) to severe artifact (4). Küstner *et al*[80] try both a GAN and a variational autoencoder to remove motion artefacts from both brain and abdominal liver scans. The GAN was able to reduce the presence of motion artefacts by 67% and 65% when evaluated by two experienced radiologists. The same group had also previously used a patch based CNN to predict the amount of motion in a specific region of an image, achieving an accuracy of 72% ± 5% in classifying the images into motion from no motion to strong motion[81]. As many of the above techniques rely on radiologist qualitative assessment, they can be heavily biased by the skill of those doing the check, and as such can't be compared well as the improvement is highly subjective. More importantly though all studies showed an improvement when comparing before and after, and all the radiologists were suitably blinded. Oh *et al*[82] used an unsupervised GAN to correct for motion in Gd-EOB-DTPA-enhanced MR images. They did this by down sampling k space in each input image and regenerating the fully sampled image. This would train the network to reconstruct the missing data from what it is given, and so generate data without artefacts if clean data is given. They then apply it to artefact degraded images, achieving an improvement from 3.20 ± 1.28 to 1.95 ± 0.94 on a scale of 1 (no artefacts) to 5 (non-diagnostic) when applied to artefact degraded images. Wang *et al*[83] used a two-step approach by segmenting the liver from MR scans using a U-Net, then using this to extract patches from the liver which are classified into diagnostic and non-diagnostic. They achieved a DICE of 0.90 ± 0.05 in their liver segmentation, and an AUROC of 0.911 [95% confidence interval (CI): 0.882-0.939, $P < 0.05$] when classifying. The predictive performance when using patches extracted from the liver was better than trying to directly classify from the whole image (AUROC of 0.802, 95%CI: 0.759-0.846, $P < 0.05$). Though this final method shows a greater performance when using patches, we believe it is unlikely that each individual patch was classified for whether it was diagnostic or non-diagnostic, therefore this process would fail if applied to artefacts which only have affect a sub region of an image.

IMAGE REGISTRATION

Registration of two MR images into a shared cartesian space is an important step in allowing comparisons to be made. This could be longitudinal comparisons in a single participant in order to stage disease progression and treatment response, or it could be latitudinal comparisons within a patient cohort for research studies. Additionally, the registration of two different modalities is important when differing but complimentary clinical information is in different scan types such as CT and MR. In all cases, the manual task of registering images can be time consuming and is often composed of rigid body transformations and as such it is hard to compare between two participants of differing dimensions. AI methods can help solve these issues by introducing fast, reliable non-rigid deformation techniques for image registration.

Kuznetsova *et al*[84] looked into the use of a commercial AI based registration software for the registration of CT and MRI. They assessed the performance of their registration for three different seed points, using the liver contour, using an internal liver structures such as the inferior vena cava (IVC) or portal region (PR), and using

internal liver structures along with the liver contour. They achieved the highest performance when using just the liver contour, with a DICE score of 0.89 in the liver segmentation and 0.76 in the IVC segmentation when compared between MR and CT segmentations. As they used commercial software, we are not able to comment on the model used, however it does show that these methods have already been developed for those who need them. Fu *et al*[85] similarly assessed the performance of their bespoke MRI and CT registration CNN by assessing the DICE score between the two segmentations. They achieved a score of 0.93 ± 0.02 in the whole liver segmentation, outperforming the previous study.

CONCLUSION

Current challenges and future directions

Though the benefits of AI algorithms in Liver MRI have been displayed above, there are also many obstacles in the way of application in the clinic where they can have an impact. The first and foremost is that of open data, *i.e.*, the access to large publicly-available clinical databanks. Many of the studies above have used internal datasets which are specific to a certain hospital or patient group. Though performing well in their specific setting, they are limited in scope and generalizability due to un-modelled variations across different hospitals. Additionally, these datasets are rather small for the purpose of training ML algorithms which perform better when trained on more data, and will thus benefit from a larger suitable dataset. However, of the large datasets available, such as UKBiobank, most are focused on healthy volunteers and not clinically relevant patient cohorts. This means any AI algorithm trained on these datasets must be applied with care and knowledge of their limitations. By pooling datasets of clinical patients, the AI algorithms will both perform better, due to the increased data to learn from, and be universally applicable, due to the increased variation.

The second challenge will be overcoming scepticism towards AI algorithms. Deep learning algorithms are often termed "black boxes", due to their lack of interpretability. This is problematic when the model fails, as it is impossible to reason why. Therefore, care must be taken to apply models in their correct setting, *i.e.*, on data that fits within the distribution of that which the model was trained and tested. If interpretability is desired and a-priori knowledge and physical/biological assumptions are to be incorporated in the model, then traditional ML methods should be used, as they allow to select features and focus on ROIs more easily than with DL. Radiomics is an example of this, as you are able to determine how the model you use weighs the importance of each input feature. From this you can start to reason why the model might fail. As with deep learning methods though, when used in conjunction with radiologists, it can be a vital tool in getting the cases which are traditionally missed.

Finally, the third challenge is translating these networks into clinical workflows. The above papers have shown an ability to either speed up or achieve a radiologist level accuracy in many tasks they perform. However, until recently, there was no standard protocol into getting these networks approved for mainstream use. In April 2019, the US Food and Drug Administration published a paper on the proposed regulatory framework for AI/ML based software as a medical device and have since developed new rules and processes for approval of AI assisted software[86]. Since these new rules have been implemented, multiple AI methods have been given approval, but their wide spread use is still limited. Therefore, developing a framework for widespread distribution should be implemented.

If the above challenges can be addressed, the techniques shown in this review and those yet to be invented can positively transform many aspects of medical imaging in years to come.

Abstract

The prognosis of pancreatic cancer is poor with the overall 5-year survival rate of less than 5% changing minimally over the past decades and future projections predicting it developing into the second leading cause of cancer related mortality within the next decade. Investigations into the mechanisms of pancreatic cancer development, progression and acquired chemoresistance have been constant for the past few decades, thus resulting in the identification of human nucleoside transporters and factors affecting cytotoxic uptake *via* said transporters. This review summaries the aberrant expression and role of human nucleoside transports in pancreatic cancer, more specifically human equilibrative nucleoside transporter 1/2 (hENT1, hENT2), and human concentrative nucleoside transporter 1/3 (hCNT1, hCNT3), while briefly discussing the connection and importance between these nucleoside transporters and mucins that have also been identified as being aberrantly expressed in pancreatic cancer. The review also discusses the incidence, current diagnostic techniques as well as the current therapeutic treatments for pancreatic cancer. Furthermore, we address the importance of chemoresistance in nucleoside analogue drugs, in particular, gemcitabine and we discuss prospective therapeutic treatments and strategies for overcoming acquired chemoresistance in pancreatic cancer by the enhancement of human nucleoside transporters as well as the potential targeting of mucins using a combination of mucolytic compounds with cytotoxic agents.

Key Words: Pancreatic cancer; Gemcitabine; Human nucleoside transporters; Human equilibrative nucleoside transporters; Human concentrative nucleotide transporters; Mucins

Core Tip: Pancreatic cancer continues to be one of the leading causes of cancer-related mortality worldwide, with prevalence expected to increase drastically within the next decade primarily due to difficulties in diagnosis and acquired resistance to chemotherapeutic drugs. Due to this, in-depth work is extremely important for the future diagnosis and treatment of the disease. Human Nucleoside Transporters have been identified as a key target in not only diagnosis but also overcoming chemoresistance. Here, we summarize the information currently available on Pancreatic Cancer and the role of Nucleoside Transporters in chemoresistance.

INTRODUCTION

Pancreatic cancer is the seventh leading cause of cancer-related mortality[1], and is ranked as the 14th most common cancer worldwide[2]. The prognosis of pancreatic cancer is often poor with an average five-year survival rate of less than 5%[3]. This poor prognosis has been attributed, in part, to the difficulties in early-stage detection, advancement of disease at the time of diagnosis, frequent recurrence and lack of effective treatment therapies specifically targeting tumour cells[4,5].

Pancreatic ductal adenocarcinoma (PDAC), which accounts for > 90% of all pancreatic cancer cases is characterized by dense desmoplastic stromal development proximal to cancerous tissue, as well as the aberrant expression of mucins and nucleoside transporters[6,7]. Three different preneoplastic lesions of the pancreatic duct have been identified as precursors of PDAC those being, pancreatic intraepithelial neoplasia (PanIN), mucinous cystic neoplasm (MCN) and intraductal papillary mucinous neoplasm (IPMN)[3].

PanIN accounts for 85% of PDAC cases and is categorised into PanIN1A, PanIN1B, PanIN2 and PanIN3[8]. Prior to PanIN progression, normal pancreatic ductal cells express mucin proteins MUC1/5AB/6/17 which have been identified in assisting cancer cell in evading immune systems[3]. PanIN1A/1B is described as hyperplasia without dysplasia, followed by PanIN2 with dysplasia at variable rates and a loss of polarity and finally PanIN3, representative of an in-situ carcinoma. For all PanIN, increased expression can be seen for MUC1/6/16 and neoexpression is observed for MUC3/4/5AC (Figure 1)[4,9].

MCN and IPMN account for the remainder 15% of PDAC cases, with MCN characterized as cyst forming pancreatic epithelial neoplasms that produce mucin, have a distinct stroma type, and have a broad spectrum of dysplasia. Importantly, MCN's are also representative of early Kras mutations as well as late oncogene SMAD4 and proto-oncogene TP53 inactivation and lastly, increased MUC1 expression and neoexpression of MUC2/5AC [2-4].

IPMN which originates from the main pancreatic duct is characterized by the increased secretion of select mucins (MUC1/6), neoexpression of MUC2/4/5AC, and a large dilation of the ducts or cysts formation. Much like MCN, IPMN presents with a Kras mutation and the inactivation of TP53 and P16/CDKN2A. MCN and IPMN may further progress into adenocarcinoma where an increased expression of MUC1/6 and neoexpression of MUC3/4/5AC/5AB/7/13/16/17 is observed (Figure 1)[3,4].

The aim of this review is to outline the role of nucleoside transporters in pancreatic cancer progression and their contribution to chemotherapeutic drug resistance. This review will also examine the current treatments and therapies to overcome cancer progression and acquired resistance to nucleoside analogue drugs, specifically, gemcitabine.

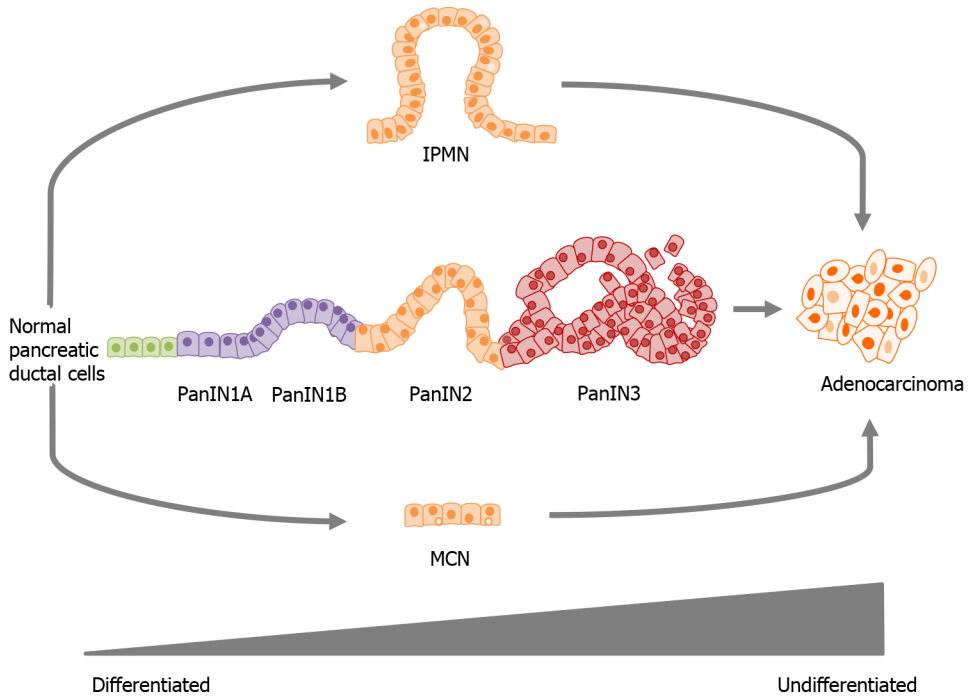

Figure 1 Pancreatic cancer progression beginning with normal pancreatic ductal cells which express MUC1, MUC5AB, MUC6, MUC17, and MUC20. Pancreatic ductal cells progress to hyperplasia (PanIN21A/1B) with columnar cells, followed by dysplasia (PanIN2) with a loss of polarity, papillary and finally In-situ carcinoma (PanIN3) with a loss in cell polarity, papillary, budding off and mitosis. An increased expression of MUC1, MUC6, MUC16 and neoexpression of MUC3, MUC4, and MUC5AC can be seen in pancreatic intraepithelial neoplasia's. Pancreatic ductal cells also progress into MCN which has an increased expression of MUC1 and the neoexpression of MUC2 and MUC5AC. Early Kras mutation as well as late SMAD4 and TP53 inactivation is seen in both PanIN and MCN. Finally pancreatic ductal cells can progress into IPMN which are mucin producing neoplasms that present with an increased expression of MUC1 and MUC6 as well as neoexpression of MUC2, MUC4 and MUC5AC. IPMN also presents with a Kras mutation and the inactivation of TP53 and P16/CDKN2A. IPMN and MCN further progress to adenocarcinoma where MUC1, and MUC6 expression is increased and MUC3, MUC4, MUC5AC, MUC5AB, MUC7, MUC13, MUC16 and MUC17 are neoexpressed[2-4,68]. IPMN: Intraductal papillary mucinous neoplasm; PanIN: Pancreatic intraepithelial neoplasia; MCN: Mucinous cystic neoplasm.

INCIDENCE

The incidence rates of pancreatic cancer have significant variation between countries; however, the higher rates can be seen in developed countries (North America and Europe) compared to developing countries (South Central Asia and Africa). World-wide incidence and mortality rates correlate with ageing and a higher prevalence is observed in men compared to woman. In western societies, the incidence of pancreatic cancer has been steadily increasing with predictions that by 2030 it will be the 2nd greatest cause of death related to cancer in the United States[1,2]

Despite the cause of pancreatic cancer being multifactorial and complex, several factors whether modifiable or non-modifiable have been identified as having a direct association. Non-modifiable factors include age, sex, ethnicity, blood group, family history, genetic susceptibility, gut microbiota, and diabetes. The modifiable risk factors that have been identified are smoking, alcohol consumption, obesity, chronic pancreatitis, dietary factors, and helicobacter pylori infections[1,2,10].

DIAGNOSIS

There are significant challenges with the diagnosis of pancreatic cancer with most patients presenting with late-stage tumour development at the time of diagnosis. The reasons of late-stage progression diagnosis are multi-factorial and therefore, several factors must be assessed[1,10]. Firstly, the initial stage of pancreatic cancer is, for the most part, clinically silent. This results in patients not presenting with symptoms until being in advanced stages of disease. Presenting symptoms are non-specific and can include jaundice, dark urine, abdominal pain, acholic stools and pruritus. Due to the broad range of non-specific symptoms, there are several diseases that require differentiation, including but not limited to: pancreatitis, gastritis, abdominal aortic aneurysm, and pancreas. As a result, diagnosis can be missed or delayed which results in

pancreatic cancer being the most commonly detected tumour during autopsy studies [2,10,11].

Currently, several diagnostic tools are available for the diagnosis of pancreatic cancer, such as magnetic resonance imaging (MRI), abdominal ultrasonography, endoscopic ultrasound-guided fine-needle aspiration and the standard for staging and diagnosis tri-phase pancreatic protocol CT. Additionally, the cancer biomarker serum cancer antigen 19-9 (CA 19-9) is the only approved marker for pancreatic cancer and is used to assist in diagnosis and to predict patient prognosis and recurrence post resection. Unfortunately, the CA19-9 biomarker is not tumour-specific and therefore is not capable for use as a screening tool for the patients that are asymptomatic[1,2,10].

Recently, biomarkers for early diagnosis have been investigated, including plasma-based metabolite panels, increased concentrations of volatile organic compounds in exhaled air, DNA mutations such as p53 in pancreatic juice, and tumour markers such as CA125, CA242, CEA, NSE[2,12]. Despite continued investigation into diagnostic biomarkers, the lack of a specific and validated biomarker as well as sensitive screening programs remains a major issue.

TREATMENT

The treatment strategy for pancreatic cancer is dependent on the primary tumour resectability, which is defined by the absence of distance metastasis as well as the locoregional anatomical contacts allowing for a R0 resection. For patients eligible, the primary treatment that presents a possible cure for pancreatic cancer is surgical resection in addition to chemotherapy[2,13].

The surgical options for achieving surgical resection are open Pacnreatico-duodenectomy and total or distal pancreatectomy, either open or laparoscopic. The surgical method employed is dependent on the tumour or tumour's anatomical location. It is important to mention that the survival rates following surgical resection alone are low with approximately 10% after 5 years. Despite observed benefits when adjuvant therapies are utilised, the recurrence rates remain high, with a 2-year relapse of approximately 70%[2,13,14].

Unfortunately, as previously mentioned, at the time of diagnosis approximately 90% of patients present with tumours that are locally advanced or metastatic, making them ineligible for surgical resection. The only options for these patients are the management of jaundice, system control, palliative radiotherapy, and chemotherapy. A variety of chemotherapeutic drugs are used to treat pancreatic cancer including Oxaliplatin, Paclitaxel, Leucovorin, Irinotecan, Doxorubicin, and 5-fluorouracil (5-FU) (Table 1)[15,16]. Currently, the standard of care for patient's ineligible for surgical resection remains FOLFIRINOX (Fluorouracil, Oxaliplatin, Leucovorin and Irinotecan) or Gemcitabine (2′,2′-diflurodeoxyxytidine) either in combination with Paclitaxel or as a single agent[3,4,14,17,18].

The most effective treatment regimen is guided by patient fitness, FOLFIRNOX is administered to fit patients with tumours in the tail, body, and head of the pancreas, with treatment resulting in significant longer cancer-specific, metastasis-free, disease-free, and overall survival (11.1 mo) when compared to Gemcitabine (6.8 mo). However, a significantly increased risk of adverse effects and complications is seen in patients that receive FOLFIRNOX when compared to Gemcitabine. Gemcitabine +/- Capecitabine is relative safe compared to other chemotherapy options and is therefore the standard treatment for patients that are ineligible for FOLFIRNOX treatment regimens. It has been found to provide improved system control, a higher response rate and a greater overall survival rate compared to 5-FU (4.41 mo)[2,14,19]. Despite the poor survival outcomes, 5-FU is used for periampullary tumours primarily due to insufficient evidence for other chemotherapeutic agents specifically targeting said tumour types[2]. Due to the clinical benefits of Gemcitabine compared to other treatment regimes, it has become the standard reference agent in the first line treatment choice of pancreatic cancer[20,21]. This shows that the patient benefit to current treatments is minimal, hence identifying better targets and more efficient treatments is required.

GEMCITABINE

Gemcitabine is a cytotoxic pyrimidine nucleoside analogue that has been utilized as a chemotherapeutic agent for not only pancreatic cancer but for a variety of solid

Table 1 The current chemotherapeutic and chemoprotectant agents used to treat pancreatic cancer, their classification, action, and chemical structure

Drug	Classification	Action
Gemcitabine (Gemzar)	Antimetabolite	Pyrimidine antagonist
Doxorubicin (Rubex)	Anthracycline Antibiotic	Cell-cycle specific antagonist
Fluorouracil (5-FU)	Antimetabolite	Pyrimidine antagonist
Paclitaxel (Abraxane)	Plant alkaloid, Taxane, Antimircotubule	Inhibition of cell microtubule structures
Oxaliplatin (Eloxatin)	Alkylating agent	Cell-cycle non-specific antagonist
Leucovorin (Folinic acid)	Chemoprotectant	Enhancement anti-cancer effects
Irinotecan (Camptosar)	Plant alkaloid, Topoisomerase I inhibitor	Camptothecan analogs
Erlotinib (Tarceva)	Tyrosine kinase inhibitor	Ant-EGFR
Cetuximab (Erbitux)	Biologic	Anti-EGFR
Bevacizumab (Avastin)	Biologic	Anti-VEGF

tumours and more recently in certain lymphomas[22]. Due to the hydrophilic nature of gemcitabine, passive diffusion is slow through cellular membranes and therefore requires transportation into cells by specialized integral membrane proteins known as human nucleotide transporters (NTs)[16,23,24].

To exert clinical action, gemcitabine needs to be metabolized and requires multiple kinases to initiate serial phosphorylation. Once transported intracellularly, gemcitabine (dFdC) is catalyzed by deoxycytidine kinase (dCK) resulting in gemcitabine monophosphate (dFdCMP) and is then phosphorylated to gemcitabine diphosphate (dFdCDP) by nucleotide monophosphate kinase (NMPK) and finally gemcitabine triphosphate (dFdCTP) by nucleoside-diphosphate kinase (NDPK). The successful uptake and metabolism of gemcitabine to results in the inhibition of DNA repair and replication (Figure 2). Finally, Gemcitabine or its phosphorylated metabolites are exported into the extracellular space by multidrug resistance protein 5 (MRP5). An additional mechanism that gemcitabine exerts actions is self-potentiation by the inhibition of enzymes associated with deoxynucleotide metabolism[22,25-27].

Although gemcitabine and other chemotherapeutic drugs have been proven effective among patients with various stages of pancreatic cancer, the effectiveness of gemcitabine is severely limited due to the development of chemoresistance[19]. Chemoresistance is simply the ability of cancer cells to survive or evade therapeutics and can be intrinsic or acquired during treatment[28]. Chemotherapeutic drug resistance is widely common in pancreatic cancer with less than 30% of patients showing improvement post treatment and previous studies have identifying a heightened resistance to gemcitabine in comparison to other chemotherapeutic drugs in pancreatic cancer cells[19,29,30].

To date, several mechanisms have been identified as contributors to acquired gemcitabine resistance in pancreatic cancer due to the drugs rapid metabolism and hydrophilic nature including increased levels of ribonucleotide reductase subunit II and II (RRM1/2), mucins, deoxycytidine kinase (dCK), as well as concentrative and equilibrative nucleoside transporters (hCNT/hENT). Regrettably, many of these mechanisms are complex and the identification of their specific roles and consequences in chemoresistance remains unclear[19,31,32]. As nucleoside transporters are required for gemcitabine uptake into pancreatic cancer cells, they have been identified as key contributing factors to chemoresistance which will be discussed in the following sections.

NUCLEOSIDE TRANSPORTERS

Nucleoside transporters (NTs) are a group of membrane proteins that transport the analogs of both natural and synthetic nucleosides that act as anticancer agents across

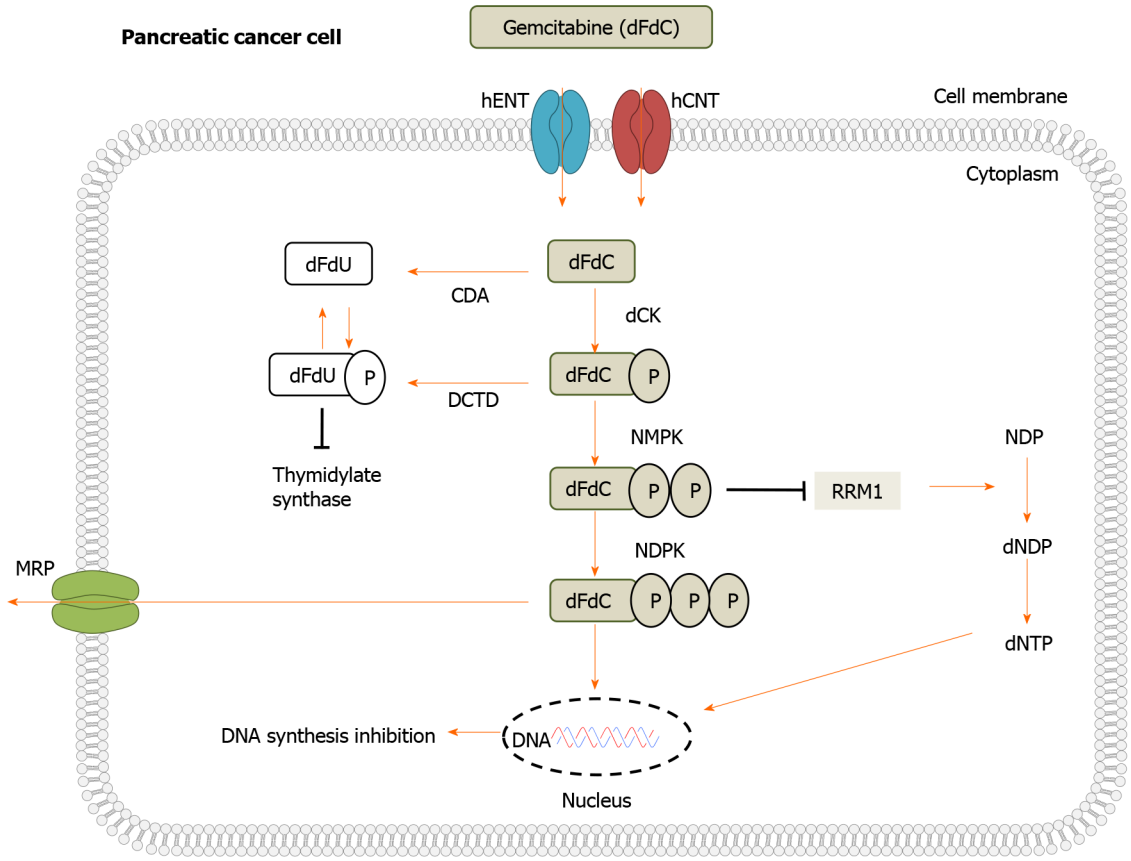

Figure 2 Schematic representation of Gemcitabine transport, metabolism, intracellular activation, and deactivation. Gemcitabine (dFdC) is transported into the cell by nucleoside transporters: human equilibrative nucleoside transporter (hENT) human concentrative nucleoside transporter (hCNT) and is then catalysed by deoxycytidine kinase (dCK), which results in gemcitabine monophosphate (dFdCMP). It is then phosphorylated by nucleotide monophosphate kinase (NMPK) to gemcitabine diphosphate (dFdCDP). Finally, it is phosphorylated into gemcitabine triphosphate (dFdCTP) by nucleoside-diphosphate kinase (NDPK). Once metabolism is completed, gemcitabine enters the DNA resulting in the inhibition of DNA repair and replication. Gemcitabine or its phosphorylated metabolites are finally exported into the extracellular matrix by multidrug resistance protein 5 (MRP5)[22,26,27,41,69]. RRM1: Ribonucleotide reductase; CDA: Cytidine deaminase; DCTD: Deoxycytidylate deaminase; NDP: Nucleotide diphosphate.

the membranes of vesicles and cells. There are two classes of transporter proteins that are encoded by two different solute carrier families (SLC), SLC28 known as human concentrative nucleoside transports and SLC29 also known as human equilibrative nucleoside transporters[33].

There are three members of the human concentrative nucleoside transporter family including, hCNT1, hCNT2 and hCNT3. These transporters mediate the unidirectional co-transport of Na+ and/or H+ and nucleosides into cells at a 1:1 coupling ratio for hCNT1 and hCNT2 and a 2:1 ratio for hCNT3. Initially, hCNTs were believed to be expressed only in polarized epithelia, however, recent studies have identified the expression to be considerably broader. These proteins favour nucleoside transepithelial flux as they present at an ideal localization on the apical side of polarized epithelial tissue[33].

Human equilibrative nucleoside transporters include four members, hENT1, hENT2, hENT3 and hENT4. These proteins are bio-directional and mediate the facilitative transport of nucleosides and select hENTs also facilitate the transportation of nucleobases dependent on their concentration gradient. Except for hENT4, hENT proteins can transport both pyrimidines and purines, they have a broad permeant selectivity, and are widely distributed in a variety of cell types. Despite their similarities, hENT1, 2 and 3 differ in in nucleoside specificity, however, they all present with a lower substrate affinity then the members of the hCNT family[16,23,33].

NUCLEOSIDE TRANSPORTERS AND PANCR-EATIC CANCER

Due to the importance of gemcitabine in pancreatic cancer treatment and the requirement of transporters for drug uptake, extensive research has been undertaken

on transports and their role in tumorigenesis. Alterations in the expression of transporters have been identified in the progression of normal pancreatic cells to malignant pancreatic cancer cells. Despite significant efforts of researchers to identify the roles transporters undertake in substrate translocation and their functions in cell physiology, more research evaluating the clinical application of transporters as potential biomarkers or therapeutical targets is required. The primary transporter that efficiently mediates the cellular uptake of gemcitabine is hENT1 (SLC29A1), however, evidence suggests minor cellular uptake of gemcitabine *via* hENT2 (SLC29A2), hCNT1 (SLC28A1) and hCNT3 (SLC28A3)[15,16,23,26]. Each transporter undertakes specific functions (Table 2), and each will be discussed as follows:

HUMAN EQUILIBRATIVE NUCLEOSIDE TRANSPORTERS IN PANCREATIC CANCER

hENT1

The hENT1 protein is a transmembrane glycoprotein that is localized to plasma membranes and is widely expressed with a broad selectivity for pyrimidines and purines[16]. In a healthy pancreas, hENT1 has medium expression in exocrine glandular cells and low expression in islets of Langerhans. In comparison, pancreatic tumours present with a decrease in hENT1 expression[34].

Previous clinical studies on pancreatic cancer patients and various cell lines have identified that that low levels of hENT1 expression on pancreatic tumour cells correlates with a significant reduction in progression free survival (PFS) and disease-free survival (DFS) when compared to patients with medium to high levels of hENT1 expression[7,35]. If gemcitabine is incapable of cellular uptake due to a lack of transportation into the cell, it is unable to inhibit cell growth and therefore the abundance of hENT1 may contribute to gemcitabine resistance as a result of reduced intracellular build-up. In fact, previous studies reported the inhibition of hENT1 in cancer cell lines with NBMPR (nucleoside analogue nitrobenzylmercaptopurine ribonucleoside - a potent inhibitor of hENT1) resulted in cell chemoresistance to gemcitabine[34,36,37]. Thus, further supporting the importance of hENT1 in gemcitabine sensitivity.

This research indicates that hENT1 Levels are correlated with gemcitabine response as the upregulation of hENT1 proteins results in the enhancement of gemcitabine's cytotoxic effects, while the loss of hENT1 protein expression results in the development of gemcitabine resistance. Due to this, hENT1 is an attractive potential prognostic biomarker in pancreatic cancer patients for gemcitabine treated patients[7,19].

It is important to note that the hENT1 gene itself is not reduced in the development of chemoresistance to gemcitabine, nor does it correlate with gemcitabine's IC_{50} values for several pancreatic cancer cell lines. This suggests that hENT1 expression is not solely alone in patients acquired and inherent chemoresistance to gemcitabine[34].

hENT2

The hENT2 protein is encoded by the gene SLC29A2 and transports a range purine and pyrimidine nucleosides as well as select nucleobases across cells membranes with broad affinity. The protein is present in a wide range of cell types though its gene expression is greatest in the skeletal muscle. The hENT2 protein is highly expressed in the pancreatic cells of healthy individuals but is shown to be reduced in pancreatic cancer patients and pancreatic cancer cell lines[38,39].

hENT2 has recently been identified as being a key element in the regulation of nucleotide and nucleoside pool for effective cell cycle progression and synthesis of DNA. This evidence indicates that hENT2 is partly responsible for transporting, into the nucleus, the supply of nucleotides required for DNA replication. Therefore, the dysregulation of this transporter protein may have adverse effects on cell homeostasis and possibly contribute to tumour progression[33].

hENT2 has also been the subject of several investigations due to its ability to transport gemcitabine into cells. It is however proven to transport the chemotherapeutic drug with a much lower affinity when compared to hENT1[38]. Unlike the extensive research undertaken on hENT1 which has proven a link between the protein and chemoresistance, there are few studies investigating the importance of hENT2 [22]. hENT2 protein expression has been identified in various pancreatic cancer cell lines, although less than the expression of hENT1 transporters[25].

Table 2 The mechanisms, efficacy, toxicity, affinity, and disadvantages of human nucleoside transporters

Transporter	Mechanisms of action	Efficacy, toxicity, and affinity	Known disadvantages	Ref.
hENT1 (SLC29A1)	Nucleoside-derived anticancer drug update. Antiviral drug uptake. Cellular uptake of nucleosides for RNA or DNA synthesis. Adenosine signalling	Clear correlation between the efficacy of nucleoside analog chemotherapeutic treatment and expression of hENT1. Increase in chemotherapeutic drug efficacy with an increase in transporter expression. Highly sensitive to NBMPR, draflazine, dilazep, and dipyridamole.Increase in cell toxicity with an increase in transporter expression. Highest affinity for gemcitabine uptake	Mutations in the SLC29A1 gene associated with Faisalabad histiocytosis, pigmented hypertrichosis including insulin dependent diabetes, and H syndrome. Select variants of the gene highly immunogenic, may result in haemolytic disease of newborns and foetus as well as acute haemolytic transfusion reaction	[72-77]
hENT2 (SLC29A2)	Nucleoside-derived anticancer drug update. Antiviral drug uptake Mediates the influx and efflux of pyrimidine and purine nucleosides as well as the purine base hypoxanthine. Transport's bile salts, metal ions, organic acids, amine compounds, glucose and other sugars	Although identified to transport gemcitabine into cells, it is less effective than hENT1 at cytotoxic drug uptake. Minimally sensitive to inhibition *via* NBMPR, draflazine, dilazep, and dipyridamole. Higher affinity for nucleobases when compared to hENT1	Mutations in the SLC29A2 gene associated with familial and Histiocytosis-Lymphadenopathy Plus Syndrome and hepatic Adenomas. Dysregulation may result in have adverse effects on cell homeostasis and possibly contribute to tumour progression	[33, 37, 38, 40, 78]
hCNT1 (SLC28A1)	Transport's bile salts, metal ions, organic acids, amine compounds, glucose and other sugars. Transport's nucleosides, related molecules, and vitamins. Nucleoside binding. Nucleoside sodium symporter activity. Nucleoside-derived anticancer drug update. Antiviral pyrimidine nucleoside analog drug uptake	Minimally effective at cytotoxic drug uptake. Expression is negatively regulated by MUC4 in gemcitabine resistant pancreatic cancer cells. Has a selective inhibition for thymidine, adenosine, uridine, inosine, guanosine, and cytidine	Mutations in the SLC28A1 gene are associated with Uridine-Cytidineuria disease. Overexpression of protein may result in translocation of pyrimidine alone, resulting in modifications of cell physiology	[16, 45, 51, 79]
hCNT3 (SLC28A3)	Regulates cellular processes, such as vascular tone, neurotransmission, surface receptors, the concentration of adenosine in the vicinity of cell as well as transport, and finally the metabolism of nucleoside drugs. hCNT3 has a broad specificity for pyrimidine and purine nucleosides	Clear correlation between hCNT3 downregulation and gemcitabine toxicity	Mutations in the *SLC28A3* gene results in the altered sensitivity to the compound BMS-536924	[80-82]

hENT1/2: Human equilibrative nucleoside transporter 1/2; hCNT1/3: Human concentrative nucleoside transporter 1/3.

Previous studies aimed at investigating hENT2 Levels in chemoresistance pancreatic cancer cell lines identified the expressed protein had a lower expression after gemcitabine treatment[37,40]. In cohesion with the reduction in protein expression, hENT2 mRNA levels are also reduced following gemcitabine treatment. Furthering these studies, the inactivation of hENT2 *via* exposure to dilazep (a hENT2 inhibitor), in conjunction with the inhibition of hENT1 *via* NBMPR, results in a reduction of gemcitabine uptake and sensitivity. However, the decrease in hENT2 expression may not provide an explanation for the limited uptake of gemcitabine into cells and therefore chemoresistance, as the expression of other gemcitabine transporters are not affected by hENT2 downregulation[37,40].

These results provide evidence that hENT2 when aberrantly expressed may contribute to gemcitabine resistance, however, more extensive research is required to understand the exact impact hENT2 expression has on other mechanisms of chemoresistance in addition to pancreatic cancer cells.

HUMAN CONCENTRATIVE NUCLEOTIDE TRANSPORTERS IN PANCREATIC CANCER

hCNT1

The hCNT1 protein, encoded by the SLAC28A1 gene, is a sodium dependant transporter with a high affinity for pyrimidines[25]. It is broadly detected in epithelia with a moderate to high expression in healthy pancreatic tissue. The expression of hCNT1 is decreased to an almost negligible in undifferentiated states such as fetal hepatocytes, intestinal crypt cells and human tumours, namely pancreatic and breast tumours[41].

The exact role hCNT1 undertakes in the regulation of gemcitabine resistance and cytotoxicity in pancreatic cancer cells is yet to be described, however, data obtained from multiple studies have indicated that the hCNT1 expression is frequently reduced in pancreatic cancer cell lines and tumours when compared to unaffected pancreatic cells[42-44]. In chemoresistant pancreatic cancer cells, hCNT1 expression is limited and can be correlated with limited influx of gemcitabine into target cells. However, investigations into the pharmacological inhibition of the degradation of hCNT1 results in a moderate increase of the cellular transport of gemcitabine thus suggesting the transporter as a possible target mechanism for increasing chemosensitivity and drug transport[42].

Due to the correlation between decreased hCNT1 expression levels and the increased chemoresistance of pancreatic cancer cells, recent research has investigated the mechanisms that decrease transporter expression. As a result, it has been identified that the transmembrane mucin MUC4 utilises the NF-KB pathway to inhibit hCNT1 [45]. The increase of MUC4 expression is commonly observed in pancreatic cancer cells, which results in a higher rate of inhibition of hCNT1 transporters and therefore an increase in chemoresistance. Importantly, studies have shown that the inhibition of MUC4 oncogenic receptor Erb2 resulted in the increase of hCNT1 expression and an increased uptake and sensitivity to gemcitabine[42]. Although more extensive work is needed to determine the processes affecting hCNT1 expression, mucins are an interesting contributing factor.

hCNT3

The hCNT3 transporter belongs to the SLC28 family and is characterized by the broadest tissue specificity and tissue distribution. It is a symporter that couples the transportation of a nucleoside to the symport of one proton or two Na^+ ions. In healthy individuals the transporter is expressed at high levels in the pancreas, mammary glands and in bone marrow. HCNT3 is also expressed in low levels in the prostate, liver, testis, lungs, and intestines[46].

The importance of hCNT3 in pancreatic cancer is of clinical and pharmacological significance due to its ability to transport a large variety of nucleoside-derived drugs such as valacyclovir for viral infections and more importantly gemcitabine for solid tumors. Due to this, it is identified as a crucial mediator of drug response and the development of resistance to anti-cancer drugs[46].

The aberrant expression of hCNT3 has been observed in various pancreatic tumors and pancreatic cancer cell lines. More specifically, a decrease in expression is observed which has been correlated with increased gemcitabine cytotoxicity[45]. Furthermore, uncharacterized polymorphisms of hCHT3 such as the nonsynonymous A25G mutation, have been associate with tumor response to drug toxicity and therapy in pancreatic cancer patients[24]. It has also been shown that hCNT3 expression in pancreatic tumors correlates with overall patient survival, with an increased expression of the transporter associated with a longer overall patient survival[45]. Recent studies investigating the mechanisms that regulate hCNT3 expression in tumor cells suggest that ErbB2 expression and epithelial to mesenchymal transition (EMT) have a negative impact on the regulation of transporter expression[47].

hCNT3 has been observed to have multiple advantages over other NTs capable of gemcitabine uptake, primarily as a potential therapeutic target for reducing resistance of toxic nucleoside analog treatments. Despite extensive research aimed at hENT1 as a therapeutic target for overcoming gemcitabine resistance in pancreatic cancer patients, Paproski *et al*[23] identified an 8-fold uptake of gemcitabine in hCNT3 transfected cells with functional hENTs and 142-434-fold uptake in cells without hENT activity. The evidence suggesting that functional hENTs present in cells result in a decrease in gemcitabine uptake. However, another study undertaken by Maréchal *et al*[26] identified pancreatic cancer patients that presented with both high hENT1 and high hCNT3 expression had a 5-fold longer overall survival than those with one favorable prognostic factor and a 7-fold overall survival length than individuals with no favorable prognostic factors.

POSSIBLE STRATEGIES TO OVERCOME CHEMORESISTANCE

To date, several strategies aim at effectively treating pancreatic cancer and overcoming chemoresistance commonly seen in patients undertaking chemotherapeutic treatments. A variety of techniques and agents are currently or have previously been investigated for their effectiveness against not only pancreatic cancer, but also

gastrointestinal, peritoneal, and respiratory mucous tumours[3,48].

Numerous target treatments have been investigated and evaluated either alone or in combination with chemotherapeutic agents for pancreatic cancer. Currently, the only targeted therapeutic agent to have statistically significant benefit for patient survival is the tyrosine kinase inhibitor (TKI) erlotinib in combination with gemcitabine with a 2-week mean survival benefit over gemcitabine as a single agent. Though promising, erlotinib is clinically marginal and further investigations are required[48,49].

Other investigated drugs include multikinase inhibitors exhibiting antiangiogenic activity like axitinib, sunitinib and sorafenib and antiangiogenic drugs including vascular endothelial growth factor (VEGF) inhibitors aflibercept and bevacizumab. Recently, compounds targeting signalling cascades such as the multikinase inhibitor masitinib67, phosphoinositide 3-kinase inhibitor rigosertib, and anti-insulin-like growth factor 1 receptor antibodies cixutumumab65,66 and ganitumab have been investigated in combination with gemcitabine. Regrettably, these agents have shown no improvement in patient survival, they have however, provided insight into the cause of futility, with the dense stroma surrounding pancreatic cancer cells speculated to be a key contributor[48,50].

The microenvironment of pancreatic tumours is composed of fibrotic stroma including inflammatory cells, fibroblasts, nerve cells, blood vessels, hyaluronan, fibronectin, and collagen. The theory of targeting the stroma of pancreatic tumours to enhance the effectiveness of chemotherapeutic drugs is of great interest. It is hypothesised that due to the poor vascularization and deposition of extracellular matrix component causes increased hydrostatic pressure and stiffness resulting in a barrier of drug uptake. Currently investigated treatments included calcipotriol for the inactivation of pancreatic stellate cells (PSCs), smoothened homologue inhibitor IPI-926 for the inhibition of collagen deposition and myofibroblast growth and finally evofosfamide which inhibits DNA replication. As seen with other therapeutic treatments, agents attacking the stroma are still in the early stages of investigation and more work is required[48,50].

POSSIBLE STRATEGIES TO ENHANCE NUCLEOSIDE TRANSPORTERS

To date, no viable agents specifically targeting nucleoside transporters in relation to chemoresistance has been developed. Though *in vivo* investigations into the upregulation of hCNT1 expression have shown promising results, the clinical application of these techniques is not yet applicable[51,52]. Although, it has been hypothesised that the overexpression of selected mucins in pancreatic cancer is a contributing factor to nucleoside transporter efficacy and therefore chemoresistance[53]. This mucin overexpression results in the production of a thick, mucinous physical barrier between cancer cells and the extracellular matrix, thus inhibiting the ability of intracellular drug uptake *via* nucleoside transporters and affecting the drugs cytotoxicity. Due to this, several agents have been investigated for their mucolytic properties[42,53].

Much of this research has focused on agents that involve the immune system, such as adoptive immunotherapy, oncolytic viral therapy, peptide vaccines to enhance the cytotoxic T cell or T helper cell response, or specific antibodies. These techniques have shown promising results for patients with metastasised disease, when implemented in pre-clinical as well as early-stage clinical trials. However, many of these approaches are limited in their targeting abilities and have only been examined in small patient cohorts[2,3].

Another avenue readily investigated is gene editing technology specifically targeting the mechanisms that have been identified as contributors of disease progression. These methods can include transfection of cells, silencing, and upregulating genes *via* gene promotors, and at the transcriptional level, targeting epigenetic regulation. It is important to note, despite the promising results obtained *in vitro* and in early clinical stages for these treatments, there are issues surrounding the effectiveness of treatment delivery *in vivo*. Due to this, further research is required on the feasibilities of implementing these treatments to patients[2,3,54].

A variety of micro RNAs (miRs), pharmacological and natural agents have also been investigated for their ability to limit pancreatic cancer progression by specifically targeting and downregulating well known mucins such as MUC1 and MUC4[54,55].

miRs are small noncoding RNAs that occur naturally, functioning in gene regulation and have been identified as possible regulators of mucin expression in pancreatic cancer. Four key miRs have been investigated and provided positive results, those being, miR-Let-7b, miR-150, miR-219-1-3p, and miR-200c. All mentioned miRs have

been found to downregulate MUC4 expression, miR-150 directly targets MUC4 resulting in inhibition and is therefore a MUC4-regulating miR. Despite the promising effect of miRs in regulating mucins, there are minimal studies aimed at assessing their viability against established pancreatic tumors *in vivo* and further studies are required prior to clinical application[36,56-58].

Regarding pharmacological agents, the modulation of mucins, specifically MUC4, is achieved through anti-inflammatory drugs, corticosteroids. Key investigated corticosteroids include dexamethasone, as well as afatinib and canertinib, two pan-EGFR family inhibitors. These agents had various levels of effectiveness with dexamethasone providing variable modulation results, while afatinib and canertinib resulted in the downregulation of MUC4 expression. Interestingly, canertinib, unlike afatinib, is an irreversible inhibitor and treatment resulted in not only downregulation of MUC4, but also reduction in tumor growth. Though promising, the variable effects due to corticosteroids not only on mucins, but other mechanisms of disease have limited the possibility of clinical application[54,59,60].

Natural agents are of great significance in the treatment of pancreatic cancer due to their ability to target inflammation signaling pathways and regulate the expression of mucins. Several of these agents have been identified as possible pancreatic cancer treatments, including, Thymoquinone, Guggulsterone, Graviola extract, Bromelain and N-acetylcysteine.

Guggulsterone is a phytosteroid derived from the resin of Commiphora Mukul plants. Historically, it has been utilized for the treatment of atherosclerosis, hyperlipidemia, diabetes, hypertension, and obesity. More recently, it has been investigated for its anti-proliferative activity, ability to induce apoptosis and inhibit cell invasion and motility in various tumor types whether *in vitro* or *vivo*. Furthermore, Guggulsterone has shown a synergistic effect with gemcitabine against pancreatic cancer, as well as the reversal of multidrug resistance in breast cancer cell lines. In addition to its anti-tumor properties, Guggulsterone has been identified to decrease the activation of STAT/JAK pathways, downregulating MUC4 as a result. Accounting for all the possible benefits of Guggulsterone it is an attractive agent for clinical application in combination with Gemcitabine against pancreatic cancer[54,61].

Thymoquinone is a bioactive constitute derived from black seed oil (Nigella sativa). It has previously been identified as having several promising pharmacological properties against diseases due to its anti-inflammatory, antioxidant, and anticancer activities. More recently, it has been shown to exhibit antineoplastic properties against pancreatic cancer cell lines FG/ COLO357 and CD18/HPAF. Treatment with Thymoquinone against these cell lines resulted in the downregulation of MUC4 resulting in the increased apoptosis and decrease of migration of tumor cells. The downregulation of MUC4 results in the activation of c-Jun-(NH2)-terminal kinase and p38 MAP kinase, thereby implicating MUC4 as a key target of Thymoquinone. As seen with other natural agents, synergistic effects have been observed both *in vitro* and vivo with Thymoquinone and chemotherapeutic agents, specifically, Gemcitabine and Oxaliplatin[54,62,63].

Annona muricata (Graviola) evergreen trees are the source of medicinal treatment for inflammatory conditions such as insomnia, hypertension, rheumatism, diabetes, and neuralgia. Within the last decade, investigations into the effect of extracted graviola on pancreatic cancer cell lines have been undertaken *in vitro* and vivo. It has been identified that graviola downregulated genes associated with glycolysis and hypoxia, and more importantly, downregulated MUC4, while exhibiting antimetastatic and antiproliferative effects[54,64]. Interestingly, graviola has been shown effective in destroying chemoresistant breast cancer cells[65]. This study indicating graviola to be an attractive agent of investigation for chemoresistant cancer cells.

Bromelain is a cysteine proteolytic enzyme extracted from the stem of immature pineapple plants (Ananas comosus). The enzyme is well known for its anti-inflammatory and mucolytic properties as well as its uses for relief of indigestion, thrombosis, fevers, wound debridement, and edema. Bromelain was originally utilised for its anti-cancer properties in ovarian and breast cancer, with clinical trials of administration resulting in a decrease of metastasis and the resolution of tumour masses. When administered in combination treatments with chemotherapeutic agents such as 5-FU greater patient outcomes and further tumour regression has been observed[66]. Interestingly, bromelain has been recently investigated for its proteolytic properties, specifically its ability to target and disrupt glycosidic linkages in mucins resulting in the disruption of the protective mucolytic layer. The disruption of mucolytic layers produced by mucins on cancerous cells enables the effective uptake of cytotoxic drugs into cells resulting in better patient survival[3,53,66].

N-acetyl cystine (NAC) is a sulphur containing amino acid that is commonly used for the treatment of acetaminophen toxicity and to liquify the thick mucus formed in respiratory diseases such as chronic obstructive pulmonary disorder (COPD) and cystic fibrosis[66]. Due to its chemical composition, NAC holds the ability to reduce disulphide bonds (S-S) to sulphydryl (S-H) bonds in glycoproteins and therefore convert purulent and viscous mucin into an aqueous state resulting in ciliary elimination in the respiratory system[66].

A further strategy for overcoming chemoresistance and increasing patient survival is combination therapy with chemotherapeutic and mucolytic agent. Two natural agents have been identified as effective against mucous cancers when combined, those being bromelain and NAC[67].

Recently, studies into the efficiency of these agents as single agents, in combination with each other and in combination with gemcitabine and 5-FU against pancreatic cancer cell lines has been investigate with promising results[53]. This can present beneficial outcomes for clinical application due to the ease of application as well as a reduction in required chemotherapeutic doses therefore reduced toxicity when compared to currently utilised chemotherapeutic drugs[3,53].

The combination of bromelain and NAC has been shown to have a synergistic cytotoxic effect against several tumour types. It is known that late-stage pancreatic tumours express high amounts of MUC1, MUC4, MUC16 which have been associated with invasiveness, cellular proliferation, metastasis and chemoresistance. Previous studies have shown that a bromelain and NAC combination treatment resulted in the reduction of mucin expression both *in vitro* and *vivo*[53,68]. Recent *in vivo* investigations into combination therapy of bromelain and NAC with the addition of cytotoxic agents such as gemcitabine resulted in observed synergism and introduce the possibility of reducing the clinical cytotoxic dosage required for treatment and therefore reducing side effects that commonly present with high dose treatments[53]. It is thought that the combination of bromelain and NAC will disrupt the glycosylic linkages and disulphate bonds within mucins allowing for gemcitabine to effectively enter the cells *via* nucleoside transporters resulting in its ability to incite its cytotoxic effect[53].

CONCLUSION

Pancreatic cancer is a deadly disease with a high mortality rate attributed to late tumour detection, disease aggressiveness and chemoresistance. Although predicted to be the second leading cause of cancer associated mortality within the next 10 years, steady progress has been achieved in determining the mechanisms that contributes to the poor progression of the disease, which, in turn contributes to the development of diagnostic and therapeutic targets.

One of these mechanisms has been identified as human nucleoside transporters, namely for their importance in the transportation of chemotherapeutic drugs into diseased cells along with their contribution to acquired chemoresistance. Primarily, investigations have been undertaken on the nucleoside transporters hENT1, hENT2, hCNT1, and hCNT3, namely due to their ability to transport the nucleoside analogue gemcitabine, however, more research is needed to evaluate their use not only as diagnostic markers but as therapeutic targets.

The expression of nucleoside transporter proteins has been shown to be adverse in pancreatic cancer cells, with decreased protein expression correlating with not only reductions in progression and disease-free patient survival but also an increase in acquired chemoresistance. The lack or inability of nucleoside transporter proteins to facilitate the uptake of chemotherapeutic drugs has been identified as a contributor of gemcitabine chemoresistance and although the majority of research has been focused on hENT1, all examine nucleoside transporters have exhibited this correlation.

There have been several suggestions on overcoming the factors contributing to nucleoside transport related chemoresistance, with treatment options such as mucins being of great interest. Specific mucins have been shown to be overexpressed in pancreatic cancer cells and new combination treatment therapies, such as bromelain + NAC + gemcitabine, targeting the linkages seen in mucins expose the encased nucleoside transporters, allowing for the uptake of cytotoxic drugs which is advantageous for several reasons. The two main benefits being increased drug uptake, and reduction of required cytotoxic dose although further research of this strategy for not only the treatment of pancreatic cancer but also overcoming chemoresistance is required.

ACKNOWLEDGEMENTS

We would like to thank the team at the Department of Surgery at St George Hospital, UNSW for all of their support.

Abstract

Chronic viral hepatitis is one of the leading causes of cirrhosis worldwide. Chronic hepatitis B is more common in the Asia-Pacific region due to the larger population and lower screening availability. Hepatitis C predominates in the west due to injection drug abuse. The discovery of (oral) direct-acting antiviral agents (DAAs) has changed the landscape of chronic hepatitis C (CHC) management. Nucleos(t)ide analogs (NUCs) have also changed the approach to the treatment of chronic hepatitis B (CHB). Oral NUCs and DAAs have excellent efficacy and patient acceptance as well as a lower risk of resistance. However, certain populations have no robust data and safety and efficacy of such oral drugs is still evolving. In this review, we provide an overview of the management of CHB and CHC in special populations, such as those with chronic kidney disease, pregnant women, healthcare workers, and those undergoing chemo- or immunosuppressive therapy.

Key Words: Chronic kidney disease; Pregnancy; Hepatitis B; Hepatitis C; Health care professionals; Tenofovir

Core Tip: Hepatitis B and hepatitis C are leading causes of liver disease and pose significant burdens on healthcare and the economy, especially in developing countries. The management of chronic hepatitis B and C in special populations is less known. In this review, we discuss the indications, timing of treatment, and safety of drugs in special populations infected with hepatitis B or C. The special populations discussed herein are those with chronic kidney disease, pregnant women, coinfected patients, healthcare workers, and patients undergoing chemotherapy.

INTRODUCTION

Hepatitis B and C together constitute a major etiology of cirrhosis of the liver, especially in the Asia-Pacific region[1-3]. Nucleos(t)ide analogs and direct-acting antivirals (DAAs) are breakthrough treatments for chronic hepatitis B (CHB) and chronic hepatitis C (CHC), respectively. The management of Hepatitis B and C in an adult population without comorbidities is well known. Special population groups are those who are less often studied, and the drugs cannot be tested in such populations due to ethical reasons. The data on management strategies are still evolving for special populations. Such populations include patients with chronic kidney disease (CKD), patients on hemodialysis (HD), pregnant women, coinfected patients, healthcare workers, and patients undergoing chemotherapy[4]. In this review, we discuss the indications and safety of antiviral agents in special populations.

CHRONIC KIDNEY DISEASE AND HEMODIALYSIS

Hepatitis B and CKD

Hepatitis B is associated with proteinuria and a higher risk of CKD[5,6]. Hepatitis B virus (HBV)-infected treatment naïve patients have a higher incidence of hematuria, glycosuria, and leukocyturia[7]. Nearly 28%-40% of CHB patients have a glomerular filtration rate (GFR) < 90 mL/min/1.73 m^2[7,8]. The prevalence of CKD in CHB patients is 3%-8%, with increasing prevalence with age[9]. This translates into an enormous burden of CKD due to the higher prevalence of CHB in the Asia-Pacific region. The presence of hypertension, diabetes mellitus, and cirrhosis further increases the risk of CKD in CHB[9]. Smoking and physical inactivity can also increase the risk of CKD[10]. The presence of CKD can also increase the risk of HBV infection due to immuno-suppression (rising the risk of viral infections), frequent requirements of blood transfusions (for anemia of chronic disease), and HD. The ideal endpoints of CHB treat-ment are HBsAg loss and anti-HBs seroconversion, which are challenging to attain. Long-term DNA suppression, normalization of alanine transaminase (ALT), and HBeAg loss (in those who are HBe-positive with or without anti-HBe seroconversion) remain the primary achievable endpoints in the treatment of CHB[4]. The data on the management of CHB in CKD are limited. Since ALT levels are suppressed in CKD (and those on HD), initiating treatment in individuals with HBV DNA > 2000 IU/mL (irrespective of ALT levels) is recommended, especially if > F1 fibrosis is documented either by biopsy or noninvasively[11]. Vaccination remains the best preventive strategy for CKD and HD patients. One milliliter each (containing 20 mcg) should be given intramuscularly (in deltoid muscle) four times at 0, 1 mo, 2 mo and 6 mo. The initial anti-HBs titer should be done two months after the first schedule and then annually thereafter. A booster dose is recommended if the anti-HBs is < 10 IU/mL in CKD patients[12]. Tenofovir disoproxil fumarate (TDF), tenofovir alafenamide fumarate (TAF), and entecavir (ETV) have a low risk of resistance and high efficacy in CKD patients[11,13]. Lamivudine, telbivudine, and adefovir are less effective, nephrotoxic, and are associated with risk of resistance. Interferon-α therapy is less tolerated and is not preferred over NUCs, although the advantage of IFN-α of limited duration therapy cannot be ignored. IFN-α can be used in young patients without cirrhosis, psychosis, or autoimmune disease and GFR > 30 mL/min/1.73 $m^2$13 (Table 1).

Hepatitis C and CKD

Extrahepatic manifestations are more common in hepatitis C virus (HCV) than HBV [14]. CHC patients may have renal failure even in the absence of liver disease[15]. HCV-infected individuals have a 23% higher risk of developing CKD than non-HCV-infected individuals[16]. Hepatitis C is a leading cause of liver disease among patients with CKD, particularly those on dialysis. The seroprevalence of HCV in the Asian population in patients on dialysis ranges between 1%-18%, with higher a prevalence in

Table 1 Hepatitis B in chronic kidney disease

	HBV and CKD
Prevalence of CKD in HBV patients	8%
Pathogenesis	Direct cytopathic effect of the HBV on cells of the kidney; Glomerular deposition of immune complexes; Virus-induced specific immunological effector mechanisms (specific T lymphocyte or antibody); CHB induced cytokine toxicity on renal tissue
Risk factors	Smoking, diabetes mellitus, hypertension, cirrhosis.
Common type of renal injury	Membranous GN; Membranoproliferative GN; Polyarteritis nodosa; IgA nephropathy
Treatment indication	HBV DNA 2000 IU/mL with or without elevated ALT; Liver biopsy-chronic hepatitis with > F1 fibrosis; If planned for renal transplant, initiate NUCs 2 wk before transplant even if DNA ≤ 2000 IU/mL
Safe drugs	TAF (no dose adjustment till eGFR < 15 mL); ETV and TDF (If GFR > 50: ETV 0.5 mg/d or TDF 300 mg/d; GFR 30-49: ETV 0.5 mg alternate day or TDF 300 mg alternate day; GFR 10-29: ETV 0.5 mg once in 3 d and TDF 300 mg once in 3 d; on HD-ETV 0.5 mg or TDF 300 mg after every dialysis or every 7 d)
Prevention	Regular screening; Vaccination (double dose); Serology should be performed every year, and a booster dose should be given if antibody titers are below 10 mIU/mL.

HBV: Hepatitis B virus; CKD: Chronic kidney disease; CHB: Chronic hepatitis B; NUC: Nucleos(t)ide analogues; TDF: Tenofovir disoproxil fumarate; TAF: Tenofovir alafenamide fumarate; ETV: Entecavir; GFR: Glomerular filtration rate; GN: Glomerulonephritis; ALT: Alanine transaminase.

those on HD than in those on peritoneal dialysis, *i.e.*, 8 ± 5.5%[17]. Due to a higher number of adverse effects, the use of pegylated IFN plus ribavirin is not recommended [18]. Glecaprevir and pibrentasvir are NS3/4A protease and NS5A inhibitors, respectively, which have pangenotypic activity. Glecapravir 300 mg and pibrentasvir 120 mg in a fixed-dose combination are the treatments of choice for patients with chronic hepatitis C and stage 4 or 5 CKD (including those on HD)[19,20]. In patients with stage 1-3 CKD, similar dosing of DAA without dose adjustments is recommended. However, glecaprevir and pibrentasvir are not available in all countries. Another option for genotype 1b CHC is grazoprevir, 100 mg and elbasvir, 50 mg for 12 wk, which is still unavailable in many countries[21]. Sofosbuvir-based regimens are also safe in patients with renal impairment and cirrhosis (both decompensated and compensated)[22]. Sofosbuvir 400 mg and velpatasvir 100 mg fixed-dose combination is safe and effective for renal impairment patients (even HD patients) with CHC[23]. In patients with CHC and compensated cirrhosis, the recommended duration is 12 wk, while it is 24 wk for decompensated cirrhosis[20]. Sofosbuvir (400 mg) + ledipasvir (90 mg) also has proven efficacy for Genotype 1b with renal impairment but not on HD [24]. Ribavirin may be added for decompensated cirrhosis patients in combination with sofosbuvir-ledipasvir or in persons with HCV genotype 1a who are receiving treatment with elbasvir-grazoprevir and who have baseline NS5A resistance-associated variants for elbasvir. The dose of ribavirin is 200 mg/d for patients with creatinine clearance < 30 mL/min and 200/400 mg alternate day for patients with creatinine clearance between 30 mL/min and 50 mL/min. American Association for the study of Liver Disease (AASLD)/Infectious Disease Society of America (IDSA) has approved the use of sofosbuvir-velpatasvir; however, in some countries, it is still used as an off-label indication in patients with renal impairment[25]. Strict adherence to infection control protocols during dialysis is the only way to prevent HCV spread[26]. To date, no vaccines have succeeded in preventing chronic HCV infection[27]. Anti-HCV antibodies should be tested before initiation of dialysis and then biannually[28]. Monthly ALT estimation is also recommended for those on dialysis (Table 2).

Pregnancy

Pregnancy is an opportunity to diagnose chronic viral hepatitis. Screening for hepatitis B and C is recommended for all individuals to prevent mother-to-child transmission (MTCT) and prevent transmission to health care professionals[29].

HBV and pregnancy: Nearly 10% of childbearing women in the Asia-Pacific region are infected with HBV[30]. There can be four situations in pregnancy: (1) First time incidentally diagnosed CVH during pregnancy; (2) Individuals are infected and are already on treatment with antiviral therapy; (3) Individuals are under surveillance for CVH and are contemplating pregnancy; and (4) Cirrhosis due to viral hepatitis.

Table 2 Hepatitis C in chronic kidney disease

	HCV and CKD
Prevalence of HCV in CKD patients	10%-14%
Pathogenesis	Pronounced leucocyte infiltration of glomerular capillaries and the precipitation of immunoglobulins, immune complexes/cryoglobulins; Glomerular deposition of HCV protein
Risk factors	Age, male gender, lack of HCV treatment, concomitant HAV/HBV infection; Diabetes mellitus
Common types of renal injury	Membranous GN; Membranoproliferative GN; Essential mixed cryoglobulinemia (type II); IgA nephropathy; Polyarteritis nodosa
Treatment indication	Viremia
Safe drugs	Glecapravir + Pibrentasvir; Sofofbuvir + Velpatasvir; Sofosbuvir + Ledipasvir; Grazoprevir + Elbasvir
Prevention	Regular screening and strict infection control procedures; Effective dialysis machine decontamination

HCV: Hepatitis C virus; CKD: Chronic kidney disease; HAV: Hepatitis A virus; GN: Glomerulonephritis.

The risk of transmission to the newborn is as high as 90% if the mother is HBeAg (e antigen)-positive and 10%-12% if the mother is HBeAg-negative and HBeAb (e antibody)-positive[31]. The risk of transmission is also directly proportional to viral load. The risk of progression to chronicity is nearly 90% if the newborn becomes infected[30]. Hence, preventing MTCT is of utmost importance. Screening for HBsAg is mandatory for all pregnant individuals in the first trimester. It is prudent to test HBeAg, HBeAb, and DNA levels by the end of the second trimester. Treatment is indicated if HBV DNA > 200000 IU/mL or HBsAg levels > 4 Log10 IU/mL. TDF can be started at 24-32 wk of gestation and must be continued for up to 12 wk after delivery[4]. Currently, TAF has no data to support its use during pregnancy. However, an initial review of data on TAF in pregnancy is encouraging[32]. If a woman is infected and is already on treatment with antivirals, the treatment must be continued. TDF is the recommended drug of choice during pregnancy, and if the individual is on ETV or any other antivirals, she should be switched to TDF[29]. If the individual is infected and is contemplating pregnancy, it is advised to postpone the treatment until childbirth unless the woman fulfills CHB treatment criteria (presence of advanced fibrosis or high viral load)[29]. Cirrhosis patients who wish to becomes pregnant should be counseled about the risk of decompensations during pregnancy. Pregnancy-induced volume disturbances are similar to cirrhosis, *i.e.*, reduction in systemic vascular resistance and rise in blood volume and splanchnic vasodilation, which may exacerbate pre-existing portal hypertension[29]. Newborns of HBV-positive mothers should receive active and passive immunization. The newborn should be tested for HBsAb 3 mo after complete immunization (*i.e.*, > 9 mo of age)[33]. Chronic HBV infection may not influence pregnancy outcomes; however, postpregnancy, there may be a flare of HBV due to immune restoration[29,30]. Breastfeeding is not contraindicated, and cesarean section is not indicated for HBV-infected mothers.

HCV and pregnancy: The prevalence of HCV infection is high in Western countries due to injection drug abuse; however, the Asia-Pacific region has a lower prevalence than the west. Due to the large population, the incidence of HCV is considered high in the Asia-Pacific region. The prevalence of HCV in the Asia-Pacific region is 0.1%-5% [34]. The lack of sensitive universal testing in developing countries is a major hindrance to diagnose HCV infection. Further transient elastography is not recommended in pregnant individuals to stage fibrosis.

HCV can affect pregnancy outcomes. HCV, a cytopathic virus, has been linked to intrahepatic cholestasis of pregnancy[35]. HCV can also downregulate multidrug resistance protein 2 (MRP2), which would induce a failure to transport toxic substances and subsequent defects in bile transport; high estrogen and progesterone levels would further compound this effect on MRP2 during pregnancy[35,36]. HCV-infected women also have a higher risk of preterm birth[37]. In contrast, pregnancy being immunosuppressed does not affect HCV. However, in the postpartum period, women may clear the virus spontaneously due to immune reconstitution and HCV-specific T-cell response development[36]. The pooled incidence of MTCT is 6%[38]. Concomitant human immunodeficiency virus (HIV) infection, high HCV viral load, and injection drug abusers (due to acute hepatitis) are at higher risk of transmitting the infection to the newborn[38,39]. MTCT occurs most often in late stages, either during

intrauterine or intrapartum transmission[29]. There is no added benefit of cesarean section and hence is not indicated for patients with HCV infection to prevent transmission. Breastfeeding is not contraindicated[40]. Prolonged rupture of membranes (> 6 h) and invasive tests such as internal fetal monitoring, amniocentesis, and chorionic villous sampling have the potential risk of transmission[41]. Episiotomy should also be avoided, if possible, in HCV-infected pregnant individuals[41]. None of the DAAs have been approved to be used in pregnancy yet. DAAs are category B drugs in pregnancy. Sofosbuvir with ledipasvir has been shown to be effective and safe in pregnancy[42]. The drug was initiated in the 2nd or early third trimester. There are two trials underway assessing DAAs in pregnancy. The first trial evaluating sofosbuvir plus ledipasvir initiated at 24 wk of gestation (ClinicalTrials.gov Identifier: NCT02683005). Another trial assessing sofosbuvir plus velpatasvir commenced six months postpartum (ClinicalTrials.gov Identifier: NCT03570112). The results of these trials are expected soon. Differences in HBV and HCV management are shown in Table 3.

HEALTHCARE WORKERS

Healthcare workers (HCWs) are attending clinicians, surgeons, employees, students, contractors, public-safety workers, or volunteers whose activities involve contact with patients or with blood or other body fluids from patients in healthcare, laboratory, or public-safety settings[43]. HCWs are at risk of becoming infected and can also be a potential source of transmission to patients. The risk of transmission is, although rare from providers to patients, it is recommended to treat HCWs even with a low viral load (HBV DNA < 1000 IU/mL)[44]. Prior to universal vaccination, the risk of transmission was 5%-13% from HBeAg-positive HCWs to patients and 0.8%-3.5% from HBeAg-negative HCWs to patients[45]. The prevalence of HBV among HCWs ranges between 5%-7% in developing countries[46,47]. The presence of HBV infection does not preclude the HCWs from practicing medicine (dentistry or surgery, or any allied health care work) as per the Centers for Disease control and Prevention (CDC) [44]. The European Association for the Study of the Liver recommends treating HCWs if DNA levels are more than 200 IU/mL[4]. The CDC recommends treating HCWs if DNA >1000 IU/mL and prohibits HCWs from performing exposure-prone procedures if DNA >1000 IU/mL[44]. In contrast, transmission of HCV from HCWs to patients is rare. HCWs are at higher risk of becoming infected by patients. A meta-analysis reported higher odds of infection among HCWs than controls[48]. HCWs with viremia should be treated.

COINFECTION

HBV with HIV: The prevalence of HBV HIV coinfection ranges between 5%-20%, with a higher prevalence among injection drug abusers[49]. The risk of liver-related mortality is twice as high in patients with coinfection as in those with HIV monoinfection[50]. HBV also increases overall mortality and hepatocellular carcinoma in HIV-infected patients[51,52]. Coinfected patients have higher levels of HBV viremia and lower rates of HBeAg clearance[53]. HIV-infected patients are prone to drug-induced liver injuries (especially from nevirapine-based regimens) and hepatitis flares[54]. HBV is reported to increase the risk of acquired immunodeficiency syndrome development, but this report was contraindicated in later studies[55]. All coinfected patients should be treated with ART (antiretroviral therapy) irrespective of the CD4 count[4,56]. ART should contain tenofovir as a part of the regimen. Lamivudine + emtricitabine and tenofovir (TDF or TAF) should be used for treating coinfected patients. TDF + lamivudine+ efavirenz or nevirapine combination has a lower attrition rate and is associated with lower mortality in HIV/HBV infected patients[57]. A fixed drug combination of elvitegravir, cobicistat, emtricitabine, and TAF has excellent efficacy in HIV/HBV coinfected patients[58]. Dolutegravir, emtricitabine and TDF/TAF fixed dose combinations may also be considered for patients with HIV/HBV coinfection[59]. All HBsAg patients should be screened for HIV infection prior to initiating tenofovir-based therapy (to prevent resistance), and HIV-infected patients should be screened for HBsAg prior to initiation of ART[56]. If negative, it is recommended to vaccinate the individual to achieve an anti-HBs of ≥ 10 mIU/mL.

Table 3 Hepatitis B and Hepatitis C in pregnancy

	HBV	HCV
MTCT	90% if HBeAg+; 10% if HBeAg-; Directly proportional to viral load	6%; Higher risk with concomitant HIV infection, higher viral load, IV drug abuse; Higher risk with PROM and CVS
Treatment	TDF is safe; Can be initiated in third trimester	DAAs are not approved; Treat prior to pregnancy or 6 mo postpartum
Effect on pregnancy outcome	None	Preterm birth, ICP
Effect of pregnancy on virus	None	None
Effect of postpartum (immune restoration) on virus	Risk of HBV flares	Higher chance of viral clearance
Timing of transmission	Intrapartum > intrauterine	Intrapartum > intrauterine
C-section for all	Not indicated	Not indicated
Breastfeeding	Not contraindicated	Not contraindicated
Prevention	Active and passive immunization to child prevents 90% of transmission; Failure is nearly 15% if the viral load in mother is > log6	None
Confirming the perinatal transmission	Persistence of HBsAg in newborn for > 6 mo	Anti-HCV positive at 18 mo of age HCV RNA positive after 2 mo on 2 different samples
Confirming the protection	Anti-HBs titers at 9 mo	Negative Anti-HCV at 18 mo

HBV: Hepatitis B virus; HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; IV: Intravenous; MTCT: Mother-to-child transmission; PROM: Prolonged rupture of membranes; CVS: Chorionic villous sampling; Ag: Antigen; ICP: Intrahepatic cholestasis of pregnancy; C-section: Cesarean section.

HCV and HIV coinfection is common in injection drug abusers. HCV does not alter the natural history of HIV; however, HIV infection significantly alters the natural history of HCV. HIV leads to a rapid worsening of liver disease, shortens survival, and increases the risk of decompensations in HCV-related cirrhosis patients[60]. HIV also hastens fibrosis progression in CHC patients. Spontaneous clearance of HCV is noted in 5%-10% of patients with HIV infection, whereas nearly 15%-30% of HIV noninfected patients clear HCV spontaneously[61]. The indication for treating HCV and HIV is similar to those infected with either alone. However, it is recommended to avoid HCV treatment until the CD4 count > 200/μL in coinfected patients[62]. Sofosbuvir (400 mg) plus velpatasvir (100 mg) is the recommended drug of choice for HCV for 12 wk in cirrhosis and noncirrhosis[63]. Glecapravir and pibrentasvir are other options for HIV and HCV coinfected patients for 8 wk (no cirrhosis) or 12 wk (cirrhosis)[20] (Figure 1).

HBV with HCV coinfection: The prevalence of HBV/HCV coinfection varies across the globe. The prevalence of HBV coinfection in HCV-positive individuals ranges from 0.7%-5.8%, and the prevalence of HCV coinfection in HBsAg-positive individuals is between 3.4%-23.0%[64,65]. The presence of HCV coinfection leads to rapid progression of liver disease, fibrosis and accelerates the development of hepatocellular carcinoma (HCC)[65]. Patients with HCV viremia should be treated with DAAs, and those satisfying criteria for treatment for HBV should be treated with NUCs. However, if the patient is HBsAg-positive (not satisfying the treatment criteria for HBV) but requires DAA therapy for HCV, NUCs should be initiated[4]. NUCs should be continued for 12 wk post DAA to prevent reactivation of HBV[4]. HCV core protein strongly inhibits HBV replication, and post DAA lack of HCV core poses a risk for HBV reactivation. The incidence of HBV reactivation is around 12%-14% after HCV treatment[66].

CHEMOTHERAPY AND HEMATOLOGICAL MALIGNANCIES

Patients planned for chemotherapy or immunosuppression should be evaluated for HBV and HCV infection[4]. HBV and HCV are strongly associated with non-Hodgkin's lymphoma[67-69]. Approximately 7%-23% of NHL patients have HBV infection, and 3%-10% harbor HCV infection[69-71]. The risk of HBV reactivation in HBsAg-positive patients undergoing chemotherapy ranges from 26%-53%[72]. HCV

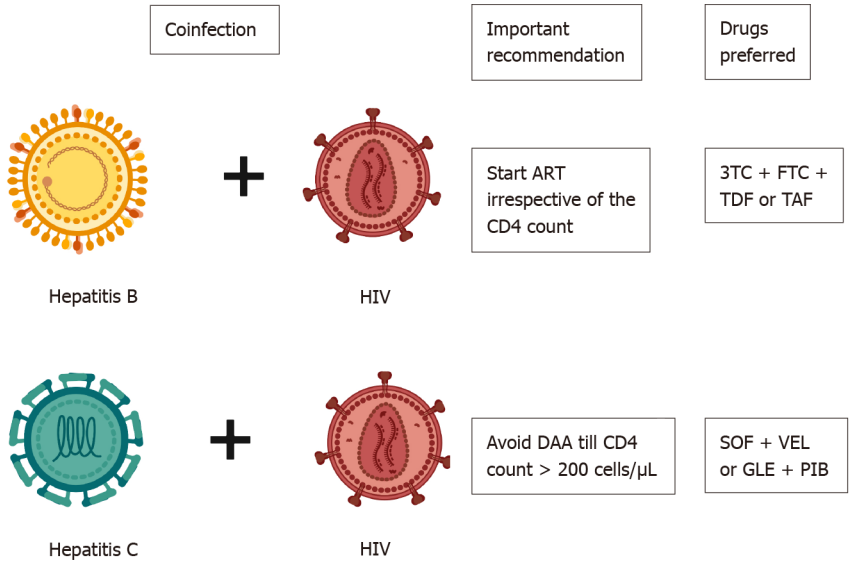

Figure 1 Management of coinfection. Created with biorender.com. HIV: Human immunodeficiency virus; ART: Antiretroviral therapy; 3TC: Lamivudine; FTC: Emtricitabine; TDF: Tenofovir disoproxil fumarate; TAF: Tenofovir alafenamide fumarate; DAA: Directly acting antiviral agents; SOF: Sofosbuvir; VEL: Velpatasvir; GLE: Glecaprevir; PIB: Pibrentasvir.

reactivation is noted in 11% of patients undergoing chemotherapy[73]. If the surface antigen is positive (irrespective of viremia), it is recommended to start NUCs (TDF, TAF, or ETV)[4,72]. Therapy should be continued for 12 mo (18 mo for those on rituximab) after the cessation of immunosuppressive therapy. The stopping rules for those satisfying the standard treatment criteria are the same as those not on immunosuppression.

Patients with HCV viremia should be treated with DAA therapy; however, the timing of therapy is still controversial. If malignancy treatment is deemed urgent, then DAA can be initiated six months after malignancy remission. However, the patient should be monitored for flares. If the malignancy is suspected to be related to the virus itself, then DAAs should be initiated, and viral suppression should be documented prior to chemotherapy initiation[74].

CHILDREN

HBV and children

Chronicity in children is common and depends on the age of acquisition of infection. Perinatally infected patients have a 90% chance of progression to chronicity, while patients infected before 5 years of age have a 25%-50% chance of progression to chronicity. Data on the treatment of the pediatric population are limited. The global prevalence of HBsAg positivity of among children < 5 years of age is 1.3%[75]. The indication for treatment is slightly different from that in the adult population. The presence of cirrhosis (regardless of decompensation status) requires treatment[56]. However, it is recommended to assess the inflammation and stage of fibrosis *via* liver biopsy in all patients prior to therapy. Children with persistently elevated ALT levels (> 1.5 times the upper limit) for ≥ 6 mo who are HBeAg-positive (or ≥ 1 year for HBeAg-negative) with a DNA > 2000 IU/mL and biopsy evidence of moderate to severe necroinflammation or fibrosis require treatment[76]. For patients with a family history of HCC treatment should be initiated even if necroinflammation/fibrosis is mild or absent provided that DNA is > 2000 IU/mL and the ALT levels are elevated [56,76]. TAF (25 mg/d) and ETV (0.015 mg/kg; maximum of 0.5 mg/d) are drugs with high genetic barriers to resistance that are approved for patients aged ≥ 12 years and ≥ 2 years, respectively[75,77]. Last, interferon α-2b (6 million IU/m^2 thrice weekly) is also approved for children aged ≥ 1 year[75]. For HBeAg-positive children, the drug can be stopped 1 year after HBeAg seroconversion[77]. However, the duration of therapy for HBeAg-negative patients is unknown.

HCV and Children: Nearly 0.15% of the global population aged < 18 years has HCV viremia, which corresponds to 3.26 million (2.07-3.9) children. The seropositivity ranges between 0.2% and 0.4% of the population aged < 18 years[78,79]. Interestingly,

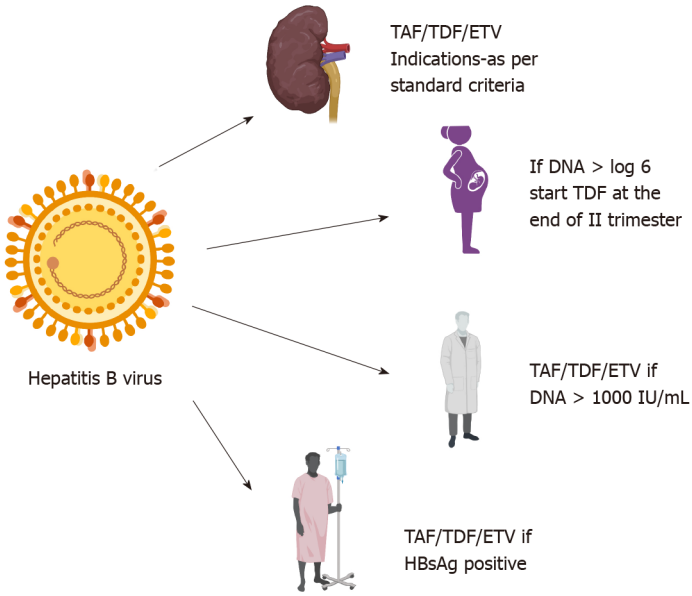

Figure 2 Indications and safety of drugs in special circumstances for hepatitis B. Created with biorender.com. TAF: Tenofovir alafenamide fumarate; TDF: Tenofovir disoproxil fumarate; ETV: Entecavir.

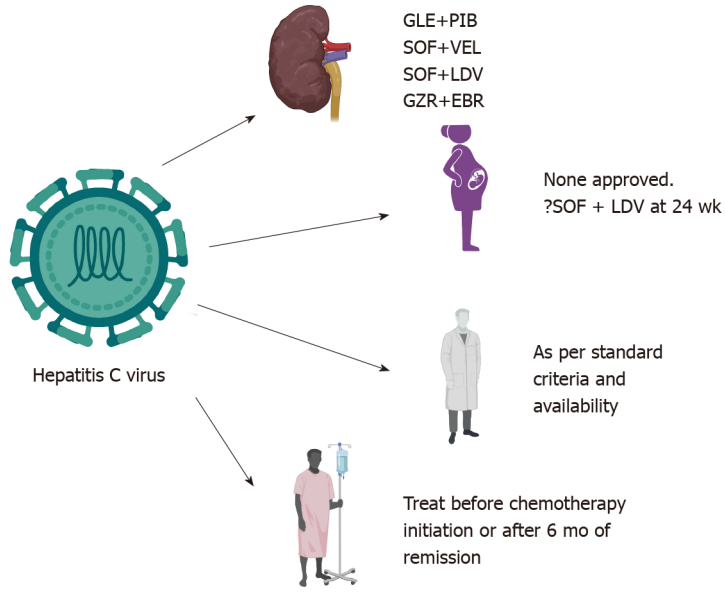

Figure 3 Indications and safety of drugs in special circumstances for hepatitis C. Created with biorender.com. GLE: Glecaprevir; PIB: Pibrentasvir; SOF: Sofosbuvir; VEL: Velpatasvir; LDV: Ledipasvir; GZR: Grazoprevir; EBR: Elbasvir.

25%-40% of children with perinatal transmission spontaneously achieve viral clearance, usually by age 2, and an additional 6%-12% of those with chronic hepatitis C infection may clear the virus before adulthood[80]. Hence, children born to HCV-positive mothers should undergo antibody testing after 18 mo of age[36]. If they are antibody-positive, then their HCV RNA should be assessed after the age of 3 years to confirm the chronicity of infection. The AASLD/IDSA approved drugs widely available are sofosbuvir/Ledipasvir for children aged ≥ 3 years and sofosbuvir/velpatasvir for children aged ≥ 6 years. The doses of these drugs are weight based (sofosbuvir/ledipasvir: < 17 kg: 150 mg/33.75 mg; 17-35 kg: 200 mg/45 mg; ≥ 35 kg: 400 mg/90 mg and sofosbuvir/velpatasvir: 17-30 kg: 200 mg/50 mg; ≥ 30 kg: 400 mg/100 mg) (https://www.hcvguidelines.org/node/2376/summary).

CONCLUSION

Although there are recommendations for each of the above conditions described, further research is required in many areas. The role of TAF in pregnancy is unknown. Since newborns have a higher risk of progression to chronicity if infected, is it prudent to treat all the pregnant mothers' pre-emptively needs to be assessed. Furthermore, in countries in which vertical transmission is the most common mode of infection and testing resources (or ability to provide passive immunization to newborns) are limited, is it beneficial to treat all pregnant women infected with HBV needs to be evaluated. There are some data on the safety of concomitant DAA therapy in patients undergoing chemotherapy without any adverse drug-drug interactions[81]. However, prospective trials are still lacking. The most important aspects of managing HBV and HCV in CKD, pregnant patients, HCWs, and immunosuppressed patients are depicted in Figure 2 and 3.

Abstract

Endoscopic ultrasound (EUS) is one of the significant breakthroughs in the field of advanced endoscopy. In the last two decades, EUS has evolved from a diagnostic tool to a real-time therapeutic modality. The luminal gastrointestinal (GI) tract provides a unique opportunity to access multiple vascular structures, especially in the mediastinum and abdomen, thus permitting a variety of EUS-guided vascular interventions. The addition of the doppler and contrast-enhanced capability to EUS has further helped provide real-time visualization of blood flow in vessels through the GI tract. EUS-guided vascular interventions rely on standard endoscopic accessories and interventional tools such as fine-needle aspiration needles and fine-needle biopsy. EUS allows the visualization of various structures in real-time by differentiating tissue densities and vascularity, thus, avoiding radiation exposure. EUS-guided techniques also allow real-time microscopic examination after target biopsy. Furthermore, many necessary interventions can be done during the same procedure after diagnosis. This article provides an overview of EUS-guided vascular interventions such as variceal, non-variceal bleeding interventions, EUSguided portal vein (PV) access with the formation of an intrahepatic portosystemic shunt, and techniques related to diagnosis of GI malignancies. Furthermore, we discuss current insights and future outlook of

Core Tip: Endoscopic ultrasound (EUS) technology has evolved rapidly in clinical practice, first as merely a diagnostic tool and now a therapeutic modality. EUS-guided interventions involve combining real-time imaging capability with invasive therapeutic interventions. The gastrointestinal (GI) tract has proximity to various vascular structures in the abdomen and mediastinum and thus provides a unique window to access these structures with EUS to render EUS-guided vascular interventions. Herein, this article provides an overview of EUS-guided vascular interventions for GI bleeding, portal vein access, and therapeutic implications, tumor diagnosis, and access to non-GI structures.

INTRODUCTION

Endoscopic ultrasound (EUS) is a minimally invasive specialized procedure that blends endoscopy with ultrasound. The endoscope allows visualizing the gastrointestinal (GI) tract lining, and ultrasound allows visualization of the GI tract walls, surrounding organs, and blood vessels with high-frequency waves. Three different types of echoendoscopes are available: Linear, radial, and mini-probes. Linear echoendoscopes are preferred for pancreaticobiliary interventions such as acquiring tissue, drainage of collections, and injections. Radial echoendoscopes are preferred for the staging of esophageal and gastric cancers[1,2]. Mini probes are more useful in diagnosing mucosal malignancy, pancreaticobiliary diseases (such as malignancy or stricture) because of their high frequency[1]. EUS can visualize both solid and fluid structures in the GI lumen and extraluminal. Various structures accessible with EUS include the luminal wall of the GI tract (esophagus, stomach, duodenum, and rectum), liver, pancreas, gallbladder, biliary tree, mediastinum, and lymph nodes. In addition, EUS can identify various arterial and venous vascular structures in proximity to the GI tract are accessible. Feeding vessels from small branches of vessels and aberrant vascular shunts can also be visualized by EUS[2,3].

Since the introduction of EUS in 1980 for diagnostic purposes, significant evolution has occurred (Figures 1 and 2). Its application on humans dates back to 1982[4]. This evolved in 1991 when EUS-guided fine-needle aspiration (FNA) was first introduced, and it allowed to do therapeutic interventions outside the lumen of the GI tract[5]. In 1996, EUS-guided cholangiography and EUS-guided biliary drainage were introduced [6]. Furthermore, the role of EUS expanded rapidly over the last 20 years from the diagnostic to the therapeutic tool as it provides direct visualization, access to structures within and outside the GI tract. Several new advancements in EUS-guided vascular procedures have emerged due to the proximity of many blood vessels to the GI tract and the ability to deliver precise real-time interventions. It has been further expanded to target gastric variceal bleeding by cyanoacrylate (CYA) injection[7]. In 2008, EUS-guided glue injection and micro coil embolization were used to treat a patient with refractory gastric variceal bleeding. Additionally, EUS can obtain real-time portal pressures in patients suspected of portal hypertension (PH) and obtain liver core biopsies to evaluate for fibrosis in one setting. Given its ability to access the portal vein (PV), interventions such as PV thrombectomy have been possible. Given these advances, we aim to discuss updates and emerging trends in EUS related

vascular interventions.

ROLE OF EUS IN THE MANAGEMENT OF GI BLEEDING

Variceal bleeding

Esophageal varices: Endoscopic band ligation (EBL) is the preferred treatment for bleeding and non-bleeding esophageal varices. However, endoscopic sclerotherapy is an additional treatment that is still used, especially when EBL is not feasible[8]. Although these therapies are successful, the rate of recurrent bleeding can range up to 15%-65%[9]. The higher recurrence is most likely due to failure to treat perforating and collateral vessels. Echoendoscope provides benefits over endoscope due to its ability to visualize and target these high-risk vessels under direct visualization[10,11]. EUS-guided sclerotherapy for esophageal varices was first described in 2000 by Lahoti *et al* [12] in a study of 5 patients. A sclerosing agent such as sodium morrhuate was injected into target perforating vessels under EUS guidance until complete blood flow cessation was confirmed with the doppler. A mean of 2.2 sessions (range 2-3 sessions) were required to achieve the complete eradication of varices. No recurrence of bleeding or death was reported during 15 mo follow-up. Only one patient developed esophageal stricture, which was managed with balloon dilation[12].

The above study showed comparable results of EUS-guided sclerotherapy for esophageal varices. Therefore, EBL is still a preferred treatment for esophageal varices. Large, randomized trials are needed to show the clinical benefits of EUS-guided sclerotherapy compared to EBL to consider it as one of the first-line treatments.

Gastric varices: Although gastric varices (GV) are less common than esophageal varices, it affects around 20% of patients with PH[13,14]. GV can occasionally cause bleeding, leading to iron deficiency anemia, and the risk of rebleeding (34%-89%) is much higher than compared to esophageal varices (15%-65%)[13]. There are no well-

established treatment guidelines for the management of GV compared to esophageal varices[15]. EBL is not recommended for managing GV as they are larger in size, with thick overlying gastric mucosa making it difficult to band. EBL of GV can lead to life-threatening bleeding due to post-band ulcerations, developed due to a failure to capture the contralateral wall of varices during the procedure[16]. In a study of 22 patients with bleeding GV treated with EBL, 18.2% developed early rebleeding even after complete hemostasis was achieved in all cases on EBL[17]. Endoscopic sclerosing therapy should also be avoided in bleeding GV as it provides only temporary control of bleed and a higher incidence of adverse events like gastric ulcerations, perforations, and rebleeding in 37%–53% of cases[18].

Glue therapy with CYA is the primary treatment of choice for GV. It was first described in 1986 as it has higher rates (> 90%) of achieving hemostasis and a lower rate of rebleeding (0%-40%) compared to other therapies (EBL and sclerotherapy)[19, 20]. However, there are reports of significant adverse effects associated with CYA injections like systemic embolization (cardiac embolism, pulmonary embolism, splenic vein thrombosis, splenic artery embolism, renal vein thrombosis, and cerebral infarct), which is thought to be related to the volume of CYA injection[21]. EUS assists in both the diagnosis and treatment of GV. It helps in diagnosis and allows a precise evaluation of pathological vessels, improving therapeutic targeting. Color doppler also permits to differentiation of GV from other structures and can help confirm eradication of varices. EUS has provided us a new array of treatment options, including coil embolization with or without glue therapy and thrombin injection *etc.*, in the treatment of GV[13,20].

Glue therapy. Endoscopic-CYA injection has been shown to control bleeding, but there is a high recurrence of bleeding, probably due to incomplete obliteration of varices. EUS-guided CYA glue injection can minimize recurrent bleeding and decrease CYA volume by directly visualizing the perforating vessels, thus more precise obliteration of varices. Theoretically, the risk of embolization also decreases as it allows precise CYA injection into the target vessel[7].

A total of six patients with GV, including four for secondary prophylaxis, were treated with EUS-guided coil embolization followed by CYA glue injection in a single-center retrospective study. Complete eradication of GV was achieved in 3 patients. One patient had pulmonary embolism as a complication of CYA glue injection[22]. In a large single-center study, 40 patients underwent EUS-guided n-butyl-2-CYA for GV. Out of 40 patients, 13 patients were treated during active bleeding and another 23 within 24 h of bleeding. Thus, bleeding was acutely controlled in 100% of cases after treatment with EUS-guided n-butyl-2-CYA therapy. Only six patients required additional intervention for long-term management (Table 1)[23].

In a single-center study, 40 patients with actively/recently bleeding or high-risk GV treated with direct endoscopic injection of CYA were compared with 64 patients treated prospectively with EUS-guided fine needle injection CYA. Gastroesophageal varices type 2 was the most common type of varices seen in both groups. During the procedure, a greater number of varices were obliterated in EUS-guided fine needle injection of the CYA group (1.6 ± 0.7) than the direct endoscopic injection of the CYA group (1.1 ± 0.4, $P < 0.001$). Whereas the mean volume of CYA was injected more in the direct endoscopic injection-CYA group (3.3 ± 1.3 mL) compared to EUS-guided fine needle injection of the CYA group (2.0 ± 0.8 mL, $P < 0.001$). Overall post-procedure GV rebleeding (23.7% *vs* 8.8%, $P = 0.045$) and non-GV-related GI bleeding (GIB) (27.5% *vs* 10.9%, $P = 0.030$) were found to be higher in the direct endoscopic injection of CYA group compared to EUS-guided fine needle injection of CYA group. No significant difference was found in the overall rate of adverse events in the direct endoscopic injection of CYA group (17.5%) and EUS-guided fine needle injection of CYA (20.3%, $P = 0.361$)[24]. EUS-guided glue injection appears to be safe and effective in decreasing the risk of rebleeding in patients with active or recent bleeding GV when compared to the endoscopic injection of CYA.

Coil embolization. EUS-guided coil application is another treatment modality for GV. Coils are commonly used for various interventional radiology procedures (Table 1). These micro coils can obliterate GV and avoids adverse effects associated with CYA use, such as embolization coils are made up of light metal alloy and are covered with synthetic fibers to induce clot formation and subsequent hemostasis. Furthermore, fibers can act as a scaffold for CYA if injected during the same procedure. Varices are identified and punctured through standard FNA size needles like 19G (0.035-inch coil) or a 22G (0.018-inch coil). These coils are then advanced from the needle into varix using the stylet as a pusher. The coil sizes are selected based on the size of varix[25,26].

Table 1 Endoscopic ultrasound-guided gastric varices treatment

Type of Intervention	Year	Ref.	Number of patients, *n* (%)	Follow up (mo)	Obliteration of varices/Clinical success %	Recurrent bleeding rate %	Adverse events %

CYA: Cyanoacrylate.

A retrospective multicenter study compared EUS-guided CYA injection (n = 19) to EUS-guided coil embolization (n = 11) patients with GV. There was no statistically significant difference in obliteration rate, the mean number of sessions required, and recurrence noted during follow-up. However, adverse events were reported to be higher in the CYA group in [11/19 (57%)] when compared to EUS-guided coil embolization [1/11 (9.1%), P < 0.01]. A post-procedure computed tomography (CT) scan was performed in all patients, and nine patients in the CYA group were found to have asymptomatic glue embolism on imaging[26] (Table 1). This was the first study to compare coil embolization and CYA directly. Both procedures showed comparable results in terms of GV obliteration, but fewer adverse events were noted with coil embolization.

In another study, ten patients with GV underwent EUS-guided coil embolization and then reinforcement by gelatin sponges. Nine patients had either active bleeding or recently bled GV. A 100% obliteration of GV was achieved. Patients were followed for six mo, and only 1/10 patients developed severe abdominal pain as a complication. Further large prospective studies are needed describing its direct comparison with other treatment modalities like CYA or CYA and coil embolization combined[27].

Combined coiling and glue therapy. Although endoscopic CYA injection is considered primary therapy for GV, it is associated with systemic glue embolization. Synthetic fibers in the covering of coils function as a scaffold to keep CYA in varices; thus, a decrease of CYA reagent is needed to eradicate gastric fundal varices (GFV) and also may reduce the risk of glue embolization. In another study by Kozieł *et al*[14], four patients were treated with coils, and 12 patients were treated with EUS-guided coil and CYA injection. These patients were followed for an average of 327 d. The technical success rate was 94%, and the mean number of CYA volume and coils needed *per* procedure was 2 mL and 1.7, respectively. No serious complications like embolization or death were noted (Table 1).

A randomized pilot trial was conducted comparing the safety and efficacy of EUS-guided coil and CYA (n = 16) to EUS-guided CYA in GV patients, and these patients were followed for an average of 9.9 mo. EUS doppler was done in all cases to determine flow within varix after the procedure, and thoracic and abdomen CT was done in all cases 1 wk after the procedure. Repeat CT scans were done in symptomatic cases only afterward. In the EUS-guided coil and CYA *vs* EUS-guided CYA group, the total reduction inflow in the treated vessel was 37.5% *vs* 50% (P = 0.476) and 73% *vs* 80% (P = 1) immediately and at 30 d after the procedure, respectively. In addition,

asymptomatic pulmonary embolism was found to be in 25%, and 50% cases (P = 0.144) in EUS-guided combined coil and CYA and EUS-guided CYA, respectively[13] (Table 1).

A metanalysis and systematic review was conducted comparing EUS-guided CYA injection, EUS-guided coil embolization and CYA injection combined, and EUS-guided coil injection alone. Combined EUS-guided CYA and coiling were found to have better technical and clinical success rate compared coil embolization alone (99% *vs* 97%; P < 0.001 and 96% *vs* 90%; P < 0.001) and CYA alone (100% *vs* 97%; P < 0.001 and 98% *vs* 96%; P < 0.001). Similarly, lower adverse events were found to be with EUS-guided CYA and coil combined compared to coil embolization (10% *vs* 3%; P = 0.057) and CYA alone (10% *vs* 21%; P < 0.001)[15]. Given the above results from various studies, EUS-guided coil embolization and CYA injection combined therapy could be preferred compared to EUS-guided monotherapy with either coil or CYA injection alone.

Thrombin injection. Recently, a study of eight patients (three with active bleeding and five as elective prevention) with GFV treated with EUS-guided thrombin injection was published. About 2/3 of patients with active bleeding had successful hemostasis and obliteration of varices. All five patients who underwent the procedure for prevention of future bleeding had complete obliteration of varices. No direct procedure-related complications were observed. Although this series showed positive results, further large prospective studies are needed[19].

Ectopic varices: Ectopic varices can develop at any site, including duodenal, small bowel, colon, rectum, common bile duct, and peristomal, with duodenum ectopic varices are being the most frequent to bleed[25,28]. Many case reports have described the use of EUS for variceal bleeding at ectopic sites. Cases of duodenal variceal bleed treated with EUS-guided coil and CYA have been described without any complications[29].

Rectal varies are reported in 44%-89% of cirrhosis patients because of PH[30]. It can also be seen in patients with vascular anomalies, mesenteric vein obstruction, adhesions, and heart failure. However, rectal varices are a lower bleeding risk than esophageal and GV[11]. EUS can help detect and treat the presence of rectal varices better than the endoscopy (Table 2). Although most of the data for EUS-guided intervention for bleeding ectopic varices is based on case reports/series, it is emerging as a viable option.

Non-variceal GIB

GIB can be due to variceal or non-variceal causes[31]. Standard endoscopic treatments for non-variceal bleeding include injection (epinephrine), thermal (argon plasma coagulation, electrosurgical coagulation), and mechanical therapy (such as clipping). Despite these interventions, rebleeding or refractory bleeding is reported as high as 10%-24% in these patients[31]. EUS-guided therapies are advantageous over endoscopic therapy due to the ability to directly visualize target vessels buried in the walls of the organ along with real-time doppler. A literature review of 35 patients who underwent EUS-guided treatment of non-variceal GIB (NVGIB) showed a favorable clinical outcome in 32/35 (91.4%) patients, with recurrent bleeding in only three patients. Moreover, bleeding eventually stopped in all cases. The median follow-up time was 11 mo, and no complications or adverse events were reported during or after the procedure[32]. EUS-guided treatment can also be used as an adjunct treatment in refractory and recurrent disease.

Dieulafoy's lesions

The first use of EUS-guided therapy for Dieulafoy's lesion was described in 1996 when EUS was used to detect and treat eight patients referred for suspicion of Dieulafoy's lesion. A large vessel was identified in the stomach wall in all eight patients, which was treated with adrenaline/polidocanol injection using a sclerotherapy needle. Two patients had rebleeding during follow-up, one with recurrent bleeding from Dieulafoy's lesion and the other from duodenal ulcer. EUS-guided angiotherapy was described by Levy *et al*[33] in a case series of five patients with refractory bleeding due to hemosuccus pancreaticus, Dieulafoy lesion, duodenal ulcer, GI stromal tumor (GIST), and occult GIB. These patients had failed at least two conventional treatment options and received an average of 18 units of packed red blood cell transfusions. Patients were treated by injecting CYA (3-5 mL) or 99% alcohol into a feeding vessel using a 22G FNA needle under EUS-guidance. Doppler was used to ensuring the absence of blood flow after treatment. These patients were followed up for a mean 12-mo period (range 0.4-23 mo), no rebleeding or complication was reported[33].

Table 2 Case report studies on endoscopic ultrasound-guided rectal varices treatment

Ref.	Presenting symptom	Number of patients, age, sex	Rectal varices size	Therapy	Results	Follow up	Results on follow up
Philips and Augustine[64], 2017	Rectal bleeding	1, 48 yr, M	Large rectal varix	EUS-guided embolization coil and glue	No further bleeding	1 mo	No rebleeding
Bazarbashi *et al* [65], 2020	Rectal bleeding	1, 71 yr, M	Large rectal varices (4 mm in diameter)	EUS-guided coil embolization	No further bleeding	6 mo	No bleeding
Mukkada *et al* [66], 2017	Rectal bleeding	1, 65 yr, M	Large rectal varices	First EUS-guided sclerotherapy, but unable to achieve hemostasis, EUS guided glue	No further bleeding	1 wk	Rebleeding and then required EUS-guided coil embolization

F: Female; M: Male; EUS: Endoscopic ultrasound; N/A: Not applicable.

Law *et al*[34] performed EUS-guided hemostatic interventions between June 2003 to May 2014 for 17 patients with refractory NVGIB. Causes of GIB were GIST, colorectal, vascular malformations, Dieulafoy lesions, duodenal ulcers, masses or polyps, rectally invasive prostate cancer, pancreatic pseudoaneurysms, ulcerated esophageal cancer, and ulceration after Roux-en-Y gastric bypass. These patients were treated with epinephrine, 99% ethanol, coil embolization, band ligation, hyaluronate, and CYA using a therapeutic curvilinear echoendoscope with a 22G standard FNA needle. On median follow-up of 12 mo (range 3 wk-120 mo), 15/17 (88%) patients didn't have any recurrence. However, one patient required repeat EUS-guided band ligation for gastric Dieulafoy lesion, and another patient with rectally invasive prostate cancer experienced ongoing bleeding despite a decrease in vessel flow after treatment with 99% ethanol injection.

Pseudoaneurysms

Pseudoaneurysms are a known complication of pancreatitis with a risk of rupture and life-threatening bleeding. The risk of rupture is as high as 50%, with 15%-40% of mortality after rupture. Gamanagatti *et al*[35] described a case series of three patients with pancreatitis-related pseudoaneurysm, which were technically challenging to treat by the endovascular route. These cases were managed with EUS-guided thrombin injection, which resulted in complete thrombosis of the pseudoaneurysms. There were no immediate or late complications on follow-up. In a prospective study, eight patients with symptomatic visceral artery pseudoaneurysm who were unable to undergo angioembolization underwent EUS-guided thrombin injection for pseudoaneurysm. Out of eight patients, 5 had pseudoaneurysm of the splenic artery, 2 had pseudoaneurysm of the hepatic artery, and one patient had pseudoaneurysm of the gastroduodenal artery. Five patients with splenic artery and gastroduodenal artery aneurysms had chronic pancreatitis due to alcohol abuse. The pseudoaneurysm's median size was 2.9 cm × 2.6 cm (range 1.8 cm × 1.9-4 cm × 5 cm), and the median dose of thrombin injected was 400 IU (200-500 IU). Thrombin was injected under EUS guidance with 100% technical success. Repeat EUS after 72 h and 4 wk showed obliteration of pseudoaneurysm in all patients. Whereas on median six mo (1-9 mo) follow up, EUS showed obliterated pseudoaneurysm in 7 patients, and one patient had recurrence requiring recanalization after 6 wk[36]. There are few case reports describing the use of EUS-guided intervention for pseudoaneurysms (Table 3).

GIST

EUS is traditionally used to evaluate GI luminal tumors and obtain a tissue diagnosis. Bleeding GISTs are traditionally managed by either surgical resection, radiologic embolization, or rarely with endoscopic therapies like hemoclips and endoloop® ligation. In an elderly patient with a bleeding ulcer due to GIST who was not a candidate for surgery due to comorbidities, EUS-guided angiotherapy was done. A deep vessel was identified to bleeding GIST ulcer *via* echoendoscope, and the target vessel was treated with CYA, which stopped bleeding. Doppler confirmed the absence of vascularity, and the patient had no further bleeding at 6 mo follow-up[37]. In a study, 32 consecutive patients with submucosal tumors of the upper GI tracts underwent EUS examination with either radial or linear echoendoscope with color and

Table 3 Case report studies on endoscopic ultrasound-guided treated for pseudoaneurysm

F: Female; M: Male; EUS: Endoscopic ultrasound; GI: Gastrointestinal; N/A: Not applicable.

Doppler capabilities: 51.4% had a discrepancy between suspected endoscopic and EUS diagnosis, 83.3% of malignant GISTs had significant intratumoral vessels seen on doppler or color EUS compared to 28% in benign GIST. Three patients were found to have vascular lesions, hemangioma on color Doppler EUS. In two patients, these lesions were treated with EUS-directed therapy consisted of ligation, coagulation, injection of sclerosing agents, or histoacryl resulting in complete eradication of lesions. One patient required surgery due to the severity of the bleeding. The patients remained asymptomatic on a mean follow-up of 48 mo[38].

Although the results of EUS-guided therapies in non-variceal bleeding are encouraging, most of the data is based on case reports and case series. No studies have compared EUS treatment with other management therapies such as endoscopic, surgical, and interventional radiology. Further large-scale studies comparing the standard treatment are needed. At present, EUS-guided therapies are available only at high-level care centers when other treatment options fail.

EUS-GUIDED PV INTERVENTIONS

PV access and pressure measurement

PV access can help to manage patients with the hepatobiliary diseases and PH. PV is not easy to access with traditional routes. Nevertheless, PV can easily be seen from the stomach and duodenum with EUS and accessed using a standard FNA needle. EUS, along with doppler, is used for needle puncture and withdrawal without hemorrhage [39]. Initial studies of EUS-guided PV access were performed in animals.

The measurement of PH can help to stage cirrhosis and thus prognosis. Portal pressure gradient (PPG) reflects the degree of PH. PPG ≥ 10 mmHg is associated with esophageal varices, and ≥ 12 mmHg is associated with variceal bleeding[40]. Currently, PH is evaluated by indirect measurement of the hepatic venous pressure gradient (HVPG), which poorly correlates with directly measured portal pressure in presinusoidal PH. Presinusoidal PH can be seen in the case of PV thrombosis, schistosomiases, and non-cirrhotic portal fibrosis[41-43].

The first human pilot study conducted to measure EUS-guided PPG measurement included 28 patients with a history of liver disease or suspected cirrhosis. The PV and hepatic vein (or inferior vena cava) were punctured with a 25G FNA needle under EUS guidance either through a transgastric or transduodenal approach. A 100% technical success with no complications was reported. PPG measurement showed a correlation with clinical and endoscopic parameters of PH, including the presence of varices (P = 0.0002), portal hypertensive gastropathy (P = 0.007), and thrombocytopenia (P = 0.036). PPG was shown to increase in patients with high clinical evidence of cirrhosis (P = 0.005)[40]. This study showed that the EUS-guided PPG measurement is safe in humans and further large clinical trials to evaluate safety and efficacy, especially compared to standard HVPG measurement methods, as intrahepatic portosystemic shunt (IPSS).

Transjugular IPSS (TIPS) is performed by interventional radiologists to reduce the PPG. TIPS decompresses the portal system and reduces complications due to PH, such as recurrent variceal bleeding and refractory ascites. It is usually performed in patients with refractory variceal bleed. TIPS involves catheter advancement and guidewire through the right heart and then inferior venacava (IVC) *via* transjugular route. It can expose patients to unintentional carotid or tracheal puncture, cardiac arrhythmias, and pneumothorax. Also, the transjugular approach for TIPS can be technically challenging in patients with IVC and hepatic vein obstruction, including Budd-Chiari syndrome. EUS-guided IPSS offer benefit as it does not involve heart catheterization, avoiding the related complications[44-48].

A study was conducted to create IPSS using lumen opposing metal stent (LAMS) in a porcine model. PV was accessed by puncturing through the stomach wall and IVC with a 19G needle under EUS guidance. A distal flange of the stent was deployed in the PV and the proximal flange in IVC. Gross necropsy of all five animals showed the correct placement of a stent and no tissue injury or hematoma[49]. Although IPSS has shown promising results in animal models, more studies are needed to evaluate the efficacy and safety of this technique.

PV embolization

Preoperative PV embolization induces the atrophy of the embolized liver lobe to be resected and compensatory hypertrophy of non-embolized remnant liver to increase future liver volume to prevent postoperative liver dysfunction. It is performed in patients with hepatocellular carcinoma (HCC), intrahepatic or hilar cholangiocarcinoma receiving extensive liver resection[25,50]. Liver resection should be performed 2 to 6 wk after PV embolization as compensatory hypertrophy of non-embolized remnant liver occurs in 6 wk with a maximum in the first 2 wk after the procedure. Proceduralists should have meticulous knowledge of liver and portal venous system anatomy before performing this procedure[51]. Presently it is performed through a percutaneous transhepatic approach by vascular interventional radiologist[50]. In a live porcine model to study EUS-guided selective intrahepatic PV embolization, PV was punctured with a 19G FNA needle under EUS guidance, the first coil, and then CYA was injected through the same FNA needle. Doppler was used to evaluating the blood flow. Coil and CYA delivery had a success rate of 88.9% and 87.5%, respectively. In one case, the embolized coil migrated to hepatic parenchyma, and CYA injection failed one case due to the early clogging of CYA in the FNA needle. One wk later, postoperative necropsy showed total occlusion of selected PV with embolus and no evidence of damage to any other organ[50]. Further studies are needed comparing the EUS-guided PV embolization to the percutaneous approach and evaluate the long-term effects.

Portal venous blood sampling

Pancreaticobiliary cancers (PBCs) are usually at advance to late stages at the time of diagnosis. Circulating tumor cells (CTCs) circulate from the primary tumor to distant sites through vascular supply, and their number is usually low in peripheral blood. In the case of PBCs, CTCs can be detected in the portal circulation before the peripheral blood and can be used to detect metastasis[25,52,53].

In a single-center cohort study, 18 patients with suspected PBCs had blood aspirated from PV *via* a 19G FNA needle through a EUS-guided transhepatic approach. Paired peripheral blood samples were also collected. Epithelial-derived CTCs were isolated. CTCs were detected from PV samples in all 18 patients (100%), whereas only in peripheral blood samples of four patients (22.2%). These CTCs isolated from PV can also provide sufficient cells to do genomic and proteomic tumor profiling[52].

In another study performed on patients undergoing pancreaticoduodenectomy for presumed periampullary or pancreatic adenocarcinoma without metastatic disease, PV and peripheral venous samples were collected simultaneously at the time of surgery. Sixty patients were monitored postoperatively every three months for one year with imaging for liver metastasis. CTCs were detected in 58% of cases in PV blood compared to 40% in a peripheral blood sample ($P = 0.0098$). CTCs count was also high PV sample than peripheral blood sample (mean, 230.1 *vs* 71.7, $P = 0.0002$). Liver metastasis was detected in 11 of 13 patients with high portal CTCs count (> 112 CMx Platform estimated CTCs in 2 mL blood) compared to 6 of 47 patients with low portal CTCs count ($P < 0.0001$) at 6-mo follow-up after surgery. The results of this study concluded that the CTCs can be used as a predictor for liver metastases within six months after surgery in patients undergoing pancreaticoduodenectomy for presumed periampullary or pancreatic adenocarcinoma[53]. Unfortunately, PV blood sampling with an evaluation of CTCs is only available in the limited number of specialized

tertiary care centers. Further larger studies are needed to ensure the efficacy and safety of the procedure before making it standard of care to predict hepatic metastasis in patients with pancreatic adenocarcinoma.

FNA of PV thrombus

PV thrombosis due to tumor invasion by direct venous extension or metastasis is seen in up to 70% of cases of HCC[54]. Patients with HCC can also have nontumor (bland) thrombosis of PV. It could be challenging to differentiate PV tumor thrombosis (PVTT) from bland PV thrombosis based on routine radiographic imaging. It is essential to diagnose PVTT as it is a poor prognostic sign, and curative resection or liver transplantation is contraindicated if the patient has PVTT. Transabdominal ultrasound-guided FNA has limited utility due to the difficulty of sample thrombus in the central main PV without contaminating with normal hepatocytes or liver mass, which can affect results. Furthermore, this procedure can have several complications, including vascular injury, pseudoaneurysm formation, and bile duct injury. EUS-guided FNA can directly access the extrahepatic PV without passing the needle through liver tissue[54,55]. Several case reports of EUS-guided FNA of PV thrombosis for diagnosis and staging of HCC even in patients when imaging did not show any liver mass[54-56].

Liver-directed PV injection chemotherapy

The liver is a common site of metastasis from other primary tumors. Patients with diffuse liver metastasis usually resort to palliative systemic chemotherapy given limited options available. It is hypothesized that the direct injection of chemotherapy into PV may increase the drug level in hepatic tissue while decreasing systemic side effects[25,57]. In a study, EUS-guided portal injection chemotherapy (EPIC) was performed by injecting irinotecan (100 mg) loaded microbeads by using a 22G FNA needle, and the control group had saline injected to PV and irinotecan (100 mg) injected into the jugular vein. EPIC resulted in twice a level of irinotecan in hepatic tissue after 1 h. and half the irinotecan level in plasma after 15 min[57]. These animal studies showed that EPIC could be an option for patients with diffuse liver metastasis; however, no human studies are available currently.

ROLE IN TUMOR DIAGNOSIS

Invasion of the vascular structures by tumor impacts staging and therapeutic options, including tumor resectability. Vascular invasion can often be diagnosed based on radiographic imaging like CT, magnetic resonance imaging (MRI), or positron emission tomography scans. However, sometimes it is difficult to judge based on the imaging as in pancreatic ductal adenocarcinoma. Similarly, tumor thrombi can be challenging to differentiate from bland thrombi based on imaging. EUS-guided FNA and elastography can be helpful in these cases.

In a retrospective study, forty-four patients with pancreatic ductal adenocarcinoma underwent dynamic CT and EUS, EUS-B mode imaging was taken, and also EUS elastography was done in all cases. Sensitivity, specificity and accuracy (95%CI) for vascular invasion were 0.733, 0.697 and 0.708 on dynamic CT; 0.733, 0.606 and 0.646 in EUS B-mode; and 0.917, 0.900 and 0.906 in EUS elastography. EUS-B mode and EUS elastography should be considered in patients with pancreatic ductal adenocarcinoma, where dynamic cannot detect vascular invasion[58].

ACCESS TO NON-GI STRUCTURES

The heart and pulmonary vascular systems can be easily accessed *via* EUS because of their proximity to the esophagus. Transesophageal echocardiography is routinely done in cardiac patients for various conditions[59]. Fritscher-Ravens *et al*[60] conducted a study where they performed EUS-guided puncture of the heart in a porcine model using a linear array echoendoscope followed by three clinical cases. In the porcine study, 22- and 19-gauge EUS needles were used to access the left atrium, left ventricle, coronary arteries, and aortic valve. In the porcine group, procedures performed included needle biopsy of cardiac muscle; contrast injection into the left atrium, ventricle, coronary arteries; radiofrequency ablation of aortic and mitral valves; and passage of a guidewire. No arrhythmias were reported during the procedures. During

necropsy, penetration sites were identified, but they were unremarkable in appearance; no bleeding or hematoma was noticed. Subsequently, EUS-guided cardiac access was performed in three patients. In two patients, pericardial fluid was aspirated for diagnostic purposes using a 22-gauge EUS needle, and the third patient had the FNA of atrial mass. No adverse events were observed after procedures in these patients.

Somani *et al*[61] described EUS-guided thrombolysis of pulmonary artery thrombus in a 57-year-old patient who presented with shortness of breath, shock, and acute abdominal pain. The patient had a superior mesenteric vein and right pulmonary artery thrombus. Given the shock state and history of recent hemorrhagic stroke, EUS-guided thrombolysis of pulmonary artery thrombus was done with Tenecteplase using 25G needle. Repeat EUS after 48 h and one before 15 d showed a reduction in the volume of thrombus.

Gaps in knowledge

The GI tract provides access to several vascular structures in the mediastinum, abdominal, and pelvis. Currently, most vascular interventions are done by an interventional radiologist through a percutaneous route. EUS provides access to most of the vasculature through the GI tract and the ability to do real-time interventions. Various studies have shown promising results for the safety, clinical and technical success of EUS-guided vascular intervention concluding that it should be considered either as first-line therapy or when conventional treatment fails. Although results are promising, it is based on case reports and series except in GV management, for which relatively more extensive studies are available.

Given that most data is available from case studies and series, it increases the risk of selection bias. Furthermore, these studies are available from tertiary care centers due to the limited availability of EUS and specialist trained in echoendoscope. EUS will eventually offer a less invasive and safer approach to various vascular interventions as this field expands further.

CONCLUSION

The GI tract provides a unique window to vascular structures in the mediastinum and abdomen, which can be accessed through FNA needle. Various studies have shown promising results for the safety, clinical and technical success of EUS-guided vascular intervention concluding that it should be considered either as first-line therapy or when conventional treatment fails. Although results are promising, it is based on case reports and series except in GV management for which relatively more extensive studies are available. Given that most data is available from case studies and series, it increases the risk of selection bias. Furthermore, these studies are available from tertiary care centers due to the limited availability of EUS and specialist trained in echoendoscope. As this field advances, EUS will offer a less invasive and safer approach to various vascular interventions.

Abstract

BACKGROUND

Fuzi (*Radix aconiti* lateralis)-*Gancao* (*Radix glycyrrhizae*) is one of the most classical drug pairs of traditional Chinese medicine. In clinical practice, decoctions containing *Fuzi-Gancao* (F-G) are often used in the treatment of liver diseases such as hepatitis and liver failure.

AIM

To investigate the metabolomics of F-G in CCl_4 induced acute liver injury in rats and its regulatory effect on the bile acid profile.

METHODS

The pharmacodynamic effect of F-G on CCl_4 induced acute liver injury in rats was evaluated, and an ultra performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS) method for the simultaneous determination of 92 metabolites from multiple pathways was established to explore the protective metabolic mechanism of F-G in serum on the liver.

RESULTS

Twenty-four differential metabolites were identified in serum samples. The primary bile acid biosynthetic metabolic pathway was the major common pathway in the model group and F-G group. Subsequently, a UPLC-MS/MS method for simultaneous determination of 11 bile acids, including cholic acid,

University Research Ethics Committee.

ursodeoxycholic acid, glycochenodeoxycholic acid, glycochenodeoxycholic acid, taurocholic acid, glycocholic acid, chenodeoxycholic acid, deoxycholic acid, taurochenodeoxycholic acid, taurocholic acid, and glycinic acid, was established to analyze the regulatory mechanism of F-G in serum. F-G decreased the contents of these 11 bile acids in serum in a dose-dependent manner compared with those in the model control group.

CONCLUSION

F-G could protect hepatocytes by promoting the binding of free bile acids to glycine and taurine, and reducing the accumulation of free bile acids in the liver. F-G could also regulate the compensatory degree of taurine, decreasing the content of taurine-conjugated bile acids to protect hepatocytes.

INTRODUCTION

The liver is an important metabolic organ of the human body that has the physiological functions of detoxification, phagocytosis, and defense[1]. With the development of modern industry, liver injury caused by environmental pollution is gradually increasing. Liver injury is an important pathophysiological process in the development of hepatitis, liver fibrosis, liver cirrhosis, and liver cancer. Therefore, the treatment of liver injury is important for the prevention, treatment, and recovery of a variety of liver diseases[2,3].

Bile acids are one of the most sensitive indicators for the clinical diagnosis of liver diseases[4,5]. When the liver system is diseased, it can cause a disturbance in the metabolism of bile acids in the body, thus causing a significant change in the amount of bile acids in the blood. Therefore, biomarkers of the bile acid metabolism pathway are very important diagnostic and therapeutic indicators for liver disease[4-6]. Liver diseases such as liver injury, hepatitis, cirrhosis, and hepatocellular carcinoma have significantly increased serum total bile acid levels, and changes in total bile acid levels are usually analyzed in clinical tests but are not highly specific[6,7]. Therefore, the changes in the bile acid profile based on the metabolic pathway of bile acids have important significance for the prevention and treatment of liver diseases. Bile acids can be divided into primary and secondary bile acids[8,9]. Primary bile acids are bile acids synthesized directly from cholesterol by hepatocytes and mainly include cholic acid (CA) and chenodeoxycholic acid (CDCA). Secondary bile acids are free bile acids produced by the primary bile acids deoxycholic acid (DCA) and lithocholic acid (LCA) after 7α-hydroxy deoxygenation of the intestinal flora. These free bile acids bind with glycine and taurine to form conjugated secondary bile acids such as glycocholic acid (GCA), glycochenodeoxycholic acid (GCDCA), glycochenodeoxycholic acid (GDCA), taurocholic acid (TCA), taurochenodeoxycholic acid (TCDCA), ursodeoxycholic acid (UDCA), glycinic acid (GLCA), and taurocholic acid (TUDCA).

Chinese herbal compounds have been used clinically for thousands of years in the treatment of liver system diseases, among which *Fuzi* (*Radix aconiti* Lateralis)-*Gancao* (

P-Editor: Li JH

Radix glycyrrhizae) is one of the most common drug pairs in Chinese herbal compounds, and Chinese herbal compounds containing *Fuzi-Gancao* (F-G), such as *Yinchen Sifu* decoction, *Sini* decoction, and *Fuzi Lizhong* decoction, are often used in the treatment of liver diseases such as hepatitis and liver failure[10-13]. Modern pharmacological studies have shown that herbal compounds containing *Fuzi* and *Gancao* can reduce the biochemical indexes of liver injury model animals by inhibiting inflammatory stress, lipid peroxidation, and apoptosis and have significant pharmacological activity to prevent liver injury[14-16].

Fuzi and *Gancao* are important medicinal materials in classic prescriptions, such as *Sini* decoction and *Fuzi Lizhong* decoction. Aconite alkaloids in *Fuzi* and flavonoids in *Gancao* are the main active ingredients in F-G drug pairs. Alkaloids are the main active ingredients in aconite, and thus far, nearly 200 alkaloids have been isolated and identified. These alkaloids are mainly classified into nonester alkaloids, monoester diterpene alkaloids (MDAs), diester diterpene alkaloids (DDAs), and lipoalkaloids according to their structural properties[17]. MDAs and DDAs have very well-defined pharmacological activities, such as cardiotonic[18-20], anti-inflammatory and analgesic [21], antitumor[22], antioxidation[23], and hepatoprotective[24,25] activities. Flavonoids are the main active ingredients of *Gancao* and have well-defined pharmacological anti-inflammatory[26-28], antibacterial[29], antioxidant[30], hepatoprotective, and antitumor[31] activities. The Chinese Pharmacopoeia (2015 edition) prescribes the compatibility ratio of *Fuzi* and *Gancao* as 1:1, which could decrease the toxins caused by aconite alkaloids and enhance the treatment effect compared with other ratios[32-34].

In a previous study, a rapid, convenient, and stable method for the simultaneous quantitative determination of six alkaloids and three flavonoids in *Radix aconiti* lateralis and *Radix glycyrrhizae* by ultra performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS) was established[17]. In this study, the effects of the F-G water extract on the prevention of liver injury induced by tetrachloride (CCl_4) were evaluated. Then, the metabolic mechanism was studied by UPLC-MS/MS. Finally, a method of simultaneous quantitative detection of 11 bile acids was established, and the mechanism of F-G in the regulation of the serum bile acid profile was analyzed by UPLC-MS/MS.

MATERIALS AND METHODS

Plant materials

Radix aconiti lateralis (*Fuzi*) pieces were purchased from Huang Gang Jingui Traditional Chinese Medicine Industry Development Co., Ltd. (Sichuan, China), and *Radix glycyrrhizae* (*Gancao*) was purchased from Bozhou Jinshaotang Herbal Decoction Co., Ltd. (Anhui, China). The medicinal materials were identified by Professor Fu Xiao at the First Affiliated Hospital of Jinzhou Medical University.

Chemicals and Reagents

The aspartate aminotransferase (AST) and alanine aminotransferase (ALT) assay kits were purchased from Nanjing Jiancheng Bioengineering Co., Ltd.; silybin was purchased from Solarbio Biotech Co., Ltd.; L-leucine, L-tryptophan, L-kynurenine, 5-Hydroxytryptamine (5-HT), 5-hydroxytryptophan (5-HTP), cholic acid, N-phenylacetylglycine, glutathione (GSH), glutathione oxidized (GSSG), N-ethylmaleimide, and formic acid were purchased from Sigma-Aldrich (United States); L-phenylalanine (Ring-D5) was purchased from Cambridge isotope laboratories; UDCA, GDCA, GCDCA-Na, TCA-Na, and GCA were purchased from Meryer Co., Ltd.; CDCA, DCA, TCDCA, TUDCA, and GLCA were obtained from Shanghai Macklin Biochemical Co., Ltd; d4-GCDCA was purchased from Shanghai Zhenzun Biochemical Co., Ltd; MS-grade methanol and acetonitrile were purchased from Merck; water for MS analysis was prepared using a Milli-Q water purification system; phosphate buffered solution (PBS) was purchased from HyClone Co., Ltd; CCl4 was purchased from Yongsheng Chemical Co., Ltd; alcohol was purchased from Kermel Chemical Co.; pentobarbital sodium was purchased from Shanghai Experimental Chemical Reagent Co., Ltd.; and normal saline was purchased from Qingdao Huaren Pharmaceutical Co., Ltd.

Animals

Male Sprague-Dawley rats (200 g ± 20 g) were purchased from the Laboratory Animal Center of Chinese Medical University (animal license No.: SCXK (Liao) 2008-0005). The rats were housed under SPF laboratory conditions at a temperature of 25 ± 2 °C, a

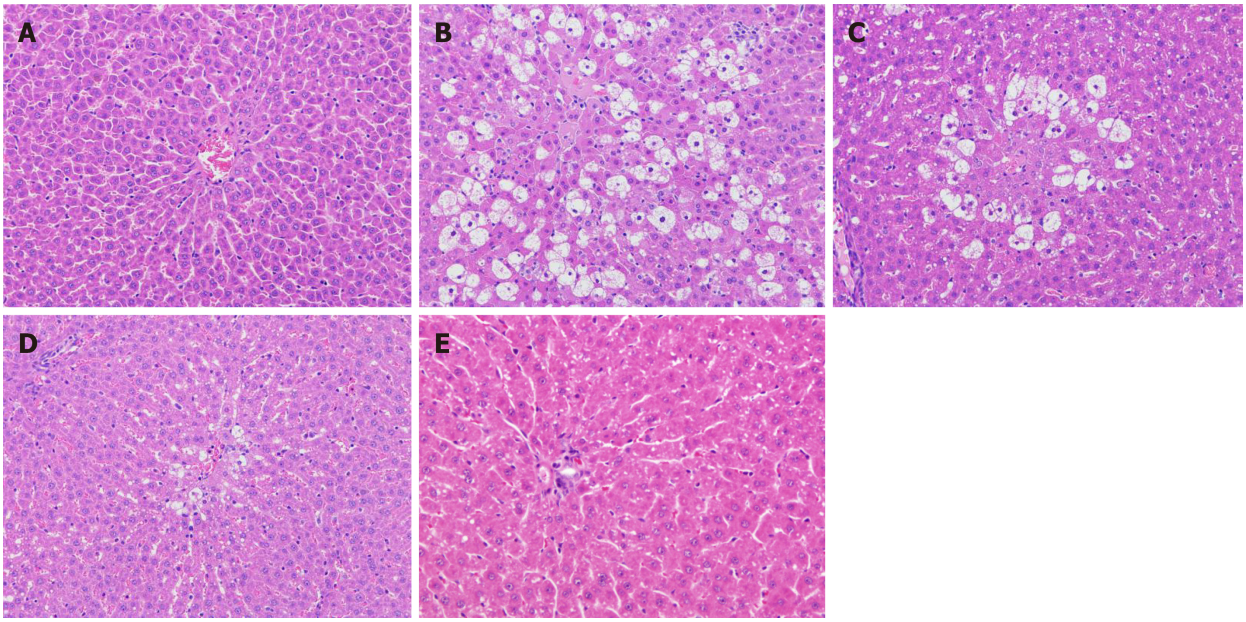

Figure 1 Histological changes in various groups of rats. HE staining, magnification: 400 ×. A: Normal control group; B: Model control group; C: *Fuzi-Gancao* (F-G) group (15 g/kg); D: F-G group (30 g/kg); E: Positive control group (silybin).

relative humidity of 40 ± 5%, and a 12-h circadian cycle for 1 wk. All procedures were performed according to the National Institute of Health guidelines regarding the principles of animal care.

Preparation of the F-G extract

Fuzi (1.3 kg) and *Gancao* (1.3 kg) were mixed and soaked in water (26 L) for 0.5 h, and then the mixture was refluxed for 2 h. The supernatant was then concentrated under vacuum to obtain the F-G extract. The extract was diluted with water to a final concentration of 1.5 g/mL (crude drug), and all the extracts were stored at 4 °C before use.

Protective effect of F-G on acute liver injury induced by CCl_4

Forty male rats were randomly divided into five groups (n = 8): Normal control group, model control group, positive control group, F-G group with 15 g/kg crude drug, and F-G group with 30 g/kg crude drug. The positive control group was orally administered with silybin at 50 mg/kg daily, and the normal control group and model control group were given the same volume of normal saline daily by gavage once a day for 8 d.

On the 7th day, 40% CCl_4 (v/v, olive oil) was intraperitoneally injected in the positive control group, model control group, and F-G groups at a dose of 2 mL/kg. The rats were anesthetized using sodium pentobarbital 2 h after administration on the 8th day. Blood samples were collected from the abdominal aorta and centrifuged at 3500 rpm for 10 min (4 °C) to obtain serum samples for transaminase (ALT and AST) and metabolic analysis. Liver tissue samples were taken for pathological analysis.

Metabolic analysis

To elucidate the mechanism of F-G in the treatment of liver injury, three groups of serum samples, including that from the normal control group, model control group, and F-G group (30 g/kg), were used for metabolic analysis by UPLC-MS according to a method published by the authors with minor modifications[35].

Preparation of "stripped" serum: One hundred milliliters of rat serum including activated charcoal powder (6 g) was incubated at room temperature for 2 h. After centrifugation at 13000 rpm for 20 min (4 °C), the supernatant was filtered successively through microporous membranes with pore sizes of 5 μm, 1.2 μm, and 0.45 μm to obtain "stripped" serum.

Samples for metabolic analysis: Two hundred microliters of the serum sample was pipetted into a 1.5 mL centrifuge tube, followed by adding 200 μL of PBS solution containing NEM (10 mmol/L) and 1000 μL of methanol solution with L-phenylalanine (Ring-D5; 10 ng/mL, internal standard) in sequence, vortexing for 30 s, and incubating

the sample at -20 °C for 15 min after mixing. After incubation, 1000 μL of supernatant

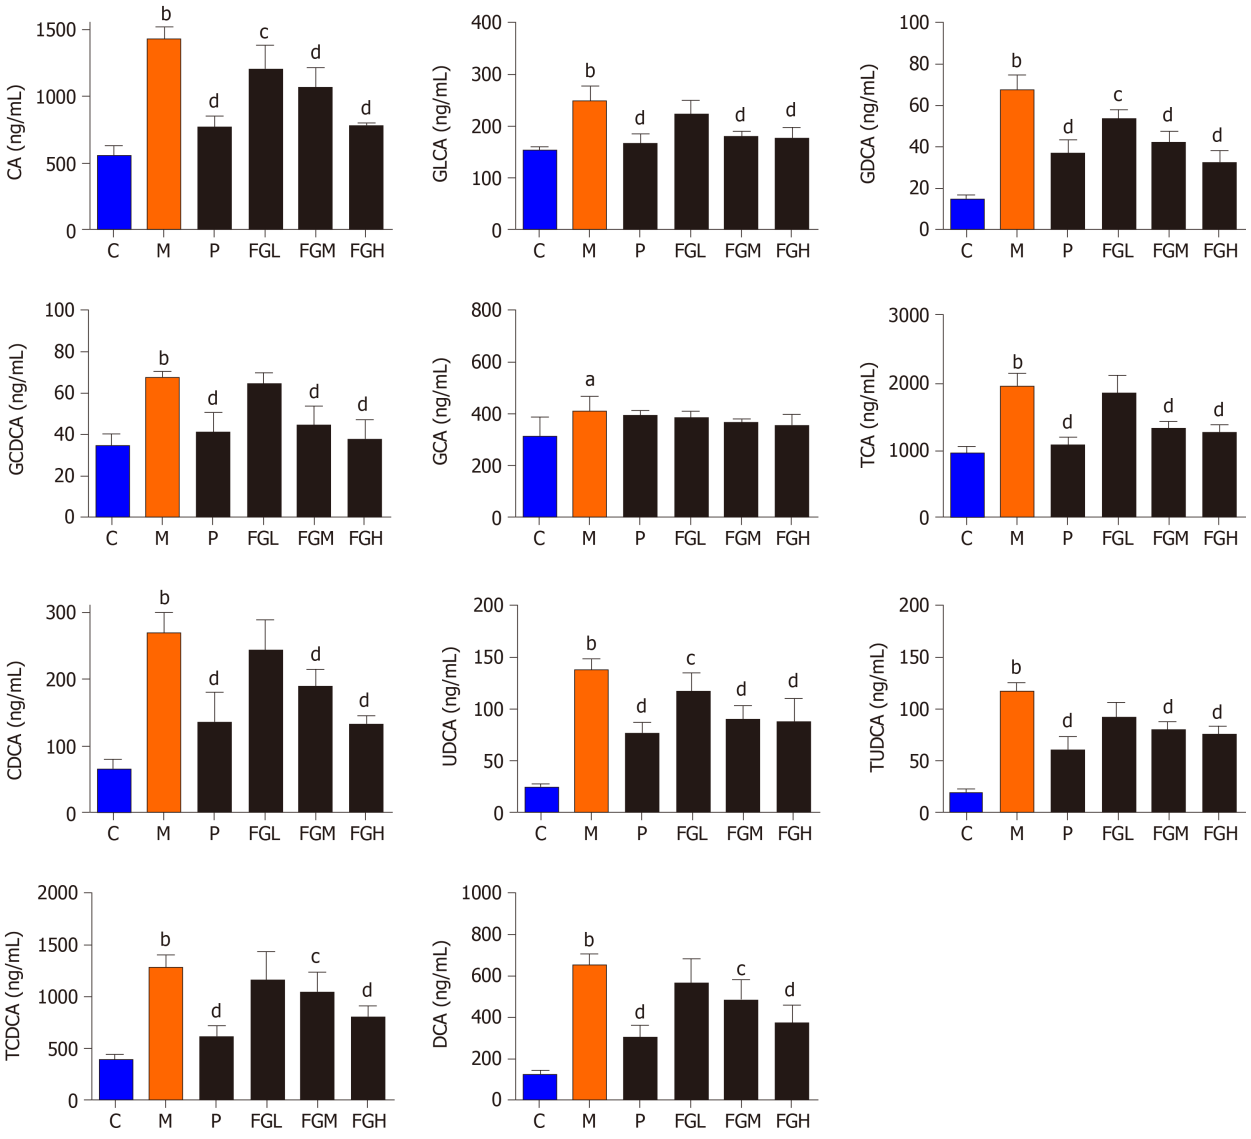

Figure 4 Bile acids in rats (*n* = 6, mean ± SD). $^{a}P < 0.05$, $^{b}P < 0.01$ for each treatment group and model control group, respectively; $^{c}P < 0.05$, $^{d}P < 0.01$ for the model control group and normal control group, respectively.

Preparation of standard solution: L-Leucine, 5-HT, N-phenylacetylglycine, L-tryptophan, L-kynurenine, 5-HTP, cholic acid, and GSSG were accurately weighed and dissolved in methanol to make stock solutions at a concentration of 1 mg/mL. GSH was accurately weighed and dissolved in methanol containing NEM (10 mmol/L) to make a solution at a concentration of 0.5 mg/mL. Each standard solution was mixed proportionally and serially diluted with 50% methanol-water to obtain a series of mixed standard solutions.

Method validation: Calibrators of the nine metabolites (L-Leu, 5-HT, N-Phe, L-Try, L-Kyn, 5-HTP, CA, GSH, and GSSG) were generated from the mixed standard working solutions in "stripped" serum. The linear regression standard curve was calculated with 1/x weighting and plotted with the concentrations and the peak area ratio of each analyte to the internal standard.

Pooled standard solutions were added to "stripped" serum to prepare QC samples of three different concentrations, which were then processed as described in "Samples for metabolic analysis". Intraday precision was calculated according to the content of nine metabolites from the QC sample in six consecutive analyses. The interday precision was obtained after continuous analysis of the QC sample for 3 d. Precision is expressed as the relative standard deviation (RSD, %).

Three concentrations of the mixed standard solutions were added to the samples of a definite content and processed for analysis six times to obtain recovery. Recovery was calculated according to the formula:

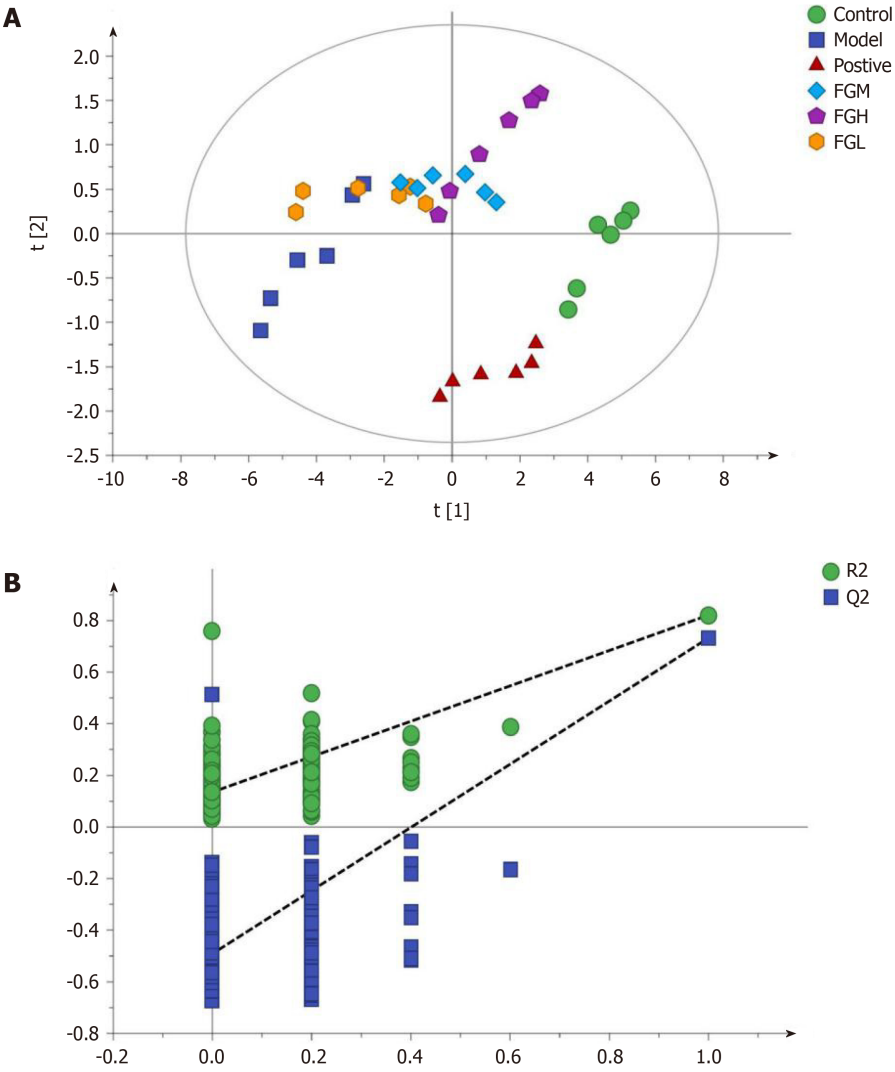

Figure 5 Bile acids in rats. A: Partial Least-Squares Discriminant Analysis; B: P-test analysis.

Recovery (%) = (C-A)/B × 100% (A is the measured content of the test sample, B is the amount of standard content, and C is the measured content).

UPLC-MS/MS analysis: Samples were separated using a Waters ACQUITY ultra-performance liquid chromatographer with a Waters BEH column (1.7 μm, 2.1 × 50 mm, C-18) and a mobile phase consisting of 0.1% formic acid in water (A) and acetonitrile (B) using a gradient system with the following elution procedures: 0-2.0 min, 5% B; 2.0-5.0 min, 5-50% B; 5.0-6.0 min, 50% B; 6.0-17.0 min, 50-95% B; 18.0-22.0 min, 95-5% B; and 22.0-25.0 min, 5% B. The flow rate was 0.3 mL/min, and the column temperature was set at 25 °C. Mass spectral analysis was achieved using an AB 4000 Q-TRAP system with ESI in positive and negative ionization modes and multiple reaction monitoring (MRM) mode. The MS parameters were as follows: Ion spray voltage, ± 4500 V; curtain gas, 20 psi; temperature, 450 °C; and ion source gas, 40 psi. All the metabolites were analyzed using precursor ions (Q1), product ions (Q3), declustering energy, entrance pressure, collision energy, and collision cell exit potential as detection parameters.

Bile acid analysis

Thirty-six male SD rats were randomly divided into six groups (n = 6): Normal control group, model control group, positive control group, and F-G groups including FGL (10 g/kg), FGM (20 g/kg), and FGH (30 g/kg). The positive control group was given 50 mg/kg silybin, the normal group and model group were given the same volume of normal saline, and all the groups were administered for 8 d.

On the 7th day, 40% CCl_4 (v/v, olive oil) solution was injected intraperitoneally (2 mL/kg), and the same dose of olive oil was injected intraperitoneally in the control group. The rats were anesthetized 2 h after administration on the 8th day. Blood

samples were collected from the abdominal aorta and centrifuged at 4000 rpm for 10 min (4 °C) to obtain serum samples for the analysis of bile acids.

Preparation of standard solutions: CDCA, DCA, UDCA, GLCA, GCDCA, GDCA, GCA, TCDCA, TCDCA, TUDCA, and TCA were accurately weighed and dissolved in methanol to prepare stock solutions at a concentration of 1 mg/mL and stored at -80 °C. Solutions were serially diluted with 50% methanol-water prior to testing. d_4-GCDCA was accurately weighed and dissolved in methanol to make an internal standard solution. All the solutions were stored at -80 °C prior to use.

Sample preparation: Two hundred microliters of serum was added to 1000 μL of methanol containing internal standard (d4-GCDCA, 20 ng/mL). The samples were centrifuged at 12000 rpm for 15 min (4 °C) after mixing, and then 1000 μL of the supernatant was dried with nitrogen and stored at -80 °C. The dried residue was reconstituted with 50 μL of 80% methanol-water solution prior to analysis, vortexed for 1 min, and centrifuged at 12000 rpm for 15 min (4 °C). Then, 30 μL of supernatant was aspirated accurately into an injection vial, and 10 μL of each sample was injected into the UPLC-MS/MS system for bile acid quantification.

UPLC-MS analysis: Samples were separated using a Waters Acquity Uplc instrument and an Agilent ZORBAX SB-C18 column (3.5 μm, 2.1 mm × 100 mm) and a mobile phase consisting of 0.1% formic acid in water (A) and methanol (B) using a gradient system with the following elution procedure: 0-2.0 min, 10% B; 2.0-9.0 min, 10%-80% B; 9.0-11.0 min, 80% B; 11.0-20.0 min, 80%-90% B; and 20.0-25.0 min, 90%-10% B. Ten microliters of the sample was injected at a flow rate of 0.4 mL/min and column temperature of 25 °C. Mass spectral analysis was achieved using a Thermo Scientific

acid analysis six times to obtain recovery.

Three concentrations of 11 mixed bile acid standard solutions were used to investigate the stability of QC samples under different storage conditions and processing procedures. Short-term stability was assessed by analyzing the QC samples that were kept at room temperature for 12 h. Long-term stability was assessed by storing the QC samples at -20 °C for 20 d. Freeze-thaw stability was assessed after the QC samples were frozen at -80 °C and thawed at 4 °C in 1 d for 3 consecutive days. Postpreparation stability was assessed by analyzing the QC samples that were kept at 4 °C for 12 h.

Data analysis

Metabolic analysis was calibrated and integrated using AB Analyst (version 1.6.2, AB Applied Biosystems). Quantitative analyses of bile acids were performed using Thermo Scientific TSQ Quantum Workstation analysis software. Pathway analyses were achieved using SIMCA-P, Metaboanalyst, and KEGG software. The experimental data are expressed as the mean ± SD. The data were analyzed with SPSS 19.0 statistical software ($P < 0.05$ and $P < 0.01$).

Table 5 Serum metabolites in CCl_4-induced acute liver injury in rats (n = 8)

Metabolite	Model group	Control group	FG group

RESULTS

Effects of F-G on acute liver injury

Histological analysis: The liver tissue of rats in each group was macroscopically observed. The livers of the normal control group rats had a normal morphology, a red color, no adhesion between the lobules, a smooth surface, and no bleeding spots. In the model group, the surface of the liver was milky white, and there was obvious adhesion between the lobules of the liver and the mucous membranes. In the F-G group, the adhesion degree between the lobules and mucous membrane was significantly decreased, and the color was rosier than that of the model rats. The morphological results showed that F-G extract could significantly relieve liver injury induced by CCl_4 (Figure 1).

Histological analysis indicated that the structure of liver tissue in the normal control group was normal, the liver cells were neatly arranged, and there were no pathological changes, such as hepatocyte swelling, inflammatory cell infiltration, blood stasis, or steatosis of hepatocytes. Compared with the normal control group, the model control group showed a significant increase in the number of hepatocytes with extensive hydrodegeneration, steatosis, hepatocyte necrosis, and inflammatory cell infiltration. Compared with the model control group, F-G groups (15 g/kg and 30 g/kg) indicated

a decrease in the amount of water-like degeneration in the liver, steatotic cells, and swelling hepatocytes with a significant dose-effect relationship.

Assay of ALT and AST: ALT and AST in the serum of rats were detected by ELISA. The results indicated that the contents of ALT and AST in the model control group were significantly higher than those in the normal control group ($P < 0.01$). Both transaminase levels were significantly reduced in the F-G groups compared to those in the model control group, but the magnitude of the reduction was still different from that of the positive control group (Table 1).

Metabolic analysis

Linearity: The calibration curve of each standard was plotted with the concentrations of nine biomarkers and the ratio of the peak area of each component to that of the internal standard with weighted (1/x) least-square linear regression. The calibration curves of the nine analytes exhibited a good linearity with coefficient of correlation (R^2) values better than 0.9926. The lowest concentration of the linear regression for each sample was determined to be the limit of quantification (Table 2).

Accuracy, precision, and recovery: The accuracy and precision of analytes in the QC samples were less than 9.24% and 8.10%, respectively (Table 3), and the recovery of

analytes is shown in Table 4. All the analytical values of the nine analytes had satisfactory results within the acceptable criteria according to the bioanalytical method validation guidance of the United States FDA.

Metabolic analysis: Analysis of 92 metabolites was achieved by UPLC-QTRAP-LC-MS/MS. NEM was used to improve the stability of GSH. Twenty-four differential metabolites in the serum (normal control group *vs* model control group and F-G groups *vs* model control group) were confirmed according to statistical analysis (Table 5).

Partial Least-Squares Discriminant Analysis (PLS-DA) (Figure 2) was performed on the data matrix of the variation in individual metabolites in Table 4. The results showed that the samples of the negative control group, model control group, and F-G groups were distributed in different areas and could be separated completely, but samples of the same group had the tendency to aggregate (Figure 2A). The results showed that the difference in all metabolites between the negative control group and the model control group was significant, indicating that the contents of these 24 metabolites were significantly changed in acute liver injury induced by CCl_4. The difference in all metabolites between the F-G groups and the model control group was also significant, indicating that the administration of the F-G extract could cause a

CDCA: Chenodeoxycholic acid; UDCA: Ursodeoxycholic acid; GCA: Glycocholic acid; GDCA: Glycochenodeoxycholic acid; TCA: Taurocholic acid; TUDCA: Taurocholic acid; GCDCA: Glycochenodeoxycholic acid; GLCA: Glycinic acid; DCA: Deoxycholic acid; CA: Cholic acid.

significant reduction in the metabolite contents in the serum of rats with acute liver injury induced by CCl_4, which could cause a significant change in the metabolic network. In the PLS-DA plot, samples of the F-G groups were closer to those of the negative control group than those of the model control group, indicating a significant difference in the metabolite contents in rats with liver injury compared to those in the negative control group after treatment with F-G. P-test analysis (Figure 2B) showed that there was no overfitting of the separation model between groups.

Combined with the variable importance in the projection (VIP) value based on PLS-DA, it was shown that the metabolites with a VIP value greater than 1.0 contributed greatly to the difference before and after treatment with the F-G extract and were the key metabolites. There were 14 key metabolites in the model control group *vs* the negative control group (Table 6) and 13 key metabolites in the F-G groups *vs* the model control group (Table 7). Ten common metabolites, namely, GSSG, cholic acid, N-phenylacetylglycine, hippuric acid, uric acid, hypoxanthine, (E)-butenedioic acid, pantothenic acid, C16:1 LPC, and C18:0 LPC, were observed.

Pathway analysis: Metaboanalyst software was used to analyze the metabolic mechanism. Metabolic pathway differences between the negative control group and model control group and between the model control group and F-G group were analyzed by topological and enrichment analyses to confirm the important metabolic pathway effects of F-G in acute liver injury induced by CCl_4.

The results indicated that the primary bile acid biosynthesis pathway was the most important metabolic pathway affected in the model control group *vs* the negative control group (Figure 3A). Other pathways, such as pyrimidine metabolism, glutathione metabolism, glutamate metabolism, and phenylalanine metabolism, are also affected by CCl_4. The pantothenate and CoA biosynthesis, primary bile acid biosynthesis, and pyruvate metabolism pathways were significantly affected by the administration of the F-G extract (Figure 3B).

Bile acids analysis

Method validation: The calibration curve of each standard was plotted on the concentrations of 11 bile acids and the ratio of the peak area of each component to that of the internal standard with weighted (1/x) least square linear regression. The calibration curves of the 11 analytes exhibited a good linearity (Table 8).

The intraday precision of QC samples with three concentrations of bile acids ranged from 1.20% to 6.57%, the interday precision ranged from 2.10% to 6.35%, and the recovery of each analyte was greater than 80% (Table 9). Eleven bile acid analytes exhibited good stability (short-term stability, long-term stability, freeze-thaw stability, and postpreparation stability) (Table 10). All the analytical values of the 11 analytes had satisfactory results within the acceptable criteria.

Bile acids analysis: Liver injury induced by CCl_4 in rats could reduce bile secretion and rapidly alter the distribution of bile acid stores, resulting in a significant increase in serum bile acid concentrations. The results indicated that the contents of 11 analytes (CDCA, DCA, UDCA, GLCA, GLCA, GCDCA, GDCA, GCA, TCDCA, TUDCA, and TCA) in the serum of the model control group, compared with the negative control group, were significantly increased (P < 0.01), and the contents of the 11 bile acids in

the serum of the F-G groups were decreased in a dose-dependent manner (Figure 4).

PLS-DA analysis was performed using a data matrix on the effect of F-G on serum bile acid levels in rats with CCl_4 induced acute liver injury. As seen from the PLS-DA analysis (Figure 5A), the samples of the negative control group and model control group are distributed in different areas and far away from each other and can be completely separated from each other. The content differences of bile acids between

the negative control group and model control group were significant. At the same time, the samples of the F-G group (10 g/kg) were partially overlapping those of the model control group, but with increasing dose, the samples of the mid-dose and high-dose F-G groups (20 g/kg and 30 g/kg) were clearly separated from those of the model control group, indicating that the dose-dependent relationship between the bile acid level and the dose of F-G extract was apparent in the overall analysis. P-test analysis showed that there was no overfitting of the between-group separation model (Figure 5B).

DISCUSSION

Analysis of 24 differential metabolites by UPLC-QTRAP-LC-MS/MS showed that CCl_4 could affect a variety of metabolic pathways, such as primary bile acid biosynthesis, glutathione metabolism, pyrimidine metabolism, and phenylalanine metabolism. The F-G extract could affect the metabolic pathways of pantothenic acid and CoA biosynthesis, primary bile acid biosynthesis, and pyruvate biosynthesis. The primary bile acid synthesis pathway was the most important common pathway affected by CCl_4 and the F-G extract. Subsequently, a UPLC-QQQ-LC-MS/MS method was established for the simultaneous quantitative detection of 11 bile acids, and the regulatory mechanism of the F-G extract on bile acids in the prevention of acute liver injury induced by CCl_4 was obtained.

Since the content of different bile acids varied greatly in the serum, we first used the relative variation in each bile acid for analysis. This analysis evaluated the relative changes in bile acids for each group based on their primary contents (1.0) in the negative control group (Table 11). Free and conjugated bile acids are the two bile acid types in the liver and blood. CA, CDCA, and DCA are the main free bile acids, and bile acids conjugated with glycine or taurine compose the combined bile acids. In this study, a relatively higher increase in taurine-conjugated bile acids, except TCA, was observed in the model control group than in the negative control group (TUDCA, 6.00; TCDCA, 3.24), whereas the increase in glycine conjugated bile acids, except GDCA, was relatively low (GLCA, 1.61; GCDCA, 1.74; GCA, 1.30). Taurine possessed protective effects on hepatocellular injury and apoptosis. When hepatocellular injury occurs, the body can regulate the compensatory increase in taurine and further increase the content of taurine-conjugated bile acids[36]. The content of taurine conjugated bile acids was significantly decreased after treatment with the F-G extract in a dose-dependent manner.

Bile acids exhibit different hydrophilic and hydrophobic properties according to their chemical structure. Hydrophobic bile acids can lyse cell membrane lipids, exhibiting "decontamination", resulting in hepatocellular necrosis. Therefore, the accumulation of hydrophobic bile acids in the liver is a major and important cause of liver injury. UDCA is a nontoxic hydrophilic bile acid. Taurine conjugated bile acids (TCA, TCDCA, and TDCA) and glycine conjugated bile acids (GLCA, GDCA, GCDCA, and GCA) exhibit low toxicity due to some hydrophobicity, while CA, CDCA, and DCA are free and hydrophobic bile acids that show strong hepatotoxicity. DCA is one of the most toxic bile acids. The accumulation of DCA in the liver or blood leads to mitochondrial destruction, cell membrane rupture, and the production of reactive oxygen species in hepatocytes, leading to apoptosis and necrosis[36,37]. In this study, three hydrophobic components, CA, CDCA, and DCA, were significantly increased in the model control group, showing a positive correlation with the toxic effects reported[38]. The F-G extract can promote the binding of CA, CDCA, and DCA to taurine and glycine to reduce the accumulation of free CA, CDCA, and DCA *in vivo*, thus preventing acute liver injury induced by CCl_4.

When acute liver injury was caused by CCl_4 in rats, the hepatocytes were damaged, and the activities of cholesterol 7α-hydroxylase and cholesterol 12α-hydroxylase in hepatocytes were decreased, resulting in decreased CA and CDCA produced by cholesterol synthesis. However, due to impaired hepatic uptake of bile acids, the uptake of these two bile acids in the enterohepatic circulation is greatly reduced, resulting in a significant increase in the concentrations of bile acids in the serum. In this study, CA and CDCA were significantly increased in the model control group, showing liver damage and leading to bile acid malabsorption in the hepatoenteric circulation. The F-G extract decreased the contents of CA and CDCA in serum in a dose-dependent manner, indicating that the F-G extract could repair liver injury, improve enterohepatic circulation, and promote the absorption of CA and CDCA, exhibiting almost the same pharmacological effect as silybin.

Table 11 Ratio of bile acids in each experimental group to corresponding composition of negative control group

Bile acid	Negative	Model	Positive	FGL	FGM	FGH
CA	1.00	2.57	1.38	2.16	1.92	1.40
GLCA	1.00	1.61	1.08	1.45	1.17	1.15
GDCA	1.00	4.45	2.43	3.53	2.78	2.14
GCDCA	1.00	1.74	1.18	1.85	1.28	1.09
GCA	1.00	1.30	1.25	1.22	1.16	1.12
TCA	1.00	1.99	1.11	1.90	1.37	1.31
CDCA	1.00	4.12	2.08	3.76	2.90	2.03
UDCA	1.00	5.68	3.17	4.87	3.72	3.62

TCDCA	1.00	3.24	1.57	2.92	2.63	2.03
DCA	1.00	5.16	2.40	4.48	3.84	2.95

CDCA: Chenodeoxycholic acid; UDCA: Ursodeoxycholic acid; GCA: Glycocholic acid; GDCA: Glycochenodeoxycholic acid; TCA: Taurocholic acid; TUDCA: Taurocholic acid; GCDCA: Glycochenodeoxycholic acid; GLCA: Glycinic acid; DCA: Deoxycholic acid; CA: Cholic acid.

CONCLUSION

In this study, the effects of F-G extract in preventing acute liver injury induced by CCl_4 have been assayed. The F-G extract decreases the adhesion between the lobules and the mucosa, reduces the bleeding point on the surface of the liver, effectively decreases ALT and AST in a rat model of acute liver injury in a dose-dependent manner, and reduces hepatocellular swelling, inflammatory cell infiltration, blood stasis, hepatic steatosis, and other pathological changes in rats.

ARTICLE HIGHLIGHTS

Research background

Fuzi (*Radix aconiti* lateralis)-*Gancao* (*Radix glycyrrhizae*) (F-G) is often used in the treatment of liver diseases such as hepatitis and liver failure.

Research motivation

This study can clarify the bile acid mechanism of F-G in the treatment of liver injury, and establish a complete bile acid spectrum research method, so as to provide reference for future research.

Research objectives

To study the molecular mechanism and action mechanism of F-G in the treatment of liver injury, and to provide a theoretical basis for the clinical research of F-G.

Research methods

An ultra performance liquid chromatography tandem mass spectrometry (UPLC-MS/MS) method for the simultaneous determination of 92 metabolites from multiple pathways was established to explore the protective metabolic mechanism of F-G in serum on the liver.

Research results

A UPLC-MS/MS method for simultaneous determination of 11 bile acids was established to analyze the regulatory mechanism of F-G in serum. F-G decreased the contents of 11 bile acids in the serum in a dose-dependent manner.

Research conclusions

F-G could promote the conjugation of free bile acids to glycine and taurine, reduce the

accumulation of free bile acids in the liver, regulate the compensatory degree of taurine, and decrease the content of taurine conjugated bile acids.

Research perspectives

The research group will continue to study the effect of bile acid metabolism regulation on molecular regulation in the body.

Abstract

BACKGROUND

Hepatic stellate cells (HSCs) are the key effector cells mediating the occurrence and development of liver fibrosis, while aerobic glycolysis is an important metabolic characteristic of HSC activation. Transforming growth factor-β1 (TGF-β1) induces aerobic glycolysis and is a driving factor for metabolic reprogramming. The occurrence of glycolysis depends on a high glucose uptake level. Glucose transporter 1 (GLUT1) is the most widely distributed glucose transporter in the body and mainly participates in the regulation of carbohydrate metabolism, thus affecting cell proliferation and growth. However, little is known about the relationship between TGF-β1 and GLUT1 in the process of liver fibrosis and the molecular mechanism underlying the promotion of aerobic glycolysis in HSCs.

AIM

To investigate the mechanisms of action of GLUT1, TGF-β1 and aerobic glycolysis in the process of HSC activation during liver fibrosis.

METHODS

Immunohistochemical staining and immunofluorescence assays were used to examine GLUT1 expression in fibrotic liver tissue. A Seahorse extracellular flux (XF) analyzer was used to examine changes in aerobic glycolytic flux, lactate

Hospital of Guizhou Medical University.

Institutional animal care and use committee statement: All animal experiments conformed to the internationally accepted principles for the care and use of laboratory animals (license No. 2000719). All animal interventions were approved by the Institutional Animal Care and Use Committee (IACUC) of Guizhou Medical University.

Conflict-of-interest statement: The authors declare no conflicts of interest related to this study.

Data sharing statement: No additional data are available.

ARRIVE guidelines statement: The authors have read the ARRIVE Guidelines, and the manuscript was prepared and revised according to the ARRIVE Guidelines.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. production levels and glucose consumption levels in HSCs upon TGF-β1 stimulation. The mechanism by which TGF-β1 induces GLUT1 protein expression in HSCs was further explored by inhibiting/promoting the TGF-β1/mothers-against-decapentaplegic-homolog 2/3 (Smad2/3) signaling pathway and inhibiting the p38 and phosphoinositide 3-kinase (PI3K)/AKT signaling pathways. In addition, GLUT1 expression was silenced to observe changes in the growth and proliferation of HSCs. Finally, a GLUT1 inhibitor was used to verify the *in vivo* effects of GLUT1 on a mouse model of liver fibrosis.

RESULTS

GLUT1 protein expression was increased in both mouse and human fibrotic liver tissues. In addition, immunofluorescence staining revealed colocalization of GLUT1 and alpha-smooth muscle actin proteins, indicating that GLUT1 expression was related to the development of liver fibrosis. TGF-β1 caused an increase in aerobic glycolysis in HSCs and induced GLUT1 expression in HSCs by activating the Smad, p38 MAPK and P13K/AKT signaling pathways. The p38 MAPK and Smad pathways synergistically affected the induction of GLUT1 expression. GLUT1 inhibition eliminated the effect of TGF-β1 on HSC proliferation and migration. A GLUT1 inhibitor was administered in a mouse model of liver fibrosis, and GLUT1 inhibition reduced the degree of liver inflammation and liver fibrosis.

CONCLUSION

TGF-β1 induces GLUT1 expression in HSCs, a process related to liver fibrosis progression. *In vitro* experiments revealed that TGF-β1-induced GLUT1 expression might be one of the mechanisms mediating the metabolic reprogramming of HSCs. In addition, *in vivo* experiments also indicated that the GLUT1 protein promotes the occurrence and development of liver fibrosis.

Core Tip: Liver fibrosis is a repair response of the liver to various chronic injuries. However, fibrosis may eventually evolve into liver cirrhosis or even liver cancer if it progresses. Hepatic stellate cell activation is the initiating factor for liver fibrosis. Transforming growth factor-β1 (TGF-β1) is a pleiotropic cytokine that induces aerobic glycolysis. Glucose transporter 1 (GLUT1) regulates glucose metabolism. This study examined the effects of TGF-β1-mediated pathways on GLUT1 expression *in vivo* and *in vitro*, explored the relationship between GLUT1 and TGF-β1 and further investigated the potential underlying mechanisms.

INTRODUCTION

Liver fibrosis is the inevitable result of chronic liver inflammation caused by various etiologies. With progressive destruction of liver parenchymal cells, liver fibrosis eventually develops into liver cirrhosis and even liver cancer[1,2]. Although liver cirrhosis and liver cancer are irreversible, liver fibrosis can be reversed. Therefore, the mechanism of and clinical studies on liver fibrosis have always been the focus of liver disease research. The main pathological feature of liver fibrosis is the excessive

deposition of extracellular matrix (ECM), while the key initiating factors are activation of quiescent hepatic stellate cells (HSCs) and transformation of their phenotypes and functions[3]. The transforming growth factor-β1 (TGF-β1) pathway is the key fibrogenic pathway that drives HSC activation and induces ECM production. HSC activation requires metabolic reprogramming and a continuous energy supply[4,5]. Aerobic glycolysis is an important metabolic characteristic of the transdifferentiation of quiescent stellate cells, a process similar to the Warburg effect in tumor cells, and the core metabolic changes include a transition from oxidative phosphorylation to aerobic glycolysis[6]. Dysregulated glycolysis has been implicated in experimental models of lung and liver fibrosis, and inhibition of glycolysis reduces ECM accumulation[7]. In view of the mechanisms involved, targeting and inhibiting the metabolic reprogramming of activated HSCs during liver fibrosis may be a promising anti-liver fibrosis strategy.

TGF-β1 is a multifunctional cytokine and a major profibrotic cytokine that regulates cell differentiation, cell proliferation and ECM production and directly regulates multiple cellular signal transduction networks[8]. In the canonical TGF-β1/mothers-against-decapentaplegic-homolog 2/3 (Smad2/3) pathway, ligands induce the assembly of the TGF-β1 receptor I (TβRI)/TGF-β1 receptor II (TβRII) heterocomplex, which targets Smad4 *via* Smad2 and Smad3 proteins to form the Smad complex, leading to phosphorylation and nuclear translocation of Smad2/3; this R-Smad/Co-Smad4 complex translocates to the nucleus where it binds to DNA either directly or in association with other DNA-binding proteins[9-11]. Phosphorylated Smad2/3 binds to specific Smad binding elements (SBEs) in gene promoter regions to activate/suppress the expression of target genes[12,13]. In addition to Smads, TGF-β1 also triggers other protein-mediated signaling pathways, *e.g.*, p38, mitogen-activated protein kinases (MAPKs) and phosphoinositide 3-kinase (PI3K). Some functions of TGF-β1 have been studied in depth, such as the mediation of cell differentiation and proliferation. However, TGF-β1 has recently been reported to induce aerobic glycolysis and is considered a driving factor in metabolic reprogramming[14]. TGF-β is also a strong activator of glycolysis in mesenchymal cells[15]. Extracellular accumulation of lactic acid induces epithelial-mesenchymal transition (EMT) by directly reconstituting the ECM and releasing activated TGF-β1. EMT induced by TGF-β in hepatocellular carcinoma cells reprograms lipid metabolism to sustain the elevated energy requirements associated with this process[16]. Research on the mechanism of idiopathic pulmonary fibrosis has shown that TGF-β1-induced aerobic glycolysis causes lactic acid accumulation and changes the cellular microenvironment, thereby activating latent TGF-β1 in the ECM and eventually forming a positive feedback loop to promote the effects of TGF-β1[17].

Glucose transporter 1 (GLUT1) is a member of the GLUT transporter family, the most conserved and most widely distributed glucose transporter in mammals and the main transporter regulating glucose uptake[18]. An increasing number of studies have found that GLUT1 plays an important role in accelerated metabolism. Research on the mechanism of neurodegenerative diseases has revealed that GLUT1 controls the activation of microglia by promoting aerobic glycolysis[19]. GLUT1 enhances the stimulating effect of TGF-β1 on mesangial cells, breast cancer cells and pancreatic cancer cells. As glucose uptake increases during TGF-β1-induced EMT of breast cancer cells, GLUT1 expression also increases and is correlated with EMT markers (including E-cadherin and vimentin). GLUT1 is the key mediator of the aerobic glycolysis phenotype in ovarian cancer and is required to maintain a high level of basic aerobic glycolysis. In models of bleomycin-induced pulmonary fibrosis, GLUT1-dependent aerobic glycolysis has been reported to be essential for pulmonary parenchymal fibrosis[20-23]. Certain signaling molecules (such as cAMP, p53, PI3K and AKT) reduce alpha-smooth muscle actin (α-SMA) protein expression in primary mouse fibroblasts by inhibiting GLUT1 expression. Exosomes secreted by activated HSCs affect the metabolic switch of liver nonparenchymal cells through delivery of the glycolysis-related proteins GLUT1 and PKM2; GLUT1 is involved in metabolic reprogramming of HSCs[24]. TGF-β1 and GLUT1 play important regulatory roles in metabolic reprogramming. To date, however, researchers have not explored whether the increases in TGF-β1 and GLUT1 Levels during HSC activation are related. Therefore, this study investigated the effect of the TGF-β1 signaling pathway on the regulation of GLUT1 and aerobic glycolysis. We hypothesized that TGF-β1 drives HSC activation and aerobic glycolysis by inducing GLUT1 expression, thereby promoting liver fibrosis progression. As shown in the present study, GLUT1 expression was significantly increased in mouse and human fibrotic liver tissue samples. Further *in vitro* experiments showed that the aerobic glycolysis capacity of HSCs was enhanced and GLUT1 expression increased with increasing TGF-β1 Levels. Inhibition/

promotion of the Smad2/3 signaling pathway and inhibition of the p38 and PI3K/AKT signaling pathways confirmed that TGF-β1 induced GLUT1 expression by targeting the pSmad2/3, p38 and PI3K/AKT pathways, thus promoting HSC activation. Finally, administration of a specific GLUT1 inhibitor in a mouse model of liver fibrosis resulted in a significant reduction in liver fibrosis. Based on these findings, the TGF-β1 signaling pathway enhances aerobic glycolysis by promoting GLUT1 expression, thereby promoting the development of liver fibrosis.

MATERIALS AND METHODS

Reagents and antibodies

The TGF-β1 antibody was purchased from R&D Systems (Minneapolis, MN, United States); antibodies against GLUT1, p-Smad2/3, Smad2/3, p-P38, p-AKT and desmin were purchased from Abcam (Cambridge, MA, United States), and the tubulin antibody was purchased from Research Diagnostics (Flanders, NJ, United States). The anti-α-SMA antibody, carbon tetrachloride (CCl_4), corn oil, OptiPrep and other chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MO, United States) and Fisher Scientific (Waltham, MA, United States). A TβRI/II inhibitor (APExBIO Technology, United States) was used at 2 μmol/L. Inhibitors of p38 MAPK and PI3K, namely, SB203580 and LY294002, respectively, were purchased from Abcam (Cambridge, MA, United States). The Smad3 inhibitors SIS3 and phloretin were purchased from Abcam (Cambridge, MA, United States).

Generation of a mouse model of liver fibrosis

The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimated to laboratory conditions (22 °C, 12-h/12-h light/dark cycle, 50% humidity, *ad libitum* access to food and water) for 1 wk prior to experimentation. The methods and experimental procedures were carried out in accordance with the relevant guidelines and regulations. Mice (C57BL6, eight to ten weeks old) were housed in standard conditions, and sex-matched mice were treated with 2.0 μL/g body weight CCl_4 [diluted 1:10 (v/v) with corn oil] or corn oil as a control by intraperitoneal (i.p.) injections three times per week for 4 wk[25]. Mice were challenged with CCl_4 or corn oil (control), followed by an i.p. injection of phloretin (10 mg/kg, three times per week for 2 wk) or 0.9% saline (vehicle). Mice were sacrificed at 48 h after the experiment ended, and tissues were harvested.

Patient liver samples

Normal and liver fibrosis tissue samples were obtained from patients treated at the Department of Hepatobiliary Surgery of the Affiliated Hospital of Guizhou Medical University (Guiyang, China). Written informed consent was obtained from the patients.

Western blot analysis

Immunoblotting was performed using whole-liver tissue lysates or whole-cell lysates prepared in buffer containing 1% NP-40 as described previously[26]. Total proteins were extracted and quantified using Bradford protein quantification kits. Protein samples (40 μg each) were resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The proteins were transferred onto polyvinylidene fluoride (PVDF) membranes and incubated with primary antibodies overnight at 4 °C. On the next day, signals were developed with an electrochemiluminescence detection kit after incubation with the appropriate secondary antibodies.

Cells and cell culture

Primary mouse HSCs were isolated and cultured as described previously[26]. Briefly, cells were isolated from livers through in situ liver perfusion with pronase, Liberase and collagenase followed by density gradient centrifugation. The dispersed cell suspension was filtered and gradiently centrifuged for 2 min to remove hepatocytes. The remaining cell fraction was washed and resuspended in 11.5% OptiPrep and then gently transferred to a tube containing 15% OptiPrep at the bottom, followed by PBS addition as the top layer. The cell fraction was then centrifuged at 1400 rpm/min for 20 min. The HSC fraction layer was obtained at the interface between the top and intermediate layers. The purity of the HSC fraction was estimated based on autofluorescence 1 d after isolation and was always greater than 97%. Flow cytometry was used

to identify the purity of primary cells. In brief, the cells were digested with trypsin, centrifuged at 1000 rpm/min for 10 min, washed twice with PBS, resuspended in EP tubes (100 μL/tube) and centrifuged at 2000 rpm/min for 6 min. Then, the supernatant was discarded, 100 μL of PBS was added, and the cells were resuspended and dispersed. A mouse monoclonal antibody against desmin (desmin is a typical molecular marker of HSCs) was added, and the cells were incubated at 1:100 for 1.5 h and centrifuged at 2000 rpm/min for 6 min. Centrifugation was repeated twice. The cells were resuspended and dispersed by adding 100 μL of PBS. Fluorescence-labeled anti-mouse secondary antibody (1:1000) was added, followed by incubation at 4 °C for 30 min in the dark. Next, 1 mL of PBS was added to each tube, followed by centrifugation at 2000 rpm/min for 6 min, which was repeated twice. Finally, 0.5 mL of PBS was added to resuspend the cells, and then the cells were subjected to flow cytometry measurements. HSCs were also confirmed to lack E-cadherin expression. Cell viability was also examined, and HSCs were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum and antibiotics as described previously[26]. Cells were starved or treated on day 2 after isolation, and the duration of starvation or treatment is described in each figure legend. The duration of the whole experiment was 5-7 d after HSC isolation, and cells at passages 1-2 were used (as cells were passaged from regular culture flasks to experimental cell culture wells for some experiments).

Histological and immunohistochemical studies

Liver samples were fixed with formalin, embedded in paraffin, sectioned and processed routinely for Masson's trichrome and Sirius red staining. Antibodies used for immunohistochemical (IHC) staining of GLUT1 and α-SMA were purchased from Abcam Technology, United States.

RNA interference

Cells were transfected with small interfering RNAs (siRNAs) using Lipofectamine 3000 (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's recommendations. The siRNAs used were an siRNA mix targeting sequences in Smad2 and Smad3 purchased from Santa Cruz Biotechnology (siRNA Smad2/3) and siRNAs targeting four different sequences of Smad4 purchased from Santa Cruz Biotechnology. GLUT1 siRNA was purchased from Cell Signaling Technology. The sequences of the siRNAs used are shown in Table 1.

Glycolytic function assay and lactate measurements

Primary mouse HSCs were plated on XF96 cell culture microplates. The extracellular acidification rate (ECAR), a glycolytic flux parameter, was measured with a Seahorse XF96 bioanalyzer using the XF Glycolysis Stress Test kit according to the manufacturer's instructions (102194-100, Seahorse Bioscience). Lactate levels were measured spectrophotometrically in 700 μL of supernatants from cells receiving the corresponding treatment using standard enzymatic methods.

Cell counting kit-8 assay

Primary mouse HSCs were seeded in a 96-well plate at a density of 3000 cells per well. CCK-8 reagent was added to each well every 24 h, and the plates were incubated for an additional 1 h at 37 °C and measured by recording the absorbance at 450 nm with an Elx800™ spectrophotometer (BioTek, Winooski, VT, United States).

Biochemical function analysis

Alanine aminotransferase (ALT) and aspartate transaminase (AST) levels in mouse serum samples and the supernatant of cell culture medium were detected using an automatic biochemical analyzer (Siemens Advia 1650; Siemens, Bensheim, Germany).

RNA extraction and real-time polymerase chain reaction

GLUT1, hexokinase 2 (HK-2), pyruvate kinase 2 (PKM-2) and α-SMA mRNA levels were determined using real-time polymerase chain reaction (RT-PCR) with a SYBR Green Master Mix Kit (Roche, Indianapolis, IN, United States). The primer sequences used are shown in Table 2.

Transwell migration assay

The migratory properties of HSCs were assessed using a Transwell assay. Cells were seeded at a density of 4×10^5 cells/well in the upper compartment of Transwell chambers with serum-free medium, and the lower compartment contained 700 μL of

Tissue immunofluorescence staining

Tissue sections were placed at room temperature for 10 min and deparaffinized in water for further antigen retrieval. After the sections were dried slightly, a histochemical pen was used to draw circles around the tissue, and 3%-5% BSA was added dropwise inside the circle for blocking, followed by incubation for 30 min. The primary antibody was added dropwise at the recommended ratio to the sections, and the sections were placed in a refrigerator (4 °C) and incubated overnight. After 3 washes, the sections were incubated with a FITC (CK-18)-labeled secondary antibody at room temperature for 45 min, and nuclei were stained with DAPI (300 nmol/L) for 1-5 min. After 3 washes, an antifluorescence quencher was added, and the sections were sealed with resin. Photographs of random fields were taken under an upright fluorescence microscope (ZEISS Axiovert).

Statistical analysis

Data were analyzed using Student's t test (SigmaPlot, SPSS 17.0, United States) to determine differences between two groups and are presented as the mean ± SE. For comparisons between multiple groups, three-way analysis of variance was performed, followed by t tests with Bonferroni correction using SAS 9.3 software (SAS Institute Inc., Cary, NC, United States). In addition, a log-rank test was used for survival analysis. All experiments were repeated at least three times. Differences were considered statistically significant at $P < 0.05$ ($^{a}P < 0.05$, $^{b}P < 0.01$).

RESULTS

GLUT1 expression is correlated with liver fibrosis progression

The classic mouse model of CCl_4-induced liver fibrosis was used to first clarify whether GLUT1 is related to liver fibrosis. Successful establishment of the liver fibrosis model was confirmed by Sirius red staining and α-SMA IHC staining (Figure 1A-C). Notably, a significant increase in GLUT1 expression was detected in the liver tissue specimens from the model group (Figure 1A and D). Subsequently, tissue immunofluorescence staining was performed, and the results showed significantly increased GLUT1 expression in liver tissue samples from the CCl_4 liver fibrosis model. More importantly, GLUT1 colocalized with α-SMA, indicating a correlation between GLUT1 and liver fibrosis (Figure 1E). IHC staining for GLUT1 and α-SMA was performed using human liver fibrosis specimens and liver specimens from a healthy control group; as expected, GLUT1 expression was significantly higher in the human liver fibrosis specimens (Figure 1F). Finally, whole-liver lysates were prepared from human liver tissue specimens and specimens from the mouse liver fibrosis model, and GLUT1 protein expression was analyzed. The results were consistent with the IHC data (Figure 1G-H). In summary, these results indicate that GLUT1 expression is related to liver fibrosis progression.

TGF-β1 stimulates HSC activation by inducing GLUT1 expression and promoting aerobic glycolysis

We found that GLUT1 colocalized with α-SMA, indicating that GLUT1 expression was increased mainly in activated HSCs because α-SMA is a major marker of HSC transdifferentiation. TGF-β1 is a very important profibrotic factor and regulates metabolic reprogramming in pulmonary fibrosis[27], as reported in some studies. Therefore, we questioned whether the increase in GLUT1 expression in liver fibrosis and TGF-β1 are related. This study first determined the effect of TGF-β1 on glycolysis in HSCs. To assess the dose responses to TGF-β1, we incubated HSCs with different TGF-β1 concentrations ranging from 3 ng/mL to 5 ng/mL, and the results showed similar effects on GLUT1 protein levels (Supplementary Figure 1). Therefore, a TGF-β1 concentration of 3 ng/mL was used for subsequent experiments. Mouse primary HSCs were isolated and cultured, and the cells were stimulated with TGF-β1 for 24 h prior to the experiments. TGF-β1 stimulation led to an early and continuous increase in the ECAR (an indicator of extracellular acid production) in HSCs, indicating that glycolysis was enhanced in these cells (Figure 2A and B). In addition, the intracellular and extracellular levels (in the medium) of lactic acid were examined to further confirm the glycolytic changes in HSCs. Both intracellular and extracellular lactic acid levels were significantly increased. Consistent with the increase in glycolysis, the level of glucose consumption also increased in these cells (Figure 2C and D). Therefore, TGF-β1 induces glycolysis during the process of HSC transdifferentiation. The expression levels of key glycolytic enzymes in these cells were evaluated; the expression levels of HK-2, PKM-2 and GLUT1 were upregulated, and the increase in GLUT1 expression was particularly significant (Figure 2F-H). Based on these findings, the increase in glycolysis during HSC transdifferentiation is related to the upregulation of key glycolysis enzymes. Similarly, the expression of α-SMA, a marker of transdifferentiation, also increased during the TGF-β1-mediated activation of HSCs (Figure 2I). GLUT1 protein expression was examined at various time points after stimulating HSCs with TGF-β1 (3 ng/mL) to determine whether TGF-β1 stimulates GLUT1 expression in a time-dependent manner, and the results showed that GLUT1 expression increased 2 h after stimulation with TGF-β1 and peaked at 8 h. These results indicate a time-dependent relationship between the increase in GLUT1 expression and TGF-β1 stimulation, which is consistent with the early increase in aerobic glycolysis in HSCs (Figure 2J). Finally, the addition of an inhibitor of the type 1 TGF-β1 receptor inhibited TGF-β1-induced GLUT1 expression in HSCs, suggesting that GLUT1 induction was mediated by TGF-β1 (Figure 2K). Based on these data, TGF-β1 is involved in glycolysis during HSC transdifferentiation and mediates GLUT1 expression, thereby promoting HSC transdifferentiation.

TGF-β1 induces GLUT1 expression through the Smad pathway

After finding that TGF-β1 stimulation induces GLUT1 expression, the specific mechanism by which TGF-β1 induces GLUT1 expression was further explored. Changes in the expression levels of Smad proteins in the canonical pathway activated by TGF-β1 stimulation were first examined. Western blot analysis revealed a time-dependent relationship between Smad2/Smad3 phosphorylation and TGF-β1

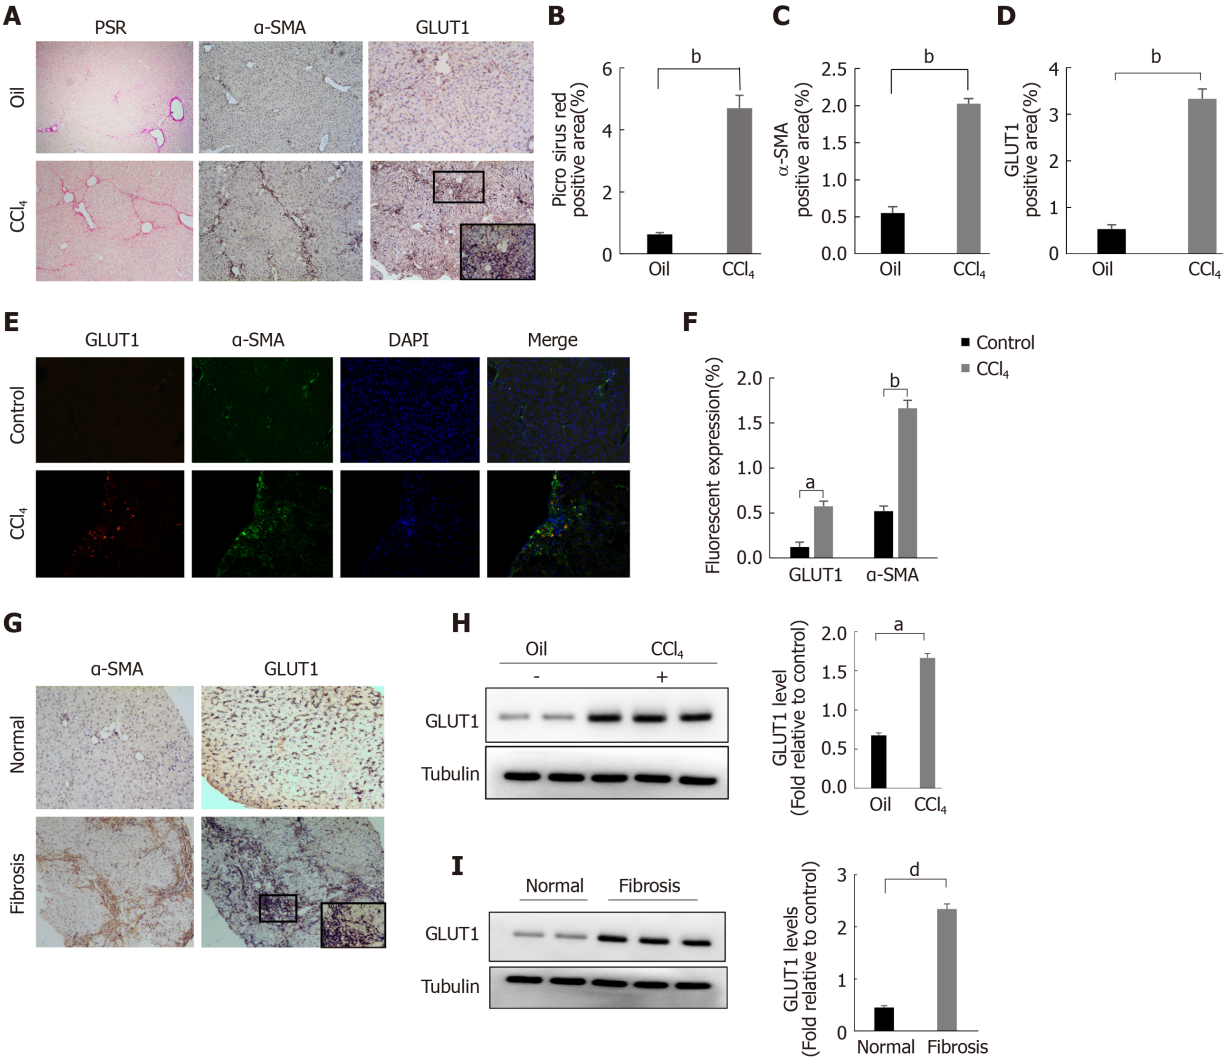

Figure 1 Glucose transporter 1 expression is correlated with liver fibrosis progression. A-D: The classic mouse model of CCl_4-induced liver fibrosis was used to first clarify whether glucose transporter 1 (GLUT1) is related to liver fibrosis. Sirius red staining and alpha-smooth muscle actin (α-SMA) immunohistochemical (IHC) staining were used to confirm that the liver fibrosis model was successfully established, and then the mice were randomly divided into the CCl_4 group and the control oil group (n = 6-10 mice/group) (A); Evaluation of liver fibrosis using Sirius red staining (B); Determination of the area ratio of positive IHC staining for α-SMA in the mouse CCl_4-induced liver fibrosis model (C); GLUT1 expression was more abundant in the liver tissue samples from the model group (D); E and F: Immunofluorescence staining for GLUT1 (red) and α-SMA (green) in the CCl_4 model. Cell nuclei were counterstained with DAPI. Scale bar for immunofluorescence staining, 200 μm; scale bars for IHC staining and Sirius red staining, 200 μm; G: IHC staining for α-SMA and GLUT1 in the healthy control and liver fibrosis groups (scale bar, 100 μm); H: Western blot analysis of changes in GLUT1 protein levels in the oil group and the CCl_4 model group; I: Western blot analysis of GLUT1 protein expression in human liver tissues from the healthy control group and the liver fibrosis group. Data in B-D, G and H are presented as the mean ± SE. Statistically significant differences were detected (compared with the oil group, $^aP < 0.05$ and $^bP < 0.01$; compared with the healthy control group, $^dP < 0.05$). GLUT1: Glucose transporter 1; α-SMA: Alpha-smooth muscle actin.

stimulation (Figure 3A and B), and phosphorylation occurred at time points close to when GLUT1 expression increased. Next, the direct role of Smads in GLUT1 induction was explored. Smad3 or Smad4 overexpression plasmids were first transiently transfected into HSCs, and then certain groups of HSCs were induced with TGF-β1 for 4 h. Smad3 or Smad4 overexpression promoted GLUT1 expression, and TGF-β1 addition amplified these effects, resulting in a further increase in GLUT1 expression (Figure 3C and D). Smad2/3 and/or Smad4 siRNAs were used to silence their expression levels and to better understand the roles of Smads in the relationship between TGF-β1 and GLUT1 expression, and the analysis performed at 48 h after the transfection of Smad2/3 and/or Smad4 siRNAs showed that TGF-β1-mediated GLUT1 expression was significantly reduced. This change was more significant and the decrease in GLUT1 expression was more substantial when the cells were transfected simultaneously with both siRNAs (Figure 3G and H). Finally, HSCs were sequentially treated with the Smad inhibitor SIS3 for 2 h and then with TGF-β1 for 4 h, resulting in

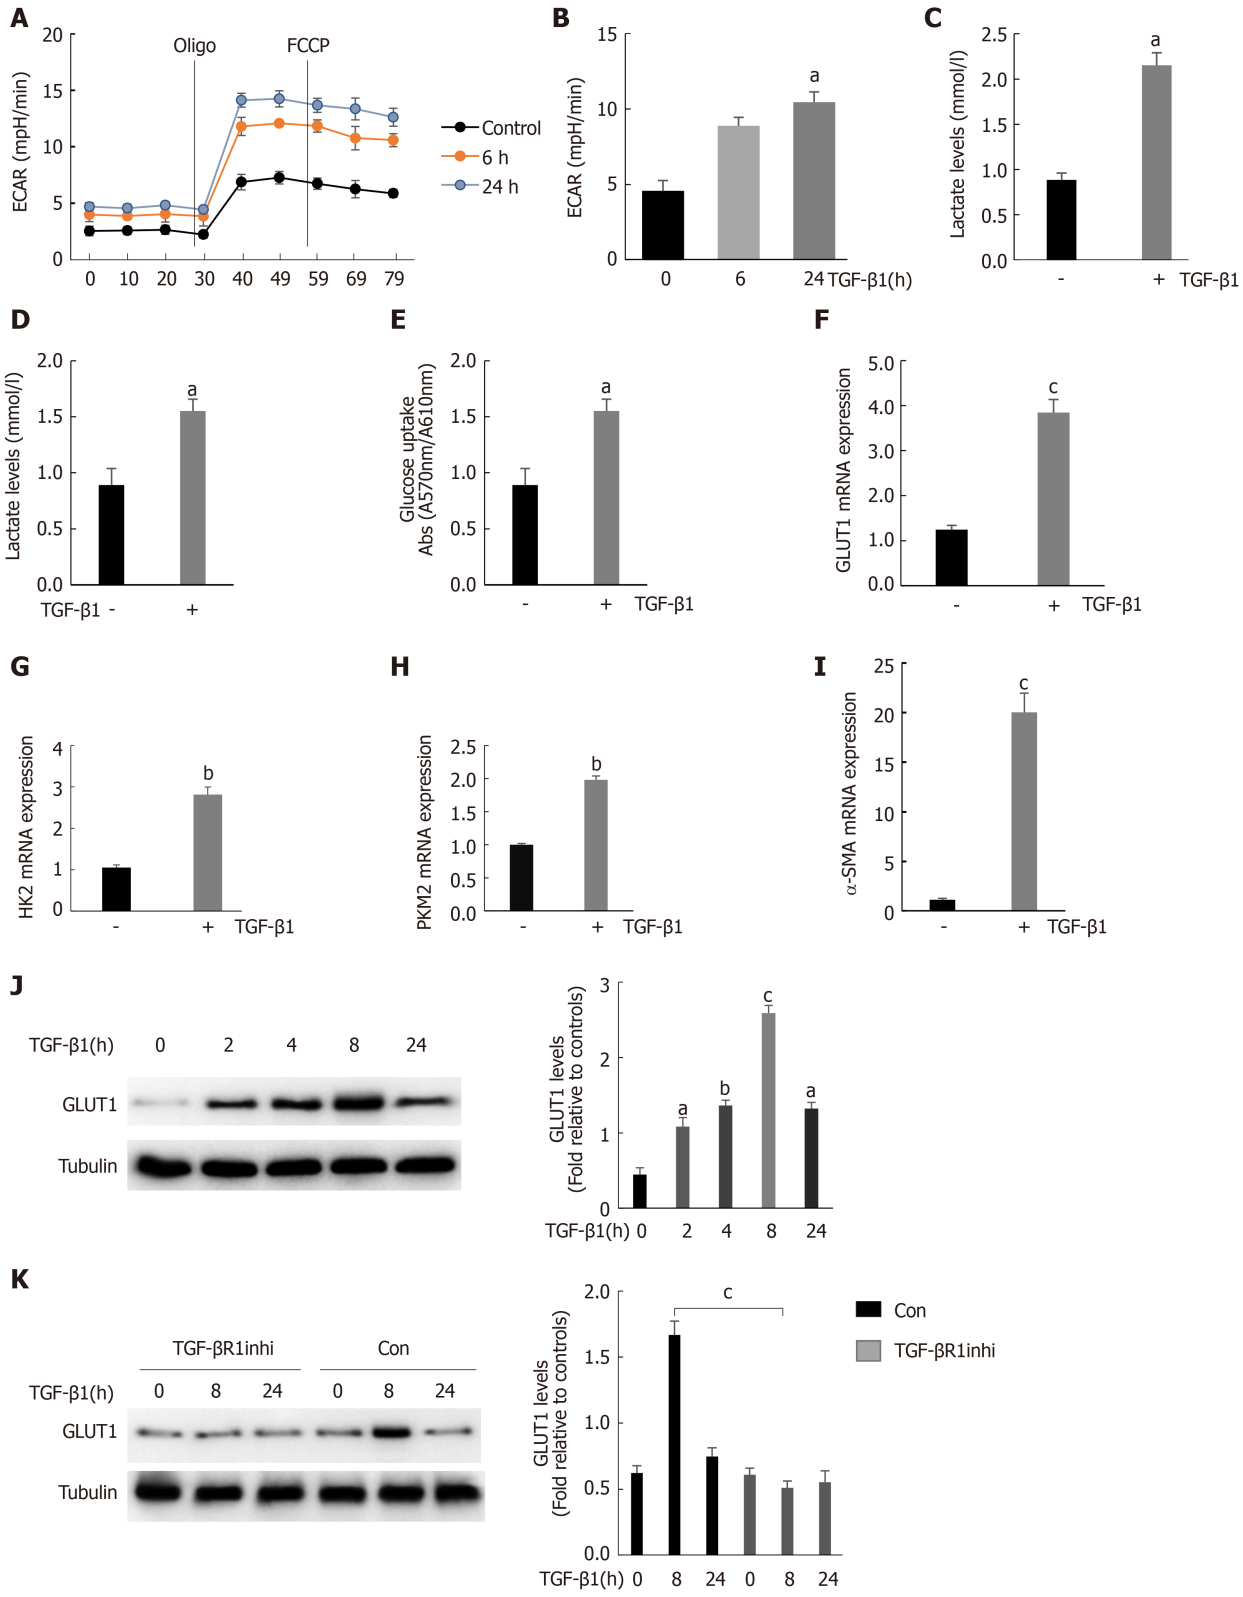

Figure 2 Stimulation of hepatic stellate cells with transforming growth factor-β1 induces glucose transporter 1 expression and promotes glycolysis. A: Serum-starved (for 20 h) primary mouse hepatic stellate cells (HSCs) were seeded into Seahorse XF-24 cell culture microplates (5×10^4 cells/well). The cells were first treated with transforming growth factor-β1 (TGF-β1) (3 ng/mL) for 0, 6 or 24 h, followed by sequential treatment with oligomycin (Oligo) and carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP). The extracellular acidification rate (ECAR) was recorded in real time; B: The basic ECAR. $n = 6$; the mean ± SE; $^aP < 0.05$ compared to the level before TGF-β1 treatment (0 h); unpaired *t* test; C and D: Mouse HSCs were treated with or without TGF-β1 (3 ng/mL) for 24 h. The cells were then lysed, and the lactic acid contents in the cell lysate (C) and the culture medium (D) were examined; E: Determination of glucose consumption in the culture medium; F-I: Mouse HSCs were treated with or without TGF-β1 (3 ng/mL) for 24 h. RNA was purified, and RT-PCR was performed to examine the expression levels of glucose transporter 1 (GLUT1) (F), HK-2 (G), PKM-2 (H) and α-SMA (I), $n = 5$, the mean ± SE; $^aP < 0.05$, $^bP < 0.01$ and $^cP < 0.001$ compared with those at 0 h or those in the TGF-β1-untreated group; one-way analysis of variance (ANOVA); J: Western blot analysis of the expression levels of

GLUT1 and tubulin at various time points after HSCs were treated with TGF-β1 (3 ng/mL); K: Examination of the changes in GLUT1 and tubulin levels after sequential treatment with a type 1 TGF-β receptor inhibitor (LY2109761, 2 μm) for 1 h and then with TGF-β1 (3 ng/mL) for 0, 8 or 24 h. All experiments shown in A-E and F-I were performed 2-3 times. Inhi: Inhibitor; Con: Control; FCCP: Carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone; ECAR: Extracellular acidification rate; GLUT1: Glucose transporter 1; TGF-β1: Transforming growth factor-β1.

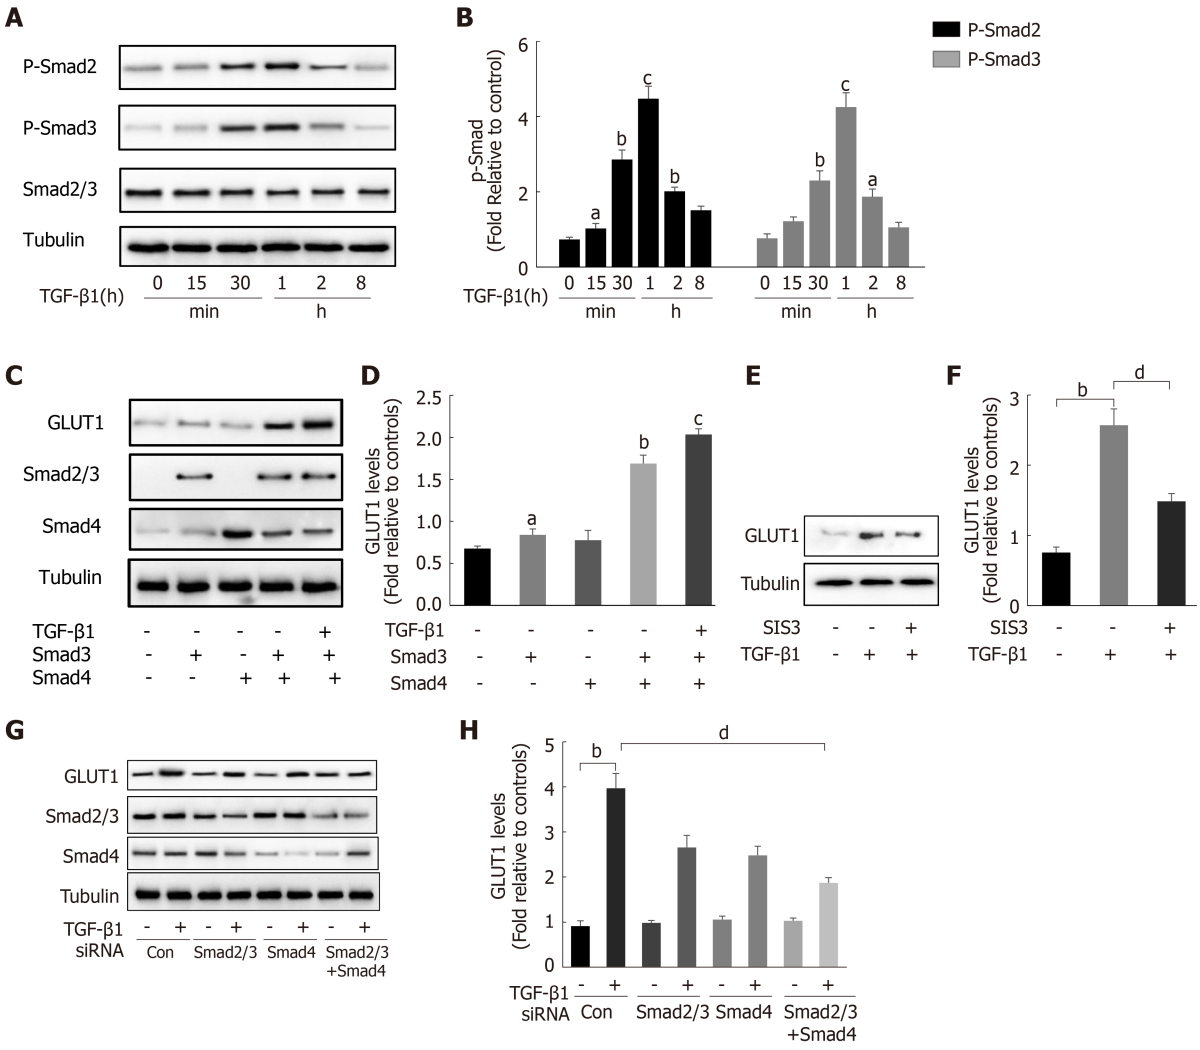

Figure 3 Transforming growth factor-β1 induces glucose transporter 1 expression through the Smad pathway. A and B: Serum-starved (for 20 h) primary mouse hepatic stellate cells (HSCs) were treated with transforming growth factor-β1 (TGF-β1) (3 ng/mL) and examined at various time points. Western blot analysis using specific antibodies (A). Quantitative analysis of the levels of the p-Smad2 and p-Smad3 proteins in five independent experiments (B); C and D: After transiently transfecting HSCs with 2 μg of Smad3 and/or Smad4 expression plasmids, the cells were cultured in serum-free medium for 48 h and then treated with TGF-β1 (3 ng/mL) for 4 h. Green fluorescent protein (GFP) was used as a transfection control. Western blot analysis using specific antibodies (C). Quantitative analysis of glucose transporter 1 (GLUT1) protein expression in five independent experiments (D); E and F: HSCs were first pretreated with a Smad3 inhibitor (SIS3, 20 μm) for 1 h and then treated with TGF-β1 (3 ng/mL) for 4 h. Western blot analysis using specific antibodies (E). Quantitative analysis of the GLUT1 protein level in five independent experiments (F); G and H: Mouse primary HSCs were transfected with 20 μmol/L control small interfering RNAs (siRNAs) or siRNAs targeting Smad2/3 and Smad4. After transfection in serum-free medium for 48 h, the cells were treated with TGF-β1 (3 ng/mL) for 4 h. Western blot analysis using specific antibodies (G). Quantitative analysis of the GLUT1 protein level in five independent experiments (H) (the mean ± SE; $^{a}P < 0.05$, $^{b}P < 0.01$ and $^{c}P < 0.001$ compared with that in the group of cells without TGF-β1; $^{d}P < 0.05$ for the comparison of the groups treated with TGF-β1 and the groups treated with TGF-β1 and different additional reagents; Student's *t* test). GLUT1: Glucose transporter 1; TGF-β1: Transforming growth factor-β1; Con: Control; siRNAs: Small interfering RNAs.

a significant decrease in GLUT1 protein expression (Figure 3E and F). These results preliminarily indicate the important regulatory role of Smad proteins in TGF-β1-mediated GLUT1 expression and suggest that Smad proteins directly participate in the regulation of GLUT1 by TGF-β1.

The noncanonical p38 MAPK and PI3K/AKT signaling pathways are also involved in TGF-β1-mediated GLUT1 induction

During fibrosis development, TGF-β1 activates not only the canonical Smad pathway

but also noncanonical pathways (such as the PI3K/AKT and p38 MAPK signaling pathways). In addition, the Smad pathway and non-Smad pathways are mutually dependent[28]. Therefore, we questioned whether a non-Smad pathway is involved in the TGF-β1-mediated induction of GLUT1. Changes in the phosphorylation levels of p38 and AKT in HSCs after TGF-β1 stimulation were examined to answer this question. Western blot analyses showed increased levels of phosphorylated p38 and AKT in HSCs after TGF-β1 treatment (Figure 4A-C). HSCs were pretreated with the specific p38 MAPK inhibitor SB203580 and the PI3K inhibitor LY294002 for 1 h and then induced with TGF-β1 to understand the bridging role of p38 MAPK and AKT in TGF-β1-mediated GLUT1 expression. Western blot analyses showed that p-AKT activity was significantly inhibited and that GLUT1 protein expression was significantly reduced (Figure 4D). S6 ribosomal protein and heat shock protein 25 (Hsp25) are downstream proteins in the PI3K/AKT and p38 MAPK pathways, and their phosphorylation was also inhibited. Addition of the p38 inhibitor reduced the phosphorylation of the S6 protein, and the phosphorylation level of Smad2 was also affected; however, Smad3 was not significantly affected (Figure 4D and E). The above results indicate that (1) GLUT1 expression in HSCs did not rely solely on the TGF-β1-mediated Smad pathway, *i.e.*, the p38 MAPK and PI3K/AKT signaling pathways were also involved in TGF-β1-mediated GLUT1 expression, and (2) TGF-β1-mediated pathways did not act independently, as mutual restrictions and interactions between the pathways were observed. Based on the results described above, the effects of inhibiting the Smad3, p38 MAPK and PI3K/AKT pathways on GLUT1 expression were analyzed, and the simultaneous addition of inhibitors of the Smad3, p38 MAPK and PI3K/AKT pathways significantly reduced TGF-β1-mediated GLUT1 expression (Figure 4F and G). In summary, TGF-β1 requires the participation of non-Smad pathways to induce GLUT1 expression during HSC activation.

The effect of GLUT1 on HSC migration and proliferation

Cells were first treated with phloretin (a specific inhibitor of GLUT1) for 30 min or transfected with an siRNA targeting GLUT1, followed by treatment with TGF-β1 for 4 h. The targeted inhibition of GLUT1 by phloretin and the siRNA suppressed the effect of TGF-β1 on the migration and proliferation of HSCs (Figure 5A, B and E). Western blot analyses also showed that siRNA transfection effectively inhibited TGF-β1-induced GLUT1 expression (Figure 5C and D). Therefore, inhibition of GLUT1 expression reverses the effect of TGF-β1 on the migration and proliferation of HSCs and delays the process of HSC transdifferentiation into myofibroblasts. No noticeable effect of the control siRNA on proliferation was identified between TGF-β1-treated cells and TGF-β1/siRNA-control-treated cells or between control/saline-treated cells and saline/siRNA-control-treated cells (Figure 5E). In addition, no obvious effect of siRNA interference on cell viability (Supplementary Figure 2) or the expression of TGF-β receptors was found (Supplementary Figure 3).

GLUT1 inhibition delays the development of liver fibrosis in a mouse model of liver fibrosis

In vitro experiments confirmed the importance of GLUT1 in liver fibrosis. Next, we examined whether inhibition of GLUT1 expression suppressed liver fibrosis *in vivo*. Phloretin, a specific inhibitor of GLUT1, was used, and its effect on CCl_4-induced liver fibrosis was examined. After successful establishment of the CCl_4-induced model, an i.p. injection of phloretin was administered three times a week; the intervention was discontinued after 2 wk. A simple technical roadmap is shown in Figure 6A. Compared with those in the model group, the areas of collagen fiber deposition were significantly reduced in the liver tissues from mice in the drug intervention group; these findings were confirmed by Masson's trichrome and Sirius red staining (Figure 6B-D). The degree of liver inflammation was determined by performing serological assessments of changes in ALT and AST levels, and the results indicated that the degree of inflammation was significantly reduced in the drug intervention group (Figure 6E and F). Therefore, the *in vivo* results revealed that GLUT1 inhibition reduces CCl_4-induced liver fibrosis.

DISCUSSION

In normal liver tissues, quiescent HSCs express TGF-β1 at low levels, while TGF-β1 is immediately upregulated after acute or chronic liver injury and interacts with multiple signaling pathways to induce HSC activation and proliferation and extensive ECM

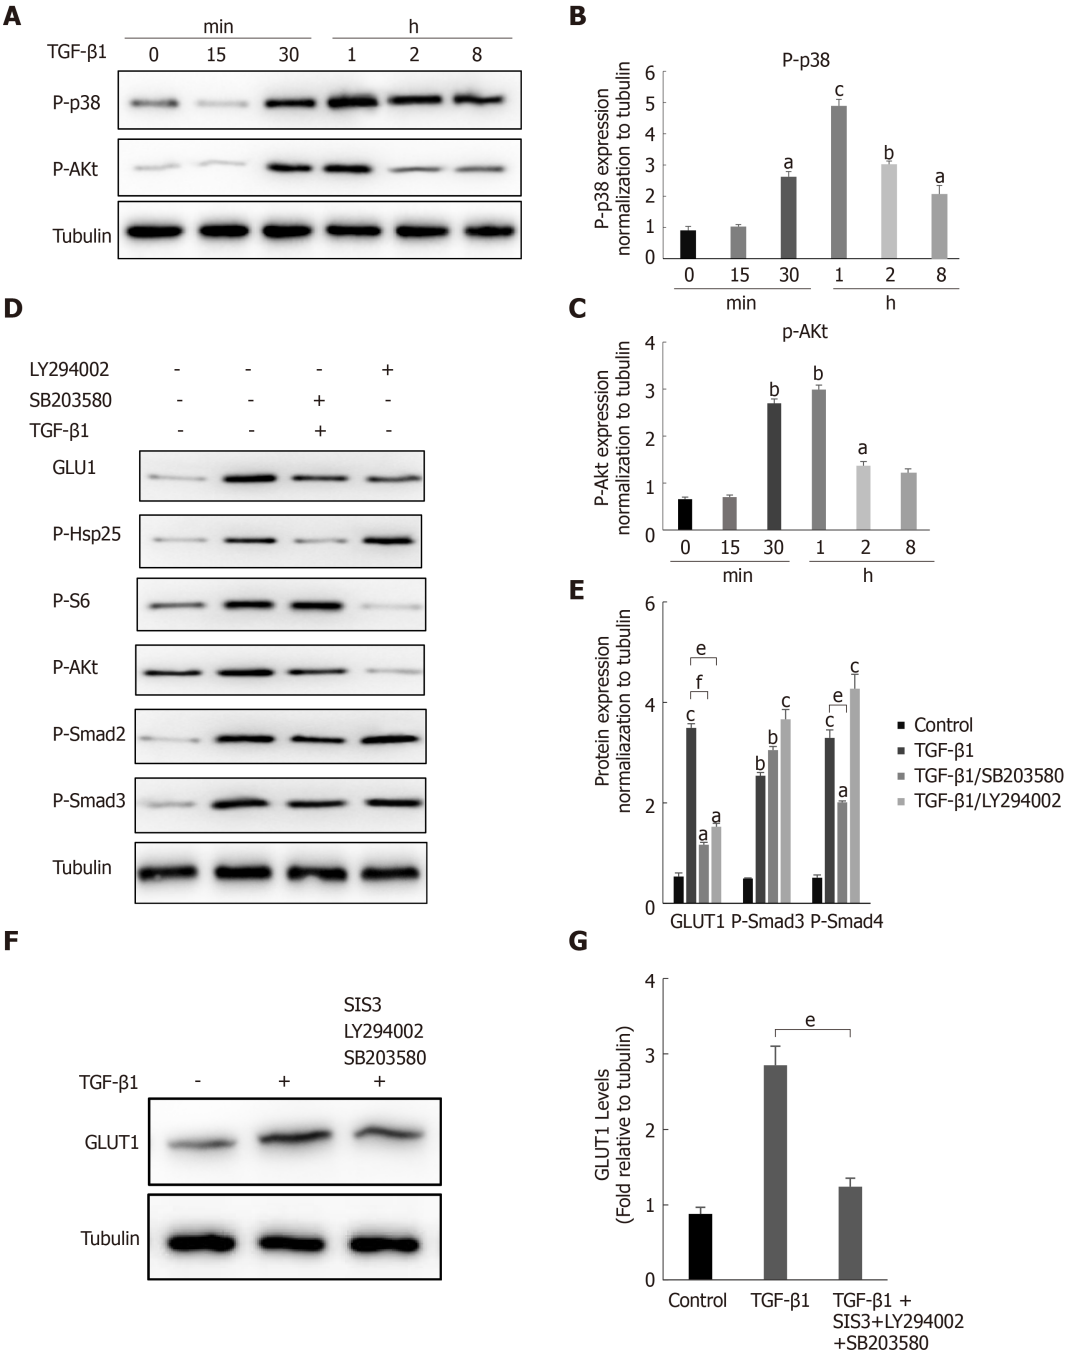

Figure 4 The noncanonical p38 MAPK and PI3K/AKT signaling pathways are also involved in transforming growth factor-β1-mediated glucose transporter 1 expression. A-C: Serum-starved (for 20 h) primary mouse hepatic stellate cells (HSCs) were treated with transforming growth factor-β1 (TGF-β1) (3 ng/mL) and examined at different time points. Western blot analysis using specific antibodies (A). Five independent experiments were performed to quantitatively analyze the levels of phosphorylated p38 (B) MAPK and AKT (C); D and E: HSCs cultured in serum-free medium were pretreated with the p38 MAPK inhibitor SB203580 (10 μm) or the PI3K inhibitor LY294002 (10 μm) for 1 h and then treated with TGF-β1 (3 ng/mL) for 4 h. production[29,30]. TGF-β1 enhances aerobic glycolysis, amino acid uptake and lactic acid production in Ras- and Myc-transformed cells. TGF-β1 contributes to the metabolic reprogramming of cancer cells and tumor-associated stromal cells[31]. When used to replace a peritoneal dialysis solution, TGF-β1 stimulates glycolysis and inhibits mitochondrial respiration of mesothelial cells, thus promoting the development of peritoneal fibrosis[32]. Preliminary yet strong evidence supporting the importance of

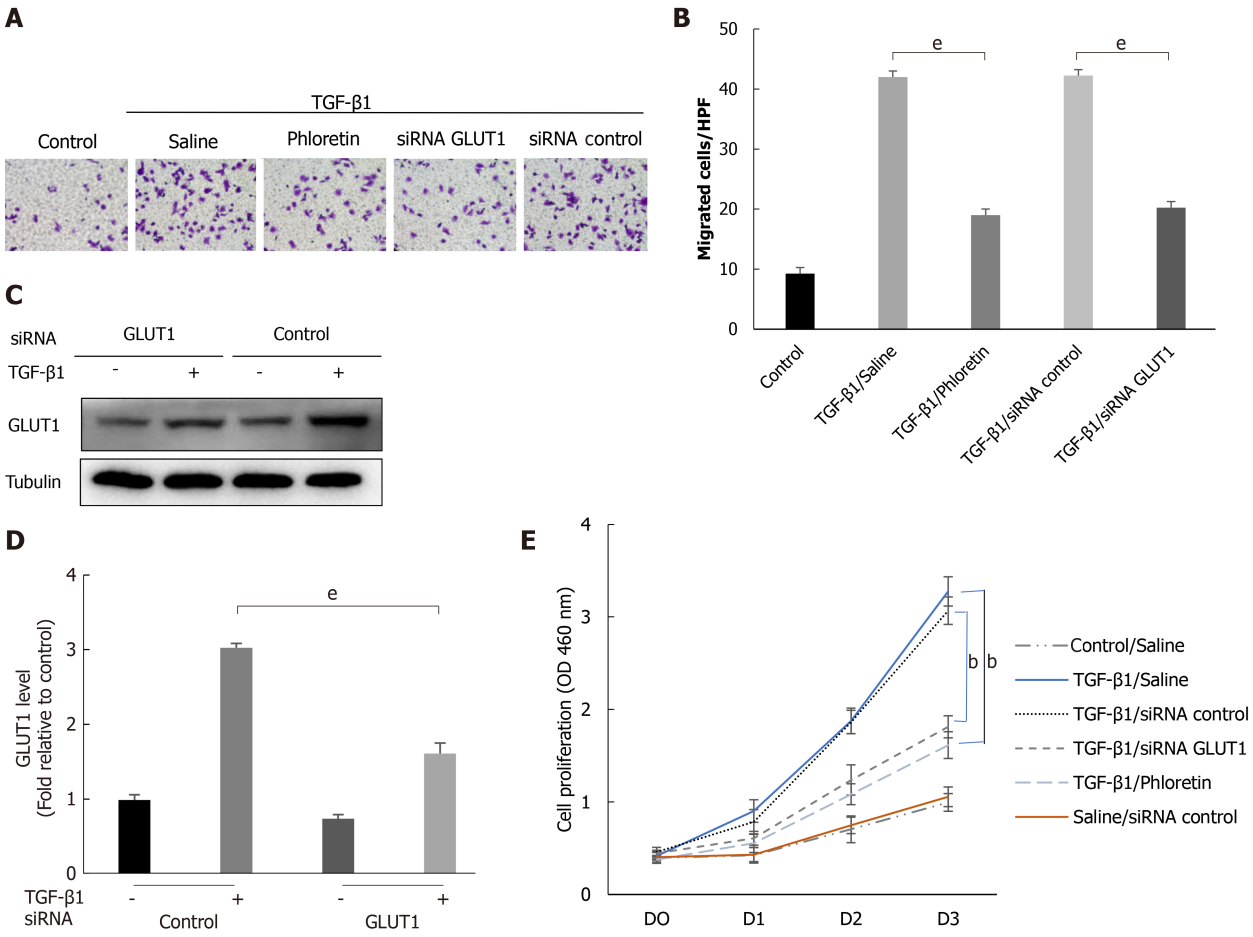

Figure 5 The effect of glucose transporter 1 on the growth and proliferation of hepatic stellate cell. Mouse primary hepatic stellate cells (HSCs) were 1) pretreated with the glucose transporter 1 (GLUT1) inhibitor phloretin (50 μm) for 30 min and then treated with transforming growth factor-β1 (TGF-β1) (3 ng/mL) for 4 h or 2) transiently transfected with small interfering RNAs that inhibited GLUT1 expression, cultured in serum-free medium for 24 h and then treated with TGF-β1 (3 ng/mL) for 4 h. A: Cells were seeded in serum-free medium (4 × 10^5 cells/well) in the upper chambers of a Transwell system. The lower chambers were filled with 5% glucose medium (700 μL per well). Changes in cell migration were observed. GLUT1: Glucose transporter 1; TGF-β1: Transforming growth factor-β1; siRNAs: Small interfering RNAs.

metabolic reprogramming in the activation of fibroblasts is steadily accumulating. Research on the mechanism of organ fibrosis also shows that TGF-β1 is related to the occurrence of aerobic glycolysis and mitochondrial dysfunction. The transdifferentiation of resting HSCs into hepatic fibroblasts has been confirmed to be related to mutual transformation between glycolytic enzymes and gluconeogenic enzymes triggered by Hedgehog signaling[33]. Glycolysis is an important pathway of glucose metabolism, and GLUT1 is the most widely expressed glucose transporter in mammals; its expression is regulated by changes in metabolic status and oxidative stress. GLUT1 is also an important marker of liver carcinogenesis and metabolic liver diseases[34]. GLUT1-dependent glycolysis exacerbates lung fibrogenesis during *Streptococcus pneumoniae* infection *via* AIM2 inflammasome activation[35]. In the pathogenesis of diabetic glomerulosclerosis, TGF-β1 triggers GLUT1 activation by stretching glomerular mesangial cells. In breast cancer cells, long-term exposure to TGF-β1 restores GLUT1 expression and results in stable EMT and unlimited cell proliferation[36,37]. Therefore, we questioned whether TGF-β1 and GLUT1 are related to liver fibrosis.

This study showed a significant increase in GLUT1 expression in human and mouse fibrotic liver tissues, which is consistent with the research results of Wan *et al*[24]. With the increase in TGF-β1 Levels, the gene expression levels of key enzymes, including GLUT1, in the glycolytic pathway are elevated, glucose consumption and intracellular lactate production are also increased, and glycolytic flux by HSCs is enhanced. As expected, the results of this study are consistent with those of previous studies

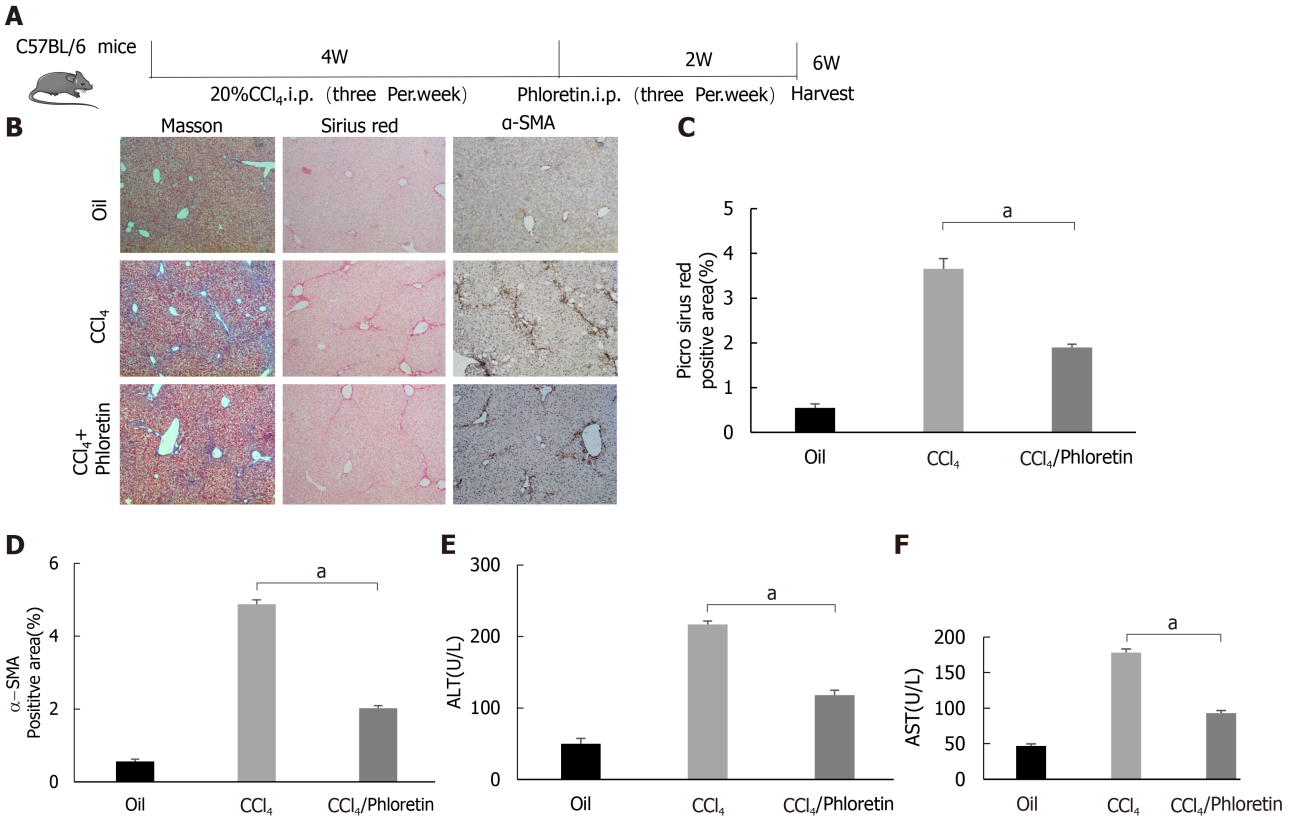

Figure 6 Glucose transporter 1 inhibition delays the development of liver fibrosis in a mouse model of liver fibrosis. A: Schematic diagram of the experiment. C57BL/6 mice were injected intraperitoneally with CCl_4 to induce liver fibrosis. The model was successfully established after 4 wk. Among the treatment groups, the CCl_4 + phloretin group was intraperitoneally injected with phloretin (10 mg/kg) three times a week, and the CCl_4 group was injected with normal saline as a control. The treatments were discontinued after 2 wk; B: Mouse livers were collected, and liver tissue sections were prepared. The sections were subjected to Masson's trichrome staining, Sirius red staining and alpha-smooth muscle actin (α-SMA) immunohistochemical (IHC) staining (original magnification, × 10); C: The positive area ratio detected using Sirius red staining; D: The positive area ratio for α-SMA IHC staining; E and F: Serological analysis of ALT (E) and AST (F) levels (n = 5-7; the mean ± SE; scale bar, 100 μm; $^aP < 0.05$ for the comparison between the CCl_4 group and the CCl_4 + phloretin group; Student's t test). α-SMA: Alpha-smooth muscle actin.

assessing the mechanism of metabolic reprogramming of pulmonary fibrotic fibroblasts[38], indicating that TGF-β1 induces aerobic glycolysis and drives the occurrence of metabolic reprogramming during the process of stromal cell transdifferentiation. Increased GLUT1 expression also contributes to an elevated glycolytic rate, increased lactic acid production and enhanced glucose-dependent metabolic pathways in cells. In contrast, GLUT1 expression decreased significantly after the addition of a TGF-β1 receptor inhibitor, indicating that GLUT1 expression is related to TGF-β1 signaling. Experiments involving Smad overexpression, siRNA-mediated knockout and Smad inhibitors showed that the response of GLUT1 to TGF-β1 was at least partially dependent on the Smad pathway. Studies have identified a cascade of related pathways activated by TGF-β1. Therefore, this study attempted to verify whether non-Smad pathways were also involved in the induction of GLUT1 expression in HSCs. The noncanonical PI3K/AKT and p38 MAPK pathways activated by TGF-β1 were examined. In colorectal cancer (CRC) cells, silencing GLUT1 expression inactivates the TGF-β1/PI3K/AKT signaling pathway, inhibits the proliferation of CRC cells and promotes apoptosis. MAPK activation by TGF-β1 may trigger GLUT1 synthesis[39, 40]. Based on the results of the present study, the simultaneous addition of specific inhibitors of the PI3K/AKT and p38 pathways, *i.e.*, SB203580 and LY294002, respectively, reduced TGF-β1-induced GLUT1 protein expression. The addition of the p38 pathway inhibitor resulted in a decrease in Smad2 protein phosphorylation, changes in the phosphorylated AKT level and changes in the phosphorylation level of a protein downstream of PI3K/AKT signaling (namely, S6); therefore, we speculated that the p38 MAPK pathway acted as a bridge between the TGF-β1-mediated Smad and AKT pathways in HSCs and that reduced activation of the p38 MAPK pathway would inhibit the latter two pathways. In addition, the p38 MAPK pathway might limit Smad pathway-mediated GLUT1 expression to a certain extent. These results are consistent with the previously reported crosstalk between Smad and p38 MAPK in

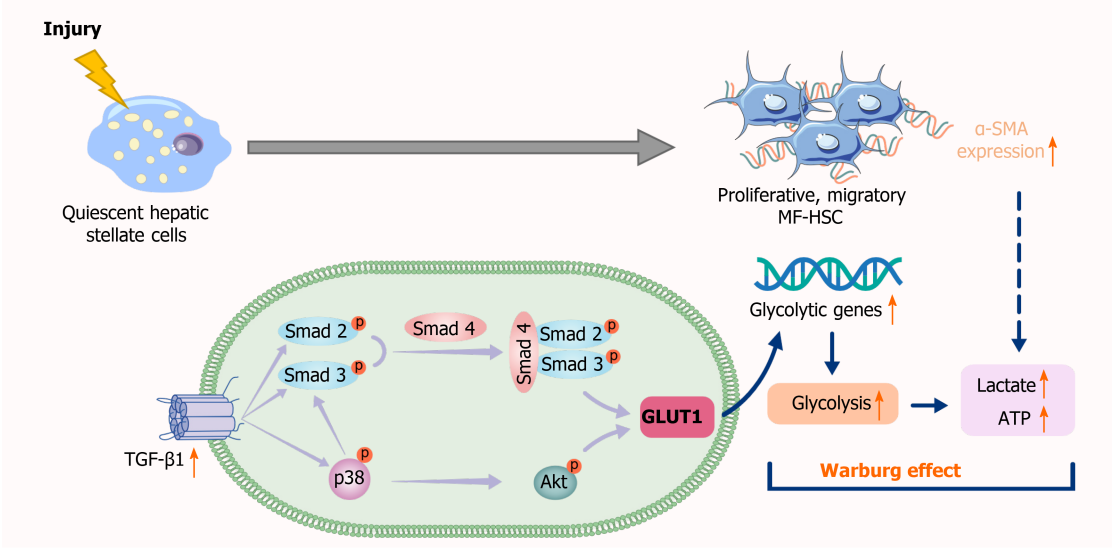

Figure 7 Schematic representation of the mechanisms implicated in canonical and noncanonical transforming growth factor-β pathways regulating glucose transporter 1 expression. TGF-β1: Transforming growth factor-β1; GLUT1: Glucose transporter 1; MF-HSC: Myofibroblasts-hepatic stellate cells; α-SMA: Alpha-smooth muscle actin.

TGF-β1 signal transduction in human glioblastoma cells[41]. However, the specific mechanism underlying the interaction among TGF-β1 pathways in the induction of aerobic glycolysis in stellate cells requires further study. The significant reduction in GLUT1 protein expression was related to the simultaneous inhibition of the Smad3, p38 MAPK and PI3K signaling pathways, indicating that GLUT1 protein expression during stellate cell activation requires the activation and signaling of these three pathways. Moreover, activation of the p38 MAPK pathway might result in a certain synergistic effect with the Smad2/3 pathway (Figure 7).

TGF-β1 is a pleiotropic cytokine with an important role in the occurrence of liver fibrosis. According to previous studies, TGF-β1 signaling clearly promotes cell migration, matrix synthesis and HSC differentiation toward myofibroblasts. Moreover, the effect of TGF-β1 on fibroblast migration and proliferation depends on changes in the microenvironment[42]. As shown in the present study, TGF-β1 promoted the proliferative and migratory capabilities of HSCs, functions that are hallmarks of cell transformation. The addition of a pharmacological inhibitor of GLUT1 activity (phloretin, an effective GLUT1 inhibitor capable of inhibiting bleomycin-induced pulmonary fibrosis *in vivo*[43]) and silencing of the GLUT1 gene eliminated TGF-β1-induced proliferation, growth and migration. Finally, a GLUT1 inhibitor was used in *in vivo* experiments, and the degree of mouse liver fibrosis improved, collagen fiber deposition decreased, and the degree of inflammation decreased. Given the importance of GLUT1, the experimental results revealed that GLUT1 is involved in aerobic glycolysis during HSC activation and that aerobic glycolysis is a response to TGF-β1 signaling mediated by the Smad, PI3K/AKT and p38 MAPK pathways.

CONCLUSION

In summary, TGF-β1-induced GLUT1 expression may be one of the mechanisms involved in the reprogramming of HSCs, providing an expanded basis and new insights for the mechanism of action of TGF-β1 in metabolic reprogramming during liver fibrosis. GLUT1 plays an important role in aerobic glycolysis in HSCs and in promoting cell proliferation and transformation. GLUT1 inhibition may be an alternative therapy to the current traditional treatments for liver fibrosis. However, the extent to which GLUT1 inhibition contributes to elimination of the profibrotic effect of TGF-β1 and the specific molecular mechanisms of the interaction between the two may require verification using approaches combining proteomics and single-cell sequencing, which may be an attractive research direction in the future.

ARTICLE HIGHLIGHTS

Research background

Liver fibrosis is a refractory disease that develops progressively and eventually evolves into liver cirrhosis or even liver cancer. Hepatic stellate cell (HSC) activation is the initiating factor for liver fibrosis, while aerobic glycolysis is one of the main metabolic characteristics. Transforming growth factor-β1 (TGF-β1) is the most important profibrotic factor in HSCs, and TGF-β1 drives metabolic reprogramming. Glucose transporter 1 (GLUT1) is the most widely distributed glucose transporter in mammals and is related to glycolytic metabolism. However, the role of GLUT1 in liver fibrosis and the relationship between GLUT1 and TGF-β1 remain unclear and require further investigation.

Research motivation

The results of this study might provide a basis for the application of GLUT1 in the treatment of liver fibrosis and provide an expanded basis for understanding the mechanism of action of TGF-β1 in metabolic reprogramming during liver fibrosis.

Research objectives

This study examined changes in GLUT1 expression in human and mouse fibrotic liver tissues and differences in extracellular acid production and in the expression levels of key glycolytic enzymes and GLUT1 during HSC activation induced by TGF-β1-related pathways. In addition, this study further explored the relationship between TGF-β1 pathways and GLUT1 expression and the potential underlying molecular mechanisms.

Research methods

IHC was employed to examine changes in GLUT1 expression in human and mouse fibrotic liver tissues. Immunofluorescence staining was performed to examine changes in GLUT1 and alpha-smooth muscle actin (α-SMA) expression in mouse fibrotic liver tissue. Primary mouse stellate cells were isolated. After activation of the cells by TGF-β 1 stimulation, changes in extracellular acid production, key glycolytic enzymes and glucose consumption were examined. In addition, changes in GLUT1 expression were explored by activating/inhibiting the Smad2/3 pathway and inhibiting the expression of proteins related to the p38 and PI3K/AKT pathways. Finally, in mice with liver fibrosis, the effect of a GLUT1 inhibitor on liver fibrosis was investigated by performing Masson's trichrome staining and Sirius red staining and analyzing serological inflammatory markers.

Research results

The expression of the GLUT1 protein was increased in both mouse and human fibrotic liver tissue.immunofluorescence staining revealed the colocalization of GLUT1 and α-SMA proteins, indicating that GLUT1 expression was related to the development of liver fibrosis. TGF-β1 induced an increase in aerobic glycolysis in HSCs and induced GLUT1 expression in HSCs by activating the canonical and noncanonical signaling pathways. The p38 MAPK pathway and the Smad pathway synergistically affected the induction of GLUT1 expression. GLUT1 inhibition eliminated the effect of TGF-β1 on the proliferation and migration of HSCs. A GLUT1 inhibitor was administered to a mouse model of liver fibrosis, and GLUT1 inhibition reduced the degree of liver inflammation.

Research conclusions

GLUT1 expression was upregulated in liver fibrosis, and the underlying mechanism was related to activation of the Smad2/3, p38 and PI3K/AKT pathways by TGF-β1, which directly induced GLUT1 expression and promoted glycolysis. GLUT1 inhibition eliminated TGF-β1-induced HSC activation, proliferation and migration, and GLUT1 inhibition exerted an antifibrotic effect.

Research perspectives

The results of this study reveal that the TGF-β1 pathway directly induces GLUT1 expression and aerobic glycolysis, thus promoting liver fibrosis. This study preliminarily clarified the mechanism underlying the interaction between TGF-β1 and GLUT1 in liver fibrosis, thus providing a deeper understanding of the mechanism of liver fibrosis and providing guidance for the selection of targets to treat liver fibrosis. The results from this study indicate that GLUT1 inhibitors may have certain

prospective applications as therapeutic drugs for liver fibrosis.

Abstract

BACKGROUND

Quantitative hepatitis B core-related antigen (qHBcrAg) has a better correlation with intrahepatic hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) than HBV DNA or hepatitis B e antigen (HBeAg), but data are still lacking for its clinical application.

AIM

The aim was to investigate serum qHBcrAg levels in patients with chronic hepatitis B and assess the correlation of serum qHBcrAg with pregenomic RNA (pgRNA), cccDNA, and HBeAg seroconversion.

METHODS

This study was a secondary analysis of patients who underwent percutaneous liver biopsy between July 2014 and June 2019 in two multicenter randomized controlled clinical trials of peginterferon *vs* nucleos(t)ide analog (NUC)-based therapy (NCT03509688 and NCT03546530). Serum qHBcrAg, pgRNA, HBV DNA, hepatitis B core antigen, HBeAg, liver cccDNA, and HBV DNA were measured. The correlations of serum qHBcrAg with other biomarkers were analyzed.

RESULTS

A total of 139 patients were included. The mean qHBcrAg levels were 5.32 ± 1.18 $\log_{10}$ U/mL at baseline and decreased during treatment (all $P < 0.0001$). Serum qHBcrAg levels were positively correlated with pgRNA ($r = 0.597$, $P < 0.0001$) and cccDNA ($r = 0.527$, $P < 0.0001$) levels. The correlation of serum qHBcrAg level and

University.

Informed consent statement: Informed consent was obtained from each patient for the original trials, with clauses for possibly secondary analyses. The original studies were registered (ClinicalTrials.gov NCT03509688 and NCT03546530).

Conflict-of-interest statement: The authors declare that they have no conflicting interests.

Data sharing statement: The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request.

STROBE statement: The authors have read the STROBE Statement-checklist of items, and the manuscript was prepared and revised according to the STROBE Statement-checklist of items.

intrahepatic HBV DNA levels at baseline was weak but significant (r = 0.399, P < 0.0001). HBcrAg predicted HBeAg seroconversion, with areas under the receiver operating characteristics curve of 0.788 at 24 wk and 0.825 at 48 wk. Log HBcrAg at wk 24 and 48 was independently associated with HBeAg seroconversion [odds ratio (OR) = 2.402, 95% confidence interval (CI): 1.314-4.391, P = 0.004; OR = 3.587, 95%CI: 1.315-9.784, P = 0.013].

CONCLUSION

Serum HBcrAg levels were correlated with HBV virological markers and could be used to predict HBeAg seroconversion.

INTRODUCTION

Chronic hepatitis B (CHB) is a liver disease caused by a chronic infection with the hepatitis B virus (HBV) and is potentially life-threatening. CHB is a global health problem that affects about 250 million people worldwide, with a prevalence of < 2% in the United States and other Western countries and > 5% in East Asia, Southeast Asia, and sub-Saharan Africa[1-3]. The disease is particularly endemic in China, where there are about 84 million individuals infected with HBV[4], with a prevalence as high as 6.3% in some rural areas[5]. All-cause mortality associated with HBV infection is about 6%-8%, and 15%-40% of untreated patients with CHB develop serious conditions such as cirrhosis and hepatocellular carcinoma[3,6].

The HBV genome exists in the nuclei of infected hepatocytes as a 3.2-kb double-stranded episomal DNA called covalently closed circular DNA (cccDNA). cccDNA is a key component in the HBV life cycle since it is the template for all viral genomic and subgenomic transcripts, including pregenomic RNA (pgRNA), and its level is correlated with the proliferative potential of HBV[7]. cccDNA serves as the template for pgRNA production, which is the main step in HBV replication[7]. The control of intrahepatic levels of HBV cccDNA and/or controlling the transcriptional activity of cccDNA are critical to prevent the occurrence of decompensated cirrhosis and hepatocellular carcinoma, which is the ultimate goal of anti-HBV therapies[8,9]. Hence, changes in the intrahepatic level of cccDNA can be used to monitor the efficacy of antiviral therapies and evaluate the possibility of viral rebound after stopping treatment[10-12]. The direct method to measure liver cccDNA levels is liver biopsy, but it is an invasive procedure not easily accepted by the patients[13]. Therefore, searching for surrogate indicators of intrahepatic HBV cccDNA is important to optimize patient management and quality of life.

Although sustained serum HBV DNA suppression and hepatitis B e antigen (HBeAg) seroconversion are associated with disease remission[8], their performance in reflecting the changes in intrahepatic cccDNA is poor[14,15]. Hepatitis B core-related antigen (HBcrAg) is an emerging marker of HBV DNA suppression[16,17]. HBcrAg consists of hepatitis B core antigen (HBcAg), HBeAg, and p22cr. HBcAg and HBeAg share the first 149 amino acids (aa) encoded by the core gene, overlapping the -10 to 183 aa region[18]. A study showed that quantitative HBcrAg (qHBcrAg) better reflects intrahepatic cccDNA levels than HBV DNA or HBeAg[15]. In addition, intrahepatic cccDNA can be determined with an enzyme immunoassay for HBcrAg[19,20]. Nevertheless, HBcrAg is still not widely used by clinicians worldwide because not enough data are currently available.

Therefore, this study aimed to investigate the serum qHBcrAg levels of patients with CHB and assess the correlation of serum qHBcrAg with pgRNA, cccDNA, and HBeAg seroconversion. The results will add to the sparse literature about qHBcrAg and could eventually lead to its wider use in the clinical setting.

MATERIALS AND METHODS

Study design and patients

This study was a secondary analysis of a cohort of patients who underwent percutaneous liver biopsy at baseline and after 48 wk of therapy between July 2014 and June 2019 during their participation in two multicenter randomized controlled clinical trials of peginterferon (Peg-IFN) or nucleos(t)ide analog (NUC)-based therapy. The study was approved by the ethics committee of the First Hospital of Jilin University. Informed consent was obtained from each patient for the original trials, with clauses for possible secondary analyses. The original studies were registered (ClinicalTrials.gov NCT03509688 and NCT03546530).

All patients were diagnosed with CHB according to the criteria of detectable HBV DNA ≥ 10^5 IU/mL, alanine aminotransferase (ALT) 1.5-10 times the upper limit of normal, and HBeAg positivity[3,6]. The inclusion criteria were: (1) Diagnosis of CHB; (2) Treatment with Peg-IFN or NUC-based therapy for at least 48 wk; and (3) Available serum samples and liver specimens at baseline and 48 wk. The exclusion criteria were: (1) A history of hepatitis C virus or hepatitis D virus infection; (2) Human immunodeficiency virus; (3) Inflammatory diseases such as rheumatoid arthritis, diabetes, autoimmune hepatitis, hypertension, or kidney disease; or (4) Recent infectious disease.

Treatment

The treatment regimens followed the clinical practice guidelines OF the Asian-Pacific Association for the Study of the Liver on the management of hepatitis B[21]. In one of the original trials, the patients received entecavir (ETV) (Cosunter Pharmaceutical, China) 0.5 mg once daily po for 144 wk with/without resveratrol 1000 mg once daily for 48 wk or thymosin α1 twice-weekly sc for 24 wk. In the other trial, the patients received interferon (IFN, Kawin Technology, China) 1.5 μg/kg per week sc for 48 wk with/without resveratrol 1000 mg once daily for 48 wk. The patients who underwent liver biopsy before and after 48 wk of treatment were included in the present study. In the two trials, 139 patients completed 48 wk treatment with both biopsies (Figure 1). In each original trial[22-24], the patients were randomly assigned to the trial drugs.

Quantitative serum HBcrAg assay

The quantification of HBcrAg was performed using a fully automated Lumipulse chemiluminescence enzyme immunoassay analyzer (Fujirebio Inc., Tokyo, Japan) according to the manufacturer's instructions. Serum was pretreated with sodium dodecyl sulfate and incubated with monoclonal antibodies against denatured HBcAg and HBeAg. After washing and incubation with secondary antibodies, the concentrations of HBcrAg were determined by relative chemiluminescence intensity and compared with a standard curve. Because the general analytic measurement range of the assay was between 1000 U/mL (3 $\log_{10}$ U/mL) and 10000000 U/mL (7 $\log_{10}$ U/mL), serial dilutions of the serum sample were needed when the serum qHBcrAg level was above the detection limit of the assay.

Biochemistry and other indicators

Fasting venous blood was centrifuged at 4000 rpm for 10 min to obtain serum. All laboratory assessments were performed at baseline and weeks 4, 12, 24, 48, and 96.

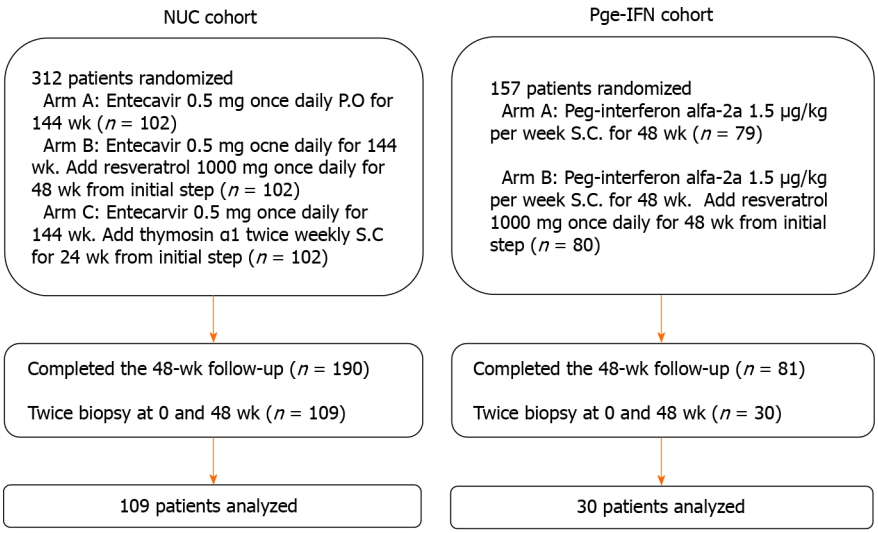

Figure 1 Patient flowchart. NUC: Nucleos(t)ide analog; Peg-IFN: Peginterferon.

HBV DNA was detected by quantitative polymerase chain reaction (PCR) using the Roche COBAS AmpliPrep/COBAS TaqMan system (Roche Diagnostics, Basel, Switzerland). The lowest detection limit was 20 IU/mL. Hepatitis B surface antigen (HBsAg), anti-HBs, HBeAg, anti-HBe, and anti-HBc were detected by chemiluminescence microparticle immunoassays using the Architect i2000SR platform and Abbott Architect reagents (Abbott Laboratories, Abbott Park, IL, United States). Serum HBsAg levels were measured with a dynamic range of 0-250 IU/mL. If qHBsAg levels were > 250 IU/mL, the samples were retested with a stepwise dilution of 1:10,000. ALT and aspartate aminotransferase were measured at each participating medical site. ALT, HBsAg, HBeAg, and HBV DNA were directly detected immediately at each time point. The HBV genotype was determined at screening. HBV pgRNA was measured at Peking University Health Science Center (Beijing, China), as previously described[25]. HBV genotypes were determined by real-time PCR with Taqman probe technology (Shanghai ZJ Bio-Tech, Shanghai, China). A FibroScan system was used to measure liver stiffness (Echosens, Paris, France).

Intrahepatic indicators

All patients in this study underwent liver biopsy before treatment and after 48 wk of treatment. The remaining liver tissue was stored in liquid nitrogen. Quantitative intrahepatic cccDNA was detected by PCR-fluorescent probing (SUPBIO Biotechnology, Beijing, China) following the manufacturer's instructions. Intrahepatic HBV DNA was detected by quantitative PCR using the Roche COBAS AmpliPrep/COBAS TaqMan system (Roche Diagnostics, Basel, Switzerland).

Statistical analyses

Continuous data were expressed as means ± SD and analyzed using Student's *t*-test or Mann-Whitney *U*-test, as appropriate based on the results of the Kolmogorov-Smirnov test. Intragroup analyses were performed using the paired ˆ-test or repeated-measure analysis of variance. Categorical variables were reported as numbers and percentages (%) and analyzed using Fisher's exact test. The correlation between two continuous variables was analyzed using Spearman's bivariate correlation, with a two-tailed significance level of $P < 0.01$. Receiver operating characteristic (ROC) curves were generated to compare the relative sensitivity and specificity of HBcrAg as a predictor of HBeAg seroconversion. A multivariable logistic regression model was used to determine whether the level of HBcrAg was a risk factor of HBeAg seroconversion. Otherwise, two-tailed *P* values of < 0.05 were considered statistically significant in all analyses. The statistical analysis were performed with SPSS 18.0 (IBM, Armonk, NY, United States).

RESULTS

Patient Characteristics

From the two original trials, 139 patients were eligible (Table 1). Among them, 69.1% were men, and 30.9% were women. There were more patients with HBV genotype C (79.9%) than B (20.1%). At baseline, the mean levels of intrahepatic HBV cccDNA were 26.65 ± 11.03 copies/cell. The mean levels of serum HBV DNA and HBsAg were 7.59 ± 1.05 $\log_{10}$ IU/mL and 3.81 ± 0.69 $\log_{10}$ IU/mL, respectively. The detailed baseline characteristics of the patients in the ETV and Peg-IFN cohorts are shown in Supplementary Table 1. The patients in the Peg-IFN cohort were younger than those in the ETV cohort (P = 0.045); there were no significant differences in the other characteristics.

Serum HBcrAg distribution

The serum qHBcrAg levels were different among the 139 patients with different phases of HBV infection and treatment. Indeed, the levels of qHBcrAg were 2.30-7.80 $\log_{10}$ U/mL. The mean levels were 5.24 ± 1.07 $\log_{10}$ U/mL in the ETV group (Figure 2A) and 5.38 ± 1.22 in the Peg-IFN group (Figure 2B) at baseline. The mean levels of qHBcrAg were 5.32 ± 1.18 $\log_{10}$ U/mL at baseline and 3.50 ± 1.31 $\log_{10}$ U/mL at week 48, showing decreases at each time point after treatment initiation (all P < 0.0001. Figure 2A-C), and there were no differences between the two groups (P = 0.6291, Figure 2D).

Comparison of the changes in qHBcrAg with other markers during treatment

Among the 139 patients, the serum qHBcrAg levels were positively correlated with cccDNA (r = 0.527, P < 0.0001; r = 0.323, P = 0.0001) and pgRNA (r = 0.597, P < 0.0001; r = 0.592, P = 0.0001) levels before and after treatment (Figure 3A and B). The correlation of serum qHBcrAg levels and intrahepatic HBV DNA levels was statistically significant at week 0 (r = 0.399, P < 0.0001, Figure 3A) and at week 48 (r = 0.213, P = 0.001) (Figure 3B). The serum qHBcrAg levels and FibroScan score weakly correlated (r = −0.278, P = 0.0099) (Supplementary Figure 1). Correlations were also observed between serum HBsAg (r = 0.514, P < 0.0001) and HBeAg (r = 0.744, P < 0.0001), but there was no significant correlation with HBcAb (r = −0.151, P = 0.0758) (Supplementary Figure 1).

Correlation between serum HBsAg and cccDNA

Serum HBsAg was weakly correlated with cccDNA levels at baseline (r = 0.265, P < 0.001) and week 48 (r = 0.141, P = 0.092; Figure 4A and B). The correlation between HBsAg and cccDNA levels at week 48 was weak in both treatment cohorts (Figure 4C and D).

Performance of HBcrAg levels for HBeAg negative conversion prediction

The levels of serum HBcrAg were significantly lower in patients with HBeAg conversion compared with those without (Figure 5A). The area under the ROC curve of HBcrAg levels for the prediction of HBeAg seroconversion was 0.643 [95% confidence interval (CI): 0.484-0.802, P = 0.072], 0.750 (95%CI: 0.629-0.872, P = 0.002), 0.794 (95%CI: 0.679-0.908, P < 0.001), and 0.825 (95%CI: 0.738-0.913, P < 0.001) at baseline, 12, 24, and 48 wk, respectively (Figure 5B). At baseline, the best cutoff of HBcrAg was 5.29 $\log_{10}$ U/mL, with 73.3% sensitivity and 66.5% specificity for predicting HBeAg seroconversion. At 12 wk, the cutoff of HBcrAg was 3.22 $\log_{10}$ U/mL, with 66.7% sensitivity and 78.2% specificity. At 24 wk, the cutoff of HBcrAg was 3.00 $\log_{10}$ U/mL, with 86.7% sensitivity and 74.8% specificity. At 48 wk, the cutoff of HBcrAg was 2.68 $\log_{10}$ U/mL, with 80.0% sensitivity and 78.6% specificity. In the multivariable model of HBeAg seroconversion, Log_{10}HBcrAg at weeks 24 and 48 was independently associated with HBeAg [odds ratio (OR) = 2.402, 95%CI: 1.314-4.391, P = 0.004; OR = 3.587, 95%CI: 1.315-9.784, P = 0.013].

DISCUSSION

qHBcrAg better represents intrahepatic levels of HBV cccDNA than HBV DNA or HBeAg[19,20,26], but data are still lacking in support of its wide clinical application. Therefore, this study aimed to investigate serum qHBcrAg levels in patients with CHB and assess the correlation of serum qHBcrAg with pgRNA and cccDNA. As expected,

Table 1 Baseline characteristics of the patients

Characteristic	*n* = 139
Age, yr, median (range)	30.4 (19-62)
Sex (male/female, %)	96/43 (69.1/30.9)
HBV genotype, *n* (%)	
B	28 (20.1)
C	111 (79.9)
ALT, U/mL, mean ± SD	174.07 ± 119.82
Serum HBV DNA, $\log_{10}$ IU/mL, mean ± SD	7.59 ± 1.05
Serum pgRNA, $\log_{10}$ copies/mL, mean ± SD	7.82 ± 1.17
ihHBV cccDNA, copies/cell	26.65 ± 11.03
ihHBV DNA, copies/cell	385.13 ± 86.09
Serum HBsAg, $\log_{10}$ IU/mL, mean ± SD	3.81 ± 0.69
Serum HBeAg, $\log_{10}$ S/CO, mean ± SD	2.49 ± 0.82
HBcrAg, $\log_{10}$ U/mL, mean ± SD	5.32 ± 1.18

ALT: Alanine transaminase; cccDNA: Covalently closed circular DNA; HBcrAg: Hepatitis B core-related antigen. HBeAg: Hepatitis B e antigen; HBsAg: Hepatitis B surface antigen; HBV: Hepatitis B virus; ihHBV: Intrahepatic hepatitis B virus.

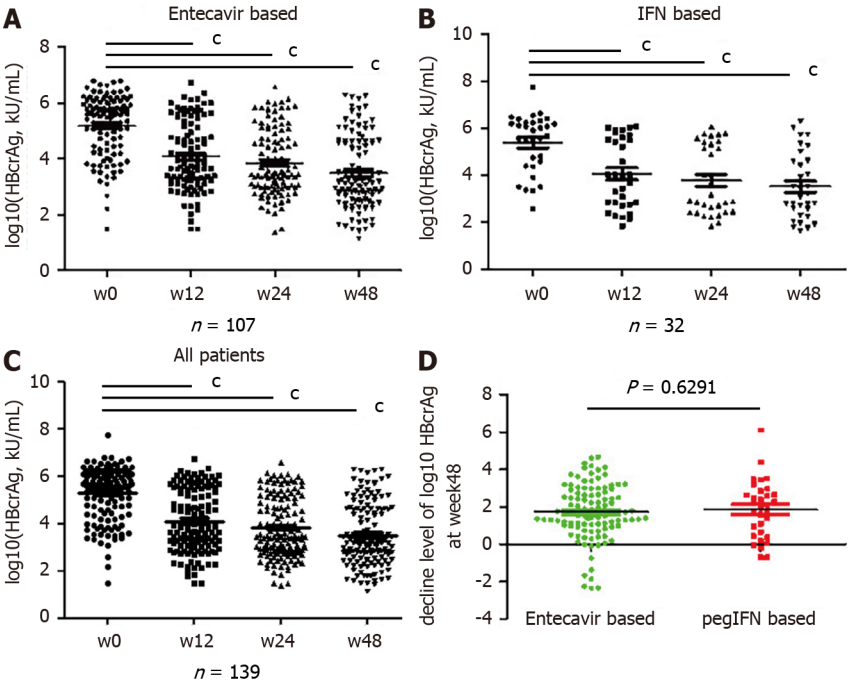

Figure 2 Time-dependent distribution of serum quantitative hepatitis B core-related antigen in patients with chronic hepatitis B and treated with different regimens. A: Changes in hepatitis B core-related antigen (HBcrAg) levels during treatment in the entecavir group; B: Changes in HBcrAg levels during treatment in the peginterferon group; C: Changes in HBcrAg levels during treatment in all patients; D: Comparison of the decrease in HBcrAg levels from baseline to week 48 between the entecavir and peginterferon groups. °P < 0.0001. HBcrAg: Hepatitis B core-related antigen; IFN: Interferon.

serum qHBcrAg was significantly and positively associated with the intrahepatic levels of cccDNA in CHB, and the association was stronger than the correlation between serum qHBsAg and intrahepatic cccDNA. Furthermore, antiviral therapy reduced the serum levels of HBcrAg and HBV DNA and the intrahepatic levels of cccDNA. The results suggest that serum HBcrAg levels correlate with HBV virological markers and could be used to predict CHB treatment outcomes, especially HBeAg seroconversion.

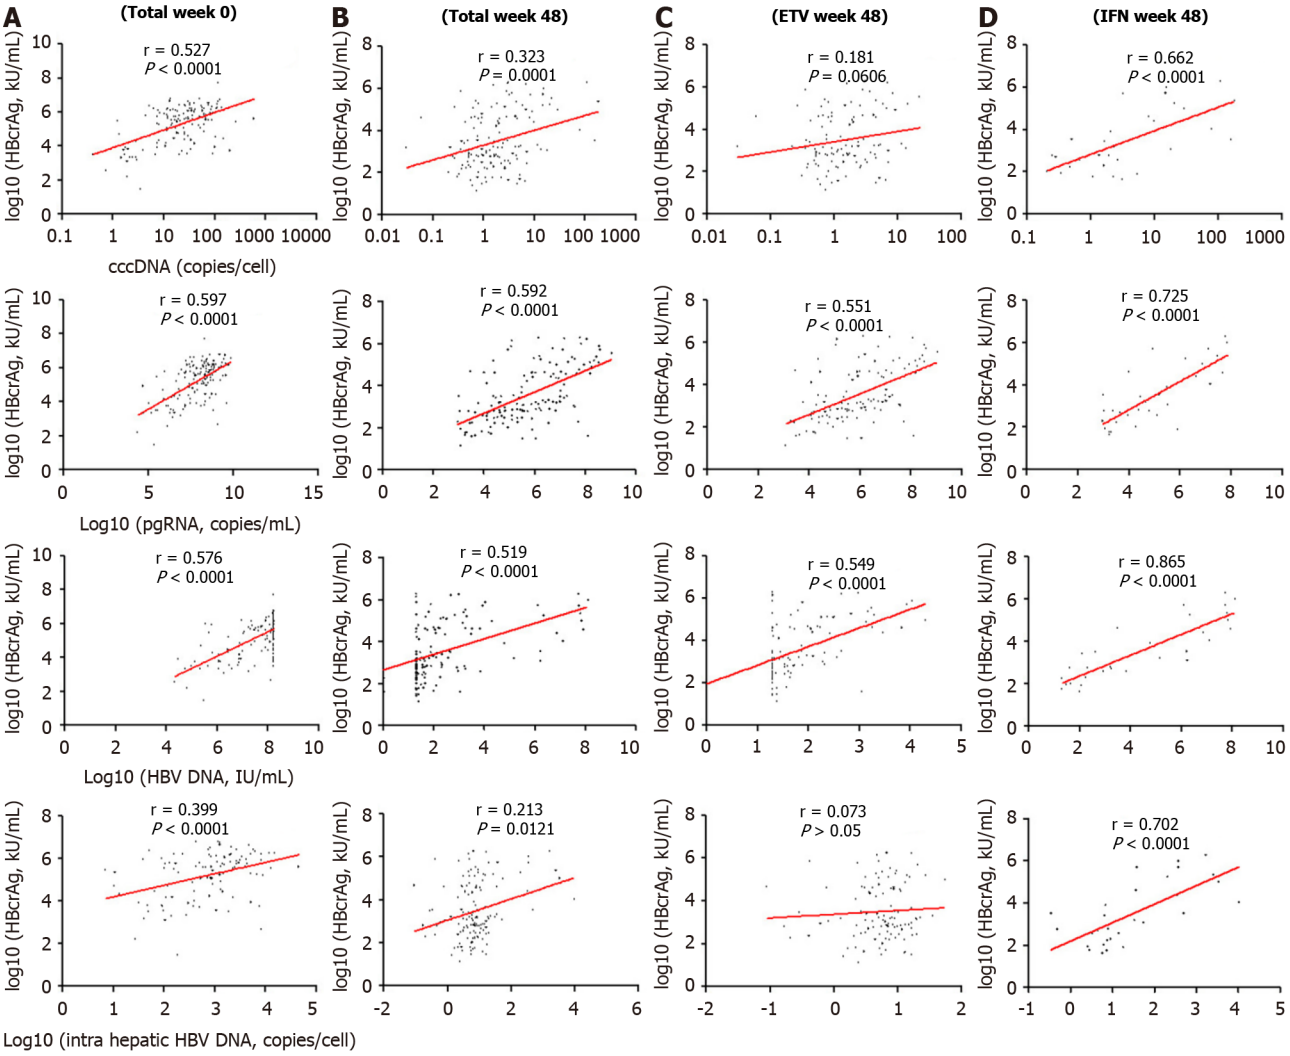

Figure 3 Correlation of serum quantitative hepatitis B core-related antigen with covalently closed circular DNA, pregenomic RNA, serum, and intrahepatic hepatitis B virus DNA level. A: In all patients at baseline; B: In all patients at week 48; C: Entecavir at week 48; D: Peginterferon at week 48. cccDNA: Covalently closed circular DNA; ETV: Entecavir; HBV: Hepatitis B virus; IFN: Interferon. pgRNA: Pregenomic RNA.

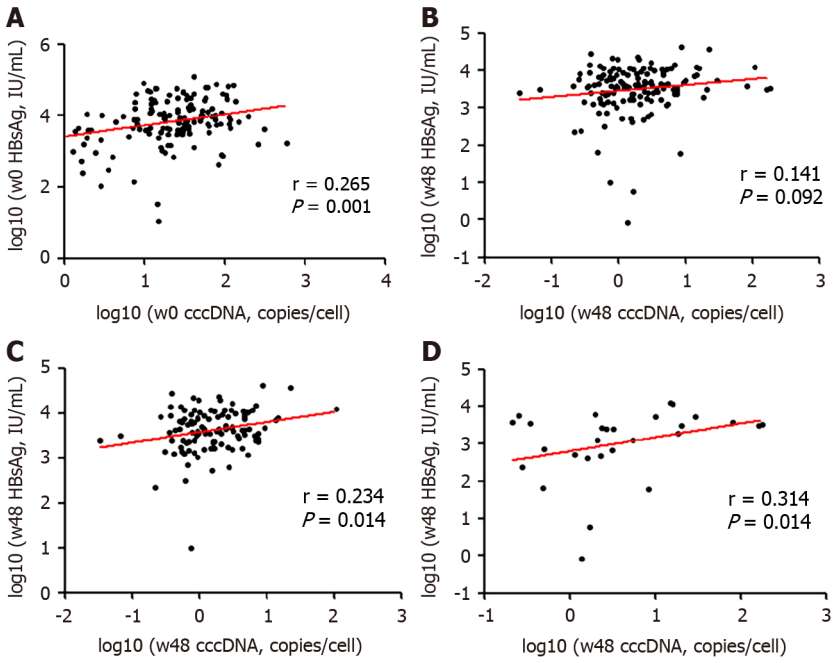
Serum levels of HBV DNA have been considered for many decades as a marker of the intrahepatic levels of cccDNA in untreated patients with CHB, but not when they are under treatment with NUCs. Indeed, under treatment, the decrease of the intrahepatic levels of cccDNA was not proportional to the steep decrease of the serum levels of HBV DNA[19,20]. Therefore, more reliable biomarkers were sought, and HBcrAg was found to be a potential additional biomarker of HBV infection, with a good correlation with intrahepatic levels of cccDNA[19,25,26]. HBcrAg was also suggested to be a reliable surrogate of cccDNA in two previous studies, as qHBcrAg was strongly correlated with intrahepatic cccDNA (r = 0.929 and 0.70, respectively), which is superior to that of qHBsAg and HBV DNA[27,28]. Hence, this study first aimed to investigate the correlation between the serum levels of qHBcrAg and the intrahepatic levels of cccDNA during CHB in Chinese patients. It showed that qHBcrAg was correlated with cccDNA before and after 48 wk of treatment, and the findings are supported by two previous studies[14,29]. HBcrAg more effectively represents cccDNA levels because HBcrAg includes three proteins: HBeAg, p22cr, and HBsAg. HBeAg is secreted by hepatocytes, p22cr represents empty virions, and HBsAg represents both empty virions and viable Dane particles[30]. Therefore, HBcrAg comprehensively encompasses the whole process of viral replication from cccDNA.

Of importance, decreases of the serum HBcrAg level were positively associated with decreases of the intrahepatic levels of cccDNA, even under therapy. Hence, the serum levels of HBcrAg could be a biomarker for the intrahepatic levels of cccDNA. In addition, because the changes in HBcrAg parallel those of intrahepatic cccDNA during treatment, it might be a better long-term prognostic indicator of CHB outcomes than



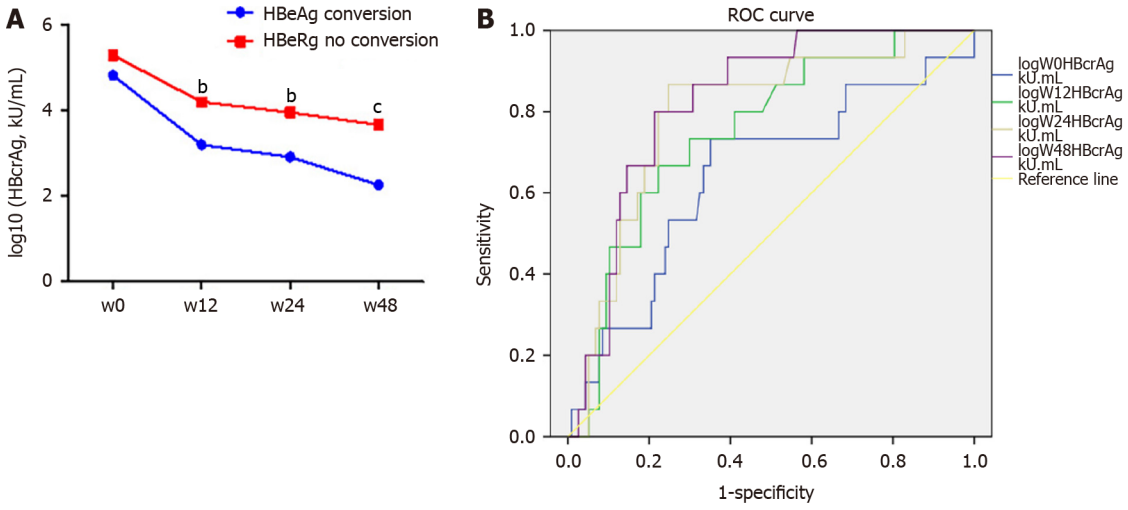


Figure 4 Correlation of serum hepatitis B surface antigen with covalently closed circular DNA. A: Correlation between serum hepatitis B surface antigen (HBsAg) and intrahepatic covalently closed circular DNA (cccDNA) at baseline; B: Correlation between serum HBsAg and intrahepatic cccDNA and at week 48; C: Correlation between cccDNA and HBsAg levels at weeks 48 in the entecavir cohort; D: Correlation between cccDNA and HBsAg levels at weeks 48 in the interferon cohort. HBsAg: Hepatitis B surface antigen; cccDNA: Covalently closed circular DNA.

other biomarkers (*i.e.* serum HBV DNA and HBeAg). HBcrAg levels are determined by the transcription level of cccDNA. Therefore, decline of the HBcrAg levels with NUCs is slower than the decline of the serum levels of HBV DNA in patients. The slower decline might also explain why the serum levels of HBcrAg were positively correlated with the intrahepatic levels of cccDNA, either before or after ETV treatment.

In addition, the levels of serum qHBcrAg were higher in this study than in a previous study[31], which might have been the result of the high proportion of HBeAg-positive patients in this study. Considering that viral replication and host immune responses can be influenced by the HBV genotype, the distribution of the serum levels of HBcrAg was examined between patients carrying the HBV genotypes B and C, but the difference was not statistically significant. HBcrAg is a pre-core protein encoded by the pre-core/core regions of the HBV genome. Hence, the production of HBcrAg is not affected by the promoters found in the S region[18], possibly explaining the similar distribution of HBcrAg between the genotypes.

The serum levels of qHBsAg reflect the intrahepatic levels of cccDNA[19,20]. Still, in this study, the correlation between qHBsAg and intrahepatic cccDNA was weaker than the correlation between serum qHBcrAg and intrahepatic cccDNA, both without and under treatment. Most patients with HBsAg loss or seroconversion still had detectable levels of intrahepatic cccDNA and HBV DNA. Thus, according to the currently available evidence, serum levels of qHBcrAg could be more appropriate than HBsAg as a biomarker of the intrahepatic levels of cccDNA, but that needs to be confirmed in larger studies. The predictive value of qHBcrAg for HBeAg seroconversion was the best at 24 and 48 wk. That could be because baseline qHBcrAg is not predictive of the response to treatment, and that 12 wk is too early to observe a proper response. Additional studies are necessary to determine the best timing of qHBcrAg measurement for the prognosis of CHB. Nevertheless, qHBcrAg levels at the other time points were still associated with HBeAg seroconversion, as observed in previous studies[32-35]. HBsAg and HBeAg each represent only a part of the process of HBV production and assembly, and that could explain why they have a lower prognostic value, especially HBsAg at 48 wk[30].

The study has limitations. It was a secondary analysis of patients from two different trials with two different antiviral treatments and different regimens. Not all patients underwent two biopsies, leading to a selection bias and a small sample size. Importantly, a biopsy was performed at 48 wk in both studies. Still, the patients were followed for up to 144 wk in the ETV group and 96 wk in the Peg-IFN group, but the patients were only treated with Peg-IFN for 48 wk, and the long-term changes in HBcrAg are unknown. HBV genotype D is very rare in China and was not included in the two trials. Therefore, future studies should address those points.

CONCLUSION

Serum qHBcrAg levels were correlated with the intrahepatic levels of cccDNA in patients with CHB and might be an acceptable surrogate marker for cccDNA. HBcrAg levels correlated with HBV virological markers and could be used to predict CHB treatment outcomes, especially HBeAg seroconversion. Hence, serum qHBcrAg might be used in the clinical setting for monitoring intrahepatic HBV status and determining the long-term prognosis of patients with CHB.

ACKNOWLEDGMENTS

We are very grateful to the following professors for their selfless help in the process of collecting and treating clinical cases: Yu L, Chen YP, Shang J, Liu LG, Zhang SQ, Jiang YF, Zhang MX, Tong QX, Zhang LL, Tan YW, Ma AL, Dang SS, Xu B, Jin ZJ, Li J and Li XB.

ARTICLE HIGHLIGHTS

Research background

Quantitative hepatitis B core-related antigen (qHBcrAg) had a better correlation with intrahepatic hepatitis B virus (HBV) covalently closed circular DNA (cccDNA) than either HBV DNA or hepatitis B e antigen (HBeAg).

Research motivation

Data are still lacking for the widespread clinical application of qHBcrAg.

Research objectives

This study aimed to investigate the serum qHBcrAg levels in patients with chronic hepatitis B (CHB) and to assess the correlation of serum qHBcrAg with pregenomic RNA (pgRNA), cccDNA, and HBeAg seroconversion.

Research methods

This was a secondary analysis of patients who underwent percutaneous liver biopsy in two multicenter, randomized, controlled clinical trials. Serum qHBcrAg, pgRNA, HBV DNA, hepatitis B core antigen, and HBeAg and liver cccDNA, and HBV DNA were measured. The correlations of serum qHBcrAg with other biomarkers were tested.

Research results

Serum qHBcrAg levels were positively associated with pgRNA ($r = 0.597$, $P < 0.0001$) and cccDNA ($r = 0.527$, $P < 0.0001$) levels. HBcrAg predicted HBeAg seroconversion, with an area under the receiver operating characteristics curve of 0.788 at 24 wk and 0.825 at 48 wk.

Research conclusions

Serum HBcrAg levels correlated with HBV virological markers and could be used to predict HBeAg seroconversion.

Research perspectives

Serum qHBcrAg might be used in the clinical setting to monitor intrahepatic HBV status and determine the long-term prognosis of patients with CHB.

Retrospective Cohort Study

Long-term follow-up of liver alveolar echinococcosis using echinococcosis multilocularis ultrasound classification

Jasmin Schuhbaur, Melissa Schweizer, Jana Philipp, Julian Schmidberger, Patrycja Schlingeloff, Wolfgang Kratzer

ORCID number: Jasmin Schuhbaur 0000-0003-2284-9948; Melissa Schweizer 0000-0002-5826-942X; Jana Philipp 0000-0001-8091-1864; Julian Schmidberger 0000-0002-9960-9574; Patrycja Schlingeloff 0000-0003-3514-7347; Wolfgang Kratzer 0000-0002-9727-3843.

Author contributions: Kratzer W and Schuhbaur J planned and designed the study; The data were evaluated by Kratzer W and Schuhbaur J; all authors were involved in the interpretation of the results; Kratzer W, Schuhbaur J, Schmidberger J, Schlingeloff P, Schweizer M and Philipp J prepared the first draft; the statistical analysis was performed by Schmidberger J and Schlingeloff P; all authors read, amended, and approved the final version of the manuscript.

Institutional review board statement: The study was approved by the local ethics committee and conducted in accordance with the Declaration of Helsinki (ref. No. 166/13). Because of its retrospective design and pseudonymised evaluation of imaging, no ethics approval was necessary. All data were analysed anonymously.

Abstract

BACKGROUND

When *Echinococcus multilocularis* infects humans as a false intermediate host, alveolar echinococcosis (AE) usually manifests primarily intrahepatically and is initially asymptomatic. If the disease remains undiagnosed and untreated, progressive growth occurs, reminiscent of malignant tumours. The only curative therapy is complete resection, which is limited to localised stages, and palliative drug therapy is used otherwise. Consequently, early diagnosis and reliable detection of AE lesions are important. For this reason, abdominal ultrasonography, as the most common primary imaging for AE, relies on classification systems.

AIM

To investigate how hepatic AE lesion sonomorphology changes over time in the Echinococcosis Multilocularis Ulm Classification (EMUC)-ultrasound (US) classification.

METHODS

Based on data from Germany's national echinococcosis database, we evaluated clinical and US imaging data for 59 patients according to the AE case definition in our preliminary retrospective longitudinal study. There had to be at least two liver sonographies ≥ 6 mo apart, ≥ 1 hepatic AE lesion, and complete documentation in all US examinations. The minimum interval between two separately evaluated US examinations was 4 wk. The AE reference lesion was the largest hepatic AE lesion at the time of the first US examination. To classify the sonomorphologic pattern, we used EMUC-US. In addition to classifying the findings of the original US examiner, all reference lesions at each examination time point were assigned EMUC-US patterns in a blinded fashion by two investigators experienced in US diagnosis. Statistical analysis was performed using SAS version

9.4 (SAS Institute Inc., Cary, NC, United Stated). *P* values < 0.05 were considered statistically significant.

RESULTS

The preliminary study included 59 patients, 38 (64.5%) women and 21 (35.6%) men. The mean age at initial diagnosis was 59.9 ± 16.9 years. At the time of initial ultrasonography, a hailstorm pattern was present in 42.4% (25/59) of cases, a hemangioma-like pattern in 16.9% (10/59), a pseudocystic pattern in 15.3% (9/59), and a metastasis-like pattern in 25.4% (15/59). For the hailstorm pattern, the average lesion size was 67.4 ± 26.3 mm. The average lesion size was 113.7 ± 40.8 mm with the pseudocystic pattern and 83.5 ± 27.3 mm with the hemangioma-like pattern. An average lesion size of 21.7 ± 11.0 mm was determined for the metastasis-like pattern. Although the sonomorphologic pattern remained unchanged in 84.7% (50/59) of AE reference lesions, 15.3% (9/59) showed a change over time. A change in pattern was seen exclusively for AE lesions initially classified as hemangioma-like or pseudocystic. A total of 70% (7/10) of AE lesions initially classified as hemangioma-like showed a relevant change in pattern over time, and 85.7% (6/7) of these were secondarily classified as having a hailstorm pattern, with the remainder (1/7; 14.3%) classified as having a pseudocystic pattern. A total of 22.2% (2/9) of AE lesions initially classified as pseudocystic showed a relevant change in pattern over time and were classified as having a hailstorm pattern. For AE lesions initially classified as having a hailstorm or metastatic pattern, no pattern change was evident. All patients with pattern change were on continuous drug therapy with albendazole.

CONCLUSION

The sonomorphology of hepatic AE lesions may change over time. The hemangioma-like and pseudocystic patterns are affected.

Core Tip: Alveolar echinococcosis is potentially fatal. In approximately 98% of cases, it manifests in the liver, similar to a primary malignant or metastatic tumour. The sonomorphological appearance of the disease is varied and easily confused with other differential diagnoses. Sonography is the most important tool in diagnostics, but how the known patterns change over time is unclear. The evidence that certain sonographic patterns in particular change over time shows a possible evolutionary approach to the disease and may, in the long term, make lifelong drug therapy unnecessary in non-operable patients when non-active stages can be clearly identified.

INTRODUCTION

Fox tapeworm disease (alveolar echinococcosis, AE) is a zoonotic disease caused by the larval stage of the cestode *Echinococcus multilocularis*, in which humans act as the major false intermediate host[1,2]. After a host accidentally ingests infectious worm eggs, the eggs penetrate the wall of the small intestine and usually first reach the liver, the most common primary site of AE in humans, Via the enterohepatic circulation[1,3,4].

AE is primarily asymptomatic and progressive in the therapy-naive state[5]. Only as the disease progresses do patients develop nonspecific symptoms, including abdominal tenderness or pain, jaundice, unwanted weight loss, and diffuse deterioration of general condition[6,7]. In Europe, the diagnosis of AE is usually made as an incidental finding in asymptomatic stages, and in China, diagnosis frequently is made in the setting of locally advanced growth with a complicated clinical course. Radical surgical resection of an AE lesion is considered the only potentially curative therapeutic option, followed by anthelmintic therapy for 2 years[8]. In case of an unresectable finding at diagnosis, long-term and often lifelong conservative medical therapy with benzimidazoles is required.

The high rate of advanced AE foci and inoperable disease at diagnosis underscore the need for early, definitive diagnosis. In clinical practice, B-scan ultrasonography is the most common primary imaging modality for evaluating nonspecific abdominal complaints and for the differential diagnostic assessment of hepatic incidentalomas[9].

The sonomorphology of hepatic AE foci is heterogeneous. The Echinococcosis Multilocularis Ulm Classification (EMUC)-ultrasound (US) classification, published in 2015, describes five sonomorphologic appearances of hepatic AE lesions and provides important guidance for their recognition and follow-up[10]. Five patterns are distinguished: hailstorm, hemangioma-like, pseudocystic, metastasis-like, and ossification. Conventional cross-sectional imaging [computed tomography (CT), magnetic resonance imaging (MRI)], with the appropriate classification schemes, is particularly useful for assessing spatial spread, potential infiltration of adjacent organs, and extrahepatic manifestations[11]. The gold standard for estimating parasitic activity is ^{18}FDG positron emission tomography (PET)[12,13]. Contrast-enhanced sonography of the liver also plays an increasing role in the evaluation of hepatic AE[14-16]. Available studies and analyses on the sonomorphology of AE have largely been cross-sectional, and we are not aware of any longitudinal studies assessing sonomorphology and a classification scheme for individual AE lesions.

The aim of our preliminary study is to investigate whether a change in pattern and size over time can be identified in patients with hepatic AE during follow-up, using the EMUC-US classification.

MATERIALS AND METHODS

Ethics statement

The study was approved by the local ethics committee and conducted in accordance with the Declaration of Helsinki (ref. No. 166/13). Because of its retrospective design and pseudonymised evaluation of imaging, no ethics approval was necessary. All data were analysed anonymously.

Study collective

For our preliminary retrospective evaluation, we used the clinical and imaging data of the national Echinococcosis Database in Germany. A main prerequisite for inclusion was confirmed or probable AE disease according to the AE case definition "confirmed" or "probable"[5]. Other inclusion criteria were at least two liver sonographies performed over a period of at least 6 mo, the presence of at least one hepatic AE lesion at the time of US 1, and complete documentation of the AE lesion defined as the reference lesion at all further observation time points. In total, 59 patients with data included in the Echinococcosis Database Germany were included (Figure 1 and Table 1).

Parameter

Initially, a hepatic AE reference lesion was defined per patient; this was measured by the largest diameter (in mm) at the time of the first US examination (US 1). At each time point, the number of all hepatic AE lesions in each patient was documented. The reference lesion was evaluated according to its maximum diameter and its EMUC-US pattern classification[10]. In addition to the AE case definition ("confirmed", "probable", "possible"), the clinical data included the therapy (surgical, conservative). A surgical procedure resulted in study exclusion. All study patients received oral anthelmintic therapy, and the preparation, time of initiation of therapy, and daily medication dose were documented.

AE: Alveolar echinococcosis; US: Ultrasound.

US examinations and EMUC-US

All US examinations were performed using convex probes (C5-1 MHz, C9-1 MHz) with state-of-the-art US equipment (Aplio 500 Toshiba, Siemens S3000, Philips Epiqu 7, Philips IU22). The sonomorphology of the hepatic AE reference lesion was assigned to a pattern according to EMUC-US in each examination[10]. At each examination time point, three different examiners performed a pattern assignment of the reference lesion. The pattern assignment of examiner 1 was taken from the written documentation as the initial examiner. Investigators 2 and 3 performed follow-up of all US images relevant to the study in all included patients. The physicians who performed the follow-up were blinded to the initial examination and independently performed an EMUC-US assessment (Figure 2).

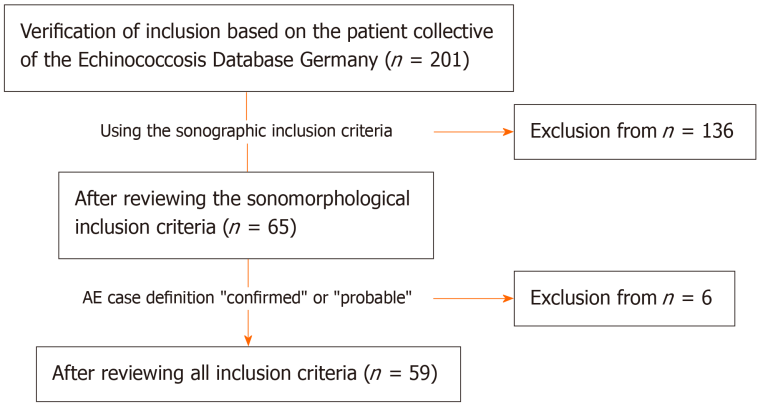

Figure 1 Flowchart illustrating case selection, including inclusion and exclusion criteria starting from the patient collective of the alveolar echinococcosis database in Germany. AE: Alveolar echinococcosis.

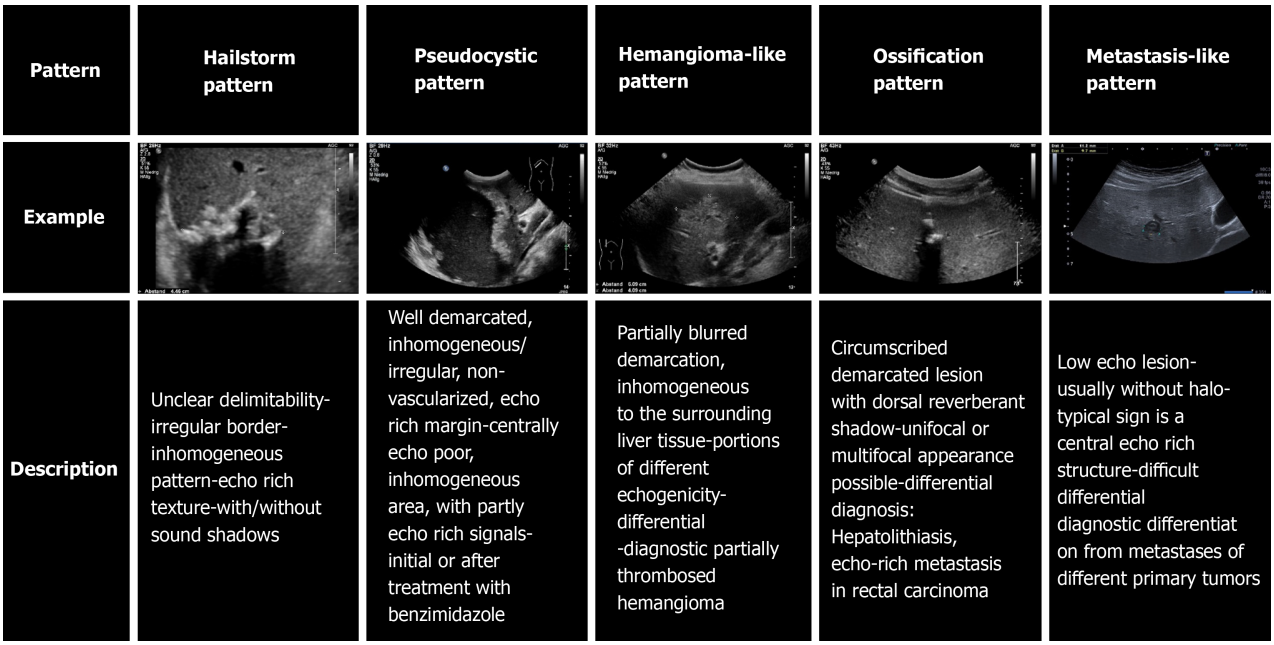

Figure 2 Echinococcosis Multilocularis Ulm Classification-ultrasound.

Statistical analysis

We performed statistical analyses using SAS Version 9.4 (SAS Institute Inc., Cary, NC, United Stated). Descriptive analysis of the data was performed to obtain absolute and relative frequencies, as well as measures of central tendency and dispersion. Pearson's χ^2 and exact fisher tests were used to determine possible relationships and differences in the frequency distribution between dichotomous variables. Wilcoxon rank sum test was performed to determine differences between variables without a normal distribution. All tests were performed two-sided. The level of significance was set at $\alpha = 0.05$, and a $P < 0.05$ was considered to be statistically significant with a 5% probability of error.

Biostatistics

The statistical methods of this study were reviewed by Dr. Schmidberger J, MPH, Ph.D., from the Department of Internal Medicine I, University Hospital Ulm, Albert-Einstein-Allee 23, 89081 Ulm, Germany.

RESULTS

Patient collective

The study included 59 patients, including 38 (64.5%) women and 21 (35.6%) men. The mean age at initial diagnosis was 59.9 ± 16.9 years, with a mean age at first sonographic examination of 60.4 ± 16.8 years. A World Health Organization case definition of "confirmed" was present in 26 (44.1%) patients, and a case definition of "probable" was present in 33 (55.9%). The 59 included patients underwent a total of 244 US examinations for a mean of 4.1 sonographic examinations per patient (2-15 ± 2.1 US examinations). A total of 58/59 (98.3%) received initial benzimidazole therapy using albendazole (Tables 1 and 2).

Lesion sizes, localisation, and distribution of EMUC-US patterns

At the time of initial US, 42.4% (25/59) corresponded to the hailstorm pattern, 16.9% (10/59) to the hemangioma-like pattern, 15.3% (9/59) to the pseudocystic pattern, and 25.4% (15/59) to the metastasis-like pattern. None of the reference lesions were initially assigned to the ossification pattern. For those with the hailstorm pattern, the mean lesion size was 67.4 ± 26.3 mm. The average lesion size with the pseudocystic pattern was 113.7 ± 40.8 mm, and that of the hemangioma-like pattern was 83.5 ± 27.3 mm. An average lesion size of 21.7 ± 11.0 mm was determined for the metastasis-like pattern (Figure 3).

In 34/59 (57.6%) of patients, the reference echinococcosis-associated lesion was right hepatic, and in 19/59 (32.3%), it was left hepatic. Bihepatic involvement was identified in 6/59 (10.2%).

Change in EMUC-US patterns

Over the whole observation period, the predominant pattern of hepatic AE reference lesions according to EMUC-US remained unchanged in 50/59 (84.7%). In 9/59 (15.3%) of the findings, however, a change in sonomorphology was observed. Of the 10 reference lesions initially classified as hemangioma-like, 7/10 (70.0%) showed a relevant change in sonomorphologic criteria. Of these, 6/7 (85.7%) were assigned to the hailstorm pattern in subsequent US examinations, and 1/7 (14.3%) showed a change toward the pseudocystic pattern. Lesions initially classified as having a pseudocystic pattern showed a change to a hailstorm pattern over time in 2/9 (22.2%) of cases. In all cases of a change in the pattern of AE reference lesions over time, the patients had taken albendazole continuously through the observation period (Figures 4 and 5). For the metastatic pattern, there were no pattern changes over time, but an increase in the size of the central echo-rich laminar body was observed (Figure 6). The mean time from initial diagnosis of AE to a pattern change was 24.2 ± 35.6 mo.

Number of lesions and lesion size according to EMUC-US

The study further revealed statistically significant differences in the number of hepatic AE lesions among EMUC-US types ($P < 0.05$) (Table 2). There were further statistically significant differences in lesion size between the metastatic pattern compared to the hailstorm pattern (21.7 ± 11.0 *vs* 67.4 ± 26.3; $P < 0.0001$), the pseudocystic pattern (21.7 ± 11.0 *vs* 113.7 ± 40.8; $P < 0.0001$), and the hemangioma-like pattern (21.7 ± 11.0 *vs* 83.5 ± 27.3; $P < 0.0001$) (Table 3). In the 9/59 (15.3%) cases with morphologic change in the EMUC-US pattern, there was a nonsignificant size regrowth from the initial examination (88.8 ± 30.6 *vs* 71.9 ± 29.6; $P = 0.1641$). For the 7/9 (77.8%) cases initially classified as having a hemangioma-like pattern, the mean average lesion size was 81.4 ± 29.4 mm initially *vs* 72.4 ± 21.4 mm after the pattern change. For the 2/9 (22.2%) cases initially classified as having a pseudocystic pattern, the mean lesion size at initial examination was 114.5 ± 24.8 mm *vs* 70.0 ± 65.1 mm after the pattern change.

DISCUSSION

Our work is the first preliminary longitudinal study tracking changes in sonomorphology during the follow-up of hepatic AE lesions using a sonomorphologic classification scheme. We found that the sonographic characteristics of individual subtypes of hepatic AE lesions change over time under anthelmintic therapy and exhibit size regrowth, resulting in a pattern classification that diverges from that assigned at the initial examination. A change in sonomorphology leading to pattern reclassification

was seen for the hemangioma-like and pseudocystic patterns. A total of 70% of the reference lesions initially classified as hemangioma-like shifted to a different pattern classification. Of these, 85% were assigned to the hailstorm pattern and 15% to the pseudocystic pattern. A total of 22.2% (2/9) of the hepatic AE lesions initially described as pseudocystic were assigned to the hailstorm pattern during follow-up (Figures 5 and 7).

In agreement with our results, a Polish working group using the EMUC-US classification confirmed the hailstorm pattern as the most frequent[14]. However, a correlation between the sonographic EMUC-US patterns and the PNM (P = parasitic mass in the liver, N = involvement of neighbouring organs, and M = metastasis) scheme could not be demonstrated in this retrospective work[16]. In addition to the EMUC-US scheme, classification schemes are currently available for CT and MRI[11]. In a recent 39.8-mo follow-up study of our working group 72 patients on albendazole therapy with hepatic AE using the EMUC-CT classification, only one case had a pattern change reassignment from type IIIa (primarily cystoid) to type V (calcified). This result clearly contrasts with our current findings. To compare the different patterns of hepatic AE between the different imaging modalities, appropriate prospective comparative studies are necessary and as yet are unavailable. However, in a further retrospective study we compared EMUC-US and EMUC-CT, no clear assignment could be found for the sonographic hemangioma-like pattern in the EMUC-CT classification. In that study, the sonographic pseudocystic pattern could be

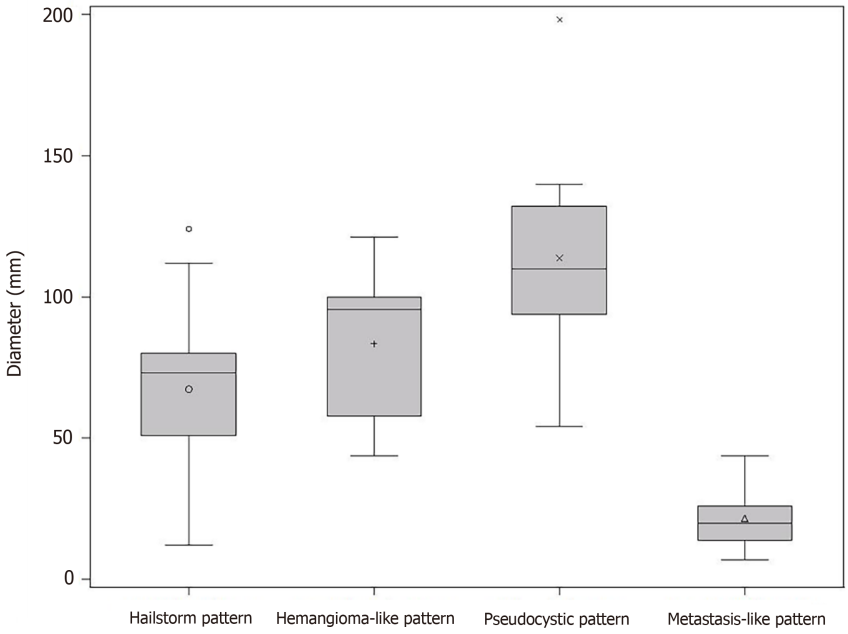

Figure 3 Diameter of hepatic alveolar echinococcosis reference lesion sorted by sonomorphological pattern analogous to Echinococcosis Multilocularis Ulm Classification-ultrasound classification.

predominantly classified as type I (diffuse-infiltrating) of the EMUC-CT classification. A study comparing MRI and PET-CT demonstrated an association between positron emission activity of hepatic AE lesions and microcysts[17]. A correlation between increased PET activity and calcifications could not be shown in this work[17]. This result contrasts with those of others results of our group who reported increased PET activity depending in particular on microcalcifications. The hailstorm pattern has significantly more calcifications than the hemangioma-like pattern, so these findings offer support for our hypothesis that a shift from hemangioma-like to hailstorm may indicate disease progression. In a recent retrospective study using the EMUC-CT classification in comparison to histology, a possible disease progression could be postulated for EMUC-CT patterns I-III[18]. In further confirmation of our hypothesis that the hemangioma-like pattern may represent an earlier disease stage, Zeng *et al* [19], using contrast-enhanced sonography with a four-type classification, visualised echo-rich masses corresponding to the EMUC-US hemangioma-like pattern.

The development of different manifestation patterns does not seem to be exclusively an expression of the temporal course of the disease, however, and appears to be

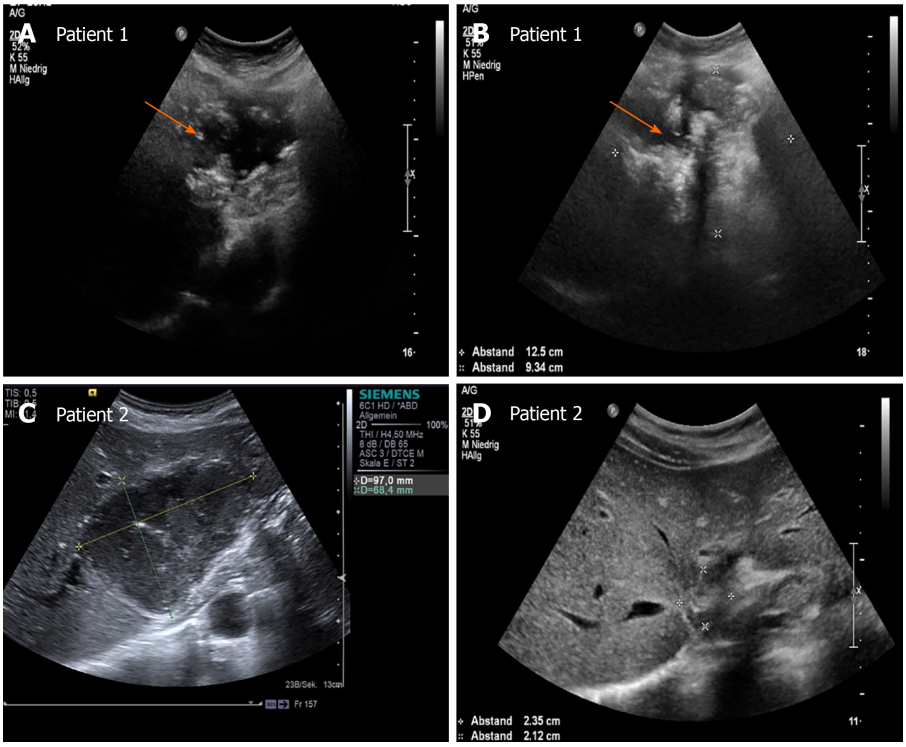

Figure 5 Hepatic alveolar echinococcosis reference lesions (arrow) in segment II/IVa/VIII (patient 1) and segment II/III (patient 2), respectively. A and C: initially classified as pseudocystic pattern (patient 1: A, patient 2: C); B and D: In the course of each case loss of the centrally echo-poor, liquid-impressive zone and increasing calcification structures, indicating a change in sonomorphology with a transition to a hailstorm pattern (patient 1: B; patient 2: D). The ultrasound images shown are from the current patient collective.

significantly related to the immunological and constitutional state of the host/misintermediate host (patient)[20]. In addition to the intraindividual immune response of the patient, one of the major difficulties in performing longitudinal imaging morphological studies is the apparent slow growth of the parasite with corresponding morphological changes in the liver. The use of international prospective database analysis studies could address this problem in the long term.

Limits of the study

The retrospective design of the preliminary cohort study must be seen as a limitation. It must also be taken into account that the number of cases in the individual EMUC-US patterns is very small, so that small effects may not be validly detected. Due to the sample size and study design, no calculation of interobserver variability between examiner 1 and examiner 2 and 3 was performed. Further prospective studies with larger numbers of cases, especially multicentre and international studies, are necessary

to confirm the preliminary study results.

CONCLUSION

Our preliminary study demonstrates not only great heterogeneity in the sonomorphology of hepatic AE lesions at the initial diagnosis but also that sonomorphologic classification can change during disease progression.

ARTICLE HIGHLIGHTS

Research background

Alveolar echinococcosis (AE) is a human parasitosis caused by *Echinococcus multilocularis*.

Research motivation

Early diagnosis of AE is important to initiate prompt therapy and improve patient prognosis. Abdominal ultrasonography is the most common primary imaging modality and allows for classification of hepatic lesion morphology.

Research objectives

We address the question of whether (and how) the sonomorphology of individual AE lesions can change over time.

Research methods

In our preliminary retrospective longitudinal study, based on data from the national echinococcosis database in Germany, we evaluated clinical and ultrasound (US) imaging data for 59 patients according to AE case definition of confirmed (n = 26) or probable (n = 33) AE. The AE reference lesion was the largest hepatic AE lesion at the time of the first US examination. We used the Echinococcosis Multilocularis Ulm Classification (EMUC)-US to classify the sonomorphologic pattern.

Research results

The study included 59 patients, 38 (64.5%) women and 21 (35.6%) men. The mean median age at initial diagnosis was 59.9 ± 16.9 years. At the time of initial US, 42.4% (25/59) had a hailstorm pattern, 16.9% (10/59) had a pseudohemangioma-like pattern, 15.3% (9/59) had a pseudocystic pattern, and 25.4% (15/59) had a metastasis-like pattern. Although the sonomorphologic pattern remained unchanged in 84.7% (50/59) of the AE reference lesions, 15.3% (9/59) showed a pattern change over time. A change in pattern was seen exclusively for AE lesions initially classified as hemangioma-like or pseudocystic.

Research conclusions

The sonomorphology of hepatic AE lesions may change over time, particularly hemangioma-like and pseudocystic patterns.

Research perspectives

Further research should clarify whether the patterns evolve and change according to a sonomorphological evolution.

Abstract

BACKGROUND

Various liver and gastrointestinal involvements occur in patients with coronavirus disease 2019 (COVID-19) at variable prevalence. Most studies report mild liver function disturbances correlated with COVID-19 severity, though liver failure is unusual.

AIM

To study liver and gastrointestinal dysfunctions in Egyptian patients with COVID-19 and their relation to disease outcomes

METHODS

This multicentre cohort study was conducted on 547 Egyptian patients from April 15, 2020 to July 29, 2020. Consecutive polymerase chain reaction-confirmed COVID-19 cases were included from four quarantine hospitals affiliated to the Egyptian ministry of health. Demographic information, laboratory characteristics, treatments, fibrosis-4 (FIB-4) index, COVID-19 severity, and outcomes were recorded and compared according to the degree of liver enzyme elevation and the presence of gastrointestinal symptoms. Follow-ups were conducted until discharge or death. Regression analyses were performed to determine the independent factors affecting mortality.

RESULTS

This study included 547 patients, of whom 53 (9.68%) died during hospitalization and 1 was discharged upon his request. Patients' mean age was 45.04 ± 17.61 years, and 21.98% had severe or critical COVID-19. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were available for 430 and 428 patients, respectively. In total, 26% and 32% of patients had elevated ALT and AST, respectively. Significant liver injury with ALT or AST elevation exceeding 3-fold was recorded in 21 (4.91%) and 16 (3.73%) patients, respectively. Male gender, smoking, hypertension, chronic hepatitis C, and lung involvement were associated with elevated AST or ALT. AST was elevated in 50% of patients over 60-years-old. FIB-4 was significantly higher in patients admitted to the intensive care unit (ICU), those with more severe COVID-19, and non-survivors. The independent variables affecting outcome were supplementary vitamin C intake (1 g daily capsules) [odds ratio (OR): 0.05, 95% confidence interval (CI): 0.008–0.337]; lung consolidation (OR: 4.540, 95%CI: 1.155–17.840); ICU admission (OR: 25.032, 95%CI: 7.110–88.128); and FIB-4 score > 3.25 (OR: 10.393, 95%CI: 2.459-43.925). Among 60 (13.98%) patients with gastrointestinal symptoms, 52 (86.67%) had diarrhoea. Patients with gastrointestinal symptoms were predominantly females with higher body mass index, and 50 (83.40%) patients had non-severe COVID-19.

CONCLUSION

Few Egyptian patients with COVID-19 developed a significant liver injury. The independent variables affecting mortality were supplementary vitamin C intake, lung consolidation, ICU admission, and FIB-4 score.

patients with COVID-19. In this study, we analyzed multicentre data of patients with polymerase chain reaction-confirmed COVID-19 from April 15, 2020 to July 29, 2020. Based on these data, we assessed the degree of liver injury and presence of gastrointestinal symptoms concerning COVID-19 disease severity, intensive care unit admission, and outcome.

INTRODUCTION

Hepatic and gastrointestinal (GI) involvement occurs in 16% to 78% of patients infected with the novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)[1-3]. In some of these populations, liver enzyme elevation exceeds five times the upper limit of normal (ULN)[4]. Most studies report mild liver function disturbances correlated with coronavirus disease 2019 (COVID-19) severity, though liver failure is unusual[5]. Hepatic and GI involvement can occur with and without pulmonary manifestations of COVID-19[1]. Different underlying mechanisms may contribute to liver injury related to COVID-19, including a direct viral effect, as the virus enters through the angiotensin-converting enzyme-2 receptor on cholangiocytes. Other indirect pathways include sepsis, drug-related hepatic injury, uncontrolled immune reactions, and cytokine storm[6].

Diarrhoea is the most frequently recorded GI symptom reported with COVID-19, ranging from 3% to 30%, followed by anorexia, nausea, vomiting, and abdominal pain [7]. SARS-CoV-2 RNA has been detected in stool specimens from patients with polymerase chain reaction-confirmed COVID-19 in respiratory samples. Those patients showed extended viral shedding in stool up to 11.2 d after viral eradication from respiratory specimens, suggesting faecal-oral transmission and warranting subsequent precautions[8]. The possible underlying mechanisms for GI involvement are the direct viral invasion of cells in the GI tract *via* the angiotensin-converting enzyme-2 receptor on gastric and duodenal glandular cells and proximal and distal enterocytes[8]. This viral invasion disrupts absorption and intestinal secretions, which activates the enteric nervous system and causes diarrhoea[9]. Other indirect mechanisms include antibiotic-associated diarrhoea, indirect inflammatory damage, and the ''gut-lung axis'' theory of immune-mediated effects on the respiratory tract by disturbed digestive tract flora[1,10]. This study aimed to determine the prevalence and extent of liver and GI derangements in Egyptian patients with COVID-19 infection and their relation to COVID-19 disease outcomes.

MATERIALS AND METHODS

Study population and data collection

This multicentre, prospective cohort study recruited 547 consecutive patients from April 15, 2020 to July 29, 2020 who were hospitalized in four quarantine centres affiliated to the Egyptian Ministry of Health and Population in three Egyptian governorates: 15 Mayo Smart Hospital in Cairo governorate, National Hepatology and Tropical Medicine Research Institute in Cairo governorate, Students Hospital in Giza governorate, and Alraghy Hospital in Assuit Governorate. This study included patients with a confirmed diagnosis of SARS-CoV-2, defined as a positive real-time reverse-transcriptase polymerase chain reaction assay of nasal and pharyngeal swab specimens. Patients were followed until discharge or death.

Ethics statement

The authors assert that all procedures contributing to this work complied with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008. All procedures involving human subjects or patients were approved by the research ethics committee of the Faculty of Medicine at Cairo University (number N-37-2020, May 14, 2020) and the research ethics committee of the Ministry of Health and Population (number 17-2020/8, June 21, 2020). Written informed consent was obtained from all patients before they participated in the study.

Methods

Collected baseline data included demographic information (age, gender, cigarette smoking, comorbidities), presenting symptoms (general, respiratory, GI), and laboratory features [complete blood count, liver and renal function, coagulation test, D-dimer, ferritin, C-reactive protein (CRP)]. Liver injury was defined as transaminase elevation exceeding three times the ULN[5]. The fibrosis-4 index (FIB-4) was calculated on admission using Sterling's formula: Age (years) × aspartate aminotransferase (AST) (IU/L) / platelet count (10^9/L) × [alanine aminotransferase (ALT) (IU/L) × 1/2][11]. Patients were classified according to the respective FIB-4 cut-off values (≤ 1.45 and ≥ 3.25) for predicting advanced liver fibrosis. Other baseline data included chest computed tomography (CT) findings, treatments administered, and COVID-19 disease classification and outcome. Laboratory results before discharge were collected.

COVID-19 severity was categorized as mild, moderate, or severe according to the management protocol of the Egyptian Ministry of Health and Population. Mild cases included asymptomatic and symptomatic cases with lymphopenia (defined as an absolute lymphocyte count < 1.0 × 10^3/L)[12] or leukopenia[12] (defined as a total leucocyte count < 4.0 × 10^3/L) and no radiological evidence of pneumonia. Moderate cases included symptomatic patients with radiological features of pneumonia with or without leukopenia and lymphopenia. Severe and critical cases were defined by the presence of any of the following: Respiratory rate > 30 per min, SaO_2 < 92 without oxygen therapy; PaO_2/FiO_2 ratio < 300 without oxygen or < 200 with oxygen, chest radiology showing more than 50% lung involvement, or progressive lung involvement within 24 h to 48 h. Severe and critical cases were indicated for intensive care unit (ICU) admission. Treatments were applied according to the protocol[13].

Statistical analysis

Analysis of data was performed using SPSS 25 for Windows (Armonk, NY, United States). Numerical variables are presented as mean, standard deviation, median, and

Data are presented as median and interquartile range (IQR). AST: Aspartate transaminase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyl transferase; IQR: Interquartile range.

25th and 75th percentiles. Categorical variables are presented as numbers (*n*) and percentages (%). According to the distribution of numerical data, suitable tests for inferential statistics were used. The Kruskal-Wallis and Wilcoxon or the Mann–Whitney U test was used for comparing two groups of independent variables [14]. Comparisons between categorical variables were carried out by Chi-square test (χ^2)[15]. Fisher's exact test was used instead of the Chi-square test when one expected cell or more was ≤ 5[15]. Results are expressed as *P*-values. Both univariate and multivariate logistic regression analyses were performed to identify the factors associated with outcome (death/recovery)[16].

RESULTS

This study included 547 COVID-19 patients hospitalized in four quarantine hospitals affiliated to the Egyptian Ministry of Health and Population (see Supplementary Tables 1 and 2 for baseline clinical, laboratory, imaging, treatment, and outcome features of the studied cohort). Of the 547 patients, 53 (9.68%) died during hospitalization, 493 (90.46%) recovered and were discharged, and 1 was discharged upon his request. The most common symptoms were fever (54.66%), cough (52.47%), dyspnoea (32.54%), and fatigue (30.71%), and 118 (21.57%) patients were asymptomatic. The mean age of the studied patients was 45.04 ± 17.61 years (the median age interquartile range) was 45.00 (30.00:60.00) years and 300 (54.84%) were male. Diabetes was the

AST: Aspartate transaminase; CT: Computed tomography.

most common comorbidity (24.86%), followed by hypertension (23.77%) and coronary artery disease (4.20%). Chronic liver disease was reported in 18 (3.29%) patients: 14 had chronic hepatitis C (of whom 7 had liver cirrhosis), 2 had chronic hepatitis B, and 2 had fatty liver disease. We confirmed their liver condition using their most recent abdominal ultrasound study before hospitalization for COVID-19. Regarding COVID-19, 427 (78.02%) had mild and moderate disease, 120 (21.98%) had severe or critical disease, and 122 (22.34%) were admitted to the ICU during their hospitalization. Flow chart of the study cohort is illustrated in Figure 1.

In our study, ALT and AST were available for 430 and 428 patients, respectively, and their other liver function tests and inflammatory markers were also available. Most patients had normal AST (291; 67.99%) and normal ALT levels (318; 74%). We divided patients as follows: Those with liver enzyme levels within the normal range, 1–2 fold over the ULN, 2–3 fold over the ULN, or >3 fold over the ULN (Tables 1-4). Among patients who required ICU admission, 48.50% had elevated AST and 35.60% had elevated ALT. On admission, FIB-4 was significantly higher in patients admitted to the ICU, those with more severe COVID-19 disease, and non-survivors (Supplementary Table 3).

We found that male gender, cigarette smoking, systemic hypertension, chronic hepatitis C, and abnormal chest CT findings were associated with significant elevation of baseline AST and ALT. Also, AST levels were elevated in patients older than 60 years, and diabetes mellitus was associated with elevation of baseline ALT. Elevated AST was also associated with elevated white blood cell count, absolute neutrophils count, neutrophils/lymphocytes ratio, ALT, gamma-glutamyl transferase (GGT), D-dimer, ferritin, and CRP and negatively correlated with absolute lymphocyte count and serum albumin. Elevated ALT was associated with elevated white blood cell count, Absolute Neutrophils count, neutrophils/lymphocytes ratio, AST, alkaline phosphatase (ALP), GGT, D-dimer, ferritin, and CRP and negatively correlated with absolute lymphocyte count and serum albumin (Tables 1-4).

No patient under 18-years-old showed elevated ALT levels, and only 1 had less than a 2-fold elevation of AST. All patients under 18 recovered and were discharged. Elevated AST levels were observed in 32 (18.4%) patients with mild disease and 23 (44.20%) with the critical disease, whereas elevated ALT levels were observed in 33 (19%) patients with mild disease and 32 (61.5%) with the critical disease (Supplementary Table 3).

Univariate analysis revealed several factors associated with survival (age < 60 years; no fever; no dyspnoea; normal findings on chest CT) and several associated with increased mortality (age > 60 years; leucocytosis; increased neutrophil/lymphocyte ratio; elevated AST, CRP, D-dimer or ferritin; baseline renal function impairment with elevations 1–2 above ULN) (Table 5).

AST: Aspartate transaminase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyl transferase; IQR: Interquartile range; UNL: Upper limit normal.

Patients were followed up till discharge or death. On discharge, patients showed significant improvement in haemoglobin, gamma-glutamyl transferase, serum albumin, ferritin, CRP, and lactate dehydrogenase levels with mild elevations in ALT and AST levels (Supplementary Table 4).

Multiple stepwise logistic regression analyses were conducted to identify significant predictors for outcomes of death and recovery. Independent variables included age, asymptomatic status, fever, dry cough, dyspnoea, sore throat, steroid use, supplementary vitamin C intake, azithromycin intake, subcutaneous heparin, chest CT findings, ICU admission, FIB-4 score, creatinine level, and urea level. The model was significant [χ^2 (144)], and the *P*-value was < 0.001, meaning the independent variable could explain the change in the dependent variable by up to 90.8%. Significant predictors in our model included treatment with supplementary vitamin C (1 g daily capsules according to the Egyptian Ministry of Health protocol[13]) [odds ratio (OR): 0.05, 95% confidence interval (CI): 0.008–0.337]; lung consolidation (OR: 4.540, 95%CI: 1.155–17.840); ICU admission (OR: 25.032, 95%CI: 7.110–88.128), and FIB-4 score > 3.25 (OR: 10.393, 95%CI: 2.459-43.925). The most significant predictor was ICU admission (Table 6).

Within our cohort, 60 (13.98%) patients presented with GI symptoms in addition to respiratory symptoms. They were predominantly females with significantly higher body mass index. Diarrhoea was the most common symptom, affecting 52 (86.67%) patients. Headache and sore throat were more frequent in patients with GI symptoms compared to those without GI symptoms; 83.4% of patients with GI symptoms had non-severe COVID-19 presentations with fewer ICU admissions. There was no difference in FIB-4 scores among patients with and without GI symptoms (Table 7).

[1]Data are presented as median (interquartile range). COVID-19: Coronavirus disease 2019; AST: Aspartate transaminase; ALT: Alanine aminotransferase; IQR: Interquartile range; CT: Computed tomography; ICU: Intensive care unit; BMI: Body mass index; GIT: Gastrointestinal tract.

DISCUSSION

This is the first report from Egypt specifically exploring hepatic and GI disturbances in patients with COVID-19. Within our cohort, AST was more frequently elevated (32.10% of cases), compared with ALT (26% of cases). Only 21 (4.91%) and 16 (3.70%) patients, respectively, had a significant liver injury with AST or ALT elevation > 3-fold. The cholestatic pattern of elevated bilirubin > 1.1 mg/dL, elevated ALP >147 U/L, and GGT > 48 U/L was observed in only 8 (1.86%) patients. Our study findings align with those of other studies showing a direct relationship between elevated liver enzymes and COVID-19 disease activity.

Similar to our study, most other studies reveal a predominant pattern of disturbances in liver enzymes in COVID-19 patients, specifically higher AST elevation than ALT elevation[17-19]. A meta-analysis by Wu *et al*[20] found that low serum albumin and high GGT were the most frequent abnormalities on admission and that ALT elevation occurred most frequently during hospitalization, which they speculate may be due to the inclusion of patients with pre-existing liver disease. In our study, we observed no difference between survivors and non-survivors in serum albumin level. Wu *et al*[20] and Liu *et al*[21] found that serum albumin was significantly lower in non-survivors.

Chronic liver disease was reported in 3.29% of our patients. Phipps *et al*[4] reported that the severity and type of underlying chronic liver disease (*e.g.*, non-alcoholic fatty liver disease and chronic hepatitis B or C) were not significantly associated with hepatic disturbances related to COVID-19, which could be due to the small numbers of

those cases with chronic liver diseases in their study.

In our study, AST was significantly higher in non-survivors, but no significant difference was observed in ALT levels between survivors and non-survivors, which is similar to previous meta-analyses[17,18]. Patients with severe COVID-19 and patients admitted to the ICU had higher transaminase levels, as confirmed by previous meta-analyses[17-19,21,22]. Ponziani *et al*[23] reported that alterations in transaminase levels in patients with COVID-19 were mild to moderate, whereas significant liver injury with transaminases > 3 times the ULN and pure cholestatic injuries occurred in a minority of patients[23]. Phipps *et al*[4] showed that 6.4% of their patients had a severe liver injury with ALT > 5 times above the ULN. They also found that peak ALT, older age, diabetes mellitus, and intubation were independent predictors of mortality. A meta-analysis by Kulkarni *et al*[22] found that severe liver injury occurred in 10.7% of 3440 patients with COVID-19: 24.9% among 358 patients with the non-severe disease and 41.5% among 317 patients with severe disease.

Other causes of liver injury in patients with COVID-19 include medication, such as acetaminophen at doses exceeding 7.5–10 g and combined use of antivirals and antibiotics. Systemic effects of SARS-CoV-2 infection can be hepatotoxic. For example, hypoxia due to lung injury and, in severe cases, sepsis, acute respiratory distress syndrome, and multi-organ failure precipitate hypoxia and ischemia of the liver, causing elevated serum ALT, AST, and total bilirubin levels[17].

In this study, baseline FIB-4 was an independent factor affecting mortality, and it was significantly higher in patients admitted to the ICU, those with more severe COVID-19 disease, and non-survivors. FIB-4, which predicts significant hepatic fibrosis in patients with liver disease, comprises four variables: Age, AST, ALT, and platelet count[11]. These factors are deranged in COVID-19 disease due to systemic inflammation, bone marrow suppression, injury of the skeletal muscles, elevated pressure in the right heart system with subsequent liver congestion, and elevated liver stiffness that occurs in the disease[24,25]. Sterling *et al*[23] showed that gender, diabetes mellitus, and FIB-4 ≥ 2.67 were associated with increased mortality. Another recent study by Li *et al*[25] found that FIB-4 correlated with mortality and severe COVID-19, noting that FIB-4 normalized in the survivors only. They also found that baseline FIB-4 correlated with SARS-CoV-2 viral load and their studied monocyte/interferon-I-related cytokines (interleukin-6 and interferon-gamma–induced protein 10)[25]. Rentsch *et al*[26] and Price-Haywood *et al*[27] found that FIB-4 scores > 3.25 and ≥ 2.67, respectively, were associated with hospitalization and with ICU admission and mechanical support.

Within our cohort, 60 patients (13.98%) presented with GI symptoms in addition to respiratory symptoms. The prevalence of diarrhoea, nausea, vomiting, and abdominal pain was 9.51%, 2.01%, 3.11%, and 3.84%, respectively. Diarrhoea was the most common GI symptom in our cohort, similar to findings from Wang *et al*[28].

The prevalence of diarrhoea, nausea/vomiting, and abdominal pain in their systematic review and meta-analysis was 9.1%, 5.2%, and 3.5%, respectively. The predominant GI symptoms differ among countries[28-30]. In China, for example, Luo *et al*[29] reported anorexia, nausea, and vomiting as the frequent symptoms in two-thirds of their patients, while diarrhoea and abdominal pain presented in 37%and 25% of their patients, respectively. A meta-analysis by Wan *et al*[30] (included 55 studies

AST: Aspartate transaminase; ALT: Alanine aminotransferase; CT: computed tomography; COVID-19: Coronavirus disease 2019; BMI: Body mass index; QR: Interquartile range; GIT: Gastrointestinal tract.

from China, 1 from Austria, 1 from the United States, 1 from Spain, and 2 from Singapore) reported the prevalence of GI symptoms as diarrhoea (53 studies, 8604 patients: 11.2%), nausea and vomiting (33 studies, 6165 patients: 10.0%), loss of appetite (15 studies, 2540 patients: 21.3%), and abdominal pain 14 studies, 2203 patients: (4.6%). Another meta-analysis by Parasa *et al*[31] reported that diarrhoea occurred in 4.3%–12.2%, and nausea, or vomiting occurred in 2.6%–8.0% of their included 4805 patients[31]. A study from the United States showed that GI symptoms were present in 61.3% of their patients (the most common was loss of appetite (34.8%) followed by diarrhoea (33.7%) and nausea (26.4%))[32].

In our study, 83.4% of patients with GI symptoms had non-severe COVID-19. The presence of diarrhoea or other GI symptoms did not impact COVID-19 mortality. Wang *et al*[28] also found no difference in the prevalence of diarrhoea among severe and non-severe cases, and the presence of GI symptoms did not affect mortality. Nobel *et al*[33] found that COVID-19 patients with GI symptoms had lower mortality and no difference in ICU admission rates, compared with patients without GI symptoms[33]. In contrast, Zhong *et al*[8] and Wan *et al*[30] reported a correlation between diarrhoea and severity of COVID-19, showing that patients with diarrhoea needed more ICU care and ventilator support.

In our cohort, there was no significant difference in transaminases level among patients with and without GI symptoms, which contrasts with a meta-analysis by Wijarnpreecha *et al*[17] showing higher transaminases in patients with GI symptoms. The results of our study are similar to Zhou *et al*[34], who found that GI symptoms were more common in females, sore throat was also more common in their patients with GI symptoms, and haemoglobin level was significantly lower in their patients with GI symptoms. In contrast to our study, ALT was higher in their non-medical group of patients with GI symptoms but not in the medical group, and CRP was

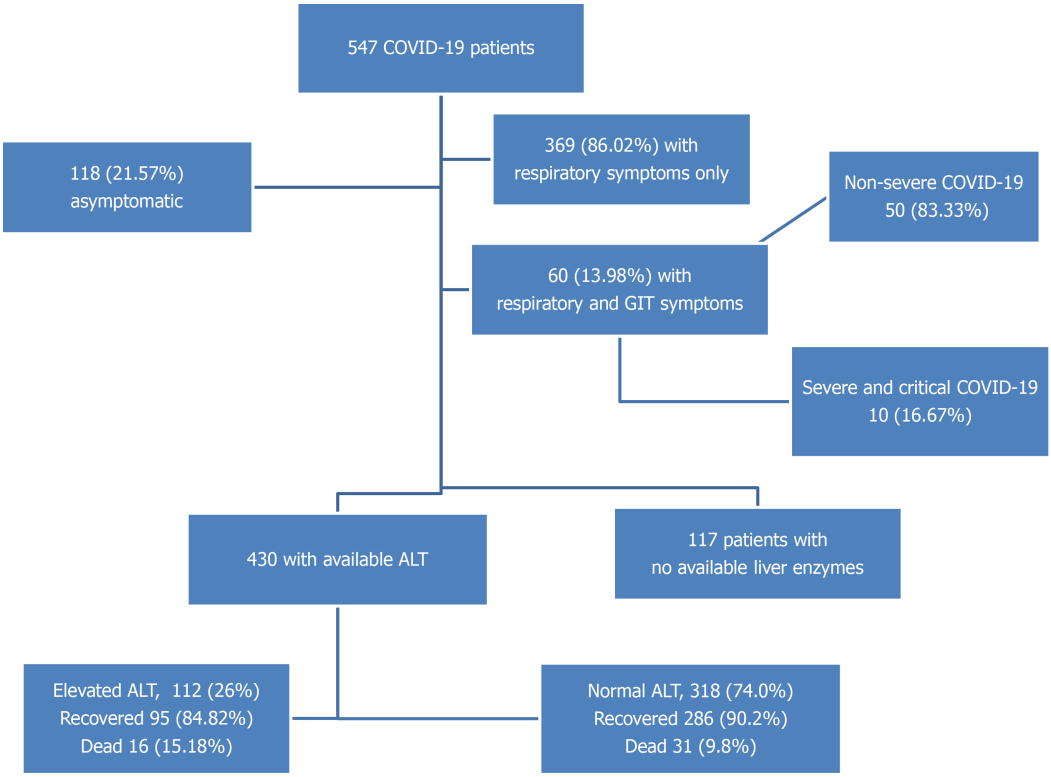

Figure 1 Flow chart of the study cohort. COVID-19: Coronavirus disease 2019; ALT: Alanine aminotransferase.

higher in their patients with GI symptoms. Limitations of our study include inconclusive reports about medications received before hospitalization and the possibility of underlying undiagnosed liver disease, such as non-alcoholic fatty liver disease and unavailability of creatine phosphokinase enzyme results, as it was not tested at the time of the study in the quarantine hospitals affiliated with the Egyptian Ministry of Health.

CONCLUSION

In conclusion, within our cohort of Egyptian patients with COVID-19, elevated AST, ALT, total bilirubin ,and GGT were present in 32.1%, 26%, 5.8%, and 1.86% of our patients, respectively. Significant liver injury (AST and ALT three times higher than the ULN) affected 4.91% and 3.70% of patients, respectively. Male gender, smoking, hypertension, chronic hepatitis C, and lung involvement were significantly associated with elevated AST and ALT. FIB-4 scores were significantly higher in patients admitted to the ICU, those with more severe COVID-19, and non-survivors. The independent variables affecting outcome were supplementary vitamin C intake, lung consolidation, ICU admission, and FIB-4 score. GI symptoms were significantly more frequent in women, patients with higher body mass index, and those with non-severe COVID-19.

ARTICLE HIGHLIGHTS

Research background

Hepatic and gastrointestinal (GI) disturbances have been reported in patients with coronavirus disease 2019 (COVID-19) with variable prevalence according to disease severity and population characteristics. This could be due to direct severe acute respiratory syndrome coronavirus 2 invasion through the angiotensin-converting enzyme 2 receptors or indirect effects such as an uncontrolled immune response, drug-induced injury, or sepsis.

Research motivation

Comprehensive researches on hepatic and GI derangements in patients with COVID-19 are still lacking, and they are needed for better understanding of the underlying factors, clinical presentations, and disease outcome

Research objectives

We aimed to study the prevalence and severity of liver and GI derangements in Egyptian patients with COVID-19 infection and their relation to disease outcomes.

Research methods

This multicentre cohort study was conducted on 547 COVID-19 cases from four quarantine hospitals during the period from April 15, 2020 to July 29, 2020. Clinical, laboratory features, fibrosis-4 (FIB-4) index, COVID-19 severity, and outcomes were recorded. Follow-ups were conducted until discharge or death.

Research results

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were elevated in 26% and 32% of patients while elevations above 3 fold were recorded in 4.91% and 3.73% patients, respectively. Male gender, smoking, hypertension, chronic hepatitis C, and lung involvement were associated with elevated AST or ALT. FIB-4 was significantly higher in patients admitted to the intensive care unit (ICU), those with more severe COVID-19, and non-survivors. The independent variables affecting outcome were supplementary vitamin C intake, lung consolidation, ICU admission, and FIB-4 score > 3.25. GI symptoms were present in 60 (13.98%) patients. They were predominantly females with higher body mass index, and 50 (83.40%) patients had non-severe COVID-19.

Research conclusions

Significant liver injury was uncommon among Egyptian patients with COVID-19. The independent variables affecting mortality were supplementary vitamin C intake, lung consolidation, ICU admission, and FIB-4 score.

Research perspectives

Variables independently affecting mortality were supplementary vitamin C intake, FIB-4 score > 3.25, lung consolidation, and ICU admission. GI symptoms occurred in patients with non-severe COVID-19.

Abstract

BACKGROUND

Depression, anxiety, and altered self-care ability are among the most important factors affecting the quality of life of liver transplant recipients. Depending on the severity of the underlying liver disease, signs and symptoms of anxiety and depression may become more pronounced.

AIM

To evaluate the factors affecting depression, anxiety and self-care abilities of liver transplant recipients.

METHODS

Recipients who are ≥ 18 years and who underwent liver transplantation at Inonu University Liver Transplantation Institute were included in this descriptive and cross-sectional study. Sample size analysis showed that the minimum number of recipients should be 301 (confidence level = 95%, confidence interval = 2.5, population = 1382). Three hundred and twenty recipients were interviewed and 316 recipients that have answered the questionnaires accurately were analyzed. The dependent variables were the Beck Depression Scale, State-Trait Anxiety Scale (Form I and II), and Self-Care Agency Scale. The independent variables of the study were sociodemographic characteristics, biliary complications, hepato-cellular carcinoma, recommending liver transplantation to other patients, and the interval of out-patient clinic visits.

RESULTS

Self-care ability scores were lower (P = 0.002) and anxiety scores were higher (P = 0.004) in recipients with biliary complications. On the other hand, in recipients with hepatocellular carcinoma, self-care scores were lower (P = 0.006) while depression (P = 0.003) and anxiety scores (P = 0.009) were higher. Liver transplantation recipients with a monthly income < 3000 Turkish liras had higher depression (P < 0.001) and anxiety (P = 0.003) scores. The recipients who stated that they would not recommend liver transplantation to others had lower self-care scores (P = 0.002), higher depression (P < 0.001), higher state anxiety (P = 0.02), and trait anxiety (P < 0.001) scores.

CONCLUSION

Presence of biliary complications and hepatocellular carcinoma, low income level, and an obligation for monthly visits to the outpatient clinic are factors that are found to affect self-care capability, depression, and anxiety.

Key Words: Liver transplantation; Biliary complications; Hepatocellular carcinoma; Socioeconomic status; Depression; Anxiety; Self-care capabilities

Core Tip: Depression, anxiety, and deficiency in self-care ability are among the most important factors affecting the quality of life of liver transplant recipients. This descriptive, cross-sectional questionnaire-based study shows that presence of biliary complications and hepatocellular carcinoma, low monthly income level, and monthly visits to the outpatient clinic are factors that affect self-care capability, depression, and anxiety.

INTRODUCTION

Since the first successful liver transplantation (LT) performed by Starzl *et al*[1] in 1967, LT has become the gold standard treatment modality for end stage liver failure and acute liver failure. In recent years, advancements in immunosuppressive medication, management of postoperative complications, and surgical technique have resulted in extended survival periods for transplant recipients[2,3]. The expectations in quality of life (QOL) of the LT recipients became more prominent with the increased survival rates of the recipients.

The parameters, signs, and symptoms related to QOL, such as the preoperative depression, anxiety, or need for support of a relative, can be exacerbated or can initially be seen in the postoperative period depending on the severity of preoperative psychosocial problems, operative trauma of a major operation, such as LT, long duration of hospitalization in either intensive care unit or in patient-wards, adverse effects of immunosuppressive agents (diabetes mellitus, osteoporosis, infection risk, hypertension, renal failure *etc*.), development of postoperative biliary complications that require interventions, the fear of recurrence of the underlying disease, such as hepatocellular carcinoma (HCC), the fear of the risk of acute or chronic organ rejection, loss of occupation that result in economic losses, and the need for regular postoperative follow-up[4-13]. The major factors affecting the QOL related with health are presence of preoperative co-morbidities (diabetes, hypertension, pulmonary disease), advanced age, female gender, occupation, low socioeconomic status, and financial burden[14-16]. Therefore, all these data suggest that strict surveillance of the transplant recipients in the preoperative and postoperative period in terms of psychosocial status and treatment of any psychosocial problems with psychotherapy and medication may increase the physical and mental QOL and may have a positive

revised according to the STROBE Statement-checklist of items.

impact on the life expectancy of the individuals[7,8].

Depression, anxiety, and the ability of self-care seem to be the most important parameters in the recipients in the postoperative period. Furthermore, some recipients may develop anxiety and depression depending on the risk factors mentioned above that may have an impact on the postoperative mental and physical QOL of the individual. In the present study on patients who received a LT, the anxiety was evaluated by State-Trait Anxiety Scale (STAI; Form I and II), depression was evaluated using the Beck Depression Scale (BDS), and the self-care was evaluated using the Self-Care Agency Scale (SCAS). All these scoring systems and scales were individually used in previous studies involving solid organ transplantation[17-19]. However, we have not encountered any study involving all three scales used together to evaluate a population of recipients. The aim of the present study is to analyze the relationship between sociodemographic characteristics, presence of biliary complications, presence of HCC, preference of recommendation of LT to others, and frequency of out-patient clinic control and some post-transplant QOL indicators (depression, anxiety, self-care ability).

MATERIALS AND METHODS

Type, duration, and location of the study

The preset study is descriptive, cross-sectional questionnaire-based study on patients transplanted between March 2002 and December 2018 at Inonu University Liver Transplant Institute. The recipients that are compliant with regular out-patient follow-up were selected for evaluation in the study, and face-to-face interview technique was applied to all these recipients. This study was reviewed and approved by the Inonu University institutional review board for non-interventional studies (3/27/2019).

Study population and sample size

The study population included 1382 recipients who met the above-mentioned criteria. The sample size was calculated (from the website https://www.surveysystem.com/sscalc.htm) using the confidence level of 95% and patient population (n = 1382) and the calculation showed that minimum of 301 individuals were required for evaluation in the present study. We interviewed 320 recipients in the present study considering the proportion of the recipients with missing data. Of those, the 316 recipients who answered the questionnaire forms accurately were included in the present study.

Inclusion and exclusion criteria

LT recipients who were discharged that were equal to or greater than 18 years old, who can communicate verbally, and understand and answer the questions were included in the present study. At the time of this study, LT was not performed for patients with intellectual disability in our liver transplant institute. Foreigners who lacked sufficient Turkish to answer the questions and recipients younger than 18 years were excluded from the study.

Parameters and scales used in the study

Demographic and clinical characteristics form: Age, gender, marital status, blood type, residency (city center, town, or village), monthly income [≤ 1000 Turkish liras (TL), 1000-3000 TL, ≥ 3000 TL], underlying liver disease (hepatitis B, hepatitis C, HCC *etc.*), type of LT (living donor LT, deceased donor LT), smoking status, alcohol consumption, type of immunosuppressive agent that is being used (tacrolimus, everolimus, cyclosporin, mycophenolate mofetil, corticosteroids, *etc.*), presence of postoperative biliary complications, co-morbidities (cardiac, pulmonary, metabolic *etc.*), and the frequency of the out-patient visits [monthly or once in every 3 mo (quarterly)] were all evaluated for the present study.

BDS: BDS is designed to evaluate how the individual feels about one-self that was defined by Beck *et al*[20] for the first time in 1961. Hisli[21] evaluated the validity and reliability of the Turkish version in 1989 (Cronbach's alpha = 0.80). BDS includes 21 articles that are scored between 0 and 3 points. The scores obtained from BDS range between 0 and 63 points and it evaluates the presence and the severity of depression in individuals. The severity of depression according to the scores of the individuals are minimal depression (0-9 points), mild depression (10-16 points), moderate depression (17-29 points), and severe depression (30-63 points)[22].

STAI: STAI was first defined by Spielberger *et al*[23] in 1970 to define the reaction of individuals with newly-developed or pre-existent anxiety. The validity and reliability of the scale was performed by Oner and LeCompte in 1983[24]. The Cronbach's alpha reliability coefficient for instantaneous and continuous anxiety scores calculated were 0.96 and 0.83, respectively[24]. The scale includes STAI Form-I (State) and STAI Form-II (Trait) parts. The first part of the form evaluates the recent anxiety status of the individual and the later part of the form evaluates the general anxiety status of the patient. The answers to the first part of the form are as follows: not at all (= 1), somewhat (= 2), moderately so (= 3), and very much so (= 4). The answers to the second part of the form are as follows: almost never (= 1), sometime (= 2), often (= 3), and almost always (= 4). In the STAI-I scale questions 1, 2, 5, 8, 10, 11, 15, 16, 19, and 20 are graded inversely (1 = 4 points, 2 = 3 points, 3 = 2 points, and 4 = 1 points). The other questions are graded directly (1 = 1 points, 2 = 2 points, 3 = 3 points, 4 = 4 points). In a similar fashion, in the STAI-II scale, 21, 26, 27, 30, 36, and 39th questions are graded inversely as explained before. At the end of evaluation, the anxiety is classified as high if the points are high; and is considered as low if the points are low. The total points from the instantaneous and the continuous parts is also helpful for the diagnosis of anxiety. If the total points are ≥ 35 points, this indicates the presence of anxiety and if the total points are < 35, this suggests that there is no anxiety in the patients[24,25].

SCAS: SCAS was first developed in 1979 by Kearney and Fleischer[26] to evaluate the self-care ability of individuals. The validation of the Turkish version in healthy subjects was performed by Nahcivan[27] in 1993 (Cronbach's alpha = 0.89). All 35 questions in the questionnaire are designed in a five-point Likert scale: It does not define me at all (= 0), it does not define me entirely (= 1), I have no idea (= 2), it defines me a little (= 3), and it defines me completely (= 4). In the questionnaire, the question 6, 9, 13, 19, 22, 26, and 31 are graded inversely (0 = 4 points, 1 = 3 points, 2 = 2 points, 3 = 1 points, 4 = 1 points). The other questions are graded directly (0 = 1 points, 1 = 1 points, 2 = 2 points, 3 = 3 points, 4 = 4 points). Maximum points obtained from the scale can be 140, and higher scores indicate higher self-care ability.

Statistical analysis

All statistical analyses are performed by Statistical Software Package for Social Sciences (SPSS v. 25). The Kolmogorov-Smirnov test was used to evaluate the normality of distribution of the variables. Some of the variables did not distribute normally and, therefore, all the continuous variables were expressed as median and interquartile range (IQR = Q3-Q1). Qualitative variables were expressed as the number of affected individuals (*n*) and percentage (%). Two-independent groups were compared using the Mann-Whitney *U* test, Pearson Chi-Square test, and Chi-Square test with Yates correction. For three-independent group comparisons, the Chi-Square test was used for qualitative variables and the Kruskal-Wallis test was used for continuous variables. For parameters that showed significant differences in the Kruskal-Wallis test, these parameters were further evaluated with Kruskal-Wallis One-way ANOVA (k sample) to determine the source of difference among the multiple groups. The correlation between the discrete variables was evaluated using Spearman's Rho correlation analysis. The correlation between the qualitative and quantitative variables were evaluated using the Point Double-Series Correlation Coefficient. Partial correlation analysis was performed to evaluate the individual contribution of variables to the correlation. The Correlation coefficient (r) was classified according to the power of the correlation; as defined before: very weak (*r* = 0.00-0.25), weak (*r* = 0.00-0.25), moderate (*r* = 0.50-0.69), high (*r* = 0.70-0.89), and very high (*r* = 0.90-1.00). Any *P* value less than 0.05 was considered as being statistically significant.

RESULTS

A total 316 patient with an age ranging from 18 to 76 years (median = 50, IQR = 58-36) were included in the present study. There were 189 (59.8%) male and 127 (40.2%) female patients included in the study. The demographic and sociocultural characteristics, clinical characteristics related with LT, and data regarding self-care ability, depression and anxiety status of the recipients are summarized in Tables 1-3.

BMI: Body mass index; IQR (Q3-Q1): Inter-quartile range.

Evaluation of the patients according to the presence of biliary complications

The recipients were classified into two groups according to presence (n = 200) and absence (n = 116) of biliary complications. Body mass index (P = 0.038), type of liver graft (P < 0.001), SCAS (P = 0.002), and STAI-I (P = 0.004) were significantly different among the groups. In recipients with biliary complications SCAS scores were found to be low and STAI-I scores were high. The median BDS scores did not significantly change. However, when the BDS scores were classified, there was a significant difference among the recipients with and without biliary complications (P = 0.04). The moderate to severe depression rate was higher in recipients with biliary complications. Total STAI scores were classified according to the anxiety of the recipients and the severity of anxiety was higher in recipients with biliary complications (57.5%, P = 0.009). There was no statistically significant difference in other variables according to the presence of biliary complications (Table 4).

Evaluation of the patients according to the presence of HCC

The recipients were classified according to presence (n = 32) or absence (n = 284) of HCC (Table 5). SCAS (P = 0.006), BDS (P = 0.003), and STAI-II scores (P = 0.009) were significantly different among recipients with and without HCC. While mild and moderate depressive symptoms were more pronounced in recipients with HCC, minimal depressive symptoms were higher in recipients without HCC. Other variables showed no difference according to presence or absence of HCC (Table 5).

Evaluation of the patients according to monthly income

The recipients were grouped in to three groups according to their monthly income (TL): ≤ 1000 (n = 18), 1000-3000 (n = 260), and ≥ 3000 (n = 38) (Table 6). There were significant differences in gender (P < 0.001), place or residence (P = 0.002), BDS scores (P < 0.001), and STAI-II scores (P = 0.003) among groups. In recipients with monthly income ≥ 3000 TL, the depressive symptoms were minimal; while, in recipients with low income, higher rates of mild and moderate depressive symptoms were observed. Other parameters did not show difference according to income of the recipients (Table 6).

Evaluation of the patients according to their inclination towards recommendation of LT to others

The recipients were grouped according to their preference of recommending (n = 285) or not recommending (n = 31) LT to others. The groups showed statistically significant difference in terms of SCAS (P = 0.002), BDS scores (P < 0.001), STAI-I (P = 0.02), and STAI-II scores (P < 0.001). In the group of recipients that do not recommend LT to others, about half of the individuals had moderate to severe depressive symptoms which was significantly higher than the recipients in the group that do recommend LT (48.5% *vs* 11.6%; P < 0.001). All STAI scores were stratified according to the anxiety of the recipients and the rate of anxiety was significantly higher in recipients in the group that do not recommend LT (100% *vs* 85.6%; P = 0.021). There was no significant difference in other variables according to inclination towards recommending or not recommending LT to others (Table 7).

Evaluation of the patients according to frequency of out-patient clinic visits

The data of the 264 LT recipients that come to out-patient clinic monthly were compared to 52 recipients who come to out-patient visits quarterly. Age (P = 0.047) and BDS scores (P = 0.028) showed significant difference among the groups. The

Table 3 Evaluation of the Study group according to the scores obtained Self-Care Agency Scale, Beck Depression Scale and State-Trait Anxiety Scale

Parameters	Results
SCAS scores	
Median	95
IQR	108-86
BDS scores	
Median	9
IQR	14-5
STAI-I (state) scores	
Median	35
IQR	41-28
STAI-II (trait) scores	
Median	42
IQR	50-36
STAI-I (state) (categorized form)	
Presence anxiety (≥ 35 point)	164 (51.9)
Absence anxiety (< 35 point)	152 (48.1)
STAI-II (trait) (categorized form)	
Presence anxiety (≥ 35 point)	275 (87.0)
Absence anxiety (< 35 point)	41 (13.0)
BDS (categorized form)	
Minimal depression (0-9 point)	183 (57.9)
Mild depression (10-16 point)	85 (26.9)
Moderate depression (17-29 point)	45 (14.2)
Severe depression (30-63 point)	3 (0.9)

BDS: Beck Depression Scale; IQR (Q3-Q1): Inter-quartile range; SCAS: Self-Care Agency Scale; STAI: State-Trait Anxiety Scale.

moderate depression rate of the recipients that come to monthly controls were significantly higher (16.7% *vs* 1.9%; $P = 0.004$). Other variables did not show significant difference according to the frequency of out-patient clinical visits (Table 8).

The results of correlation statistics between the scales

SCAS and BDS showed a significant but weak and negative correlation ($P < 0.001$; $r = -0.340$). There was also a significant but weak and negative correlation between SCAS and STAI-I scales ($P < 0.001$; $r = -0.473$) and SCAS and STAI-II scales ($P < 0.001$; $r = -0.391$). There was a significant but weak positive correlation between BDS and STAI-I scores ($P < 0.001$; $r = +0.498$) and between BDS and STAI-II scores ($P < 0.001$; $r = +0.455$). There was a significant, moderate, and positive correlation between STAI-I and STAI-II scores ($P < 0.001$; $r = +0.539$). The impact of presence of biliary complications, HCC, and the frequency of out-patient clinic visits on correlations observed between STAI-I, STAI-II, BDS, and SCAS scores were further analyzed using partial correlation analyses techniques which showed that the correlation between different scales were independent from the factors that were investigated.

DISCUSSION

With the advances in surgical techniques, perioperative patient management, the treatment of postoperative complications with minimally invasive methods, and the development of targeted immunosuppressive treatment protocols with fewer side effects, significant reductions in mortality and morbidity rates have been achieved in

patients who received LT during the last quarter century[8]. The 1- and 5-years survival rates of the patients following LT were 85%-86% and 68%-74%, respectively [28]. On the other hand, together with the long-term survival rates obtained, the QOL of the recipients started to become one of the major concerns for both the physicians and the relatives of the recipients[8].

According to the World Health Organization (WHO), healthy individual is not only free of disease or disability but also defined as a state of psychological and physical well-being[8-10]. From this WHO's perspective, technical and medical success following LT does not necessarily indicate health of the individual; the recipients should also be in the acceptable range of well-being in psychosocial terms as well. For this reason, physicians should also aim to mediate the factors that affect the psychosocial QOL of the individuals following the LT procedures. In the last two decades the studies regarding the QOL of the living donors and recipients after LT have increased tremendously[8,29-33].

Biliary complications are frequently encountered following LT and especially after living donor LT[34,35]. The treatment involves a combination of surgical therapy and endoscopic or interventional radiology assisted percutaneous stenting or catheter placement[36-39]. These complications result in prolonged hospitalization, repeated interventions, and frequent outpatient clinic visits. Therefore, the QOL of the recipients with biliary complications are expected to be lower than recipients without biliary complications[6,40-42]. We have seen that there are no studies analyzing the relationship between biliary complications and the QOL of the recipients. The majority of the published studies state that the biliary complications that develop can adversely

affect the QOL of the recipients[6,8,40]. In the present study, the self-care ability of the recipients with biliary complications was found to be low (P = 0.002) and the instantaneous anxiety index was found to be increased (P = 0.004). Furthermore, in recipients with biliary complications, 17% showed moderate depression and 57.5% showed signs

BDS: Beck Depression Scale; IQR (Q3-Q1): Inter-quartile range; SCAS: Self-Care Agency Scale; STAI: State-Trait Anxiety Scale.

of instantaneous anxiety. In our opinion, this observation can be explained by prolonged hospitalization, pain and discomfort that is caused by percutaneous catheter placement, the fear of losing the transplanted organ, and the necessity of frequent outpatient clinic visits.

Another factor that has a major impact on the QOL is the presence of HCC diagnosis before the LT. Mabrouk *et al*[43] have stated that the QOL parameters in recipients transplanted for HCC were significantly worse than that of the recipients transplanted for other etiologies; the reason for this was correlated with anxiety related with the probability of a recurrence of the HCC in the post-LT period. On the

other hand, Castaldo *et al*[44] suggested that the diagnosis of HCC had a positive impact on the physical and mental components of QOL for the recipients. On the other hand, Heits *et al*[45] have found no relation between HCC and QOL parameters. In Europe and the United States, recipients with HCC receive additional points during the waiting list and recipients are transplanted in early disease stages, which results in a favorable prognosis compared to recipients without HCC. In the present study, in patients with HCC, the self-care ability was low (P = 0.006) while depression (P = 0.003) and continuous anxiety indices (P = 0.009) were higher than recipients without HCC. Furthermore, 31.3% of the patients with HCC had signs and symptoms of moderate depression. We agree with the Mabrouk *et al*[43] regarding this issue; however, we believe that the negative effect on the QOL parameters should be further investigated regarding the impact of HCC diagnosis and the cumulative effect of the various other factors on this outcome. The cadaveric organ donations in Turkey are significantly lower than that of the developed western countries, and, for this reason, the recipients with HCC have almost no chance for deceased donor LT and the majority need a living liver donation from a family member or a relative[46]. Therefore, the patients have to live with HCC for a period of time before the LT, with some patients requiring bridging procedures, such as chemoembolization, radioembolization, microwave or radiofrequency ablation, and surgical resection. This prolonged and hard waiting period may be the cause of the adverse effects observed on the QOL parameters in the post-LT period.

Other important factors that have an impact on the QOL of the recipients following LT is the income and the frequency of the required out-patient clinic visits of the recipients. The studies have shown that the recipients taking long journeys to come for an out-patient control visit had detrimental economical consequences and reduction in QOL of the recipients[47]. Furthermore, the prolonged hospitalization and frequent hospital visits delay the time to return to work, which reduce the household income. This will inevitably result in psychosocial problems in the recipients. Previous studies from our institute have shown that families of pediatric recipients with a low incomes experienced severe social and economic problems following the transplant procedure [48]. In the present study, we have shown that as the monthly income increased, the parameters related with depression (P < 0.001) and continuous anxiety indices (P = 0.003) decreased significantly. The symptoms related with moderate depression was observed in 22.2% of the patients with a monthly income lower than 1000 TL; on the other hand, patients with 1000-3000 TL and ≥ 3000 TL had moderate depression rate of 15.4% and 2.6%, respectively (P = 0.004). Similarly, the depression level of the recipients who were required to attend frequent visits to the out-patient clinic were significantly higher than recipients who only had to attend quarterly (P = 0.028). In other words, 22.2% of the patients that had to come to out-patient clinic monthly showed signs and symptoms of moderate depression (P = 0.004).

Immunosuppressive drugs that are being used to prevent organ rejection also have a significant impact on the QOL of the recipients. Zaydfudim *et al*[49] have stated that high dose steroid use in recipients have reduced the physical and mental health of the recipients and caused majority of the anxiety related symptoms of the individuals. Lerut[50] stated that reduction or even discontinuation of steroids and other immunosuppressives would eliminate their adverse effects and would increase the QOL of the recipients. In the preset study, we found no difference between the Beck's depression score, instantaneous or continuous anxiety indices, and self-care ability of the patients who did or did not use steroids. Braun *et al*[51] have suggested that recipients that are treated with cyclosporin had better QOL when compared to patients treated with tacrolimus. However, there are contradicting studies that show better QOL with tacrolimus treatment when compared to patients that are on cyclosporin treatment[52,53]. In the present study, the type of immunosuppressive (tacrolimus *vs* cyclosporin) did not have significant impact on the BDS, STAI-I, STAI-II, and SCAS scores of the recipients. Similarly, we found no difference in terms of the BDS, STAI-I, STAI-II, and SCAS among the patients who did or did not receive cyclosporin treatment. However, we found that the BDS scores of the recipients that are on tacrolimus therapy were significantly higher (P = 0.018) and the SCAS scores (P = 0.001) were significantly lower than the recipients that are not receiving tacrolimus therapy. In general, our results suggest that there is no impact of either cyclosporin or tacrolimus on the QOL parameters of the recipients. However, our results regarding the impact of tacrolimus on the self-care abilities of the recipients are original and need to be validated by prospective studies.

The decision to recommend LT to others and its relationship with the QOL parameters requires further analysis. Our review of current literature showed that there are no studies addressing this problem. In the present study, we have found that

the SCAS scores were lower (P = 0.002) and BDS (P < 0.001), STAI-I (P = 0.020), and STAI-II (P < 0.001) scores were higher in patients who stated that they would not to recommend LT to others. Furthermore, moderate depression rate and signs of prominent anxiety was present in 38.7% and 100% of the recipients who did not recommend LT to others, respectively. The recipients that did or did not recommend LT did not differ in terms of incidence of biliary complications (P = 0.660), presence of HCC (P = 1.000), and use of tacrolimus (P = 0.056) as immunosuppressive treatment. However, 36.1% of the recipients that did recommend LT and 16.1% of the recipients that did not recommend LT were using everolimus (P = 0.042). Patients that do or do not use everolimus did not significantly differ in terms of depression, anxiety, and self-care ability. Therefore, our results need validation and further analyses by studies that will be conducted in future.

CONCLUSION

Biliary complications cause depression, reduced self-care ability, and cause anxiety in patients after LT. This has a major impact on the QOL of the recipients. HCC reduces the QOL by increasing depression and anxiety and reducing self-care ability of the recipients. These recipients have HCC that exceed the acceptable limits in the preoperative period, and they receive multiple procedures to down-stage the tumors. This results in frustration and concerns of recurrence of the tumor in the postoperative period. The monthly income and frequent out-patient clinic visits have a significant impact on the QOL of the recipients. The recipients and their relatives cannot return to work until they recover fully after the LT procedure. Furthermore, frequent visits to the out-patient clinic further compromise return to work for the recipients which has a major impact on the income of the recipients. All recipients should be examined by psychiatry in the preoperative period and should receive medico-social therapy in necessary situations. Routine postoperative follow-up of the recipients with a psychologist and physiotherapists are very important for physical and mental QOL of the recipients. Transplant centers should also employ physiotherapists and psychologists that will work with specifically with recipients.

ARTICLE HIGHLIGHTS

Research background

Depression, anxiety, and status of self-care ability are among the most important factors affecting the quality of life of patients who have undergone liver transplantation. Depending on the severity of the underlying liver disease, signs and symptoms of anxiety and depression may become more pronounced.

Research motivation

Depression, anxiety, and deficiency in self-care ability are among the most important factors affecting the quality of life of liver transplant recipients. This descriptive, cross-sectional questionnaire-based study shows that presence of biliary complications and hepatocellular carcinoma, low monthly income level, and monthly visits to the outpatient clinic are factors that are found to affect self-care capability, depression, and anxiety.

Research objectives

The main objective of this study is to analyze the relationship between sociodemographic characteristics, presence of biliary complications, presence of hepatocellular carcinoma, preference of recommendation of liver transplantation to others, and frequency of out-patient clinic control, and some post-transplant quality of life indicators (depression, anxiety, self-care ability).

Research methods

This study is descriptive, cross-sectional questionnaire-based study on patients transplanted between 2002 and 2018 at our Liver Transplant Institute. The recipients who were discharged that were equal to or greater than 18-years-old and who can communicate verbally and understand and answer the questions were included in the present study. We interviewed 320 liver transplant recipients in the present study

considering the proportion of the recipients with missing data. Of those, 316 recipients who answered the questionnaire forms accurately were included in the present study. The dependent variables were Beck Depression Scale, State-Trait Anxiety Scale (Form I and II) and Self-Care Agency Scale. The independent variables of the study were sociodemographic characteristics, biliary complications, hepatocellular carcinoma, recommending liver transplantation to other patients, and the interval of out-patient clinic visits.

Research results

Self-care ability scores were lower and anxiety scores were higher in recipients with biliary complications. On the other hand, in recipients with hepatocellular carcinoma, self-care scores were lower and depression and anxiety scores were higher. In liver transplantation recipients with a monthly income < 3000 Turkish liras had higher depression and anxiety scores. The recipients who stated that they would not recommend liver transplantation to others had lower self-care scores and higher depression, state anxiety, and trait anxiety scores.

Research conclusions

Presence of biliary complications and hepatocellular carcinoma, low income level, and an obligation monthly visits to the outpatient clinic are factors that are found to affect self-care capability, depression and anxiety.

Research perspectives

To our knowledge, this study is one of the most comprehensive studies examining the relationships between post liver transplant quality of life indicators and various clinical parameters.

Abstract

BACKGROUND

Despite the improvement in the endoscopic hemostasis of non-variceal upper gastrointestinal bleeding (NVUGIB), rebleeding remains a major concern.

AIM

To assess the role of prophylactic transcatheter arterial embolization (PTAE) added to successful hemostatic treatment among NVUGIB patients.

METHODS

We searched three databases from inception through October 19th, 2020. Randomized controlled trials (RCTs) and observational cohort studies were eligible. Studies compared patients with NVUGIB receiving PTAE to those who did not get PTAE. Investigated outcomes were rebleeding, mortality, reintervention, need for surgery and transfusion, length of hospital (LOH), and intensive care unit (ICU) stay. In the quantitative synthesis, odds ratios (ORs) and weighted mean differences (WMDs) were calculated with the random-effects model and interpreted with 95% confidence intervals (CIs).

quality and risk assessment; Oš tarijaš E did the visualisation; Erőss B did the conceptualization, supervision, and wrote the original draft; All authors certify that they have participated sufficiently in the work to take public responsibility for the content, including participation in the concept, design, analysis, writing, or revision of the manuscript.

Peer-review report's scientific quality classification

Grade A (Excellent): A
Grade B (Very good): B, B, B

RESULTS

We included a total of 3 RCTs and 9 observational studies with a total of 1329 patients, with 486 in the intervention group. PTAE was associated with lower odds of rebleeding (OR = 0.48, 95%CI: 0.29–0.78). There was no difference in the 30-d mortality rates (OR = 0.82, 95%CI: 0.39–1.72) between the PTAE and control groups. Patients who underwent PTAE treatment had a lower chance for reintervention (OR = 0.48, 95%CI: 0.31–0.76) or rescue surgery (OR = 0.35, 95%CI: 0.14–0.92). The LOH and ICU stay was shorter in the PTAE group, but the difference was non-significant [WMD = -3.77, 95%CI: (-8.00)–0.45; WMD = -1.33, 95%CI: (-2.84)–0.18, respectively].

CONCLUSION

PTAE is associated with lower odds of rebleeding and any reintervention in NVUGIB. However, further RCTs are needed to have a higher level of evidence.

Core Tip: Rebleeding remains a significant concern in patients with non-variceal upper gastrointestinal bleeding (NVUGIB), despite the improvements in endoscopic and pharmacologic treatments. Our systematic review and meta-analysis indicate that prophylactic transcatheter arterial embolization (PTAE) compared to standard of care is accompanied by lower odds of rebleeding, need for rescue surgery, and reinterventions NVUGIB. However, we could not justify a beneficial effect of PTAE on mortality rates compared with the standard of care. In line with our results, we suggest using PTAE in selected cases, where risk stratification predicts high rebleeding risk or the anatomical situation makes the secure and permanent endoscopic hemostasis impossible.

INTRODUCTION

Acute upper gastrointestinal bleeding (UGIB) remains a common medical emergency with an incidence of 47-90/100000[1-3]. The age-standardized incidence of ulcer bleeding decreased by 41.6% between 1983 and 2004 in a prospective observational study; notable the decrease occurred only in people younger than 70 years of age[1]. Mortality in UGIB ranges between 1.1%–11%[4], although it has significantly decreased due to improvements and innovation in both endoscopic and pharmacologic treatments[1,4]. The UGIB population characteristics have changed considerably, the mean age of the patients has increased, the prevalence of co-morbidities is higher than before, and the use of nonsteroidal anti-inflammatory, antiplatelet and anticoagulant drugs is more widespread[1,5,6].

Rebleeding is a significant concern in patients with UGIB, occurring in 7%–16% of cases despite endoscopic therapy[6]. As published in a study from the United Kingdom in 2007, rebleeding is associated with a higher mortality rate, potentially induces more extended hospital stay and need for reintervention[5]. Thus, preventing rebleeding is a critical factor from the patients' and a healthcare economic view. The management of non-variceal UGIB (NVUGIB) is well established in guidelines based on a high level of evidence. In the post-endoscopy care of NVUGIB, a strong recommendation is to use high-dose proton pump inhibitors and eradicate *Helicobacter pylori (H. pylori)* if presence is established[7]. On the other hand, if rebleeding happens,

the patient should receive a repeat upper gastrointestinal endoscopy[7]. In the case of failure of this second attempt with endoscopic hemostasis, either transcatheter angiographic embolization (TAE) or rescue surgery are indicated, as they provide the same level of efficacy[8,9].

In contrast, there are only a few studies about the potential role of prophylactic transcatheter arterial embolization (PTAE) in the management of NVUGIB. A recent randomized controlled trial suggested that PTAE may reduce the incidence of recurrent bleeding (10.2% *vs* 11.4%, $P = 0.745$), but they could not show a clear benefit in adding angiographic embolization to endoscopic hemostasis in NVUGIB patients [10]. Investigating a subset of patients with ulcers 15mm or more in size, PTAE significantly reduced the risk of rebleeding (23.1% *vs* 4.5%, $P = 0.027$)[10]. A similar improvement in the rebleeding rate after PTAE was observed in some cohort studies [11-13].

Our study aimed to assess the role of PTAE among NVUGIB patients. We hypothesized that PTAE could reduce the risk of rebleeding and even the mortality rate among NVUGIB patients and improve other outcomes.

MATERIALS AND METHODS

We are reporting our systematic review and meta-analysis in line with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 Statement [14] (Supplementary Table 1) and also in line with the Meta-analysis Of Observational Studies in Epidemiology (MOOSE) guidelines[15] because we included both RCTs and observational cohort studies. Methods of the analysis and inclusion criteria were established in advance, and the protocol was documented on the International Prospective Register of Systematic Reviews (PROSPERO, registration number CRD42021223726).

Systematic search

Three databases, MEDLINE (via PubMed), EMBASE, and Cochrane Central Register of Controlled Trials (CENTRAL), were searched from inception through October 19th, 2020. We applied the following search key: (embolization OR embolisation) AND (peptic OR ulcer OR "gastrointestinal bleeding" OR nonvariceal OR non-variceal OR "gastrointestinal hemorrhage" OR "gastrointestinal haemorrhage"). We did not use any restrictions or filters during the search. We provide the complete search strategy in Supplementary Appendix 1.

Selection and eligibility

After the automatic and manual removal of duplicates with a reference manager software (EndNote X9, Clarivate Analytics, Philadelphia, PA, United States), screening and selection for the title, abstract, and full text were undertaken independently by two review authors. Cohen's kappa coefficient (κ) was calculated after each step to measure inter-reviewer reliability[16]. Disagreements were resolved through discussion with a third author. The references of the selected studies were examined to identify any additional relevant studies.

To identify eligible studies, we used the population-intervention-control-outcome (PICO) framework. Our investigated population (P) consisted of adult patients (age > 18 years) with endoscopy, digital subtraction angiography, or computed tomography angiography proved NVUGIB source, who either underwent successful endoscopic hemostasis or during angiography, there was no detectable contrast extravasation described. Studies compared the outcomes of patients who received PTAE (I) to patients who did not receive PTAE (C). The primary outcomes (O) were rebleeding and 30-d mortality rate, and the secondary outcomes were in-hospital or overall mortality rate, reintervention, need for salvage surgery, need of transfusion, length of hospital (LOH), and intensive care unit (ICU) stay. We pooled studies with different measurement time points regarding rebleeding (such as in-hospital, 28- and 30-d). If articles did not provide a precise measurement time point for mortality, we referred to that as "overall mortality". We defined reintervention as any repeated invasive treatment of rebleeding such as embolization, endoscopy, or surgery. Randomized controlled trials, prospective and retrospective observational cohort studies were eligible. Case reports, case series with less than ten patients, and review articles that did not report original research were excluded. In the case of publications using data with overlapping study populations, we used the one with the bigger sample size.

Data collection

Two independent review authors extracted data from eligible studies into a predesigned data collection form. The following data were collected from each study: first author, year of publication, study design, study period, study site (country), demographic features of the study population, the number of participants with PTAE, the number of patients without PTAE, bleeding etiology, type of embolic agents, data on outcomes (rebleeding, surgery, mortality, reintervention, LOH stay, ICU stay, and blood transfusion) in the intervention and control groups. In the case of the RCTs, intention-to-treat and per-protocol data were collected separately.

Data synthesis and statistical analysis

A biomedical statistician performed the statistical analysis of the study. Calculations were made by Stata 16 data analysis and statistical software (Stata Corp LLC, College Station, TX, United States). In the case of dichotomous categorical outcomes (mortality, rebleeding rate, *etc.*), we determined odds ratios (ORs) with 95% confidence intervals (95%CIs) from two-by-two tables (intervention *vs* control, outcome present and absent). For continuous variables, weighted mean difference (WMD) with 95%CIs were calculated. A P value less than 0.05 was considered a statistically significant difference. The random-effects model, according to the method of DerSimonian-Laird [17], was used to calculate the pooled estimates. We used forest plots to present the results of the meta-analyses.

I^2 and χ^2 tests were performed to assess heterogeneity. I^2 values were described as "minimal" (0%–40%), "moderate" (30%–60%), "substantial" (50%–90%), and "considerable" (75%–100%) heterogeneity, with a P value < 0.1 considered significant, as suggested by the Cochrane Handbook[18]. For the outcome of rebleeding, publication bias was assessed by visual inspection of a funnel plot and Egger's test. As for the other outcomes, we were unable to determine the presence of publication bias because of the low number of studies included in each analysis.

Sensitivity analysis was carried out by removing each trial analysis in turn in the case of rebleeding, reintervention, surgery, and need of transfusion outcome (the leave-one-out-method).

We performed a subgroup analysis for rebleeding and compared randomized controlled studies (RCTs) with non-randomized studies. For RCTs, we analyzed the intention-to-treat and per-protocol analysis results separately. Trial Sequential Analysis (TSA 0.9.5.10.) was performed for the RCTs regarding rebleeding to control random errors and estimate the optimal information size.

Risk of bias assessment and certainty of the evidence

Two independent review authors carried out the risk of bias assessment. Discrepancies were resolved by third-party arbitration. We followed the recommendations of the Cochrane Prognosis Methods group, and we used the revised Risk of Bias (RoB) 2 tool for randomized and the Risk of Bias In Non-randomized Studies - of Interventions (ROBINS-I) tool for non-randomized studies[19,20]. We used the Risk-of-bias VISualization (robvis) web-based tool[21].

Two independent review authors assessed the overall quality of evidence following the recommendation of the "Grades of Recommendation, Assessment, Development, and Evaluation (GRADE)" workgroup[22]. A third author resolved disagreements. Summary of Findings table and the additional tables were prepared with the GRADE profiler (GRADEpro) tool [GRADEpro Guideline Development Tool (Software)]. McMaster University, 2020 (developed by Evidence Prime, Inc.).

RESULTS

Search and selection

We identified 10591 records in three databases for evaluation. After removing duplicates and careful selection by title and abstract, 46 articles were eligible for full-text assessment. Altogether, 14 papers were retrieved for qualitative and 12 for quantitative synthesis. Two studies[23,24] were excluded from the quantitative synthesis due to major differences in intervention or outcome compared to other included articles. In the study of Ying *et al*[23], the intervention group got not only PTAE but also superior mesenteric arterial hypophysin infusion, which was too much alteration from our PICO and inclusion criteria. In the publication of Yonemoto *et al* [24], different outcomes (statistical analysis for laboratory data, number of endoscopic

treatments) were presented than we were assessing in our meta-analysis. The selection process is detailed in Figure 1.

Characteristics of the studies included

The 14 included studies are summarized in Table 1. We included in the quantitative synthesis three randomized controlled trials[10,25,26], two prospective[11,12], and seven retrospective cohort studies[13,27-32]. The source of bleeding was peptic ulcer lesions in eight studies[10-13,25,29,30,32], while in four studies[26-28,31], NVUGIB lesion was used as a generic term for various bleeding sources (*e.g.*, angiodysplasia, solid tumors, peptic ulcers). Each study had a relatively small sample size, with similar characteristics between intervention groups. The eligibility criteria of the studies included are presented in Supplementary Table 2. Most of the studies did not report any adverse events during or after PTAE. Information about the reported endoscopic treatments, technical success rate of PTAE, adverse events, and standard of care are summarized in Supplementary Table 3.

Prophylactic transcatheter arterial embolization is associated with lower odds of rebleeding

In our meta-analysis, we included a total of twelve studies with 1329 patients evaluating the clinical effect of PTAE on various outcomes. In the intervention group, 486 patients received PTAE in addition to standard of care. There was a total of 843 patients in the control group.

PTAE is connected with significantly lower chance for rebleeding compared to the control group (OR = 0.48, 95%CI: 0.29–0.78, P = 0.003; in a mildly heterogenous dataset, I^2 = 33.0%, P = 0.126) (Figure 2).

For this comparison, publication bias assessment by visual inspection of a funnel-plot and Egger's test was carried out, suggesting a likelihood for publication bias. (Supplementary Figure 1). Leave-one-out analysis showed no significant change in the overall odds for rebleeding (Supplementary Figure 2).

According to the RCT subgroup analysis with intention-to-treat data, there was no significant difference between the PTAE and control group in the rate of rebleeding (OR = 0.58, 95%CI: 0.27–1.25, P = 0.165; in a mildly heterogeneous dataset, I^2 = 12.6%, P = 0.319) (Figure 2). However, with available per-protocol analysis results, the odds of rebleeding were significantly lower in the PTAE group, compared to the control group even according to the RCT subgroup analysis (OR = 0.42, 95%CI: 0.19–0.93, P = 0.033; [I^2 = 0.0%, P = 0.712]) (Supplementary Figure 3). The performed TSA showed that the required information size was reached neither in the intention-to-treat nor in the per-protocol calculation (Supplementary Figure 4A and 4B).

Prophylactic transcatheter arterial embolization is not associated with mortality in non-variceal upper gastrointestinal bleeding

There was no significant difference neither in 30-day mortality [OR = 0.82, 95%CI: 0.39–1.72, P = 0.594; (I^2 = 19.6%, P = 0.290)], nor in in-hospital mortality rates [OR = 0.46, 95%CI: 0.19–1.14, P = 0.092; (I^2 = 0.0%, P = 0.713), respectively] between the PTAE and control group (Figure 3A).

Prophylactic transcatheter arterial embolization seems to improve secondary outcomes in non-variceal upper gastrointestinal bleeding

Patients who underwent PTAE treatment were less likely to need any kind of reintervention caused by rebleeding, compared to those without PTAE (OR = 0.48, 95%CI: 0.31–0.76, P = 0.002; in a homogenous dataset, I^2 = 0.0%, P = 0.636) (Figure 3B). We found that PTAE group has significantly lower odds of rescue surgery in contrast with the control group [OR = 0.35, 95%CI: 0.14–0.92, P = 0.033; (I^2 = 44.1%, P = 0.128)] (Supplementary Figure 5). Leave-one-out analysis showed no major change in the overall odds of reintervention or rescue surgery (Supplementary Figure 6 and 7).

The length of hospital stay was reported in four studies[10-12,25]. Our meta-analysis established no statistically significant difference between the intervention and the control group in the length of hospital stay [WMD = -3.77 days, 95%CI: (-8.00)–0.45, P = 0.08; considerable heterogenous dataset, I^2 = 90.7%, P < 0.001] (Figure 3C). In parallel, three publications[10-12] reported the length of ICU stay, however the difference between the PTAE and control group was non-significant [WMD = -1.33 days, 95%CI: (-2.84)–0.18, P = 0.084; I^2 = 84.8%, P = 0.001] (Supplementary Figure 8).

Lastly, the PTAE group needed significantly more units of blood transfusion, than

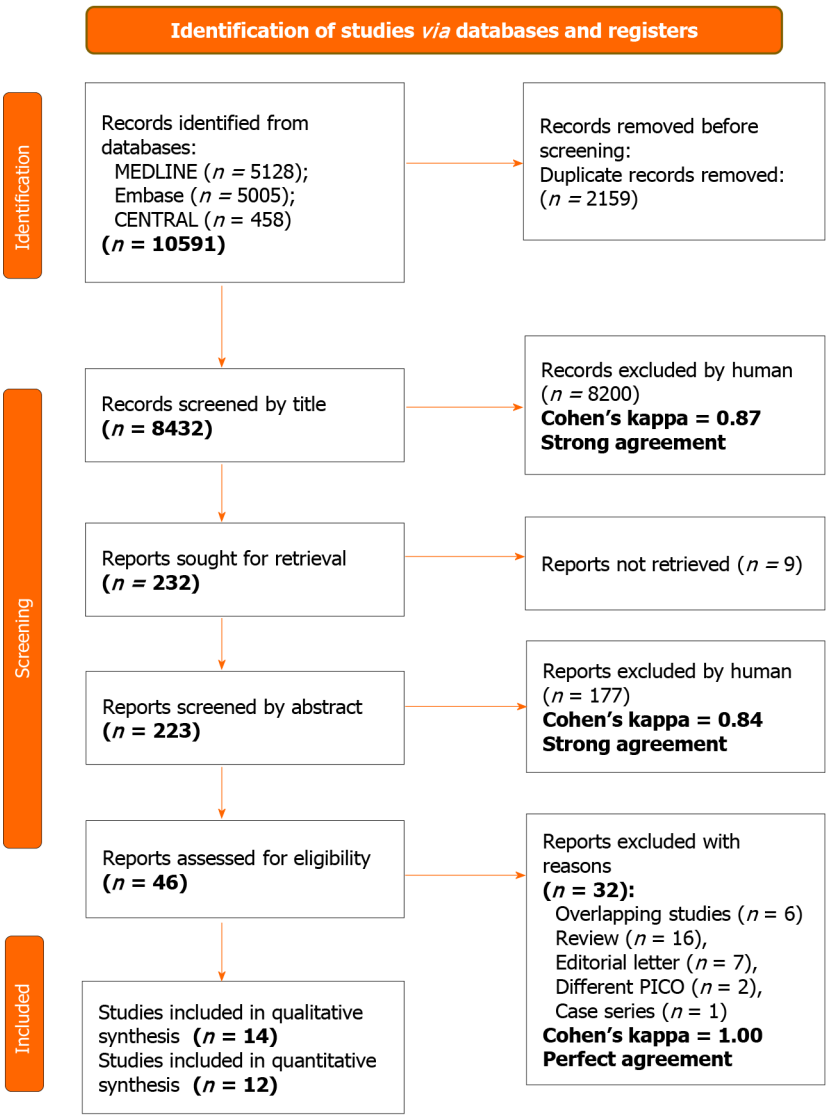

Figure 1 Preferred reporting in systematic reviews and meta-analyses flowchart showing the selection process.

Risk of bias assessment and quality of evidence

Among the included studies, four[10-12,25] were of low overall risk of bias, two[29,30] were of high overall risk of bias, all the other studies were rated to carry moderate overall risk of bias. The summary of the risk of bias assessment is shown in Supplementary Figure 11-18.

We included all outcomes in the "Summary of findings table" (Supplementary Table 4). The certainty of the evidence is very low for every outcome because our meta-analysis mainly contained observational studies. We calculated the quality of evidence among the RCT subgroup in rebleeding, and we found a moderate certainty of the evidence for PTAE, lowering the chance of rebleeding.

DISCUSSION

In this study, we assessed the effect of PTAE in addition to the successful endoscopic treatment of NVGUIB or PTAE as the first treatment option in case of not actively bleeding patients with NVUGIB lesions. Based on our findings, PTAE is associated with lower odds of rebleeding, need for additional reintervention, and rescue surgery compared to standard of care. We found a roughly 50% lower rate of the outcomes mentioned above, which is a considerable proportion, especially considering the prevalence of NVUGIB.

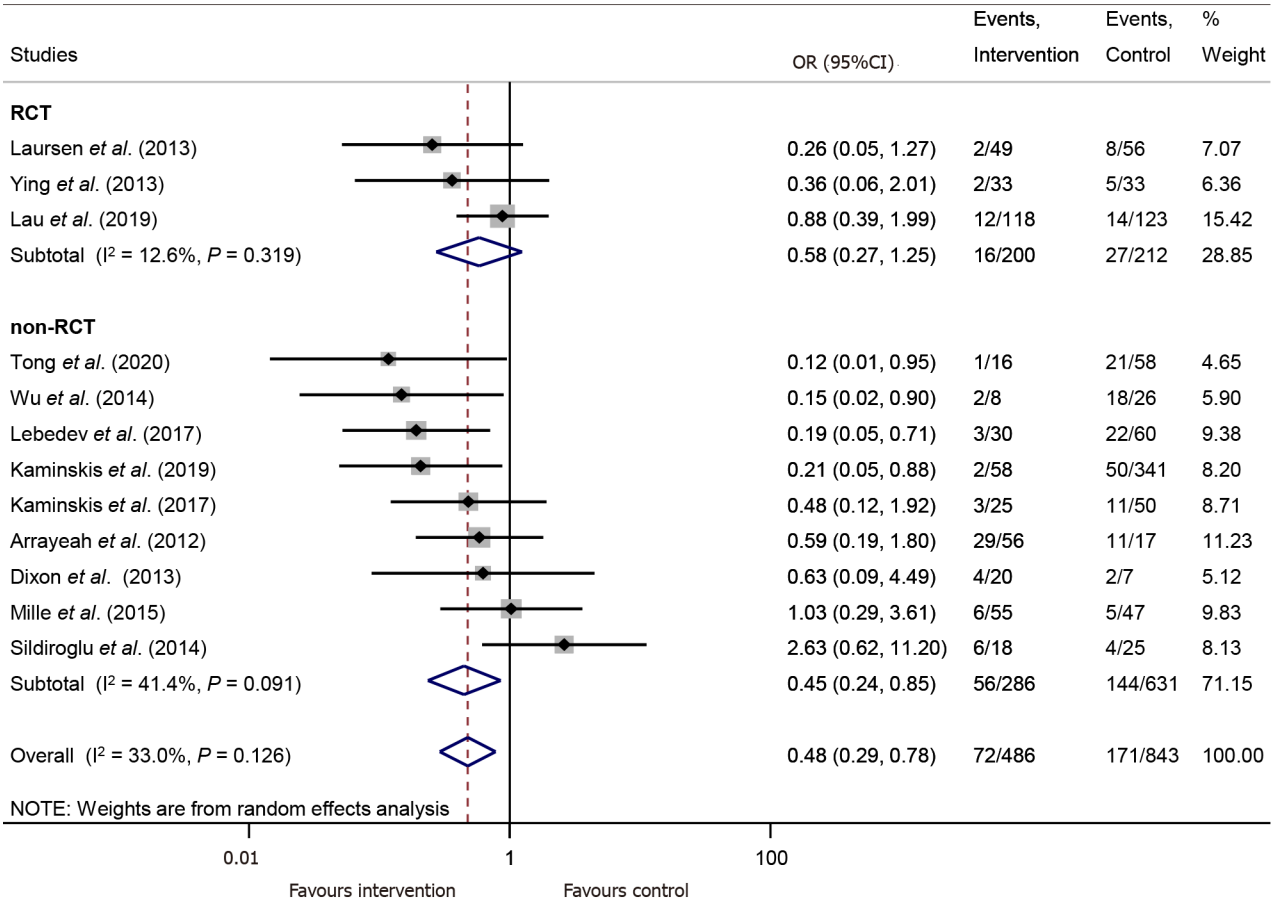

Figure 2 Forest plot of studies divided into subgroups representing that the overall odds of rebleeding were significantly lower in the prophylactic transcatheter arterial embolization group. However, among the RCT studies, the difference was not statistically significant. RCT: Randomized controlled trial; OR: Odds ratio; 95%CI: Confidence interval.

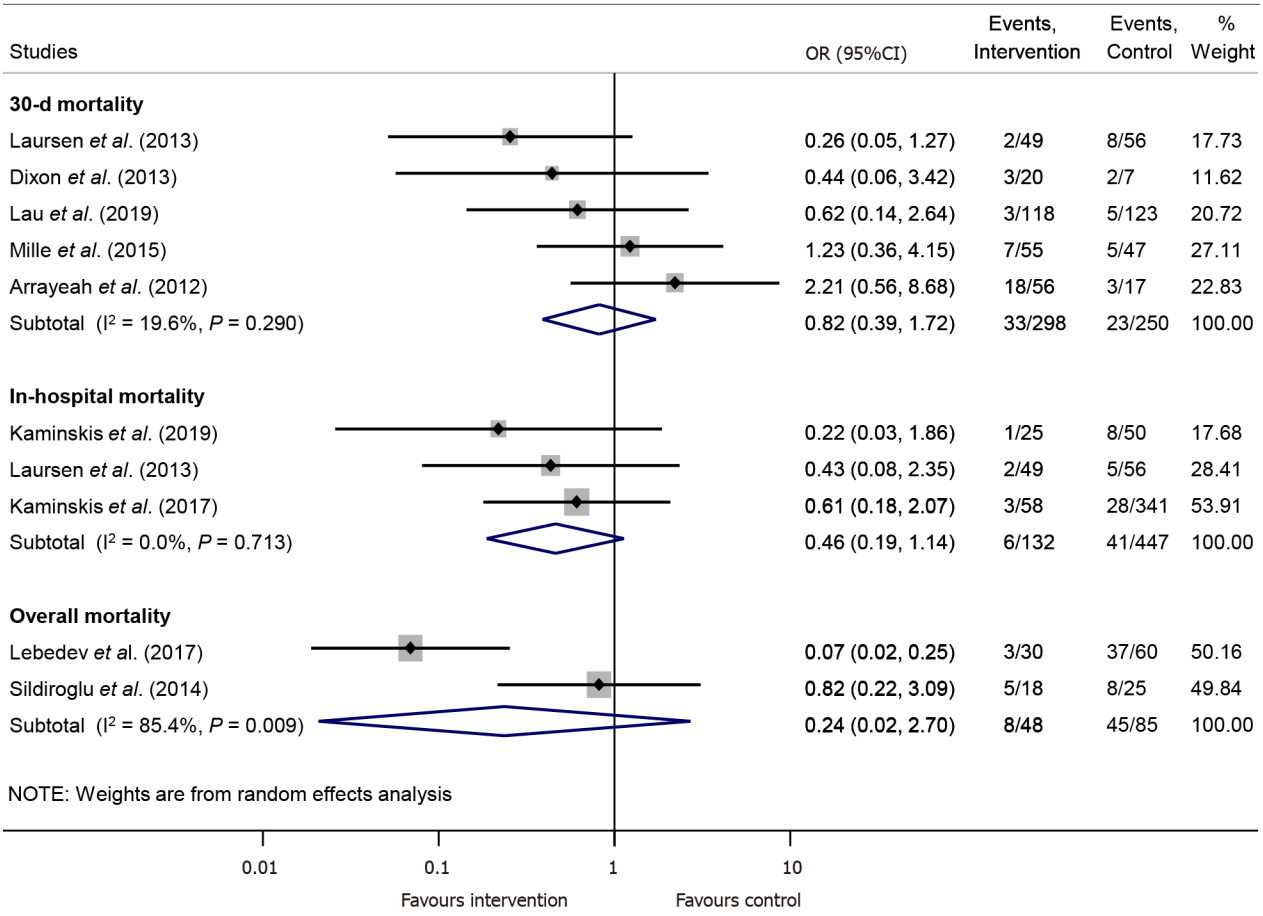
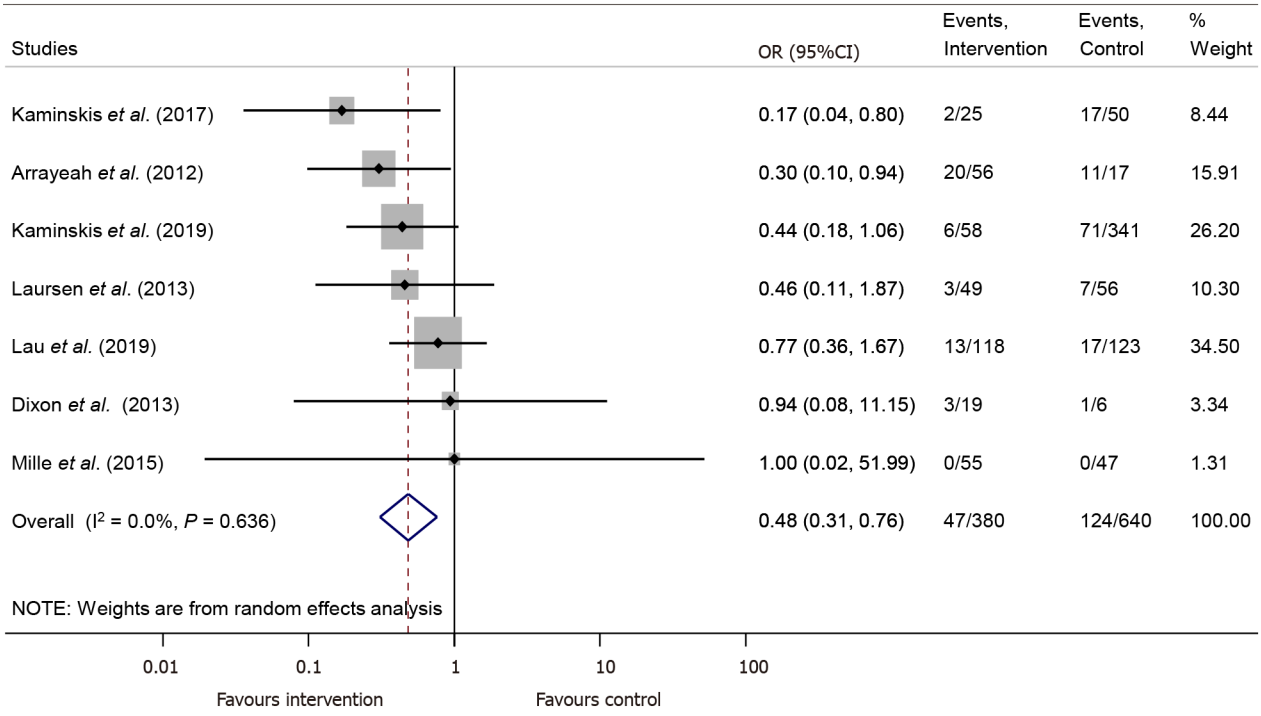
A recent meta-analysis of Chang *et al*[33] attempted to evaluate the role of PTAE in the management of patients with high-risk peptic ulcer bleeding. They included only 2 RCTs and 3 observational studies in their meta-analysis while narrowing their search to patients with a high risk of rebleeding. We designed our systematic search for NVUGIB without restriction to high-risk peptic ulcer bleeding because of the various NVUGIB bleeding etiologies that could be treated with TAE[9].



Rebleeding in the randomized controlled trials

We found three eligible RCTs[10,25,26], which provide the core of our meta-analysis and the highest level of evidence. When we performed a subgroup analysis of the RCTs for the rebleeding outcome, we found no significant difference between PTAE and the control group. We think that the main reason why with intention-to-treat data, we could not demonstrate the clear beneficial effect of PTAE is that in Lau *et al*[10]'s study, 22 patients out of 118 (18.6%), and Laursen *et al*[25], 18 out of 49 (36.7%) did not receive embolization at all despite being in the embolization arm of the studies. When we used per-protocol data, also in the RCT subgroup, there was a significantly lower risk for rebleeding in the PTAE group. However, the TSA calculation showed that the required information size was not reached, and our results are inconclusive.



It is important to note that in Laursen *et al*[25]'s study, 9% of the potentially eligible patients were excluded because they were admitted to the hospital on weekends. These patients could not receive the allocated intervention due to the lack of staff in interventional radiology. This highlights that PTAE could be the most beneficial treatment option in centers with well-established interventional radiology units.

According to Lau *et al*[10], the chance of recurrent bleeding was significantly reduced in ulcers 15 mm in size or greater. Unfortunately, there was not enough data on the size of the culprit lesions in the other included studies to perform a meta-analysis. Nevertheless, risk stratification is essential before choosing between multiple possible treatment modalities in the case of NVUGIB. Several studies[10-13,25] used the Forrest classification, Rockall score, or the American Society of Anesthesiologists

score to assess the baseline risk of rebleeding or mortality among the patients, and it was approximately the same between the PTAE and the control group.

Rebleeding in cohort studies

The publication of Mille *et al*[30] described that only high rebleeding risk patients got PTAE, and in the control group were only low-risk patients. We consider this a selection bias, causing confounding of the measured outcomes, which could explain why they did not manage to find any difference in the rebleeding, reintervention, or rescue surgery rate between the intervention and the control group. Applying the leave-one-out method in the case of the study of Mille *et al*[30], there was no major change in the overall odds for rebleeding, reintervention, and rescue surgery.

The study of Sildiroglu *et al*[31] was the only one where the PTAE group had a worse rebleeding rate than the control group. There was no data on the baseline characteristics of the two treatment groups, so we cannot explain this contradicting result.

We included in our analyses four studies[26-28,31], with a definition of NVUGIB including various sources such as peptic ulcers, tumors, Dieulafoy lesion, Mallory-Weiss tear. Arrayeh *et al*[27] carried out a retrospective analysis that compared three therapeutic options: angiography without embolization, PTAE, and TAE with an abnormal angiogram. They published the interesting observation that patients with duodenal bleeding due to a mass (various types of malignant) lesion had a greater primary hemostasis rate 30 d after angiography compared with patients with nonmass (different types of benign) sources of duodenal bleeding (100% *vs* 54%; $P = 0.008$). This difference was not detectable between mass and nonmass lesions in the case of gastric bleeding. We did not find data in other studies about the investigated outcomes separated by the type of the bleeding lesion.

The rebleeding rate could also depend on whether NVUGIB has a gastric or duodenal source. According to Arrayeh *et al*[27], PTAE may be advantageous in patients with a duodenal source of bleeding but not in patients with gastric hemorrhage. We did not identify enough evidence to support this inference because none of the other included studies reported gastric and duodenal bleeding separately.

Evidence about secondary outcomes

Our results indicated that PTAE does not improve the mortality rates of NVUGIB significantly. We could not draw a clear conclusion about this outcome because of the different time-frames for mortality assessment used between the different studies: 30-d mortality was used in five studies[10,25,27,28,30], in-hospital mortality in three[11,12,25] and two studies[29,31] did not report any time-frame for mortality. Mortality is strongly associated with pre-endoscopy and complete Rockall score, according to Hearnshaw *et al*[5] We can only speculate that numerous major confounding factors affect the mortality of NVUGIB patients, and only one of them is the chosen treatment modality.

We had predicted a shorter hospital stay and ICU stay in the PTAE group, but our findings could not prove a significant difference between the two groups. Interestingly, if we analyzed only the data coming from RCTs, there was an apparent reduction in the length of hospital and ICU stay in the PTAE group compared with the control group. This result highlights the possible bias of the observational cohort studies.

The PTAE group needed slightly more red blood cell transfusion than the control group, although the heterogeneity between the studies suggests a careful interpretation of this finding. Since we assume a major confounding factor in the publication of Mille *et al*[30], the difference was no longer statistically significant between the PTAE and the control group after applying the leave-one-out method.

Methods reducing rebleeding risk in non-variceal upper gastrointestinal bleeding

There are a few therapies, which are already proved to reduce rebleeding from NVUGIB. Proton pump inhibitors (PPI) significantly decrease the recurrence of bleeding compared to control (placebo or histamine type 2 receptor antagonists); pooled rates were 10.6% with PPI *vs* 17.3% with control treatment (OR = 0.49; 95%CI: 0.37-0.65) in a Cochrane review comprising 24 RCTs[34]. Our recent meta-analysis showed that PPIs given either orally or intravenously are equally efficacious in preventing rebleeding[35].

After peptic ulcer bleeding, investigation for the presence of *H. pylori* should be mandatory. Our network meta-analysis[36] demonstrated that none of the individual tests or the strategy of combined tests is superior in detecting *H. pylori*. Gisbert *et al*[37] reported that rebleeding did not occur in patients with complicated ulcers after *H. pylori* eradication; moreover, maintenance of anti-ulcer therapy is unnecessary if eradication was achieved.

Endoscopic Doppler probe guided hemostasis significantly reduced the 30-d rates of rebleeding compared with standard visually guided hemostasis in an RCT (11.1% *vs* 26.3%), and the use of the endoscopic Doppler probe was suggested for risk stratification in the management of NVUGIB[38].

Another promising endoscopic technique to reduce the rebleeding rate of peptic ulcers is over-the-scope clipping (OTSC), which is superior to standard therapy with through-the-scope clips in preventing further bleeding according to the prospective RCT of Schmidt *et al*[39].

A recent meta-analysis[40] showed that the routine second-look endoscopy was not superior to a single endoscopy with complete endoscopic hemostasis in reducing the risk of recurrent bleeding, mortality, or need for surgery in patients with acute UGIB due to peptic ulcer disease. In contrast, according to our results, PTAE added to the standard of care could decrease the probability of rebleeding. Moreover, PTAE might reduce the need for surgery and any reintervention.

Strengths and limitations

Our work is assessing the potential effects of PTAE compared to the standard of care in the treatment of NVUGIB. We used a rigorous methodology and followed a transparent protocol, combined with a comprehensive statistical analysis as possible. We collected a total of 486 patients who received PTAE, which is an infrequent therapeutic choice so far.

The main limitation of our meta-analysis is that we collected our data mostly from observational cohort studies, and we found only three RCTs comparing PTAE to the standard of care. Thus, the quality of evidence for every outcome in our meta-analysis is very low based on the GRADE framework. When we assessed the quality of evidence regarding rebleeding in the RCT subgroup, we found moderate evidence for the risk reduction with PTAE. The diversity of the NVUGIB population in some studies could also limit our results and explain the statistical heterogeneity in some cases. Significant differences are present in the embolic agents utilized for PTAE

among publications. There was very restricted data on the endoscopic treatment before PTAE, which could also influence the outcomes. The included studies contain only limited information on secondary outcomes, so our conclusions about these are less certain.

Implications for practice

In selected cases, where the previous risk stratification suggests high rebleeding risk or the anatomical situation makes the secure and permanent endoscopic hemostasis impossible, we can consider the routine use of PTAE. Considering the demographic trends of NVUGIB, we predict that elderly, high-risk patients with co-morbidities could benefit the most from PTAE as a therapeutic approach.

Implications for research

Further RCTs are warranted to achieve a higher level of evidence about the potentially beneficial effects of PTAE. Developing an accurate risk stratification system would be crucial to select the ideal candidates for PTAE. Clinical trials investigating the use of existing risk scores or creating a new risk stratification tool of NVUGIB could help clinicians choose between the emerging number of treatment options.

CONCLUSION

PTAE is accompanied by lower odds of rebleeding, need for surgery, and reinterventions in NVUGIB. However, our meta-analysis could not justify a beneficial effect of *PTAE* on mortality rates compared with the standard of care in *NVUGIB*.

ARTICLE HIGHLIGHTS

Research background

The prevention of rebleeding is one of the main goals in managing non-variceal upper gastrointestinal bleeding (NVUGIB). Prophylactic transcatheter arterial embolization (PTAE) can be used in NVUGIB as second-line therapy.

Research motivation

The results of the individual studies about the beneficial effects of PTAE among NVUGIB patients were contradictory.

Research objectives

The authors aimed to carry out a comprehensive systematic review and meta-analysis. The authors compared the PTAE to no embolization as a second line, prophylactic treatment among NVUGIB patients.

Research methods

The authors conducted a systematic search in three databases (MEDLINE, EMBASE, CENTRAL). The eligible studies compared patients with NVUGIB receiving PTAE to those who did not get PTAE. The authors calculated odds ratios (ORs) with 95% confidence intervals (CI) for rebleeding, mortality, reintervention, need for surgery, and weighted mean differences (WMDs) of need for transfusion, length of hospital (LOH), and intensive care unit (ICU) stay.

Research results

PTAE was associated with significantly lower odds of rebleeding, reintervention and rescue surgery (OR = 0.48, 95%CI: 0.29–0.78; OR = 0.48, 95%CI: 0.31–0.76; OR = 0.35, 95%CI: 0.14–0.92; respectively). There was no significant difference in the mortality rates, LOH, and ICU stays between the PTAE and control groups. The quality of evidence for every outcome in our meta-analysis is very low based on the GRADE framework.

Research conclusions

The results suggest that PTAE is a reasonable therapeutic choice to prevent rebleeding or reintervention in NVUGIB, although it did not improve the mortality rates of NVUGIB.

Research perspectives

Further randomized controlled trials are needed about the use of PTAE. We also propose a clinical trial that could recommend a new risk stratification tool of NVUGIB, helping clinicians choose between treatment options.

Abstract

Since the coronavirus disease 2019 (COVID-19) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has rapidly spread worldwide, there is still limited knowledge about this condition and its natural history. Children have been relatively spared during COVID-19 pandemic but a novel syndrome known as multisystem inflammatory syndrome (MIS-C) has emerged, following a SARS-CoV-2 infection in children and adolescents. This syndrome can lead to shock and multiple organ failure requiring intensive care. Although COVID-19 clinical research focuses on respiratory symptoms, extrapulmonary involvement such as gastrointestinal (GI) and hepatic manifestations should also be considered. In fact, GI and hepatic involvement play an important role among the most common presenting symptoms of both pediatric and adult COVID-19 and MIS-C. This involvement can not only be one of the most common presenting clinical features but also one of the sequelae of these syndromes. Abdominal ultrasonography monitoring could be very useful to identify a potential involvement of the GI tract and liver. Moreover, long-term follow-up is needed and would be essential to define the long-term outcomes of these patients.

Key Words: SARS-CoV-2; COVID-19; Multisystem inflammatory syndrome; Gastrointestinal tract; Liver; Ultrasonography

and adolescents has emerged. Among the most common presenting symptoms of MIS-C, we found gastrointestinal and hepatic involvement. As gastrointestinal and hepatic involvement might play a major role in the clinical spectrum and possible sequelae of this novel condition, physicians should not underestimate these clinical manifestations. Therefore, abdominal ultrasonography monitoring and long-term follow-up could be useful to evaluate this potential damage and the possible outcome of these patients.

TO THE EDITOR

We read with great interest the review by Mohamed *et al*[1] about manifestations, mechanisms and management of the gastrointestinal (GI) and hepatic diseases during the coronavirus disease 2019 (COVID-19) pandemic. Although the large majority of concern about COVID-19 and its outcomes is centered on pulmonary manifestations and sequelae, we must be aware that GI and hepatic involvement could play a major role in the clinical spectrum of this novel disease as well as in virus transmission *via* the fecal-oral route. Hence, we agree with the authors' purpose that physicians should not underestimate digestive symptoms during COVID-19. In fact, GI manifestations in COVID-19 patients, including diarrhea, nausea, vomiting, anorexia and abdominal pain are common features of the disease with diarrhea being the most common among these symptoms[2,3].

The pathophysiologic mechanism of GI and hepatic injury during COVID-19 is still debated. Mohamed *et al*[1] reported that GI damage might be due to direct infection of GI cells. We appreciate the great relevance the authors gave to angiotensin-converting enzyme 2 (ACE2) receptors' expression over the small intestine cells, cholangiocytes and hepatocytes and the role it plays in severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection and in the pathophysiology of both GI and hepatic injury. Also, SARS-CoV-2 can induce cells expressing ACE2 to release inflammatory cytokines leading to a cytokine storm and multiple organ failure[4]. As Mohamed *et al*[1] well reported, SARS-CoV-2 binding to ACE2 receptor can lower the critical receptor level, reducing the absorption of tryptophan on the lumen surface of intestinal epithelial cells. It is known that tryptophan is absorbed on the lumen surface of intestinal epithelial cells *via* the B0AT1/ACE2 transport route inducing the mammalian target of rapamycin which controls the appearance of antimicrobial peptides influencing the components of gut flora. Therefore, the reduced absorption of tryptophan caused by SARS-CoV-2 can ultimately unbalance the gut flora resulting in diarrhea. The changings in the GI flora also stimulate the polarization of T helper 17 cells, and eventually, interleukin 17A induces the recruitment of neutrophils[1]. Moreover, changes in intestinal flora might affect the respiratory tract and *vice versa via* the gut-lung axis, subsequently enhancing the inflammatory and immune-mediated damage in the small intestine.

A study by Pirola and Sookoian[5] demonstrates that gene expression levels for ACE2 are highest in cholangiocytes compared to alveolar type 2 cells, followed in turn by sinusoidal endothelial cells and hepatocytes, thus supporting the possibility that SARS-CoV-2 may cause direct liver injury through a viral cytopathic effect. Nevertheless, GI mucosal damage and unbalance in the gut flora may lead to liver dysfunction through the gut-liver axis.

However, we should not forget that GI tract symptoms and liver injury may also be due to cytokine storm, hypoxic-shock conditions due to acute respiratory distress syndrome and drug-induced injury[6,7].

It is generally accepted that the existence of comorbidities in COVID-19 patients can dramatically increase the risk of poor outcome. Besides, the impact of the COVID-19 pandemic on preexisting GI, liver and pancreatic diseases is still under investigation. We appreciate the importance the authors gave to patients affected by inflammatory bowel diseases (IBD). Actually, these patients are more at risk for infectious diseases

due to the immunosuppressive therapy they undergo. Thus, IBD patients may potentially be more at risk for SARS-CoV-2 infection and severe COVID-19. The prognostic value of the elevation of liver enzymes and indices of cholestasis reflecting hepatic injury and cholangiocellular damage respectively, is still debated. Conversely, pre-existing chronic liver diseases seem to be independent risk factors for poor outcome in COVID-19, and cirrhosis grade has been defined as a predictor of mortality in SARS-CoV-2 infected patients[6].

We are thankful to the authors for their contribution to current literature and we would like to implement the authors' excellent work by reporting our experience with SARS-CoV-2 infection in the Pediatric population.

We would like to emphasize that COVID-19 in children and adolescents may often be asymptomatic or cause only mild symptoms. The most prevalent symptom of COVID-19 in children and adolescents is fever, followed by cough, upper respiratory tract symptoms, diarrhea and nausea/vomiting. In a multinational, multicenter cohort study, 22% of patients had GI symptoms and 7% of those had no respiratory symptoms[8]. Also, neurological manifestations must be considered as they might be a direct result of central nervous system viral invasion or post-infection immuno-mediated disease[9]. Interestingly, in the latter half of April 2020 a previously unknown SARS-CoV-2-related clinical syndrome emerged. Initially this novel entity was named pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2 (PIMS-TS) by the European Centre for Disease Prevention and Control and then multisystem inflammatory syndrome in children (MIS-C) by the Centers for Disease Control and Prevention (CDC) in the United States and by the World Health Organization. This syndrome can lead to shock and multiple organ failure requiring a Pediatric Intensive Care Unit. Its features resemble those of known entities such as Kawasaki Disease, toxic shock syndrome, and macrophage activation syndrome. The CDC issued a case definition of MIS-C specifying that the patient should be < 21-year-old, have fever, laboratory evidence of inflammation, and evidence of a clinically severe illness requiring hospitalization, with multisystem (> 2) organ involvement (cardiac, renal, respiratory, hematological, GI, dermatological, or neurological), in the absence of an alternative plausible diagnosis, and evidence of SARS-CoV-2 infection or exposure[10]. It was initially thought that this syndrome was specific of children, but recent reports have shown that it can also occur in adults. In a case series comparing children and adolescents with MIS-C *vs* those with severe COVID-19, MIS-C was distinguished by having a more severe cardiovascular and mucocutaneous involvement and a worse inflammation with a higher neutrophil/Leukocyte ratio, higher c-reactive protein level and lower thrombocytopenia compared to patients with COVID-19[11].

The pathophysiology of this syndrome is under intense investigation but so far it remains unclear. It is believed that this syndrome results from an abnormal immune response to the virus. Interestingly, among the most common presenting symptoms of MIS-C from reports worldwide we found GI involvement, including vomiting, abdominal pain, and/or diarrhea. Moreover, there are reports in literature reporting cases of MIS-C presenting with acute abdomen and pseudo appendicular syndrome with shock, clinical symptoms suggestive of appendicitis, functional intestinal obstruction and ischemic bowel lesions[12,13]. Furthermore, abdominal imaging findings such as hepatomegaly, nephromegaly, gallbladder wall edema, ascites, intestinal inflammation and mesenteric lymphadenopathy are very common[14]. The role of SARS-CoV-2 in some of these clinical presentations seems more likely to be temporal rather than causative but it causes diagnostic and management dilemmas for treating physicians.

Regarding the experience of our Department of Pediatrics, we recently reported the case of a 14-year-old non-obese boy with MIS-C who presented with jaundiced skin, a diffusely painful abdomen and palpable hepatosplenomegaly. He was in a condition of multiorgan failure with a compromised hemodynamic status with reduction of left ventricular ejection fraction and elevated values of alanine aminotransferase, aspartate aminotransferase and indices of cholestasis. Notably, our patient fully recovered from MIS-C, with an excellent cardiac and renal outcome but during the follow-up visit program he was diagnosed with a new onset hepatic steatosis. Therefore, we suggest that hepatic steatosis might be one of the sequelae following SARS-CoV-2 infection, MIS-C or its treatment, mainly due to prolonged use of corticosteroids, probably through an inhibition of mitochondrial fatty acid oxidation[15].

We fully agree with the authors' suggestion that liver function should be monitored during COVID-19, particularly in more severe cases. Furthermore, we think that hepatic involvement after COVID-19 and MIS-C could be underdiagnosed as few patients undergo abdominal ultrasonography monitoring. Diagnosis of hepatic

steatosis is easily accessible through an abdominal ultrasound, which is a low-cost, non-invasive examination. To date, abdominal ultrasound monitoring for these patients is not supported by evidence but we suggest that it could be very useful to identify this potential damage early and evaluate the possible outcome of these patients.

In conclusion, GI and hepatic involvement in COVID-19 and MIS-C should not be underestimated because potential damage could be underdiagnosed. Further studies and long-term follow ups are needed to completely understand the pathophysiology and possible implications that GI and hepatic involvement might have in COVID-19 and MIS-C.
